There have been several studies demonstrating improved machine translation performance by reordering source side sentences based on rules applied to the source side parse during training and decoding. Much of this work has used hand written rules and several language pairs have been studied e.g German to English (Collins et al., 2005), Chinese to English (Wang et al., 2007), English to Hindi (Ramanathan et al., 2009), English to Arabic (Badr et al., 2009) and Japanese to English (Lee et al., 2010). There have also been some studies where the rules are learned from the data (Genzel, 2010; Visweswariah et al., 2010; Xia and McCord, 2004). In addition there has been work (Yamada and Knight, 2002; Zollmann and Venugopal, 2006; Galley et al., 2006; Liu et al., 2006) which uses source and/or target side syntax in a Context Free Grammar framework which results in machine translation decoding being considered as a parsing problem. In this paper we propose a model that does not require either source or target side syntax while also preserving the efficiency of reordering techniques based on rules applied to the source side parse.

In work that is closely related to ours, (Tromble and Eisner, 2009) formulated word reordering as a Linear Ordering Problem (LOP), an NP-hard permutation problem. They learned LOP model weights capable of assigning a score to every possible permutation of the source language sentence from an aligned corpus by using a averaged perceptron learning model. The key difference between our model and the model in (Tromble and Eisner, 2009) is that while they learn costs of a word w_i appearing *anywhere* before w_j, we learn costs of w_i *immediately preceding* w_j. This results in more compact models and (as we show in Section 5) better models.

Our model results in us having to solve a TSP instance. The relation between the TSP and machine translation decoding has been explored before. (Knight, 1999) showed that TSP is a sub-class of MT decoding and thus established that the latter is NP-hard. (Zaslavskiy et al., 2009) casts phrase-based

decoding as a TSP and they show favorable speed performance trade-offs compared with *Moses*, an existing state-of-the-art decoder. In (Tillmann and Ney, 2003), a beam-search algorithm used for TSP is adapted to work with an IBM-4 word-based model and phrase-based model respectively. As opposed to calculating TSP distances from existing machine translation components (viz. the translation, distortion and language model probabilities) we *learn model weights* to reorder source sentences to match target word order using an informative feature set adapted from graph-based dependency parsing (McDonald et al., 2005a).

3 Hindi-English reordering issues

This section provides a brief survey of constructions that the two languages in question differ as well as have in common. (Ramanathan et al., 2009) notes the following divergences:

- English follows SVO order while Hindi follows SOV order
- English uses prepositions while Hindi uses post-positions
- Hindi allows greater word order freedom
- Hindi has a relatively richer case-marking system

In addition to these differences, (Visweswariah et al., 2010) mention the similarity in word order in the case of adjective noun sequences (*some books* vs. *kuch kitab*).

4 Reordering model

Consider a source sentence $\mathbf{w}$ consisting of a sequence of n words w_1, w_2, ... w_n that we would like to reorder into the target language order. Given a permutation π of the indices $1..n$, let the candidate reordering be w_{π_1}, w_{π_2}, ..., w_{π_n}. Thus, π_i denotes the index of the word in the source sentence that maps to position i in the candidate reordering. Clearly there are $n!$ such permutations. Our reordering model assigns costs to candidate permutations as:

$$C(\pi|\mathbf{w}) = \sum_i c(\pi_{i-1}, \pi_i).$$

The cost $c(m, n)$ can be thought of as the cost of the word at index m immediately preceding the word with index n in the candidate reordering. In this paper, we parametrize the costs as:

$$c(m, n) = \theta^T \Phi(\mathbf{w}, m, n),$$

where θ is a learned vector of weights and Φ is a vector of feature functions.

Given a source sentence $\mathbf{w}$ we reorder it according to the permutation π that minimizes the cost $C(\pi|\mathbf{w})$. Thus, we would like our cost function $C(\pi|\mathbf{w})$ to be such that the correct reordering π^* has the lowest cost of all possible reorderings π. In Section 4.1 we describe the features Φ that we use, and in Section 4.2 we describe how we train the weights θ to obtain a good reordering model.

Given our model structure, the minimization problem that we need to solve is identical to solving a Asymmetric Traveling Salesman Problem (ATSP) with each word corresponding to a city, and the costs $c(m, n)$ representing the pairwise distances between the cities. Consider the following example:

English input: John eats apples

Hindi: John seba(apples) khaataa hai(eats)

Desired reordered English: John apples eats

The ATSP that we need to solve is represented pictorially in Figure 1 with sample costs. Note that we have one extra node numbered 0. We start and end the tour at node 0, and this determines the first word in the reordered sentence. In this example the minimum cost tour is:

Start $\rightarrow$ *John* $\rightarrow$ *apple* $\rightarrow$ *eats*

recovering the right reordering for translation into Hindi.

Solving the ATSP (which is a well known NP hard problem) efficiently is crucial for the efficiency of our reordering model. To solve the ATSP, we first convert the ATSP to a symmetric TSP and then use the Lin-Kernighan heuristic as implemented in *Concorde*, a state-of-the-art TSP solver (Applegate et al., 2005). We also experimented with using the exact TSP solver in *Concorde* but since it was slower and did not improve performance we preferred using the Lin-Kernighan heuristic. To convert the ATSP to a symmetric TSP we double the size of the original problem creating a node $N^{'}$ for every node N in the original graph. Following (Hornik and

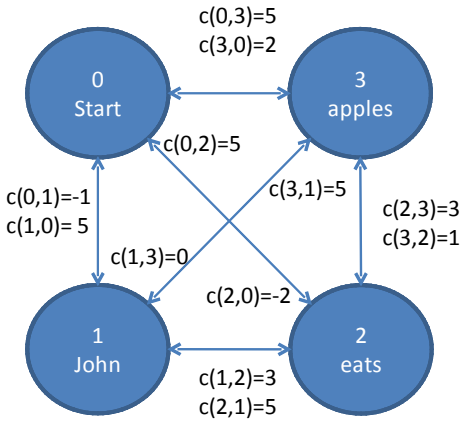

Figure 1: Example of an ATSP for reordering the sentence: *John eats apples*.

Table 1: Bigram feature templates used to calculate the cost that word at position i immediately precedes word at position j in the target word order. w_i (p_i) denotes the word (POS tag) at position i in the source sentence. Each of the templates is also conjoined with i-j the signed distance between the two words in the source sentence.

Hahsler, 2009), we then set new costs as follows: $c^{'}(A, B) = \infty$, $c^{'}(A, B^{'}) = c^{'}(B^{'}, A) = c(A, B)$ and $C(A, A^{'}) = -\infty$. Even with this doubling of the number of nodes, we observed that solving the TSPs with the Lin-Kernighan heuristic is very fast, taking roughly 10 milliseconds per sentence on average. Overall, this means that our reordering model is as fast as parsing and hence our model is comparable in performance to techniques based on applying rules to the parse tree.

4.1 Features

Since we would like to model reordering phenomena which are largely related to analyzing the syntax of the source sentence, we chose to use features based on those that have in the past been used for parsing (McDonald et al., 2005a). A subset of the features we use was also used for reordering in (Tromble and Eisner, 2009).

To be able to generalize from relatively small amounts of data, we use features that in addition to depending on the words in the input sentence $\mathbf{w}$ depend on the part-of-speech (POS) tags of the words in the input sentence. All features $\Phi(\mathbf{w}, i, j)$ we use are binary features, that fire based on the identities of the words and POS tags at or surrounding positions i and j in the source sentence. The first set of feature templates we use are given in Table 1. These features depend only on the identities of the word and POS tag of the two positions i and j and we call these Bigram features.

The second set of feature templates we use are given in Table 2. These features, in addition to examining positions i and j examine the surrounding positions. We instantiate these feature templates separately for the POS tag sequence and for the word sequence. We call these two feature sets ContextPOS and ContextWord respectively. When instantiated with POS tags, the first row of Table 2 looks at all POS tags between positions i and j. (Tromble and Eisner, 2009) use Bigram and ContextPOS features, while we extend their feature set with the use of ContextWord features. Since Hindi is verb final, in Hindi sentences with multiple verb groups it is rare for words with a verb in between to be placed together in the reordering to match English. Looking at the POS tags of words between positions i and j allows us to penalize such reorderings.

Each of the templates described in Table 1 and Table 2 is also conjoined with i-j the signed distance between the two words in the source sentence. The values of i-j between 5 and 10, and greater than 10 are quantized (negative values are similarly quantized).

In Section 5.2 we report on experiments showing the relative performance of these different feature

o_{i-1}	o_i	o_{i+1}	o_b	o_{j-1}	o_j	o_{j+1}

Table 2: Context feature templates used to calculate the cost that word at position i immediately precedes word at position j in the target word order. o_i denotes the observation at position i in the source sentence and o_b denotes an observation at a position between i and j (i.e $i+1 \leq b \leq j-1$). Each of the templates is instantiated with the observation sequence $\mathbf{o}$ taken to be the word sequence $\mathbf{w}$ and the POS tag sequence $\mathbf{p}$. Each of the templates is also conjoined with i-j the signed distance between the two positions in the source sentence.

types for the task of reordering Hindi sentences to be in English word order.

4.2 Training

To train the weights θ in our model, we need a collection of sentences, where we have the desired reference reordering $\pi^*(\mathbf{x})$ for each input sentence $\mathbf{x}$. To obtain these reference reorderings we use word aligned source-target sentence pairs. The quality and consistency of these reference reorderings will depend on the quality of the word alignments that we use. Given word aligned source and target sentences, we drop the source words that are not aligned. Let m_i be the mean of the target word positions that the source word at index i is aligned to. We then sort the source indices in increasing order of m_i. If $m_i = m_j$ (for example, because w_i and w_j are aligned to the same set of words) we keep them in the same order that they occurred in the source sentence. Obtaining the target ordering in this manner, is certainly not the only possible way and we would like to explore better treatment of this in future work.

We used the single best Margin Infused Relaxed Algorithm (MIRA) ((McDonald et al., 2005b), (Crammer and Singer, 2003)) with the online updates to our parameters being given by

$$\begin{aligned} \theta_{i+1} = & \arg\min_{\theta} ||\theta - \theta_i|| \\ & s.t. \quad C(\pi^*|\mathbf{w}) < C(\hat{\pi}|\mathbf{w}) - L(\pi^*, \hat{\pi}). \end{aligned}$$

In the equation above,

$$\hat{\pi} = \arg\min_{\pi} C(\pi|\mathbf{x})$$

is the best reordering based on the current parameter value and L is a loss function. We take the loss of a reordering to be the number of words for which the preceding word is wrong relative to the reference target order.

We also experimented with the averaged perceptron algorithm (Collins, 2002), but found single best MIRA to work slightly better and hence used MIRA for all our experiments.

5 Experiments

In this section we report on experiments to evaluate our reordering model. The first method we use for evaluation (monolingual BLEU) is by generating the desired reordering of the source sentence (as described in Section 4.2) and compare the reordered output to this desired reordered sentence using the BLEU metric. In addition, to these monolingual BLEU results, we also evaluate (in Section 5.5) the reordering by its effect on eventual machine translation performance.

We note that our reordering techniques uses POS information for the input sentence. The POS taggers used in this paper are Maximum Entropy Markov models trained using manually annotated POS corpora. For Hindi, we used roughly fifty thousand words with twenty six tags from the corpus described in (Dalal et al., 2007). For Urdu we used roughly fifty thousand words and forty six tags from the CRULP corpus (Hussain, 2008) and for English we used the Wall Street Journal section of the Penn Treebank.

5.1 Reordering model training data and alignment quality

To train our reordering models we need training data where we have the input source language sentence and the desired reordering in the target language. As described in Section 4.2 we derive the reference reordered sentence using word alignments. Table 3 presents our monolingual BLEU results for Hindi to English reordering as the source of the word alignments is varied. All results in Table 3 are with Bigram and ContextPOS features. We have word alignments from three sources: A small set of hand aligned sentences, HMM alignments (Vogel et al., 1996) and alignments obtained using a supervised Maximum Entropy aligner (Ittycheriah and Roukos, 2005) trained on the hand alignments. The F-measure for the HMM alignments were 65% and 78% for the Maximum Entropy model alignments. We see that the quality of the alignments is an important determiner of reordering performance. Row 1 shows the BLEU for unreordered (baseline) Hindi compared with the Hindi sentences reordered in English Order. Using just HMM alignments to train our model we do worse than unreordered Hindi. Although using the Maximum Entropy alignments is better than using HMM alignments, we do not improve upon a small number of hand alignments by using all the Maximum Entropy alignments.

To improve upon the model trained with only hand alignments we selected a small number of snippets of sentences from our Maximum Entropy alignments. The goal was to pick parts of sentences where the alignment is reliable enough to use for training. The heuristic we used in the selection of snippets was to pick maximal snippets of at least 7 consecutive Hindi words with all Hindi words aligned to a consecutive span of English words, with no unaligned English words in the span and no English words aligned to Hindi words outside the span. Adding snippets selected with this heuristic improves the reordering performance of our model as seen in the last row of Table 3.

5.2 Feature set comparison

In this section we report on experiments to determine the performance of the different classes of features (Bigram, ContextPos and ContextWord) discussed in Section 4.1. Table 4 shows monolingual BLEU results for training with different features sets for Hindi to English reordering. In all cases, we use a set of 6000 sentence pairs which were hand aligned to generate the training data. It is clear that all three sets of features contribute to performance of the reordering model, however the number of ContextWord features is larger than the number of Bigram and ContextPOS features put together, and it may be desirable to select from this set of features especially when training on large amounts of data.

HMM	MaxEnt	Hand	BLEU
-	-	-	35.9
220K	-	-	35.4
-	220K	-	47.0

-	-	-	35.9
×	-	-	43.8
×	×	-	49.0
×	×	×	**51.3**

Table 4: Monolingual BLEU scores for Hindi to English reordering using models trained with different feature sets and tested on a development set of 280 Hindi sentences (5590 tokens).

5.3 Monolingual reordering comparisons

Table 5 compares our reordering model with a reimplementation of the reordering model proposed in (Tromble and Eisner, 2009). Both the models use exactly the same features (bigram features and ContextPOS features) and are trained on the same data. To generate our training data, for Hindi to English and English to Hindi we use a set of 6000 hand aligned sentences, for Urdu to English we use a set of 8500 hand aligned sentences and for English to French we use a set of 10000 hand aligned sentences (a subset of Europarl and Hansards corpus). Our

Language pair		Monolingual BLEU		
Source	Target	Unreordered	LOP	TSP
Hindi	English	35.9	36.6	**49.0**
English	Hindi	34.4	48.4	**56.7**
Urdu	English	35.6	39.5	**49.9**
English	French	64.4	78.2	**81.2**

Table 5: Monolingual BLEU scores comparing the original source order with desired target reorder without reordering, and reordering using our model (TSP) and the model proposed in (Tromble and Eisner, 2009) (LOP).

test data consisted of 280 sentences for Hindi to English and 400 sentences for all other language pairs generated from hand aligned sentences. We include English-French here to compare on a fairly similar language pair with local reordering phenomena (the main difference being that in French adjectives generally follow nouns). We note that our model outperforms the model proposed in (Tromble and Eisner, 2009) in all cases.

5.4 Analysis of reordering performance

To get a feel for the qualitative performance of our reordering algorithm and the kind of phenomena it is able to capture, we analyze the reordering performance in terms of (i) whether the clause restructuring is done correctly – these can be thought of as medium-to-long range reorderings, (ii) whether clause boundaries are respected, and (iii) whether local (short range) reordering is performed correctly. The following analysis is for Hindi to English reordering with the best model (this is also the model used for Machine Translation experiments reported on in Section 5.5).

- **Clause structure**: As discussed in Section 3, the canonical clause order in Hindi is SOV, while in English it is SVO. However, variations on this structure are possible and quite frequent (e.g., clauses with two objects). To evaluate clause restructuring, we compared sequences of subjects, objects and verbs in the output and reference reorderings.

  We had a set of 70 sentences annotated with subject, direct object, indirect object and verb information – these annotations were made on the head word of each phrase, and the comparisons were on sequences of these words alone and not the entire constituent phrase. 52 sentences were reordered by the model to match the order of the corresponding reference. Eight sentences were ordered correctly but differently from the reference, because the reference was expressed in non-canonical fashion (e.g., in the passive) – note that these cases negatively impact the monolingual BLEU score. The following example shows a sentence being reordered correctly, where, however, the reference is expressed differently (note the position of the subject "policy" (*niiti*) in the reference and the reordered output) [1]:

  Input: aba$_1$ (now) taka$_2$ (till) aisii$_3$ (this) *niiti*$_4$ (policy) kabhii$_5$ (ever) nahii$_6$ (not) rahii$_7$ (has) hai$_8$ (been)

  Reordered: taka$_2$ (till) aba$_1$ (now) aisii$_3$ (this) *niiti*$_4$ (policy) hai$_8$ (been) kabhii$_5$ (ever) nahii$_6$ (not) rahii$_7$ (has)

  Reference: taka$_2$ (till) aba$_1$ (now) aisii$_3$ (this) kabhii$_5$ (ever) nahii$_6$ (not) rahii$_7$ (has) hai$_8$ (been) *niiti*$_4$ (policy)

  English: Till now this never has been the *policy*

  The remaining ten sentences were reordered incorrectly. These errors are largely in clauses which deviate from the SVO order in some way – clauses with multiple subjects or objects, clauses with no object, etc.. For example, the following sentence with two subjects and objects corresponding to the verb *wearing* has not been reordered correctly.

  Input: sabhii$_1$ (all) purusha$_2$ (men) safeda$_3$ (white) evama$_4$ (and) mahilaaen$_5$ (women) kesariyaa$_6$ (saffron) vastra$_7$ (clothes) dhaarana$_8$ (wear) kiye$_9$ hue$_{10}$ (-ing) thiin$_{11}$ (were)

  Reordered: sabhii$_1$ (all) purusha$_2$ (men) safeda$_3$ (white) evama$_4$ (and) mahilaaen$_5$ (women) kesariyaa$_6$ (saffron) vastra$_7$ (clothes) dhaarana$_8$ (wear) thiin$_{11}$ (were) kiye$_9$ hue$_{10}$ (-ing)

  Reference: sabhii$_1$ (all) purusha$_2$ (men) thiin$_{11}$ (were) dhaarana$_8$ (wear) kiye$_9$ hue$_{10}$ (-

[1] The numeric subscripts in the examples indicate word positions in the input.

ing) safeda$_3$ (white) evama$_4$ (and) mahilaaen$_5$ (women) kesariyaa$_6$ (saffron)

English: All men were wearing white and the women saffron

The model possibly needs more data with patterns that deviate from the standard SOV order to learn to reorder them correctly. We could also add to the model, features pertaining to subject, object, etc.

- **Clause boundaries**: Measured on a set of 844 sentences which were marked with clause boundaries, 37 sentences (4.4 %) had reorderings that violated these boundaries. An example of such a clause-boundary violation is below:

  Input: main$_1$ (I) sarakaara$_2$ (government) kaa$_3$ (of) dhyaana$_4$ (attention) *maananiiya$_5$ (honourable) pradhaana$_6$ (prime) mantri$_7$ (minister) dvaaraa$_8$ (by) isa$_9$ (this) sabhaa$_{10}$ (house) me$_{11}$ (in) kiye$_{12}$ gaye$_{13}$ (made) isa$_{14}$ (this) vaade$_{15}$ (promise)* ki$_{16}$ ora$_{17}$ (towards) dilaanaa$_{18}$ (to bring) chaahuungaa$_{19}$ (would like)

  Reordered: main$_1$ (I) chahuungaa$_{19}$ (would like) dilaanaa$_{18}$ (to bring) kii$_{16}$ ora$_{17}$ (towards) *isa$_9$ (this) vaade$_{15}$ (promise) kiye$_{12}$ gaye$_{13}$ (made) dvaaraa$_8$ (by) maananiiya$_5$ (honourable) mantri$_7$ (minister) pradhaana$_6$ (prime)* dhyaana$_4$ (attention) kaa$_3$ (of) sarakaara$_2$ (government) *men$_{11}$ (in) isa$_{14}$ (this) sabhaa$_{10}$ (house)*

  Reference: main$_1$ (I) chahuungaa$_{19}$ (would like) dilaanaa$_{18}$ (to bring) dhyaana$_4$ (attention) kaa$_3$ (of) sarakaara$_2$ (government) *kii$_{16}$ ora$_{17}$ (towards) isa$_9$ (this) vaade$_{15}$ (promise) kiye$_{12}$ gaye$_{13}$ (made) dvaaraa$_8$ (by) maananiiya$_5$ (honourable) mantri$_7$ (minister) pradhaana$_6$ (prime) men$_{11}$ (in) isa$_9$ (this) sabhaa$_{10}$ (house)*

  English I would like to bring the attention of the government towards this promise *made by the honourable prime minister in this house*.

  Note how the italicized clause, which is kept together in the reference, is split up incorrectly in the reordered output. The proportion of such boundary violations is, however, quite low, because Hindi being a verb-final language, most clauses end with a verb and it is probably quite straightforward for the model to keep clauses separate. A clause boundary detection program should make it possible to eliminate the remaining errors.

- **Local reordering**: To estimate the short range reordering performance, we consider how often different POS bigrams in the input are reordered correctly. Here, we expect the model to reorder prepositions correctly, and to avoid any reordering that moves apart nouns and their adjectival pre-modifiers or components of compound nouns (see Section 3). Table 6 summarizes the reordering performance for these categories for a set of 280 sentences (same as the test set used in Section 5.1). Each row in Table 6 indicates the total number of correct instances for the pair, i.e., the number of instances of the pair in the reference (column titled *Total*), the number of instances that already appear in the correct order in the input (column *Input*), and the number that are ordered correctly by the reordering model (column *Reordered*). The first two rows show that adjective-noun and noun-noun (compounds) are in most cases correctly retained in the original order by the model. The final row shows that while many prepositions have been moved into their correct positions, there are still quite a few mismatches with the reference. An important reason why this happens is that nouns modified by prepositional phrases can often also be expressed as noun compounds. For example, *vidyuta (electricity) kii (of) aavashyakataaen (requirements)* in Hindi can be expressed either as "requirements of electricity" or "electricity requirements". The latter expression results in a match with the input (explaining many of the 104 correct orders in the input) and a mismatch with the model's reordering. The same problem in the training data would also adversely impact the learning of the preposition reordering rule.

POS pair	Total	Input	Reordered
adj-noun	234	192	196
noun-noun	46	44	42
prep-noun	436	104	250

Table 6: An analyis of reordering for a few POS bigrams

Language pair		BLEU	
Source	Target	Unreordered	Reordered
Hindi	English	14.7	**16.7**
Urdu	English	23.3	**24.8**
English	Hindi	20.7	**22.5**

Table 7: Translation performance without reordering (baseline) compared with performance after preordering with our reordering model.

5.5 Machine translation results

We now present experiments in incorporating the reordering model in machine translation systems. For all results presented here, we reorder the training and test data using the single best reordering based on our reordering model for each sentence. For each of the language pairs we evaluated, we trained Direct Translation Model 2 (DTM) systems (Ittycheriah and Roukos, 2007) with and without reordering and compared performance on test data. We note that the DTM system includes features that allow it to model lexicalized reordering phenomena. The reordering window size was set to +/-8 words for both the baseline and our reordered input. In our experiments, we left the word alignments fixed, i.e we reordered the existing word alignments rather than realigning the sentences after reordering. Redoing the word alignments with the reordered data could potentially give further small improvements. We note that we obtained better baseline performance using DTM systems than the standard Moses/Giza++ pipeline (e.g we obtained a BLEU of 14.9 for English to Hindi with a standard Moses/Giza++ pipeline). For all of our systems we used a combination of HMM (Vogel et al., 1996) and MaxEnt alignments (Ittycheriah and Roukos, 2005).

For our Hindi-English experiments we use a training set of roughly 250k sentences (5.5M words) consisting of the Darpa-TIDES dataset (Bojar et al., 2010) and an internal dataset from several domains but dominated by news. Our test set was roughly 1.2K sentences from the news domain with a single reference. To train our reordering model, we used roughly 6K alignments plus 17K snippets selected from MaxEnt alignments as described in Section 5.1 with bigram, ContextPOS and ContextWord features. The monolingual reordering BLEU (on the same data reported on in Section 5.3) was 54.0 for Hindi to English and 60.8 for English to Hindi.

For our Urdu-English experiments we used 70k sentences from the NIST MT-08 training corpus and used the MT-08 eval set for testing. We note that the MT-08 eval set has four references as compared to one reference for our Hindi-English test set. This largely explains the improved baseline performance for Urdu-English as compared to Hindi-English. We present averaged results for the Web and News part of the test sets. To train the reordering model we used 9K hand alignments and 11K snippets extracted from MaxEnt alignments as described in Section 5.1 with bigram, ContextPOS and ContextWord context feature. The monolingual reordering BLEU for the reordering model thus obtained (on the same data reported on in Section 5.3) was 52.7.

Table 7 shows that for Hindi to English, English to Hindi and for Urdu to English we see a gain of 1.5 - 2 BLEU points. For English $\rightarrow$ Hindi we also experimented with a system that uses rules (learned from the data using the methods described in (Visweswariah et al., 2010)) applied to a parse to reorder source side English sentences. This system had a BLEU score of 21.2, which is an improvement over the baseline, but our reordering model is better by 1.3 BLEU points.

An added benefit of our reordering model is that the decoder can be run with a smaller search space exploring only a small amount of reordering without losing accuracy but running substantially faster. Table 8 shows the variation in machine Hindi to English translation performance with varying skip size (this parameter sets the maximum number of words skipped during decoding, lower values are associated with a restricted decoder search space and increased speed).

skip	Unreordered	Reordered
2	12.2	16.7
4	13.4	16.7
8	14.7	16.4

Table 8: Translation performance with/without reordering with varying decoder search space.

6 Conclusion and future work

In this paper we presented a reordering model to reorder source language data to make it resemble the target language word order without using either a source or target parser. We showed consistent gains of up to 2 BLEU points in machine translation performance using this model to preorder training and test data. We show better performance compared to syntax based reordering rules for English to Hindi translation. Our model used only a part of speech tagger (sometimes trained with fairly small amounts of data) and a small corpus of word alignments. Considering the fact that treebanks required to build high quality parsers are costly to obtain, we think that our reordering model is a viable alternative to using syntax for reordering. We also note, that with the preordering based on our reordering model we can achieve the best BLEU scores with a much tighter search space in the decoder. Even accounting for the cost of finding the best reordering according to our model, this usually results in faster processing than if we did not have the reordering in place.

In future work we plan to explore using more data from automatic alignments, perhaps by considering a joint model for aligning and reordering. We would also like to explore doing away with the requirement of having a POS tagger, using completely unsupervised methods to class words. We currently only look at word pairs in calculating the loss function used in MIRA updates. We would like to investigate the use of other loss functions and their effect on reordering performance. We also would like to explore whether the use of scores from our reordering model directly in machine translation systems can improve performance relative to using just the single best reordering.

Abstract

We present an accurate word alignment algorithm that heavily exploits source and target-language syntax. Using a discriminative framework and an efficient bottom-up search algorithm, we train a model of hundreds of thousands of syntactic features. Our new model (1) helps us to very accurately model syntactic transformations between languages; (2) is language-independent; and (3) with automatic feature extraction, assists system developers in obtaining good word-alignment performance off-the-shelf when tackling new language pairs. We analyze the impact of our features, describe inference under the model, and demonstrate significant alignment and translation quality improvements over already-powerful baselines trained on very large corpora. We observe translation quality improvements corresponding to 1.0 and 1.3 BLEU for Arabic-English and Chinese-English, respectively.

1 Introduction

In recent years, several state-of-the-art statistical machine translation (MT) systems have incorporated both source and target syntax into the grammars that they generate and use to translate. While some tree-to-tree systems parse source and target sentences separately (Galley et al., 2006; Zollman and Venugopal, 2006; Huang and Mi, 2010), others project syntactic parses across word alignments (Li et al., 2009). In both approaches, as in largely all statistical MT, the quality of the alignments used to generate the rules of the grammar are critical to the success of the system. However, to date, most word alignment systems have not considered the same degree of syntactic information that MT systems have.

Extending unsupervised models, like the IBM models (Brown et al., 1993), generally requires changing the entire generative story. The additional complexity would likely make training such models quite expensive. Already, with ubiquitous tools like GIZA++ (Och and Ney, 2003), training accurate models on large corpora takes upwards of 5 days.

Recent work in discriminative alignment has focused on incorporating features that are unavailable or difficult to incorporate within other models, e.g. (Moore, 2005; Ittycheriah and Roukos, 2005; Liu et al., 2005; Taskar et al., 2005b; Blunsom and Cohn, 2006; Lacoste-Julien et al., 2006; Moore et al., 2006). Even more recently, motivated by the rise of syntax-based translation models, others have sought to inform alignment decisions with syntactic information (Fraser and Marcu, 2007; DeNero and Klein, 2007; May and Knight, 2007; Fossum et al., 2008; Haghighi et al., 2009; Burkett et al., 2010; Pauls and Klein, 2010; Riesa and Marcu, 2010).

Motivated by the wide modeling gap that still remains between syntax-based translation and word-alignment models, in this paper we expand on previous work in discriminative alignment, and move forward in three key areas:

1. We *heavily exploit both source and target syntax* in ways that most models can not. In addition, during training we extract and learn hundreds of thousands of features automatically, learning both the structure and parameters for the model at the same time.

2. Our model and inference support *arbitrary features*, and easily scale to millions of features.

3. Having strengthened the synchronicity between

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 497–507,
Edinburgh, Scotland, UK, July 27–31, 2011.

alignment and syntax-based translation models, we *advance state-of-the-art performance* in terms of both alignment and translation quality over already-powerful baselines on very large corpora.

2 A Feature-Rich Syntax-Aware Alignment Model

We follow Riesa and Marcu (2010) for efficient inference with arbitrary features, but do not rely upon hand-crafted syntactic patterns; rather, we extract syntactic features automatically from training data. We also introduce, in Section 5, an iterative approximate Viterbi inference procedure to deal with the asymmetry of the model. We show that this boosts both alignment and downstream translation quality even further.

The model itself is a linear combination of features, whose parameters are learned online via a structured perceptron (Collins, 2002). However, as we describe in Section 3, the features of the model are not known a priori. In what follows, we describe the search algorithm so that the reader has an understanding of the domain of locality before we begin to describe features and how they are learned.

2.1 Search Overview

We formulate the search for the best alignment as bottom-up parsing. Given a syntactic parse tree on one side of a parallel sentence, we use the structure of the tree to guide the search process. The key idea is that complex interactions between alignments are less likely to cross constituents, so we search recursively on the tree.

As an illustrative example, we point to the structure of the hypergraph search depicted in Figure 1. Here we are aligning the sentence pair:

a flag hung from the stage
台 上 挂 着 国旗
tái shàng guà zhe guóqí

The figure shows the search process for a small example with beam size k. Each black square represents a **partial alignment**. Each partial alignment at each node is ranked according to its model score. In this figure, the 1-best hypothesis at the leftmost NP node is constructed by composing the best hypothesis at its child DT and the 2nd-best hypothesis at its child NN. At the root node, we have a k-best list of full alignments.

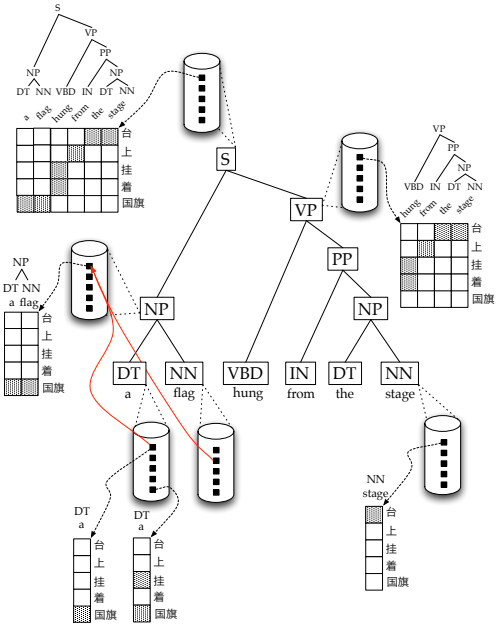

Figure 1: Approximate search through a hypergraph with beam size $k = 5$. Each black square represents a partial alignment; larger grey-shaded boxes are links in an alignment. Each partial alignment at each node is ranked according to its model score. The root node, S, contains a k-best list of full alignments.

We continue with a procedural description of the algorithm.

2.1.1 Initialization

We begin by visiting each preterminal node in sequence. We enumerate and score all one-to-one links as well as the unaligned link (aligned to null). Next, for a given preterminal node, we use cube pruning (Chiang, 2007) to find the top k one-to-two alignments, given the scores of the one-to-one links. We perform additional iterations of cube pruning to find top k sets of one-to-m links. In theory, we could increase m to the length of the foreign sentence and enumerate top k lists for each English word aligned to between 0 and all foreign words. However, in practice we set m to limit time spent here, while maintaining acceptable recall. In our experiments we set $m = 2$ for both English-Arabic and English-Chinese.

2.1.2 Combination

We continue traversing the tree bottom-up. At each nonterminal node, a k-best list of partial alignments from each of its child nodes are combined into a larger span. We use cube pruning to do this efficiently.[1] Nodes in different subtrees are processed independently of one another; i.e., for any node, alignment information at that node's sister is unavailable. For example, in Figure 1, alignment information at the leftmost NP is unavailable to us while we are constructing partial alignments at the PP. Search continues recursively up the tree, until we have reached the root node. The root node again computes the top k alignments from its children, and these comprise our final k-best list of full alignments.

In our experiments we only make use of the 1-best alignment for evaluation and translation. Previous work has shown that only shallow k-best lists of alignments may be beneficial, and that very deep k-best lists are not especially useful in improving final downstream translation grammar extraction due to rapid degradation in quality (Venugopal et al., 2008; Liu et al., 2009b); though they may have other uses.

3 Automatically Exploiting Syntactic Features for Alignment

Up to now, previous work in syntax-based alignment has largely modeled alignments based on features encoding target-side English syntactic and lexical information, but only lexical information on the source side.

However, there is much more data waiting to be exploited, and the flexible model and efficient and modular learning framework of hierarchical discriminative alignment afford us this possibility. Here, we discuss our target-side features, source-side features, and features that jointly take into account both source- and target-side information.

3.1 Target Syntax Features

Most alignment systems currently function without explicit regard to the downstream translation model. Some notable exceptions are May and Knight (2007) who generate syntactic alignments by re-aligning word-to-word alignments with a syntactic model; and Pauls and Klein (2010) who generate syntactic alignments with a synchronous ITG (Wu, 1997) approach. We depart from ITG-based models (Cherry and Lin, 2006; Haghighi et al., 2009) because of their complexity ($O(n^6)$ in the synchronous case), requiring heavy pruning or the computation of outside cost estimates (DeNero and Klein, 2010). Instead, we use linguistically motivated target-side parse trees to constrain search, as described above. These trees are output from the Berkeley parser (Petrov and Klein, 2007) and fixed at alignment time. We use these trees not only as a vehicle for search, but also for features.

A significant motivation for this work is the desire to make the connection, at alignment time, between translation rules used in decoding and the alignments that yield such translation rules. To do this, we fold the rule extraction process into the alignment search. At each step in the search process, we can extract translation rules from a given partial alignment and encode them as binary features.

Importantly, the rule extraction process itself is not directly tied to the alignment system, but rather to the downstream translation model. We can drop in any type of rule extraction we like into the alignment system, though some may generalize better than others to new data in a large corpus. This is key for supervised training conditions with relatively small amounts of annotated data.[2] In this work we focus on string-to-tree translation and the translation rule space described in (Galley et al., 2004; Galley et al., 2006).

During training and inference, we are constantly scoring partial alignments. Every time we have a partial alignment to score, we can extract all potential translation rules implied by that alignment, and encode those rules as features. In this case, we are doing two important things:

1. informing the alignment search with the rules of the translation model, and

2. modeling actual translation rules – the model parameters give us a way to quantify the relative importance of each rule.

For example, we learn that:

[1] Cube pruning is approximate when we have nonlocal combination features, and most of our features are of this type.

[2] For example, fully lexicalized phrase-based rules are less useful here than gapped phrases or hierarchical rules.

(1) Chinese VP and NP tend to be reordered around the 的 particle when translating to English.

feature	weight
NP(NP$_{\boxed{1}}$ VP$_{\boxed{2}}$) ↔ $\boxed{2}$ 的 $\boxed{1}$	1.01304

(2) When translating an Arabic NP as part of a VP, we often insert "is".

feature	weight
VP((VBZ is) NP$_{\boxed{1}}$) ↔ $\boxed{1}$	0.67252

From this process we extract and learn 326,239 lexicalized and non-lexicalized translation rule features in our Arabic-English model; 234,972 in our Chinese-English model. Those features for which a positive weight is learned tend to generalize well over the training data; negatively weighted features do not, and are generally learned from alignments with mistakes during search. See Figure 2 for additional examples of rule features learned for Arabic-English alignment.

Negative evidence Nearly 67% of the rule features we learn for Chinese-English, and 55% of the rule features we learn for Arabic-English are negatively weighted. Early experiments involved only firing indicator rule features when an extracted rule at alignment-time matched in a set of rules extracted offline from our hand-aligned data. However, coverage from such rules will always be limited; firing every rule as a feature as it is encountered during search gives us many more darts to throw. Using only rule features extracted from gold data lowers F-measure by close to 5 points.

3.2 Source Syntax Features and Joint Features

Source syntactic trees have recently been shown to be helpful in machine translation decoding (Zhang et al., 2008; Liu et al., 2009a; Chiang, 2010), but to our knowledge have not been used in alignment models other than that of Burkett et al. (2010). We parse the source side of our data using the Berkeley parser (Petrov and Klein, 2007), and encode information provided by the source syntax as features in the model in two ways: (1) as tree-distance features[3], and (2) as joint source-target syntax features.

[3]These features parameterize the intuition that if two source words align to a single target word, we prefer them to be members of the same constituent, or having a short path through the tree from one word to the other, e.g. (in, 在...中), or the first and last Chinese words in the examples in Figure 3.

Extracted Rule Feature	Weight
NP → JJ$_{[1]}$ NN$_{[2]}$ ↔ [2] [1]	1.11908
NP → JJ$_{[1]}$ NN$_{[2]}$ ↔ [1] [2]	–0.15417
PP → IN$_{[1]}$ NP$_{[2]}$ ↔ [1] [2]	1.15328
PP → IN$_{[1]}$ NP$_{[2]}$ ↔ [2] [1]	–0.65943

Figure 2: Translation rules as features extracted during Arabic-English alignment. These rules show that we learn to reorder adjectives and nouns inside noun phrases, and that prepositions before sister NPs prefer to be translated monotonically. For Chinese-English, we learn the opposite.

3.2.1 Source-Target Coordination Features

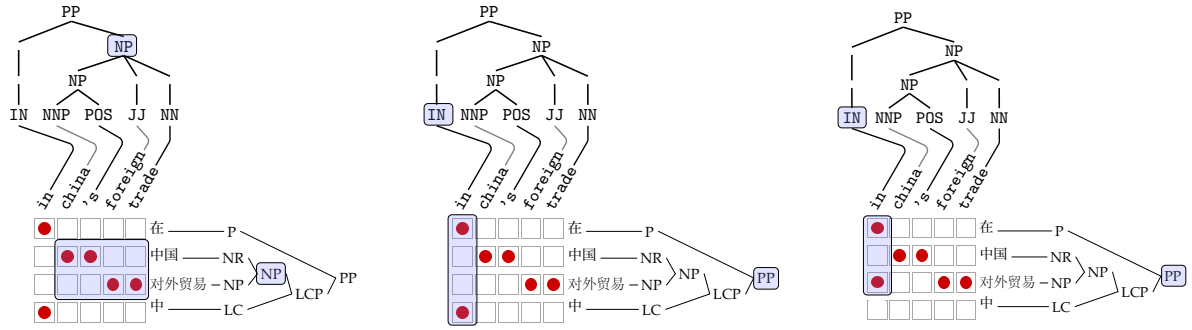
Drawing on work by Chiang (2010) in stochastically rewriting syntactic constituents across languages in a translation model, we adapt the general idea to alignment modeling. Chiang calls these features *fuzzy syntax* features; here, we simply call them *coordination* features in our adaptation for alignment, so as to avoid the implication that we are rewriting.

This feature family is a set of binary features that may fire at any nonterminal node in the tree during bottom-up search. A feature fires for each combination of two nonterminal source and target nodes s and t, respectively, that match the following conditions:

1. t is the label of the current target tree node in the bottom-up search.

2. s is the label of the source tree node of maximal depth (i.e. closest to leaf nodes) that spans all links also spanned by t.

Figure 3 shows three examples of this joint feature over source and target trees. In Figure 3a, the maximal-depth source tree node that spans every link also spanned by the shaded target tree NP



(a) Source/target tree feature firing at node NP, with value ⟨ NP ; NP ⟩. The maximal-depth source tree node that spans every link also spanned by the shaded target tree NP is also labeled NP.

(b) Source/target tree feature firing at node IN, returning value ⟨ IN ; PP ⟩.

(c) In this figure, depicting an incorrect alignment, the same feature value is fired as for the correct alignment in 3b: ⟨ IN ; PP ⟩. We need more contextual annotation to create more discriminative power.

Figure 3: Two examples of joint features over monolingual parse trees. The value of the feature depends on the shaded areas.

is also labeled NP. So, the feature returns a value of ⟨NP; NP⟩. In Figure 3b, PP is the label of the maximal-depth source tree node that spans every link also spanned by the shaded target tree IN node; the feature fires a value ⟨IN ; PP⟩. We might expect this pairing of IN with PP, or of IN with P, but we would expect to learn a penalizing parameter weight for the pairing of, say, IN with NP.

Adding more context Powerful as this feature is, it is not quite discriminating enough; it may return the same feature value for both a correct and incorrect alignment, as shown in Figure 3c. To overcome this, we introduce additional features annotated with the left-most and right-most tags in the current span. For example, in this figure, we also fire ⟨ IN ; PP(P,NP) ⟩, and learn a negative weight of −0.638 denoting a poor choice of alignment. We also find it helpful to keep the original unannotated feature as a poor-man's backoff.

Some examples Table 1 shows some of the maxmially and minimally-weighted features learned. As the more highly weighted features show, both models learn to prefer alignments that result in the coordination of similar constituent labels. For example, the Chinese model learns a very high weight for aligning sets of English words that form prepositional phrases to sets of Chinese words that also form prepositional phrases[4].

	Ara-Eng Model			Chi-Eng Model		
	eng	ara	w	eng	chi	w
[1]	SBAR	SBAR	6.40	PP	PP	10.3
[2]	S	S(CC,PU)	4.91	NP	NP	9.38
[3]	PP	PP	4.20	SBAR	VP(VV,PU)	6.97
[4]	VP	VP	3.90	NP	NP(DT,NN)	6.67
[5]	SBAR	PP	2.58	PP	PP(P,LC)	6.38
[6]	NP	S	-2.80	NP	PP	-6.82
[7]	NP	VP	-3.01	S	IP(PU,PU)	-7.44
[8]	NP	NP(NN,IN)	-4.52	PP	IP	-7.33
[9]	PP	VP	-5.13	SBAR	VP	-7.72
[10]	PP	S	-7.37	NP	IP	-7.83

Table 1: This table shows a sampling of the highest and lowest-weighted coordination features applied when scoring partial alignments at nodes in the tree. Preterminal tags inside parentheses indicate the POS tags on the left and right edge of a given constituent.

Inversely, we learn high negative weights for model features that fire for alignments that oblige the firing of features of very dissimilar nonterminal labels, and that often yield asynchronous bracketing. For example, the Arabic model learns that English words that form prepositional phrases should

[4] In Table 1, Chinese feature [1].

not align to sets of Arabic words that form entire sentences or verb phrases[5].

In total, we learn 127,932 syntactic coordination features in our Arabic-English model; 59,239 for Chinese-English.

4 Learning

We learn feature weights using a parallelized implementation of online averaged perceptron (Collins, 2002). We distribute training examples to CPUs in a cluster and essentially run several perceptron learners in parallel. We communicate and average the weight vectors of each learner according to the Iterative Parameter Mixing strategy described by McDonald et al. (2010).

Let y_i be the correct output for input x_i. Here, y_i is an alignment; x_i is a sentence pair and parse tree. At each iteration, our perceptron update is:

$$\mathbf{w} \leftarrow \mathbf{w} + \mathbf{h}(y_i) - \mathbf{h}(\hat{y}) \tag{3}$$

And we define:

$$\hat{y} = \arg\max_{y \in \mathcal{Y}(x_i)} \ell(y_i, y) + \mathbf{w} \cdot \mathbf{h}(y) \tag{4}$$

$$\ell(y_i, y) = 1 - F_1(y_i, y) \tag{5}$$

with $\mathbf{w}$ our weight vector, $\mathbf{h}(y)$ our sparse vector of feature values, $\mathcal{Y}(x_i)$ all possible outputs for input x_i, and $F_1(y_i, y)$ balanced F-measure. The loss, $\ell(y_i, y)$, is a measure of how bad it would be to guess $\hat{y}$ instead of y.

In selecting $\hat{y}$, we draw upon the loss-augmented inference literature (Tsochantaridis et al., 2004; Taskar et al., 2005a). Alignment $\hat{y}$ is the output candidate maximizing the sum of both the loss and model score. This guess appears attractive to the model, yet has low F-measure, and so is exactly the sort of output we would like to update away from.

During training, we learn both the parameters and model structure. Figure 4b shows how the size of the model grows over time. As described in Sections 2 and 3, we automatically extract and fire features given an alignment configuration and our current position in the tree. We see a steep initial growth in model size, and then begin to trail off as the number of new unique rules and negative evidence we encounter diminishes.

[5] In Table 1, Arabic features [6] and [7].

Model Selection Among models from the first iteration up to convergence, we choose the model parameters from the best performing model as measured by F-measure on a held-out development set of alignments.

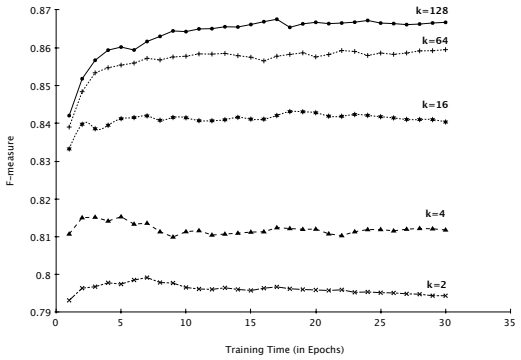
5 Iterative Approximate Viterbi Inference

Though up to now we have described features that fire during bottom-up search on the target-language tree, we can also search bottom-up on the source-language tree. The syntactic features we have described are generic enough that they will still be extractable and applicable. Because our model and inference procedure are asymmetric, a search on the source-language tree will generate alignments from a different space, and can provide a unique signal we would not otherwise have. We can use the Viterbi alignments from each model to inform the other. In the following we describe a method for simultaneously training both target-tree and source-tree models but with features to enforce agreement, somewhat similar to (Nivre and McDonald, 2008) in integrating two dependency parsing models.

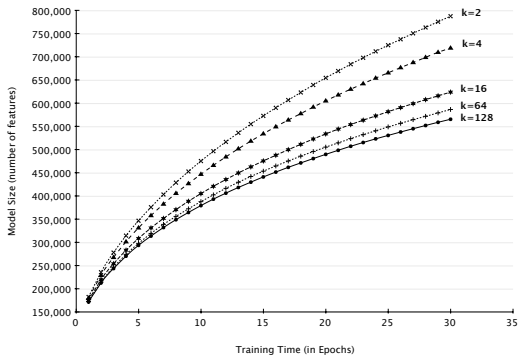
We begin by training two models, one that operates on the target tree, and one that operates on the source tree. Call the parameters learned from these models $\mathbf{w}_1^t$ and $\mathbf{w}_1^s$, respectively. Then, performing inference under these models yields alignments a_1^t and a_1^s.

In the next iteration we learn parameters $\mathbf{w}_2^t$ and $\mathbf{w}_2^s$, and introduce agreement features. In this step, during training to find $\mathbf{w}_2^t$, the target-tree model uses a_1^s to fire indicator features. These fire for any alignment link that was also present in the previous iteration's source-tree alignment, a_1^s. Analogously, when searching for the best $\mathbf{w}_2^s$, we use a_1^t to fire indicator features that fire for any alignment link also present in the previous iteration's target-tree alignment, a_1^t.

This process of using the alignment from the previous iteration's opposing tree continues until convergence, i.e. until we no longer see improvement in our 1-best source-tree and target-tree alignments. When we use these alignments for downstream translation, we symmetrize with the *grow-diag-final* heuristic, which continues to work remarkably well in practice. We also experiment with the intersection of both final alignments.



(a) Learning curves (Arabic-English): F-measure accuracy on heldout development data over time for five different beam settings, k=2, k=4, k=16, k=64 and k=128. For Arabic-English, improvements are minimal with beams larger than k=128; and for Chinese-English, with beams larger than k=256.



(b) Model size as a function of time for five different beam settings (Arabic-English): We see a steep initial growth, and then begin to trail off as the number of new unique extractable features and negative evidence we encounter diminishes. Growth rate is higher for models with narrower beams that make more mistakes.

Figure 4: Learning feature-rich alignment models. Figure 4a shows learning curves on heldout data for five different beam sizes. Figure 4b shows how the models dynamically grow over time. In Figure 4b we notice that less accurate models with narrower beams need to add more complexity in an attempt to make up for their many more mistakes.

6 Evaluation

6.1 Alignment Quality

From LDC2006E86 and LDC2006E83, we use as training data 2,280 hand-aligned sentence pairs of Arabic-English and 1,102 for Chinese-English. We measure training convergence using a held-out development set of 100 sentence pairs for each language pair, and evaluate with F-measure on a held-out test set of 184 sentences pairs for Chinese-English and 364 sentence pairs for Arabic-English. We use instances of the Berkeley parser (Petrov and Klein, 2007) trained on the English Penn Treebank, Chinese Treebank 6, and the Arabic Treebank parts 1–3; for each language, trees are fixed at alignment time using the 1-best output from each parser.

We use Model-4 symmetrized with the grow-diag-final heuristic, trained with GIZA++ as a baseline alignment model. We train two GIZA++ models on our largest available Chinese-English and Arabic-English parallel corpora. These consist of 261M and 223M English words,[6] respectively. The size of these corpora make for quite a powerful unsupervised baseline.

In training our alignment model, we use the syntactic features discussed in Section 3, plus word-based lexical features $t(e \mid f)$ and $t(f \mid e)$ used during initialization, extracted offline directly from the translation-table of GIZA++. Using these features alone results in an F-measure of 59.1 for Arabic-English, and 55.6 for Chinese-English. Our automatically extracted syntactic features and iterative inference algorithm get us the rest of the way, bringing performance up to 87.6 and 87.0, respectively.

Table 2 shows the results on our held-out 100-sentence test set. In an intrinsic evaluation on an alignment task, our F-measure scores are more than 15 points higher than the baseline for both language pairs.

6.2 Translation Quality

In evaluating downstream translation quality, we build three translation systems each for Arabic-English and Chinese-English: one with alignments from GIZA++, one with alignments from our syntactically-informed discriminative model, and one with alignments from our model with iterative inference (Section 5). For each of these systems we

[6]These counts correspond to 240M words of Chinese and 194M words of Arabic.

	Arabic-English			Chinese-English		
	F	P	R	F	P	R
GIZA++ M4 grow-diag-final	72.5	74.5	70.5	71.7	71.4	72.0
Target-tree alignments only	86.8	89.1	84.6	84.4	89.4	80.0
with Iterative Inference (grow-diag-final)	**87.6**	89.7	**85.6**	**87.0**	90.0	**84.1**
with Iterative Inference (intersection)	83.4	**93.1**	75.6	83.1	**95.4**	73.6

Table 2: F-measure, Precision, Recall for GIZA++ Model-4, and for alignments from this work. GIZA++ was trained on 223M words for Arabic-English, and 261M words for Chinese-English. We observe very large gains in accuracy of 15 points for both language pairs. Iterative inference with source and target-tree alignments yields a large effect on Chinese-English recall, and a modest improvement in Arabic-English.

align our parallel training corpora described in Section 6.1, and compute word-based lexical weighting features (Koehn et al., 2003) based on these alignments.

Because of the number of experiments involved in this research, we needed to accelerate our downstream experimental pipeline. While we align our full training corpus, we extract translation rules from a subset of our alignment training data; the quality of the translation rules extracted is still a function of the original alignment model.

We train a syntax-based string-to-tree translation model (Galley et al., 2004; Galley et al., 2006) and extract translation rules[7] using alignments produced by each system from 4.25+5.43M words for Arabic-English and 31.8+37.7M words for Chinese-English. For Arabic-English, we tune our MT system on a held-out development corpus of 1,172 parallel sentences, and test on a heldout set of 746 parallel sentences with four references each. For Chinese-English we tune our MT system on a held-out development corpus of 4,089 parallel sentences, and test on a set of 4,060 sentences with four references each. We tune the translation models for these systems with MIRA (Watanabe et al., 2007; Chiang et al., 2008). Our tuning and test corpora are drawn from the NIST 2004 and 2006 evaluation data, disjoint from our rule-extraction data. All systems used two language models; one trained on the combined English sides of our Arabic-English and Chinese-English data (480M words), and one trained on 4 billion words of English data.

MT results are shown in Table 3. We show a gain of 1.0 and 1.3 BLEU points over GIZA++ Model-4. Each is statistically significant over the baseline.

Alignment model	ara-eng **BLEU**	chi-eng **BLEU**
GIZA++ Model-4	47.6	26.2
Target-tree alignments only	48.3*	26.4+
+Iterative Inference (gdf)	48.4	27.0*
+Iterative Inference (intersection)	**48.6**+	**27.5***

Table 3: IBM BLEU scores using a syntax-based MT system. We show statistically significant gains in both language pairs over unsupervized GIZA++ Model 4 trained on very large corpora. An asterisk (*) denotes a statistically significant improvement with $p < 0.01$ over the number immediately above; a (+) denotes $p < 0.05$.

In the case of Chinese-English, we see a 1.1 BLEU gain when using iterative inference over the standard model which provides only target-tree alignments. As measured by a bootstrap resampler, this improvement is statistically significant, with $p < 0.01$.

For Arabic-English, we see a BLEU gain of 0.7 with target-tree alignments alone, and a total 1.0 BLEU gain over the baseline with iterative inference and our joint-agreement features.

We expect the limited improvement of iterative inference for Arabic-English is due to at least two factors:

1. the relative weakness of our Arabic parser, and
2. as shown in Table 2, our Arabic target-tree alignments are already quite accurate.

[7] We use the so-called *composed* rules of (Galley et al., 2006).

7 Discussion

We achieve our best downstream BLEU results when using iterative inference with source-tree and target-tree alignments, keeping the intersection.[8] These alignments have been shown to have recall in a similar neighborhood as our unsupervised baseline, but extremely high precision.

As DeNero and Klein (2010) and others have observed, the relationship between word alignment evaluation metrics and BLEU score remains tenuous at best. While we are able to induce some of the most accurate alignments we have seen to date, it remains unclear, given our gold hand-aligned data, whether we are optimizing for the right function ultimately for the translation task. Related metrics, like Rule F-measure (Fossum et al., 2008) and Translation Unit Error Rate (Søgaard and Kuhn, 2009), are still functions of a given gold alignment. If the gold alignment is not ideally annotated for the translation task, it matters little what our alignment evaluation metric is.

Why do grow-diag-final alignments (for our system) not perform as well? We believe the answer lies in the fact that these alignments *too closely* resemble the gold alignments with word-alignment annotation standards[9] that do not handle function words ideally for the translation task. Indeed, Hermjakob (2009) reports improved BLEU with a hand-modified gold standard.

Interestingly, the places in which our source-tree and target-tree alignments most often disagree is in the alignment of function words with no clear translation in the opposite language. For example, English *the* has no translation in Chinese. Our intersection alignments generally leave *the* unaligned to Chinese words, whereas in our gold alignments *the* is generally aligned to the same word as the head of the NP in which it appears.[10]

We see our best translation performance with our intersection alignments because we believe it largely leaves untranslated words and words without clear translations in the opposite language unaligned; we believe this may be the right thing to do.[11] Continuing with the *the* example, our translation model learns to insert words like *the* where appropriate, and such insertion rules are validated by the language model. We learn with good coverage accurate high-precision translation rules for content words, and general insertion rules for words like *the*, instead of learning two unique lexicalized rules for a given content word, one with and one without *the*. In this way, we are learning a more general grammar that explains the data.

8 Conclusion

In this work we are closing the gap between translation and alignment models in terms of syntactic sophistication. We have (1) shown how to efficiently extract hundreds of thousands of language-independent syntactic features useful for alignment, (2) given a detailed analysis of the types of linguistic phenomena these varied features generalize, and (3) report significant gains not only on alignment quality but also on downstream machine translation quality (1.0+ BLEU) over very strong baselines across diverse language pairs.

We have also hinted at roadblocks to improved discriminative alignment modeling for translation. We expect that an accurate discriminative word alignment system, such as the one presented here, in conjunction with better annotation standards for alignment will take us even farther beyond the advancements in translation quality shown here.

[8] Intersection symmetrization does not help GIZA++ because the resulting recall is so low as to severely limit the usefulness of direct translation rule extraction with such alignments (49.7 Recall for Chi-Eng; 47.2 Recall for Ara-Eng).

[9] We refer to those used for data used in this work, LDC2006E86 and LDC2006E93, as well as the standards for later hand-aligned data developed for the GALE program.

[10] E.g., ⟨(the country , 国家)⟩; but not, ⟨(the, ∅); (country, 国家)⟩

[11] Naively leaving all function words unaligned is likely suboptimal, as many have seem to have direct translations in some contexts; cf. (of, من) and (of, 的).

Abstract

We propose an algorithm allowing to efficiently retrieve example treelets in a parsed tree database in order to allow on-the-fly extraction of syntactic translation rules. We also propose improvements of this algorithm allowing several kinds of flexible matchings.

1 Introduction

The popular Example-Based (EBMT) and Statistical Machine Translation (SMT) paradigms make use of the translation examples provided by a parallel bilingual corpus to produce new translations. Most of these translation systems process the example data in a similar way: The parallel sentences are first word-aligned. Then, translation rules are extracted from these aligned sentences. Finally, the translation rules are used in a decoding step to translate sentences. We use the term translation rule in a very broad sense here, as it may refer to substring pairs as in (Koehn et al., 2003), synchronous grammar rules as in (Chiang, 2007) or treelet pairs as in (Quirk et al., 2005; Nakazawa and Kurohashi, 2008).

As the size of bilingual corpus grow larger, the number of translation rules to be stored can easily become unmanageable. As a solution to this problem in the context of phrase-based Machine Translation, (Callison-Burch et al., 2005) proposed to pre-align the example corpora, but delay the rule extraction to the decoding stage. They showed that using Suffix Arrays, it was possible to efficiently retrieve all sentences containing substrings of the sentence to be translated, and thus extract the needed translation rules on-the-fly. (Lopez, 2007) proposed an extension of this method for retrieving discontinuous substrings, making it suitable for systems such as (Chiang, 2007).

In this paper, we propose a method to apply the same idea to Syntax-Based SMT and EBMT (Quirk et al., 2005; Mi et al., 2008; Nakazawa and Kurohashi, 2008). Since Syntax-Based systems usually work with the parse trees of the source-side sentences, we will need to be able to retrieve efficiently examples trees from fragments (treelets) of the parse tree of the sentence we want to translate. We will also propose extensions of this method allowing more flexible matchings.

2 Overview of the method

2.1 Treelet retrieval

We first formalize the setting of this chapter by providing some definitions.

Definition 2.1 (Treelets). A *treelet* is a connected subgraph of a tree. A treelet T_1 is a *subtreelet* of another treelet T_2 if T_1 is itself a connected subgraph of T_2. We note $|T|$ the number of nodes in a treelet. If $|T| = 1$, T is called an *elementary treelet*. A *linear treelet* is a treelet whose nodes have at most 1 child. A *subtree* rooted at node n of a tree $\mathcal{T}$ is a treelet containing all nodes descendants of n.

Definition 2.2 (Sub- and Supertreelets). If T_1 is a subtreelet of T_2 and $|T_1| = |T_2| - 1$, we call T_1 an *immediate subtreelet* of T_2. Reciprocally, T_2 is an *(immediate) supertreelet* of T_1. Furthermore, if T_2 and T_1 are rooted at the same node in the original tree, we say that T_2 is a *descending supertreelet* of T_1. Otherwise it is an *ascending supertreelet* of T_1.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 508–518,
Edinburgh, Scotland, UK, July 27–31, 2011.

In treelet retrieval, we are given a certain treelet type and want to find all of the tokens of this type in the database $\mathcal{DB}$. Each token of a given treelet type will be identified by a mapping from the node of the treelet type to the nodes of the treelet token in the database.

Definition 2.3 (Matching). Given a treelet T and a tree database $\mathcal{DB}$, a matching of T in $\mathcal{DB}$ is a function M that associate the treelet T to a tree $\mathcal{T}$ in $\mathcal{DB}$ and every node of T to nodes of $\mathcal{T}$ in such a way that: $\forall n \in T, label(M(n)) = label(n)$ and $\forall (n_1, n_2) \in T$ s.t n_2 is a child of n_1, $M(n_2)$ is a child of $M(n_1)$.

In the common case where the siblings of a tree are ordered, a matching must satisfy the additional restriction: $\forall n_1, n_2 \in T, n_1 <_s n_1 \Leftrightarrow M(n_1) <_s M(n_1)$, where $<_s$ is the partial order relation between nodes meaning "is a sibling and to the left of"

We note $occ(T)$ (for "occurrences of T ") the set of all possible matchings from T to $\mathcal{DB}$. We will call *computing* T the task of finding $occ(T)$. If $|occ(T)| = 0$, we call T an *empty treelet*. *Computing a query tree* $\mathcal{T}_Q$ means computing all of its treelets.

Definition 2.4 (Notations). Although treelets are themselves trees, we will use the word *treelet* to emphasize they are a subpart of a bigger tree. We will note T a treelet, and $\mathcal{T}$ a tree. $\mathcal{T}_Q$ is the query tree we want to compute. $\mathcal{DB}$ will refer to the set of trees in our database. We will use a bracket notation to describe trees or treelets. Thus "a(b c d(e))" is the tree at the bottom of figure 2.

2.2 General approach

There exists already a large body of research about tree pattern matching (Dubiner et al., 1994; Bruno et al., 2002). However, our problem is quite different from finding the tokens of a given treelet in a database. We actually want to find all the tokens of all of the treelets of a given query tree. The query tree itself is unlikely to appear in full even once in the database. In this respect, our approach will have many similarities with (Callison-Burch et al., 2005) and (Lopez, 2007), and can be seen as an extension of these works.

The basis of the method in (Lopez, 2007) is to look for the occurrences of continuous substrings using a Suffix Array, and then intersect them to find the occurrences of discontinuous substrings. We will have a similar approach with two variants. The first variant consists in using an adaptation of the concept of suffix arrays to trees, which we will call Path-To-Root Arrays (section 3.4), that allows us to find efficiently the set of occurrences of a linear treelet. Occurrences of non-linear treelets can then be computed by intersection. The second variant is to use an inverted index (section 3.5). Then the occurrences of all treelets, even the linear treelets, are computed by intersection.

The main additional difficulty in considering trees instead of strings is that while a string has a quadratic number of continuous substrings, a tree has in general an exponential number of treelets (eg. several trillion for the dependency tree of a 70 words sentence). There is also an exponential number of discontinuous substrings, but (Lopez, 2007) only consider substrings of bounded size, limiting this problem. We will not try to bound the size of treelets retrieved. It is therefore crucial to avoid computing the occurrences of treelets that have no occurrences in the database, and also to eliminate as much redundant calculation as is possible.

Lopez proposes to use Prefix Trees for avoiding any redundant or useless computation. We will use a similar idea but with an hypergraph that we will call "computation hypergraph" (section 3.2). This hypergraph will not only fit the same role as the Prefix Tree of (Lopez, 2007), but also will allow us to easily implement different search strategies for flexible search (section 6).

2.3 Representing positions

Whether we use a Path-to-Root Array or an inverted index, we will need a compact way to represent the position of a node in a tree. It is straightforward to define such a position for strings, but slightly less for trees. Especially, if we consider ordered trees, we will want to be able to compare the relative location of the nodes by comparing their positions.

The simplest possibility is to use an integer corresponding to the rank of the node in a in-order depth-first traversal of the tree. It is then easy, for two nodes b and c, children of a parent node a, to check if b is on the left of c, or on the left of a, for example.

A more advanced possibility is to use a representation inspired from (Zhang et al., 2001), in which

the position of a node is a tuple consisting of its rank in a preorder (ie. children last) and a postorder (children first) depth-first traversal, and of its distance to the root. This allows to test easily whether a node is an ancestor of another, and their distance to each other. This allows in turn to compute by intersection the occurrences of discontinuous treelets, much like what is done in (Lopez, 2007) for discontinuous strings. This is discussed in section 7.2.

3 Computing treelets incrementally

We describe here in more details how the treelets can be efficiently computed incrementally.

3.1 Dependence of treelet computation

Let us first define how it is possible to compute a treelet from two of its subtreelets. Let us consider a treelet T and two treelets T_1 and T_2 such that $T = T_1 \cup T_2$, where, in the equality and the union, the treelet are seen as the set of their nodes. There are two possibilities. If $T_1 \cap T_2 = \emptyset$, then the root of T_1 is a child of a node of T_2 or vice-versa. We then say that T_1 and T_2 form a disjoint coverage (abbreviated as D-coverage) of T. If $T_1 \cap T_2 \neq \emptyset$, we will say that T_1 and T_2 form an overlapping coverage (abbreviated as O-coverage) of T.

Given two treelets T_1 and T_2 forming a coverage of T, we can compute $occ(T)$ from $occ(T_1)$ and $occ(T_2)$ by combining their matchings.

Definition 3.1 (compatibility for O-coverage). Let T be a treelet of $\mathcal{T}_Q$. Let T_1 and T_2 be 2 treelets forming a O-coverage of T. Let $M_1 \in occ(T_1)$ and $M_2 \in occ(T_2)$. M_1 and M_2 are compatible if and only if $M_1|_{T_1 \cap T_2} = M_2|_{T_1 \cap T_2}$ and $\mathcal{I}(M_1|_{T_1 \setminus T_2}) \cap \mathcal{I}(M_2|_{T_2 \setminus T_1}) = \emptyset$.

In the definition above, $|_S$ is the restriction of a function to a set S and $\mathcal{I}$ is the image set of a function.

If the children of a tree are ordered, we must add the additional restriction: $\forall (n_1, n_2) \in (T_1 \setminus T_2) \times (T_2 \setminus T_1), n_1 <_s n_2 \Leftrightarrow M_1(n_1) <_s M_2(n_2)$.

Definition 3.2 (compatibility for D-coverage). Let T_1 and T_2 be 2 treelets forming a D-coverage of T. Let's suppose that the root n_2 of T_2 is a child of node n_1 of T_1. Let $M_1 \in occ(T_1)$ and $M_2 \in occ(T_2)$. M_1 and M_2 are compatible if and only if $M_2(n_2)$ is a child of $M_1(n_1)$.

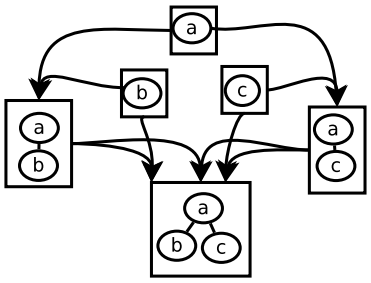

Figure 1: A computing hypergraph for "a(b c)".

Definition 3.3 (intersection ($\otimes$) operation). If two matchings are compatible, we can form their union, which is defined as $(M_1 \cup M_2)(n) = M_1(n)$ if $n \in T_1$ and $M_2(n)$ else. We note $occ(T_1) \otimes occ(T_2) = \{M_1 \cup M_2 \mid M_1 \in occ(T_1), M_2 \in occ(T_2)$ and M_1 is compatible with $M_2\ \}$. Then,we have the property: $occ(T) = occ(T_1) \otimes occ(T_2)$

In practice, the intersection operation will be implemented using merge and binary merge algorithms (Baeza-Yates and Salinger, 2005), following (Lopez, 2007).

3.2 The computation hypergraph

We have seen that it is possible to compute $occ(T)$ from two subtreelets forming a coverage of T. This can be represented by a hypergraph in which nodes are all the treelets of a given query tree, and every pair of overlapping or adjacent treelet is linked by an hyperedge to their union treelet. Whenever we have computed two starting points of an hyper-edge, we can compute its destination treelet. An example of a small computation hypergraph is described in figure 1.

It is very convenient to represent the incremental computation of the treelets as a traversal of this hypergraph. First because it contributes to avoid redundant computations: each treelet is computed only once, even if it is used to compute several other treelets. Also, if a query tree contains two distinct but identical treelets, only one computation will be done, provided the two treelets are represented by the same node in the hypergraph. The hypergraph also allows us to avoid computing empty treelets, as we describe in next section. This hypergraph therefore has the same role for us as the prefix tree used

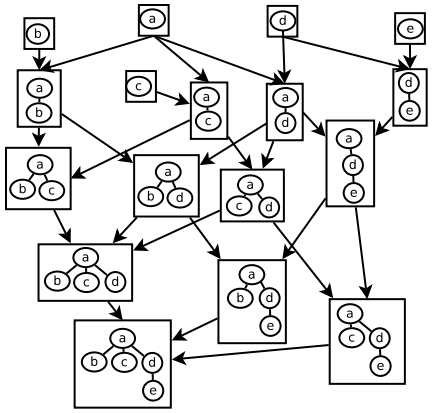

Figure 2: Inclusion DAG for the tree $a(bcd(e))$

in (Lopez, 2007). Of course, the hypergraph is generated on-the-fly during the traversal.

Furthermore, different traversals will define different computation strategies, and we will be able to use some more advanced graph exploration methods in section 6.

3.3 The Immediate Inclusion DAG

In many cases (but not always: see section 4.3), the most optimal computation strategy should be to always compute a treelet from two of its immediate subtreelets. This is because the computation time will be proportional to the size of the smallest occurrence set of the two treelets, and thus the "cheapest" subtreelet is always one of the immediate subtreelets. With this computation strategy, we can replace the general computation hypergraph by a DAG (Directed Acyclic Graph) in which every treelet point to its immediate supertreelets. An example is given on figure 2. We will call this DAG the (Immediate) Inclusion DAG.

Traversals of the Inclusion DAG should be pruned when an empty treelet is found, since all of its supertreelets will also be empty. The algorithm 1 provide a general traversal of the DAG avoiding to compute as many empty treelets as possible. It uses a queue $\mathcal{D}$ of discovered treelets, and a data-structure $\mathcal{C}$ that associate a treelet to those of its subtreelets that have been already computed. Once a treelet T has been computed and is found to be non empty, we discover its immediate supertreelets $T^{S1}, T^{S2}, \ldots$ (if they have not been discovered already) and add T to $\mathcal{C}$ (T^{S1}), $\mathcal{C}$ (T^{S2}), ... The operation min($\mathcal{C}$ (T)) retrieve the 2 subtreelets from $\mathcal{C}$ (T) that have the least occurrences. If one of them is empty, we can directly conclude that T is empty. No treelet whose all immediate subtreelets are empty is ever put in the discovered queue, which allows us to prune most of the empty treelets of the Inclusion DAG.

Algorithm 1: Generic DAG traversal

```
1  Add the set of precomputed treelets to 𝒟;
2  while ∃T ∈ 𝒟 s.t T ∈ precomputed or |𝒞(T)| > 2
   do
3      pop T from 𝒟;
4      if T in precomputed then
5          occ(T) ← precomputed[T];
6      else
7          T1,T2=min(𝒞 (T));
8          if |occ(T1)| = 0 then
9              occ(T) ← ∅;
10         else
11             occ(T) ← occ(T1) ⊗ occ(T2);
12     for T^S ∈ supertree(T) do
13         if occ(T^S) = undef then
14             Add T to 𝒞(T^S);
15             if |occ(T)| > 0 and T^S ∉ 𝒟 then
16                 Add T^S to 𝒟;
```

A treelet in the inclusion DAG can be computed as soon as two of its antecedents have been computed. To start the computation (or rather, "seed" it), it is necessary to know the occurrences of treelet of smaller size. In the following sections 3.4 and 3.5, we describe two methods for efficiently obtaining the set of occurrences of some initial treelets.

3.4 Path-to-Root Array

We present here a method to compute very efficiently $occ(T)$ when T is linear. This method is similar to the use of Suffix Arrays (Manber and Myers, 1990) to find the occurrences of continuous substrings in a text.

Definition 3.4 (Paths-to-Root Array). Given a labeled tree $\mathcal{T}$ and a node $n \in \mathcal{T}$, the path-to-root of n is the sequence of labels from n to the root. The *Paths-to-Root Array* of a set of trees $\mathcal{DB}$ is the lexicographically sorted list of the Path-to-Roots of every node in $\mathcal{DB}$.

Just as with suffixes, a path-to-root can be represented compactly by a pointer to its starting node in $\mathcal{DB}$. We then need to keep the database $\mathcal{DB}$ in

	Pos	PtR		Pos	PtR		Pos	PtR
1	3:4	a	8	2:2	bf	15	1:3	fba
2	1:7	a	9	1:6	ca	16	3:3	fga
3	2:6	af	10	1:8	da	17	3:2	ga
4	1:4	afba	11	2:7	daf	18	2:1	gbf
5	3:7	ba	12	3:1	ega	19	1:5	gca
6	1:2	ba	13	2:3	f	20	1:1	hba
7	2:5	baf	14	3:8	fba	21	3:5	heba

Figure 3: Path To Root Array for a set of three trees. "Pos." is the position of the starting point of a given path-to-root (noted as indexOfTree:positionInTree), and PtR is the sequence of labels on this path-to-root. The path-to-root are sorted in lexicographic order. We can find the set of occurrences of any linear treelet with a binary search. For example, the treelet a(b) corresponds to the label sequence "ba". With a binary search, we find that the path-to-root starting with "ba" are between indexes 5 and 7. The corresponding occurrences are then 3:7, 1:2 and 2:5.

memory to retrieve efficiently the pointed-to path-to-root. Once the Path-to-Root Array is built, for a linear treelet T, we can find its occurrences by a binary search of the first and last path-to-root starting with the labels of T. See figure 3 for an example.

Memory cost is quite manageable, since we only need 10 bytes per nodes in total. 5 bytes per pointer in the array (tree id: 4 bytes, start position: 1 byte), and 5 bytes per nodes to store the database in memory (label id:4 bytes, parent position: 1 byte).

All the optimization tricks proposed in (Lopez, 2007) for Suffix Arrays can be used here, especially the optimization proposed in (Zhang and Vogel, 2005).

3.5 Inverted Index and Precomputation

Instead of a Path-to-Root array, one can simply use an inverted index. The inverted index associates with every label the set of its occurrences, each occurrences being represented by a tuple containing the index of the tree, the position of the label in the tree, and the position of the parent of the label in the tree. Knowing the position of the parent will allow to compute treelets of size 2 by intersection (D-coverage). This is less effective than the Path-To-Root Array approach, but open the possibilities for the flexible search discussed in section 6.

Taking the idea further, we can actually consider the possibility of precomputing treelets of size greater than 1, especially if they appear frequently in the corpus.

4 Practical implementation of the traversal

4.1 Postorder traversal

The way we choose the treelet to be popped out on line 3 of algorithm 1 will define different computation strategies. For concreteness, we describe now a more specific traversal. We will process treelets in an order depending on their root node. More precisely, we consider the nodes of the query tree in the order given by a depth-first postorder traversal of the query tree. This way, when a treelet rooted at n is processed, all of the treelets rooted at a descendant of n have already been processed.

We can suppose that every processed treelet is assigned an index that we note $\#T$. This allows a convenient recursive representation of treelets.

Definition 4.1 (Recursive representation). Let T be a treelet rooted at node n of $\mathcal{T}_Q$. We note n_i the i^{th} child of n in $\mathcal{T}_Q$. For all i, t_i is the subtree of T rooted at n_i. We note $t_i = \emptyset$ and $\#t_i = 0$ if T does not contain n_i. The recursive representation of T is then: $[n, (\#t_1, \#t_2, \ldots, \#t_m)]$. We note T^i the value $\#t_i$.

For example, if $\mathcal{T}_Q$ ="a(b c d(e))" and the treelets "b" and "d(e)" have been assigned the indexes 2 and 4, the recursive representation of the treelet "a(b d(e))" would be [a,(2,0,4)].

Algorithm 2 describes this "postorder traversal". $\mathcal{D}_{Node}$ is a priority queue containing the treelets rooted at $Node$ discovered so far. The priority queue pop out the smallest treelets first. Line 14 maintain a list $\mathcal{L}$ of processed treelets and assign the index of T in $\mathcal{L}$ to $\#T$. Line 22 keeps track of the non-empty immediate supertreelets of every treelet through a dictionary $\mathcal{S}$. This is used in the procedure *compute-supertreelets* (algorithm 3) to generate the immediate supertreelets of a treelet T given its recursive representation. In this procedure, line 6 produces the

Algorithm 2: DAG traversal by query-tree postorder

```
1  for Node in postorder-traversal(query-tree) do
2      T_elem = [Node, (0, 0, .., 0)];
3      D_Node ← T_elem;
4      while |D_Node| > 0 do
5          T=pop-first(D_Node);
6          if T in precomputed then
7              occ(T) ← precomputed[Node.label];
8          else
9              T_1, T_2=min(C (t));
10             if |occ(T_1)| = 0 then
11                 occ(T) ← ∅;
12             else
13                 occ(T) ← occ(T_1) ⊗ occ(T_2);
14         Append T to L;
15         #T ← |L|;
16         for T^S in compute-supertree(T, #T) do
17             Add T to C(T^S);
18             if |occ(T)| > 0 then
19                 if T^S ∉ D_Node and
                   root(T^S)=Node then
20                     Add T^S to D;
21                 for #t in C (T) do
22                     Add #T to S(#t);
```

Algorithm 3: compute-supertrees

```
   Input: T,#T
   Output: lst: list of immediate supertreelets of T
1  m ← |root(T)|;
2  for i in 1 . . . m do
3      for #T^S in S(#T^i) do
4          if root(#T^S) ≠ root(T) then
5              T_new ← [root(T), T^0, ..#T', . . . , T^m];
6              Append T_new to lst;
7  T_new ← [parent(root(T)), (0, . . . , #T, . . . , 0)];
8  Append T_new to lst;
```

descending supertreelets, and line 8 produces the ascending supertreelet. Figure 4 describes the content of all these data structures for a simple run of the algorithm.

This postorder traversal has several advantages. A treelet is only processed once all of its immediate supertreelets have been computed, which is optimal to reduce the cost of the $\otimes$ operation. The way the procedure *compute-supertreelets* discover supertreelets from the info in $\mathcal{S}$ has also several benefit. One is that, by not adding empty treelets (line 18) to $\mathcal{S}$, we naturally prevent the discovery of larger empty treelets. Similarly, in the next section, we will be able to prevent the discovery of non-maximal treelets by modifying $\mathcal{S}$. Modifications of *compute-supertreelets* will also allow different kind of retrieval in section 6.

4.2 Pruning non-maximal treelets

We now try to address another aspect of the overwhelming number of potential treelets in a query tree. As we said, in most practical cases, most of the larger treelets in a query tree will be empty. Still, it is possible that some tree exactly identical to the query tree (or some tree having a very large treelet in common with the query tree) do exist in the database. This case is obviously a best case for translation, but unfortunately could be a worst-case for our algorithm, as it means that all of the (possibly trillions of) treelets of the query tree will be computed.

To solve this issue, we try to consider a concept analogous to that of maximal substring, or substring class, found in Suffix Trees and Suffix Arrays (Yamamoto and Church, 2001). The idea is that in most cases where a query tree is "full" (that is all of its treelets are not empty), most of the larger treelets will share the same occurrences (in the database trees that are very similar to the query tree). We formalize this as follow:

Definition 4.2 (domination and maximal treelets). Let T_1 be a subtreelet of T_2. If for every matching M_1 of $occ(T_1)$, there exist a matching M_2 of $occ(T_2)$ such that $M_2|_{T1} = M_1$, we say that T_1 is dominated by T_2. A treelet is maximal if it is not dominated by any other treelet.

If T_1 is dominated by T_2, it means that all occurrences of T_1 are actually part of an occurrence of T_2. We will therefore be, in general, more interested by the larger treelet T_2 and can prune as many non-maximal treelets as we want in the traversal. The key point is that the algorithm has to avoid discovering most non maximal treelets.The algorithm 2 can easily be modified to do this. We will use the following property.

Property 4.1. Given k treelets $T_1 \dots T_k$ with k distinct roots, all the roots being children of a same node n. We note $n(T_1 \dots T_k)$ the treelet whose root is n, and for which the k subtrees rooted at the k

T	d	e	b	b(d) *[Empty]*	b(e)	b(d e) *[Empty]*	c	a	a(b)	a(b(e))	a(c)	a(b c)	a(b(e) c)
#	1	2	3	4	5	6	7	8	9	10	11	12	13
R	d	e	b(..)	b(1.)	b(.2)	b(1 2)	c	a(..)	a(3.)	a(5.)	a(.7)	a(3 7)	a(5 7)
$\mathcal{C}$	-	-	-	1,3	2,3	4,5	-	-	8,3	5,9	7,8	9,11	10,12
$\mathcal{S}$	-	-	5	-	-	-	-	9,11	10,12	13	12	13	-

Figure 4: A run of the algorithm 2, for the query tree a(b(d e) c). The row "T" represents the treelets in the order they are discovered. The row "#" is the index #T, and the row "R" is the recursive representation of the treelet. Also represented are the content of $\mathcal{C}$ and $\mathcal{S}$ at the end of the computation. When a treelet is poped out of $\mathcal{D}_{Node}$, occ(T) is computed from the treelets listed in $\mathcal{C}$ (T). If occ(T) is not empty, the entries of the immediate subtreelets of T in $\mathcal{S}$ are updated with #T. We suppose here that $|occ($ b(d))|=0. Then, b(d e) is marked as empty and neither b(d) nor b(d e) are added to the entries of their subtreelets in $\mathcal{S}$. This way, when considering treelets rooted at the upper node "a", the algorithm will not discover any of the treelets containing b(d).

children of n are $T_1 \dots T_k$. Let us further suppose that for all i, T_i is dominated by a descending supertreelet T_i^d (with the possibility that $T_i = T_i^d$). Then $n(T_1 \dots T_k)$ is dominated by $n(T_1^d \dots T_k^d)$. For example, if b(c) is dominated by b(c d), then a(b(c) e) will be dominated by a(b(c d) e).

In algorithm 2, after processing each node, we proceed to a cleaning of the $\mathcal{S}$ dictionary in the following way: for every treelet T (considering the treelets by increasing size) that is dominated by one of its supertreelets $T^S \in \mathcal{S}(T)$ and for every subtreelet T' of T such that $T \in \mathcal{S}(T')$, we replace T by T^S in $\mathcal{S}(T')$. The procedure *compute-supertreelets*, when called during the processing of the parent node, will thus skip all of the treelets that are "trivially" dominated according to property 4.1.

Let's note that testing for the domination of a treelet T by one of its supertrelets T^S is not a matter of just testing if $|occ(T)| = |occ(T^S)|$, as would be the case with substring: a treelet can have less occurrences than one of its supertreelets (eg. b(a) has more occurrences than b in b(a a)). An efficient way is to first check that the two treelets occurs in the same number of sentences, then confirm this with a systematic check of the definition.

4.3 The case of constituent trees

We have focused our experiments on dependency trees, but the method can be applied to any tree. However, the computations strategies we have used might not be optimal for all kind of trees. In a dependency tree, nodes are labeled by words and most non-elementary treelets have a small number of occurrences. In a constituent tree, many treelets containing only internal nodes have a high frequency and will be expensive to compute.

If we have enough memory, we can solve this by precomputing the most common (and therefore expensive) treelets.

However, it is usually not very interesting to retrieve all the occurrences of treelets such as "NP(Det NN)" in the context of a MT system. Such very common pattern are best treated by some pre-computed rules. What is interesting is the retrieval of lexicalized rules. More precisely, we want to retrieve efficiently treelets containing at least one leaf of the query tree. Therefore, an alternative computation strategy would only explore treelets containing at least one terminal node. We would thus compute successively "dog", "NN(dog)" "NP(NN(dog))", "NP(Det NN(dog))", etc.

4.4 Complexity

Processing time will be mainly dependent on two factors: the number of treelets in a query tree that need to be computed, and the average time to compute a treelet.

Let N_C be the size of the corpus. It can be shown quite easily that the time needed to compute a treelet with our method is proportional to its number of occurrences, which is itself growing as $O(N_C)$.

Let m be the size of the query tree. The number of treelets needing to be computed is, in the worst case, exponential in m. In practice, the only case where most of the treelets are non-empty is when the database contains trees similar to the query tree in the database, and this is handled by the modification of the algorithm is section 4.2. In other cases, most of the treelets are empty, and empirically, we find that the number of non-empty treelets in a query tree

Database size (#nodes)	6M	60M
Largest non-empty treelet size	4.6	8.7
Processing time (PtR Array)	0.02 s	0.7 s
Processing time (Inv. Index)	0.02 s	0.9 s
Size on disk	40 MB	500 MB

Figure 5: Performances averaged on 100 sentences.

Method	Treelet dictionary	Our method
Disk space used	23 GB	500 MB
BLEU	11.6%	12.0%

Figure 6: Comparison with a dictionary-based baseline (performances averaged over 100 sentences).

grows approximately as $O(m \cdot N_C^{0.5})$. It is also possible to bound the size of the retrieved treelets (only retrieving treelets with less than 10 nodes, for example), similarly to what is done in (Lopez, 2007). The number of treelets will then only grows as $O(m)$.

The total processing time of a given query tree will therefore be on the order of $O(m \cdot N_C^{1.5})$ (or $O(m \cdot N_C)$ if we bound the treelet size). The fact that this give a complexity worse than linear with respect to the database size might seem a concern, but this is actually only because we are retrieving more and more different types of treelets. The cost of retrieving one treelet remain linear with respect to the size of the corpus. We empirically find that even for very large values of N_C, processing time remain very reasonable (see next section).

It should be also noted that the constant hidden in the big-O notation can be (almost) arbitrarily reduced by precomputing more and more of the most common (and more expensive) treelets (a time-memory trade-off).

5 Experiments

We conducted experiments on a large database of 2.9 million automatically parsed dependency trees, with a total of nearly 60 million nodes[1]. The largest trees in the database have around 100 nodes. In order to see how performance scale with the size of the database, we also used a smaller subset of 230,000 trees containing near 6 million nodes.

We computed, using our algorithm, 100 randomly selected query trees having from 10 to 70 nodes, with an average of 27 nodes per tree. Table 5 shows the average performances per sentence. Considering the huge size of the database, a processing time below 1 second seems reasonable. The increase in processing time between the small and the large database is in line with the explanations of section 4.4. Path-to-Root Arrays are slightly better than Inverted indexes (we suspect a better implementation could increase the difference further). Both methods use up about the same disk space: around 500MB. We also find that the approach of section 4.2 brings virtually no overhead and gives similar performances whether the query tree is in the database or not (effectively reducing the worst-case computation time from days to seconds).

We also conducted a small English-to-Japanese translation experiment with a simple translation system using Synchronous Tree Substitution Grammars (STSG) for translating dependency trees. The system we used is still in an experimental state and probably not quite at the state-of-the-art level yet. However, we considered it was good enough for our purpose, since we mainly want to test our algorithm is a practical way. As a baseline, from our corpus of 2.9 millions dependency trees, we automatically extracted STSG rules of size smaller than 6 and stored them in a database, considering that extracting rules of larger sizes would lead to an unmanageable database size. We compared MT results using only the rules of size smaller than 6 to using all the rules computed on-the-fly after treelet retrieving by our method. These results are summarized on figure 6.

6 Flexible matching

We now describe an extension of the algorithm for approximate matching of treelets. We consider that each node of the query tree and database is labeled by 2 labels (or more) of different generality. For concreteness, let's consider dependency trees whose nodes are labeled by words and the Part-Of-Speech (POS) of these words. We want to retrieve treelets

[1]This database was an aggregate of several Japanese-English corpora, notably the Yomiuri newspaper corpus (Utiyama and Isahara, 2003) and the JST paper abstract corpus created at NICT(www.nict.go.jp) through (Utiyama and Isahara, 2007).

that match by word or POS with the query tree.

6.1 Processing multi-Label trees

To do this, the inverted index will just need to include entries for both words and POS. For example, the dependency tree "likes,V:1 (Paul,N:0 Salmon,N:2 (and,CC:3 (Tuna,N:4)))" would produce the following *(node,parents)* entries in the inverted index: {N:[(0,1) (2,1) (4,3)], Paul:[(0,1)], Salmon:[(2,1)],...}. This allows to search for a treelet containing any combination of labels, like "likes(N Salmon(CC(N)))".

We actually want to compute all of the treelets of a query tree $\mathcal{T}_Q$ labeled by words and POS (meaning each node can be matched by either word or POS).

We can compute $\mathcal{T}_Q$ without redundant computations by slightly modifying the algorithm 2. First, we modify the recursive representation of a treelet so that it also includes the chosen label of its root node. Then, the only modifications needed in algorithm 2 are the following: 1- at initialization (line 3), the elementary treelets corresponding to every possible labels are added to the discovered treelets set $\mathcal{D}$; 2- in procedure *compute-supertrees*, at line 8, we generate one ascending supertreelet per label.

6.2 Weighted search

While the previous method would allow us to compute as efficiently as possible all the treelets included in a multi-labeled query tree, there is still a problem: even avoiding redundant computations, the number of treelets to compute can be huge, since we are computing all combinations of labels. For each treelet of size m we would have had in a single label query tree, we now virtually have 2^m treelets. Therefore, it is not reasonable in general to try to compute all these treelets.

However, we are not really interested in computing all possible treelets. In our case, the POS labels allow us to retrieve larger examples when none containing only words would be available. But we still prefer to find examples matched by words rather than by POS. We therefore need to tell the algorithm that some treelets are more important that some others. While we have used the Computation Hypertree representation to compute treelets efficiently, we can also use it to prioritize the treelets we want to compute. This is easily implemented by giving a weight to every treelet. We can then modify our traversal strategy of the Inclusion DAG to compute treelets having the biggest weights first: we just need to specify that the treelet popped out on line 3 is the treelet with the highest score (more generally, we could consider a A* search).

POS matchings	Without	With
Processing time	0.9 s	22 s
Largest non-empty treelet size	8.7	11.4
Treelets of size>8	0.4	102
BLEU	12.0%	12.1%

Figure 7: Effect of POS-matching

6.3 Experiments

Using the above ideas, we have made some experiments for computing query dependency trees labeled with both words and POS. We score the treelets by giving them a penalty of -1 for each POS they contain, and stop the search when all remaining treelets have a score lower than -2 (in other words, treelets are allowed at most 2 POS-matchings). We also require POS-matched nodes to be non-adjacent.

We only have some small modifications to do to algorithm 2. In line 3 of algorithm 2, elementary treelets are assigned a weight of 0 or -1 depending on whether their label is a word or POS. Line 5 is replaced by "pop the first treelet with minimal weight and break the loop if the minimal weight is inferior to -2". In *compute-supertreelets*, we give a weight to the generated supertreelets by combining the weights of the child treelets.

Table 7 shows the increase in the size of the biggest non-empty treelets when allowing 2 nodes to be matched by POS. It also shows the impact on BLEU score of using these additional treelets for on-the-fly rule generation in our simple MT system. Improvement on BLEU is limited, but it might be due to a very experimental handling of approximately matched treelet examples in our MT system.

The computation time, while manageable, was much slower than in the one-label case. This is due to the increased number of treelets to be computed, and to the fact that POS-labeled elementary treelets have a high number of occurrences. It would be more efficient to use more specific labeling (e.g V-

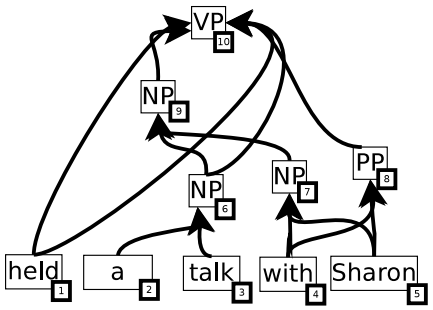

Figure 8: A packed forest.

mvt for verbs of movement instead of V).

7 Additional extensions

We briefly discuss here some additional extensions to our algorithm that we will not detail for lack of room and practical experiments.

7.1 Packed forest

Due to parsing ambiguities and automatic parsers errors, it is often useful to use multiple parses of a given sentence. These parses can be represented by a packed forest such as the one in figure 8. Our method allows the use of packed representation of both the query tree and the database.

For the inverted index, the only difference is that now, an occurrence of a label can have more than one parent. For example, the inverted index of a database containing the packed forest of figure 8 would contain the following entries: {held: [(1,10a),(1,10b)], NP: [(6,9),(7,9),(9,10a)], VP:[(10,N)], PP:[(8,10b)], a:[(2,6)], talk:[(3,6)], with:[(4,7) (4,8)], Sharon:[(5,7) (5,8)]}. Where 10a and 10b are some kind of virtual position that help to specify that *held* and NP_8 belong to the same children list. We could also include a cost on edges in the inverted index, which would allow to prune matchings to unlikely parses.

The inverted index can now be used to search in the trees contained in a packed forest database without any modification. Modifications to the algorithm in order to handle a packed forest query are similar to the ones developed in section 6.

7.2 Discontinuous treelets

As we discussed in section 2.3, using a representation for the position of every node similar to (Zhang et al., 2001), it is possible to determine the distance and ancestor relationship of two nodes by just comparing their positions. This opens the possibility of computing the occurrences of discontinuous treelets in much the same way as is done in (Lopez, 2007) for discontinuous substrings. We have not studied this aspect in depth yet, especially since we are not aware of any MT system making use of discontinuous syntax tree examples. This is nevertheless an interesting future possibility.

8 Related work

As we previously mentioned, (Lopez, 2007) and (Callison-Burch et al., 2005) propose a method similar to ours for the string case.

We are not aware of previous proposals for efficient on-the-fly retrieving of translation examples in the case of Syntax-Based Machine Translation. Among the works involving rule precomputation, (Zhang et al., 2009) describes a method for efficiently matching precomputed treelets rules. These rules are organized in a kind of prefix tree that allows efficient matching of packed forests. (Liu et al., 2006) also propose a greedy algorithm for matching TSC rules to a query tree.

9 Conclusion and future work

We have presented a method for efficiently retrieving examples of treelets contained in a query tree, thus allowing on-the-fly computation of translation rules for Syntax-Based systems. We did this by building on approaches previously proposed for the case of string examples, proposing an adaptation of the concept of Suffix Arrays to trees, and formalizing computation as the traversal of an hypergraph. This hypergraph allows us to easily formalize different computation strategy, and adapt the methods to flexible matchings. We still have a lot to do with respect to improving our implementation, exploring the different possibilities offered by this framework and proceeding to more experiments.

Abstract

This paper presents a generative model for the automatic discovery of relations between entities in electronic medical records. The model discovers relation instances and their types by determining which context tokens express the relation. Additionally, the valid semantic classes for each type of relation are determined. We show that the model produces clusters of relation trigger words which better correspond with manually annotated relations than several existing clustering techniques. The discovered relations reveal some of the implicit semantic structure present in patient records.

1 Introduction

Semantic relations in electronic medical records (EMRs) capture important meaning about the associations between medical concepts. Knowledge about how concepts such as medical problems, treatments, and tests are related can be used to improve medical care by speeding up the retrieval of relevant patient information or alerting doctors to critical information that may have been overlooked. When doctors write progress notes and discharge summaries they include information about how treatments (e.g., aspirin, stent) were administered for problems (e.g. pain, lesion) along with the outcome, such as an improvement or deterioration. Additionally, a doctor will describe the tests (e.g., x-ray, blood sugar level) performed on a patient and whether the tests were conducted to investigate a known problem or revealed a new one. These textual descriptions written in a patient's record encode important information about the relationships between the problems a patients has, the treatments taken for the problems, and the tests which reveal and investigate the problems.

The ability to accurately detect semantic relations in EMRs, such as *Treatment-Administered-for-Problem*, can aid in querying medical records. After a preprocessing phase in which the relations are detected in all records they can be indexed and retrieved later as needed. A doctor could search for all the times that a certain treatment has been used on a particular problem, or determine all the treatments used for a specific problem. An additional application is the use of the relational information to flag situations that merit further review. If a patient's medical record indicates a test that was found to reveal a critical problem but no subsequent treatment was performed for the problem, the patient's record could be flagged for review. Similarly, if a *Treatment-Worsens-Problem* relation is detected previously in a patient's record, that information can be brought to the attention of a doctor who advises such a treatment in the future. By considering all of the relations present in a corpus, better medical ontologies could be built automatically or existing ones can be improved by adding additional connections between concepts that have a relation in text.

Given the large size of EMR repositories, we argue that it is quite important to have the ability to perform relation discovery between medical concepts. Relations between medical concepts benefit translational medicine whenever possible relations are known. Uzuner et al. (2011) show that super-

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 519–528,
Edinburgh, Scotland, UK, July 27–31, 2011.

vised methods recognize such relations with high accuracy. However, large sets of annotated relations need to be provided for this purpose. To address both the problem of discovering unknown relations between medical concepts and the related problem of generating examples for known relations, we have developed an unsupervised method. This approach has the advantages of not requiring an expensive annotation effort to provide training data for semantic relations, which is particularly difficult for medical records, characterized by many privacy concerns. Our analysis shows a high level of overlap between the manually annotated relations and those that were discovered automatically. Our experimental results show that this approach improves upon simpler clustering techniques.

The remainder of this paper is organized as follows. Section 2 discusses the related work. Section 3 reports our novel generative model for discovering relations in EMRs, Section 4 details the inference and parameter estimation of our method. Section 5 details our experiments, Section 6 discusses our findings. Section 7 summarizes the conclusions.

2 Related Work

Previous methods for unsupervised relation discovery have also relied on clustering techniques. One technique uses the context of entity arguments to cluster, while another is to perform a post-processing step to cluster relations found using an existing relation extraction system. The approaches most similar to ours have taken features from the context of pairs of entities and used those features to form a clustering space. In Hasegawa et al. (2004), those features are tokens found within a context window of the entity pair. Distance between entity pairs is then computed using cosine similarity. In another approach, Rosenfeld and Feldman (2007) use hierarchical agglomerative clustering along with features based on token patterns seen in the context, again compared by cosine similarity.

Other approaches to unsupervised relation discovery have relied on a two-step process where a number of relations are extracted, usually from a predicate-argument structure. Then similar relations are clustered together since synonymous predicates should be considered the same relation (e.g. "acquire" and "purchase"). Yates (2009) considers the output from an open information extraction system (Yates et al., 2007) and clusters predicates and arguments using string similarity and a combination of constraints. Syed and Viegas (2010) also perform a clustering on the output of an existing relation extraction system by considering the number of times two relations share the same exact arguments. Similar relations are expected to have the same pairs of arguments (e.g. "Ford produces cars" and "Ford manufactures cars"). These approaches and others (Agichtein and Gravano, 2000; Pantel and Pennacchiotti, 2006) rely on an assumption that relations are context-independent, such as when a person is born, or the capital of a nation. Our method will discover relations that can depend on the context as well. For instance, "penicillin" may be causally related to "allergic reaction" in one patient's medical record but not in another. The relation between the two entities is not globally constant and should be considered only within the scope of one patient's records.

Additionally, these two-step approaches tend to rely on predicate-argument structures such as subject-verb-object triples to detect arbitrary relations (Syed and Viegas, 2010; Yates et al., 2007). Such approaches can take advantage of the large body of research that has been done on extracting syntactic parse structure and semantic role information from text. However, these approaches can overlook relations in text which do not map easily onto those structures. Unlike these approaches, our model can detect relations that are not expressed as a verb, such as "[cough] + [green sputum]" to express a conjunction or "[Cl] 119 mEq / L [High]" to express that a test reading is indicating a problem.

The 2010 i2b2/VA Challenge (Uzuner et al., 2011) developed a set of annotations for medical concepts and relations on medical progress notes and discharge summaries. One task at the challenge involved developing systems for the extraction of eight types of relations between concepts. We use this data set to compare our unsupervised method with others.

The advantage of our work over existing unsupervised approaches is the simultaneous clustering of both argument words and relation trigger words. These broad clusters handle: (i) synonyms, (ii) argu-

ment semantic classes, and (iii) words belonging to the same relation.

3 A Generative Model for Discovering Relations

3.1 Unsupervised Relation Discovery

A simple approach to discovering relations between medical entities in clinical texts uses a clustering approach, e.g. Latent Dirichlet Allocation (LDA) (Blei et al., 2003). We start with an assumption that relations exist between two entities, which we call arguments, and may be triggered by certain words between those entities which we call *trigger words*. For example, given the text "[x-ray] revealed [lung cancer]", the first argument is *x-ray*, the second argument is *lung cancer*, and the trigger word is *revealed*. We further assume that the arguments must belong to a small set of semantic classes specific to the relation. For instance, *x-ray* belongs to a class of medical tests, whereas *lung cancer* belongs to a class of medical problems. While relations may exist between distant entities in text, we focus on those pairs of entities in text which have no other entities between them. This increases the likelihood of a relation existing between the entities and minimizes the number of context words (words between the entities) that are not relevant to the relation.

With these assumptions we build a baseline relation discovery using LDA. LDA is used as a baseline because of its similarities with our own generative model presented in the next section. Each consecutive pair of entities in text is extracted, along with the tokens found between them. Each of the entities in a pair is split into tokens which are taken along with the context tokens to form a single *pseudo-document*. When the LDA is processed on all such pseudo-documents, clusters containing words which co-occur are formed. Our assumption that relation arguments come from a small set of semantic classes should lead to clusters which align with relations since the two arguments of a relation will co-occur in the pseudo-documents. Furthermore, those argument tokens should co-occur with relation trigger words as well.

This LDA-based approach was examined on electronic medical records from the 2010 i2b2/VA Challenge data set (Uzuner et al., 2011). The data set contains manually annotated medical entities which were used to form the pairs of entities needed. For example, Figure 1 illustrates examples of two clusters out of 15 discovered automatically using LDA on the corpus. The first cluster appears to contain words which indicate a relation whose two arguments are both medical problems (e.g. "disease", "cancer", "edema"). The trigger words seem to indicate a possible causal relation (e.g., "due", "related", "secondary"). The second cluster contains words relevant to medical tests (e.g. "examination", "culture") and their findings ("revealed", "showed", "positive"). As illustrated in Figure 1, some of the context words are not necessarily related to the relation. The word "patient" for instance is present in both clusters but is not a trigger word because it is likely to be seen in the context of any relation in medical text. The LDA-based model treats all words equally and cannot identify which words are likely trigger words and which ones are *general words*, which merely occur frequently in the context

Cluster 1
Words: secondary, due, likely, patient, disease, liver, abdominal, cancer, pulmonary, respiratory, elevated, volume, chronic, edema, related
"Correct" instances: [Metastatic colon cancer] with [abdominal carcinomatosis]; [symptoms] were due to [trauma]
"Incorrect" instances: [mildly improving symptoms] , plan will be to continue with [his current medicines]; [prophylaxis] against [peptic ulcer disease]
Cluster 2:
Words: examination, no, positive, culture, exam, blood, patient, revealed, cultures, physical, out, urine, notable, showed, cells
"Correct" instances: [a blood culture] grew out [Staphylococcusaureus]; [tamponade] by [examination]
"Incorrect" instances: [the intact drain] draining [bilious material]; [a Pseudomonas cellulitis] and [subsequent sepsis]

Figure 1: Two clusters found by examining the most likely words under two LDA topics. The instances are pseudo-documents whose probability of being assigned to that cluster was over 70%

of a relation.

In addition, while the LDA approach can detect argument words which co-occur with trigger words (e.g., "examination" and "showed"), the clusters produced with LDA do not differentiate between contextual words and words which belong to the arguments of the relation. An approach which models arguments separately from context words could learn the semantic classes of those arguments and thus better model relations. Considering the examples from Figure 1, a model which could cluster "examination", "exam", "cultures", and "culture" into one *medical test* cluster and "disease", "cancer" and "edema" into a *medical problem* cluster separate from the relation trigger words and general words should model relations more accurately by better reflecting the implicit structure of the text. Because of these limitations many relations discovered in this way are not accurate, as can be seen in Figure 1.

3.2 Relation Discovery Model (RDM)

The limitations identified in the LDA-based approach are solved by a novel relation discovery model (RDM) which jointly models relation argument semantic classes and considers them separately from the context words. Relations triggered by pairs of medical entities enable us to consider three observable features: (A1) the first argument; (A2) the second argument; and (CW) the context words found between A1 and A2.

For instance, in sentence S1 the arguments are A1="some air hunger" and A2="his tidal volume" while the context words are "last", "night", "when", "I", and "dropped".

S1: *He developed [some air hunger]$_{PROB}$ last night when I dropped [his tidal volume]$_{TREAT}$ from 450 to 350.*

In the RDM, the contextual words are assumed to come from a mixture model with 2 mixture components: a relation trigger word ($x = 0$), or a general word ($x = 1$), where x is a variable representing which mixture component a word belongs to. In sentence S1 for example, the word "dropped" can be seen as a trigger word for a *Treatment-Causes-Problem* relation. The remaining words are not trigger words and hence are seen as general words.

Under the RDM's mixture model, the probability of a context word is:

$$P(w^C|t^r, z) = P(w^C|t^r, x = 0) \times P(x = 0|t^r) + P(w^C|z, x = 1) \times P(x = 1|t^r)$$

Where w^C is a context word, the variable t^r is the relation type, and z is the general word class. The variable x chooses whether a context word comes from a relation-specific distribution of trigger words, or from a general word class. In the RDM, the two argument classes are modeled jointly as $P(c^1, c^2|t^r)$, where c^1 and c^2 are two semantic classes associated with a relation of type t^r. However the assignment of classes to arguments depends on a directionality variable d. If $d = 0$, then the first argument is assigned semantic class c^1 and the second is assigned class c^2. When $d = 1$ however, the class assignments are swapped. This models the fact that a relation's arguments do not come in a fixed order, "[MRI] revealed [tumor]" is the same type of relation as "[tumor] was revealed by [x-ray]". Figure 2 shows the graphical model for the RDM. Each candidate relation is modeled independently, with a total of I relation candidates. Variable w^1 is a word observed from the first argument, and w^2 is a word observed from the second argument. The model takes parameters for the number of relations types (R), the number of argument semantic classes (A), and the number of general word classes (K). The generative process for the RDM is:

1. For relation type $r = 1..R$:
   (a) Draw a binomial distribution σ_r from $Beta(\alpha^x)$ representing the mixture distribution for relation r
   (b) Draw a joint semantic class distribution $\psi_r^{1,2} \in \mathbb{R}^{C \times C}$ from $Dirichlet(\alpha^{1,2})$.
2. Draw a categorical word distribution $\phi_{z'}^z$ from $Dirichlet(\beta^z)$ for each general word class $z' = 1..K$
3. Draw a categorical word distribution $\phi_{r'}^r$ from $Dirichlet(\beta^r)$ for each $r' = 1..R$
4. for semantic class $a' = 1..A$:
   (a) Draw categorical word distributions $\omega_{a'}^1$ and $\omega_{a'}^2$ from $Dirichlet(\beta^1)$ and $Dirichlet(\beta^2)$ for the first and second arguments, respectively.

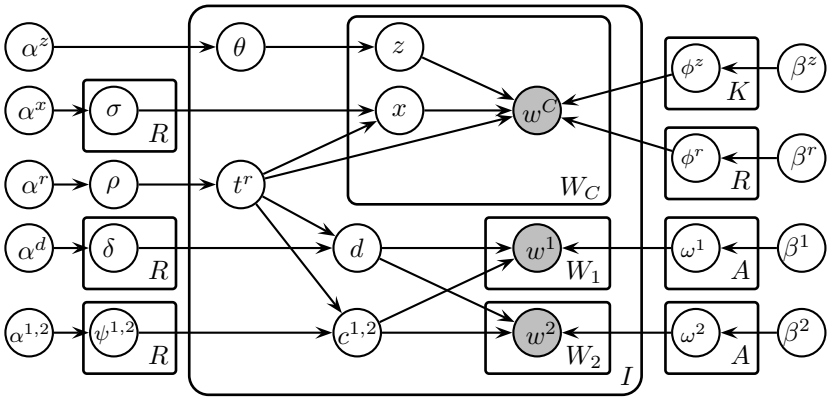

Figure 2: Graphical model for the RDM. $c^{1,2}$ represents the joint generation of c^1 and c^2

$$P(t^r, d|\boldsymbol{t^r_{-i}}, \boldsymbol{d_{-i}}, \boldsymbol{c^{1,2}_{-i}}, \boldsymbol{x_{-i}}, \boldsymbol{z_{-i}}, \boldsymbol{w^C_{-i}}, \boldsymbol{w^1_{-i}}, \boldsymbol{w^2_{-i}}; \boldsymbol{\alpha}, \boldsymbol{\beta}) \propto u_1 \times u_2 \times u_3$$

$$u_1 = \frac{f(t^r)+\alpha^r}{I+R\alpha^r} \times \frac{f(t^r,d)+\alpha^d_d}{f(t^r)+\alpha^d_0+\alpha^d_1} \times \frac{f(t^r,c^1,c^2)+\alpha^{1,2}}{f(t^r)+C\times C\alpha^{1,2}}$$

$$u_2 = \prod_j^{W_C} \frac{f_i(z_j)+\alpha^z}{W_C+K\alpha^z} \times \frac{f(t^r,x_i)+\alpha^x}{f(t^r)+2\alpha^x} \times (\mathbf{1}_{x=0}\frac{f(t^r,w^C_j)+\beta^r}{f(t^r)+W\beta^r} + \mathbf{1}_{x=1}\frac{f(z_j,w^C_j)+\beta^z}{f(z_j)+W\beta^z})$$

$$u_3 = \prod_j^{W_1} \frac{f(a^1,w^1_j)+\beta^1}{f(a^1)+W\beta^1} \times \prod_j^{W_2} \frac{f(a^2,w^2_j)+\beta^2}{f(a^2)+W\beta^2}$$

Figure 3: Gibbs sampling update equation for variables t^r and d for the i^{th} relation candidate. The variables $a^1 = c^1$ and $a^2 = c^2$ if $d = 0$, or $a^1 = c^2$ and $a^2 = c^1$ if $d = 1$. W is the size of the vocabulary. $f(\bullet)$ is the count of the number of times that event occurred, excluding assignments for the relation instance being sampled. For instance, $f(t^r, d) = \sum_{k\neq i}^{I} I[t^r_k = t^r_i \wedge d_k = d_i]$

5. Draw a categorical relation type distribution ρ from $Dirichlet(\alpha^r)$
6. For each pair of consecutive entities in the corpus, $i = 1..I$:
   (a) Sample a relation type t^r from ρ
   (b) Jointly sample semantic classes c^1 and c^2 for the first and second arguments from $\psi^{1,2}_{t^r}$
   (c) Draw a general word class categorical distribution θ from $Dirichlet(\alpha^z)$
   (d) For each token $j = 1..W_1$ in the first argument: Sample a word w^1_j from $\omega^1_{c^1}$ if $d = 0$ or $\omega^2_{c^2}$ if $d = 1$
   (e) For each token $j = 1..W_2$ in the second argument: Sample a word w^2_j from $\omega^2_{c^2}$ if $d = 0$ or $\omega^1_{c^1}$ if $d = 1$
   (f) For each token $j = 1..W_C$ in the context of the entities:
      i. Sample a general word class z from θ
      ii. Sample a mixture component x from σ_{t^r}
      iii. Sample a word from $\phi^r_{t^r}$ if $x = 0$ or ϕ^z_z if $x = 1$.

In the RDM, words from the arguments are informed by the relation through an argument semantic class which is sampled from $P(c^1, c^2|t^r) = \psi^{1,2}_{t^r}$. Furthermore, words from the context are informed by the relation type. These dependencies enable more coherent relation clusters to form during parameter estimation because argument classes and relation trigger words are co-clustered.

We chose to model two distinct sets of entity words (ω^1 and ω^2) depending on whether the entity occurred in the first argument or the second argument of the relation. The intuition for using disjoint sets of entities is based on the observation that an entity may be expressed differently if it comes first or second in the text.

4 Inference and Parameter Estimation

Assignments to the hidden variables in RDM can be made by performing collapsed Gibbs sampling (Griffiths and Steyvers, 2004). The joint probability of the data is:

$$P(\boldsymbol{w^C}, \boldsymbol{w^1}, \boldsymbol{w^2}; \boldsymbol{\alpha}, \boldsymbol{\beta}) \propto$$
$$P(\sigma|\alpha^x)P(\rho|\alpha^r)P(\delta|\alpha^d)P(\psi^{1,2}|\alpha^{1,2})$$
$$\times P(\phi^z|\beta^z)P(\phi^r|\beta^r)P(\omega^1|\beta^1)P(\omega^2|\beta^2)$$
$$\times \prod_i^I [P(\theta_i|\alpha^z)P(t_i^r|\rho)P(d_i|t^r, \delta_{t^r})P(c_i^1, c_i^2|t^r, \psi^{1,2})$$
$$\times \prod_j^{W_{C,i}} P(z_{i,j}|\theta_i)P(x_{i,j}|t_i^r, \sigma_{t_i^r})P(w_{i,j}^C|x_{i,j}, t_i^r, z_{i,j})$$
$$\times \prod_j^{W_{1,i}} P(w_j^1|d_i, c_i^{1,2}, \omega^1)$$
$$\times \prod_j^{W_{2,i}} P(w_j^2|d_i, c_i^{1,2}, \omega^2)]$$

We need to sample variables t^r, d, $c^{1,2}$, x, and z. We sample t^r and d jointly while each of the other variables is sampled individually. After integrating out the multinomial distributions, we can sample t^r and d from the equation in Figure 3

The update equations for the remaining variables can be derived from the same equation by dropping terms which are constant across changes in that variable.

In our experiments the hyperparameters were set to $\alpha^x = 1.0, \alpha^z = 1.0, \alpha^{1,2} = 1.0, \alpha_0^d = 2, \alpha_1^d = 1, \beta^r = 0.01, \beta^z = 0.01, \beta^1 = 1.0, \beta^2 = 1.0$. Changing the hyperparameters did not significantly affect the results.

5 Experimental Results

5.1 Experimental Setup

We evaluated the RDM using a corpus of electronic medical records provided by the 2010 i2b2/VA Challenge (Uzuner et al., 2011). We used the training set, which consists of 349 medical records from 4 hospitals, annotated with medical concepts (specifically problems, treatments, and tests), along with any relations present between those concepts. We used these manually annotated relations to evaluate how well the RDM performs at relation discovery. The corpus is annotated with a set of eight relations: *Treatment-Addresses-Problem*, *Treatment-Causes-Problem*, *Treatment-Improves-Problem*, *Treatment-Worsens-Problem*, *Treatment-Not-Administered-due-to-Problem*, *Test-Reveals-Problem*, *Test-Conducted-for-Problem*, and *Problem-Indicates-Problem*. The data contains 13,460 pairs of consecutive concepts, of which 3,613 (26.8%) have a relation belonging to the list above. We assess the model using two versions of this data set consisting of: those pairs of consecutive entities which have a manually annotated relation (DS1), and secondly, all consecutive pairs of entities (DS2). DS1 allows us to assess the RDM's clustering without the noise introduced from those pairs lacking a true relation. Evaluations on DS2 will indicate the level of degradation caused by large numbers of entity pairs that have no true relation. We also use a separate test set to assess how well the model generalizes to new data. The test set contains 477 documents comprising 9,069 manually annotated relations.

Figure 4: Relation trigger words found by the RDM

5.2 Analysis

Figure 4 illustrates four of the fifteen trigger word clusters (most likely words according to ϕ^r) learned from dataset DS1 using the best set of parameters according to normalized mutual information (NMI) as described in section 5.3. These parameters were: $R = 9$ relations, $K = 15$ general word classes, and $A = 15$ argument classes. Examination of the most likely words reveals a variety of trigger words, beyond obvious explicit ones. Example sentences for the relation types from Figure 4 are presented in Figure 5 and discussed below.

Relation Type 1

Instances of this discovered relation are often found embedded in long lists of drugs prescribed to the patient. Tokens such as "p.o." and "p.r.n.", meaning respectively "by mouth" and "when necessary", are indicative of a prescription relation. The learned relation specifically considers arguments of a drug

Instances of Relation Type 1

1. Haldol 0.5-1 milligrams p.o. q.6-8h. p.r.n. agitation
2. plavix every day to prevent failure of these stents
3. KBL mouthwash , 15 ccp .o. q.d. prn mouth discomfort
4. Miconazole nitrate powder tid prn for groin rash
5. AmBisome 300 mg IV q.d. for treatment of her hepatic candidiasis

Instances of Relation Type 2

1. MAGNESIUM HYDROXIDE SUSP 30 ML) , 30 mL , Susp , By Mouth , At Bedtime , PRN , For Constipation
2. Depression , major (ICD9 296.00 , Working , Problem) cont NOS home meds
3. Diabetes mellitus type II (ICD9 250.00 , Working , Problem) cont home meds
4. ASCITES (ICD9 789.5 , Working , Diagnosis) on spironalactone
5. *Dilutional hyponatremia (SNMCT **ID-NUM , Working , Diagnosis) improved with fluid restriction

Instances of Relation Type 3

1. ESRD secondary to her DM
2. slightly lightheaded and with increased HR
3. a 40% RCA , which was hazy
4. echogenic kidneys consistent with renal parenchymal disease
5. *Librium for alcohol withdrawal

Instances of Relation Type 4

1. V-P lung scan was performed on May 24 2007 , showed low probability of PE
2. a bedside transthoracic echocardiogram done in the Cardiac Catheterization laboratory without evidence of an effusion
3. exploration of the abdomen revealed significant nodularity of the liver
4. Echocardiogram showed moderate dilated left atrium
5. An MRI of the right leg was done which was equivocal for osteomyelitis

Figure 5: Examples for four of the discovered relations. Those marked with an asterisk have a different manually chosen relation than the others

and a symptom treated by that drug. The closest manually chosen relation is *Treatment-Addresses-Problem* which included drugs as treatments.

Relation Type 2

Relation 2 captures a similar kind of relation to Relation 1. All five examples for Relation 1 in Figure 5 came from a different set of hospitals than the examples for Relation 2. This indicates the model is detecting stylistic differences in addition to semantic differences. This is one of shortcomings of simple generative models. Because they cannot reflect the true underlying distribution of the data they will model the observations in ways that are irrelevant to the task at hand. Relation 2 also contains certain punctuation, such as parentheses which the examples show are used to delineate a treatment code. Instances of Relation 2 were often marked as *Treatment-Addresses-Problem* relations by annotators.

Relation Type 3

The third relation captures problems which are related to each other. The manual annotations contain a very similar relation called *Problem-Indicates-Problem*. This relation is also similar to Cluster 1 from Section 3.1, however under the RDM the words are much more specific to the relation. This relation is difficult to discover accurately because of the infrequent use of strong trigger words to indicate the relation. Instead, the model must rely more on the semantic classes of the arguments, which in this case will both be types of medical problems.

Relation Type 4

The fourth relation is detecting instances where a medical test has revealed some problem. This corresponds to the *Test-Reveals-Problem* relation from the data. Many good trigger words for that relation have high probability under Relation 4. A comparison of the RDM's Relation 4 with LDA's cluster 2 from Figure 1 shows that many words not relevant to the relation itself are now absent.

Argument classes

Figure 6 shows the 3 most frequent semantic classes

Concept 1	Concept 2	Concept 3
CT	pain	Percocet
scan	disease	Hgb
chest	right	Hct
x-ray	left	Anion
examination	renal	Vicodin
Chest	patient	RDW
EKG	artery	Bili
MRI	-	RBC
culture	symptoms	Ca
head	mild	Gap

Figure 6: Concept words found by the RDM

for the first argument of a relation (ω^1). Most of the other classes were assigned rarely, accounting for only 19% of the instances collectively. Human annotators of the data set chose three argument classes: *Problems*, *Treatments*, and *Tests*. Concept 1 aligns closely with a test semantic class. Concept 2 seems to be capturing medical problems and their descriptions. Finally, Concept 3 appears to be a combination of treatments (drugs) and tests. Tokens such as "Hgb", "Hct", "Anion", and "RDW" occur almost exclusively in entities marked as tests by annotators. It is not clear why this cluster contains both types of words, but many of the high ranking words beyond the top ten do correspond to treatments, such as "Morphine", "Albumin", "Ativan", and "Tylenol". Thus the discovered argument classes show some similarity to the ones chosen by annotators.

5.3 Evaluation

For a more objective analysis of the relations detected, we evaluated the discovered relation types by comparing them with the manually annotated ones from the data using normalized mutual information (NMI) (Manning et al., 2008). NMI is an information-theoretic measure of the quality of a clustering which indicates how much information about the gold classes is obtained by knowing the clustering. It is normalized to have a range from 0.0 to 1.0. It is defined as:

$$NMI(\Omega;\mathbb{C}) = \frac{I(\Omega;\mathbb{C})}{[H(\Omega)+H(\mathbb{C})]/2}$$

where Ω is the system-produced clustering, $\mathbb{C}$ is the gold clustering, I is the mutual information, and H is the entropy. The mutual information of two clusterings can be defined as:

$$I(\Omega,\mathbb{C}) = \sum_k \sum_j \frac{|\omega_k \cap c_j|}{N} log_2 \frac{N|\omega_k \cap c_j|}{|\omega_k||c_j|}$$

where N is the number of items in the clustering. The entropy is defined as

$$H(\Omega) = -\sum_k \frac{|\omega_k|}{N} log_2 \frac{|\omega_k|}{N}$$

The reference clusters consist of all relations annotated with the same relation type. The predicted clusters consist of all relations which were assigned the same relation type.

In addition to NMI, we also compute the F measure (Amigó et al., 2009). The F measure is computed as:

$$F = \sum_i \frac{|L_i|}{n} \text{max}_j\{F(L_i,C_j)\}$$

where

$$F(L_i,C_j) = \frac{2 \times Recall(L_i,C_j) \times Precision(L_i,C_j)}{Recall(L_i,C_j) + Precision(L_i,C_j)}$$

and $Precision$ is defined as:

$$Precision(C_i,L_j) = \frac{|C_i \cap L_j|}{|C_i|}$$

while $Recall$ is simply precision with the arguments swapped:

$$Recall(L,C) = Precision(C,L)$$

Table 1 shows the NMI and F measure scores for several baselines along with the RDM. Evaluation was performed on both DS1 (concept pairs having a manually annotated relation) and DS2 (all consecutive concept pairs). For DS2 we learned the models using all of the data, and evaluated on those entity pairs which had a manual relation annotated. The LDA-based model from Section 3.1 is used as one baseline. Two other baselines are K-means and Complete-Link hierarchical agglomerative clustering using TF-IDF vectors of the context and argument words (similar to Hasegawa et al. (2004)).

Method	DS1		DS2	
	NMI	F	NMI	F
Train set				
Complete-link	4.2	37.8	N/A	N/A
K-means	8.25	38.0	5.4	38.1
LDA baseline	12.8	23.0	15.6	26.2
RDM	18.2	39.1	18.1	37.4
Test set				
LDA baseline	10.0	26.1	11.5	26.3
RDM	11.8	37.7	14.0	36.4

Table 1: NMI and F measure scores for the RDM and baselines. The first two columns of numbers show the scores when evaluation is restricted to only those pairs of concepts which had a relation identified by annotators. The last two columns are the NMI and F measure scores when each method clusters all consecutive entity pairs, but is only evaluated on those with a relation identified by annotators.

Complete-link clustering did not finish on DS2 because of the large size of the data set. This highlights another advantage of the RDM. Hierarchical agglomerative clustering is quadratic in the size of the number of instances to be clustered, while the RDM's time and memory requirements both grow linearly in the number of entity pairs. The scores shown in Table 1 use the best parameterization of each model as measured by NMI. For DS1 the best LDA-based model used 15 clusters. K-means achieved the best result with 40 clusters, while the best Complete-Link clustering was obtained by using 40 clusters. The best RDM model used parameters $R = 9$ relation, $K = 15$ general word classes, and $A = 15$ argument classes. For DS2 the best number of clusters for LDA was 10, while K-means performed best with 58 clusters. The best RDM model used $R = 100$ relations, $K = 50$ general word classes, and $A = 15$ argument classes. The LDA-based approach saw an improvement when using the larger data set, however the RDM still performed the best.

To assess how well the RDM performs on unseen data we also evaluated the relations extracted by the model on the test set. Only the RDM and LDA models were evaluated as clusters produced by K-means and hierarchical clustering are valid only for the data used to generate the clusters. Generative models on the other hand can provide an estimate of the probability for each relation type on unseen text. For each model we generate 10 samples after a burn in period of 30 iterations and form clusters by assigning each pair of concepts to the relation assigned most often in the samples. The results of this evaluation are presented in Table 1. While these cluster scores are lower than those on the data used to train the models, they still show the RDM outperforming the LDA baseline model.

6 Discussion

The relation and argument clusters determined by the RDM provide a better unsupervised relation discovery method than the baselines. The RDM does this using no knowledge about syntax or semantics outside of that used to determine concepts. The analysis shows that words highly indicative of relations are detected and clustered automatically, without the need for prior annotation of relations or even the choice of a predetermined set of relation types. The discovered relations can be interpreted by a human or labeled automatically using a technique such as the one presented in Pantel and Ravichandran (2004). The fact that the discovered relations and argument classes align well with those chosen by annotators on the same data justify our assumptions about relations being present and discoverable by the way they are expressed in text. Table 1 shows that the model does not perform as well when many of the pairs of entities do not have a relation, but it still performs better than the baselines.

While the RDM relies in large part on trigger words for making clustering decisions it is also capable of including examples which do not contain any contextual words between the arguments. In addition to modeling trigger words, a joint distribution on argument semantic classes is also incorporated. This allows the model to determine a relation type even in the absence of triggers. For example, consider the entity pair "[lung cancer] [XRT]", where XRT stands for external radiation therapy. By determining the semantic classes for the arguments (lung cancer is a Problem, and XRT is a test), the set of possible relations between the arguments can be narrowed down. For instance, XRT is unlikely to be in a causal relationship with a problem, or to make

a problem worse. A further aid is the fact that the learned relationships may be specialized. For instance, there may be a learned relation type such as "Cancer treatment addresses cancer problem". In this case, seeing a type of cancer (lung cancer) and a type of cancer treatment (XRT) would be strong evidence for that type of relation, even without trigger words.

7 Conclusions

We presented a novel unsupervised approach to discovering relations in the narrative of electronic medical records. We developed a generative model which can simultaneously cluster relation trigger words as well as relation arguments. The model makes use of only the tokens found in the context of pairs of entities. Unlike many previous approaches, we assign relations to entities at the location those entities appear in text, allowing us to discover context-sensitive relations. The RDM outperforms baselines built using Latent Dirichlet Allocation and traditional clustering methods. The discovered relations can be used for a number of applications such as detecting when certain treatments were administered or determining if a necessary test has been performed. Future work will include transforming the RDM into a non-parametric model by using the Chinese Restaurant Process (CRP) (Blei et al., 2010). The CRP can be used to determine the number of relations, argument classes, and general word classes automatically.

Abstract

We consider the problem of performing learning and inference in a large scale knowledge base containing imperfect knowledge with incomplete coverage. We show that a soft inference procedure based on a combination of constrained, weighted, random walks through the knowledge base graph can be used to reliably infer new beliefs for the knowledge base. More specifically, we show that the system can learn to infer different target relations by tuning the weights associated with random walks that follow different paths through the graph, using a version of the Path Ranking Algorithm (Lao and Cohen, 2010b). We apply this approach to a knowledge base of approximately 500,000 beliefs extracted imperfectly from the web by NELL, a never-ending language learner (Carlson et al., 2010). This new system improves significantly over NELL's earlier Horn-clause learning and inference method: it obtains nearly double the precision at rank 100, and the new learning method is also applicable to many more inference tasks.

1 Introduction

Although there is a great deal of recent research on extracting knowledge from text (Agichtein and Gravano, 2000; Etzioni et al., 2005; Snow et al., 2006; Pantel and Pennacchiotti, 2006; Banko et al., 2007; Yates et al., 2007), much less progress has been made on the problem of drawing reliable inferences from this imperfectly extracted knowledge. In particular, traditional logical inference methods are too brittle to be used to make complex inferences from automatically-extracted knowledge, and probabilistic inference methods (Richardson and Domingos, 2006) suffer from scalability problems. This paper considers the problem of constructing inference methods that can scale to large knowledge bases (KB's), and that are robust to imperfect knowledge. The KB we consider is a large triple store, which can be represented as a labeled, directed graph in which each entity a is a node, each binary relation $R(a, b)$ is an edge labeled R between a and b, and unary concepts $C(a)$ are represented as an edge labeled "isa" between the node for the entity a and a node for the concept C. We present a trainable inference method that learns to infer relations by combining the results of different random walks through this graph, and show that the method achieves good scaling properties and robust inference in a KB containing over 500,000 triples extracted from the web by the NELL system (Carlson et al., 2010).

1.1 The NELL Case Study

To evaluate our approach experimentally, we study it in the context of the NELL (Never Ending Language Learning) research project, which is an effort to develop a never-ending learning system that operates 24 hours per day, for years, to continuously improve its ability to read (extract structured facts from) the web (Carlson et al., 2010). NELL began operation in January 2010. As of March 2011, NELL had built a knowledge base containing several million candidate beliefs which it had extracted from the web with varying confidence. Among these,

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 529–539,
Edinburgh, Scotland, UK, July 27–31, 2011.

NELL had fairly high confidence in approximately half a million, which we refer to as NELL's *(confident) beliefs*. NELL had lower confidence in a few million others, which we refer to as its *candidate beliefs*.

NELL is given as input an ontology that defines hundreds of categories (e.g., person, beverage, athlete, sport) and two-place typed relations among these categories (e.g., *atheletePlaysSport*(⟨athlete⟩, ⟨sport⟩)), which it must learn to extract from the web. It is also provided a set of 10 to 20 positive seed examples of each such category and relation, along with a downloaded collection of 500 million web pages from the ClueWeb2009 corpus (Callan and Hoy, 2009) as unlabeled data, and access to 100,000 queries each day to Google's search engine. Each day, NELL has two tasks: (1) to extract additional beliefs from the web to populate its growing knowledge base (KB) with instances of the categories and relations in its ontology, and (2) to learn to perform task 1 better today than it could yesterday. We can measure its learning competence by allowing it to consider the same text documents today as it did yesterday, and recording whether it extracts more beliefs, more accurately today.[1]

NELL uses a large-scale semi-supervised multi-task learning algorithm that couples the training of over 1500 different classifiers and extraction methods (see (Carlson et al., 2010)). Although many of the details of NELL's learning method are not central to this paper, two points should be noted. First, NELL is a multistrategy learning system, with components that learn from different "views" of the data (Blum and Mitchell, 1998): for instance, one view uses orthographic features of a potential entity name (like "contains capitalized words"), and another uses free-text contexts in which the noun phrase is found (e.g., "X frequently follows the bigram 'mayor of' "). Second, NELL is a bootstrapping system, which self-trains on its growing collection of confident beliefs.

1.2 Knowledge Base Inference: Horn Clauses

Although NELL has now grown a sizable knowledge base, its ability to perform inference over this knowledge base is currently very limited. At present its only inference method beyond simple inheritance involves applying first order Horn clause rules to infer new beliefs from current beliefs. For example, it may use a Horn clause such as

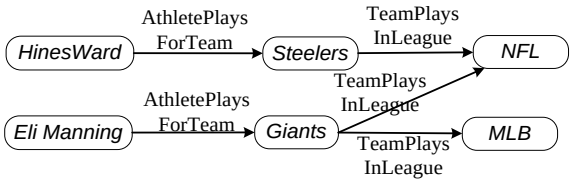

Figure 1: An example subgraph.

$$\begin{aligned} & \textit{AthletePlaysForTeam}(a, b) \\ \wedge \quad & \textit{TeamPlaysInLeague}(b, c) \\ \Rightarrow \quad & \textit{AthletePlaysInLeague(a,c)} \end{aligned} \tag{1}$$

to infer that *AthletePlaysInLeague(HinesWard,NFL)*, if it has already extracted the beliefs in the preconditions of the rule, with variables a, b and c bound to *HinesWard*, *PittsburghSteelers* and *NFL* respectively as shown in Figure 1. NELL currently has a set of approximately 600 such rules, which it has learned by data mining its knowledge base of beliefs. Each learned rule carries a conditional probability that its conclusion will hold, given that its preconditions are satisfied.

NELL learns these Horn clause rules using a variant of the FOIL algorithm (Quinlan and Cameron-Jones, 1993), henceforth N-FOIL. N-FOIL takes as input a set of positive and negative examples of a rule's consequent (e.g., $+$*AthletePlaysInLeague(HinesWard,NFL)*, $-$*AthletePlaysInLeague(HinesWard,NBA)*), and uses a "separate-and-conquer" strategy to learn a set of Horn clauses that fit the data well. Each Horn clause is learned by starting with a general rule and progressively specializing it, so that it still covers many positive examples but covers few negative examples. After a clause is learned, the examples covered by that clause are removed from the training set, and the process repeats until no positive examples remain.

Learning first-order Horn clauses is computationally expensive—not only is the search space large, but some Horn clauses can be costly to evaluate (Cohen and Page, 1995). N-FOIL uses two tricks to improve its scalability. First, it assumes that the consequent predicate is functional—e.g., that

[1] NELL's current KB is available online at `http://rtw.ml.cmu.edu`.

each *Athlete* plays in at most one *League*. This means that explicit negative examples need not be provided (Zelle et al., 1995): e.g., if *AthletePlaysInLeague(HinesWard,NFL)* is a positive example, then *AthletePlaysInLeague(HinesWard,c′)* for any other value of c' is negative. In general, this constraint guides the search algorithm toward Horn clauses that have fewer possible instantiations, and hence are less expensive to match. Second, N-FOIL uses "relational pathfinding" (Richards and Mooney, 1992) to produce general rules—i.e., the starting point for a predicate R is found by looking at positive instances $R(a, b)$ of the consequent, and finding a clause that corresponds to a bounded-length path of binary relations that link a to b. In the example above, a start clause might be the clause (1). As in FOIL, the clause is then (potentially) specialized by greedily adding additional conditions (like *ProfessionalAthlete*(a)) or by replacing variables with constants (eg, replacing c with *NFL*).

For each N-FOIL rule, an estimated conditional probability $\hat{P}(conclusion|preconditions)$ is calculated using a Dirichlet prior according to

$$\hat{P} = (N_+ + m * prior)/(N_+ + N_- + m) \quad (2)$$

where N_+ is the number of positive instances matched by this rule in the FOIL training data, N_- is the number of negative instances matched, $m = 5$ and $prior = 0.5$. As the results below show, N-FOIL generally learns a small number of high-precision inference rules. One important role of these inference rules is that they contribute to the bootstrapping procedure, as inferences made by N-FOIL increase either the number of candidate beliefs, or (if the inference is already a candidate) improve NELL's confidence in candidate beliefs.

1.3 Knowledge Base Inference: Graph Random Walks

In this paper, we consider an alternative approach, based on the Path Ranking Algorithm (PRA) of Lao and Cohen (2010b), described in detail below. PRA learns to *rank* graph nodes b relative to a query node a. PRA begins by enumerating a large set of bounded-length edge-labeled path types, similar to the initial clauses used in NELL's variant of FOIL. These path types are treated as ranking "experts", each performing a random walk through the graph, constrained to follow that sequence of edge types, and ranking nodes b by their weights in the resulting distribution. Finally, PRA combines the weights contributed by different "experts" using logistic regression to predict the probability that the relation $R(a, b)$ is satisfied.

As an example, consider a path from a to b via the sequence of edge types *isa*, isa^{-1} (the inverse of *isa*), and *AthletePlaysInLeague*, which corresponds to the Horn clause

$$\begin{aligned} & isa(a, c) \wedge isa^{-1}(c, a') \\ \wedge \quad & AthletePlaysInLeague(a', b) \\ \Rightarrow \quad & AthletePlaysInLeague(a, b) \end{aligned} \quad (3)$$

Suppose a random walk starts at a query node a (say a=*HinesWard*). If *HinesWard* is linked to the single concept node *ProfessionalAthlete* via *isa*, the walk will reach that node with probability 1 after one step. If A is the set of *ProfessionalAthlete*'s in the KB, then after two steps, the walk will have probability $1/|A|$ of being at any $a' \in A$. If L is the set of athletic leagues and $\ell \in L$, let A_ℓ be the set of athletes in league ℓ: after three steps, the walk will have probability $|A_\ell|/|A|$ of being at any point $b \in L$. In short, the ranking associated with this path gives the prior probability of a value b being an athletic league for a—which is useful as a feature in a combined ranking method, although not by itself a high-precision inference rule.

Note that the rankings produced by this "expert" will change as the knowledge base evolves—for instance, if the system learns about proportionally more soccer players than hockey players over time, then the league rankings for the path of clause (3) will change. Also, the ranking is specific to the query node a. For instance, suppose the KB contains facts which reflect the ambiguity of the team name "Giants"[2] as in Figure 1. Then the path for clause (1) above will give lower weight to $b =$ *NFL* for $a =$ *EliManning* than to $b =$ *NFL* for $a =$ *HinesWard*.

The main contribution of this paper is to introduce and evaluate PRA as an algorithm for making probabilistic inference in large KBs. Compared to Horn clause inference, the key characteristics of this new inference method are as follows:

[2]San Francisco's Major-League Baseball and New York's National Football League teams are both called the "Giants".

- The evidence in support of inferring a relation instance $R(a, b)$ is based on many existing paths between a and b in the current KB, combined using a learned logistic function.
- The confidence in an inference is sensitive to the current state of the knowledge base, and the specific entities being queried (since the paths used in the inference have these properties).
- Experimentally, the inference method yields many more moderately-confident inferences than the Horn clauses learned by N-FOIL.
- The learning and inference are more efficient than N-FOIL, in part because we can exploit efficient approximation schemes for random walks (Lao and Cohen, 2010a). The resulting inference is as fast as 10 milliseconds per query on average.

The Path Ranking Algorithm (PRA) we use is similar to that described elsewhere (Lao and Cohen, 2010b), except that to achieve efficient model learning, the paths between a and b are determined by the statistics from a population of training queries rather than enumerated completely. PRA uses random walks to generate relational features on graph data, and combine them with a logistic regression model. Compared to other relational models (e.g. FOIL, Markov Logic Networks), PRA is extremely efficient at link prediction or retrieval tasks, in which we are interested in identifying top links from a large number of candidates, instead of focusing on a particular node pair or joint inferences.

1.4 Related Work

The TextRunner system (Cafarella et al., 2006) answers list queries on a large knowledge base produced by open domain information extraction. Spreading activation is used to measure the closeness of any node to the query term nodes. This approach is similar to the random walk with restart approach which is used as a baseline in our experiment. The FactRank system (Jain and Pantel, 2010) compares different ways of constructing random walks, and combining them with extraction scores. However, the shortcoming of both approaches is that they ignore edge type information, which is important for achieving high accuracy predictions.

The HOLMES system (Schoenmackers et al., 2008) derives new assertions using a few manually written inference rules. A Markov network corresponding to the grounding of these rules to the knowledge base is constructed for each query, and then belief propagation is used for inference. In comparison, our proposed approach discovers inference rules automatically from training data.

Similarly, the Markov Logic Networks (Richardson and Domingos, 2006) are Markov networks constructed corresponding to the grounding of rules to knowledge bases. In comparison, our proposed approach is much more efficient by avoiding the harder problem of joint inferences and by leveraging efficient random walk schemes (Lao and Cohen, 2010a).

Below we describe our approach in greater detail, provide experimental evidence of its value for performing inference in NELL's knowledge base, and discuss implications of this work and directions for future research.

2 Approach

In this section, we first describe how we formulate link (relation) prediction on a knowledge base as a ranking task. Then we review the Path Ranking Algorithm (PRA) introduced by Lao and Cohen (2010b; 2010a). After that, we describe two improvements to the PRA method to make it more suitable for the task of link prediction in knowledge bases. The first improvement helps PRA deal with the large number of relations typical of large knowledge bases. The second improvement aims at improving the quality of inference by applying low variance sampling.

2.1 Learning with NELL's Knowledge Base

For each relation R in the knowledge base we train a model for the link prediction task: given a concept a, find all other concepts b which potentially have the relation $R(a, b)$. This prediction is made based on an existing knowledge base extracted imperfectly from the web. Although a model can potentially benefit from predicting multiple relations jointly, such joint inference is beyond the scope of this work.

To ensure a reasonable number of training instances, we generate labeled training example queries from 48 relations which have more than 100 instances in the knowledge base. We create two tasks for each relation—i.e., predicting b given a and predicting a given b— yielding 96 tasks in all. Each node a which has relation R in the knowledge base with any other node is treated as a training query, the actual nodes b in the knowledge base known to satisfy $R(a, b)$ are treated as labeled positive examples, and any other nodes are treated as negative examples.

2.2 Path Ranking Algorithm Review

We now review the Path Ranking Algorithm introduced by Lao and Cohen (2010b). A *relation path* P is defined as a sequence of relations $R_1 \dots R_\ell$, and in order to emphasize the types associated with each step, P can also be written as $T_0 \xrightarrow{R_1} \dots \xrightarrow{R_\ell} T_\ell$, where $T_i = range(R_i) = domain(R_{i+1})$, and we also define $domain(P) \equiv T_0$, $range(P) \equiv T_\ell$. In the experiments in this paper, there is only one type of node which we call a *concept*, which can be connected through different types of relations. In this notation, relations like "the team a certain player plays for", and "the league a certain player's team is in" can be expressed by the paths below (respectively):

$$P_1: \quad concept \xrightarrow{AtheletePlayesForTeam} concept$$

$$P_2: \quad concept \xrightarrow{AtheletePlayesForTeam} concept \xrightarrow{TeamPlaysInLeague} concept$$

For any relation path $P = R_1 \dots R_\ell$ and a seed node $s \in domain(P)$, a *path constrained random walk* defines a distribution $h_{s,P}$ recursively as follows. If P is the empty path, then define

$$h_{s,P}(e) = \begin{cases} 1, & \text{if } e = s \\ 0, & \text{otherwise} \end{cases} \quad (4)$$

If $P = R_1 \dots R_\ell$ is nonempty, then let $P' = R_1 \dots R_{\ell-1}$, and define

$$h_{s,P}(e) = \sum_{e' \in range(P')} h_{s,P'}(e') \cdot P(e|e'; R_\ell), \quad (5)$$

where $P(e|e'; R_\ell) = \frac{R_\ell(e',e)}{|R_\ell(e',\cdot)|}$ is the probability of reaching node e from node e' with a one step random walk with edge type R_ℓ. $R(e', e)$ indicates whether there exists an edge with type R that connect e' to e.

More generally, given a set of paths $P_1, \dots, P_n$, one could treat each $h_{s,P_i}(e)$ as a *path feature* for the node e, and rank nodes by a linear model

$$\theta_1 h_{s,P_1}(e) + \theta_2 h_{s,P_2}(e) + \dots \theta_n h_{s,P_n}(e)$$

where θ_i are appropriate weights for the paths. This gives a ranking of nodes e related to the query node s by the following scoring function

$$score(e; s) = \sum_{P \in \mathbf{P}_\ell} h_{s,P}(e)\theta_P, \quad (6)$$

where $\mathbf{P}_\ell$ is the set of relation paths with length $\leq \ell$.

Given a relation R and a set of node pairs $\{(s_i, t_i)\}$ for which we know whether $R(s_i, t_i)$ is true or not, we can construct a training dataset $\mathbf{D} = \{(\mathbf{x}_i, y_i)\}$, where $\mathbf{x}_i$ is a vector of all the path features for the pair (s_i, t_i)—i.e., the j-th component of $\mathbf{x}_i$ is $h_{s_i,P_j}(t_i)$, and where y_i is a boolean variable indicating whether $R(s_i, t_i)$ is true. We then train a logistic function to predict the conditional probability $P(y|\mathbf{x}; \theta)$. The parameter vector θ is estimated by maximizing a regularized form of the conditional likelihood of y given $\mathbf{x}$. In particular, we maximize the objective function

$$O(\theta) = \sum_i o_i(\theta) - \lambda_1|\theta|_1 - \lambda_2|\theta|_2, \quad (7)$$

where λ_1 controls L_1-regularization to help structure selection, and λ_2 controls L_2-regularization to prevent overfitting. $o_i(\theta)$ is the per-instance weighted log conditional likelihood given by

$$o_i(\theta) = w_i[y_i \ln p_i + (1 - y_i) \ln(1 - p_i)], \quad (8)$$

where p_i is the predicted probability $p(y_i = 1|\mathbf{x}_i; \theta) = \frac{\exp(\theta^T \mathbf{x}_i)}{1+\exp(\theta^T \mathbf{x}_i)}$, and w_i is an importance weight to each example. A biased sampling procedure selects only a small subset of negative samples to be included in the objective (see (Lao and Cohen, 2010b) for detail).

2.3 Data-Driven Path Finding

In prior work with PRA, $\mathbf{P}_\ell$ was defined as all relation paths of length at most ℓ. When the number of edge types is small, one can generate $\mathbf{P}_\ell$ by

Table 1: Number of paths in PRA models of maximum path length 3 and 4. Averaged over 96 tasks.

	ℓ=3	ℓ=4
all paths up to length L	$15,376$	$1,906,624$
+query support$\geq \alpha = 0.01$	522	5016
+ever reach a target entity	136	792
+L_1 regularization	63	271

Table 2: Comparing PRA with RWR models. MRRs and training times are averaged over 96 tasks.

	ℓ=2		ℓ=3	
	MRR	**Time**	**MRR**	**Time**
RWR(no train)	0.271		0.456	
RWR	0.280	3.7s	0.471	9.2s
PRA	0.307	5.7s	0.516	15.4s

enumeration; however, for domains with a large number of edge types (e.g., a knowledge base), it is impractical to enumerate all possible relation paths even for small ℓ. For instance, if the number of edge types related to each node type is 100, even the number of length three paths types easily reaches millions. For other domains like parsed natural language sentences, useful relation paths can be as long as ten relations (Minkov and Cohen, 2008). In this case, even with smaller number of possible edge types, the total number of relation paths is still too large for systematic enumeration.

In order to apply PRA to these domains, we modify the path generation procedure in PRA to produce only relation paths which are potentially useful for the task. Define a query s to be *supporting* a path P if $h_{s,P}(e) \neq 0$ for any entity e. We require that any path node created during path finding needs to be supported by at least a fraction α of the training queries s_i, as well as being of length no more than ℓ (In the experiments, we set $\alpha = 0.01$) We also require that in order for a relation path to be included in the PRA model, it must retrieve at least one target entity t_i in the training set. As we can see from Table 1, together these two constraints dramatically reduce the number of relation paths that need to be considered, relative to systematically enumerating all possible relation paths. L1 regularization reduces the size of the model even more.

The idea of finding paths that connects nodes in a graph is not new. It has been embodied previously in first-order learning systems (Richards and Mooney, 1992) as well as N-FOIL, and relational database searching systems (Bhalotia et al., 2002). These approaches consider a single query during path finding. In comparison, the data-driven path finding method we described here uses statistics from a population of queries, and therefore can potentially determine the importance of a path more reliably.

2.4 Low-Variance Sampling

Lao and Cohen (2010a) previously showed that sampling techniques like finger printing and particle filtering can significantly speedup random walk without sacrificing retrieval quality. However, the sampling procedures can induce a loss of diversity in the particle population. For example, consider a node in the graph with just two out links with equal weights, and suppose we are required to generate two walkers starting from this node. A disappointing result is that with 50 percent chance both walkers will follow the same branch, and leave the other branch with no probability mass.

To overcome this problem, we apply a technique called Low-Variance Sampling (LVS) (Thrun et al., 2005), which is commonly used in robotics to improve the quality of sampling. Instead of generating independent samples from a distribution, LVS uses a single random number to generate all samples, which are evenly distributed across the whole distribution. Note that given a distribution $P(x)$, any number r in $[0, 1]$ points to exactly one x value, namely $x = \arg\min_j \sum_{m=1..j} P(m) \leq r$. Suppose we want to generate M samples from $P(x)$. LVS first generates a random number r in the interval $[0, M^{-1}]$. Then LVS repeatedly adds the fixed amount M^{-1} to r and chooses x values corresponding to the resulting numbers.

3 Results

This section reports empirical results of applying random walk inference to NELL's knowledge base after the 165th iteration of its learning process. We first investigate PRA's behavior by cross validation on the training queries. Then we compare PRA and N-FOIL's ability to reliably infer new beliefs, by leveraging the Amazon Mechanical Turk service.

3.1 Cross Validation on the Training Queries

Random Walk with Restart (RWR) (also called personalized PageRank (Haveliwala, 2002)) is a general-purpose graph proximity measure which has been shown to be fairly successful for many types of tasks. We compare PRA to two versions of RWR on the 96 tasks of link prediction with NELL's knowledge base. The two baseline methods are an untrained RWR model and a trained RWR model as described by Lao and Cohen (2010b). (In brief, in the trained RWR model, the walker will probabilistically prefer to follow edges associated with different labels, where the weight for each edge label is chosen to minimize a loss function, such as Equation 7. In the untrained model, edge weights are uniform.) We explored a range of values for the regularization parameters L_1 and L_2 using cross validation on the training data, and we fix both L_1 and L_2 parameters to 0.001 for all tasks. The maximum path length is fixed to 3.[3]

Table 2 compares the three methods using 5-fold cross validation and the Mean Reciprocal Rank (MRR)[4] measure, which is defined as the inverse rank of the highest ranked relevant result in a set of results. If the the first returned result is relevant, then MRR is 1.0, otherwise, it is smaller than 1.0. Supervised training can significantly improve retrieval quality (p-value=9×10^{-8} comparing untrained and trained RWR), and leveraging path information can produce further improvement (p-value=4×10^{-4} comparing trained RWR with PRA). The average training time for a predicate is only a few seconds.

We also investigate the effect of low-variance sampling on the quality of prediction. Figure 2 compares independent and low variance sampling when applied to finger printing and particle filtering (Lao and Cohen, 2010a). The horizontal axis corresponds to the speedup of random walk compared with exact inference, and the vertical axis measures the quality of prediction by MRR with three fold cross validation on the training query set. Low-variance

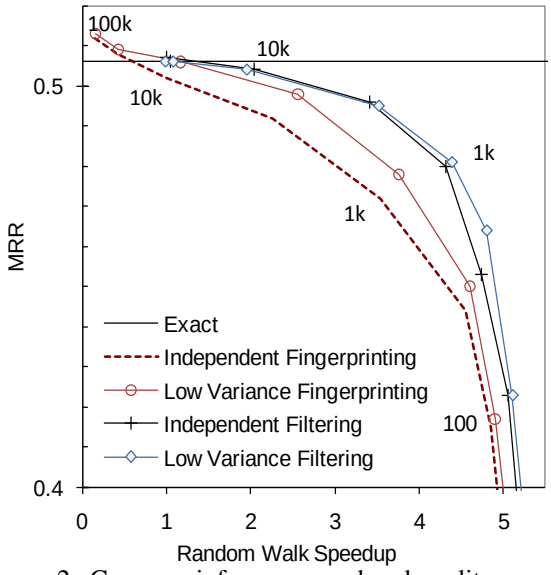

Figure 2: Compare inference speed and quality over 96 tasks. The speedup is relative to exact inference, which is on average 23ms per query.

sampling can improve prediction for both finger printing and particle filtering. The numbers on the curves indicate the number of particles (or walkers). When using a large number of particles, the particle filtering methods converge to the exact inference. Interestingly, when using a large number of walkers, the finger printing methods produce even better prediction quality than exact inference. Lao and Cohen noticed a similar improvement on retrieval tasks, and conjectured that it is because the sampling inference imposes a regularization penalty on longer relation paths (2010a).

3.2 Evaluation by Mechanical Turk

The cross-validation result above assumes that the knowledge base is complete and correct, which we know to be untrue. To accurately compare PRA and N-FOIL's ability to reliably infer new beliefs from an imperfect knowledge base, we use human assessments obtained from Amazon Mechanical Turk. To limit labeling costs, and since our goal is to improve the performance of NELL, we do not include RWR-based approaches in this comparison. Among all the 24 functional predicates, N-FOIL discovers confident rules for 8 of them (it produces no result for the other 16 predicates). Therefore, we compare the quality of PRA to N-FOIL on these 8 predicates only. Among all the 72 non-functional predicates—which

[3] Results with maximum length 4 are not reported here. Generally models with length 4 paths produce slightly better results, but are 4-5 times slower to train

[4] For a set of queries Q, $MRR = \frac{1}{|Q|} \sum_{q \in Q} \frac{1}{\text{rank of the first correct answer for } q}$

Table 3: The top two weighted PRA paths for tasks on which N-FOIL discovers confident rules. c stands for *concept*.

N-FOIL cannot be applied to—PRA exhibits a wide range of performance in cross-validation. The are 43 tasks for which PRA obtains MRR higher than 0.4 and builds a model with more than 10 path features. We randomly sampled 8 of these predicates to be evaluated by Amazon Mechanical Turk.

Table 3 shows the top two weighted PRA features for each task on which N-FOIL can successfully learn rules. These PRA rules can be categorized into broad coverage rules which behave like priors over correct answers (e.g. 1-2, 4-6, 15), accurate rules which leverage specific relation sequences (e.g. 9, 11, 14), rules which leverage information about the synonyms of the query node (e.g. 7-8, 10, 12), and rules which leverage information from a local neighborhood of the query node (e.g. 3, 12-13, 16). The synonym paths are useful, because an entity may have multiple names on the web. We find that all 17 general rules (no specialization) learned by N-FOIL can be expressed as length two relation paths such as path 11. In comparison, PRA explores a feature space with many length three paths.

For each relation R to be evaluated, we generate test queries s which belong to $domain(R)$. Queries which appear in the training set are excluded. For each query node s, we applied a trained model (either PRA or N-FOIL) to generate a ranked list of candidate t nodes. For PRA, the candidates are sorted by their scores as in Eq. (6). For N-FOIL, the candidates are sorted by the estimated accuracies of the rules as in Eq. (2) (which generate the candidates). Since there are about 7 thousand (and 13 thousand) test queries s for each functional (and non-functional) predicate R, and there are (potentially) thousands of candidates t returned for each query s, we cannot evaluate all candidates of all queries. Therefore, we first sort the queries s for each predicate R by the scores of their top ranked candidate t in descending order, and then calculate precisions at top 10, 100 and 1000 positions for the list of result $R(s^{R,1}, t_1^{R,1}), R(s^{R,2}, t_1^{R,2}), ...$, where $s^{R,1}$ is the first query for predicate R, $t_1^{R,1}$ is its first candidate, $s^{R,2}$ is the second query for predicate R, $t_1^{R,2}$ is its first candidate, so on and so forth. To reduce the labeling load, we judge all top 10 queries for each predicate, but randomly sample 50 out of the top 100, and randomly sample 50 out of the top 1000. Each belief is evaluated by 5 workers at Mechanical Turk, who are given assertions like "*Hines Ward* plays for the team *Steelers*", as well as Google search links for each entity, and the combination of both entities. Statistics shows that the workers spend on average 25 seconds to judge each belief. We also remove some workers' judgments which are obviously incorrect[5]. We sampled 100 beliefs, and compared their voted result to gold-standard labels produced by one author of this paper. Table 5 shows that 74% of the time the workers' voted result agrees with our judgement.

Table 5: Comparing Mechanical Turk workers' voted assessments with our gold standard labels based on 100 samples.

	AMT=F	AMT=T
Gold=F	25%	15%
Gold=T	11%	49%

Table 4 shows the evaluation result. The $P_{majority}$ column shows for each predicate the accuracy achieved by the majority prediction: given a query $R(a, ?)$, predict the b that most often satisfies R over all possible a in the knowledge base. Thus, the higher $P_{majority}$ is, the simpler the task. Predicting the functional predicates is generally easier predicting the non-functional predicates. The #Query column shows the number of queries on which N-FOIL is able to match any of its rules, and hence produce a candidate belief. For most predicates, N-FOIL is only able to produce results for at most a few hundred queries. In comparison, PRA is able to produce results for 6,599 queries on average for each functional predicate, and 12,519 queries on average for each non-functional predicate. Although the precision at 10 (p@10) of N-FOIL is comparable to that of PRA, precision at 10 and at 1000 (p@100 and p@1000) are much lower[6].

The #Path column shows the number of paths learned by PRA, and the #Rule column shows the number of rules learned by N-FOIL, with the numbers before brackets correspond to unspecialized rules, and the numbers in brackets correspond to

[5]Certain workers label all the questions with the same answer

[6]If a method makes k predictions, and $k < n$, then p@n is the number correct out of the k predictions, divided by n

specialized rules. Generally, specialized rules have much smaller recall than unspecialized rules. Therefore, the PRA approach achieves high recall partially by combining a large number of unspecialized paths, which correspond to unspecialized rules. However, learning more accurate specialized paths is part of our future work.

A significant advantage of PRA over N-FOIL is that it can be applied to non-functional predicates. The last eight rows of Table 4 show PRA's performance on eight of these predicates. Compared to the result on functional predicates, precisions at 10 and at 100 of non-functional predicates are slightly lower, but precisions at 1000 are comparable. We note that for some predicates precision at 1000 is better than at 100. After some investigation we found that for many relations, the top portion of the result list is more diverse: i.e. showing products produced by different companies, journalist working at different publications. While the lower half of the result list is more homogeneous: i.e. showing relations concentrated on one or two companies/publications. On the other hand, through the process of labeling the Mechanical Turk workers seem to build up a prior about which company/publication is likely to have correct beliefs, and their judgments are positively biased towards these companies/publications. These two factors combined together result in positive bias towards the lower portion of the result list. In future work we hope to design a labeling strategy which avoids this bias.

4 Conclusions and Future Work

We have shown that a soft inference procedure based on a combination of constrained, weighted, random walks through the knowledge base graph can be used to reliably infer new beliefs for the knowledge base. We applied this approach to a knowledge base of approximately 500,000 beliefs extracted imperfectly from the web by NELL. This new system improves significantly over NELL's earlier Horn-clause learning and inference method: it obtains nearly double the precision at rank 100. The inference and learning are both very efficient—our experiment shows that the inference time is as fast as 10 milliseconds per query on average, and the training for a predicate takes only a few seconds.

There are several prominent directions for future work. First, inference starting from both the query nodes and target nodes (Richards and Mooney, 1992) can be much more efficient in discovering long paths than just inference from the query nodes. Second, inference starting from the target nodes of training queries is a potential way to discover specialized paths (with grounded nodes). Third, generalizing inference paths to inference trees or graphs can produce more expressive random walk inference models. Overall, we believe that random walk is a promising way to scale up relational learning to domains with very large data sets.

Exploring Supervised LDA Models for Assigning Attributes to Adjective-Noun Phrases

Matthias Hartung and **Anette Frank**
Computational Linguistics Department
Heidelberg University
{hartung,frank}@cl.uni-heidelberg.de

Abstract

This paper introduces an attribute selection task as a way to characterize the inherent meaning of property-denoting adjectives in adjective-noun phrases, such as e.g. *hot* in *hot summer* denoting the attribute TEMPERATURE, rather than TASTE. We formulate this task in a vector space model that represents adjectives and nouns as vectors in a semantic space defined over possible attributes. The vectors incorporate latent semantic information obtained from two variants of LDA topic models. Our LDA models outperform previous approaches on a small set of 10 attributes with considerable gains on sparse representations, which highlights the strong smoothing power of LDA models. For the first time, we extend the attribute selection task to a new data set with more than 200 classes. We observe that large-scale attribute selection is a hard problem, but a subset of attributes performs robustly on the large scale as well. Again, the LDA models outperform the VSM baseline.

1 Introduction

Corpus-based statistical modeling of semantics is gaining increased attention in computational linguistics. This field of research includes distributional vector space models (VSMs), i.e., models that represent the semantics of words or phrases as vectors over high-dimensional cooccurrence data (Turney and Pantel, 2010; Baroni and Lenci, 2010, i.a.), as well as latent variable models (LVMs) which aggregate distributional observations in 'hidden', or latent variables, thereby reducing the dimensionality of the data. An example of the latter are topic models (Blei et al., 2003), which have recently been applied to modeling selectional preferences of verbs (Ritter et al., 2010; Ó Séaghdha, 2010), or word sense disambiguation (Li et al., 2010).

A topic that is increasingly studied in distributional semantics is the semantics of adjectives, both in isolation (Almuhareb, 2006) and in compositional adjective-noun phrases (Hartung and Frank, 2010; Guevara, 2010; Baroni and Zamparelli, 2010).

In this paper, we propose a new approach to a problem we denote as *attribute selection*: The task is to predict the hidden attribute meaning expressed by a property-denoting adjective in composition with a noun. The adjective *hot*, e.g., may denote attributes such as TEMPERATURE, TASTE or EMOTIONALITY. These adjective meanings can be combined with nouns such as *tea, soup* or *debate*, which can be characterized in terms of attributes as well. The goal of the task is to determine the hidden attribute meaning predicated over the noun in a given adjective-noun phrase, as illustrated in (1).

(1) a. a $\text{hot}_{\text{value}}$ $\text{summer}_{\text{concept}}$
b. TEMPERATURE(*summer*) = *hot*

It is by way of the composition of adjective and noun that specific attributes are selected from the adjective's space of possible attribute meanings, and typically lead to a disambiguation of the adjective and possibly the noun. Hartung and Frank (2010) were the first to model this insight in a VSM by representing the meaning of adjectives and nouns in semantic vectors defined over attributes. The meaning of adjective-noun phrases is computed by means of

Figure 1: Vectors for *enormous* ($\vec{e}$) and *ball* ($\vec{b}$)

vector composition, such that the 'hidden' attribute meaning of the phrase can be 'selected' as a prominent component from the composed vector. This is illustrated in Fig. 1 for the adjective *enormous* ($\vec{e}$) in combination with the noun *ball* ($\vec{b}$), with alternative composition operations: vector multiplication ($\times$) and addition ($+$).[1] Both yield SIZE as the most prominent component in the composed vector.

In the present paper we offer a new approach to this formalization of the compositional meaning of adjectives and nouns that owes to both distributional VSMs and LVMs. Through this combination, we attempt to improve on earlier work in Almuhareb (2006) and Hartung and Frank (2010), which are both embedded in a purely distributional setting.

Specifically, we use Latent Dirichlet Allocation (LDA; Blei et al. (2003)) to train an attribute model that captures semantic information encoded in adjectives and nouns independently of one another. Following Hartung and Frank (2010), this model is embedded into a VSM that employs vector composition to combine the meaning of adjectives and nouns. We present two variants of LDA that differ in the way attributes are associated with the induced LDA topics: Controled LDA (C-LDA) and Labeled LDA (L-LDA; Ramage et al. (2009)). Both will be presented in detail in Section 3.

Our aims in this paper are two-fold: (i) We investigate LDA as a modeling framework in the attribute selection task, as its use of topics as latent variables may alleviate inherent sparsity problems faced by prior work using pattern-based (Almuhareb, 2006) or vector space models (Hartung and Frank, 2010). (ii) While these prior approaches were restricted to a confined set of 10 attributes, we will we apply our models on a much larger space of attributes, to probe their capacity on a more realistic data set.

The remainder of this paper is divided as follows. Section 2 reviews related work on distributional models of adjective semantics, and introduces the two frameworks in which we ground our approach: LVMs and VSMs. In Section 3 we introduce two LDA models for attribute selection: C-LDA and L-LDA. Section 4 describes the settings for two experiments: In the first experiment, we perform attribute selection confined to a space of 10 attributes to compare against prior work. In the second setting we perform attribute selection on a large scale, using 206 attributes. Section 5 presents and discusses the results. Section 6 concludes.

2 Related Work

Distributional models of adjective semantics. Almuhareb (2006) aims at capturing the relationship between adjectives and attributes based on lexico-syntactic patterns, such as *the ATTR of the * is ADJ*. Apart from inherent sparsity issues, his approach does not account for the compositional nature of the problem, as the contextual information contributed by a noun is neglected: For instance, his model is unable to predict that *hot* is unlikely to denote TASTE in the context of *summer*, other than in *hot meal*.

Compositionality of adjective-noun phrases and how it can be adequately modeled in VSMs is the main concern in Baroni and Zamparelli (2010) and Guevara (2010), who are in search of the best composition operator for combining adjective with noun meanings. While these works adhere to a purely latent representation of meaning, Hartung and Frank (2010) include attributes as symbolic 'hidden' meanings of adjectives, nouns and adjective-noun phrases in a distributional VSM.

Finally, a large body of work dealing with compositionality in distributional frameworks is not confined to the special case of adjective-noun composition (Mitchell and Lapata (2008), Rudolph and Giesbrecht (2010), i.a.). All these approaches regard composition as a process combining vectors (or matrices, resp.) to yield a new, contextualized vector representation within the same semantic space.

Latent Dirichlet Allocation, aka. Topic Models (TMs). LDA is a generative probabilistic model

[1] The figure is adopted from the distributional setting of Hartung and Frank (2010), with component values defined by pattern frequency counts for the chosen attribute nouns.

for document collections. Each document is represented as a mixture over latent *topics*, where each topic is a probability distribution over words (Blei et al., 2003). These topics can be used as dense features for, e.g., document clustering. Depending on the number of topics, which has to be pre-specified, the dimensionality of the document representation can be considerably reduced in comparison to simple bag-of-words models. The remainder of this paper will assume some familiarity with LDA and the LDA terminology as introduced in Blei et al. (2003).

Recent work investigates ways of accommodating supervision with LDA, e.g. supervised topic models (Blei and McAuliffe, 2007), Labeled LDA (L-LDA) (Ramage et al., 2009) or DiscLDA (Lacoste-Julien et al., 2008). We will discuss L-LDA in Section 3.

Distributional VSMs and TMs. The idea to integrate topic models and VSMs goes back to Mitchell and Lapata (2009) who build a distributional model with dimensions set to topics over bag-of-words features. In their setting, LDA merely serves the purpose of dimensionality reduction, whereas our particular motivation is to use topics as probabilistic indicators for the prediction of attributes as semantic target categories in adjective-noun composition. Mitchell and Lapata (2010) compare VSMs defined over bags of context words vs. latent topics in a similarity judgement task. Their results indicate that a multiplicative setting works best for vector composition in word-based models, while vector addition is better suited for topic vectors.

3 Topic Models for Attribute Selection

3.1 Using LDA for modeling lexical semantics

Recently, LDA has been used for problems in lexical semantics, where the primary goal is not document modeling but the induction of semantic knowledge from high-dimensional co-occurrence data. Ritter et al. (2010) and Ó Séaghdha (2010) model selectional restrictions of verbs by inducing topic distributions that characterize 'mixtures of topics' observed in verb argument positions. As a basis for LDA modeling, they collect *pseudo-documents*, i.e. bags of words that co-occur in syntactic argument positions.

We apply a similar idea to the attribute selection problem: we collect pseudo-documents that characterize attributes by adjectives and nouns that co-occur with the attribute nouns in local contextual relations. The topic distributions obtained from fitting an LDA model to the collection of these pseudo-documents can then be injected into semantic vector representations for adjectives and nouns.

In its original statement, LDA is a fully unsupervised process (apart from the desired number of topics which has to be specified in advance) that estimates topic distributions over documents θ_d and topic-word distributions ϕ_t with topics represented as latent variables. Estimating these parameters on a document collection yields *topic proportions* $P(t|d)$ and topic distributions $P(w|t)$ that can be used to compute a smooth distribution $P(w|d)$ as in (2), where t denotes a latent topic, w a word and d a document in the corpus.

$$P(w|d) = \sum_t P(w|t)P(t|d) \qquad (2)$$

Being designed for exploratory rather than discriminative analysis, LDA does not intend conditioning of words or topics on external categories. That is, the resulting topics cannot be related to previously defined target categories. For attribute selection, the LDA-inferred topics need to be linked to semantic attributes. Therefore, we apply two extensions of standard LDA that are capable of taking supervised category information into account, either implicitly or directly, by including an additional observable variable into the generative process.

In general, LVMs can be expected to overcome sparsity issues that are frequently encountered in distributional models. This positive smoothing effect is achieved by marginalization over the latent variables (cf. Prescher et al. (2000)). For instance, it is unlikely to observe a dependency path linking the adjective *mature* to the attribute MATURITY. Such a relation is more likely for *young*, for example. If *young* co-occurs with *mature* in a different pseudo-document (AGE might be a candidate), this results in a situation where (i) *young* and *mature* share one or more latent topics and (ii) the topic proportions for the attributes MATURITY and AGE will become similar to the extent of common words in their pseudo-documents. Consequently, the final attribute model is expected to assign a (small) positive probability to the relation between *mature* and MATURITY without observing it in the training data.

3.2 Controled LDA

The generative story behind C-LDA is equivalent to standard LDA. However, the collection of pseudo-documents used as input to C-LDA is structured in a controled way such that each document conveys semantic information that specifically characterizes the individual categories of interest (attributes, in our case). In line with the distributional hypothesis (Harris, 1968), we consider the pseudo-documents constructed in this way as distributional fingerprints of the meaning of the corresponding attribute.

The contents of the pseudo-documents are selected along syntactic dependency paths linking each attribute noun to meaningful context words (adjectives and nouns).[2] A corpus consisting of the two sentences in (3), e.g., yields a pseudo-document for the attribute noun SPEED containing *car* and *fast*.

(3) What is the speed of this car? The machine runs at a very fast speed.

Though we are ultimately interested in triples of attributes, adjectives and nouns that define the compositional semantics of adjective-noun phrases (cf. (1)), C-LDA is only exposed to binary tuples between attributes and adjectives or nouns, respectively. This is in line with Hartung and Frank (2010), who obtained substantial performance improvements by splitting the ternary relation into two binary relations.

Presenting LDA with pseudo-documents that characterize individual target attributes imports supervision into the LDA process in two respects: the estimated topic proportions $P(t|d)$ will be highly attribute-specific, and similarly so for the topic distributions $P(w|t)$. This makes the model more expressive for the ultimate labeling task. Moreover, since C-LDA collects pseudo-documents focused on individual target attributes, we are able to link external categories to the generative process by heuristically labeling pseudo-documents with their respective attribute as target category. Thus, we approximate $P(w|a)$, the probability of a word given an attribute, by $P(w|d)$ as obtained from LDA:

[2]The dependency paths, together with the set of attribute nouns of interest, have to be manually specified. See the supplementary material for the full list of dependency paths used.

1 For each topic $k \in \{1, \ldots, K\}$:
2 Generate $\beta_k = (\beta_{k,1}, \ldots, \beta_{k,V})^T \sim Dir(\cdot \mid \eta)$
3 For each document d:
4 For each topic $k \in \{1, \ldots, K\}$
5 Generate $\Lambda_k^{(d)} \in \{0, 1\} \sim Bernoulli(\cdot \mid \Phi_k)$
6 Generate $\alpha^{(d)} = L^{(d)} \times \alpha$
7 Generate $\theta^{(d)} = (\theta_{l_1}, \ldots, \theta_{l_{M_d}})^T \sim Dir(\cdot \mid \alpha^{(d)})$
8 For each i in $\{1, \ldots, N_d\}$:
9 Generate $z_i \in \{\lambda_1^{(d)}, \ldots, \lambda_{M_d}^{(d)}\} \sim Mult(\cdot \mid \theta^{(d)})$
10 Generate $w_i \in \{1, \ldots, V\} \sim Mult(\cdot \mid \beta_{z_i})$

Figure 2: L-LDA generative process (Ramage et al. 2009)

$$P(w|a) \approx P(w|d) = \sum_t P(w|t)P(t|d) \qquad (4)$$

3.3 Labeled LDA

L-LDA (Ramage et al., 2009) extends standard LDA to include supervision for specific target categories, yet in a different way: (i) The generative process includes a second observed variable, i.e. each document is explicitly labeled with a target category. A document may be labeled with an arbitrary number of categories; unlabeled documents are also possible. However, L-LDA permits only binary assignments of categories to documents; probabilistic weights over categories are not intended. (ii) Contrary to LDA, where the number of topics has to be specified in advance, L-LDA sets this parameter to the number of unique target categories. Moreover, the model is constrained such that documents may be assigned only those topics that correspond to their observable category label(s). That is, latent topics t in the standard formulation of LDA (2) are constrained to correspond to explicit labels a.

More specifically, L-LDA extends the generative process of LDA by constraining the topic distributions over documents $\theta^{(d)}$ to only those topics that correspond to the document's set of labels $\Lambda^{(d)}$. This is done by projecting the parameter vector of the Dirichlet topic prior α to a lower-dimensional vector $\alpha(d)$ whose topic dimensions correspond to the document labels.

This extension is integrated in steps 5 and 6 of Fig. 2: First, in step 5, the document's labels $\Lambda^{(d)}$ are generated for each topic k. The resulting vector of document's labels $\lambda^{(d)} = \{k \mid \Lambda_k^{(d)} = 1\}$ is used to define a document-specific label projection matrix

$L^{(d)}_{|\lambda^{(d)}|\times K}$, such that $L^{(d)}_{ij} = 1$ if $\lambda^{(d)}_i = j$, and 0 otherwise. This matrix is used in step 6 to project the Dirichlet topic prior α to a lower-dimensional vector $\alpha^{(d)}$, whose topic dimensions correspond to the document labels. Topic proportions are then, in step 7, generated for this reduced parameter space.

In our instantiation of L-LDA, we collect pseudo-documents for attributes exactly as for C-LDA. Documents are labeled with exactly one category, the attribute noun. Note that, even though the relationship between documents and topics is fixed, the one between topics and words is not. Any word occurring in more than one document will be assigned a non-zero probability for each corresponding topic.

Thus, with regard to attribute modeling, C-LDA and L-LDA build an interesting pair of opposites: The L-LDA model assumes that attributes are semantically primitive in the sense that they cannot be decomposed into smaller topical units, whereas words may be associated with several attributes at the same time. C-LDA, at the other end of the spectrum, licenses semantic variability on both the attribute and the word level. Particularly, a word might be associated with some of the topics underlying an attribute, but not with all of them, and an attribute can be characterized by multiple topics.

3.4 Vector Space Framework

For integrating the information obtained from C-LDA or L-LDA into a distributional VSM, we follow Hartung and Frank (2010): Adjectives and nouns are modeled as independent semantic vectors along their relationship to attributes; the most prominent attribute(s) that represent the hidden meaning of adjective-noun phrases are selected from their composition (cf. Fig. 1).

The dimensions of the VSM are set to the preselected attributes. Semantic vectors are computed for all adjectives and nouns occurring at least five times in the pseudo-documents. Vector component values $v_{\langle w,a\rangle}$ are derived from the C-LDA and L-LDA models in different ways: with C-LDA we obtain $P(w|a)$ by approximation from $P(w|d)$ (cf. equation (4)), while in L-LDA we obtain $P(w|a)$ directly from the induced topic-word distribution ϕ_t, through labeled topics $t = a$ (cf. equation (2)).

Vector composition is defined as *vector multiplication* ($\times$) or *vector addition* ($+$).

For attribute selection on the composed vector, we use two methods we found to perform best in Hartung and Frank (2010): Entropy Selection (ESel) and Most Prominent Component (MPC). ESel measures entropy over the vector components to identify components that encode a high amount of information. It selects all attributes that lead to an increase of entropy when suppressed from the vector representation. If no informative components can be detected in a vector due to a very broad, flat distribution of the probability mass (cf. $\vec{b}$ in Fig. 1), ESel yields an empty list. MPC always chooses exactly one vector component, i.e. the one with the highest value.

4 Experimental Settings

Attribute selection over small and large semantic spaces. We evaluate the performance of the VSMs based on C-LDA and L-LDA in two experimental settings, contrasting the problem of attribute selection on semantic spaces of radically different dimensionality, using sets of 10 vs. 206 attributes.

Evaluation measures. We evaluate against two gold standards consisting of adjective-noun phrases (or adjective-noun pairs) and their associated attribute meanings. We report precision, recall and f_1-score. Where appropriate, we test differences in the performance of various model configurations for statistical significance in a randomized permutation test (Yeh, 2000), using the `sigf` tool (Padó, 2006).

Baselines. We compare our models against two baselines, PATTVSM and DEPVSM. PATTSVM is reconstructed from Hartung and Frank (2010). It is grounded in a selection of lexical patterns that identify the target elements (adjectives and nouns) for the vector basis elements (i.e., the attribute nouns) in a local context window. The component values are defined using raw frequency counts over the extracted patterns. DEPVSM is similar to PATTVSM; however, it relies on dependency paths that connect the target elements and attributes in local contexts. The paths are identical to the ones used for constructing pseudo-documents in C-LDA and L-LDA. As in PATTVSM, the vector components are set to raw frequencies over extracted paths.

Implementations. To implement our models, we rely on MALLET (McCallum, 2002) for C-LDA and

the Stanford Topic Modeling Toolbox[3] for L-LDA. In both cases, we run 1000 iterations of Gibbs sampling, using default values for all hyperparameters.

Data set for attribute selection over 10 attributes. The first experiment is conducted on the data set used in Hartung and Frank (2010). It consists of 100 adjective-noun pairs manually annotated for ten attributes: COLOR, DIRECTION, DURATION, SHAPE, SIZE, SMELL, SPEED, TASTE, TEMPERATURE, WEIGHT. To enable comparison, the dimensions of our models are set to exactly these attributes.

Data set for attribute selection over a large semantic space (206 attributes). In the second experiment, we max out the attribute selection task to a much larger set of attributes in order to analyze the difficulty of the task on more representative data. We automatically construct a data set of adjective-noun phrases labeled with appropriate attributes from WordNet 3.0 (Fellbaum, 1998), relying on the assumption that examples given in glosses correspond to the respective word sense of the adjective. We first extract all adjectives that are linked to at least one attribute synset by the `attribute` relation. Next, we run the glosses of these adjectives (3592 in number) through TreeTagger (Schmid, 1994) to find examples of adjectives modifying nouns in attributive constructions. The resulting adjective-noun phrases are labeled with the attribute label linked to the given adjective sense.

This method yields 7901 labeled adjective-noun phrases. They are divided into development and test data according to a sampling procedure that respects the following criteria: (i) Both sets must contain all attributes with an equal number of phrases for each attribute; (ii) phrases with both elements contained in CoreWordNet[4] are preferred, while others are only considered if necessary to satisfy the first criterion. This procedure yields 496/345 phrases in the development/test set, distributed over 206 attributes[5].

[3] `http://nlp.stanford.edu/software/tmt/`.

[4] A subset of WordNet restricted to the 5000 most frequently used word senses. Available from: `http://wordnetcode.princeton.edu/standoff-files/core-wordnet.txt`

[5] If an attribute provides only one example, this was added to the development set. Therefore, the test set only comprises 206 attributes, while all models were trained on 262 attributes obtained from WordNet in the first extraction step.

Training data. The pseudo-documents are collected from dependency paths obtained from section 2 of the parsed pukWaC corpus (Baroni et al., 2009).

5 Discussion of Results

5.1 Experiment 1

In Experiment 1, we evaluate the performance of C-LDA and L-LDA on the attribute selection task over 10 attributes against the pattern-based and dependency-based models PATTVSM and DEPVSM as competitive baselines. Besides a comparison to standard VSMs, we are especially interested in the relative performance of the LDA models. Given that C-LDA and L-LDA estimate attribute-specific topic distributions in the structured pseudo-documents under different assumptions regarding the correspondence of attributes and topics (cf. Sec. 3.2 and 3.3), we expect the two LDA variants to differ in their capability to capture the topic distributions in the labeled pseudo-documents.

5.1.1 Attribute Selection for 10 Attributes

Tables 1 and 2 summarize the results for attribute selection over 10 attributes against the labeled adjective-noun pairs in the test set, using ESel and MPC as selection functions on vectors composed by multiplication (Table 1) and addition (Table 2). The results reported for C-LDA correspond to the best performing model (with number of topics set to 42, as this setting yields the best and most constant results over both composition operators).

C-LDA shows highest f-scores and recall over all settings, and highest precision with vector addition.[6] In line with Mitchell and Lapata (2010) (cf. Sec. 2), we obtain the best overall results with vector addition (ESel: P: 0.55, R: 0.66, F: 0.61; MPC: P: 0.59, R: 0.71, F: 0.64). The difference between C-LDA and L-LDA is small but significant for vector multiplication; for vector addition, it is not significant.

Compared to the LDA models, the VSM baselines

[6] In Tables 1 and 2, statistical significance of the differences between the models is marked by the superscripts L, D and P, denoting a significant difference over **L**-LDA, **D**epVSM and **P**attVSM, respectively. All differences reported are significant at $p < 0.05$, except for the difference between C-LDA and L-LDA in Table 3 ($p < 0.1$).

	ESel			MPC		
	P	R	F	P	R	F
C-LDA	0.58	**0.65**	**0.61**^{L,P}	0.57	**0.64**	**0.60**
L-LDA	**0.68**	0.54	0.60^{D}	0.55	0.61	0.58^{D}
DepVSM	0.48	0.58	0.53^{P}	0.57	0.60	0.58
PattVSM	0.63	0.46	0.54	**0.60**	0.58	0.59

Table 1: Attribute selection over 10 attributes ($\times$)

	ESel			MPC		
	P	R	F	P	R	F
C-LDA	**0.55**	**0.66**	**0.61**^{D,P}	**0.59**	**0.71**	**0.64**
L-LDA	0.53	0.57	0.55^{D,P}	0.50	0.45	0.47^{D,P}
DepVSM	0.38	0.65	0.48^{P}	0.57	0.60	0.58
PattVSM	0.71	0.35	0.47	0.47	0.56	0.51

Table 2: Attribute selection over 10 attributes ($+$)

are competitive, but tend to perform lower. This effect is statistically significant for ESel with vector multiplication: each of the LDA models statistically significantly outperforms one of the VSM models, DEPVSM and PATTVSM. With ESel and vector addition, both LDA models outperform both VSM models statistically significantly. The LDA$_{ESel,+}$ models outperform the PATTVSM$_{ESel,+}$ model of Hartung and Frank (2010) by a high margin in f-score: +0.14 for C-LDA; +0.08 for L-LDA. Compared to the stronger multiplicative settings PATTVSM$_{ESel,\times}$ and PATTVSM$_{MPC,\times}$ this still represents a plus of +0.07 and +0.02 in f-score, respectively. We further observe a clear improvement of the LDA models over the VSM models in terms of recall (+0.20, C-LDA$_{ESel,+}$ vs. PATTVSM$_{ESel,\times}$), at the expense of some loss in precision (-0.08, C-LDA$_{ESel,+}$ vs. PATTVSM$_{ESel,\times}$). This clearly confirms a stronger generalization power of LDA compared to VSM models.

With regard to selection functions, we observe that MPC tends to perform better for the VSM models, while ESel is more suitable in the LDA models.

Figures 3 and 4 display the overall performance curve ranging over different topic numbers for C-LDA$_{ESel,+}$ and C-LDA$_{ESel,\times}$ – compared to the remaining models that are not dependent on topic size. For topic numbers smaller than the attribute set size, C-LDA underperforms, for obvious reasons. Increasing ranges of topic numbers to 60 does not show a linear effect on performance. Parameter settings with performance drops below the VSM baselines are rare, which holds particularly for vector addition at topic ranges larger than 10. With vector addition, C-LDA outperforms L-LDA in almost all configurations, yet at an overall lower performance level of L-LDA (0.55 with addition vs. 0.6 with multiplication). Note that in the multiplicative setting, C-LDA reaches the performance of L-LDA only in its best configurations, while with vector addition it obtains high performance that exceeds L-LDA's top f-score of 0.6 for topic ranges between 10 and 20.

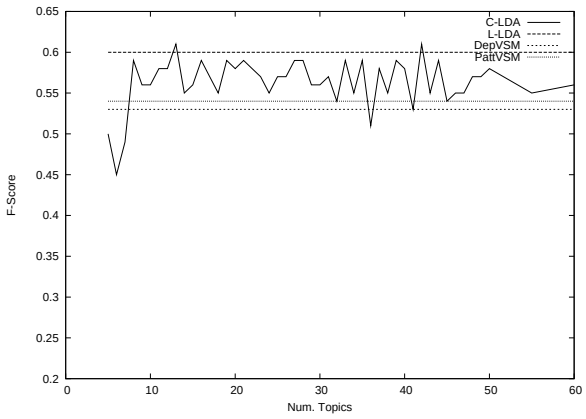

Figure 3: Performance of C-LDA$_{ESel,\times}$ for different topic numbers, compared against all other models

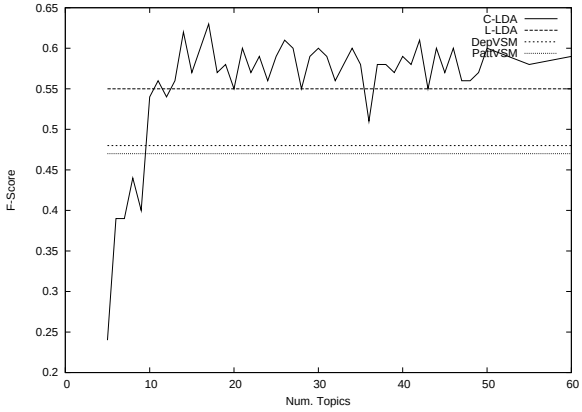

Figure 4: Performance of C-LDA$_{ESel,+}$ for different topic numbers, compared against all other models

Based on these observations, vector addition seems to offer the more robust setting for C-LDA, the model that is less strict with regard to topic-attribute correspondences. Vector multiplication, on the other hand, is more suitable for L-LDA and its stricter association of topics with class labels.

5.1.2 Smoothing Power of LDA Models

Our hypothesis was that LDA models should be better suited for dealing with sparse data, compared

	ESel			MPC		
	P	R	F	P	R	F
C-LDA	**0.39**	**0.31**	**0.35**	**0.37**	**0.27**	**0.32**
L-LDA	0.30	0.18	0.23	0.20	0.18	0.19
DepVSM	0.20	0.10	0.13	0.37	0.26	0.30
PattVSM	0.00	0.00	0.00	0.00	0.00	0.00

Table 3: Performance figures on sparse vectors ($\times$)

	ESel			MPC		
	P	R	F	P	R	F
C-LDA	**0.43**	**0.33**	**0.38**	**0.44**	**0.28**	**0.34**
L-LDA	0.34	0.16	0.22	0.37	0.18	0.24
DepVSM	0.16	0.17	0.17	0.36	0.21	0.27
PattVSM	0.13	0.04	0.06	0.17	0.25	0.20

Table 4: Performance figures on sparse vectors ($+$)

to pattern-based or purely distributional approaches. While this is broadly confirmed in the above results by global gains in recall, we conduct a special evaluation focused on those pairs in the test set that suffer from sparse data. We selected all adjective and noun vectors that did not yield any positive component values in the PATTVSM model. The 22 adjective-noun pairs in the test set affected by these 'zero vectors' were evaluated using the remaining models.

The results in Tables 3 and 4 yield a very clear picture: C-LDA obtains highest precision, recall and f-score across all settings, followed by L-LDA and DEPVSM$_{ESel}$, while their ranks are reversed when using MPC. Again, MPC works better for the VSM models, ESel for the LDA models. Vector addition performs best for C-LDA with f-scores of 0.38 and 0.34 – outperforming the pattern-based results on sparse vectors by orders of magnitude.

5.2 Experiment 2

Experiment 2 is designed to max out the space of attributes to be modeled, to assess the capacity of both LDA models and the DEPVSM baseline model in the attribute selection task on a large attribute space.[7] In contrast to Experiment 1, with its confined semantic space of 10 target attributes, this represents a huge undertaking.

5.2.1 Large-scale Attribute Selection

Table 5 (column **all**) displays the performance of all models on attribute selection over a range of 206 dimensions, contrasting vector addition and multiplication. The number of topics was set to 400. As the overall performance is close to 0 for both composition methods, no parameter setting can be identified as particularly suited for this large-scale attribute selection task. The differences between the three models are very small and not significant[8].

[7] We did not apply PATTVSM to this large-scale experiment, as only poor performance can be expected.

	all		property

5.2.2 Focused Evaluation and Data Analysis

To gain a deeper insight into the modeling capacity of the LDA models for this large-scale selection task, Table 6 (column **all**) presents a partial evaluation of attributes that could be assigned to adjective-noun pairs with an f-score >0 by C-LDA$_{ESel,\times}$.

Despite the disappointing overall performance of

[8] Again, statistically significant differences are marked by superscripts (cf. footnote 6). All differences reported are significant at $\alpha < 0.05$.

short flight	DISTANCE	DURATION
rough bark	TEXTURE	EVENNESS
faint heart	CONSTANCY	COWARDICE

Table 7: Sample of correct and false predictions of C-LDA$_{ESel,\times}$ in Experiment 2

the LDA models on this large attribute space, it is remarkable that C-LDA is able to induce distinctive topic distributions for a number of attributes with up to 0.51 f-score with balanced precision and recall, a moderate drop of only -0.10 relative to the corresponding model induced over 10 attributes.

Raising the attribute selection task from 10 to 206 attributes poses a true challenge to our models, by the sheer size and diversity of the semantic space considered. Table 7 gives an insight into the nature of the data and the difficulty of the task, by listing correct and false preditions of C-LDA for a small sample of adjective-noun pairs. Possible explanations for false predictions are manifold, among them near misses (e.g. *serious book*, *weak president*, *short flight*, *rough bark*), idiomatic expressions (e.g. *faint heart*, *blue line*) or questionable labels provided by WordNet (e.g. *serious book*).

As seen above, C-LDA achieves relatively high performance figures on selected attributes (cf. Table 6, col. **all**). In order to identify what makes these attributes different from others that resist successful modeling, we investigated three factors: (i) the amount of training data available for each attribute, (ii) the ambiguity rate per attribute, and (iii) their ontological subtype.

(i) Measuring the dependence between training data size and f-score per attribute shows that a large amount of training data is generally helpful, but not the decisive factor (Pearson's $r = 0.19$, $p < 0.01$).

(ii) The ambiguity rate AR_{attr} per attribute $attr$ is computed by averaging over all test pairs TP_{attr} labeled with $attr$, counting the total number of attributes $attr'$ that are associated with each adjective in pairs $\langle adj, n\rangle \in TP_{attr}$ in WordNet:

$$AR_{attr} = \frac{\sum_{attr'} \sum_{\langle adj,n\rangle \in TP_{attr}} |\langle adj, attr'\rangle_{WN}|}{|TP_{attr}|}$$

Correlating this figure with the performance per attribute in terms of f-score yields only a small positive correlation (Pearson's $r = 0.23$, $p < 0.01$). In fact, the qualitative analysis in Table 7 shows that C-LDA is capable of assigning meaningful attributes to adjective-noun phrases not only in easy, but also ambiguous cases (cf. *shallow water*, where DEPTH is the only attribute provided for *shallow* in WordNet vs. *short holiday*, *short hair* or *short flight*).

(iii) Although the 206 attributes used in Exp. 2 are rather diverse, including concepts such as HEIGHT, KINDNESS or INDIVIDUALITY, we observe a high number of attributes from Exp. 1 that are successfully modeled in Exp. 2 (5 out of 10, cf. column **all** in Table 6). Given that they are categorized into the *property* class in WordNet[9], we presume that the varying performance across attributes might be influenced by their ontological subtype. This hypothesis is validated in a replication of Exp. 2, with training data limited to the 73 attributes pertaining to the *property* subtype in WordNet. The test set was restricted accordingly, resulting in 112 pairs that are linked to a *property* attribute.

The overall performance of the models in this experiment is shown in Table 5 (column **property**): With vector multiplication, the best-performing operation across all models, all models benefit considerably (+0.10 or more). C-LDA shows the largest improvement, significantly outperforming both L-LDA and DEPVSM. With vector addition, the performance gains are slightly lower in general. In this setting, L-LDA shows higher f-score than C-LDA, though this difference is not statistically significant. Still, C-LDA significantly outranges DEPVSM. Note that we can not show a significant difference between C-LDA$_{ESel,\times}$ and L-LDA$_{ESel,+}$, so the comparison between these models remains inconclusive here. Note further that the affinity of C-LDA with vector addition and L-LDA with vector multiplication, respectively, is inverted in the large-scale experiment (cf. Table 5).

[9]WordNet separates attributes into *properties*, *qualities* and *states*, among several others.

While these overall results are far from satisfactory, they still clearly indicate that the LDA models work effectively for at least a subset of attributes, and outperform the VSM baseline.

Again, a more detailed analysis is given in Table 6 (column **property**), showing the performance of the best individual property attributes ($F>0$) in the restricted experiment. Average performance of the best property attributes with $F>0$, individually, amounts to $F=0.63$[10]. In comparison to the unrestricted setting (cf. column **all**), nearly all property attributes benefit from model training on selective data. Exceptions are WIDTH, WEIGHT, THICKNESS, AGE, DEGREE and LIGHT. Thus, apparently, some of the adjectives associated with non-property attributes in the full set provide some discriminative power that is helpful to distinguish property types.

In a qualitative analysis of the 133 non-property attributes filtered out in this experiment, we find that the WordNet-SUMO mapping (Niles, 2003) does not provide differentiating definitions for about 60% of these attributes, linking them instead to a single *subjective assessment attribute*. This suggests that in many cases the distinctions drawn by WordNet are too subtle even for humans to reproduce.

6 Conclusion

This paper explored the use of LDA topic models in a semantic labeling task that predicts attributes as 'hidden' meanings in the compositional semantics of adjective-noun phrases. LDA topic models are expected to alleviate sparsity problems of distributional VSMs as encountered in prior work, by incorporating latent semantic information about attribute nouns. We investigated two variants of LDA that employ different degrees of supervision for associating topics with attributes.

Our contributions are as follows. We proposed two LDA models for the attribute selection task that import supervision for a target category parameter in different ways: L-LDA (Ramage et al., 2009) embeds the target categories into the LDA process, by defining a 1:1 correspondence of topics and target categories. C-LDA, by contrast, does not affect the LDA generative process. Here, we heuristically equate pseudo-documents with target categories, to approximate category-specific word-topic distributions. By adhering to standard LDA, C-LDA accommodates a greater variety in the distributions of topics to attribute-specific documents and words, as compared to L-LDA. Combining standard LDA topic modeling with a means of interpreting the induced topics relative to a set of external categories, C-LDA offers greater flexibility and expressiveness.

Our experimental results show that modeling attributes as latent or explicit topics with C-LDA and L-LDA, respectively, outperforms the purely distributional baseline model DEPVSM and PATTVSM of prior work. Targeted evaluation on sparse data points confirms that LDA models help to overcome inherent sparsity effects of VSMs. C-LDA and L-LDA are close in performance in Experiment 1. C-LDA outperforms L-LDA only with optimal topic parameter settings.

Finally, we probed the modeling capacity of LDA and VSM models on a vast space of 206 attributes. This task proved to be extremely difficult. However, we obtain respectable results on a subset of attributes denoting properties, where C-LDA performs best in quantitative performance measures. It yields highest f-scores in full and partial evaluation – both with the full-size attribute model, and when training and testing is restricted to property attributes. The differences are small, but statistically significant between the LDA models and the VSM baseline in a setting restricted to property attributes.

Data analysis indicates that our models perform more robustly on concrete attributes in contrast to abstract attribute types that lack clear categorization. This suggests that our approach to attribute selection is most appropriate for detecting attributes that reflect clear ontological distinctions.

However, there is ample space for improvement. In Hartung and Frank (2011), we show that the quality of the noun vectors lags behind the adjective vectors. This clearly affects the performance of our models in cases where the semantic contribution of the noun is decisive for disambiguation. Future work will focus on ways to enhance the noun vector representations through additional contextual features, to make them denser and more articulated in structure.

[10] In comparison, L-LDA$_{ESel,\times}$ yields an average f-score of 0.47 for attributes with $F>0$ in the property setting.

Abstract

In this paper, we propose a novel topic model based on incorporating dictionary definitions. Traditional topic models treat words as surface strings without assuming predefined knowledge about word meaning. They infer topics only by observing surface word co-occurrence. However, the co-occurred words may not be semantically related in a manner that is relevant for topic coherence. Exploiting dictionary definitions explicitly in our model yields a better understanding of word semantics leading to better text modeling. We exploit WordNet as a lexical resource for sense definitions. We show that explicitly modeling word definitions helps improve performance significantly over the baseline for a text categorization task.

1 Introduction

Latent Dirichlet Allocation (LDA) (Blei et al., 2003) serves as a data-driven framework in modeling text corpora. The statistical model allows variable extensions to integrate linguistic features such as syntax (Griffiths et al., 2005), and has been applied in many areas.

In LDA, there are two factors which determine the topic of a word: the topic distribution of the document, and the probability of a topic to emit this word. This information is learned in an unsupervised manner to maximize the likelihood of the corpus. However, this data-driven approach has some limitations. If a word is not observed frequently enough in the corpus, then it is likely to be assigned the dominant topic in this document. For example, the word *grease (a thick fatty oil)* in a political domain document should be assigned the topic *chemicals*. However, since it is an infrequent word, LDA cannot learn its correct semantics from the observed distribution, the LDA model will assign it the dominant document topic *politics*. If we look up the semantics of the word *grease* in a dictionary, we will not find any of its meanings indicating the *politics* topic, yet there is ample evidence for the *chemical* topic. Accordingly, we hypothesize that if we know the semantics of words in advance, we can get a better indication of their topics. Therefore, in this paper, we test our hypothesis by exploring the integration of word semantics explicitly in the topic modeling framework.

In order to incorporate word semantics from dictionaries, we recognize the need to model sense-topic distribution rather than word-topic distribution, since dictionaries are constructed at the sense level. We use WordNet (Fellbaum, 1998) as our lexical resource of choice. The notion of a sense in WordNet goes beyond a typical word sense in a traditional dictionary since a WordNet sense links senses of different words that have similar meanings. Accordingly, the sense for the first verbal entry for *buy* and for *purchase* will have the same sense id (and same definition) in WordNet, while they could have different meaning definitions in a traditional dictionary such as the Merriam Webster Dictionary or LDOCE. In our model, a topic will first emit a WordNet sense, then the sense will generate a word. This is inspired by the intuition that words are instantiations of concepts.

The paper is organized as follows: In Sections 2 and 3, we describe our models based on WordNet. In Section 4, experiment results on text categorization are presented. Moreover, we analyze both qualitatively and quantitatively the contribution of modeling definitions (by teasing out the contribution of explicit sense modeling in a word sense disambiguation task). Related work is introduced in Section 5. We conclude in Section 6 by discussing some possible future directions.

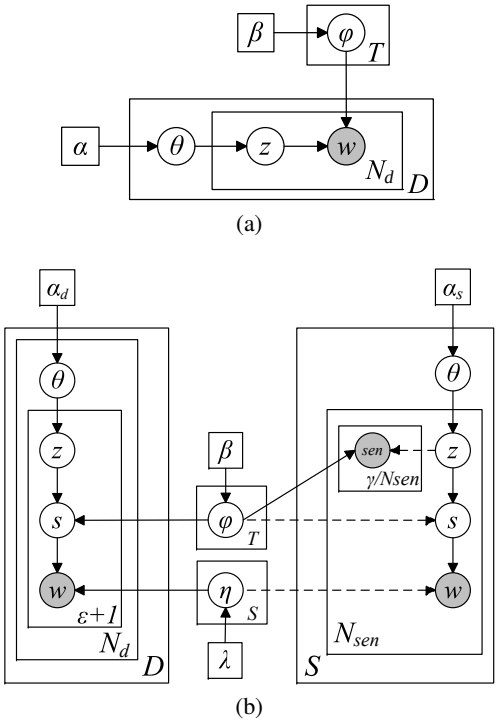

Figure 1: (a) LDA: Latent Dirichlet Allocation (Blei et al., 2003). (b) STM: Semantic topic model. The dashed arrows indicate the distributions (ϕ and η) and nodes (z) are not influenced by the values of pointed nodes.

2 Semantic Topic Model

2.1 Latent Dirichlet Allocation

We briefly introduce LDA where Collapsed Gibbs Sampling (Griffiths and Steyvers, 2004) is used for inference. In figure 1a, given a corpus with D documents, LDA will summarize each document as a normalized T-dimension topic mixture θ. Topic mixture θ is drawn from a Dirichlet distribution $Dir(\alpha)$ with a symmetric prior α. ϕ contains T multinomial distribution, each representing the probability of a topic z generating word w $p(w|z)$. ϕ is drawn from a Dirichlet distribution $Dir(\beta)$ with prior β.

In Collapsed Gibbs Sampling, the distribution of a topic for the word $w_i = w$ based on values of other data is computed as:

$$P(z_i = z|\mathbf{z_{-i}}, \mathbf{w}) \propto \frac{n^{(d)}_{-i,z} + \alpha}{n^{(d)}_{-i} + T\alpha} \times \frac{n^{w}_{-i,z} + \beta}{n_{-i,z} + W\beta} \quad (1)$$

In this equation, $n^{(d)}_{-i,z}$ is a count of how many words are assigned topic z in document d, excluding the topic of the ith word; $n^{w}_{-i,z}$ is a count of how many words $= w$ are assigned topic z, also excluding the topic of the ith word. Hence, the first fraction is the proportion of the topic in this document $p(z|\theta)$. The second fraction is the probability of topic z emitting word w. After the topics become stable, all the topics in a document construct the topic mixture θ.

2.2 Applying Word Sense Disambiguation Techniques

We add a sense node between the topic node and the word node based on two linguistic observations: a) **Polysemy**: many words have more than one meaning. A topic is more directly relevant to a word meaning (sense) than to a word due to polysemy; b) **Synonymy**: different words may share the same sense. WordNet explicitly models synonymy by linking synonyms to the same sense. In WordNet, each sense has an associated definition.

It is worth noting that we model the sense-word relation differently from (Boyd-Graber and Blei, 2007), where in their model words are generated from topics, then senses are generated from words. In our model, we assume that during the generative process, the author picks a concept relevant to the topic, then thinks of a best word that represents that concept. Hence the word choice is dependent on the relatedness of the sense and its fit to the document context.

In standard topic models, the topic of a word is sampled from the document level topic mixture θ. The underlying assumption is that all words in a document constitute the context of the target word. However, it is not the case in real world corpora. Titov and McDonald (2008) find that using global topic mixtures can only extract global topics in online reviews (e.g., Creative Labs MP3 players and iPods) and ignores local topics (product features such as portability and battery). They design the Multi-grain LDA where the local topic of a word is only determined by topics of surrounding sentences. In word sense disambiguation (WSD), an even narrower context is taken into consideration, for instance in graph based WSD models (Mihalcea, 2005), the choice of a sense for a word only depends on a local window whose size equals the length of the sentence. Later in (Sinha and Mihalcea, 2007; Guo and Diab, 2010; Li et al., 2010), people use a fixed window size containing around 12 neighbor words for WSD.

Accordingly, we adopt the WSD inspired local window strategy in our model. However, we do

not employ the complicated schema in (Titov and McDonald, 2008). We simply hypothesize that the surrounding ϵ words are semantically related to the considered word, and they construct a local sliding window for that target word. For a document d with N_d words, we represent it as N_d local windows – a window is created for each word. The model is illustrated in the left rectangle in figure 1b. The window size is fixed for each word: it contains $\epsilon/2$ preceding words, and $\epsilon/2$ following words. Therefore, a word in the original document will have ϵ copies, existing in $\epsilon+1$ local windows. Similarly, there are $\epsilon + 1$ pairs of topics/senses assigned for each word in the original document. Each window has a distribution θ_i over topics. θ_i will emit the topics of words in the window.

This approach enables us to exploit different context sizes without restricting it to the sentence length, and hence spread topic information across sentence boundaries.

2.3 Integrating Definitions

Intuitively, a sense definition reveals some prior knowledge on the topic domain: the definition of sense [*crime, offense, offence*] indicates a *legal* topic; the definition of sense [*basketball*] indicates a *sports* topic, etc. Therefore, during inference, we want to choose a topic/sense pair for each word, such that the topic is supported by the context θ and the sense definition also matches that topic.

Given that words used in the sense definitions are strongly relevant to the sense/concept, we set out to find the topics of those definition words, and accordingly assign the sense sen itself these topics. We treat a sense definition as a document and perform Gibbs sampling on it. We normalize definition length by a variable γ. Therefore, before the topic model sees the actual documents, each sense s has been sampled γ times. The γ topics are then used as a "training set", so that given a sense, ϕ has some prior knowledge of which topic it should be sampled from.

Consider the sense [*party, political party*] with a definition "an organization to gain political power" of length 6 when $\gamma = 12$. If topic model assigns *politics* topic to the words "organization political power", then sense [*party, political party*] will be sampled from $politics$ topic for $3 * \gamma/definitionLength = 6$ times.

We refer to the proposed model as Semantic Topic Model (figure 1b). For each window v_i in the document set, the model will generate a distribution of topics θ_i. It will emit the topics of $\epsilon + 1$ words in the window. For a word w_{ij} in window v_i, a sense s_{ij} is drawn from the topic, and then s_{ij} generates the word w_i. Sense-topic distribution ϕ contains T multinomial distributions over all possible senses in the corpus drawn from a symmetric Dirichlet distribution $Dir(\beta)$. From WordNet we know the set of words $W(s)$ that have a sense s as an entry. A sense s can only emit words from $W(s)$. Hence, for each sense s, there is a multinomial distribution η_s over $W(s)$. All η are drawn from symmetric $Dir(\lambda)$.

On the definition side, we use a different prior α_s to generate a topic mixture θ. Aside from generating s_i, z_i will deterministically generate the current sense sen for γ/N_{sen} times (N_{sen} is the number of words in the definition of sense sen), so that sen is sampled γ times in total.

The formal procedure of generative process is the following:

For the definition of sense sen:
- choose topic mixture $\theta \sim Dir(\alpha_s)$.
- for each word w_i:
  - choose topic $z_i \sim Mult(\theta)$.
  - choose sense $s_i \sim Mult(\phi_{z_i})$.
  - deterministically choose sense $sen \sim Mult(\phi_{z_i})$ for γ/N_{sen} times.
  - choose word $w_i \sim Mult(\eta_{s_i})$.

For each window v_i in a document:
- choose local topic mixture $\theta_i \sim Dir(\alpha_d)$.
- for each word w_{ij} in v_i:
  - choose topic $z_{ij} \sim Mult(\theta_i)$.
  - choose sense $s_{ij} \sim Mult(\phi_{z_{ij}})$.
  - choose word $w_{ij} \sim Mult(\eta_{s_{ij}})$.

2.4 Using WordNet

Since definitions and documents are in different genre/domains, they have different distributions on senses and words. Besides, the definition sets contain topics from all kinds of domains, many of which are irrelevant to the document set. Hence we prefer ϕ and η that are specific for the document set, and we do not want them to be "corrupted" by the text in the definition set. Therefore, as in figure 1b, the dashed lines indicate that when we estimate ϕ and η, the topic/sense pair and sense/word pairs in the definition set are not considered.

WordNet senses are connected by relations such as synonymy, hypernymy, similar attributes, etc.

We observe that neighboring sense definitions are usually similar and are in the same topic domain. Hence, we represent the definition of a sense as the union of itself with its neighboring sense definitions pertaining to WordNet relations. In this way, the definition gets richer as it considers more data for discovering reliable topics.

3 Inference

We still use Collapsed Gibbs Sampling to find latent variables. Gibbs Sampling will initialize all hidden variables randomly. In each iteration, hidden variables are sequentially sampled from the distribution conditioned on all the other variables. In order to compute the conditional probability $P(z_i = z, s_i = s|\mathbf{z_{-i}}, \mathbf{s_{-i}}, \mathbf{w})$ for a topic/sense pair, we start by computing the joint probability $P(\mathbf{z}, \mathbf{s}, \mathbf{w}) = P(\mathbf{z})P(\mathbf{s}|\mathbf{z})P(\mathbf{w}|\mathbf{s})$. Since the generative processes are not exactly the same for definitions and documents, we need to compute the joint probability differently. We use a type specific subscript to distinguish them: $P_s(\cdot)$ for sense definitions and $P_d(\cdot)$ for documents.

Let sen be a sense. Integrating out θ we have:

$$P_s(\mathbf{z}) = \left(\frac{\Gamma(T\alpha_s)}{\Gamma(\alpha_s)^T}\right)^S \prod_{sen=1}^{S} \frac{\prod_z \Gamma(n_z^{(sen)} + \alpha_s)}{\Gamma(n^{(sen)} + T\alpha)} \tag{2}$$

where $n_z^{(sen)}$ means the number of times a word in the definition of sen is assigned to topic z, and $n^{(sen)}$ is the length of the definition. S is all the potential senses in the documents.

We have the same formula of $P(\mathbf{s}|\mathbf{z})$ and $P(\mathbf{w}|\mathbf{s})$ for definitions and documents. Similarly, let n_z be the number of words in the documents assigned to topic z, and n_z^s be the number of times sense s assigned to topic z. Note that when s appears in the superscript surrounded by brackets such as $n_z^{(s)}$, it denotes the number of words assigned to topics z in the definition of sense s. By integrating out ϕ we obtain the second term:

$$P(\mathbf{s}|\mathbf{z}) = \left(\frac{\Gamma(S\beta)}{\Gamma(\beta)^S}\right)^T \prod_{z=1}^{T} \frac{\prod_s \Gamma(n_z^s + n_z^{(s)}\gamma/n^{(s)} + \beta)}{\Gamma(n_z + \sum_{s'} n_z^{(s')}\gamma/n^{(s')} + S\beta)} \tag{3}$$

At last, assume n_s denotes the number of sense s in the documents, and n_s^w denotes the number of sense s to generate the word w, then integrating out η we have:

$$P(\mathbf{w}|\mathbf{s}) = \prod_{s=1}^{S} \frac{\Gamma(|W(s)|\lambda)}{\Gamma(\lambda)^{|W(s)|}} \frac{\prod_w^{W(s)} \Gamma(n_s^w + \lambda)}{\Gamma(n_s + |W(s)|\lambda)}$$

With equation 2-4, we can compute the conditional probability $P_s(z_i = z, s_i = s|\mathbf{z_{-i}}, \mathbf{s_{-i}}, \mathbf{w})$ for a sense-topic pair in the sense definition. Let sen_i be the sense definition containing word w_i, then we have:

$$P_s(z_i = z, s_i = s|\mathbf{z_{-i}}, \mathbf{s_{-i}}, \mathbf{w}) \propto \frac{n_{-i,z}^{(sen_i)} + \alpha_s}{n_{-i}^{(sen_i)} + T\alpha_s} \frac{n_z^s + n_{-i,z}^{(s')}\gamma/n^{(s')} + \beta}{n_z + \sum_{s'} n_{-i,z}^{(s')}\gamma/n^{(s')} + S\beta} \frac{n_s^w + \lambda}{n_s + |W(s)|\lambda} \tag{5}$$

The subscript $-i$ in expression n_{-i} denotes the number of certain events excluding word w_i. Hence the three fractions in equation 5 correspond to the probability of choosing z from θ_{sen}, choosing s from z and choosing w from s. Also note that our model defines s that can only generate words in $W(s)$, therefore for any word $w \notin W(s)$, the third fraction will yield a 0.

The probability for documents is similar to that for definitions except that there is a topic mixture for each word, which is estimated by the topics in the window. Hence $P_d(\mathbf{z})$ is estimated as:

$$P_d(\mathbf{z}) = \prod_i \frac{\Gamma(T\alpha_d)}{\Gamma(\alpha_d)^T} \frac{\prod_z \Gamma(n_z^{(v_i)} + \alpha_d)}{\Gamma(n^{(v_i)} + T\alpha_d)} \tag{6}$$

Thus, the conditional probability for documents can be estimated by cancellation terms in equation 6, 3, and 4:

$$P_d(z_{ij} = z, s_{ij} = s|\mathbf{z_{-ij}}, \mathbf{s_{-ij}}, \mathbf{w}) \propto \frac{n_{-ij,z}^{(v_i)} + \alpha_d}{n_{-ij}^{(v_i)} + T\alpha_d} \frac{n_{-ij,z}^s + n_z^{(s')}\gamma/n^{(s')} + \beta}{n_{-ij,z} + \sum_{s'} n_z^{(s')}\gamma/n^{(s')} + S\beta} \frac{n_{-ij,s}^w + \lambda}{n_{-ij,s} + |W(s)|\lambda} \tag{7}$$

3.1 Approximation

In current model, each word appears in $\epsilon + 1$ windows, and will be generated $\epsilon + 1$ times, so there will be $\epsilon + 1$ pairs of topics/senses sampled for each word, which requires a lot of additional computation (proportional to context size ϵ). On the other hand, it can be imagined that the set of values $\{z_{ij}, s_{ij}|j - \epsilon/2 \leq i \leq j + \epsilon/2\}$ in different windows v_i should roughly be the same, since they are hidden values for the same word w_j. Therefore, to reduce computation complexity during Gibbs sampling, we approximate the values of $\{z_{ij}, s_{ij}|\ i \neq j\}$ by the topic/sense (z_{jj}, s_{jj}) that are generated from window v_j. That is, in Gibbs sampling, the algorithm does not actually sample the values of $\{z_{ij}, s_{ij}, |\ i \neq j\}$; instead, it directly assumes the sampled values are z_{jj}, s_{jj}.

4 Experiments and Analysis

Data: We experiment with several datasets, namely, the Brown Corpus (Brown), New York Times (NYT) from the American National Corpus, Reuters (R20) and WordNet definitions. In a preprocessing step, we remove all the non-content words whose part of speech tags are not one of the following set {*noun, adjective, adverb, verb*}. Moreover, words that do not have a valid lemma in WordNet are removed. For WordNet definitions, we remove stop words hence focusing on relevant content words.

Corpora statistics after each step of preprocessing is presented in Table 1. The column *WN token* lists the number of word#pos tokens after preprocessing. Note that now we treat word#pos as a word token. The column *word types* shows corresponding word#pos types, and the total number of possible sense types is listed in column *sense types*. The DOCs size for WordNet is the total number of senses defined in WordNet.

Experiments: We design two tasks to test our models: (1) text categorization task for evaluating the quality of values of topic nodes, and (2) a WSD task for evaluating the quality of the values of the sense nodes, mainly as a diagnostic tool targeting the specific aspect of sense definitions incorporation and distinguish that component's contribution to text categorization performance. We compare the performance of four topic models. (a) LDA: the traditional topic model proposed in (Blei et al., 2003) except that it uses Gibbs Sampling for inference. (b) LDA+def: is LDA with sense definitions. However they are not explicitly modeled; rather they are treated as documents and used as augmented data. (c) STM0: the topic model with an additional explicit sense node in the model, but we do not model the sense definitions. And finally (d) STMn is the full model with definitions explicitly modeled. In this setting n is the γ value. We experiment with different γ values in the STM models, and investigate the semantic scope of words/senses by choosing different window size ϵ. We report mean and standard deviation based on 10 runs.

It is worth noting that a larger window size ϵ suggests documents have larger impact on the model (ϕ, η) than definitions, since each document word has ϵ copies. This is not a desirable property when we want to investigate the weight of definitions by choosing different γ values. Accordingly, we only use z_{jj}, s_{jj}, w_{jj} to estimate ϕ, η, so that the impact of documents is fixed. This makes more sense, in that after the approximation in section 3.1, there is no need to use $\{z_{ij}, s_{ij}, \mid i \neq j\}$ (they have the same values as z_{jj}, s_{jj}).

4.1 Text Categorization

We believe our model can generate more "correct" topics by looking into dictionaries. In topic models, each word is generalized as a topic and each document is summarized as the topic mixture θ, hence it is natural to evaluate the quality of inferred topics in a text categorization task. We follow the classification framework in (Griffiths et al., 2005): first run topic models on each dataset **individually** without knowing label information to achieve document level topic mixtures, then we employ Naive Bayes and SVM (both implemented in the WEKA Toolkit (Hall et al., 2009)) to perform classification on the topic mixtures. For all document, the features are the percentage of topics. Similar to (Griffiths et al., 2005), we assess inferred topics by the classification accuracy of 10-fold cross validation on each dataset.

We evaluate our models on three datasets in the cross validation manner: The Brown corpus which comprises 500 documents grouped into 15 categories (same set used in (Griffiths et al., 2005)); NYT comprising 800 documents grouped into the 16 most frequent label categories; Reuters (R20) comprising 8600 documents labeled with the most frequent 20 categories. In R20, combination of categories is treated as separate category labels, so $money, interest$ and $interest$ are considered different labels.

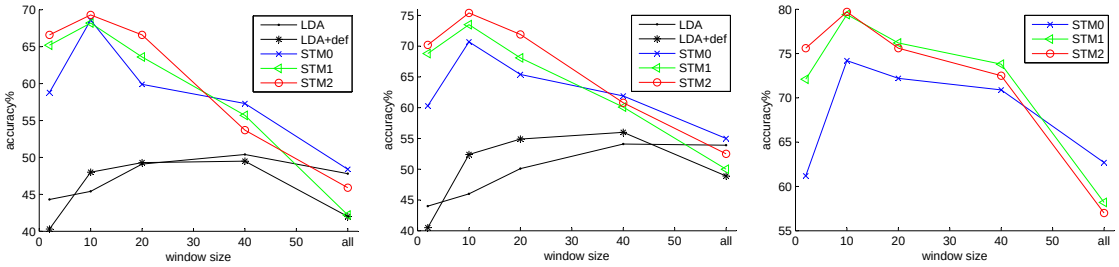
For the three datasets, we use the Brown corpus only as a tuning set to decide on the topic model parameters for all of our experimentation, and use the optimized parameters directly on NYT and R20 without further optimization.

4.1.1 Classification Results

Searching γ and ϵ on Brown: The classification accuracy on the Brown corpus with different ϵ and γ values using Naive Bayes and SVM are presented in figure 2a and 2b. In this section, the number of topics T is set to 50. The possible ϵ values in the horizontal axis are *2, 10, 20, 40, all*. The possible γ values are *0, 1, 2*. Note that $\epsilon = all$ means that no local window is used, and $\gamma = 0$ means definitions are not used. The hyper-

Corpus	DOCs size	orig tokens	content tokens	WN tokens	word types	sense types
Brown	500	1022393	580882	547887	27438	46645
NYT	800	743665	436988	393120	19025	37631
R20	8595	901691	450935	417331	9930	24834
SemCor	352	676546	404460	352563	28925	45973
WordNet	117659	1447779	886923	786679	42080	60567

Table 1: Corpus statistics



(a) Naive Bayes on Brown (b) SVM on Brown (c) SVM on NYT

Figure 2: Classification accuracy at different parameter settings

parameters are tuned as $\alpha_d = 0.1, \alpha_s = 0.01, \beta = 0.01, \lambda = 0.1$.

From figure 2, we observe that results using SVM have the same trend as Naive Bayes except that the accuracies are roughly 5% higher for SVM classifier. The results of LDA and LDA+def suggest that simply treating definitions as documents in an augmented data manner does not help. Comparing SMT0 with LDA in the same ϵ values, we find that explicitly modeling the sense node in the model greatly improves the classification results. The reason may be that words in LDA are independent isolated strings, while in STM0 they are connected by senses.

STM2 prefers smaller window sizes (ϵ less than 40). That means two words with a distance larger than 40 are not necessarily semantically related or share the same topic. This ϵ number also correlates with the optimal context window size of 12 reported in WSD tasks (Sinha and Mihalcea, 2007; Guo and Diab, 2010).

Classification results: Table 2 shows the results of our models using best tuned parameters of $\epsilon = 10, \gamma = 2$ on 3 datasets. We present three baselines in Table 2: (1) WEKA uses WEKA's classifiers directly on bag-of-words without topic modeling. The values of features are simply term frequency. (2) WEKA+FS performs feature selection using information gain before applying classification. (3) LDA, is the traditional topic model. Note that Griffiths et al.'s (2005) implementation of LDA achieve 51% on Brown corpus using Naive Bayes . Finally the Table illustrates the results obtained using our proposed models STM0 (γ=0) and STM2 (γ = 2).

It is worth noting that R20 (compared to NYT) is a harder condition for topic models. This is because fewer words (10000 distinct words versus 19000 in NYT) are frequently used in a large training set (8600 documents versus 800 in NYT), making the surface word feature space no longer as sparse as in the NYT or Brown corpus, which implies simply using surface words without considering the words distributional statistics – topic modeling – is good enough for classification. In (Blei et al., 2003) figure 10b they also show worse text categorization results over the SVM baseline when more than 15% of the training labels of Reuters are available for the SVM classifiers, indicating that LDA is less necessary with large training data. In our investigation, we report results on SVM classifiers trained on the whole Reuters training set. In our experiments, LDA fails to correctly classify nearly 10% of the Reuters documents compared to the WEKA baseline, however STM2 can still achieve significantly better accuracy (+4%) in the SVM classification condition.

Table 2 illustrates that despite the difference between NYT, Reuters and Brown (data size, genre, domains, category labels), exploiting WSD techniques (namely using a local window size coupled with explicitly modeling a sense node) yields

	Brown		NYT		R20	
	NB	SVM	NB	SVM	NB	SVM
WEKA	48	47.8	57	54.1	72.4	82.9
WEKA+FS	50	47.2	56.9	55.1	72.9	83.4
LDA	47.8±4.3	53.9±3.8	48.5±5.5	53.8±3.5	61.0±3.3	72.5±2.5
STM0	68.6±3.5	70.7±3.9	66.7±3.8	74.2±4.0	72.7±3.5	85.2±0.9
STM2	69.3±3.3	75.4±3.7	74.6±3.3	79.3±2.5	73±3.7	86.9±1.2

Table 2: Classification results on 3 datasets using hyperparameters tuned on Brown.

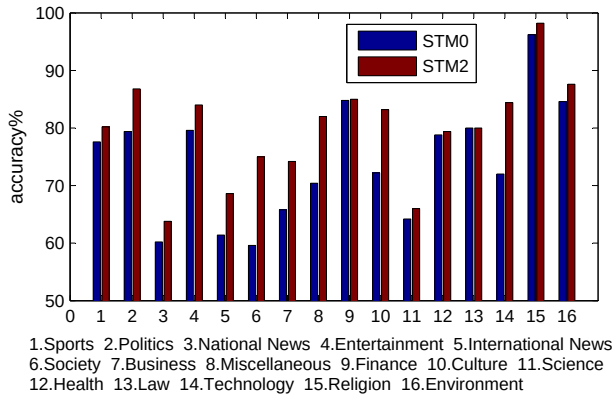


Figure 3: SVM accuracy on each category of NYT

significantly better results than all three baselines including LDA. Furthermore, explicit definition modeling as used in STM2 yields the best performance consistently overall.

Finally, in Figure 2c we show the SVM classification results on NYT in different parameter settings. We find that the NYT classification accuracy trend is consistent with that on the Brown corpus for each parameter setting of $\epsilon \in \{2, 10, 20, 40, all\}$ and $\gamma \in \{0, 1, 2\}$. This further proves the robustness of STMn.

4.2 Analysis on the Impact of Modeling Definitions

4.2.1 Qualitative Analysis

To understand why definitions are helpful in text categorization, we analyze the SVM performance of STM0 and STM2 ($\epsilon = 10$) on each category of NYT dataset (figure 3). We find STM2 outperforms STM0 in all categories. However, the largest gain is observed in *Society*, *Miscellaneous*, *Culture*, *Technology*. For *Technology*, we should credit WordNet definitions, since *Technology* may contain many infrequent technical terms, and STM0 cannot generalize the meaning of words only by distributional information due to their low frequency usage. However in some other domains, fewer specialized words are repeatedly used, hence STM0 can do as well as STM2.

For the other 3 categories, we hypothesize that these documents are likely to be a mixture of multiple topics. For example, a *Culture* news could contain topics pertaining to *religion, history, art*; while a *Society* news about crime could relate to *law, family, economics*. In this case, it is very important to sample a true topic for each word, so that ML algorithms can distinguish the *Culture* documents from the *Religion* ones by the proportion of topics. Accordingly, adding definitions should be very helpful, since it specifically defines the topic of a sense, and shields it from the influence of other "incorrect/irrelevant" topics.

4.2.2 Quantitative Analysis with Word Sense Disambiguation

A side effect of our model is that it sense disambiguates all words. As a means of analyzing and gaining some insight into the exact contribution of explicitly incorporating sense definitions (STMn) versus simply a sense node (STM0) in the model, we investigate the quality of the sense assignments in our models. We believe that the choice of the correct sense is directly correlated with the choice of a correct topic in our framework. Accordingly, a relative improvement of STMn over STM0 (where the only difference is the explicit sense definition modeling) in WSD task is an indicator of the impact of using sense definitions in the text categorization task.

WSD Data: We choose the all-words WSD task in which an unsupervised WSD system is required to disambiguate all the content words in documents. Our models are evaluated against the SemCor dataset. We prefer SemCor to all-words datasets available in Senseval-3 (Snyder and Palmer, 2004) or SemEval-2007 (Pradhan et al., 2007), since it includes many more documents than either set (350 versus 3) and therefore allowing more reliable results. Moreover, SemCor is also the dataset used in (Boyd-Graber et al., 2007), where a WordNet based topic model for WSD is introduced. The

	Total	Noun	Adjective	Adverb	Verb
sense annotated words	225992	86996	31729	18947	88320
polysemous words	187871	70529	21989	11498	83855
TF-IDF	-	0.422	0.300	0.153	0.182

Table 3: Statistics of SemCor per POS

statistics of SemCor is listed in table 3.

We use hyperparameters tuned from the text categorization task: α_d=0.1, α_s=0.01, β=0.01, δ=1, T=50, and try different values of $\epsilon \in \{10, 20, 40\}$ and $\gamma \in \{0, 2, 10\}$. The Brown corpus and WordNet definitions corpus are used as augmented data, which means the dashed line in figure 1c will become bold. Finally, we choose the most frequent answer for each word in the last 10 iterations of a Gibbs Sampling run as the final sense choice.

WSD Results: Disambiguation per POS results are presented in table 4. We only report results on polysemous words. We can see that modeling definitions (STM2 and STM10) improves performance significantly over STM0's across the board per POS and overall. The fact that STMn picks more correct senses helps explain why STMn classifies more documents correctly than STM0. Also it is interesting to see that unlike in the text categorization task, larger values of γ generate better WSD results. However, the window size ϵ, does not make a significant difference, yet we note that ϵ=10 is still the optimal value, similar to our observation in the text categorization task.

STM10 achieves similar results as in LDAWN (Boyd-Graber et al., 2007) which was specifically designed for WSD. LDAWN needs a fine grained hypernym hierarchy to perform WSD, hence they can only disambiguate nouns. They report different performances under various parameter setting. We cite their best performance of 38% accuracy on nouns as a comparison point to our best performance for nouns of 38.5%.

An interesting feature of STM10 is that it performs much better in nouns than adverbs and verbs, compared to a random baseline in Table 4. This is understandable since topic information content is mostly borne by nouns and adjectives, while adverbs and verbs tend to be less informative about topics (e.g., *even, indicate, take*), and used more across different domain documents. Hence topic models are weaker in their ability to identify clear cues for senses for verbs and adverbs. In support of our hypothesis about the POS distribution, we compute the average TF-IDF scores for each POS (shown in Table 3 according to the equation illustrated below). The average TF-IDF clearly indicate the positive skewness of the nouns and adjectives (high TF-IDF) correlates with the better WSD performance.

$$\text{TF-IDF}(pos) = \frac{\sum_i \sum_d \text{TF-IDF}(w_{i,d})}{\#\ of\ w_{i,d}}$$
$$where\ w_{i,d} \in pos.$$

At last, we notice that the most frequent sense baseline performs much better than our models. This is understandable since: (1) most frequent sense baseline can be treated as a supervised method in the sense that the sense frequency is calculated based on the sense choice as present in sense annotated data; (2) our model is not designed for WSD, therefore it discards a lot of information when choosing the sense: in our model, the choice of a sense s_i is only dependent on two facts: the corresponding topic z_i and word w_i, while in (Li et al., 2010; Banerjee and Pedersen, 2003), they consider all the senses and words in the context words.

5 Related work

Various topic models have been developed for many applications. Recently there is a trend of modeling document dependency (Dietz et al., 2007; Mei et al., 2008; Daume, 2009). However, topics are only inferred based on word cooccurrence, while word semantics are ignored.

Boyd-Graber et al. (2007) are the first to integrate semantics into the topic model framework. They propose a topic model based on WordNet noun hierarchy for WSD. A word is assumed to be generated by first sampling a topic, then choosing a path from the root node of hierarchy to a sense node corresponding to that word. However, they only focus on WSD. They do not exploit word definitions, neither do they report results on text categorization.

Chemudugunta et al. (2008) also incorporate a sense hierarchy into a topic model. In their framework, a word may be directly generated from a topic (as in standard topic models), or it can be

		Total	Noun	Adjective	Adverb	Verb
random		22.1	26.2	27.9	32.2	15.8
most frequent sense		64.7	74.7	77.5	74.0	59.6
STM0	$\epsilon = 10$	24.1±1.4	29.3±4.3	28.7±1.1	34.1±3.1	17.1±1.6
	$\epsilon = 20$	24±1.3	30.2±3.3	29.1±1.4	34.9±3.1	15.9±0.7
	$\epsilon = 40$	24±2.4	28.4±4.3	28.7±1.1	**36.4±4.7**	17.3±2.4
STM2	$\epsilon = 10$	27.5±1.1	36.1±3.8	34.0±1.2	33.4±1.8	17.8±1.4
	$\epsilon = 20$	25.7±1.3	32.0±4.2	33.5±0.7	34.2±3.4	17.3±0.7
	$\epsilon = 40$	26.1±1.3	32.5±3.9	33.6±0.9	34.2±3.4	17.5±1.4
STM10	$\epsilon = 10$	**28.8±1.1**	**38.5±2.3**	**34.7±0.8**	34.0±3.3	**18.4±1.2**
	$\epsilon = 20$	27.7±1.0	36.8±2.2	34.5±0.7	33.0±3.1	17.6±0.7
	$\epsilon = 40$	28.1±1.5	38.4±3.1	34.0±1.0	35.1±5.4	17.0±0.9

Table 4: Disambiguation results per POS on polysemous words.

generated by choosing a sense path in the hierarchy. Note that no topic information is on the sense path. If a word is generated from the hierarchy, then it is not assigned a topic. Their models based on different dictionaries improve perplexity.

Recently, several systems have been proposed to apply topic models to WSD. Cai et al. (2007) incorporate topic features into a supervised WSD framework. Brody and Lapata (2009) place the sense induction in a Baysian framework by assuming each context word is generated from the target word's senses, and a context is modeled as a multinomial distribution over the target word's senses rather than topics. Li et al. (2010) design several systems that use latent topics to find a most likely sense based on the sense paraphrases (extracted from WordNet) and context. Their WSD models are unsupervised and outperform state-of-art systems.

Our model borrows the local window idea from word sense disambiguation community. In graph-based WSD systems (Mihalcea, 2005; Sinha and Mihalcea, 2007; Guo and Diab, 2010), a node is created for each sense. Two nodes will be connected if their distance is less than a predefined value; the weight on the edge is a value returned by sense similarity measures, then the PageRank/Indegree algorithm is applied on this graph to determine the appropriate senses.

6 Conclusion and Future Work

We presented a novel model STM that combines explicit semantic information and word distribution information in a unified topic model. STM is able to capture topics of words more accurately than traditional LDA topic models. In future work, we plan to model the WordNet sense network. We believe that WordNet senses are too fine-grained, hence we plan to use clustered senses, instead of current WN senses, in order to avail the model of more generalization power.

Cooooooooooooooollllllllllllll!!!!!!!!!!!!!! Using Word Lengthening to Detect Sentiment in Microblogs

Samuel Brody
School of Communication
and Information
Rutgers University
sdbrody@gmail.com

Nicholas Diakopoulos
School of Communication
and Information
Rutgers University
diakop@rutgers.edu

Abstract

We present an automatic method which leverages word lengthening to adapt a sentiment lexicon specifically for Twitter and similar social messaging networks. The contributions of the paper are as follows. First, we call attention to lengthening as a widespread phenomenon in microblogs and social messaging, and demonstrate the importance of handling it correctly. We then show that lengthening is strongly associated with subjectivity and sentiment. Finally, we present an automatic method which leverages this association to detect domain-specific sentiment- and emotion-bearing words. We evaluate our method by comparison to human judgments, and analyze its strengths and weaknesses. Our results are of interest to anyone analyzing sentiment in microblogs and social networks, whether for research or commercial purposes.

1 Introduction

Recently, there has been a surge of interest in sentiment analysis of Twitter messages. Many researchers (e.g., Bollen et al. 2011; Kivran-Swaine and Naaman 2011) are interested in studying structure and interactions in social networks, where sentiment can play an important role. Others use Twitter as a barometer for public mood and opinion in diverse areas such as entertainment, politics and economics. For example, Diakopoulos and Shamma (2010) use Twitter messages posted in conjunction with the live presidential debate between Barack Obama and John McCain to gauge public opinion, Bollen et al. (2010) measure public mood on Twitter and use it to predict upcoming stock market fluctuations, and O'Connor et al. (2010) connect public opinion data from polls to sentiment expressed in Twitter messages along a timeline.

A prerequisite of all such research is an effective method for measuring the sentiment of a post or *tweet*. Due to the extremely informal nature of the medium, and the length restriction[1], the language and jargon which is used in Twitter varies significantly from that of commonly studied text corpora. In addition, Twitter is a quickly evolving domain, and new terms are constantly being introduced. These factors pose difficulties to methods designed for conventional domains, such as news. One solution is to use human annotation. For example, Kivran-Swaine and Naaman (2011) use manual coding of tweets in several emotion categories (e.g., joy, sadness) for their research. Diakopoulos and Shamma (2010) use crowd sourcing via Amazon's Mechanical Turk. Manual encoding usually offers a deeper understanding and correspondingly higher accuracy than shallow automatic methods. However, it is expensive and labor intensive and cannot be applied in real time. Crowd-sourcing carries additional caveats of its own, such as issues of annotator expertise and reliability (see Diakopoulos and Shamma 2010).

The automatic approach to sentiment analysis is commonly used for processing data from social networks and microblogs, where there is often a huge quantity of information and a need for low latency. Many automatic approaches (including all those used in the work mentioned above) have at their core a sentiment lexicon, containing a list of words la-

[1] Messages in Twitter are limited to 140 characters, for compatibility with SMS messaging

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 562–570,
Edinburgh, Scotland, UK, July 27–31, 2011.

beled with specific associated emotions (joy, happiness) or a polarity value (positive, neutral, negative). The overall sentiment of a piece of text is calculated as a function of the labels of the component words. Because Twitter messages are short, shallow approaches are sometimes considered sufficient (Bermingham and Smeaton, 2010). There are also approaches that use deeper machine learning techniques to train sentiment classifiers on examples that have been labeled for sentiment, either manually or automatically, as described above. Recent examples of this approach are Barbosa and Feng (2010) and Pak and Paroubek (2010).

Most established sentiment lexicons (e.g., Wilson et al. 2005, see Section 5) were created for a general domain, and suffer from limited coverage and inaccuracies when applied to the highly informal domain of social networks communication. By creating a sentiment lexicon which is specifically tailored to the microblogging domain, or adapting an existing one, we can expect to achieve higher accuracy and increased coverage. Recent work in this area includes Velikovich et al. (2010), who developed a method for automatically deriving an extensive sentiment lexicon from the web as a whole. The resulting lexicon has greatly increased coverage compared to existing dictionaries and can handle spelling errors and web-specific jargon. Bollen et al. (2010) expand an existing well-vetted psychometric instrument - Profile of Mood States (POMS) (McNair et al., 1971) that associates terms with moods (e.g. calm, happy). The authors use co-occurrence information from the Google n-gram corpus (Brants and Franz, 2006) to enlarge the original list of 72 terms to 964. They use this expanded emotion lexicon (named GPOS) in conjunction with the lexicon of Wilson et al. (2005) to estimate public mood from Twitter posts[2].

The method we present in this paper leverages a phenomenon that is specific to informal social communication to enable the extension of an existing lexicon in a domain specific manner.

[2]Although the authors state that all data and methods will be made available on a public website, it was not present at the time of the writing of this article.

2 Methodology

Prosodic indicators (such as high pitch, prolonged duration, intensity, vowel quality, etc.) have long been know (Bolinger, 1965) as ways for a speaker to emphasize or accent an important word. The ways in which they are used in speech are the subject of ongoing linguistic research (see, for example, Calhoun 2010). In written text, many of these indicators are lost. However, there exist some orthographic conventions which are used to mark or substitute for prosody, including punctuation and typographic styling (italic, bold, and underlined text). In purely text-based domains, such as Twitter, styling is not always available, and is replaced by capitalization or other conventions (e.g., enclosing the word in asterisks). Additionally, the informal nature of the domain leads to an orthographic style which is much closer to the spoken form than in other, more formal, domains. In this work, we hypothesize that the commonly observed phenomenon of lengthening words by repeating letters is a substitute for prosodic emphasis (increased duration or change of pitch). As such, it can be used as an indicator of important words and, in particular, ones that bear strong indication of sentiment.

Our experiments are designed to analyze the phenomenon of lengthening and its implications to sentiment detection. First, in Experiment I, we show the pervasiveness of the phenomenon in our dataset, and measure the potential gains in coverage that can be achieved by considering lengthening when processing Twitter data. Experiment II substantiates the claim that word lengthening is not arbitrary, and is used for emphasis of important words, including those conveying sentiment and emotion. In the first part of Experiment III we demonstrate the implications of this connection for the purpose of sentiment detection using an existing sentiment lexicon. In the second part, we present an unsupervised method for using the lengthening phenomenon to expand an existing sentiment lexicon and tailor it to our domain. We evaluate the method through comparison to human judgments, analyze our results, and demonstrate some of the benefits of our automatic method.

1. For every word in the vocabulary, extract the condensed form, where sequences of a repeated letter are replaced with a single instance of that letter.
   E.g., $niiiice \rightarrow nice,\ reallllly \rightarrow realy$ ...
2. Create sets of words sharing the same condensed form.
   E.g., $\{nice, niiice, niccccceee...\},\ \{realy, really, reallllly, ...\}$ ...
3. Remove sets which do not contain at least one repeat of length three.
   E.g.,$\{committee, committe, commitee\}$
4. Find the most frequently occurring form in the group, and mark it as the canonical form.
   E.g., $\{$**nice**$, niiice, niccccceee...\},\ \{realy,$ **really**$, reallllly, ...\}$ ...

Figure 1: Procedure for detecting lengthened words and associating them with a canonical form.

3 Data

Half a million tweets were sampled from the Twitter Streaming API on March 9th 2011. The tweets were sampled to cover a diverse geographic distribution within the U.S. such that regional variation in language use should not bias the data. Some tweets were also sampled from Britain to provide a more diverse sampling of English. We restricted our sample to tweets from accounts which indicated their primary language as English. However, there may be some foreign language messages in our dataset, since multi-lingual users may tweet in other languages even though their account is marked as "English".

The tweets were tokenized and converted to lower-case. Punctuation, as well as links, hashtags, and username mentions were removed. The resulting corpus consists of approximately 6.5 million words, with a vocabulary of 22 thousand words occurring 10 times or more.

4 Experiment I - Detection

To detect and analyze lengthened words, we employ the procedure described in Figure 1. We find sets of words in our data which share a common form and differ only in the number of times each letter is repeated (Steps 1 & 2). In Step 3 we remove sets where all the different forms are likely to be the result of misspelling, rather than lengthening. Finally, in Step 4, we associate all the forms in a single set with a canonical form, which is the most common one observed in the data.

The procedure resulted in 4,359 sets of size > 1. To reduce noise resulting from typos and misspellings, we do not consider words containing non-alphabetic characters, or sets where the canonical form is a single character or occurs less than 10 times. This left us with 3,727 sets.

Analysis Table 1 lists the canonical forms of the 20 largest sets in our list (in terms of the number of variations). Most of the examples are used to express emotion or emphasis. Onomatopoeic words expressing emotion (e.g., *ow, ugh, yay*) are often lengthened and, for some, the combined frequency of the different lengthened forms is actually greater than that of the canonical (single most frequent) one.

Lengthening is a common phenomenon in our dataset. Out of half-a-million tweets, containing roughly 6.5 million words, our procedure identifies 108,762 word occurrences which are lengthenings of a canonical form. These words occur in 87,187 tweets (17.44% or approximately one out of every six, on average). The wide-spread use of lengthening is surprising in light of the length restriction of Twitter. Grinter and Eldridge (2003) point out several conventions that are used in text messages specifically to deal with this restriction. The fact that lengthening is used in spite of the need for brevity suggests that it conveys important information.

Canonical Assumption We validate the assumption that the most frequent form in the set is the canonical form by examining sets containing one or more word forms that were identified in a standard

Can. Form	Card.	# Can.	# Non-Can.
nice	76	3847	348
ugh	75	1912	1057
lmao	70	10085	3727
lmfao	67	2615	1619
ah	61	767	1603
love	59	16360	359
crazy	59	3530	253
yeah	57	4562	373
sheesh	56	247	131
damn	52	5706	299
shit	51	10332	372
really	51	9142	142
oh	51	7114	1617
yay	45	1370	375
wow	45	3767	223
good	45	21042	3171
ow	44	116	499
mad	44	3627	827
hey	44	4669	445
please	43	4014	157

Table 1: The canonical forms of the 20 largest sets (in terms of cardinality), with the number of occurrences of the canonical and non-canonical forms.

English dictionary[3]. This was the case for 2,092 of the sets (56.13%). Of these, in only 55 (2.63%) the most frequent form was *not* recognized by the dictionary. This indicates that the strategy of choosing the most frequent form as the canonical one is reliable and highly accurate ($> 97\%$).

Implications for NLP To examine the effects of lengthening on analyzing Twitter data, we look at the difference in coverage of a standard English dictionary when we explicitly handle lengthened words by mapping them to the canonical form. Coverage with a standard dictionary is important for many NLP applications, such as information retrieval, translation, part-of-speech tagging and parsing. The canonical form for 2,037 word-sets are identified by our dictionary. We searched for occurrences of these words which were lengthened by two or more characters, meaning they would not be identified using standard lemmatization methods or spell-correction techniques that are based on edit distance. We detected 25,101 occurrences of these, appearing in 22,064 (4.4%) tweets. This implies that a lengthening-aware stemming method can be used to increase coverage substantially.

[3]We use the standard dictionary for U.S. English included in the Aspell Unix utility.

5 Experiment II - Relation to Sentiment

At the beginning of Section 2 we presented the hypothesis that lengthening represents a textual substitute for prosodic indicators in speech. As such, it is not used arbitrarily, but rather applied to subjective words to strengthen the sentiment or emotion they convey. The examples presented in Table 1 in the previous section appear to support this hypothesis. In this section we wish to provide experimental evidence for our hypothesis, by demonstrating a significant degree of association between lengthening and subjectivity.

For this purpose we use an existing sentiment lexicon (Wilson et al., 2005), which is commonly used in the literature (see Section 1) and is at the core of OpinionFinder[4], a popular sentiment analysis tool designed to determine opinion in a general domain. The lexicon provides a list of subjective words, each annotated with its degree of subjectivity (strongly subjective, weakly subjective), as well as its sentiment polarity (positive, negative, or neutral). In these experiments, we use the presence of a word (canonical form) in the lexicon as an indicator of subjectivity. It should be noted that the reverse is not true, i.e., the fact that a word is absent from the lexicon does not indicate it is objective.

As a measure of tendency to lengthen a word, we look at the number of distinct forms of that word appearing in our dataset (the cardinality of the set to which it belongs). We group the words according to this statistic, and compare to the vocabulary of our dataset (all words appearing in our data ten times or more, and consisting of two or more alphabetic characters, see Section 4). Figure 2 shows the percentage of subjective words (those in the lexicon) in each of the groups. As noted previously, this is a lower bound, since it is possible (in fact, very likely) that other words in the group are subjective, despite being absent from the lexicon. The graph shows a clear trend - the more lengthening forms a word has,

[4]http://www.cs.pitt.edu/mpqa/opinionfinderrelease/

the more likely it is to be subjective (as measured by the percentage of words in the lexicon).

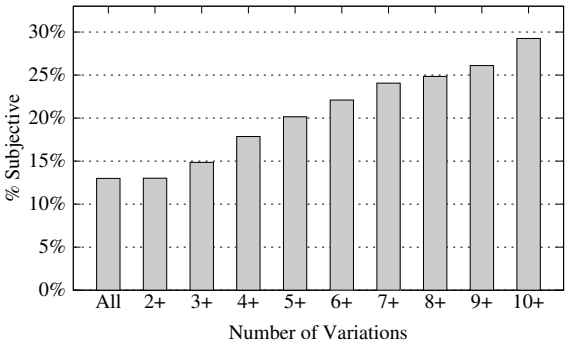
The reverse also holds - if a word is used to convey sentiment, it is more likely to be lengthened. We can verify this by calculating the average number of distinct forms for words in our data that are subjective and comparing to the rest. This calculation yields an average of 2.41 forms for words appearing in our sentiment lexicon (our proxy for subjectivity), compared to an average of 1.79 for those that aren't[5]. This difference is statistically significant at $p < 0.01\%$, using a student t-test.

The lexicon we use was designed for a general domain, and suffers from limited coverage (see below) and inaccuracies (see O'Connor et al. 2010 and below Section 6.2 for examples), due to the domain shift. The sentiment lexicon contains 6,878 words, but only 4,939 occur in our data, and only 2,446 appear more than 10 times. Of those appearing in our data, only 485 words (7% of the lexicon vocabulary) are lengthened (the bar for group 2+ in Figure 2), but these are extremely salient. They encompass 701,607 instances (79% of total instances of words from the lexicon), and 339,895 tweets. This provides further evidence that lengthening is used with salient sentiment words.

These results also demonstrates the limitations of using a sentiment lexicon which is not tailored to the domain. Only a small fraction of the lexicon is represented in our data, and it is likely that there are many sentiment words that are commonly used but are absent from it. We address this issue in the next section.

6 Experiment III - Adapting the Sentiment Lexicon

The previous experiment showed the connection between lengthening and sentiment-bearing words. It also demonstrated some of the shortcomings of a lexicon which is not specifically tailored to our domain. There are two steps we can take to use the lengthening phenomenon to adapt an existing sentiment lexicon. The first of these is simply to take lengthening into account when identifying sentiment-bearing words in our corpus. The second is to exploit the connection between lengthening and sentiment to expand the lexicon itself.



All	2+	3+	4+	5+	6+	7+	8+	9+	10+
18,817	3,727	2,451	1,540	1,077	778	615	487	406	335

Figure 2: The percentage of subjective word-sets (those whose canonical form appears in the lexicon) as a function of cardinality (number of lengthening variations). The accompanying table provides the total number of sets in each cardinality group.

6.1 Expanding Coverage of Existing Words

We can assess the effect of specifically considering lengthening in our domain by measuring the increase of coverage of the existing sentiment lexicon. Similarly to Experiment I (Section 4), we searched for occurrences of words from the lexicon which were lengthened by two or more characters, and would therefore not be detected using edit-distance. We found 12,105 instances, occurring in 11,439 tweets (2.29% of the total). This increase in coverage is relatively small[6], but comes at almost no cost, by simply considering lengthening in the analysis.

A much greater benefit of lengthening, however, results from using it as an aid in expanding the sentiment lexicon and detecting new sentiment-bearing words. This is the subject of the following section.

6.2 Expanding the Sentiment Vocabulary

In Experiment II (Section 5) we showed that lengthening is strongly associated with sentiment. Therefore, words which are lengthened can provide us with good candidates for inclusion in the lexicon. We can employ existing sentiment-detection meth-

[5]This, too, is a conservative estimate, since the later group also includes subjective words, as mentioned.

[6]Note that almost half of the increase in coverage calculated in Experiment I (Section 4) comes from subjective words!

ods to decide which candidates to include, and determine their polarity.

Choosing a Candidate Set The first step in expanding the lexicon is to choose a set of candidate words for inclusion. For this purpose we start with words that have 5 or more distinct forms. There are 1,077 of these, of which only 217 (20.15%) are currently in our lexicon (see Figure 2). Since we are looking for commonly lengthened words, we disregard those where the combined frequency of the non-canonical forms is less than 1% that of the canonical one. We also remove stop words, even though some are often lengthened for emphasis (e.g., *me, and, so*), since they are too frequent, and introduce many spurious edges in our co-occurrence graph. Finally, we filter words based on weight, as described below. This leaves us with 720 candidate words.

Graph Approach We examine two methods for sentiment detection - that of Brody and Elhadad (2010) for detecting sentiment in reviews, and that of Velikovich et al. (2010) for finding sentiment terms in a giga-scale web corpus. Both of these employ a graph-based approach, where candidate terms are nodes, and sentiments is propagated from a set of seed words of known sentiment polarity. We calculated the frequency in our corpus of all strongly positive and strongly negative words in the Wilson et al. (2005) lexicon, and chose the 100 most frequent in each category as our seed sets.

Graph Construction Brody and Elhadad (2010) considered all frequent adjectives as candidates and weighted the edge between two adjectives by a function of the number of times they both modified a single noun. Velikovich et al. (2010) constructed a graph where the nodes were 20 million candidate words or phrases, selected using a set of heuristics including frequency and mutual information of word boundaries. Context vectors were constructed for each candidate from all its mentions in a corpus of 4 billion documents, and the edge between two candidates was weighted by the cosine similarity between their context vectors.

Due to the nature of the domain, which is highly informal and unstructured, accurate parsing is difficult. Therefore we cannot employ the exact construction method of Brody and Elhadad (2010). On the other hand, the method of Velikovich et al. (2010) is based on huge amounts of data, and takes advantage of the abundance of contextual information available in full documents, whereas our domain is closer to that of Brody and Elhadad (2010), who dealt with a small number of candidates and short documents typical to online reviews. Therefore, we adapt their construction method. We consider all our candidates words as nodes, along with the words in our positive and negative seed sets. As a proxy for syntactic relationship, edges are weighted as a function of the number of times two words occurred within a three-word window of each other in our dataset. We remove nodes whose neighboring edges have a combined weight of less than 20, meaning they participate in relatively few co-occurrence relations with the other words in the graph.

Algorithm Once the graph is constructed, we can use either of the propagation algorithms of Brody and Elhadad (2010) and Velikovich et al. (2010), which we will denote Reviews and Web, respectively. The Reviews propagation method is based on Zhu and Ghahramani (2002). The words in the positive and negative seed groups are assigned a polarity score of 1 and 0, respectively. All the rest start with a score of 0.5. Then, an update step is repeated. In update iteration t, for each word x that is *not in the seed*, the following update rule is applied:

$$p^t(x) = \frac{\Sigma_{y \in N(x)} w(y,x) \cdot p^{t-1}(y)}{\Sigma_{y \in N(x)} w(y,x)} \qquad (1)$$

Where $p^t(x)$ is the polarity of word x at step t, $N(x)$ is the set of the neighbors of x, and $w(y,x)$ is the weight of the edge connecting x and y. Following Brody and Elhadad (2010), we set this weight to be $1 + log(\#co(y,x))$, where $\#co(y,x)$ is the number of times y and x co-occurred within a three-word window. The update step is repeated to convergence.

Velikovich et al. (2010) employed a different label propagation method, as described in Figure 3. Rather than relying on diffusion along the whole graph, this method considers only the single strongest path between each candidate and each seed word. In their paper, the authors claim that their algorithm is more suitable than that of Zhu and Ghahramani (2002) to a web-based dataset, which

Input: $G = (V, E), w_{ij} \in [0, 1]$
$P, N, \gamma \in \mathbb{R}, T \in \mathbb{N}$
Output: $\text{pol}_i \in \mathbb{R}^{|V|}$
Initialize: $\text{pol}_i, \text{pol}_i^+, \text{pol}_i^- = 0$ for all i
$\text{pol}_i^+ = 1.0$ for all $v_i \in P$ and
$\text{pol}_i^- = 1.0$ for all $v_i \in N$

1: $\alpha_{ij} = 0$ for all $i \neq j$, $\alpha_{ii} = 1$ for all i
2: **for** $v_i \in P$
3: $F = \{v_i\}$
4: **for** $t : 1...T$
5: **for** $(v_k, v_j) \in E$ such that $v_k \in F$
6: $\alpha_{ij} = max(\alpha_{ij}, \alpha_{ik} \cdot w_{k,j})$
$F = F \cup \{v_j\}$
7: **for** $v_j \in V$
8: $\text{pol}_j^+ = \sum_{v_i \in P} \alpha_{ij}$
9: Repeat steps 1-8 using N to compute pol^-
10: $\beta = \sum_i \text{pol}_i^+ / \sum_i \text{pol}_i^-$
11: $\text{pol}_i = \text{pol}_i^+ - \beta \text{pol}_i^-$, for all i
12: if $|\text{pol}_i| < \gamma$ then $\text{pol}_i = 0.0$ for all i

Figure 3: Web algorithm from Velikovich et al. (2010). P and N are the positive and negative seed sets, respectively, w_{ij} are the weights, and T and γ are parameters[9].

contained many dense subgraphs and unreliable associations based only on co-occurrence statistics. We ran both algorithms in our experiment[7], and compared the results.

Evaluation We evaluated the output of the algorithms by comparison to human judgments. For words appearing in the sentiment lexicon, we used the polarity label provided. For the rest, similarly to Brody and Elhadad (2010), we asked volunteers to rate the words on a five-point scale: *strongly-negative, weakly-negative, neutral, weakly-positive,* or *strongly-positive*. We also provided a *N/A* option if the meaning of the word was unknown. Each word was rated by two volunteers. Words which were labeled *N/A* by one or more annotators were considered *unknown*. For the rest, exact inter-rater agreement was 67.6%, but rose to 93% when considering adjacent ratings as equivalent[10]. This is comparable with the agreement reported by Brody and Elhadad (2010). We assigned values 1 (strongly negative) to 5 (strongly positive) to the ratings, and calculated the average between the two ratings for each word. Words with an average rating of 3 were considered neutral, and those with lower and higher ratings were considered negative and positive, respectively.

[7]We normalize the weights described above when using the Web algorithm.

[9]In Velikovich et al. (2010), the parameters T and γ were tuned on a held out dataset. Since our graphs are comparatively small, we do not need to limit the path length T in our search. We do not use the threshold γ, but rather employ a simple cutoff of the top 50 words.

		Human Judgment			
		Pos.	Neg.	Neu.	Unk.
Web	Pos.	18	2	26	2
	Neg.	8	19	17	8
Reviews	Pos.	21	6	21	2
	Neg.	9	14	11	16

Table 2: Evaluation of the top 50 positive and negative words retrieved by the two algorithms through comparison to human judgment.

Table 3: Top fifteen negative and positive words for the algorithms of Brody and Elhadad (2010) (Reviews) and Velikovich et al. (2010) (Web).

Results Table 2 shows the distribution of the human labels among the top 50 most positive and most negative words as determined by the two algorithms. Table 3 lists the top 15 of these as examples.

[10]Cohen's Kappa $\kappa = 0.853$

From Table 2 we can see that both algorithms do better on positive words (fewer words with reversed polarity)[11], and that the Web algorithm is more accurate than the Reviews method. The difference in performance can be explained by the associations used by the algorithms. The Web algorithm takes into account the strongest path to *every* seed word, while the Reviews algorithm propagates from the each seed to its neighbors and then onward. This makes the Reviews algorithm sensitive to strong associations between a word and a single seed. Because our graph is constructed with co-occurrence edges between words, rather than syntactic relations between adjectives, noisy edges are introduced, causing mistaken associations. The Web algorithm, on the other hand, finds words that have a strong association with the positive or negative seed group as a whole, thus making it more robust. This explains some of the examples in Table 3. The words *yeah* and *yea*, which often follow the negative seed word *hell*, are considered negative by the Reviews algorithm. The word *Justin* refers to Justin Beiber, and is closely associated with the positive seed word *love*. Although the Web algorithm is more robust to associations with a single seed, it still misclassifies the word *holy* as negative, presumably because it appears frequently before several different expletives.

Detailed analysis shows that the numbers reported in Table 2 are only rough estimates of performance. For instance, several of the words in the *unknown* category were correctly identified by the algorithm. Examples include *sm(f)h*, which stands for *"shaking my (fucking) head"* and expresses disgust or disdain, *sus*, which is short for *suspicious* (as in *"i hate susssss ass cars that follow me/us when i'm/we walkinggg"*), and *odee*, which means *overdose* and is usually negative (though it does not always refers to drugs, and is sometimes used as an intensifier, e.g., *"aint shit on tv odee bored"*).

There were also cases were the human labels were incorrect in the context of our domain. For example, the word *bull* is listed as positive in the sentiment lexicon, presumably because of its financial sense. In our domain it is (usually) short for *bullshit*. The word *canes* was rated as negative by one of the annotators, but in our data it refers to the Miami Hurricanes, who won a game on the day our dataset was sampled, and were the subject of many positive tweets. This example also demonstrates that our method is capable of detecting terms which are associated with sentiment at different time points, something that is not possible with a fixed lexicon.

[11] This trend is not apparent from the top 15 results presented in Table 3, but becomes noticeable when considering the larger group.

7 Conclusion

In this paper we explored the phenomenon of lengthening words by repeating a single letter. We showed that this is a common phenomenon in Twitter, occurring in one of every six tweets, on average, in our dataset. Correctly detecting these cases is important for comprehensive coverage. We also demonstrated that lengthening is not arbitrary, and is often used with subjective words, presumably to emphasize the sentiment they convey. This finding leads us to develop an unsupervised method based on lengthening for detecting new sentiment bearing words that are not in the existing lexicon, and discovering their polarity. In the rapidly-changing domain of microblogging and net-speak, such a method is essential for up-to-date sentiment detection.

8 Future Work

This paper examined one aspect of the lengthening phenomenon. There are other aspects of lengthening that merit research, such as the connection between the amount of lengthening and the strength of emphasis in individual instances of a word. In addition to sentiment-bearing words, we saw other word classes that were commonly lengthened, including intensifiers (e.g., *very, so, odee*), and named entities associated with sentiment (e.g., *Justin, 'Canes*). These present interesting targets for further study. Also, in this work we focused on data in English, and it would be interesting to examine the phenomenon in other languages. Another direction of research is the connection between lengthening and other orthographic conventions associated with sentiment and emphasis, such as emoticons, punctuation, and capitalization. Finally, we plan to integrate lengthening and its related phenomena into an accurate, Twitter-specific, sentiment classifier.

Acknowledgements

The authors would like to thank Paul Kantor and Mor Naaman for their support and assistance in this project. We would also like to thank Mark Steedman for his help, and the anonymous reviewers for their comments and suggestions.

Abstract

In recent years, the amount of user-generated opinionated texts (e.g., reviews, user comments) continues to grow at a rapid speed: featured news stories on a major event easily attract thousands of user comments on a popular online News service. How to consume subjective information of this volume becomes an interesting and important research question. In contrast to previous work on review analysis that tried to filter or summarize information for a generic *average* user, we explore a different direction of enabling personalized recommendation of such information.

For each user, our task is to rank the comments associated with a given article according to personalized user preference (i.e., whether the user is likely to like or dislike the comment). To this end, we propose a factor model that incorporates rater-comment and rater-author interactions simultaneously in a principled way. Our full model significantly outperforms strong baselines as well as related models that have been considered in previous work.

1 Introduction

Recent years have seen rapid growth in user-generated opinions online. Many of them are user reviews: a best-seller or a popular restaurant can get over 1000 reviews on top review sites like Amazon or Yelp. A large quantity of them also come in the form of user comments on blogs or news articles. Most notably, during the short period of time for which a major event is active, news stories on one single event can easily attract over ten thousand comments on a popular online news site like Yahoo! News. One question becomes immediate: how can we help people consume such gigantic amount of opinionated information?

One possibility is to take the summarization route. Briefly speaking (see Section 2 for a more detailed discussion), previous work has largely formulated review summarization as automatically or manually identify ratable aspects, and present overall sentiment polarity for each aspect (Hu and Liu, 2004; Popescu and Etzioni, 2005; Snyder and Barzilay, 2007; Titov and McDonald, 2008). A related line of research looked into predicting helpfulness of reviews in the hope of promoting those with better quality, where helpfulness is usually defined as some function over the percentage of users who found the review to be helpful (Kim et al., 2006; Liu et al., 2007; Danescu-Niculescu-Mizil et al., 2009). In short, the focus of previous work has been on distilling subjective information for an *average* user.

Whether opinion consumers are looking for quality information or just wondering what other people think, each may have different purposes or preferences that is not well represented by a generic average user. If we think about how we deal with information content overflow on the Web, there have been two main frameworks to identify relevant information for each person. One is search. Indeed many top review sites allow users to search within reviews for a given entity. But this is only useful when users have explicit information needs that can be formulated as queries. The other paradigm is recommendation: based on what users have liked or disliked in the past, the system will automatically recommend

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 571–582,
Edinburgh, Scotland, UK, July 27–31, 2011.

new items.

Can we provide similar recommendation mechanisms to help users consume large quantities of subjective information? Many commenting environments allow users to mark "like" or "dislike" over existing comments (e.g., Yahoo! News comments, Facebook posts, or review sites that allow helpfulness votes). Can we learn from users' past preferences, so that when a user is reading a new article, we have a system that automatically ranks its comments according to their likelihood of being liked by the user? This can be used directly to create personalized presentation of comments (e.g., into a "like" column and a "dislike" column), as well as enabling down-stream applications such as personalized summarization.

Recommending textual information has recently attracted more attention. So far, the focus has been mainly on recommending news articles (Ahn et al., 2007; Das et al., 2007). Our task differs in several aspects. Intuitively, recommending news articles is largely about identifying the topics of interest to a given user, and it is conceivable that unigram representation of full-length articles can reasonably capture that information. In our case, most comments for an article a user is reading are already of interest to that user topically. Which ones the user ends up liking may depend on several non-topical aspects of the text: whether the user agrees with the viewpoint expressed in the comment, whether the comment is convincing and well-written, etc. Previous work has shown that such analysis can be more difficult than topic-based analysis (Pang and Lee, 2008), and we have the additional challenge that comments are typically much shorter than full-length articles. However, the difficulty in analyzing the textual information in comments can be alleviated by additional contextual information such as author identities. If between a pair of users one consistently likes or dislikes the other, then at least for the heavy users, this authorship information alone could be highly informative. Indeed, previous work in collaborative filtering has usually found no additional gain from leveraging content information when entity-level preference information is abundant.

In this paper, we present a principled way of utilizing multiple sources of information for the task of recommending user comments, which significantly outperforms strong baseline methods, as well as previous methods proposed for text recommendation. While using authorship information alone tends to provide stronger signal than using textual information alone, to our surprise, even for heavy users, adding textual information to the authorship information yields additional improvements.

2 Related Work

There are two main bodies of related work: our problem formulation is closer to collaborative filtering, while the nature of the text we are dealing with has more in common with opinion mining and sentiment analysis.

Our approach is related to a large body of work in collaborative filtering. While a proper survey is not possible here, we describe some of the approaches that are germane. Classical approaches in collaborative filtering are based on item-item/user-user similarity, these are nearest-neighbor methods where the response for a user-item pair is predicted based on a local neighborhood mean (Sarwar et al., 2001; Wang et al., 2006). In general, neighborhoods are defined by measuring similarities between users/items through correlation measures like Pearson, cosine similarities, etc. Better approaches to estimate similarities have also been proposed in Koren (2010). However, modern methods based on matrix factorization have been shown to outperform nearest neighbor methods (Salakhutdinov and Mnih, 2008a,b; Bell et al., 2007). Generalizations of matrix factorization to include both features and past ratings have been proposed (Agarwal and Chen, 2009; Stern et al., 2009). The approach in this paper is an extension where in addition to interactions among users and items (comments in our case), we also consider the authorship information. Three-way interactions were recently studied for personalized tag recommendation (Rendle and Lars, 2010). Their model was based on the sum of two-way interactions, and was trained by using pairwise tag preferences for each (user, item) pair. However, no features were considered, which is an important consideration for us. We show using both text and authorship provides the best performance.

Our work is also related to news personalization that has received increasing attention in the last few

years. For instance, Billsus and Pazanni (2007) describes an approach to build user profile models for adaptive personalization in the context of mobile content access. Their approach is based on a hybrid model that combines content-based approaches with similarity methods used in recommender systems. This is further exemplified in the work by Ahn et al. (2007) where text processing techniques are used to build content profiles for users to recommend personalized news. In our experiments, we show that such approaches are inferior to our method. A content agnostic approach based on collaborative filtering techniques was proposed by Das et al. (2007); cold-start for new items/users was not their focus, but is important for our task — candidate comments for recommendation are often not in training data.

As discussed in Section 1, previous work in opinion mining and sentiment analysis has addressed the information consumption challenge via review summarization. Discussion of early work in that direction can be found in Pang and Lee (2008). In this line of work, opinions for each given aspect are usually summarized as the average sentiment polarity associated with that aspect. Related to that, people have looked into predicting review helpfulness given the textual information in reviews, where helpfulness is either defined as the percentage of users who have voted the review to be helpful (Kim et al., 2006), or labeled by annotators according to a set of criteria (Liu et al., 2007). Our goal differs in that we look for personalized ranking (what a specific user might like) rather than generic quality (what an average user might like). Subsequently, there has been work that tried to predict similarly defined helpfulness scores using meta-information over the reviewer. For instance, whether the author has used his/her true name or where the user is from (Danescu-Niculescu-Mizil et al., 2009), as well as graph structure in the social network between reviewers (Lu et al., 2010). In this work, we simply use author identity to provide more context to the short text; in future work, additional meta-information over users can easily be incorporated via our model.

As discussed in Section 1, whether a rater likes a comment or not may depend on whether they agree with the viewpoint expressed in the text and quality of the text. While previous work has not looked into the reader-comments relationship, there has been related work on identifying political orientations or viewpoints (Lin and Hauptmann, 2006; Lin et al., 2006; Mullen and Malouf, 2006, 2008; Laver et al., 2003); whether a piece of text expresses support or opposition in congressional debates (Thomas et al., 2006) or online debates (Somasundaran and Wiebe, 2009, 2010); as well as identifying contrastive relationship (Kawahara et al., 2010). Note that it is not trivial to use previous work along this line to directly serve as sub-components in our setting. For instance, for work on identifying political orientations or viewpoints, the training data consists of text with the desired labels. In our setting, our labels come in the form of whether users liked or disliked a previous comment. In the simplest case, we might have pair-wise constraints on whether two pieces of text have the same viewpoints (i.e., liked or disliked by the same rater), which would yield a different learning problem akin to the metric learning problem; note, however, the complication that two pieces of text receiving different labels from a given user might not necessarily contain contrasting viewpoints. Consequently, rather than trying to reduce this problem to a set of known text classification tasks, we address this task via a collaborative filtering framework that incorporates textual features.

3 Method

In this section, we describe our model that predicts rater affinity to comments. A key strength of our model is the ability to incorporate rater-comment and rater-author interactions simultaneously in a principled fashion. Our model also provides a seamless mechanism to transition from cold-start (where recommendations need to be made for users or items with no or few past ratings) to warm-start scenarios — with a large amount of data, it fits a per-rater (author) model; with increase in data sparsity, the model applies a small sample size correction through features (in our case, textual features). The exact formula for such corrections in the presence of sparsity is based on parameter estimates that are obtained by applying an EM algorithm to the training data.

3.1 Model

Notation: Let y_{ij} denote the rating that user i, called the *rater*, gives to comment j. Since throughout, we use suffix i to denote a rater and suffix j to denote a comment, we slightly abuse notation and let $\boldsymbol{x}_i$ (of dimension p_u) and $\boldsymbol{x}_j$ (of dimension p_c) denote feature vectors of user i and comment j respectively. For example, $\boldsymbol{x}_i$ can be the bag of words representation (a sparse vector) inferred through text analysis on comments voted positively by user i in the past, and $\boldsymbol{x}_j$ can be the bag of words representation for comment j. We use $a(j)$ to denote the author of comment j, and use μ_{ij} to denote the mean rating by rater i on comment j, i.e., $\mu_{ij} = E(y_{ij})$. Of course it is impossible to estimate μ_{ij} empirically since each user i usually rates a comment j at most once.

Model specification: We work in a generalized linear model framework (McCullagh and Nelder, 1989) that assumes μ_{ij} (or some monotone function h of μ_{ij}) is an additive function of (1) the rater bias α_i of user i since some users may have a tendency of rating comments more positively or negatively than others, (2) popularity β_j of comment j, which could reflect the quality of the comment in this setting, and (3) the author reputation $\gamma_{a(j)}$ of user $a(j)$ since comments by a reputed author may in general get more positive ratings. Thus, the overall bias is $\alpha_i + \beta_j + \gamma_{a(j)}$.

In addition to the bias, we include terms that capture interactions among entities (raters, authors, comments). Indeed, capturing such interactions is a non-trivial part of our modeling procedure. In our approach, we take recourse to *factor* models that have been widely used in collaborative filtering applications in recent times. The basic idea is to attach latent factors to each rater, author and comment. These latent factors are finite dimensional Euclidean vectors that are unknown and estimated from the data. They provide a succinct representation of various *aspects* that are important to explain interaction among entities. In our case, we use the following factors — (a) user factor $\boldsymbol{v}_i$ of dimension $r_v(\geq 1)$ to model rater-author affinity, (b) user factor $\boldsymbol{u}_i$ and comment factor $\boldsymbol{c}_j$ of dimension $r_u(\geq 1)$ to model rater-comment affinity. Intuitively, each could represent viewpoints of users or comments along different dimensions.

i	index for raters
j	index for comments
$a(j)$	author of comment j
y_{ij}	rating given by rater i to comment j
μ_{ij}	mean rating given by rater i to comment j
$\boldsymbol{x}_j$	feature vector of comment j (e.g., textual features in comment j)
$\boldsymbol{x}_i$	feature vector of user i (e.g., comments voted positively by user i)
bias terms:	
α_i	rater bias of user i
β_j	popularity of comment j (e.g., quality of the comment)
$\gamma_{a(j)}$	reputation of the author of comment j
interaction terms:	
$\boldsymbol{v}_i$	user factor for rater-author affinity
$\boldsymbol{u}_i$, $\boldsymbol{c}_j$	factors for rater-comment affinity

Table 1: Table of Notations.

Affinity of rater i to comment j by author $a(j)$ is captured by (1) similarity between viewpoints of users i and $a(j)$, measured by $\boldsymbol{v}_i'\boldsymbol{v}_{a(j)}$; and (2) similarity between the preferences of user i and the perspectives reflected in comment j, measured by $\boldsymbol{u}_i'\boldsymbol{c}_j$. The overall interaction is $\boldsymbol{v}_i'\boldsymbol{v}_{a(j)} + \boldsymbol{u}_i'\boldsymbol{c}_j$. Then, the mean rating μ_{ij}, or more precisely $h(\mu_{ij})$, is modeled as the sum of bias and interaction terms. Mathematically, we assume:

$$\begin{aligned} y_{ij} &\sim N(\mu_{ij},\ \sigma_y^2) \text{ or Bernoulli}(\mu_{ij}) \\ h(\mu_{ij}) &= \alpha_i + \beta_j + \gamma_{a(j)} + \boldsymbol{v}_i'\boldsymbol{v}_{a(j)} + \boldsymbol{u}_i'\boldsymbol{c}_j \end{aligned} \quad (1)$$

For numeric ratings, we use the Gaussian distribution denoted by N(mean,var); for binary ratings, we use the Bernoulli distribution. For Gaussian, $h(\mu_{ij}) = \mu_{ij}$, and for Bernoulli, we assume $h(\mu_{ij}) = \log \frac{\mu_{ij}}{1-\mu_{ij}}$, which is the commonly used logistic transformation.

Table 1 summarizes the notations for easy references. We denote the full model specified above as **vv+uc** since both user-user interaction $\boldsymbol{v}_i'\boldsymbol{v}_{a(j)}$ and user-comment interaction $\boldsymbol{u}_i'\boldsymbol{c}_j$ are modeled at the same time.

Latent factors: A natural approach to estimate latent factors in Equation 1 is through a maximum likelihood estimation (MLE) approach. This does

not work in our scenario since a large fraction of entities have small sample size. For instance, if a comment is rated only by one user and $r_u > 1$, the model is clearly overparametrized and the MLE of the comment factor would tend to learn idiosyncrasies in the training data. Hence, it is imperative to impose constraints on the factors to obtain estimates that generalize well on unseen data. We work in a Bayesian framework where such constraints are imposed through prior distributions. The crucial issue is the selection of appropriate priors. In our scenario, we need priors that provide a good *backoff* estimate when interacting entities have small sample sizes. For instance, to estimate latent factors of a user with little data, we provide a backoff estimate that is obtained by *pooling* data across users with the same user features. We perform such a pooling through regression, the mathematical specification is given below.

$$\begin{aligned} \alpha_i &\sim N(g'\boldsymbol{x}_i,\ \sigma_\alpha^2), & \boldsymbol{u}_i &\sim N(G\boldsymbol{x}_i,\ \sigma_u^2), \\ \beta_j &\sim N(d'\boldsymbol{x}_j,\ \sigma_\beta^2), & \boldsymbol{c}_j &\sim N(D\boldsymbol{x}_j,\ \sigma_c^2), \\ \gamma_{a(j)} &\sim N(0,\ \sigma_\gamma^2), & \boldsymbol{v}_i &\sim N(\mathbf{0},\ \sigma_v^2), \end{aligned}$$

where $g^{p_u \times 1}$ and $d^{p_c \times 1}$ are regression weight vectors, and $G^{r_u \times p_u}$ and $D^{r_u \times p_c}$ are regression weight matrices. These regression weights are learnt from data and provide the backoff estimate. Take the prior distribution of $\boldsymbol{u}_i$ for example. We can rewrite the prior as $\boldsymbol{u}_i = G\boldsymbol{x}_i + \boldsymbol{\delta}_i$, where $\boldsymbol{\delta}_i \sim N(\mathbf{0},\ \sigma_u^2)$. If user i has no rating in the training data, $\boldsymbol{u}_i$ will be predicted as the prior mean (backoff) $G\boldsymbol{x}_i$, a linear projection from the feature vector $\boldsymbol{x}_i$ through matrix G learnt from data. This projection can be thought of as a multivariate linear regression problem with weight matrix G, one weight vector per dimension of $\boldsymbol{u}_i$. However, if user i has many ratings in the training data, we will precisely estimate the per-user *residual* $\boldsymbol{\delta}_i$ that is not captured by the regression $G\boldsymbol{x}_i$. For sample sizes in between these two extremes, the per user residual estimate is "shrunk" toward zero — amount of shrinkage depends on the sample size, past user ratings, variability in ratings on comments rated by the user, and the value of variance components $\sigma_\cdot^2$s.

3.2 Special Cases of Our Model

Our full model (**vv+uc**) includes several existing models explored in collaborative filtering and social networks as special cases.

The matrix factorization model: This model assumes the mean rating of user i on item j is given by $h(\mu_{ij}) = \alpha_i + \beta_j + \boldsymbol{u}_i'\boldsymbol{c}_j$, and the mean of the prior distributions on $\alpha_i, \beta_j, \boldsymbol{u}_i, \boldsymbol{c}_j$ are zero, i.e., $g = d = G = D = \mathbf{0}$. Recent work clearly illustrates that this method obtains better predictive accuracy than classical collaborative filtering techniques based on item-item similarity (Bell et al. (2007)).

The **uc** *model:* This is also a matrix factorization model but with priors based on regressions (i.e., non-zero g, d, G, D). It provides a mechanism to deal with both cold and warm-start scenarios in recommender applications (Agarwal and Chen (2009)).

The **vv** *model:* This model assumes $h(\mu_{ij}) = \alpha_i + \gamma_{a(j)} + \boldsymbol{v}_i'\boldsymbol{v}_{a(j)}$. It was first proposed by Hoff (2005) to model interactions in social networks. The model was fitted to small datasets (at most a few hundred nodes) and the goal was to test certain hypotheses on social behavior, out-of-sample prediction was not considered.

The low-rank **bilinear** *regression model:* Here, $h(\mu_{ij}) = g'\boldsymbol{x}_i + d'\boldsymbol{x}_j + \boldsymbol{x}_i'G'D\boldsymbol{x}_j$. This is a regression model purely based on features with no per-user or per-comment latent factors. In a more general form, $\boldsymbol{x}_i'G'D\boldsymbol{x}_j$ can be written as $\boldsymbol{x}_i'A\boldsymbol{x}_j$, where $A^{p_u \times p_c}$ is the matrix of regression weights (Chu and Park, 2009). However, since $\boldsymbol{x}_i$ and $\boldsymbol{x}_j$ are typically high dimensional, A can be a large matrix that needs to be learnt from data. To reduce dimensionality, one can decompose A as $A = G'D$, where the number of rows in D and G are small. Thus, instead of learning A, we learn a low-rank approximation of A. This ensures scalability and provides an attractive method to avoid over-fitting.

3.3 Model Fitting

Model fitting for our model is based on the expectation-maximization (EM) algorithm (Dempster et al., 1977). For ease of exposition and space constraints, we only provide a sketch of the algorithm for the Gaussian case, the logistic model can be fitted along the same lines by using a variational approximation (see Agarwal and Chen (2009)).

Let $\boldsymbol{Y} = \{y_{ij}\}$ denote the set of the observed ratings. In the EM parlance, this is "incomplete"

data that gets augmented with the latent factors $\boldsymbol{\Theta} = \{\boldsymbol{u}_i, \boldsymbol{v}_i, \boldsymbol{c}_j\}$ to obtain the "complete" data. The goal of the EM algorithm is to find the parameter $\boldsymbol{\eta} = (g, d, G, D, \sigma_\alpha^2, \sigma_\beta^2, \sigma_u^2, \sigma_v^2, \sigma_y^2)$ that maximizes the "incomplete" data likelihood $\Pr(\boldsymbol{Y}|\boldsymbol{\eta}) = \int \Pr(\boldsymbol{Y}, \boldsymbol{\Theta}|\boldsymbol{\eta}) d\boldsymbol{\Theta}$ that is obtained after marginalization (taking expectation) over the distribution of $\boldsymbol{\Theta}$. Since such marginalization is not available in closed form for our model, we use the EM algorithm.

EM algorithm: The complete data log-likelihood $l(\boldsymbol{\eta}; \boldsymbol{Y}, \boldsymbol{\Theta})$ for the full model in the Gaussian case (where $h(\mu_{ij}) = \mu_{ij}$) is given by $l(\boldsymbol{\eta}; \boldsymbol{Y}, \boldsymbol{\Theta}) =$

$$
\begin{aligned}
&-\tfrac{1}{2}\textstyle\sum_{ij}\left((y_{ij}-\mu_{ij})^2/\sigma_y^2 + \log\sigma_y^2\right)\\
&-\tfrac{1}{2}\textstyle\sum_{i}\left((\alpha_i - g'\boldsymbol{x}_i)^2/\sigma_\alpha^2 + \log\sigma_\alpha^2\right)\\
&-\tfrac{1}{2}\textstyle\sum_{j}\left((\beta_j - d'\boldsymbol{x}_j)^2/\sigma_\beta^2 + \log\sigma_\beta^2\right)\\
&-\tfrac{1}{2}\textstyle\sum_{i}\left(\|\boldsymbol{u}_i - G\boldsymbol{x}_i\|^2/\sigma_u^2 + r_u\log\sigma_u^2\right)\\
&-\tfrac{1}{2}\textstyle\sum_{j}\left(\|\boldsymbol{c}_j - D\boldsymbol{x}_j\|^2/\sigma_c^2 + r_u\log\sigma_c^2\right),\\
&-\tfrac{1}{2}\textstyle\sum_{i}\left(\boldsymbol{v}_i'\boldsymbol{v}_i/\sigma_v^2 + r_v\log\sigma_v^2 + \gamma_i^2/\sigma_\gamma^2 + \log\sigma_\gamma^2\right),
\end{aligned}
$$

where r_u is the dimension of factors $\boldsymbol{u}_i$ and $\boldsymbol{c}_j$, and r_v is the dimension of $\boldsymbol{v}_i$. Let $\boldsymbol{\eta}^{(t)}$ denote the estimated parameter setting at the t^{th} iteration. The EM algorithm iterates through the following two steps until convergence.

- **E-step:** Compute $f_t(\boldsymbol{\eta}) = E_{\boldsymbol{\Theta}}[l(\boldsymbol{\eta}; \boldsymbol{Y}, \boldsymbol{\Theta}) \,|\, \boldsymbol{\eta}^{(t)}]$ as a function of $\boldsymbol{\eta}$, where the expectation is taken over the posterior distribution of $(\boldsymbol{\Theta} \,|\, \boldsymbol{\eta}^{(t)}, \boldsymbol{Y})$. Note that here $\boldsymbol{\eta}$ is the input variable of function f_t, but $\boldsymbol{\eta}^{(t)}$ consists of known quantities (determined in the previous iteration).
- **M-step:** Find the $\boldsymbol{\eta}$ that maximizes the expectation computed in the E-step.

$$\boldsymbol{\eta}^{(t+1)} = \arg\max_{\boldsymbol{\eta}} f_t(\boldsymbol{\eta})$$

Since the expectation in the E-step is not available in a closed form, we use a Gibbs sampler to compute the Monte Carlo expectation (Booth and Hobert, 1999). The Gibbs sampler repeats the following procedure L times. It samples α_i, γ_i, β_j, $\boldsymbol{u}_i$, $\boldsymbol{v}_j$, and $\boldsymbol{c}_j$ sequentially one at a time by sampling from the corresponding full conditional distributions. The full conditional distributions are all Gaussian, hence they are easy to sample. Once a Monte Carlo expectation is calculated from the samples, an updated estimate of $\boldsymbol{\eta}$ is obtained in the M-step. The optimization of variance components $\sigma_\cdot^2$s in the M-step is available in closed form, the regression parameters are estimated through off-the-shelf linear regression routines. We note that the posterior distribution of latent factors for known $\boldsymbol{\eta}$ is multi-modal, we have found the Monte Carlo based EM method to outperform other optimization methods like gradient descent in terms of predictive accuracy.

4 Experiments

4.1 Data

We obtained comment rating data between March and May, 2010 from Yahoo! News, with all user IDs anonymized. On this site, users can post comments on news article pages and rate the comments made by others through thumb-up (positive) or thumb-down (negative) votes. Clearly, for articles with very few comments, there is no need to recommend comments. Also, we do not expect deep personalized recommendations for users who have rated very few comments in the past. To focus on instances of interest to us, we restricted ourselves to a subset of the rating data associated with relatively heavy raters. In particular, we formed the experimental dataset by randomly selecting 9,003 raters who provided at least 200 ratings (of which at least 10 were positive and 10 were negative), 189,291 authors who received at least 20 ratings, and 5,088 news articles that received at least 40 comments in the raw dataset during the three-month period. Note that the per entity sample size in the experimental dataset can be smaller than the thresholds specified above. For instance, a rater with more than 200 ratings in the raw dataset can have fewer than 200 in the experimental dataset due to the removal of certain authors or news articles. (See Figure 2 for a distribution of users with different activity levels.) In total, we have 4,440,222 ratings on 1,197,098 comments.

The 5,088 news articles were split into training articles (the earliest 50%), tuning articles (next 5%), and test articles (the last 45%) based on their publication time. The ratings and comments were split into training, tuning, and test sets according to the article they were associated with. All tuning parameters are determined using the tuning set, and performances are reported over the test set. Note that

this training-test split ensures that performance on the test data best simulates our application scenarios. It also creates a completely cold-start situation for comments — no comment in the test set has any past rating in the training set.

4.2 Experimental Setup

Features: All comments were tokenized, lowercased, with stopwords and punctuations removed. We limited the vocabulary to the 10K most frequent tokens in all comments associated with the training articles. (See Section 4.3.3 for a discussion on the effect of the vocabulary size.) For a given comment j, $\boldsymbol{x}_j$ is its bag of words representation, L_2 normalized. For term weighting, we experimented with both presence value and tf-idf weighting. The latter gives slight better performance. Rater feature vector $\boldsymbol{x}_i$ is created by summing over the feature vectors of all comments rated positively by rater i, which is then L_2 normalized.

Methods: We compare the following methods based on our model: The full model **vv+uc**, as well as the three main special cases, **vv**, **uc**, and **bilinear**, as defined in Section 3. The dimensions of $\boldsymbol{v}_i$, $\boldsymbol{u}_i$ and $\boldsymbol{c}_j$ (i.e., r_v and r_u), and the rank of **bilinear** are selected to obtain the best AUC on the tuning set. In our experiments, $r_v = 2, r_u = 3$ and rank of **bilinear** is 3. In addition, we also evaluate the following baseline methods that predict per-user preferences in isolation, primarily based on textual information.

- **Cosine similarity (cos):** $\boldsymbol{x}_i'\boldsymbol{x}_j$. This is simply based on how similar a new comment j is to the comments rater i has liked in the past.
- **Per-user SVM (svm):** For each rater, train a support vector machine (SVM) classifier using only comments ($\boldsymbol{x}_j$) rated by that user.
- **Per-user Naive Bayes (nb):** For each rater, train a Naive Bayes classifier using only comments ($\boldsymbol{x}_j$) rated by that user.[1]

Note that SVMs typically yield the best performance on text classification tasks; a Naive Bayes classifier can be more robust over shorter text spans common in user comments given the high variance. For fair comparisons, for the three baseline methods, we use a simple way of utilizing author information: the feature space is augmented with author IDs and each $\boldsymbol{x}_j$ is augmented with $a(j)$[2]. In Section 4.3, we only report results using the augmented feature vectors since they yield better performance (though the difference is fairly small).

Performance metrics: We use two types of metrics to measure the performance of a method: (1) A global metric based on Receiver Operating Characteristic (ROC) and (2) Precision at rank k (P@k). The former measures the overall correlation of predicted scores for a method with the observed ratings in the test set, while the latter measures the performance of a hypothetical top-k recommendation scenario using the method. To summarize an ROC curve into a single number, we use the Area Under the ROC Curve (AUC). Since random guess yields AUC score of 0.5, regardless of the class distribution, using this measure makes it convenient for us to compare the performance over different subsets of the data (where class distributions could be different). The P@k of a method is computed as follows: (1) For each rater, rank comments that the rater rated in the test set according to the scores predicted by the method, and compute the precision at rank k for that rater; and then (2) average the per-rater precision numbers over all raters. To report P@k, for $k = 5, 10, 20$, we only use raters who have at least 50 ratings in the test set. Statistical significance based on a two-sample t-test across raters is also reported.

4.3 Results

4.3.1 Main comparisons

We first show the ROC curves of different methods on the test set in Figure 1, and the AUCs and precisions in Table 2. Results from significance tests are in Table 3.

First, note that while **svm** significantly outperforms random guesses and **nb**, it is worse than **bilinear**, which is also using (mostly) textual information, but learns the model for all users together,

[1] As we mentioned in Section 4.1, not all users have training data of both classes in the experimental dataset. For **svm** and **nb**, we use the following backoff: for users with training data from only c_i, we predict c_i; for users with no training data at all, we predict the majority class, in this case, the positive class.

[2] We assign weight 1 to $a(j)$, so that the author information have the same impact as the textual features.

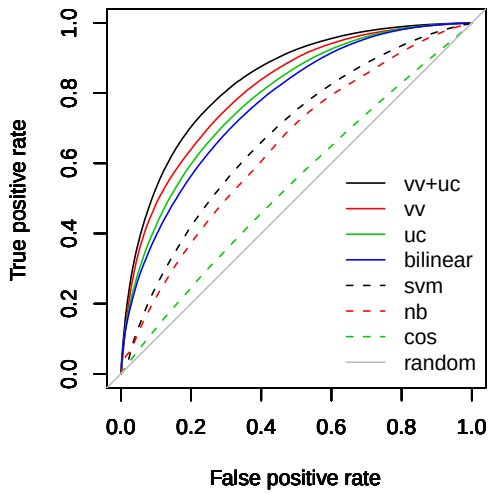

Figure 1: ROC curves of different models

Method	AUC	P@5	P@10	P@20
vv+uc	0.8360	0.9152	0.9079	0.8942
vv	0.8090	0.8810	0.8807	0.8727
uc	0.7857	0.9046	0.8921	0.8694
bilinear	0.7701	0.9028	0.8894	0.8668

rather than in isolation. Next, **uc** outperforms **bilinear** (significantly in AUC, P@10 and P@20), showing per-user and per-comment latent factors help. Note that **vv** outperforms **uc** in ROC, AUC and P@20, but is worse than **uc** in P@5 and P@10; we will take a closer look at this later. Finally, the full model **vv+uc** significantly outperforms both **vv** and **uc**, achieving 0.83 in AUC, and close to 90% in precision at rank 20.

4.3.2 Break-down by user activity level

Next, we investigate model performance in different subsets of the test set. For succinctness, we use AUC as our performance metric. In Figure 2(a), we breakdown model performance by different author activity levels. In Figure 2(b), we breakdown model performance by different voter activity levels. We also generated similar plots with the y-axis replaced by P@5, P@10 and P@20, and observed the same trend except that **vv** starts to outperform **uc** at different user activity thresholds for different metrics.

Comparison	Metrics	p-value
vv+uc $>$ **vv**	All	$< 10^{-7}$
vv+uc $>$ **uc**	All	$< 10^{-20}$
uc $>$ **bilinear**	All except P@5	< 0.006
bilinear $>$ **svm**	All	$< 10^{-20}$
vv $>$ **svm**	All	$< 10^{-20}$
svm $>$ **nb**	All	$< 10^{-8}$
nb $>$ **cos**	All	$< 10^{-20}$

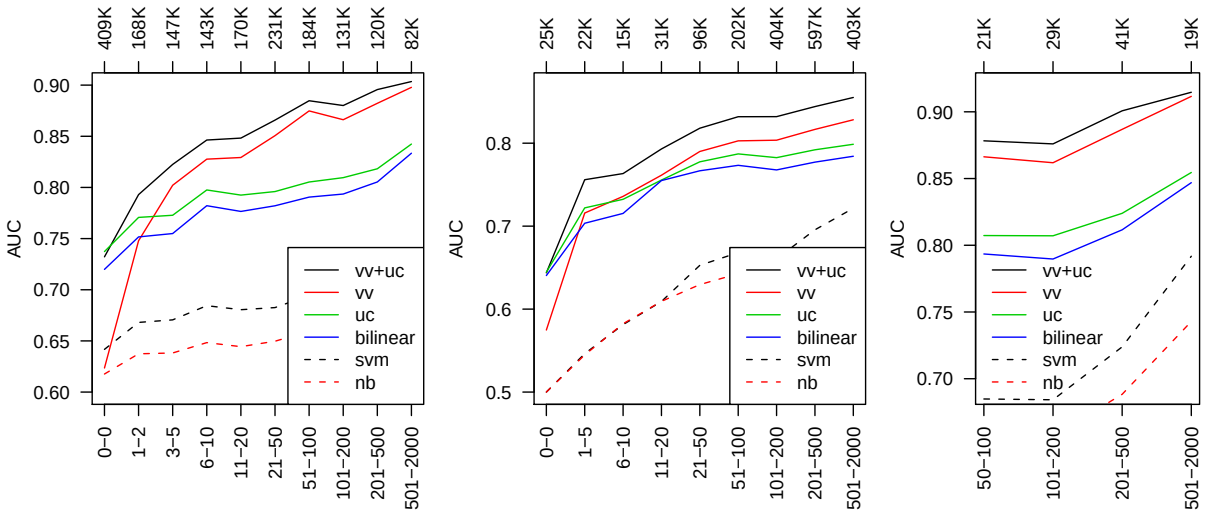
Table 3: Paired t-test results. Note that **uc** is better than **bilinear** in P@5, but not significant. The orders of **uc** and **vv** are not consistent across different metrics.

Not surprisingly, **vv** performs poorly for raters or authors with no ratings observed in the training data. However, once we have a small amount of ratings, it starts to outperform **uc**, even though intuitively, the textual information in the comment should be more informative than the authorship information alone. Using paired t-tests with significance level 0.05, we report when **vv** starts to significantly outperform **uc** in the following table, which is interpreted as follows — **vv** is not significantly worse than **uc** in metric M if the author of a test comment received at least N_{eq} ratings in the training set, and **vv** significantly outperforms **uc** in metric M if the author received at least N_{gt} ratings in the training set.

Metric M	P@5	P@10	P@20	AUC
# Ratings N_{eq}	50	5	5	5
N_{gt}	1000	50	5	5

Recall that our training/test split is by article. Since we have never observed a rater's preference over the test articles before, it is rather surprising that author information alone can yield 0.8 in AUC score, even for very light authors who have received between 3 and 5 votes in total in the training data. This suggests that users' viewpoints are quite consistent: a large portion of the ratings can be adequately explained by the pair of user identities. One interesting observation is that the number of ratings required for **vv** to outperform **uc** in P@5 is quite high. This suggests that to obtain high precision at the top of a recommended list, comment features are important.

Nonetheless, modeling textual information in addition to author information provides additional improvements. Based on paired t-tests with signifi-



(a) AUC by author activity levels (b) AUC by rater activity levels (c) AUC by user activity levels

Figure 2: AUC of different models as a function of the activity level of authors or raters. The x-axis (bottom) has the form m-n, meaning the subset of the test data in which the number of ratings that each author received (as in (a)) or each rater gave (as in (b)) in the training set is between m and n. In (c), we select both authors and raters based on the m-n criterion. The x-axis (top) denotes the number of ratings in the subset

cance level 0.05, **vv+uc** significantly outperforms **vv** in all metrics if the author received < 500 ratings in the training set. Except for the very heavy authors, even for cases where both raters and authors are heavy users (Figure 2(c)), adding the comment feature information still yields additional improvement over the already impressive performance of using **vv** alone. In spite of the simple representation we adopted for the textual information, the full model is still capable of accounting for part of the residual errors from **vv** model (that uses authorship information alone) by using comment features — what was actually written does matter.

Finally, if we breakdown the comparison between **vv+uc** and **uc** for different user activity levels, **vv+uc** significantly outperforms **uc** (with level 0.05) in all metrics if the author received at least 5 ratings in the training set.

4.3.3 Analysis of textual features

Recall that we limited the vocabulary size to the 10K most frequent terms for efficiency reasons. Is this limitation likely to affect our model performance significantly? We examined the effect of different numbers of features. In the following table, #features = n means that both $\boldsymbol{x}_i$ and $\boldsymbol{x}_j$ are bags of n words[3]. Since the **vv** model does not utilize rater or comment features, we examine AUC of the **uc** model.

#features	1K	3K	5K	10K
AUC	0.7713	0.7855	0.7872	0.7876

As can be seen, the performance improvement is in the 4th decimal place when we increase from 5K features to 10K features. Thus, we do not further increase the number of features in our experiments.

Note that our full model does not require rater features and comment features to be in the same feature space. Each is projected into the hidden "viewpoint" space, via G and D, separately. For simplicity and easy comparison to other methods, we used all comments liked by a rater in the past to build the feature vector of the rater. But since the full model already has information of the textual content of comments from the comment features, and which comments were liked by the users from the ratings, rater features constructed this way do not provide any new information. Indeed, if we model $\boldsymbol{u}_i \sim N(1, \sigma_u^2)$, instead of $\boldsymbol{u}_i \sim N(G\boldsymbol{x}_i, \sigma_u^2)$, this omission of x_i does not hurt the performance of the model. In future work, other meta-information about the rater

[3]Note that we used n most useful features in each case.

can easily be incorporated into $\boldsymbol{x}_i$ to enrich rater representation.

Recall that comment features $\boldsymbol{x}_j$ were projected to comment factors $\boldsymbol{c}_j$ via D. We envisioned that the comment factors could be representing viewpoints. Does our model conform to this intuition? Let's consider the simplest case, where we restrict $\boldsymbol{u}_i$ and $\boldsymbol{c}_j$ to be one-dimensional vectors. In this case, each can be represented by scalars u_i and c_j. If u_i and c_j are of the same sign, then the rater is likely to like the comment. Words assigned high positive weights or low negative weights via D will have significant contributions to the overall sign of c_j. Now if we examine such words, will we see any meaningful differences in the underlying viewpoints of these two groups of words?

To address this question qualitatively, we manually sampled words with heavy weights, focusing on politics-related ones (so that viewpoints are likely to be polarized and easier to interpret). At one extreme, we observe words like *repukes, repugs*, which seemed to be derogatory mentions of Republications, and likely to represent an anti-Republication point of view. At the other end, we observe terms like *libtards, nobama, obummer*. While terms like *nobama* may appear to be typos at first sight, a quick search online reveals that these are at least intentional typos expressing anti-Obama sentiments, which clearly represents an opposite underlying perspective from terms like *repukes*.

These examples also illustrate the importance to learn directly from the data of interest to us. Such indicative words would never have appeared in more formal writings. While we do not have direct labels for perspectives, our model seems to be capturing the underlying perspectives (as much as a unigram-based model could) by learning from user preference labels across different users. This allows us to learn the text features most relevant to our dataset, which is particularly important given the time-sensitive and ever-evolving nature of news-related comments.

5 Conclusions

In this paper, we promote personalized recommendation as a novel way of helping users to consume large quantities of subjective information. We propose using a principled way of incorporating both rater-comment and rater-author interactions simultaneously. Our full model significantly outperforms strong baseline methods, as well as previous methods proposed for text recommendation. In particular, learning weights over textual features across all users outperforms learning for each user individually, which holds true even for heavy raters. Furthermore, while using authorship information alone provides stronger signal than using textual information alone, to our surprise, even for heavy users, adding textual information yields additional improvements.

It is difficult to comprehensively capture user affinity to comments using a finite number of ratings observed during a certain time interval. News and comments on news articles are dynamic in nature, novel aspects may emerge over time. To capture such dynamic behavior, comment factors have to be allowed to evolve over time and such an evolution would also necessitate the re-estimation of user factors. Incorporating such temporal dynamics into our modeling framework is a challenging research problem and requires significant elaboration of our current approach.

Abstract

We present a data-driven approach to generating responses to Twitter status posts, based on phrase-based Statistical Machine Translation. We find that mapping conversational stimuli onto responses is more difficult than translating between languages, due to the wider range of possible responses, the larger fraction of unaligned words/phrases, and the presence of large phrase pairs whose alignment cannot be further decomposed. After addressing these challenges, we compare approaches based on SMT and Information Retrieval in a human evaluation. We show that SMT outperforms IR on this task, and its output is preferred over actual human responses in 15% of cases. As far as we are aware, this is the first work to investigate the use of phrase-based SMT to directly translate a linguistic stimulus into an appropriate response.

1 Introduction

Recently there has been an explosion in the number of people having informal, public conversations on social media websites such as Facebook and Twitter. This presents a unique opportunity to build collections of naturally occurring conversations that are orders of magnitude larger than those previously available. These corpora, in turn, present new opportunities to apply data-driven techniques to conversational tasks.

We investigate the problem of **response generation**: given a conversational stimulus, generate an appropriate response. Specifically, we employ a large corpus of status-response pairs found on Twitter to create a system that responds to Twitter status posts. Note that we make no mention of context, intent or dialogue state; our goal is to generate any response that fits the provided stimulus; however, we do so without employing rules or templates, with the hope of creating a system that is both flexible and extensible when operating in an open domain.

Success in open domain response generation could be immediately useful to social media platforms, providing a list of suggested responses to a target status, or providing conversation-aware autocomplete for responses in progress. These features are especially important on hand-held devices (Hasselgren et al., 2003). Response generation should also be beneficial in building "chatterbots" (Weizenbaum, 1966) for entertainment purposes or companionship (Wilks, 2006). However, we are most excited by the future potential of data-driven response generation when used inside larger dialogue systems, where direct consideration of the user's utterance could be combined with dialogue state (Wong and Mooney, 2007; Langner et al., 2010) to generate locally coherent, purposeful dialogue.

In this work, we investigate statistical machine translation as an approach for response generation. We are motivated by the following observation: In naturally occurring discourse, there is often a strong structural relationship between adjacent utterances (Hobbs, 1985). For example, consider the stimulus-response pair from the data:

> **Stimulus**: I'm slowly making this soup ..... and it smells gorgeous!

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 583–593,
Edinburgh, Scotland, UK, July 27–31, 2011.

Response: I'll bet it looks delicious too! Haha

Here "it" in the response refers to "this soup" in the status by co-reference; however, there is also a more subtle relationship between the "smells" and "looks", as well as "gorgeous" and "delicious". Parallelisms such as these are frequent in naturally occurring conversations, leading us to ask whether it might be possible to *translate* a stimulus into an appropriate response. We apply SMT to this problem, treating Twitter as our parallel corpus, with status posts as our source language and their responses as our target language. However, the established SMT pipeline cannot simply be applied out of the box.

We identify two key challenges in adapting SMT to the response generation task. First, unlike bilingual text, stimulus-response pairs are not semantically equivalent, leading to a wider range of possible responses for a given stimulus phrase. Furthermore, both sides of our parallel text are written in the same language. Thus, the most strongly associated word or phrase pairs found by off-the-shelf word alignment and phrase extraction tools are identical pairs. We address this issue with constraints and features to limit lexical overlap. Secondly, in stimulus-response pairs, there are far more unaligned words than in bilingual pairs; it is often the case that large portions of the stimulus are not referenced in the response and vice versa. Also, there are more large phrase-pairs that cannot be easily decomposed (for example see figure 2). These difficult cases confuse the IBM word alignment models. Instead of relying on these alignments to extract phrase-pairs, we consider all possible phrase-pairs in our parallel text, and apply an association-based filter.

We compare our approach to response generation against two Information Retrieval or nearest neighbour approaches, which use the input stimulus to select a response directly from the training data. We analyze the advantages and disadvantages of each approach, and perform an evaluation using human annotators from Amazon's Mechanical Turk. Along the way, we investigate the utility of SMT's BLEU evaluation metric when applied to this domain. We show that SMT-based solutions outperform IR-based solutions, and are chosen over actual human responses in our data in 15% of cases. As far as we are aware, this is the first work to investigate the feasibility of SMT's application to generating responses to open-domain linguistic stimuli.

2 Related Work

There has been a long history of "chatterbots" (Weizenbaum, 1966; Isbell et al., 2000; Shaikh et al., 2010), which attempt to engage users, typically leading the topic of conversation. They usually limit interactions to a specific scenario (e.g. a Rogerian psychotherapist), and use a set of template rules for generating responses. In contrast, we focus on the simpler task of generating an appropriate response to a single utterance. We leverage large amounts of conversational training data to scale to our Social Media domain, where conversations can be on just about any topic.

Additionally, there has been work on generating more natural utterances in goal-directed dialogue systems (Ratnaparkhi, 2000; Rambow et al., 2001). Currently, most dialogue systems rely on either canned responses or templates for generation, which can result in utterances which sound very unnatural in context (Chambers and Allen, 2004). Recent work has investigated the use of SMT in translating internal dialogue state into natural language (Langner et al., 2010). In addition to dialogue state, we believe it may be beneficial to consider the user's utterance when generating responses in order to generate locally coherent discourse (Barzilay and Lapata, 2005). Data-driven generation based on users' utterances might also be a useful way to fill in knowledge gaps in the system (Galley et al., 2001; Knight and Hatzivassiloglou, 1995).

Statistical machine translation has been applied to a smörgåsbord of NLP problems, including question answering (Echihabi and Marcu, 2003), semantic parsing and generation (Wong and Mooney, 2006; Wong and Mooney, 2007), summarization (Daumé III and Marcu, 2009), generating bid-phrases in online advertising (Ravi et al., 2010), spelling correction (Sun et al., 2010), paraphrase (Dolan et al., 2004; Quirk et al., 2004) and query expansion (Riezler et al., 2007). Most relevant to our efforts is the work by Soricut and Marcu (2006), who applied the IBM word alignment models to a discourse ordering task, exploiting the same intuition investigated

in this paper: certain words (or phrases) tend to trigger the usage of other words in subsequent discourse units. As far as we are aware, ours is the first work to explore the use of phrase-based translation in generating responses to open-domain linguistic stimuli, although the analogy between translation and dialogue has been drawn (Leuski and Traum, 2010).

3 Data

For learning response-generation models, we use a corpus of roughly 1.3 million conversations scraped from Twitter (Ritter et al., 2010; Danescu-Niculescu-Mizil et al., 2011). Twitter conversations don't occur in real-time as in IRC; rather as in email, users typically take turns responding to each other. Twitter's 140 character limit, however, keeps conversations chat-like. In addition, the Twitter API maintains a reference from each reply to the post it responds to, so unlike IRC, there is no need for conversation disentanglement (Elsner and Charniak, 2008; Wang and Oard, 2009). The first message of a conversation is typically unique, not directed at any particular user but instead broadcast to the author's followers (a status message). For the purposes of this paper, we limit the data set to only the first two utterances from each conversation. As a result of this constraint, any system trained with this data will be specialized for responding to Twitter status posts.

4 Response Generation as Translation

When applied to conversations, SMT models the probability of a response r given the input status-post s using a log-linear combination of feature functions. Most prominent among these features are the conditional phrase-translation probabilities in both directions, $P(s|r)$ and $P(r|s)$, which ensure r is an appropriate response to s, and the *language model* $P(r)$, which ensures r is a well-formed response. As in translation, the response models are estimated from counts of phrase pairs observed in the training bitext, and the language model is built using n-gram statistics from a large set of observed responses. To find the best response to a given input status-post, we employ the Moses phrase-based decoder (Koehn et al., 2007), which conducts a beam search for the best response given the input, according to the log-linear model.

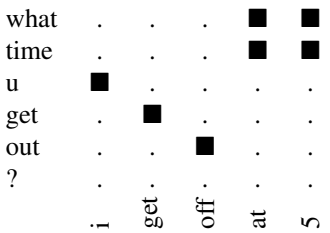

Figure 1: Example from the data where word alignment is easy. There is a clear correspondence between words in the status and the response.

4.1 Challenge: Lexical Repetition

When applied directly to conversation data, off-the-shelf MT systems simply learn to parrot back the input, sometimes with slight modification. For example, directly applying Moses with default settings to the conversation data produces a system which yields the following (typical) output on the above example:

> **Stimulus**: I'm slowly making this soup ..... and it smells gorgeous!
>
> **Response:** i'm slowly making this soup ..... and you smell gorgeous!

This "paraphrasing" phenomenon occurs because identical word pairs are frequently observed together in the training data. Because there is a wide range of acceptable responses to any status, these identical pairs have the strongest associations in the data, and therefore dominate the phrase table. In order to discourage lexically similar translations, we filter out all phrase-pairs where one phrase is a substring of the other, and introduce a novel feature to penalize lexical similarity:

$$\phi_{\text{lex}}(s,t) = J(s,t)$$

Where $J(s,t)$ is the Jaccard similarity between the set of words in s and t.

4.2 Challenge: Word Alignment

Alignment is more difficult in conversational data than bilingual data (Brown et al., 1990), or textual entailment data (Brockett, 2006; MacCartney et al., 2008). In conversational data, there are some cases in which there is a decomposable alignment between

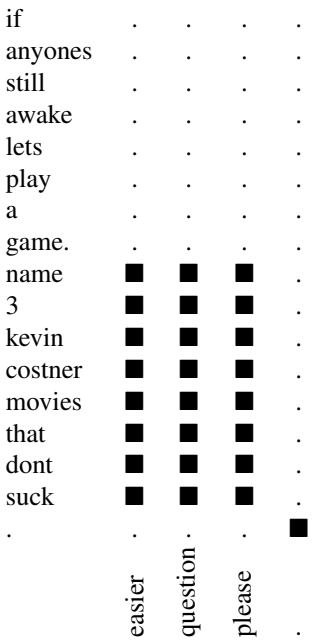

Figure 2: Example from the data where word alignment is difficult (requires alignment between large phrases in the status and response).

words, as seen in figure 1, and some difficult cases where alignment between large phrases is required, for example figure 2. These difficult sentence pairs confuse the IBM word alignment models which have no way to distinguish between the easy and hard cases.

We aligned words in our parallel data using the widely used tool GIZA++ (Och and Ney, 2003); however, the standard growing heuristic resulted in very noisy alignments. Precision could be improved considerably by using the intersection of GIZA++ trained in two directions ($s \rightarrow r$, and $r \rightarrow s$), but the alignment also became extremely sparse. The average number of alignments-per status/response pair in our data was only 1.7, as compared to a dataset of aligned French-English sentence pairs (the WMT 08 news commentary data) where the average number of intersection alignments is 14.

Direct Phrase Pair Extraction

Because word alignment in status/response pairs is a difficult problem, instead of relying on local alignments for extracting phrase pairs, we exploit information from all occurrences of the pair in determining whether its phrases form a valid mapping.

$C(s,t)$	$C(s,\neg t)$	$C(s)$
$C(\neg s,t)$	$C(\neg s,\neg t)$	$N-C(s)$
$C(t)$	$N-C(t)$	N

Figure 3: Contingency table for phrase pair (s,t). Fisher's Exact Test estimates the probability of seeing this event, or one more extreme assuming s and t are independent.

We consider all possible phrase-pairs in the training data,[1] then use Fisher's Exact Test to filter out pairs with low correlation (Johnson et al., 2007). Given a source and target phrase s and t, we consider the contingency table illustrated in figure 3, which includes co-occurrence counts for s and t, the number of sentence-pairs containing s, but not t and vice versa, in addition to the number of pairs containing neither s nor t. Fisher's Exact Test provides us with an estimate of the probability of observing this table, or one more extreme, assuming s and t are independent; in other words it gives us a measure of how strongly associated they are. In contrast to statistical tests such as χ^2, or the G^2 Log Likelihood Ratio, Fisher's Exact Test produces accurate p-values even when the expected counts are small (as is extremely common in our case).

In Fisher's Exact Test, the hypergeometric probability distribution is used to compute the exact probability of a particular joint frequency assuming a model of independence:

$$\frac{C(s)!C(\neg s)!C(t)!C(\neg t)!}{N!C(s,t)!C(\neg s,t)!C(s,\neg t)!C(\neg s,\neg t)!}$$

The statistic is computed by summing the probability for the joint frequency in Table 3, and every more extreme joint frequency consistent with the marginal frequencies. Moore (2004) illustrates several tricks which make this computation feasible in practice.

We found that this approach generates phrase-table entries which appear quite reasonable upon manual inspection. The top 20 phrase-pairs (after filtering out identical source/target phrases, substrings,

[1] We define a possible phrase-pair as any pair of phrases found in a sentence-pair from our training corpus, where both phrases consist of 4 tokens or fewer. The total number of phrase pairs in a sentence pair (s,r) is $O(|s| \times |r|)$.

Table 1: Top 20 Phrase Pairs ranked by the Fisher Exact Test statistic. Slight variations (substrings or symmetric pairs) were removed to show more variety. See the supplementary materials for the top 10k (unfiltered) pairs.

and symmetric pairs) are listed in Table 1.[2] Our experiments in §6 show that using the phrase table produced by Fisher's Exact Test outperforms one generated based on the poor quality IBM word alignments.

4.3 System Details

For the phrase-table used in the experiments (§6) we used the 5M phrases with highest association according the Fisher Exact Test statistic.[3] To build the language model, we used all of the 1.3M responses from the training data, along with roughly 1M replies collected using Twitter's streaming API.

We do not use any form of SMT reordering model, as the position of the phrase in the response does not seem to be very correlated with the corresponding position in the status. Instead we let the language model drive reordering.

We used the default feature weights provided by Moses.[4] Because automatic evaluation of response generation is an open problem, we avoided the use of discriminative training algorithms such as Minimum Error-Rate Training (Och, 2003).

5 Information Retrieval

One straightforward data-driven approach to response generation is nearest neighbour, or information retrieval. This general approach has been applied previously by several authors (Isbell et al., 2000; Swanson and Gordon, 2008; Jafarpour and Burges, 2010), and is used as a point of comparison in our experiments. Given a novel status s and a training corpus of status/response pairs, two retrieval strategies can be used to return a best response r':

IR-STATUS $[r_{\text{argmax}_i\, sim(s,s_i)}]$ Retrieve the response r_i whose associated status message s_i is most similar to the user's input s.

IR-RESPONSE $[r_{\text{argmax}_i\, sim(s,r_i)}]$ Retrieve the response r_i which has highest similarity when directly compared to s.

At first glance, IR-STATUS may appear to be the most promising option; intuitively, if an input status is very similar to a training status, we might expect the corresponding training response to pair well with the input. However, as we describe in §6, it turns out that directly retrieving the most similar response (IR-RESPONSE) tends to return acceptable replies more reliably, as judged by human annotators. To implement our two IR response generators, we rely on the default similarity measure implemented in the Lucene[5] Information Retrieval Library, which is an IDF-weighted Vector-Space similarity.

6 Experiments

In order to compare various approaches to automated response generation, we used human evalu-

[2] See the supplementary materials for the top 10k (unfiltered) phrase pairs.

[3] Note that this includes an arbitrary subset of the (1,1,1) pairs (phrase pairs where both phrases were only observed once in the data). Excluding these (1,1,1) pairs yields a rather small phrase table, 201K phrase-pairs after filtering, while including all of them led to a table which was too large for the memory of the machine used to conduct the experiments.

[4] The language model weight was set to 0.5, the translation model weights in both directions were both set to 0.2, the lexical similarity weight was set to -0.2.

[5] `http://lucene.apache.org/`

ators from Amazon's Mechanical Turk (Snow et al., 2008). Human evaluation also provides us with data for a preliminary investigation into the feasibility of automatic evaluation metrics. While automated evaluation has been investigated in the area of spoken dialogue systems (Jung et al., 2009), it is unclear how well it will correlate with human judgment in open-domain conversations where the range of possible responses is very large.

6.1 Experimental Conditions

We performed pairwise comparisons of several response-generation systems. Similar work on evaluating MT output (Bloodgood and Callison-Burch, 2010) has asked Turkers to rank more than two choices, but in order to keep our evaluation as straightforward as possible, we limited our experiments to pairwise comparisons.

For each experiment comparing 2 systems (*a* and *b*), we built a test set by selecting a random sample of 200 tweets which had received responses, and which had a length between 4 and 20 words. These tweets were selected from conversations collected from a later, non-overlapping time-period from those used in training. Each experiment used a different random sample of 200 tweets. For each of the 200 statuses, we generated a response using method *a* and *b*, then showed the status and both responses to the Turkers, asking them to choose the best response. The order of the systems used to generate a response was randomized, and each of the 200 HITs was submitted to 3 different Turkers. Turkers were paid 1¢ per judgment.

The Turkers were instructed that an appropriate response should be on the same topic as the status, and should also "make sense" in response to it. While this is an inherently subjective task, from inspecting the results, we found Turkers to be quite competent in judging between two responses.

The systems used in these pairwise comparisons are summarized in table 2, and example output generated by each system is presented in Table 3.

System Name	Description
RND-BASELINE	Picks randomly from the set of responses which are observed at least twice in the training data. The assumption is these are likely very general responses
IR-STATUS	$r_{\text{argmax}_i\, sim(s,s_i)}$ as described in §5
IR-RESPONSE	$r_{\text{argmax}_i\, sim(s,r_i)}$ as described in §5
MT-CHAT	Phrase-based translation system as described in §4
MT-BASELINE	Exactly the same as MT-CHAT, except using a phrase table extracted based on word alignments from GIZA++
HUMAN	Actual responses from the test data.

Table 2: Summary of systems compared experimentally

6.2 Results

The results of the experiments are summarized in Table 4. For each experiment we show the fraction of HITs where the majority of annotators agreed system *a* was better. We also show the p-value from an exact Binomial significance test; note that all differences are significant with above 95% confidence. Table 4 also shows the S coefficient (Bennett et al., 1954) as a measure of agreement between annotators for each experiment. S is equivalent the commonly used Kappa, except it assumes the uniform distribution when computing expected or chance agreement (Artstein and Poesio, 2008). The uniform distribution is appropriate in our setup, since annotators are not told which system generated each output, and the order of choices is randomized. If annotators were indeed choosing randomly, they would be expected to agree in 50% of cases. In most comparisons the value of S is in the range of 0.2 to 0.4, which can be considered "Fair agreement" (Landis and Koch, 1977).

Note that agreement between annotators is lower than typically reported in corpus annotation tasks. When annotating which of two automatically generated outputs is better, there is not always a clear answer; both responses might be good or bad. We can expect strong agreement only in cases where one response is clearly better. Strong agreement is not required, however, as we are using many annotations to compare each pair of systems, and the human judgments are not intended to be used as training data. Similar agreement was reported in an evaluation of automatically generated MT output as part

All differences are significant.

of the WMT09 shared tasks (Callison-Burch et al., 2009).[6]

The results of the paired evaluations provide a clear ordering on the automatic systems: IR-STATUS is outperformed by IR-RESPONSE, which is in turn outperformed by MT-CHAT. These results are somewhat surprising. We had expected that matching status to status would create a more natural and effective IR system, but in practice, it appears that the additional level of indirection employed by IR-STATUS created only more opportunity for confusion and error. Also, we did not necessarily expect MT-CHAT's output to be preferred by human annotators: the SMT system is the only one that generates a completely novel response, and is therefore the system most likely to make fluency errors. We had expected human annotators to pick up on these fluency errors, giving the the advantage to the IR systems. However, it appears that MT-CHAT's ability to tailor its response to the status on a fine-grained scale overcame the disadvantage of occasionally introducing fluency errors.[7]

Given MT-CHAT's success over the IR systems, we conducted further experiments to validate its output. In order to test how close MT-CHAT's responses come to human-level abilities, we compared its output to actual human responses from our dataset. In some cases the human responses change the topic of conversation, and completely ignore the initial status. For instance, one frequent type of response we noticed in the data was a greeting: "How have you been? I haven't talked to you in a while." For the purposes of this evaluation, we manually filtered out cases where the human response was completely off-topic from the status, selecting 200 pairs at random that met our criteria and using the actual responses as the HUMAN output.

When compared to the actual human-generated response, MT-CHAT loses. However, its output is preferred over the human responses 15% of the time, a fact that is particularly surprising given the very small – by MT standards – amount of data used to train the model. A few examples where MT-CHAT's output were selected over the human response are listed in Table 5.

We also evaluated the effect of filtering all possible phrase pairs using Fisher's Exact Test, which we did instead of conducting phrase extraction according to the very noisy word alignments. We altered our MT-CHAT system to use the standard Moses phrase-extraction pipeline, creating the system denoted as MT-BASELINE. We compared this to the complete MT-CHAT system. Note that both systems account for lexical repetition as described in §4.1. MT-CHAT's output is preferred 58% of the time over MT-BASELINE, indicating that direct phrase extraction is useful in this conversational setting.

Finally, as an additional baseline, we compared MT-CHAT's output to random responses selected from those observed 2 or more times in the training data. One might argue that short, common responses are very general, and that a reply like "lol" could be considered a good response to almost any status. However, the human evaluation shows a clear preference for MT-CHAT's output: raters favour responses that are tailored to the stimulus.

6.3 Automatic Evaluation

The field of SMT has benefited greatly from the existence of an automatic evaluation metric, BLEU (Papineni et al., 2002), which grades an output candidate according to n-gram matches to one or more reference outputs. To evaluate whether BLEU is an appropriate automatic evaluation measure for response generation, we attempted to measure its agreement with the human judgments. We calculate BLEU using a single reference derived from our parallel corpus. We show the smoothed BLEU 1-4 scores for each system on each dataset evaluated in Table 4. Although these scores are extremely low, the overall BLEU scores agree with overall annotator judgments in all cases except when comparing MT-CHAT and IR-RESPONSE. It would seem that BLEU has some agreement with human judgments on this task, but perhaps not enough to be immediately useful.

7 Conclusions

We have presented several data-driven approaches, based on information retrial and phrase-based SMT, to the task of automatically responding to open-

[6] See inter annotator agreement in table 4.

[7] Also, as one can see from the example exchanges in Table 3, fluency errors are rampant across all systems, including the gold-standard human responses.

Table 5: Examples where MT-CHAT output was preferred over HUMAN response by Turker annotators

domain linguistic stimuli.

Our experiments show that SMT techniques are better-suited than IR approaches on the task of response generation. Our system, MT-CHAT, produced responses which were preferred by human annotators over actual human responses 15% of the time. Although this is still far from human-level performance, we believe there is much room for improvement: from designing appropriate word-alignment and decoding algorithms that account for the selective nature of response in dialogue, to simply adding more training data.

We described the many challenges posed by adapting phrase-based SMT to dialogue, and presented initial solutions to several, including direct phrasal alignment, and phrase-table scores discouraging responses that are lexically similar to the status. Finally, we have provided results from an initial experiment to evaluate the BLEU metric when applied to response generation, showing that though the metric as is does not work well, there is sufficient correlation to suggest that a similar, dialogue-focused approach may be feasible.

By generating responses to Tweets out of context, we have demonstrated that the models underlying phrase-based SMT are capable of guiding the construction of appropriate responses. In the future, we are excited about the role these models could potentially play in guiding response construction for conversationally-aware chat input schemes, as well as goal-directed dialogue systems.

Abstract

We consider the problem of predicting measurable responses to scientific articles based primarily on their text content. Specifically, we consider papers in two fields (economics and computational linguistics) and make predictions about downloads and within-community citations. Our approach is based on generalized linear models, allowing interpretability; a novel extension that captures first-order temporal effects is also presented. We demonstrate that text features significantly improve accuracy of predictions over metadata features like authors, topical categories, and publication venues.

1 Introduction

Written communication is an essential component of the complex social phenomenon of science. As such, natural language processing is well-positioned to provide tools for understanding the scientific process, by analyzing the textual artifacts (papers, proceedings, etc.) that it produces. This paper is about modeling collections of scientific documents to understand how their *textual content* relates to how a scientific community responds to them. While past work has often focused on citation structure (Borner et al., 2003; Qazvinian and Radev, 2008), our emphasis is on the text content, following Ramage et al. (2010) and Gerrish and Blei (2010).

Instead of task-independent exploratory data analysis (e.g., topic modeling) or multi-document summarization, we consider supervised models of the collective *response* of a scientific community to a published article. There are many measures of impact of a scientific paper; ours come from direct measurements of the number of downloads (from an established website where prominent economists post papers before formal publication) and citations (within a fixed scientific community). We adopt a discriminative approach based on generalized linear models that can make use of any text or metadata features, and show that simple lexical features offer substantial power in modeling out-of-sample response and in *forecasting* response for future articles. Realistic forecasting evaluations require methodological care beyond the usual best practices of train/test separation, and we elucidate these issues.

In addition, we introduce a new regularization technique that leverages the intuition that the relationship between observable features and response should evolve smoothly over time. This regularizer allows the learner to rely more strongly on more recent evidence, while taking into account a long history of training data. Our time series-inspired regularizer is computationally efficient in learning and is a significant advance over earlier text-driven forecasting models that ignore the time variable altogether (Kogan et al., 2009; Joshi et al., 2010).

We evaluate our approaches in two novel experimental settings: predicting downloads of economics articles and predicting citation of papers at ACL conferences. Our approaches substantially outper-

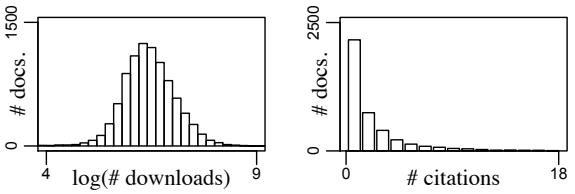

Figure 1: Left: the distribution of log download counts for papers in the NBER dataset one year after posting. Right: the distribution of within-dataset citations of ACL papers within three years of publication (outliers excluded for readability).

form text-ignorant baselines on ground-truth predictions. Our time series models permit flexibility in features and offer a novel and perhaps more interpretable view of the data than summary statistics.

2 Data

We make use of two collections of scientific literature, one from the economics domain, and the other from computational linguistics and natural language processing. Statistics are summarized in Table 1.

2.1 NBER

Our first dataset consists of research papers in economics from the National Bureau of Economic Research (NBER) from 1999 to 2009 (`http://www.nber.org`). Approximately 1,000 research economists are affiliated with the NBER. New NBER working papers are posted to the website weekly. The papers are not yet peer-reviewed, but given the prominence of many economists affiliated with the NBER, many of the papers are widely read. Text from the abstracts of the papers and related metadata are publicly available. Full text is available to subscribers (universities typically have access).

The NBER provided us with download statistics for these papers. For each paper, we computed the total number of downloads in the first year after each paper's posting.[1] The download counts are log-normally distributed, as shown in Figure 1, and so our regression models (§3) minimize squared errors in the log space. Our download logs begin in 1999. We use the 8,814 papers from 1999–2009 period (there are 16,334 papers in the full dataset dating back to 1985). We only use text from the abstracts, since we were able to obtain full texts for just a portion of the papers, and since the OCR of the full texts we do have is very noisy.

Dataset	# Docs.	Avg. # Words	Response
NBER	8,814	155	# downloads in first year (mean 761)
ACL	4,026	3,966	at least 1 citation in first 3 years? (54% no)

Table 1: Descriptive statistics about the datasets.

2.2 ACL

Our second dataset consists of research papers from the Association for Computational Linguistics (ACL) from 1980 to 2006 (Radev et al., 2009a; Radev et al., 2009b). We have the full texts for papers (OCR output) as well as structured citation data. There are 15,689 papers in the whole dataset. For the citation prediction task, we include conference papers from ACL, EACL, HLT, and NAACL.[2] We remove journal papers, since they are characteristically different from conference papers, as well as workshop papers. We do include short papers, interactive demo session papers, and student research papers that are included in the companion volumes for these conferences (such papers are cited less than full papers, but many are still cited). The resulting dataset contains 4,026 papers. The number of papers in each year varies because not all conferences are annual.

We look at citations in the three-year window following publication, excluding self-citations and only considering citations from papers within these conferences. Figure 1 shows a histogram; note that many papers (54%) are not cited at all, and the distribution of citations per paper is neither normal nor log-normal. We organize the papers into two classes: those with zero citations and those with non-zero citations in the three-year window.

[1] For the vast majority of papers, most of the downloads occur soon after the paper's posting. We explored different measures with different download windows (two years, for example) with broadly similar results. We leave a more detailed analysis of the time series patterns of downloads to future work.

[2] EMNLP is a relatively recent conference, and, in this collection, complete data for its papers postdate the end of the last training period, so we chose to exclude it from our dataset.

3 Model

Our forecasting approach is based on generalized linear models for regression and classification. The models are trained with an ℓ_2-penalty, often called a "ridge" model (Hoerl and Kennard, 1970).[3] For the NBER data, where (log) number of downloads is nearly a continuous measure, we use linear regression. For the ACL data, where response is the binary cited-or-not variable we use logistic regression, often referred to as a "maximum entropy" model (Berger et al., 1996) or a log-linear model. We briefly review the class of models. Then, we describe a time series model appropriate for time series data.

3.1 Generalized Linear Models

Consider a model that predicts a response y given a vector input $\boldsymbol{x} = \langle x_1, \ldots, x_d \rangle \in \mathbb{R}^d$. Our models are linear functions of $\boldsymbol{x}$ and parameterized by the vector $\boldsymbol{\beta}$. Given a corpus of M document features, $\boldsymbol{X}$, and responses Y, we estimate:

$$\hat{\boldsymbol{\beta}} = \operatorname{argmin}_{\boldsymbol{\beta}} R(\boldsymbol{\beta}) + \mathcal{L}(\boldsymbol{\beta}, \boldsymbol{X}, Y) \qquad (1)$$

where $\mathcal{L}$ is a model-dependent loss function and R is a regularization penalty to encourage models with small weight vectors. We describe models and loss functions first and then turn to regularization.

For the NBER data, the (log) number of downloads is continuous, and so we use least-squares linear regression model. The loss function is the sum of the squared errors for the M documents in our training data: $\mathcal{L}(\boldsymbol{\beta}, \boldsymbol{X}, Y) = \sum_{i=1}^{M} (y_i - \hat{y}_i)^2$, where the prediction rule for new documents is: $\hat{y} = \sum_{j=0}^{d} \beta_j x_j$. Probabilistically, this equates to an assumption that $\boldsymbol{\beta}^\top \boldsymbol{x}$ is the mean of a normal (i.e., Gaussian) distribution from which random variable y is drawn.

For the ACL data, we predict y from a discrete set C (specifically, the binary set of zero citations or more than zero citations), and we use logistic regression. This model assumes that for the ith training input $\boldsymbol{x}_i$, the output y_i is drawn according to:

$$p(y_i \mid \boldsymbol{x}_i) = \left(\exp \boldsymbol{\beta}_c^\top \boldsymbol{x}_i\right) / \left(\textstyle\sum_{c' \in C} \exp \boldsymbol{\beta}_{c'}^\top \boldsymbol{x}_i\right)$$

where there is a feature vector $\boldsymbol{\beta}_c$ for each class $c \in C$. Under this interpretation, parameter estimation is maximum *a posteriori* inference for $\boldsymbol{\beta}$, and $R(\boldsymbol{\beta})$ is a log-prior for the weights. The loss function is the negative log likelihood for the M documents: $\mathcal{L}(\boldsymbol{\beta}, \boldsymbol{X}, Y) = -\sum_{i=1}^{M} \log p(y_i \mid \boldsymbol{x}_i)$. The prediction rule for a new document is: $\hat{y} = \operatorname{argmax}_{c \in C} \sum_{j=0}^{d} \beta_{c,j} x_j$. Generalized linear models and penalized regression are well-studied with an extensive literature (Mccullagh and Nelder, 1989; Hastie et al., 2009). We leave other types of models, such as Poisson (Cameron and Trivedi, 1998) or ordinal (McCullagh, 1980) regression models, to future work.

3.2 Ridge Regression

With large numbers of features, regularization is crucial to avoid overfitting. In ridge regression (Hoerl and Kennard, 1970), a standard method to which we compare the time series regularization discussed in §3.3, the penalty $R(\boldsymbol{\beta})$ is proportional to the ℓ_2-norm of $\boldsymbol{\beta}$:

$$R(\beta) = \lambda \|\boldsymbol{\beta}\|_2 = \lambda \textstyle\sum_j \beta_j^2$$

where λ is a regularization hyperparameter that is tuned on development data or by cross-validation.[4] This penalty pushes many β_j close (but not completely) to zero. In practice, we multiply the penalty by the number of examples M to facilitate tuning of λ.

The ridge linear regression model can be interpreted probabilistically as each coefficient β_j is drawn i.i.d. from a normal distribution with mean 0 and variance $2\lambda^{-1}$.

3.3 Time Series Regularization

A simple way to capture temporal variation is to conjoin traditional features with a time variable. Here, we divide the dataset into T time steps (years). In the new representation, the feature space expands from $\mathbb{R}^d$ to $\mathbb{R}^{T \times d}$. For a document published at year t, the elements of $\boldsymbol{x}$ are non-zero only for those features that correspond to year-t; that is $x_{t',j} = 0$ for all $t' \neq t$.

[3] Preliminary experiments found no consistent benefit from ℓ_1 ("lasso") models, though we note that ℓ_1-regularization leads to sparse, compact models that may be more interpretable.

[4] The linear regression has a bias β_0 that is always active. The logistic regression also has an unpenalized bias $\beta_{c,0}$ for each class c. This weight is not regularized.

Estimating this model with the new features using the ℓ_2-penalty would be effectively estimating separate models for each year under the assumption that each $\beta_{t,j}$ is independent; even for features that differed only temporally (e.g., $\beta_{t,j}$ and $\beta_{t+1,j}$).

In this work, we apply time series regularization to GLMs, enabling models that have coefficients that change over time but prefer gradual changes across time steps. Boyd and Vandenberghe (2004, §6.3) describe a general version of this sort of regularizer. To our knowledge, such regularizers have not previously been applied to temporal modeling of text.

The time series regularization penalty becomes:

$$R(\boldsymbol{\beta}) = \lambda \sum_{t=1}^{T} \sum_{j=1}^{d} \beta_{t,j}^2 + \lambda\alpha \sum_{t=2}^{T} \sum_{j=0}^{d} (\beta_{t,j} - \beta_{t-1,j})^2$$

It includes a standard ℓ_2-penalty on the coefficients, and a penalty for differences between coefficients for adjacent time steps to induce smooth changes.[5] Similar to the previous model, in practice, we multiply the regularization constant λ by $\frac{M}{T}$ to facilitate tuning of λ for datasets with different numbers of examples M and numbers of time steps T. The new parameter, α, controls the smoothness of the estimated coefficients. Setting α to zero imposes no penalty for time-variation in the coefficients and results in independent ridge regressions at each time step. Also, when the number of examples is constant across time steps, setting a large α parameter ($\alpha \to \infty$) results in a single ridge regression over all years since it imposes $\beta_{t,j} = \beta_{t+1,j}$ for all $t \in T$.

The partial derivative is:

$$\begin{aligned} \partial R / \partial \beta_{t,j} = & \; 2\lambda\beta_{t,j} \\ & + \; \mathbf{1}\{t > 1\} 2\lambda\alpha(\beta_{t,j} - \beta_{t-1,j}) \\ & + \; \mathbf{1}\{t < T\} 2\lambda\alpha(\beta_{t,j} - \beta_{t+1,j}) \end{aligned}$$

This time series regularization can be applied more generally, not just to linear and logistic regression.

With either ridge regularization or this time series regularization scheme, Eq. 1 is an unconstrained convex optimization problem for the linear models we describe here. There exist a number of optimization procedures for it; we use the L-BFGS quasi-Newton algorithm (Liu and Nocedal, 1989).

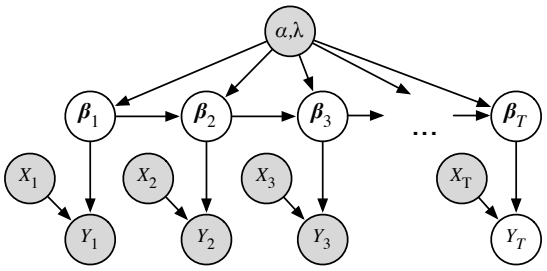

Figure 2: Time series regression as a graphical model; the variables $\boldsymbol{X}_t$ and Y_t are the sets of feature vectors and response variables from documents dated t.

Probabilistic Interpretation

We can interpret the time series regularization probabilistically as follows. Let the coefficient for the jth feature over time be $\boldsymbol{\beta}_j = \langle \beta_{1,j}, \beta_{2,j}, ..., \beta_{T,j} \rangle$. $\boldsymbol{\beta}_j$ are draws from a multivariate normal distribution with a tridiagonal precision matrix $\Sigma^{-1} = \Lambda \in \mathbb{R}^{T \times T}$:

$$\Lambda = \lambda \begin{bmatrix} 1+\alpha & -\alpha & 0 & 0 & \dots \\ -\alpha & 1+2\alpha & -\alpha & 0 & \dots \\ 0 & -\alpha & 1+2\alpha & -\alpha & \dots \\ 0 & 0 & -\alpha & 1+2\alpha & \dots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix}$$

The form of $R(\boldsymbol{\beta})$ follows from noting:

$$-2 \log p(\boldsymbol{\beta}_j; \alpha, \lambda) = \boldsymbol{\beta}_j^\top \Lambda \boldsymbol{\beta}_j + \mathit{constant}$$

The squared difference between adjacent time steps comes from the off-diagonal entries in the precision matrix.[6] Figure 2 shows a graphical representation of the time series regularization in our model. Its Markov chain structure corresponds to the off-diagonals.

There is a rich literature on time series analysis (Box et al., 2008; Hamilton, 1994). The prior distribution over the sequence $\langle \beta_{1,j}, \dots, \beta_{T,j} \rangle$ that our regularizer posits is closely linked to a first-order autoregressive process, AR(1).

[5] Our implementation of the time series regularizer does not penalize the magnitude of the weight for the bias feature (as in ridge regression). It does, however, penalize the difference in the bias weight between time steps (as with other features).

[6] Consistent with the previous section, we assume that parameters for different features, $\boldsymbol{\beta}_j$ and $\boldsymbol{\beta}_k$, are independent.

	NBER	ACL
Response	log(#downloads+1)	$\mathbf{1}\{\#\text{citations} > 0\}$
GLM type	normal / squared-loss	logistic / log-loss
Metric 1	mean absolute error	accuracy
Metric 2	Kendall's τ	Kendall's τ

Table 2: Summary of the setup for the NBER download and ACL citation prediction experiments.

4 Features

NBER metadata features

- Authors' last names. We treat each name as a binary feature. If a paper has multiple authors, all authors are used and they have equal weights regardless of their ordering.
- NBER program(s).[7] There are 19 major research programs at the NBER (e.g., Monetary Economics, Health Economics, etc.).

ACL metadata features

- Authors' last names as binary features.
- Conference venues. We use first letter of the ACL anthology paper ID, which correlates with its conference venue (e.g., *P* for the ACL main conference, *H* for the HLT conference, etc.).[8]

Text features

- Binary indicator features for the presence of each unigram, bigram, and trigram. For the NBER data, we have separate features for titles and abstracts. For the ACL data, we have separate features for titles and full texts. We pruned text features by document frequency (details in §5).
- Log transformed word counts. We include features for the numbers of words in the title and the abstract (NBER) or the full text (ACL).

[7] Almost all NBER papers are tagged with one or more programs (we assign untagged papers a "null" tag). The complete list of NBER programs can be found at `http://www.nber.org/programs`

[8] Papers in the ACL dataset have a tag which shows which workshop, conference, or journal they appeared in. However, sometimes a conference is jointly held with another conference, such that meta information in the dataset is different even though the conference is the same. For this reason, we simply use the first letter of the paper ID.

5 Experiments

For each of the datasets in §2, we test our models for two tasks: **forecasting** about future papers (i.e., making predictions about papers that appeared after a training dataset) and **modeling** held-out papers from the past (i.e., making predictions within the same time period as the training dataset, on held-out examples).

For the NBER dataset, the task is to predict the number of downloads a paper will receive in its first year after publication. For the ACL dataset, the task is to predict whether a paper will be cited at all (by another ACL paper in our dataset) within the first three years after its publication. To our knowledge, clean, reliable citation counts are not available for the NBER dataset; nor are download statistics available for the ACL dataset. Table 2 summarizes the variables of interest, model types, and evaluation metrics for the tasks.

5.1 Extrapolation

The lag between a paper's publication and when its outcome (download or citation count) can be observed poses a unique methodological challenge. Consider predicting the number of downloads over g future time steps. If t is the time of forecasting, we can observe the texts of all articles published before t. However, any article published in the interval $[t-g, t]$ is too recent for the outcome measurement of y to be taken. We refer to the interval $[t-g, t]$ as the "forecast gap". Since recent articles are sometimes the most relevant predictions at t, we do not want to ignore them. Consider a paper at time step $t', t-g < t' < t$. To extrapolate its number of downloads, we consider the observed number in $[t', t]$, and then estimate the ratio r of downloads that occur in the first $t-t'$ time steps, against the first g time steps, using the fully observed portion of the training data. We then scale the observed downloads during $[t', t]$ by r^{-1} to extrapolate. The same method is used to extrapolate citation counts.

In preliminary experiments, we observed that extrapolating responses for papers in the forecast gap led to better performance in general. For example, for the ridge regressions trained on all past years with the full feature set, the error dropped from 262 to 259 when using extrapolation compared to with-

out extrapolation. Also, the extrapolated download counts were quite close to the true values (which we have but do not use because of the forecast gap): for example, the mean absolute error of the extrapolated responses was 99 when extrapolated based on the median of the fully observed portion of the training data (measured monthly).

5.2 Forecasting NBER Downloads

In our first set of experiments, we predict the number of downloads of an NBER paper within one year of its publication.

We compare four approaches for predicting downloads. The first is a baseline that simply uses the median of the log of the training and development data as the prediction. The second and third use GLMs with ridge regression-style regularization (§3.2), trained on all past years ("all years") and on the single most recent past year ("one year"), respectively. The last model ("time series") is a GLM with time series regularization (§3.3).

We divided papers by year. Figure 3 illustrates the experimental setup. We held out a random 20% of papers for each year from 1999–2007 as a test set for the task of modeling the past. To define the feature set and tune hyperparameters, we used the remaining 80% of papers from 1999–2005 as our training data and the remaining papers in 2006 as our development data. After pruning,[9] we have 37,251 total features, of which 2,549 are metadata features. When tuning hyperparameters, we *simulated* the existence of a forecast gap by using extrapolated responses for papers in the last year of the training data instead of their true responses. We considered $\lambda \in 5^{\{2,1,\ldots,-5,-6\}}$, and $\alpha \in 5^{\{3,2,\ldots,-1,-2\}}$ and selected those that led to the best performance on the development set.

We then used the selected feature set and hyperparameters to test the forecasting and modeling capabilities of each model. For forecasting, we predicted numbers of downloads of papers in 2008 and 2009. We used the baseline median, ridge regression, and time series regularization models trained on papers in 1999–2007 and 1999–2008, respectively. We treated the last year of the training data (2007 and 2008, respectively) as a forecast gap, since we would not have observed complete responses of papers in these years when forecasting. For the "one year" models, we trained ridge regressions only on the most recent past year, using papers in 2007 and 2008, respectively, as training data.[10] To test the additive benefit of text features, we trained models with just metadata features (NBER programs and authors, denoted "Meta") and with both metadata

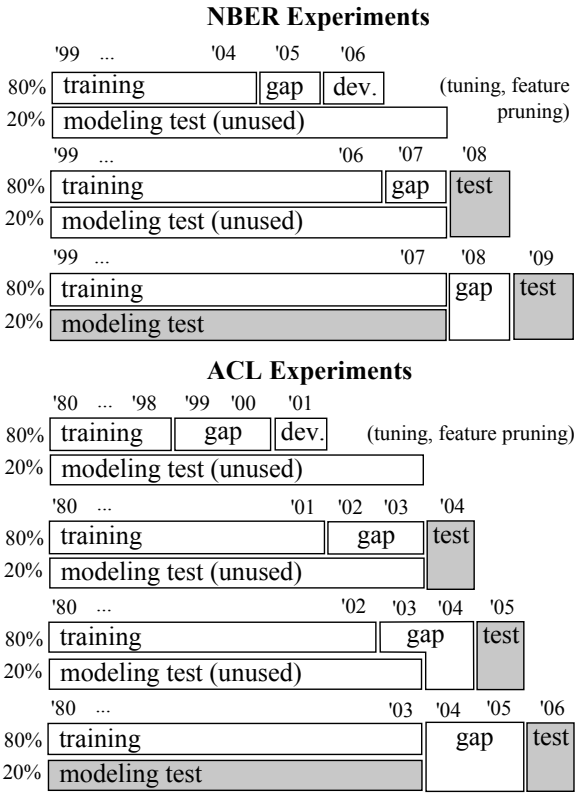

Figure 3: An illustration of how the datasets were segmented for the experiments. Portions of data for which we report results are shaded. Time spans are not to scale.

[9] For NBER, text features appearing in less than 0.1% or more than 99.9% of the training documents were removed. For ACL, the thresholds were 2% and 98%.

[10] Papers from the most recent past year in a training set have incomplete responses, so the models were trained on extrapolated responses for that year. For the NBER development set from 2005, a ridge regression on just 2004 papers (for which extrapolation is needed) outperformed a regression on just 2003 (for which extrapolation is not needed), 278 to 367 mean absolute error. For the ACL development set from 2001, a regression on just 2000 (for which extrapolation is needed) led to slightly lower performance (59% versus 61%) than a regression on just 1998 (for which extrapolation is not needed), probably due to the relatively small number of conferences and papers in 2000. For consistency with the other models and with the NBER experiments, we evaluated regressions on the most recent (extrapolated) year in our ACL experiments.

Features	Model	Modeling 1999–07	Forecasting 2008	Forecasting 2009
–	median	333	371	397
Meta	one year	279	354	375
Meta	all years	303	334	378
Meta	time series	279	353	375
Full	one year	271	346	351
Full	all years	265	†**300**	339
Full	time series	*†**245**	*321	***332**

Table 3: Mean absolute errors for the NBER download predictions. "$*$" indicates statistical significance between time series models using metadata features and the full feature set. "†" indicates statistical significance between the time series and ridge regression models using the full feature set (Wilcoxon signed-rank test, $p < 0.01$).

Feat.	Model	Modeling 1980–03	Forecasting 2004	Forecasting 2005	Forecasting 2006
–	majority	55	56	60	50
Meta	one year	61	56	54	62
Meta	all years	65	58	53	60
Meta	time series	66	56	53	56
Full	one year	69	**70**	64	67
Full	all years	67	69	**70**	70
Full	time series	**70**	*69	***70**	***72**

Table 4: Classification accuracy (%) for predicting whether ACL papers will be cited within three years. "$*$" indicates statistical significance between time series models using metadata features and the full feature set (binomial sign test, $p < 0.01$). With the full feature set, differences between the time series and ridge (all years) models are not statistically significant at the 0.01 level, but for the modeling task p is estimated at 0.026, and for the 2006 forecasting task, p is estimated at 0.050.

and text features (denoted "Full").

To evaluate the modeling capabilities, we trained the ridge regression and time series regularization models on papers from 1999–2008 and predicted the numbers of downloads of held-out papers in 1999–2007. For comparison, we also trained ridge regression models on each individual year ("one year") and predicted the numbers of downloads of the held-out papers in the corresponding year.

Table 3 shows mean absolute errors for each method on both forecasting test splits, and mean absolute errors averaged across papers over nine modeling test splits. For interpretability, we report predictions in terms of download counts, though the models were trained with log counts (§2.1). The results show that even a simple n-gram representation of text contains a valuable, learnable signal that is predictive of future downloads. While the time series model did not significantly outperform ridge regression at predicting future downloads, it did result in significantly better performance for *modeling* papers in the past.

5.3 Forecasting ACL Citations

We now turn to the problem of predicting citation levels. Recall that here we aim to predict whether an ACL paper will be cited within our dataset within three years. Our experimental setup (Figure 3) is similar to the setup for the NBER dataset, except that we use logistic regression to model the discrete cited-or-not response variable. We also make the simplifying assumption that all citations occur at the end of each year. Therefore, the forecast gap is only two years (we have observed complete citations in the test year).

After feature pruning, there were 30,760 total features, of which 1,694 are metadata features. We considered $\lambda \in 5^{\{2,1,\cdots,-8,-9\}}$ ("Full") and $\lambda \in 5^{\{2,1,\cdots,-11,-12\}}$ ("Meta"); and $\alpha \in 5^{\{6,5,\cdots,0,-1\}}$ (both "Full" and "Meta"), selecting the best values using the development data.

Again, we compare four methods: a baseline of always predicting the most frequent class in the training data, "all years" and "one year" logistic regression models, and a logistic regression with the time series regularizer.

For the forecasting task, we used papers in 2004, 2005, and 2006 as test sets. As the training sets for the "all years" and time series models, we used papers from 1980 up to the last year before each test set, with the last two years extrapolated. As the training sets for the "one year" models, we used papers from the year immediately before the test set, with extrapolated responses.

To evaluate modeling capabilities, we predicted citation levels of held-out papers in 1980–2003. We used the "all years" and time series models trained on 1980–2005. We trained "one year" models separately for each year and predicted downloads for the held-out papers in that year.

Table 4 shows classification accuracy for each model on the test data for both the forecasting and modeling tasks. It is again clear that adding text sig-

nificantly improved the performance of the model. Also, the time series regression model shows a small, though not statistically significant, gain for modeling whether past papers will be cited—as well as similarly small gains on two of the three forecasting test years.

5.4 Ranking

We can also use the models for ranking to help decide which papers are expected to have the greatest impact. With rankings, we can use the same metric both for download and citation predictions. For the NBER data, we ranked test-set papers based on the predicted numbers of downloads and computed the correlation to the actual numbers of downloads. For the ACL data, we ranked papers based on the *probability* of being cited (within the next three years) and computed the correlation to the actual numbers of citations.[11]

To measure ranking models' ranking quality, we used Kendall's τ, a nonparametric statistic that measures the similarity of two different orderings over the same set of items. Here, the items are scientific papers and the two metrics are the gold standard numbers of downloads (or citations) and model predictions for the numbers of downloads, or citation probabilities. If q is the chance that a randomly drawn pair of items will be ranked in the same way by the two metrics, then $\tau = 2(q - 0.5)$.

Table 5 shows Kendall's τ for each model for the forecasting tasks (i.e., prediction of future citations or downloads) in both datasets. As in the previous experiments, we see small benefits for the time series regression model on most held-out data splits—and larger benefits for including text features along with metadata features.

6 Analysis

An advantage of the time series regularized regression model is its interpretability. Inspecting feature coefficients in the model allows us to identify trends and changes of interests over time within a scientific community.

[11] Here, we use models of responses to individual papers for ranking (i.e., in a pointwise ranking scheme). Time series regularization could also be applied to ranking models that model pairwise preferences to optimize metrics like Kendall's τ directly, as discussed by Joachims (2002).

Feat.	Model	NBER		ACL		
		'08	'09	'04	'05	'06
Meta	one year	.29	.22	.17	.08	.16
Meta	all years	.31	.22	.15	.12	.21
Meta	time series	.29	.22	.14	.10	.17
Full	one year	.35	.31	.44	.39	.33
Full	all years	**.43**	.37	.42	.43	.40
Full	time series	**.43**	**.38**	**.47**	**.44**	**.43**

Table 5: Kendall's τ rank correlation for future prediction models on both datasets.

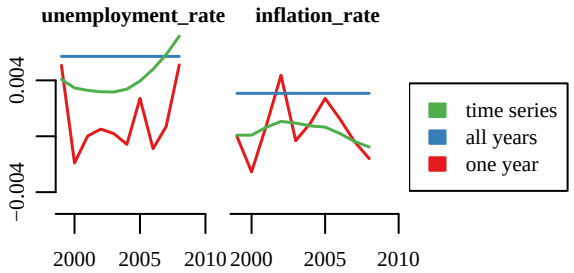

Figure 4: Coefficients for two NBER bigram features.

First, we illustrate the difference between the time series and the other models in Figure 4, for NBER models' weights for *unemployment rate* and *inflation rate* appearing in a paper's abstract. The year-to-year weights of "one year" models fluctuate substantially, and the "all years" model is necessarily constant, but the time series regularizer gives a smooth trajectory.

6.1 Trends

Previous work has examined the flow of ideas as trends in word and phrase frequencies, as in the Google Books Ngram Viewer (Michel et al., 2011).[12] Topic models have been used extensively to explore trends in low-dimensional spaces (Blei and Lafferty, 2006; Wang et al., 2008; Wang and McCallum, 2006; Ahmed and Xing, 2010). By contrast, our approach allows us to examine trends in the *impact* of text related to specific observation variables: the coefficient trendline for a feature illustrates its association with measurements of scholarly impact (citation and download frequency).

Text frequencies can be quite different from the discriminative weights our model assigns to features. Figure 5 illustrates the $\beta_{t,j}$ trends in the ACL time series model for some selected terms that oc-

[12] http://ngrams.googlelabs.com

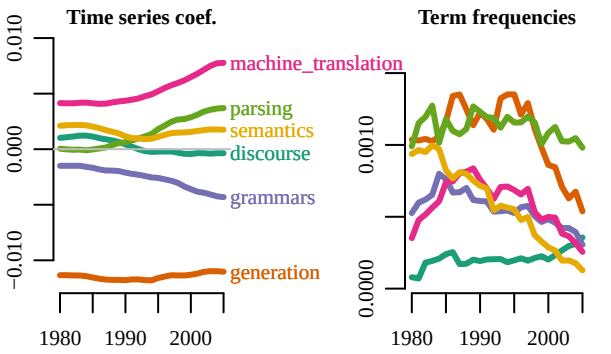

Figure 5: Feature trends: model coefficients vs. term frequencies over time in the ACL corpus. Term freq. is the fraction of tokens (or bigrams for *m.t.*) that year, that are the term, averaged over a centered five-year window.

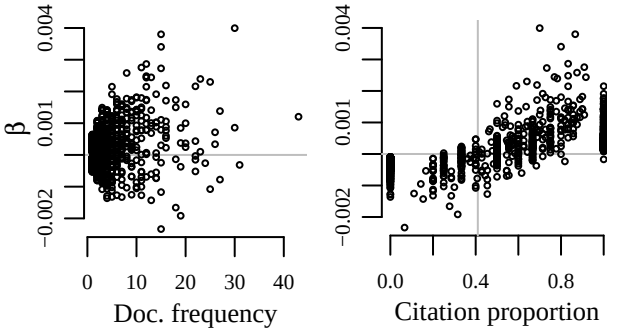

(a) Doc. freq. vs. coef. (b) Citation prop. vs. coef.

Figure 6: Analysis of author citation coefficients. Every point is one ACL author, and the vertical axis shows the citation coefficient, compared to (a) the number of documents co-authored by the author; and (b) the proportion of an author's papers that are cited within three years. The vertical bar is the *macro*-averaged citation proportion across authors, 41%.

cur frequently in conference session titles. On the right are term frequencies (with smoothing, since year-to-year frequencies are bumpy). Most terms decline over time. On the left, by contrast, are the weights learned by our time series model. They tell a very different story: for example, parsing has shown a definite increase in interest, while interest in grammars (e.g., formalisms) has declined somewhat. These trends have face validity, giving credence to our analysis; they also broadly agree with Hall et al. (2008).

6.2 Authors

The regression method also allows analysis of author influence, since we fit a coefficient for each of the authors in the ACL dataset. Figure 6(a) addresses the following question: do prolific authors get cited more often, even after accounting for the content of their papers?[13] The effect is present but relatively small according to our model: the total number of papers co-authored by an author has a weak correlation to the author's citation prediction coefficient ($\tau = 0.16$).

Next, does the model provide more information than the simple citation probability of an author? Figure 6(b) compares coefficients to an author's papers' probability of being cited. Since we did not prune author features, there are many authors with only a few papers, resulting in unsmoothed probabilities of 0, 0.5, 1, etc. (these correspond to the vertical "bands" in the plot). By contrast, the ℓ_2-penalty of the model naturally assigned coefficients close to zero for such authors if it is justified.

In general, the simple probability agrees with the coefficient, but there are differences. The semantics of the regression imply we are measuring the relative citation probability of an author, *controlling* for text and venue effects. If an author has a high citation prediction coefficient but a low citation probability, that implies the author has better-cited work than would be expected according to the n-grams in his or her papers. We have omitted names of authors from the figure for clarity and confidentiality, but high outlier authors tend to be well-known researchers in the ACL community. Obviously, since the prediction model is not perfect, it is not possible to completely verify this hypothesis, but we feel this analysis is reasonably suggestive.

7 Related Work

Previous work on modeling scientific literature mostly focused on citation graphs (Borner et al., 2003; Qazvinian and Radev, 2008). Some researchers, e.g., Erosheva et al. (2004), have used text content. Most of these are based on topic models: Gerrish and Blei (2010) measure scholarly impact, Hall et al. (2008) study the "history of ideas",

[13] More precisely: if a prolific author and a non-prolific author write a paper, does the prolific author's paper have a higher probability of being cited than the non-prolific author's, all other things being equal?

and Ramage et al. (2010) rank universities based on scholarly output using topic models.

Download rates and citation prediction were two of the main tasks in the KDD Cup 2003 (McGovern et al., 2003; Brank and Leskovec, 2003). Bethard and Jurafsky (2010) considered the problem slightly differently and proposed an information retrieval approach to citation prediction. Our approach is novel in that we formulate the problem as a forecasting task and we seek to predict *future* impact of articles.

Linear regression with text features has been used to predict financial risk (Kogan et al., 2009) and movie revenues (Joshi et al., 2010). While the forecasts in those papers are similar to ours, those authors did not consider a forecast gap or allowing the parameters of the model to vary over time.

Our time series regularization is closely related to the fused lasso (Tibshirani et al., 2005). It penalizes a loss function by the ℓ_1-norm of the coefficients and their differences. The ℓ_1-penalty for differences between coefficients encourages *sparsity* in the differences. We use the ℓ_2-norm to induce *smooth* changes across time steps.

8 Conclusions

We presented a statistical approach to predicting a scientific community's response to an article, based on its textual content. To improve the interpretability of the linear model, we developed a novel time series regularizer that encourages gradual changes across time steps. Our experiments showed that text features significantly improve accuracy of predictions over baseline models, and we found that the feature weights learned with the time series regularizer reflect important trends in the literature.

Non-parametric Bayesian Segmentation of Japanese Noun Phrases

Yugo Murawaki and **Sadao Kurohashi**

Abstract

A key factor of high quality word segmentation for Japanese is a high-coverage dictionary, but it is costly to manually build such a lexical resource. Although external lexical resources for human readers are potentially good knowledge sources, they have not been utilized due to differences in segmentation criteria. To supplement a morphological dictionary with these resources, we propose a new task of Japanese noun phrase segmentation. We apply non-parametric Bayesian language models to segment each noun phrase in these resources according to the statistical behavior of its supposed constituents in text. For inference, we propose a novel block sampling procedure named hybrid type-based sampling, which has the ability to directly escape a local optimum that is not too distant from the global optimum. Experiments show that the proposed method efficiently corrects the initial segmentation given by a morphological analyzer.

1 Introduction

Word segmentation is the first step of natural language processing for Japanese, Chinese and Thai because they do not delimit words by white-space. Segmentation for Japanese is a successful field of research, achieving the F-score of nearly 99% (Kudo et al., 2004). This success rests on a high-coverage dictionary. Unknown words, or words not covered by the dictionary, are often misidentified.

Historically, researchers have devoted extensive human resources to build and maintain high-coverage dictionaries (Yokoi, 1995). Since the orthography of Japanese does not specify a standard for segmentation, researchers define their own criteria before constructing lexical resources. For this reason, it is difficult to exploit existing external resources, such as dictionaries and encyclopedias for human readers, where entry words are not segmented according to the criteria. Among them, encyclopedias are especially important in that they contain a lot of terms that a morphological dictionary fails to cover. Most of these terms are noun phrases and consist of more than one word (morpheme). For example, an encyclopedia has an entry "常山城" (*tsuneyama-jou*, "Tsuneyama Castle"). According to our segmentation criteria, it consists of two words "常山" (*tsuneyama*) and "城" (*jou*). However, the morphological analyzer wrongly segments it into "常" (*tsune*) and "山城" (*yamashiro*) because "常山" (*tsuneyama*) is an unknown word.

In this paper, we present the first attempt to utilize encyclopedias for word segmentation. We segment each entry noun phrase into words. To do this, we examine the main text of the entry, on the assumption that if the noun phrase in question consists of more than one word, its constituents appear in the main text either freely or as part of other noun phrases. For "常山城" (*tsuneyama-jou*), its constituent "常山" (*tsune*) appears by itself and as constituents of other nouns phrases such as "常山山頂" (peak of Tsuneyama) and "常山駅" (Tsuneyama Station) while "山城" (*yamashiro*) does not.

To segment each noun phrase, we use non-parametric Bayesian language models (Goldwater et al., 2009; Mochihashi et al., 2009). Our approach

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 605–615,
Edinburgh, Scotland, UK, July 27–31, 2011.

is based on two key factors: the bigram model and type-based block sampling. The bigram model alleviates a problem of the unigram model, that is, a tendency to misidentify a sequence of words in common collocations as a single word. Type-based sampling (Liang et al., 2010) has the ability to directly escape a local optimum, making inference very efficient. However, type-based sampling is not easily applicable to the bigram model owing to sparsity and its dependence on latent assignments.

We propose a hybrid type-based sampling procedure, which combines the Metropolis-Hastings algorithm with Gibbs sampling. We circumvent the sparsity problem by joint sampling of unigram-level type. Also, instead of calculating the probability of every possible state of the jointly sampled random variables, we only compare the current state with a proposed state. This greatly eases the sampling procedure while retaining the efficiency of type-based sampling. Experiments show that the proposed method quickly corrects the initial segmentation given by a morphological analyzer.

2 Related Work

Japanese Morphological Analysis and Lexical Acquisition Word segmentation for Japanese is usually solved as the joint task of segmentation and part-of-speech tagging, which is called morphological analysis (Kurohashi et al., 1994; Asahara and Matsumoto, 2000; Kudo et al., 2004). The standard approach in Japanese morphological analysis is lattice-based path selection instead of character-based IOB tagging. Given a sentence, an analyzer first builds a lattice of words with dictionary look-up and then selects an optimal path using pre-defined parameters. This approach enables fast decoding and achieves accuracy high enough for practical use.

This success, however, depends on a high-coverage dictionary, and unknown words are often misidentified. Although a line of research attempts to identify unknown words on the fly (Uchimoto et al., 2001; Asahara and Matsumoto, 2004), it by no means provides a definitive solution because it suffers from locality of contextual information available for identification (Nakagawa and Matsumoto, 2006). Therefore we like to perform separate lexical acquisition processes in which wider context can be examined.

Our approach in this paper has a complementary relationship with unknown word acquisition from text, which we previously proposed (Murawaki and Kurohashi, 2008). Since, unlike Chinese and Thai, Japanese is rich in morphology, morphological regularity can be used to determine if an unknown word candidate in text is indeed the word to be acquired. In general, this method works pretty well, but one exception is noun phrases. Noun phrases can hardly be distinguished from single nouns because in Japanese, no morphological marker is attached to join nouns to form a noun phrase. We previously resort to a heuristic measure to segment noun phrases. The new statistical method provides a straightforward solution to this problem.

Meanwhile, our language models have their own problem. The assumption that language is a sequence of invariant words fails to capture rich morphology, as our segmentation criteria specify that each verb or adjective consists of an invariant stem and an ending that changes its form according to its grammatical roles. For this reason, we limit our scope to noun phrases in this paper.

Use of Noun Phrases Named entity recognition (NER) is a field where encyclopedic knowledge plays an important role. Kazama and Torisawa (2008) encode information extracted from a gazetteer (e.g. Wikipedia) as features of a CRF-based Japanese NE tagger. They formalize the NER task as the character-based labeling of IOB tags. Noun phrases extracted from a gazetteer are also straightforwardly represented as IOB tags. However, this does not fully solve the knowledge bottleneck problem. They also used the output of a morphological analyzer, which does not utilize encyclopedic knowledge. NER performance may be affected by segmentation errors in morphological analysis involving unknown words.

Chinese word segmentation is often formalized as a character tagging problem (Xue, 2003). In this setting, it is easy to incorporate external resources into the model. Low et al. (2005) introduce an external dictionary as features of a discriminative model. However, they only use words up to 4 characters in length. We conjecture that words in their dictionary are not noun phrases. External resources used by

Peng et al. (2004) are also lists of short words and characters.

Non-parametric Language Models Non-parametric Bayesian statistics offers an elegant solution to the task of unsupervised word segmentation, in which the vocabulary size is not known in advance (Goldwater et al., 2009; Mochihashi et al., 2009). It does not compete with supervised segmentation, however. Unsupervised word segmentation is used elsewhere, for example, with theoretical interest in children's language acquisition (Johnson, 2008; Johnson and Demuth, 2010) and with the application to statistical machine translation, in which segmented text is merely an intermediate representation (Xu et al., 2008; Nguyen et al., 2010). In this paper we demonstrate that non-parametric models can complement supervised segmentation.

3 Japanese Noun Phrase Segmentation

Our goal is to overcome the unknown word problem in morphological analysis by utilizing existing resources such as dictionaries and encyclopedias for human readers. In our settings, we are given a list of entries from external resources. Almost all of them are noun phrases and each entry consists of one or more words.

A naïve implementation would be to use noun phrases as they are. In fact, ipadic[1] regards as single words a large number of long proper nouns like "関西国際空港会社連絡橋" (literally, Kansai International Airport Company Connecting Bridge). However, this approach has various drawbacks. For example, in information retrieval, the query "Kansai International Airport" does not match the "single" word for the bridge. So we apply segmentation.

Each entry is associated with text, which is usually the main text of the entry.[2] We assume the text as the key to segmenting the noun phrase. If the noun phrase in question consists of more than one word, its constituents would appear in the text either freely or as part of other noun phrases.

We obtain the segmentation of an entry noun phrase by considering the segmentation of the whole text. One may instead consider a pipeline approach in which we first extract noun phrases in text and then identify boundaries within these noun phrases. However, noun phrases in text are not trivially identifiable in the case that they contain unknown words as their constituents. For example, the analyzer erroneously segments the word "ちんすこう" (*chiNsukou*) into "ちん" (*chiN*) and "すこう" (*sukou*), and since the latter is misidentified as a verb, the incorrect noun phrase "ちん" (*chiN*) is extracted.

We have a morphological analyzer with a dictionary that covers frequent words. Although it often misidentifies unknown words, the overall accuracy is reasonably high. For this reason, we like to use the segmentation given by the analyzer as the initial state and to make small changes to them to get a desired output. We also use an annotated corpus, which was used to build the analyzer. As the annotated corpus encodes our segmentation criteria, it can be used to force the models to stick with our segmentation criteria.

We concentrate on segmentation in this paper, but we also need to assign a POS tag to each constituent word and to incorporate segmented noun phrases into the dictionary of the morphological analyzer. We leave them for future work.[3]

4 Non-parametric Bayesian Language Models

To correct the initial segmentation given by the analyzer, we use non-parametric Bayesian language models that have been applied to unsupervised word segmentation (Goldwater et al., 2009). Specifically, we adopt unigram and bigram models. We propose a small modification to these models in order to exploit an annotated corpus when it is much larger than raw text.

4.1 Unigram Model

In the unigram model, a word in the corpus w_i is generated as follows:

$$\begin{aligned} G|\alpha_0, P_0 &\sim \mathrm{DP}(\alpha_0, P_0) \\ w_i|G &\sim G \end{aligned}$$

[1] http://sourceforge.jp/projects/ipadic/

[2] We may augment the text with related documents if the main text is not large enough.

[3] Fortunately, the morphological analyzer JUMAN is capable of handling *phrases*, each of which consists of more than one word. All we need to do is POS tagging.

where G is a distribution over a countably infinite set of words, and $\mathrm{DP}(\alpha_0, P_0)$ is a Dirichlet process (Ferguson, 1973) with the concentration parameter α_0 and the base distribution P_0, for which we use a zerogram model described in Section 4.3.

Marginalizing out G, we can interpret the model as a Chinese restaurant process. Suppose that we have observed $i-1$ words $\mathbf{w_{-i}} = w_1, \cdots, w_{i-1}$, the probability of w_i is given by

$$P_1(w_i = w|\mathbf{w_{-i}}) = \frac{n_w^{\mathbf{w_{-i}}} + \alpha_0 P_0}{i - 1 + \alpha_0}, \qquad (1)$$

where $n_w^{\mathbf{w_{-i}}}$ is the number of word label w observed in $\mathbf{w_{-i}}$.

The unigram model is known for its tendency to misidentify a sequence of words in common collocations as a single word (Goldwater et al., 2009). In preliminary experiments, we found that the unigram model often interpreted a noun phrase as a single word, even in the case that its constituents frequently appeared in text.

4.2 Bigram Model

The problem of the unigram model can be alleviated by the bigram model based on a hierarchical Dirichlet process (Goldwater et al., 2009). In the bigram model, word w_i is generated as follows:

$$\begin{aligned} G|\alpha_0, P_0 &\sim \mathrm{DP}(\alpha_0, P_0) \\ H_l|\alpha_1, G &\sim \mathrm{DP}(\alpha_1, G) \\ w_i|w_{i-1} = l, H_l &\sim H_l \end{aligned}$$

Marginalizing out G and H_l, we can again explain the model with the Chinese restaurant process. Unlike the unigram model, however, the bigram model depends on the latent table assignments $\mathbf{z_{-i}}$.

$$P_2(w_i|\mathbf{h_{-i}}) = \frac{n_{(w_{i-1},w_i)}^{\mathbf{h_{-i}}} + \alpha_1 P_1(w_i|\mathbf{h_{-i}})}{n_{(w_{i-1},*)}^{\mathbf{h_{-i}}} + \alpha_1} \qquad (2)$$

$$P_1(w_i|\mathbf{h_{-i}}) = \frac{t_{w_i}^{\mathbf{h_{-i}}} + \alpha_0 P_0(w_i)}{t_*^{\mathbf{h_{-i}}} + \alpha_0} \qquad (3)$$

where $\mathbf{h_{-i}} = (\mathbf{w_{-i}}, \mathbf{z_{-i}})$, $t_{w_i}^{\mathbf{h_{-i}}}$ is the number of tables labeled with w_i and $t_*^{\mathbf{h_{-i}}}$ is the total number of tables. Thanks to exchangeability, we do not need to track the exact seating assignments. Still, we need to maintain a *histogram* for each w that consists of frequencies of table customers (Blunsom et al., 2009).

4.3 Zerogram Model

Following Nagata (1996) and Mochihashi et al. (2009), we model the zerogram distribution P_0 with the word length k and the character sequence $w = c_1, \cdots, c_k$. Specifically, we define P_0 as the combination of a Poisson distribution with mean λ and a bigram distribution over characters.

$$\begin{aligned} P_0(w) &= P(k;\lambda)\frac{P(c_1, \cdots, c_k, k|\Theta)}{P(k|\Theta)} \\ P(k;\lambda) &= e^{-\lambda}\frac{\lambda^k}{k!} \\ P(c_1, \cdots, c_k, k|\Theta) &= \prod_{i=1}^{k+1} P(c_i|c_{i-1}) \end{aligned}$$

Θ is the zerogram model, and c_0 and c_{k+1} are a word boundary marker. $P(k|\Theta)$ can be estimated by randomly generating words from the model. We use different λ for different scripts. The Japanese writing system uses several scripts, and each word can be classified by script such as hiragana, katakana, kanji, the mixture of hiragana and kanji, etc. The optimal value for λ depends on scripts. For example, katakana, which predominantly denotes loan words, is longer on average than hiragana, which is often used for short function words.

We obtain the parameters and counts from an annotated corpus and fix them during noun phrase segmentation. This greatly simplifies inference but may make the model fragile with unknown words. For this reason, we set a hierarchical Pitman-Yor process prior (Teh, 2006; Goldwater et al., 2006) for the bigram probability $P(c_i|c_{i-1})$ with the base distribution of character unigrams. Note that even character bigrams are sparse because thousands of characters are used in Japanese.

4.4 Mixing an Annotated Corpus

An annotated corpus can be used to force the models to stick with our segmentation criteria. A straightforward way to do this is to mix it with raw text while fixing the segmentation during inference (Mochihashi et al., 2009). A word found in the annotated corpus is generally preferred because it has fixed counts obtained from the annotated corpus. We call this method direct mixing.

Direct mixing is problematic when raw text is much smaller than the annotated corpus. With this

situation, the role of raw text associated with the noun phrase in question is marginalized by the annotated corpus.

As a solution to this problem, we propose another mixing method called back-off mixing. In back-off mixing, the annotated corpus is used as part of the base distribution. In the unigram model, P_0 in (1) is replaced by

$$P_0^{\mathrm{BM}} = \lambda_{\mathrm{IP}} P_0 + (1 - \lambda_{\mathrm{IP}}) P_1^{\mathrm{REF}},$$

where λ_{IP} is a parameter for linear interpolation and P_1^{REF} is the unigram probability obtained from the annotated text. The loose coupling makes the models robust to an imbalanced pair of texts. Similarly, the back-off mixing bigram model replaces P_1 in (2) with

$$P_1^{\mathrm{BM}} = \lambda_{\mathrm{IP}} P_1 + (1 - \lambda_{\mathrm{IP}}) P_2^{\mathrm{REF}}.$$

5 Inference

Collapsed Gibbs sampling is widely used to find an optimal segmentation (Goldwater et al., 2009). In this section, we first show that simple collapsed sampling can hardly escape the initial segmentation. To address this problem, we apply a block sampling algorithm named type-based sampling (Liang et al., 2010) to the unigram model. Since type-based sampling is not applicable to the bigram model, we propose a novel sampling procedure for the bigram model, which we call hybrid type-based sampling.

5.1 Collapsed Sampling

In collapsed Gibbs sampling, the sampler repeatedly samples every possible boundary position, conditioned on the current state of the rest of the corpus. It stochastically decides whether the corresponding local area consists of a single word w_1 or two words $w_2 w_3$ ($w_1 = w_2.w_3$). The conditional probabilities can be derived from (1).

Collapsed sampling is known for slow convergence. This property is especially problematic in our settings where the initial segmentation is given by a morphological analyzer. Since the analyzer deterministically segments text using pre-defined parameters, the resultant segmentation is fairly consistent. Segmentation errors involving unknown words also occur in a regular way. Intuitively, we start with a local optimum although it is not too distant from the global optimum. The collapsed Gibbs sampler is easily entrapped by this local optimum. For this reason, the initial segmentation is usually chosen at random (Goldwater et al., 2009). Sentence-based block sampling is also susceptible to consistent initialization (Liang et al., 2010).

5.2 Type-based Sampling

To achieve fast convergence, we adopt a block sampling algorithm named type-based sampling (Liang et al., 2010). For the unigram model, a type-based sampler jointly samples multiple positions that share the same *type*. Two positions have the same type if the corresponding areas are both of the form w_1 or $w_2 w_3$. Type-based sampling takes advantage of the exchangeability of multiple positions with the same type. Given n positions with the same type, the sampler first samples the number of new boundaries m' ($0 \leq m' \leq n$), and then uniformly arranges m' boundaries out of n positions.

Type-based sampling has the ability to jump from a local optimum (e.g. consistently segmented) to another stable state (consistently unsegmented). While Liang et al. (2010) used random initialization, we take particular note of the possibility of efficiently correcting the consistent segmentation by the analyzer.

Type-based sampling is, however, not applicable to the bigram model for two reasons. The first problem is sparsity. For the bigram model, we need to consider adjacent words, w_l on the left and w_r on the right. This means that each type consists of three or four words, $w_l w_1 w_r$ or $w_l w_2 w_3 w_r$. Consequently, few positions share the same type and we fail to change closely-related areas $w_{l'} w_1 w_{r'}$ and $w_{l'} w_2 w_3 w_{r'}$, making inference inefficient.

The second and more fundamental problem arises from the hierarchical settings. Since the bigram model depends on latent table assignments, the joint distribution of multiple positions is no longer a closed-form function of counts.

Strictly speaking, we need to update the model counts even when sampling one position because the observation of the bigram $\langle w_l w_1 \rangle$, for example, may affect the probability $P_2(w_2 | \mathbf{h}_-, \langle w_l w_1 \rangle)$. Goldwater et al. (2009) approximate the probability by not updating the model counts in collapsed Gibbs

sampling (i.e. $P_2(w_2|\mathbf{h}_-, \langle w_l w_1 \rangle) \approx P_2(w_2|\mathbf{h}_-)$). They rely on the assumption that repeated bigrams are rare. Obviously this does not hold true for type-based sampling. Hence for type-based sampling, we have to update the model counts whenever we observe a new word.

One way to obtain the joint probability is to explicitly simulate the updates of histograms and other model counts. This is very cumbersome as we need to simulate $n + 1$ ways of model updates.

5.3 Hybrid Type-based Sampling

To address these problems, we propose a hybrid sampler which incorporates the Metropolis-Hastings algorithm into blocked Gibbs sampling. Metropolis-Hastings is another technique for sampling from a Markov chain. It first draws a proposed next state h' based on the current state h according to some proposal distribution $Q(h'; h)$. Then it accepts the proposal with the probability of

$$\min\left\{\frac{P(h')Q(h;h')}{P(h)Q(h';h)}, 1\right\}. \quad (4)$$

If the proposal is not accepted, the current state is used as the next state. Metropolis-Hastings is useful when it is difficult to directly sample from P.

We use the Metropolis-Hastings algorithm within Gibbs sampling. Instead of calculating the $n + 1$ probabilities of the number of boundaries, we only compare the current state with a proposed boundary arrangement. Also, the set of positions sampled jointly is chosen at unigram-level type instead of bigram-level type. The positions are no longer exchangeable. Therefore we calculate the conditional probability of one specific boundary arrangement.

When $n = 1$, the only choice is to flip the current state (i.e. $(m, m') \in \{(0, 1), (1, 0)\}$). This reduces to simple collapsed sampling. Otherwise we draw a proposed state in two steps. Given the n positions and the number of current boundaries m, we first draw the number of proposed boundaries m' from a probability distribution $f_n(m'; m)$. We then randomly arrange m' boundaries. The probability mass is uniformly divided by ${}_nC_{m'}$ arrangements. One exception is the case when $m \notin \{0, n\}$ and $m' = m$. In this case we perform permutation to obtain $h' \neq h$. To sum up, the proposal distribution

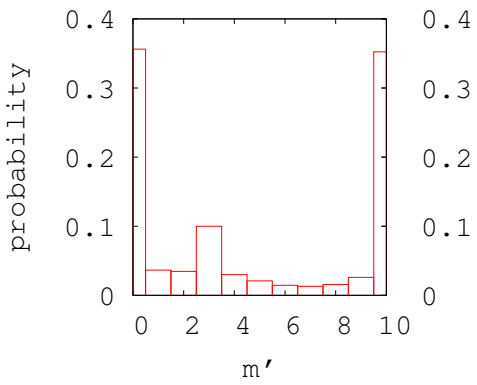

Figure 1: Probability of # of boundaries $f_{10}(m'; 3)$.

is defined as follows:

$$Q(h'; h) = \frac{f_n(m'; m)}{{}_nC_{m'} - I_n(m, m')}, \quad (5)$$

where $I_n(m, m')$ is 1 if $m \notin \{0, n\}$ and $m' = m$; otherwise 0.

We construct $f_n(m'; m)$ by discretizing a beta distribution ($\alpha = \beta < 1$) and a normal distribution with mean m, as shown in Figure 1. The former favors extreme values while the latter prefers smaller moves.

The sampling of each type is done in the following steps.

1. Collect n positions that share a unigram-level type.
2. Propose a new boundary arrangement. In what follows, we only focus on flipped boundaries because the rest does not change the likelihood ratio of the current and proposed states.
3. Calculate the current conditional probability. This can be done by repeatedly applying (2) while removing words one-by-one and updating the model counts accordingly.
4. Calculate the proposed conditional probability while adding words one-by-one.
5. Decide whether to accept the proposal according to (4). If the proposal is accepted, we finalize the arrangement; otherwise we revert to the current state.

We implement skip approximation (Liang et al., 2010) and sample each type once per iteration. This is motivated by the observation that although the

joint sampling of a large number of positions is computationally expensive, the proposal is accepted very infrequently.

5.4 Additional Constraints

Partial annotations (Tsuboi et al., 2008; Neubig and Mori, 2010) can be used for inference. If we know in advance that a certain position is a boundary or non-boundary, we simply keep it unaltered. As partially-annotated text, we can use markup. Suppose that the original text is written with wiki markup as follows:

*JR[[宇野線]][[常山駅]]
[gloss] JR Ube Line Tsuneyama Station

It is clear that the position between "線" (line) and "常" (*tsune*) is a boundary.

Similarly, we can impose our trivial rules of segmentation on the model. For example, we can keep punctuation markers (Li and Sun, 2009) separate from others.

6 Experiments

6.1 Settings

Data Set We evaluated our approach on Japanese Wikipedia. For each entry of Wikipedia, we regarded the title as a noun phrase and used both the title and main text for segmentation. We separately applied our segmentation procedure to each entry.

We constructed the data set as follows. We extracted each entry from an XML dump of Japanese Wikipedia.[4] We normalized the title by dropping trailing parentheses that disambiguate entries with similar names (e.g. "赤城 (空母)" for Akagi (aircraft carrier)). We extracted the main text from wikitext and used wiki markup as boundary markers. We applied both the title and main text to the morphological analyzer JUMAN[5] to get an initial segmentation. If the resultant segmentation conflicted with markup information, we overrode the former. The initial segmentation was also used as the baseline.

We only used entries that satisfied all of the following conditions.

1. The (normalized) title is longer than one character and contains hiragana, katakana and/or kanji.
2. The main text is longer than 1,000 characters.
3. The title appears at least 5 times in the main text.

The first condition ensures that there are segmentation ambiguities. The second and third conditions exclude entries unsuitable for statistical methods. 14% of the entries satisfied these conditions.

We randomly selected 500 entries and manually segmented their titles for evaluation. The 2-person inter-annotator Kappa score was 0.95.

As an annotated corpus, we used Kyoto Text Corpus.[6] It contained 1,675,188 characters.

Models We compared the unigram and bigram models. As for inference procedures, we used collapsed Gibbs sampling (**CL**) for both models, type-based sampling (**TB**) for the unigram model and hybrid type-based sampling (**HTB**) for the bigram model.

We tested two mixing methods of the annotated corpus, direct mixing (**DM**) and back-off mixing (**BM**).

To investigate the effect of initialization, we also tried randomly segmented text as the initial state (**RAND**). For random initialization, we placed a boundary with probability 0.5 on each position unless it was a fixed boundary.

The unigram model has one Dirichlet process concentration hyperparameter α_0 and the bigram model has α_0 and α_1. For each model, we experimented with the following values.
α_0: 0.1, 0.5, 1 5 10, 50, 100, 500, 1,000 and 5,000
α_1: 0.01, 0.05, 0.1, 0.5, 1, 5, 10, 50, 100 and 500
For comparison, we also performed hyperparameter sampling. Following Escobar and West (1995), we set a gamma prior and introduced auxiliary variables to infer concentration parameters from data. For back-off mixing, we used the linear interpolation parameter $\lambda_{\mathrm{IP}} = 0.5$. The zerogram model was trained on the annotated corpus.

In each run, we performed 10 burn-in iterations. We then performed another 10 iterations to collect samples.

Evaluation Metrics We evaluated the segmentation accuracy of 500 entry titles. Specifically we evaluated the performance of a model with precision, recall and the F-score, all of which were based on tokens. We report the score of the most frequent segmentation among 10 samples.

Following Lee et al. (2010), we report the best and median settings of hyperparameters based on the F-score, in addition to inferred values.

In order to evaluate the degree of difference between a pair of segmentations, we employed character-based evaluation. Following Kudo et al. (2004), we converted a word sequence into character-based BI labels and examined labeling disagreements. McNemar's test of significance was based on this metric.

6.2 Results

Table 1 shows segmentation accuracy of various models. One would notice that the baseline score is much lower than the score previously reported regarding newspaper articles (Kudo et al., 2004). It is because unlike newspaper articles, the titles of Wikipedia entries contain an unusually high proportion of unknown words. As suggested by relatively low precision, unknown words tend to be over-segmented by the morphological analyzer.

In the best hyperparameter settings, the back-off mixing bigram model with hybrid type-based sampling (bigram + HTB + BM) significantly outperformed the baseline and achieved the best F-score. It did not performed well in the median setting as it was sensitive to the value of α_1. Hyperparameter estimation led to catastrophic decreases in bigram models as it made the hyperparameters much larger than those in the best settings.

Collapsed sampling (+CL) returned scores comparable to that of the baseline. It is simply because it did not change the initial segmentation a lot. In contrast, type-based sampling (+TB) brought large moves to the unigram model and significantly hurt accuracy. As suggested by relatively low recall, the unigram model prefers under-segmentation.

When combined with (hybrid) type-based sampling (+TB/+HTB), back-off mixing (+BM) increased accuracy from the corresponding non-mixing models. By contrast, direct mixing (+DM) drastically decreased accuracy from the non-mixing models. We can confirm that when the main text is orders of magnitude smaller than the annotated text, the role of constituent words in the main text is underestimated. To our surprise, collapsed sampling with mixing models (+CL, +DM/+BM) outperformed the baseline. However, the scores of type-based sampling (+TB) suggest that with much more iterations, the models would converge to undesired states.

The unigram model with random initialization was indifferent from that with default initialization. By contrast, the performance of the bigram model slightly degenerated with random initialization.

6.3 Convergence

Figure 2 shows how segmentations differed from the initial state in the course of inference.[7] A *diff* is defined as the number of character-based disagreements between the baseline segmentation and a model output. Hyperparameters used were those of the best model with (hybrid) type-based sampling.

We can see that collapsed sampling was almost unable to escape the initial state. With type-based sampling (+TB), the unigram model went further than the bigram model, but to an undesired direction. The bigram model with hybrid type-based sampling (bigram + HTB) converged in few iterations. Although the model with random initialization (+RAND) converged to a nearby point, the initial segmentation by the morphological analyzer realized a bit faster convergence and better accuracy.

Figure 2 shows how acceptance rates changed during inference. For comparison, a sample by a type-based Gibbs sampler was treated as "accepted" if the number of new boundaries was different from that of the current boundaries (i.e. $m' \neq m$). The acceptance rates were low and samplers seemingly stayed around modes.

6.4 Approximation

Up to this point, we consider every possible boundary position. However, this seems wasteful, given that a large portion of text has only marginal influence on the segmentation of the noun phrase in question. For this reason, we implemented approximation named matching skip. We sampled a boundary only if the corresponding local area contained a substring of the noun phrase in question.

Table 2 shows the result of approximation. Hyperparameters used were those of the best models with full sampling. Matching skip steadily worsened performance although not to a large extent. Meanwhile it drastically reduced the number of sampled positions. The median skip rate was 90.87%, with a standard deviation of 8.5.

[7] For a fair comparison, we might need to report changes over time instead of iterations. However, the difference of convergence speed is obvious in the iteration-based comparison although (hybrid) type-based sampling takes several times longer than collapsed sampling in the current naïve implementation.

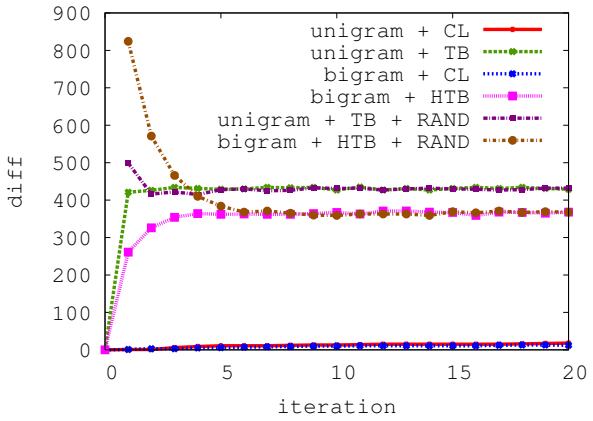

Figure 2: Diffs in the course of iteration. All models were with back-off mixing (+BM).

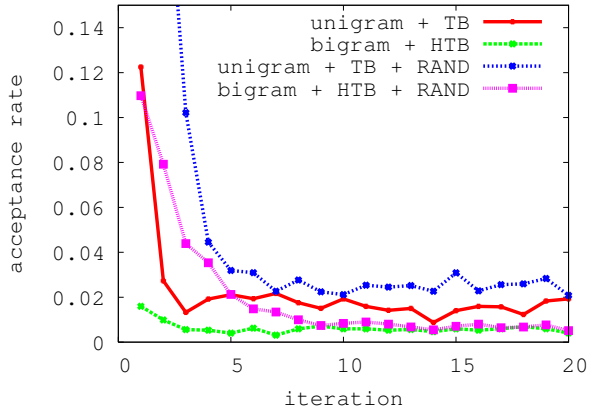

Figure 3: Acceptance rates for a noun phrase in the course of iteration. All models were with back-off mixing (+BM).

6.5 Discussion

Figure 4 shows some segmentations corrected by the back-off mixing bigram model with hybrid type-based sampling. "市比野" (*ichihino*) is a rare place name but can be identified by the model because it is frequently used in the article. "こなみるく" (*konamiruku* in hiragana) seems a pun on "粉ミルク" (*kona miruku*, "powdered milk") and "コナミ" (*konami* in katakana, a company). We consider it as a single word because we cannot reconstruct the etymology solely based on the main text. Note the different scripts. In Japanese, people often change the script to derive a proper noun from a common noun, which a naïve analyzer fails to recognize. It is

Figure 4: Examples of improved segmentations.

very important to identify hiragana words correctly. As hiragana is mainly used to write function words and other basic words, segmentation errors concerning hiragana often bring disastrous effects on applications of morphological analysis. For example, the analyzer over-segments "ちりとてちん" (*chiritotechiN*) into three shorter words among which the second word "とて" (*tote*) is a particle, and this sequence of words is transformed into a terrible parse tree.

Most improvements come from correction of over-segmentation because the initial segmentation by the analyzer shows a tendency of over-segmentation. An example of corrected under-segmentation is "contra-alto clarinet." The presence of "clarinet," "alto" and "contrabass" and others in the main text allowed the model to identify the constituents. On the other hand, the segmentation failed when our assumption about constituents does not hold. For example, the person name "菊池俊吉" (*kikuchi shuNkichi*) is two words but was erroneously combined into a single word by the model because unfortunately he was always referred to by the full name.

7 Conclusions

In this paper, we proposed a new task of Japanese noun phrase segmentation. We adopted non-parametric Bayesian language models and proposed hybrid type-based sampling that can efficiently correct segmentation given by the morphological analyzer. Although supervised segmentation is very competitive, we showed that it can be supplemented with our unsupervised approach.

We applied the proposed method to encyclopedic text to segment noun phrases in it. The proposed method can be applied to other tasks. For example, in unknown word acquisition (Murawaki and Kurohashi, 2008), noun phrases are often acquired from text as single words. We can now segment them into words in a more sophisticated way.

In the future we will assign a POS tag to each word in order to use segmented noun phrases in morphological analysis. We assume that the meaning of constituents in a noun phrase rarely depends on outer context. So it would be helpful to augment them with rich semantic information in advance instead of disambiguating their meaning every time we analyze given text.

Abstract

We present an inference algorithm that organizes observed words (tokens) into structured inflectional paradigms (types). It also naturally predicts the spelling of unobserved forms that are missing from these paradigms, and discovers inflectional principles (grammar) that generalize to wholly unobserved words.

Our Bayesian generative model of the data explicitly represents tokens, types, inflections, paradigms, and locally conditioned string edits. It assumes that inflected word tokens are generated from an infinite mixture of inflectional paradigms (string tuples). Each paradigm is sampled all at once from a graphical model, whose potential functions are weighted finite-state transducers with language-specific parameters to be learned. These assumptions naturally lead to an elegant empirical Bayes inference procedure that exploits Monte Carlo EM, belief propagation, and dynamic programming. Given 50–100 seed paradigms, adding a 10-million-word corpus reduces prediction error for morphological inflections by up to 10%.

1 Introduction

1.1 Motivation

Statistical NLP can be difficult for morphologically rich languages. Morphological transformations on words increase the size of the observed vocabulary, which unfortunately masks important generalizations. In Polish, for example, each lexical verb has literally 100 inflected forms (Janecki, 2000). That is, a single *lexeme* may be realized in a corpus as many different word types, which are differently inflected for person, number, gender, tense, mood, etc.

All this makes lexical features even sparser than they would be otherwise. In machine translation or text generation, it is difficult to learn *separately* how to translate, or when to generate, each of these many word types. In text analysis, it is difficult to learn lexical features (as cues to predict topic, syntax, semantics, or the next word), because one must learn a separate feature for each word form, rather than generalizing across inflections.

Our engineering goal is to address these problems by mostly-unsupervised learning of morphology. Our linguistic goal is to build a generative probabilistic model that directly captures the basic representations and relationships assumed by morphologists. This model suffices to *define* a posterior distribution over analyses of any given collection of type and/or token data. Thus we obtain scientific data interpretation as probabilistic inference (Jaynes, 2003). Our computational goal is to *estimate* this posterior distribution.

1.2 What is Estimated

Our inference algorithm jointly reconstructs *token*, *type*, and *grammar* information about a language's morphology. This has not previously been attempted.

Tokens: We will tag each word token in a corpus with (1) a *part-of-speech (POS) tag*,[1] (2) an *inflection*, and (3) a *lexeme*. A token of `broken` might be tagged as (1) a VERB and more specifically as (2) the past participle inflection of (3) the abstract lexeme *break*.[2]

Reconstructing the latent lexemes and inflections allows the features of other statistical models to consider them. A parser may care that `broken` is a past participle; a search engine or question answering system may care that it is a form of *break*; and a translation system may care about both facts.

* This research was done at Johns Hopkins University as part of the first author's dissertation work. It was supported by the Human Language Technology Center of Excellence and by the National Science Foundation under Grant No. 0347822.

[1] POS tagging may be done as part of our Bayesian model or beforehand, as a preprocessing step. Our experiments chose the latter option, and then analyzed only the verbs (see section 8).

[2] We use cursive font for abstract lexemes to emphasize that they are atomic objects that do not decompose into letters.

Edinburgh, Scotland, UK, July 27–31, 2011.

		singular	plural
present	1st-person	breche	brechen
	2nd-person	brichst	brecht
	3rd-person	bricht	brechen
past	1st-person	brach	brachen
	2nd-person	brachst	bracht
	3rd-person	brach	brachen

Table 1: Part of a morphological paradigm in German, showing the spellings of some inflections of the lexeme *break* (whose lemma is brechen), organized in a grid.

Types: In carrying out the above, we will reconstruct specific *morphological paradigms* of the language. A paradigm is a grid of all the inflected forms of some lexeme, as illustrated in Table 1. Our reconstructed paradigms will include our predictions of inflected forms that were never observed in the corpus. This tabular information about the types (rather than the tokens) of the language may be separately useful, for example in translation and other generation tasks, and we will evaluate its accuracy.

Grammar: We estimate *parameters* $\vec{\theta}$ that describe general patterns in the language. We learn a prior distribution over inflectional paradigms by learning (e.g.) how a verb's suffix or stem vowel tends to change when it is pluralized. We also learn (e.g.) whether singular or plural forms are more common. Our basic strategy is Monte Carlo EM, so these parameters tell us how to guess the paradigms (Monte Carlo E step), then these reconstructed paradigms tell us how to reestimate the parameters (M step), and so on iteratively. We use a few supervised paradigms to initialize the parameters and help reestimate them.

2 Overview of the Model

We begin by sketching the main ideas of our model, first reviewing components that we introduced in earlier papers. Sections 5–7 will give more formal details. Full details and more discussion can be found in the first author's dissertation (Dreyer, 2011).

2.1 Modeling Morphological Alternations

We begin with a family of joint distributions $p(x, y)$ over string pairs, parameterized by $\vec{\theta}$. For example, to model just the semi-systematic relation between a German lemma and its 3rd-person singular present form, one could train $\vec{\theta}$ to maximize the likelihood of (x, y) pairs such as (brechen, bricht). Then, given a lemma x, one could predict its inflected form y via $p(y \mid x)$, and vice-versa.

Dreyer et al. (2008) define such a family via a log-linear model with latent alignments,

$$p(x, y) = \sum_a p(x, y, a) \propto \sum_a \exp(\vec{\theta} \cdot \vec{f}(x, y, a))$$

Here a ranges over monotonic 1-to-1 character alignments between x and y. $\propto$ means "proportional to" (p is normalized to sum to 1). $\vec{f}$ extracts a vector of local features from the aligned pair by examining trigram windows. Thus $\vec{\theta}$ can reward or penalize specific features—e.g., insertions, deletions, or substitutions in specific contexts, as well as trigram features of x and y separately.[3] Inference and training are done by dynamic programming on finite-state transducers.

2.2 Modeling Morphological Paradigms

A paradigm such as Table 1 describes how some abstract lexeme (*break*) is *expressed* in German.[4] We evaluate *whole paradigms* as linguistic objects, following word-and-paradigm or realizational morphology (Matthews, 1972; Stump, 2001). That is, we presume that some language-specific distribution $p(\pi)$ defines whether a paradigm π is a grammatical—and *a priori* likely—way for a lexeme to express itself in the language. Learning $p(\pi)$ helps us reconstruct paradigms, as described at the end of section 1.2.

Let $\pi = (x_1, x_2, \ldots)$. In Dreyer and Eisner (2009), we showed how to model $p(\pi)$ as a renormalized *product* of many pairwise distributions $p_{rs}(x_r, x_s)$, each having the log-linear form of section 2.1:

$$p(\pi) \propto \prod_{r,s} p_{rs}(x_r, x_s) \propto \exp(\sum_{r,s} \vec{\theta} \cdot \overrightarrow{f_{rs}}(x_r, x_s, a_{rs}))$$

This is an undirected graphical model (MRF) over *string-valued* random variables x_s; each factor p_{rs} evaluates the relationship between some pair of strings. Note that it is still a log-linear model, and parameters in $\vec{\theta}$ can be reused across different rs pairs.

To guess at unknown strings in the paradigm, Dreyer and Eisner (2009) show how to perform approximate inference on such an MRF by loopy belief

[3] Dreyer et al. (2008) devise additional helpful features based on enriching the aligned pair with additional latent information, but our present experiments drop those for speed.

[4] Our present experiments focus on orthographic forms, because we are learning from a written corpus. But it would be natural to use phonological forms instead, or to include both in the paradigm so as to model their interrelationships.

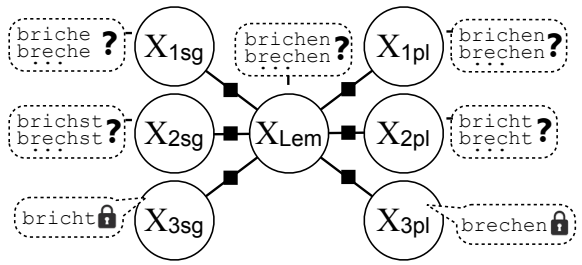

Figure 1: A distribution over paradigms modeled as an MRF over 7 strings. Random variables X_{Lem}, X_{1st}, etc., are the lemma, the 1st person form, etc. Suppose two forms are observed (denoted by the "lock" icon). Given these observations, belief propagation estimates the posterior marginals over the other variables (denoted by "?").

propagation, using finite-state operations. It is not necessary to include all rs pairs. For example, Fig. 1 illustrates the result of belief propagation on a simple MRF whose factors relate all inflected forms to a common (possibly unobserved) lemma, but not directly to one another.[5]

Our method could be used with any $p(\pi)$. To speed up inference (see footnote 7), our present experiments actually use the *directed* graphical model variant of Fig. 1—that is, $p(\pi) = p_1(x_1) \cdot \prod_{s>1} p_{1s}(x_s \mid x_1)$, where x_1 denotes the lemma.

2.3 Modeling the Lexicon (types)

Dreyer and Eisner (2009) learned $\vec{\theta}$ by partially observing some paradigms (type data). That work, while rather accurate at predicting inflected forms, sometimes erred: it predicted spellings that never occurred in text, even for forms that "should" be common. To fix this, we shall incorporate an unlabeled or POS-tagged corpus (token data) into learning.

We therefore need a model for generating tokens—a *probabilistic lexicon* that specifies which inflections of which lexemes are common, and how they are spelled. We do not know our language's probabilistic lexicon, but we assume it was generated as follows:

1. Choose parameters $\vec{\theta}$ of the MRF. This defines $p(\pi)$: which paradigms are likely *a priori*.
2. Choose a distribution over the abstract lexemes.
3. For each lexeme, choose a distribution over its inflections.
4. For each lexeme, choose a paradigm that will be used to express the lexeme orthographically.

Details are given later. Briefly, step 1 samples $\vec{\theta}$ from a Gaussian prior. Step 2 samples a distribution from a Dirichlet process. This chooses a countable number of lexemes to have positive probability in the language, and decides which ones are most common. Step 3 samples a distribution from a Dirichlet. For the lexeme *think*, this might choose to make 1st-person singular more common than for typical verbs. Step 4 just samples IID from $p(\pi)$.

In our model, each part of speech generates its own lexicon: VERBs are inflected differently from NOUNs (different parameters and number of inflections). The size and layout of (e.g.) VERB paradigms is language-specific; we currently assume it is given by a linguist, along with a few supervised VERB paradigms.

2.4 Modeling the Corpus (tokens)

At present, we use only a very simple exchangeable model of the corpus. We assume that each word was independently sampled from the lexicon given its part of speech, with no other attention to context.

For example, a token of `brechen` may have been chosen by choosing frequent lexeme *break* from the VERB lexicon; then choosing 1st-person plural given *break*; and finally looking up that inflection's spelling in *break*'s paradigm. This final lookup is deterministic since the lexicon has already been generated.

3 A Sketch of Inference and Learning

3.1 Gibbs Sampling Over the Corpus

Our job in inference is to reconstruct the lexicon that was used and how each token was generated from it (i.e., which lexeme and inflection?). We use collapsed Gibbs sampling, repeatedly guessing a reanalysis of each token in the context of all others. Gradually, similar tokens get "clustered" into paradigms (section 4).

The state of the sampler is illustrated in Fig. 2. The bottom half shows the current analyses of the verb tokens. Each is associated with a particular slot in some paradigm. We are now trying to reanalyze `brechen` at position ❼. The dashed arrows show some possible analyses.

[5] This view is adopted by some morphological theorists (Albright, 2002; Chan, 2006), although see Appendix E.2 for a caution about syncretism. Note that when the lemma is unobserved, the other forms do still influence one another indirectly.

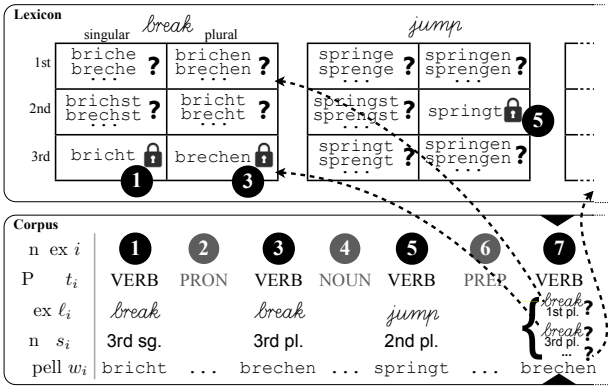

Figure 2: A state of the Gibbs sampler (note that the assumed generative process runs roughly top-to-bottom). Each corpus token i has been tagged with part of speech t_i, lexeme ℓ_i and inflection s_i. Token ❶ has been tagged as *break* and 3rd sg., which locked the corresponding type spelling in the paradigm to the spelling $w_1 =$ `bricht`; similarly for ❸ and ❺. Now w_7 is about to be reanalyzed.

The key intuition is that the current analyses of the *other* verb tokens imply a posterior distribution over the VERB lexicon, shown in the top half of the figure.

First, because of the current analyses of ❶ and ❸, the 3rd-person spellings of *break* are already constrained to match w_1 and w_3 (the "lock" icon).

Second, belief propagation as in Fig. 1 tells us which other inflections of *break* (the "?" icon) are plausibly spelled as `brechen`, and how likely they are to be spelled that way.

Finally, the fact that other tokens are associated with *break* suggest that this is a popular lexeme, making it a plausible explanation of ❼ as well. (This is the "rich get richer" property of the Chinese restaurant process; see section 6.6.) Furthermore, certain inflections of *break* appear to be especially popular.

In short, given the other analyses, we know which inflected lexemes in the lexicon are likely, *and* how likely each one is to be spelled as `brechen`. This lets us compute the relative probabilities of the possible analyses of token ❼, so that the Gibbs sampler can accordingly choose one of these analyses at random.

3.2 Monte Carlo EM Training of $\vec{\theta}$

For a given $\vec{\theta}$, this Gibbs sampler converges to the posterior distribution over analyses of the full corpus. To improve our $\vec{\theta}$ estimate, we periodically adjust $\vec{\theta}$ to maximize or increase the probability of the most recent sample(s). For example, having tagged $w_5 =$ `springt` as $s_5 =$ 2nd-person plural may strengthen our estimated probability that 2nd-person spellings tend to end in `-t`. That revision to $\vec{\theta}$, in turn, will influence future moves of the sampler.

If the sampler is run long enough between calls to the $\vec{\theta}$ optimizer, this is a Monte Carlo EM procedure (see end of section 1.2). It uses the data to optimize a language-specific prior $p(\pi)$ over paradigms—an empirical Bayes approach. (A fully Bayesian approach would resample $\vec{\theta}$ as part of the Gibbs sampler.)

3.3 Collapsed Representation of the Lexicon

The lexicon is *collapsed out* of our sampler, in the sense that we do not represent a single guess about the infinitely many lexeme probabilities and paradigms. What we store about the lexicon is information about its full posterior distribution: the top half of Fig. 2.

Fig. 2 names its lexemes as *break* and *jump* for expository purposes, but of course the sampler cannot reconstruct such labels. Formally, these labels are collapsed out, and we represent lexemes as anonymous objects. Tokens ❶ and ❸ are tagged with the *same* anonymous lexeme (which will correspond to sitting at the same table in a Chinese restaurant process).

For each lexeme ℓ and inflection s, we maintain pointers to any tokens currently tagged with the slot (ℓ, s). We also maintain an approximate marginal distribution over the spelling of that slot:[6]

1. If (ℓ, s) points to at least one token i, then we know (ℓ, s) is spelled as w_i (with probability 1).

2. Otherwise, the spelling of (ℓ, s) is not known. But if some spellings in ℓ's paradigm are known, store a truncated distribution that enumerates the 25 most likely spellings for (ℓ, s), according to loopy belief propagation within the paradigm.

3. Otherwise, we have observed nothing about ℓ: it is currently unused. All such ℓ share the same marginal distribution over spellings of (ℓ, s): the marginal of the prior $p(\pi)$. Here a 25-best list could not cover all plausible spellings. Instead we store a probabilistic finite-state language model that approximates this marginal.[7]

[6] Cases 1 and 2 below must in general be *updated* whenever a slot switches between having 0 and more than 0 tokens. Cases 2 and 3 must be updated when the parameters $\vec{\theta}$ change.

[7] This character trigram model is fast to build if $p(\pi)$ is de-

A hash table based on cases 1 and 2 can now be used to rapidly map any word w to a list of slots of existing lexemes that might plausibly have generated w. To ask whether w might instead be an inflection s of a novel lexeme, we score w using the probabilistic finite-state automata from case 3, one for each s.

The Gibbs sampler randomly chooses one of these analyses. If it chooses the "novel lexeme" option, we create an arbitrary new lexeme object in memory. The number of explicitly represented lexemes is always finite (at most the number of corpus tokens).

4 Interpretation as a Mixture Model

It is common to cluster points in $\mathbb{R}^n$ by assuming that they were generated from a *mixture of Gaussians*, and trying to reconstruct which points were generated from the same Gaussian.

We are similarly clustering word tokens by assuming that they are generated from a *mixture of weighted paradigms*. After all, each word token was obtained by randomly sampling a weighted paradigm (i.e., a cluster) and then randomly sampling a word from it.

Just as each Gaussian in a Gaussian mixture is a distribution over all points $\mathbb{R}^n$, each weighted paradigm is a distribution over all spellings Σ^* (but assigns probability > 0 to only a finite subset of Σ^*).

Inference under our model clusters words together by tagging them with the same lexeme. It tends to group words that are "similar" in the sense that the base distribution $p(\pi)$ predicts that they would tend to co-occur within a paradigm. Suppose a corpus contains several unlikely but similar tokens, such as `discombobulated` and `discombobulating`. A language might have one probable lexeme from whose paradigm all these words were sampled. It is much less likely to have several probable lexemes that all *coincidentally* chose spellings that started with `discombobulat-`. Generating `discombobulat-` only once is cheaper (especially for such a long prefix), so the former explanation has higher probability. This is like explaining nearby points in $\mathbb{R}^n$ as samples from the same Gaussian. Of course, our model is sensitive to more than shared prefixes, and it does not merely cluster words into a paradigm but assigns them to particular inflectional slots in the paradigm.

fined as at the end of section 2.2. If not, one could still try belief propagation; or one could approximate by estimating a language model from the spellings associated with slot s by cases 1 and 2.

4.1 The Dirichlet Process Mixture Model

Our mixture model uses an *infinite* number of mixture components. This avoids placing a prior bound on the number of lexemes or paradigms in the language. We assume that a natural language has an infinite lexicon, although most lexemes have sufficiently low probability that they have not been used in our training corpus or even in human history (yet).

Our specific approach corresponds to a Bayesian technique, the Dirichlet process mixture model. Appendix A (supplementary material) explains the DPMM and discusses it in our context.

The DPMM would standardly be presented as generating a distribution over countably many Gaussians or paradigms. Our variant in section 2.3 instead broke this into two steps: it first generated a distribution over countably many lexemes (step 2), and then generated a weighted paradigm for each lexeme (steps 3–4). This construction keeps distinct lexemes separate even if they happen to have identical paradigms (polysemy). See Appendix A for a full discussion.

5 Formal Notation

5.1 Value Types

We now describe our probability model in more formal detail. It considers the following types of mathematical objects. (We use consistent lowercase letters for values of these types, and consistent fonts for constants of these types.)

A **word** w, such as `broken`, is a finite string of any length, over some finite, given alphabet Σ.

A **part-of-speech tag** t, such as VERB, is an element of a certain finite set $\mathcal{T}$, which in this paper we assume to be given.

An **inflection** s,[8] such as past participle, is an element of a finite set $\mathcal{S}_t$. A token's part-of-speech tag $t \in \mathcal{T}$ determines its set $\mathcal{S}_t$ of possible inflections. For tags that do not inflect, $|\mathcal{S}_t| = 1$. The sets $\mathcal{S}_t$ are language-specific, and we assume in this paper that they are given by a linguist rather than learned. A linguist also specifies features of the inflections: the grid layout in Table 1 shows that 4 of the 12 inflections in $\mathcal{S}_{\text{VERB}}$ share the "2nd-person" feature.

[8] We denote inflections by s because they represent "slots" in paradigms (or, in the metaphor of section 6.7, "seats" at tables in a Chinese restaurant). These slots (or seats) are filled by words.

A **paradigm** for $t \in \mathcal{T}$ is a mapping $\pi : \mathcal{S}_t \to \Sigma^*$, specifying a **spelling** for each inflection in $\mathcal{S}_t$. Table 1 shows one VERB paradigm.

A **lexeme** ℓ is an abstract element of some lexical space $\mathcal{L}$. Lexemes have no internal semantic structure: the only question we can ask about a lexeme is whether it is equal to some other lexeme. There is no upper bound on how many lexemes can be discovered in a text corpus; $\mathcal{L}$ is infinite.

5.2 Random Quantities

Our generative model of the corpus is a joint probability distribution over a collection of random variables. We describe them in the same order as section 1.2.

Tokens: The corpus is represented by *token* variables. In our setting the sequence of words $\vec{w} = w_1, \ldots, w_n \in \Sigma^*$ is observed, along with n. We must recover the corresponding part-of-speech tags $\vec{t} = t_1, \ldots, t_n \in \mathcal{T}$, lexemes $\vec{\ell} = \ell_1, \ldots, \ell_n \in \mathcal{L}$, and inflections $\vec{s} = s_1, \ldots, s_n$, where $(\forall i) s_i \in \mathcal{S}_{t_i}$.

Types: The lexicon is represented by *type* variables. For each of the infinitely many lexemes $\ell \in \mathcal{L}$, and each $t \in \mathcal{T}$, the paradigm $\pi_{t,\ell}$ is a function $\mathcal{S}_t \to \Sigma^*$. For example, Table 1 shows a possible value $\pi_{\text{VERB},\textit{break}}$. The various spellings in the paradigm, such as $\pi_{\text{VERB},\textit{break}}(\text{1st-person sing. pres.}) = \texttt{breche}$, are string-valued random variables that are correlated with one another.

Since the lexicon is to be probabilistic (section 2.3), $G_t(\ell)$ denotes tag t's distribution over lexemes $\ell \in \mathcal{L}$, while $H_{t,\ell}(s)$ denotes the tagged lexeme (t, ℓ)'s distribution over inflections $s \in \mathcal{S}_t$.

Grammar: Global properties of the language are captured by *grammar* variables that cut across lexical entries: our parameters $\vec{\theta}$ that describe typical inflectional alternations, plus parameters $\vec{\phi_t}, \alpha_t, \alpha'_t, \vec{\tau}$ (explained below). Their values control the overall shape of the probabilistic lexicon that is generated.

6 The Formal Generative Model

We now fully describe the generative process that was sketched in section 2. Step by step, it randomly chooses an assignment to all the random variables of section 5.2. Thus, a given assignment's probability—which section 3's algorithms consult in order to resample or improve the current assignment—is the product of the probabilities of the individual choices, as described in the sections below. (Appendix B provides a drawing of this as a graphical model.)

6.1 Grammar Variables $p(\vec{\theta}), p(\vec{\phi_t}), p(\alpha_t), p(\alpha'_t)$

First select the grammar variables from a prior. (We will see below how these variables get used.) Our experiments used fairly flat priors. Each weight in $\vec{\theta}$ or $\vec{\phi_t}$ is drawn IID from $\mathcal{N}(0, 10)$, and each α_t or α'_t from a Gamma with mode 10 and variance 1000.

6.2 Paradigms $p(\pi_{t,\ell} \mid \vec{\theta})$

For each $t \in \mathcal{T}$, let $D_t(\pi)$ denote the distribution over paradigms that was presented in section 2.2 (where it was called $p(\pi)$). D_t is fully specified by our graphical model for paradigms of part of speech t, together with its parameters $\vec{\theta}$ as generated above.

This is the linguistic core of our model. It considers spellings: D_{VERB} describes what verb paradigms typically look like in the language (e.g., Table 1).

Parameters in $\vec{\theta}$ may be shared across parts of speech t. These "backoff" parameters capture general phonotactics of the language, such as prohibited letter bigrams or plausible vowel changes.

For each possible tagged lexeme (t, ℓ), we now draw a paradigm $\pi_{t,\ell}$ from D_t. Most of these lexemes will end up having probability 0 in the language.

6.3 Lexical Distributions $p(G_t \mid \alpha_t)$

We now formalize section 2.3. For each $t \in \mathcal{T}$, the language has a distribution $G_t(\ell)$ over lexemes. We draw G_t from a Dirichlet process $\text{DP}(G, \alpha_t)$, where G is the **base distribution** over $\mathcal{L}$, and $\alpha_t > 0$ is a **concentration parameter** generated above. If α_t is small, then G_t will tend to have the property that most of its probability mass falls on relatively few of the lexemes in $\mathcal{L}_t \stackrel{\text{def}}{=} \{\ell \in \mathcal{L} : G_t(\ell) > 0\}$. A *closed-class tag* is one whose α_t is especially small.

For G to be a uniform distribution over an infinite lexeme set $\mathcal{L}$, we need $\mathcal{L}$ to be uncountable.[9] However, it turns out[10] that with probability 1, each $\mathcal{L}_t$ is *countably* infinite, and all the $\mathcal{L}_t$ are disjoint. So each lexeme $\ell \in \mathcal{L}$ is selected by at most one tag t.

[9] For example, $\mathcal{L} \stackrel{\text{def}}{=} [0, 1]$, so that *break* is merely a suggestive nickname for a lexeme such as 0.2538159.

[10] This can be seen by considering the stick-breaking construction of the Dirichlet process that (Sethuraman, 1994; Teh et al., 2006). A separate stick is broken for each G_t. See Appendix A.

6.4 Inflectional Distributions $p(H_{t,\ell} \mid \overrightarrow{\phi_t}, \alpha'_t)$

For each tagged lexeme (t, ℓ), the language specifies some distribution $H_{t,\ell}$ over its inflections.

First we construct backoff distributions H_t that are independent of ℓ. For each tag $t \in \mathcal{T}$, let H_t be some base distribution over $\mathcal{S}_t$. As $\mathcal{S}_t$ could be large in some languages, we exploit its grid structure (Table 1) to reduce the number of parameters of H_t. We take H_t to be a log-linear distribution with parameters $\overrightarrow{\phi_t}$ that refer to *features* of inflections. E.g., the 2nd-person inflections might be *systematically* rare.

Now we model each $H_{t,\ell}$ as an independent draw from a finite-dimensional Dirichlet distribution with mean H_t and concentration parameter α'_t. E.g., *think* might be biased toward 1st-person sing. present.

6.5 Part-of-Speech Tag Sequence $p(\vec{t} \mid \vec{\tau})$

In our current experiments, $\vec{t}$ is given. But in general, to discover tags and inflections simultaneously, we can suppose that the tag sequence $\vec{t}$ (and its length n) are generated by a Markov model, with tag bigram or trigram probabilities specified by some parameters $\vec{\tau}$.

6.6 Lexemes $p(\ell_i \mid G_{t_i})$

We turn to section 2.4. A lexeme token depends on its tag: draw ℓ_i from G_{t_i}, so $p(\ell_i \mid G_{t_i}) = G_{t_i}(\ell_i)$.

6.7 Inflections $p(s_i \mid H_{t_i,\ell_i})$

An inflection slot depends on its tagged lexeme: we draw s_i from H_{t_i,ℓ_i}, so $p(s_i \mid H_{t_i,\ell_i}) = H_{t_i,\ell_i}(s_i)$.

6.8 Spell-out $p(w_i \mid \pi_{t_i,\ell_i}(s_i))$

Finally, we generate the word w_i through a deterministic *spell-out* step.[11] Given the tag, lexeme, and inflection at position i, we generate the word w_i simply by looking up its spelling in the appropriate paradigm. So $p(w_i \mid \pi_{t_i,\ell_i}(s_i))$ is 1 if $w_i = \pi_{t_i,\ell_i}(s_i)$, else 0.

6.9 Collapsing the Assignment

Again, a *full* assignment's probability is the product of all the above factors (see drawing in Appendix B).

[11] To account for typographical errors in the corpus, the spell-out process could easily be made nondeterministic, with the observed word w_i derived from the correct spelling $\pi_{t_i,\ell_i}(s_i)$ by a noisy channel model (e.g., (Toutanova and Moore, 2002)) represented as a WFST. This would make it possible to analyze `brkoen` as a misspelling of a common or contextually likely word, rather than treating it as an unpronounceable, irregularly inflected neologism, which is presumably less likely.

But computationally, our sampler's state leaves the G_t *unspecified*. So its probability is the integral of $p(\text{assignment})$ over all possible G_t. As G_t appears only in the factors from headings 6.3 and 6.6, we can just integrate it out of *their* product, to get a collapsed sub-model that generates $p(\vec{\ell} \mid \vec{t}, \vec{\alpha})$ directly:

$$\int_{G_{\text{ADJ}}} \cdots \int_{G_{\text{VERB}}} d\mathbf{G} \left(\prod_{t \in \mathcal{T}} p(G_t \mid \alpha_t) \right) \left(\prod_{i=1}^{n} p(\ell_i \mid G_{t_i}) \right)$$
$$= p(\vec{\ell} \mid \vec{t}, \vec{\alpha}) = \prod_{i=1}^{n} p(\ell_i \mid \ell_1, \ldots \ell_{i-1}\ \vec{t}, \vec{\alpha})$$

where it turns out that the factor that generates ℓ_i is proportional to $|\{j < i : \ell_j = \ell_i \text{ and } t_j = t_i\}|$ if that integer is positive, else proportional to $\alpha_{t_i} G(\ell_i)$.

Metaphorically, each tag t is a *Chinese restaurant* whose *tables* are labeled with lexemes. The tokens are hungry *customers*. Each customer $i = 1, 2, \ldots, n$ enters restaurant t_i in turn, and ℓ_i denotes the label of the table she joins. She picks an occupied table with probability proportional to the number of previous customers already there, or with probability proportional to α_{t_i} she starts a new table whose label is drawn from G (it is novel with probability 1, since G gives infinitesimal probability to each old label).

Similarly, we integrate out the infinitely many lexeme-specific distributions $H_{t,\ell}$ from the product of 6.4 and 6.7, replacing it by the collapsed distribution

$$p(\vec{s} \mid \vec{\ell}, \vec{t}, \overrightarrow{\phi_t}, \overrightarrow{\alpha'}) \qquad \textit{[recall that } \overrightarrow{\phi_t} \textit{ determines } H_t\textit{]}$$
$$= \prod_{i=1}^{n} p(s_i \mid s_1, \ldots s_{i-1},\ \vec{\ell}, \vec{t}, \overrightarrow{\phi_t}, \overrightarrow{\alpha'})$$

where the factor for s_i is proportional to $|\{j < i : s_j = s_i \text{ and } (t_j, \ell_j) = (t_i, \ell_i)\}| + \alpha'_{t_i} H_{t_i}(s_i)$.

Metaphorically, each table ℓ in Chinese restaurant t has a fixed, finite set of *seats* corresponding to the inflections $s \in \mathcal{S}_t$. Each seat is really a bench that can hold any number of customers (tokens). When customer i chooses to sit at table ℓ_i, she also chooses a seat s_i at that table (see Fig. 2), choosing either an already occupied seat with probability proportional to the number of customers already in that seat, or else a random seat (sampled from H_{t_i} and not necessarily empty) with probability proportional to α'_{t_i}.

7 Inference and Learning

As section 3 explained, the learner alternates between a Monte Carlo E step that uses Gibbs sampling to

sample from the posterior of $(\vec{s}, \vec{\ell}, \vec{t})$ given $\vec{w}$ and the grammar variables, and an M step that adjusts the grammar variables to maximize the probability of the $(\vec{w}, \vec{s}, \vec{\ell}, \vec{t})$ samples given those variables.

7.1 Block Gibbs Sampling

As in Gibbs sampling for the DPMM, our sampler's basic move is to reanalyze token i (see section 3). This corresponds to making customer i invisible and then guessing where she is probably sitting—which restaurant t, table ℓ, and seat s?—given knowledge of w_i and the locations of all other customers.[12]

Concretely, the sampler guesses location (t_i, ℓ_i, s_i) with probability *proportional* to the product of

- $p(t_i \mid t_{i-1}, t_{i+1}, \vec{\tau})$ (from section 6.5)
- the probability (from section 6.9) that a new customer in restaurant t_i chooses table ℓ_i, given the *other* customers in that restaurant (and α_{t_i})[13]
- the probability (from section 6.9) that a new customer at table ℓ_i chooses seat s_i, given the *other* customers at that table (and $\overrightarrow{\phi_{t_i}}$ and α'_{t_i})[13]
- the probability (from section 3.3's belief propagation) that $\pi_{t_i,\ell_i}(s_i) = w_i$ (given $\vec{\theta}$).

We sample only from the (t_i, ℓ_i, s_i) candidates for which the last factor is non-negligible. These are found with the hash tables and FSAs of section 3.3.

7.2 Semi-Supervised Sampling

Our experiments also consider the semi-supervised case where a few **seed paradigms**—*type* data—are fully or partially observed. Our samples should also be conditioned on these observations. We assume that our supervised list of observed paradigms was generated by sampling from G_t.[14] We can modify our setup for this case: certain tables have a **host** who dictates the spelling of some seats and attracts appropriate customers to the table. See Appendix C.

7.3 Parameter Gradients

Appendix D gives formulas for the M step gradients.

[12] Actually, to improve mixing time, we choose a currently active lexeme ℓ uniformly at random, make *all* customers $\{i : \ell_i = \ell\}$ invisible, and sequentially guess where they are sitting.

[13] This is simple to find thanks to the exchangeability of the CRP, which lets us pretend that i entered the restaurant last.

[14] Implying that they are assigned to lexemes with non-negligible probability. We would learn nothing from a list of merely *possible* paradigms, since $\mathcal{L}_t$ is infinite and every conceivable paradigm is assigned to *some* $\ell \in \mathcal{L}_t$ (in fact many!).

	50 seed paradigms			100 seed paradigms		
Corpus size	0	10^6	10^7	0	10^6	10^7
Accuracy	89.9	90.6	**90.9**	91.5	92.0	**92.2**
Edit dist.	0.20	0.19	**0.18**	0.18	**0.17**	**0.17**

Table 2: Whole-word accuracy and edit distance of predicted inflection forms given the lemma. Edit distance to the correct form is measured in characters. Best numbers per set of seed paradigms in bold (statistically significant on our large test set under a paired permutation test, $p < 0.05$). Appendix E breaks down these results per inflection and gives an error analysis and other statistics.

8 Experiments

8.1 Experimental Design

We evaluated how well our model learns German verbal morphology. As *corpus* we used the first 1 million or 10 million words from WaCky (Baroni et al., 2009). For *seed and test paradigms* we used verbal inflectional paradigms from the CELEX morphological database (Baayen et al., 1995). We fully observed the seed paradigms. For each test paradigm, we observed the lemma type (Appendix C) and evaluated how well the system completed the other 21 forms (see Appendix E.2) in the paradigm.

We simplified inference by fixing the POS tag sequence to the automatic tags delivered with the WaCky corpus. The result that we evaluated for each variable was the value whose probability, averaged over the entire Monte Carlo EM run,[15] was highest. For more details, see (Dreyer, 2011).

All results are averaged over 10 different training/test splits of the CELEX data. Each split sampled 100 paradigms as seed data and used the remaining 5,415 paradigms for evaluation.[16] From the 100 paradigms, we also sampled 50 to obtain results with smaller seed data.[17]

8.2 Results

Type-based Evaluation. Table 2 shows the results of predicting verb inflections, when running with no corpus, versus with an unannotated corpus of size 10^6 and 10^7 words. Just using 50 seed paradigms, but

[15] This includes samples from before $\vec{\theta}$ has converged, somewhat like the voted perceptron (Freund and Schapire, 1999).

[16] 100 further paradigms were held out for future use.

[17] Since these seed paradigms are sampled uniformly from a set of CELEX paradigms, most of them are regular. We actually only used 90 and 40 for training, reserving 10 as development data for sanity checks and for deciding when to stop.

Bin	Frequency	# Verb Forms
1	0–9	116,776
2	10–99	4,623
3	100–999	1,048
4	1,000–9,999	95
5	10,000–	10
all	*any*	122,552

Table 3: The inflected verb forms from 5,615 inflectional paradigms, split into 5 token frequency bins. The frequencies are based on the 10-million word corpus.

Bin	50 seed paradigms			100 seed paradigms		
	0	10^6	10^7	0	10^6	10^7
1	90.5	91.0	**91.3**	92.1	92.4	**92.6**
2	78.1	**84.5**	84.4	80.2	**85.5**	85.1
3	71.6	**79.3**	78.1	73.3	**80.2**	79.1
4	57.4	61.4	**61.8**	57.4	**62.0**	59.9
5	20.7	**25.0**	**25.0**	20.7	**25.0**	**25.0**
all	52.6	57.5	**57.8**	53.4	**58.5**	57.8
all (e.d.)	1.18	1.07	**1.03**	1.16	1.02	**1.01**

Table 4: Token-based analysis: Whole-word accuracy results split into different frequency bins. In the last two rows, all predictions are included, weighted by the frequency of the form to predict. Last row is edit distance.

no corpus, gives an accuracy of 89.9%. By adding a corpus of 10 million words we reduce the error rate by 10%, corresponding to a one-point increase in absolute accuracy to 90.9%. A similar trend can be seen when we use more seed paradigms. Simply training on 100 seed paradigms, but not using a corpus, results in an accuracy of 91.5%. Adding a corpus of 10 million words to these 100 paradigms reduces the error rate by 8.3%, increasing the absolute accuracy to 92.2%. Compared to the large corpus, the smaller corpus of 1 million words goes more than half the way; it results in error reductions of 6.9% (50 seed paradigms) and 5.8% (100 seed paradigms). Larger unsupervised corpora should help by increasing coverage even more, although Zipf's law implies a diminishing rate of return.[18]

We also tested a baseline that simply inflects each morphological form according to the basic regular German inflection pattern; this reaches an accuracy of only 84.5%.

Token-based Evaluation. We now split our results into different bins: how well do we predict the spellings of frequently expressed (lexeme, inflection) pairs as opposed to rare ones? For example, the third person singular indicative of *give* (geben) is used significantly more often than the second person plural subjunctive of *bask* (aalen);[19] they are in different frequency bins (Table 3). The more frequent a form is in text, the more likely it is to be irregular (Jurafsky et al., 2000, p. 49).

The results in Table 4 show: Adding a corpus of either 1 or 10 million words increases our prediction accuracy across *all* frequency bins, often dramatically. All methods do best on the huge number of rare forms (Bin 1), which are mostly regular, and worst on on the 10 most frequent forms of the language (Bin 5). However, adding a corpus helps most in fixing the errors in bins with more frequent and hence more irregular verbs: in Bins 2–5 we observe improvements of up to almost 8% absolute percentage points. In Bin 1, the no-corpus baseline is already relatively strong.

Surprisingly, while we always observe gains from using a corpus, the gains from the 10-million-word corpus are sometimes smaller than the gains from the 1-million-word corpus, except in edit distance. Why? The larger corpus mostly adds new infrequent types, biasing $\vec{\theta}$ toward regular morphology at the expense of irregular types. A solution might be to model irregular classes with separate parameters, using the latent conjugation-class model of Dreyer et al. (2008).

Note that, by using a corpus, we even improve our prediction accuracy for forms and spellings that are *not* found in the corpus, i.e., *novel* words. This is thanks to improved grammar parameters. In the token-based analysis above we have already seen that prediction accuracy increases for rare forms (Bin 1). We add two more analyses that more explicitly show our performance on novel words. (a) We find all paradigms that consist of novel spellings only, i.e. none of the correct spellings can be found in the corpus.[20] The whole-word prediction accuracies for the models that use corpus size 0, 1 million, and 10 million words are, respectively, 94.0%, 94.2%, 94.4% using 50 seed paradigms, and 95.1%, 95.3%, 95.2% using 100 seed paradigms. (b) Another, sim-

[18] Considering the 63,778 distinct spellings from all of our 5,615 CELEX paradigms, we find that the smaller corpus contains 7,376 spellings and the 10× larger corpus contains 13,572.

[19] See Appendix F for how this was estimated from text.

[20] This is measured on the largest corpus used in inference, the 10-million-word corpus, so that we can evaluate all models on the same set of paradigms.

pler measure is the prediction accuracy on all forms whose correct spelling cannot be found in the 10-million-word corpus. Here we measure accuracies of 91.6%, 91.8% and 91.8%, respectively, using 50 seed paradigms. With 100 seed paradigms, we have 93.0%, 93.4% and 93.1%. The accuracies for the models that use a corpus are higher, but do not always steadily increase as we increase the corpus size.

The token-based analysis we have conducted here shows the strength of the corpus-based approach presented in this paper. While the integrated graphical models over strings (Dreyer and Eisner, 2009) can learn some basic morphology from the seed paradigms, the added corpus plays an important role in correcting its mistakes, especially for the more frequent, irregular verb forms. For examples of specific errors that the models make, see Appendix E.3.

9 Related Work

Our word-and-paradigm model seamlessly handles nonconcatenative and concatenative morphology alike, whereas most previous work in morphological knowledge discovery has modeled concatenative morphology only, assuming that the orthographic form of a word can be split neatly into stem and affixes—a simplifying asssumption that is convenient but often not entirely appropriate (Kay, 1987) (how should one segment English `stopping`, `hoping`, or `knives`?).

In **concatenative** work, Harris (1955) finds morpheme boundaries and segments words accordingly, an approach that was later refined by Hafer and Weiss (1974), Déjean (1998), and many others. The unsupervised segmentation task is tackled in the annual Morpho Challenge (Kurimo et al., 2010), where ParaMor (Monson et al., 2007) and Morfessor (Creutz and Lagus, 2005) are influential contenders. The Bayesian methods that Goldwater et al. (2006b, et seq.) use to segment between words might also be applied to segment within words, but have no notion of paradigms. Goldsmith (2001) finds what he calls *signatures*—sets of affixes that are used with a given set of stems, for example (*NULL*, `-er`, `-ing`, `-s`). Chan (2006) learns sets of morphologically related words; he calls these sets *paradigms* but notes that they are not substructured entities, in contrast to the paradigms we model in this paper. His models are restricted to concatenative and regular morphology.

Morphology discovery approaches that handle **nonconcatenative** and irregular phenomena are more closely related to our work; they are rarer. Yarowsky and Wicentowski (2000) identify inflection-root pairs in large corpora without supervision. Using similarity as well as distributional clues, they identify even irregular pairs like `take`/`took`. Schone and Jurafsky (2001) and Baroni et al. (2002) extract whole conflation sets, like "`abuse`, `abused`, `abuses`, `abusive`, `abusively`, ...," which may also be irregular. We advance this work by not only extracting pairs or sets of related observed words, but whole structured inflectional paradigms, in which we can also predict forms that have never been observed. On the other hand, our present model does not yet use contextual information; we regard this as a future opportunity (see Appendix G). Naradowsky and Goldwater (2009) add simple spelling rules to the Bayesian model of (Goldwater et al., 2006a), enabling it to handle some systematically nonconcatenative cases. Our finite-state transducers can handle more diverse morphological phenomena.

10 Conclusions and Future Work

We have formulated a principled framework for simultaneously obtaining morphological annotation, an unbounded morphological lexicon that fills complete structured morphological paradigms with observed and predicted words, and parameters of a nonconcatenative generative morphology model.

We ran our sampler over a large corpus (10 million words), inferring everything jointly and reducing the prediction error for morphological inflections by up to 10%. We observed that adding a corpus increases the absolute prediction accuracy on frequently occurring morphological forms by up to almost 8%. Future extensions to the model could leverage token context for further improvements (Appendix G).

We believe that a major goal of our field should be to build full-scale explanatory probabilistic models of language. While we focus here on inflectional morphology and evaluate the results in isolation, we regard the present work as a significant step toward a larger generative model under which Bayesian inference would reconstruct other relationships as well (e.g., inflectional, derivational, and evolutionary) among the words in a family of languages.

Multilayer Sequence Labeling

Abstract

In this paper, we describe a novel approach to cascaded learning and inference on sequences. We propose a weakly joint learning model on cascaded inference on sequences, called multilayer sequence labeling. In this model, inference on sequences is modeled as cascaded decision. However, the decision on a sequence labeling sequel to other decisions utilizes the features on the preceding results as marginalized by the probabilistic models on them. It is not novel itself, but our idea central to this paper is that the probabilistic models on succeeding labeling are viewed as indirectly depending on the probabilistic models on preceding analyses. We also propose two types of efficient dynamic programming which are required in the gradient-based optimization of an objective function. One of the dynamic programming algorithms resembles back propagation algorithm for multilayer feed-forward neural networks. The other is a generalized version of the forward-backward algorithm. We also report experiments of cascaded part-of-speech tagging and chunking of English sentences and show effectiveness of the proposed method.

1 Introduction

Machine learning approach is widely used to classify instances into discrete categories. In many tasks, however, some set of inter-related labels should be decided simultaneously. Such tasks are called structured prediction. Sequence labeling is the simplest subclass of structured prediction problems. In sequence labeling, the most likely one among all the possible label sequences is predicted for a given input. Although sequence labeling is the simplest subclass, a lot of real-world tasks are modeled as problems of this simplest subclass. In addition, it might offer valuable insight and a toehold for more general and complex structured prediction problems. Many models have been proposed for sequence labeling tasks, such as Hidden Markov Models (HMM), Conditional Random Fields (CRF) (Lafferty et al., 2001), Max-Margin Markov Networks (Taskar et al., 2003) and others. These models have been applied to lots of practical tasks in natural language processing (NLP), bioinformatics, speech recognition, and so on. And they have shown great success in recent years.

In real-world tasks, it is often needed to cascade multiple predictions. A cascade of predictions here means the situation in which some of predictions are made based upon the results of other predictions. Sequence labeling is not an exception. For example, in NLP, we perform named entity recognition or base-phrase chunking for given sentences based on part-of-speech (POS) labels predicted by another sequence labeler. Natural languages are especially interpreted to have a hierarchy of sequential structures on different levels of abstraction. Therefore, many tasks in NLP are modeled as a cascade of sequence predictions.

If a prediction is based upon the result of another prediction, we call the former upper stage and the latter lower stage.

Methods pursued for a cascade of predictions – including sequence predictions, of course–, are desired to perform certain types of capability. One de-

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 628–637,
Edinburgh, Scotland, UK, July 27–31, 2011.

sired capability is rich forward information propagation, that is, the learning and estimation on each stage of predictions should utilize rich information of the results of lower stages whenever possible. "Rich information" here includes next bests and confidence information of the results of lower stages. Another is backward information propagation, that is, the rich annotated data on an upper stage should affect the models on lower stages retroactively.

Many current systems for a cascade of sequence predictions adopt a simple 1-best feed-forward approach. They simply take the most likely output at each prediction stage and transfer it to the next upper stage. Such a framework can maximize reusability of existing sequence labeling systems. On the other hand, it exhibits a strong tendency to propagate errors to upper labelers.

Typical improvement on the 1-best approach is to keep k-best results in the cascade of predictions. However, the larger k becomes, the more difficult it is to enumerate and maintain the k-best results. It is particularly prominent in sequence labeling.

The essence of this orientation is that the labeler on an upper stage utilizes the information of all the possible output candidates on lower stages. However, the size of the output space can become quite large in sequence labeling. It effectively forbids explicit enumeration of all possible outputs, so it is required to represent all the labeling possibilities compactly or employ some approximation schemes. Several studies are in this direction. In the method proposed in Finkel et al. (2006), a cascades of sequence predictions is viewed as a Bayesian network, and sample sequences are drawn at each stage according to the output distribution. The samples are then used to estimate the entire distribution of the cascade. In the method proposed in Bunescu (2008), an upper labeler uses the probabilities marginalized on the parts of the output sequences on lower stages as weights for the features. The weighted features are integrated in the model of the labeler on the upper stage. A k-best approach (e.g., (Collins and Duffy, 2002)) and the methods mentioned above are effective to improve the forward information propagation. However, they can never contribute on backward information propagation.

To improve the both directions of information propagation, Some studies propose the joint learning of multiple sequence labelers. Sutton et al. (2007) proposes the joint learning method in case where multiple labels are assigned to each time slice of the input sequences. It enables simultaneous learning and estimation of multiple sequence labelings on the same input sequences, where time slices of the outputs of all the out sequences are regularly aligned. However, it puts the distribution of states into Bayesian networks with cyclic dependencies, and exact inference is not tractable in such a model in general. Therefore, it requires some approximate inference algorithms in learning or predictions. Moreover, it only considers the cases where labels of an input sequence and all output sequences are regularly aligned. It is not clear how to build a joint labeling model which handles irregular output label sequences like semi-Markov models (Sarawagi and Cohen, 2005).

In this paper, we propose a middle ground for a cascade of sequence predictions. The proposed method adopts the basic idea of Bunescu (2008). We first assume that the model on all the sequence labeling stages is probabilistic one. In modeling of an upper stage, a feature is weighted by the marginal probability of the fragment of the outputs from a lower stage. However, this is not novel itself because it is just a paraphrase of Bunescu's core idea. Our intuition behind the proposed method is as follows. Features integrated in the model on each stage are weighted by the marginal probabilities of the fragments of the outputs on lower stages. So, if the output distributions on lower stages change, the marginal probabilities of any fragments also change, and this in turn can change the value of the features on the upper stage. In other words, the features on an upper stage indirectly depend on the models on the lower stages. Based on this intuition, the learning procedure of the model on an upper stage can affect not only direct model parameters, but also the weights of the features by changing the model on the lower stages. Supervised learning based on annotated data on an upper stage may affect the model or model parameters on the lower stages. It could be said that the information of annotation data on an upper stage is propagated back to the model on lower stages.

In the next section, we describe the formal nota-

tion of our model. In Section 3, we propose an optimization procedure according to the intuition noted above. In Section 4, we report an experimental result of our method. The proposed method shows some improvements on a real-world task in comparison with ordinary methods.

2 Formalization

In this section, we introduce the formal notation of our model. Hereafter, for the sake of simplicity, we only describe the simplest case in which there are just two stages, one lower stage of sequence labeling named L_1 and one upper stage of sequence labeling named L_2. In L_1, the most likely one among a set of possible sequences is predicted for a given input $\mathbf{x}$. L_2 is also a sequence labeling stage for the same input $\mathbf{x}$ and the output of L_1. No assumption is made on the structure of $\mathbf{x}$. The information of $\mathbf{x}$ is totally encoded in feature functions. It is only assumed that the output spaces of both L_1 and L_2 are conditioned on the initial input $\mathbf{x}$.

First of all, we describe the formalization of the probabilistic model for L_1. The model for L_1 per se is the same as ordinary ones for sequence labeling. For a given input $\mathbf{x}$, consider a directed acyclic graph (DAG) $G_1 = (V_1, E_1)$. A source of a DAG G is a node whose in-degree is equal to zero. A sink of a DAG G is nodes whose out-degree is equal to zero. Let $\mathrm{src}(G)$, $\mathrm{snk}(G)$ denote the set of source and sink nodes in G, respectively. A successful path of a DAG G is defined as a directed path on G whose starting node is a source and end node is a sink. If $\mathbf{y}$ denotes a path on a DAG, let $\mathbf{y}$ also denote the set of all the arcs appearing on $\mathbf{y}$ for the sake of shorthand. We denote the set of all the possible successful paths on G_1 by $\mathbf{Y}_1$. The space of the output candidates for L_1 is exactly equal to $\mathbf{Y}_1$. For the modeling of L_1, it is assumed that features of the form $f_{\langle 1,k_1,e_1,\mathbf{x}\rangle} \in \mathbb{R}$ $(k_1 \in \mathcal{K}_1, e_1 \in E_1)$ are allowed to be used. Here, $\mathcal{K}_1$ is the index set of the feature types for L_1. Such a feature can capture an aspect of the correlation between adjacent nodes. We call this kind of features input features for L_1. This naming is used to distinguish them from another kind of features defined on L_1, which comes later. Although features on V_1 can be also defined, they are totally omitted in this paper for brevity. Hereafter, if a symbol has subscripts, then missing subscript indicates a set that range over the omitted subscript. For example, $\mathbf{f}_{\langle 1,e_1,\mathbf{x}\rangle} \stackrel{\mathrm{def}}{\equiv} \left\{f_{\langle 1,k_1,e_1,\mathbf{x}\rangle}\right\}_{k_1\in\mathcal{K}_1}$, $\mathbf{f}_{\langle 1,k_1,\mathbf{x}\rangle} \stackrel{\mathrm{def}}{\equiv} \left\{f_{\langle 1,k_1,e_1,\mathbf{x}\rangle}\right\}_{e_1\in E_1}$, $\mathbf{f}_{\langle 1,\mathbf{x}\rangle} \stackrel{\mathrm{def}}{\equiv} \left\{f_{\langle 1,k_1,e_1,\mathbf{x}\rangle}\right\}_{k_1\in\mathcal{K}_1,e_1\in E_1}$, and so on. The probabilistic model on L_1 forms the log-linear model, that is,

$$P_1(\mathbf{y}_1|\mathbf{x};\boldsymbol{\theta}_1) \stackrel{\mathrm{def}}{\equiv} \frac{1}{Z_1(\mathbf{x};\boldsymbol{\theta}_1)} \exp\left(\boldsymbol{\theta}_1 \cdot \mathbf{F}_{\langle 1,\mathbf{y}_1,\mathbf{x}\rangle}\right) \quad (\mathbf{y}_1 \in \mathbf{Y}_1) \ , \tag{1}$$

where $\theta_{\langle 1,k_1\rangle} \in \mathbb{R}$ $(k_1 \in \mathcal{K}_1)$ is the weight for the feature of the same index k_1, and the k_1-th element of $\mathbf{F}_{\langle 1,\mathbf{y}_1,\mathbf{x}\rangle}$, $F_{\langle 1,k_1,\mathbf{y}_1,\mathbf{x}\rangle} \stackrel{\mathrm{def}}{\equiv} \sum_{e_1\in\mathbf{y}_1} f_{\langle 1,k_1,e_1,\mathbf{x}\rangle}$. Dot operator $(\cdot)$ denotes the inner product with respect to the subscripts commonly missing in both operands. Z_1 is the partition function for P_1, defined as

$$Z_1(\mathbf{x};\boldsymbol{\theta}_1) \stackrel{\mathrm{def}}{\equiv} \sum_{\mathbf{y}_1\in\mathbf{Y}_1} \exp\left(\boldsymbol{\theta}_1 \cdot \mathbf{F}_{\langle 1,\mathbf{y}_1,\mathbf{x}\rangle}\right) \ . \tag{2}$$

It is worth noting that this formalization subsumes both directed and undirected linear-chain graphical models, which are the most typical models for sequence labeling, including HMM and CRF. That is, if the elements of V_1 are aligned into regular time slices, and the nodes in each time slice are associated with possible assignments of labels for that time, we obtain the representation equivalent to the ordinary linear-chain graphical models, in which all possible label assignments for each state are expanded. In such configuration, all the possible successful paths defined in our notation have strict one-to-one correspondence to all the possible joint assignments of labels in linear-chain graphical models. We purposely employ this DAG-based notation because; it is convenient to describe the models and algorithms for our purpose, it allows for labels to stay in arbitrary time as in semi-Markov models, and it is easily extended to models for a set of trees instead of sequences by replacing the graph-based notation with hypergraph-based notation.

Next, we formalize the probabilistic model on the upper stage L_2. Like L_1, consider a DAG $G_2 = (V_2, E_2)$ conditioned on the input $\mathbf{x}$, and the set of all the possible successful paths on G_2, denoted $\mathbf{Y}_2$. The space of the output candidates for L_2 becomes $\mathbf{Y}_2$.

The form of the features available in designing the probabilistic model for L_2, denoted by P_2, is the key of this paper. A feature on an arc $e_2 \in E_2$ can access local characteristics of the confidence-rated superposition of the L_1's outputs, in addition to the information of the input $\mathbf{x}$. To formulate local characteristics of the superposition of the L_1's outputs, we first define output features of L_1, denoted by $h_{\langle 1,k'_1,e_1\rangle} \in \mathbb{R} \quad (k'_1 \in \mathcal{K}'_1,\, e_1 \in E_1)$. Here, $\mathcal{K}'_1$ is the index set of the output feature types of L_1. Before the output features are integrated into the model for L_2, they all are confidence-rated with respect to P_1, that is, each output feature $h_{\langle 1,k'_1,e_1\rangle}$ is numerically rated by the estimated probabilities summed over the sequences emitting that feature. More formally, all the L_1's output features are integrated in features for P_2 in the form of the marginalized output features, which are defined as follows;

$$\bar{h}_{\langle 1,k'_1,e_1\rangle}(\boldsymbol{\theta}_1) \stackrel{\text{def}}{\equiv} h_{\langle 1,k'_1,e_1\rangle} P_1(e_1|\mathbf{x};\boldsymbol{\theta}_1) \qquad \left(k'_1 \in \mathcal{K}'_1,\, e_1 \in E_1\right) \quad , \tag{3}$$

where

$$\begin{aligned} P_1(e_1|\mathbf{x};\boldsymbol{\theta}_1) &\stackrel{\text{def}}{\equiv} \sum_{\mathbf{y}_1 \sim e_1} P_1(\mathbf{y}_1|\mathbf{x};\boldsymbol{\theta}_1) \\ &= \sum_{\mathbf{y}_1 \in \mathbf{Y}_1} \delta_{e_1 \in \mathbf{y}_1} P_1(\mathbf{y}_1|\mathbf{x};\boldsymbol{\theta}_1) \qquad (e_1 \in E_1) \quad . \end{aligned} \tag{4}$$

Here, the notation $\sum_{\mathbf{y}_1 \sim e_1}$ represents the summation over sequences consistent with an arc $e_1 \in E_1$, that is, the summation over the set $\{\mathbf{y}_1 \in \mathbf{Y}_1 \mid e_1 \in \mathbf{y}_1\}$. $\delta_{\mathcal{P}}$ denotes the indicator function for a predicate $\mathcal{P}$. The input features for P_2 on an arc $e_2 \in E_2$ are permitted to arbitrarily combine the information of $\mathbf{x}$ and the L_1's marginalized output features $\bar{\mathbf{h}}_1$, in addition to the local characteristics of the arc at hand e_2. In summary, an input feature for L_2 on an arc $e_2 \in E_2$ is of the form

$$f_{\langle 2,k_2,e_2,\mathbf{x}\rangle}\big(\bar{\mathbf{h}}_1(\boldsymbol{\theta}_1)\big) \in \mathbb{R} \qquad (k_2 \in \mathcal{K}_2) \quad , \tag{5}$$

where $\mathcal{K}_2$ is the index set of the input feature types for L_2. To make the optimization procedure feasible, smoothness condition on any L_2's input feature is assumed with respect to all the L_1's output features, that is, $\frac{\partial f_{\langle 2,k_2,e_2,\mathbf{x}\rangle}}{\partial h_{\langle 1,k'_1,e_1\rangle}}$ is always guaranteed to exist for $^{\forall}k'_1,\, e_1,\, k_2,\, e_2$. For example, additions and multiplications between some elements of $\bar{\mathbf{h}}_1(\boldsymbol{\theta}_1)$ can appear in the definition of L_2's input features. For given input features $\mathbf{f}_{\langle 2,\mathbf{x}\rangle}\big(\bar{\mathbf{h}}_1(\boldsymbol{\theta}_1)\big)$ and parameters $\theta_{\langle 2,k_2\rangle} \in \mathbb{R} \quad (k_2 \in \mathcal{K}_2)$, the probabilistic model for L_2 is defined as follows;

$$\begin{aligned} &P_2(\mathbf{y}_2|\mathbf{x};\boldsymbol{\theta}_1,\boldsymbol{\theta}_2) \\ &\quad \stackrel{\text{def}}{\equiv} \frac{1}{Z_2(\mathbf{x};\boldsymbol{\theta}_1,\boldsymbol{\theta}_2)} \exp\big(\boldsymbol{\theta}_2 \cdot \mathbf{F}_{\langle 2,\mathbf{y}_2,\mathbf{x}\rangle}\big(\bar{\mathbf{h}}_1(\boldsymbol{\theta}_1)\big)\big) \\ &\qquad\qquad (\mathbf{y}_2 \in \mathbf{Y}_2) \quad , \end{aligned} \tag{6}$$

where $F_{\langle 2,k_2,\mathbf{y}_2,\mathbf{x}\rangle}\big(\bar{\mathbf{h}}_1(\boldsymbol{\theta}_1)\big) \stackrel{\text{def}}{\equiv} \sum_{e_2 \in \mathbf{y}_2} f_{\langle 2,k_2,e_2,\mathbf{x}\rangle}\big(\bar{\mathbf{h}}_1(\boldsymbol{\theta}_1)\big)$ and Z_2 is the partition function of P_2, defined by

$$\begin{aligned} &Z_2(\mathbf{x};\boldsymbol{\theta}_1,\boldsymbol{\theta}_2) \\ &\quad \stackrel{\text{def}}{\equiv} \sum_{\mathbf{y}_2 \in \mathbf{Y}_2} \exp\big(\boldsymbol{\theta}_2 \cdot \mathbf{F}_{\langle 2,\mathbf{y}_2,\mathbf{x}\rangle}\big(\bar{\mathbf{h}}_1(\boldsymbol{\theta}_1)\big)\big) \quad . \end{aligned} \tag{7}$$

The definition of P_2 (6) reveals one of the most important points in this paper. P_2 is viewed not only as the function of the ordinary direct parameters $\boldsymbol{\theta}_2$ but also as the function of $\boldsymbol{\theta}_1$, which represents the parameters for the L_1's model, through the intermediate variables $\bar{\mathbf{h}}_1$. So optimization procedure on P_2 may affect the determination of the values not only of the direct parameters $\boldsymbol{\theta}_2$ but also of the indirect ones $\boldsymbol{\theta}_1$.

If the result of L_1 is reduced to the single golden output $\tilde{\mathbf{y}}_1$, i.e. $P_1(\mathbf{y}_1|\mathbf{x}) = \delta_{\mathbf{y}_1 = \tilde{\mathbf{y}}_1}$, the definitions above boil down to the formulation of the simple 1-best feed forward architecture.

3 Optimization Algorithm

In this section, we describe optimization procedure for the model formulated in the previous section. Let $\mathcal{D} = \{\langle \hat{\mathbf{x}}, \langle G_1, \hat{\mathbf{y}}_1\rangle, \langle G_2, \hat{\mathbf{y}}_2\rangle\rangle_m\}_{m=1,2,\cdots,M}$ denote annotated data for the supervised learning of the model. Here, $\langle G_1, \hat{\mathbf{y}}_1\rangle$ is a pair of a DAG and correctly annotated successful sequence for L_1. The same holds for $\langle G_2, \hat{\mathbf{y}}_2\rangle$. For given $\mathcal{D}$, we can define the conditional log-likelihood function on L_1 and L_2 respectively, that is,

$$\begin{aligned} &\mathcal{L}_1(\boldsymbol{\theta}_1;\mathcal{D}) \\ &\quad \stackrel{\text{def}}{\equiv} \sum_{\langle \hat{\mathbf{x}}, \hat{\mathbf{y}}_1\rangle \in \mathcal{D}} \log\left(P_1(\hat{\mathbf{y}}_1|\hat{\mathbf{x}};\boldsymbol{\theta}_1)\right) - \frac{|\boldsymbol{\theta}_1|}{2{\sigma_1}^2} \end{aligned} \tag{8}$$

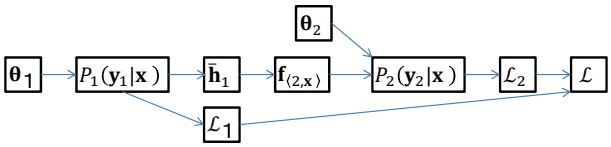

Figure 1: Computation Graph of the Proposed Model

and

$$\mathcal{L}_2\left(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2; \mathcal{D}\right) \stackrel{\text{def}}{\equiv} \sum_{\langle \hat{\mathbf{x}}, \hat{\mathbf{y}}_2 \rangle \in \mathcal{D}} \log\left(P_2\left(\hat{\mathbf{y}}_2 | \hat{\mathbf{x}}; \boldsymbol{\theta}_1, \boldsymbol{\theta}_2\right)\right) - \frac{|\boldsymbol{\theta}_2|}{2{\sigma_2}^2} \ . \tag{9}$$

Here, ${\sigma_1}^2$, ${\sigma_2}^2$ are the variances of the prior distributions of the parameters. For the sake of simplicity, we set the prior distribution as the zero-mean univariance Gaussian. To optimize the both probabilistic models P_1 and P_2 jointly, we also define the joint conditional log-likelihood function

$$\mathcal{L}\left(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2; \mathcal{D}\right) \stackrel{\text{def}}{\equiv} \mathcal{L}_1 + \mathcal{L}_2 \ . \tag{10}$$

The parameter values to be learned are the ones that (possibly locally) maximize this objective function. Note that this objective function is not guaranteed to be globally convex.

We employ gradient-based parameter optimization here. Optimization procedure repeatedly searches a direction in the parameter space which is ascendent with respect to the objective function, and updates the parameter values into that direction by small advances. Many existing optimization routines like steepest descent or conjugation gradient do that job only by giving the objective value and gradients on parameter values to be updated. So, the optimization problem here boils down to the calculation of the objective value and gradients on given parameter values.

Before entering the detailed description of the algorithm for calculating the objective function and gradients, we note the functional relations among the objective function and previously defined variables. The diagram shown in Figure 1 illustrates the functional relations among the parameters, input and output feature functions, models, and objective function. The variables at the head of a directed arrow in the figure is directly defined in terms of the ones at the tail of the same arrow. The value of the objective function on given parameter values can be calculated in order of the arrows shown in the diagram. On the other hand, the parameter gradients are calculated step-by-step in reverse order of the arrows. The functional relations illustrated in the Figure 1 ensure some forms of the chain rule of differentiation among the variables. The chain rule is iteratively used to decompose the calculation of the gradients into a divide-and-conquer fashion. These two directions of stepwise computation are analogous to the forward and back propagation for multilayer feedforward neural networks, respectively.

Algorithm 1 shows the whole picture of the gradient-based optimization procedure for our model. We first describe the flow to calculate the objective value for a given parameters $\boldsymbol{\theta}_1$ and $\boldsymbol{\theta}_2$, which is shown from line 2 through 4 in Algorithm 1. The values of marginalized output features $\bar{\mathbf{h}}_{\langle 1,\mathbf{x}\rangle}$ can be calculated by (3). Because they are the simple marginals of features, the ordinary forward-backward algorithm (hereafter, abbreviated as "F-B") on G_1 offers an efficient way to calculate their values. Although nothing definite about the forms of the input features for L_2 is presented in this paper, $\mathbf{f}_{\langle 2,\mathbf{x}\rangle}$ can be calculated once the values of $\bar{\mathbf{h}}_{\langle 1,\mathbf{x}\rangle}$ have been obtained. Finally, $\mathcal{L}_1$, $\mathcal{L}_2$ and then $\mathcal{L}$ are easy to calculate because they are no different from the ordinary log-likelihood computation.

Now we describe the algorithm to calculate the parameter gradients,

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{\theta}_1} = \frac{\partial \mathcal{L}_1}{\partial \boldsymbol{\theta}_1} + \frac{\partial \mathcal{L}_2}{\partial \boldsymbol{\theta}_1}, \qquad \frac{\partial \mathcal{L}}{\partial \boldsymbol{\theta}_2} = \frac{\partial \mathcal{L}_2}{\partial \boldsymbol{\theta}_2} \ . \tag{11}$$

Line 5 through line 7 in Algorithm 1 describe the gradient computation. The terms $\frac{\partial \mathcal{L}_1}{\partial \boldsymbol{\theta}_1}$ and $\frac{\partial \mathcal{L}_2}{\partial \boldsymbol{\theta}_2}$ in (11) become the same forms that appear in the ordinary CRF optimization, i.e., the difference between the empirical frequencies of the features and the model expectations of them,

$$\begin{aligned} \frac{\partial \mathcal{L}_1}{\partial \boldsymbol{\theta}_1} &= \tilde{E}\left[\mathbf{F}_{\langle 1,\mathbf{y}_1,\mathbf{x}\rangle}\right] - E_{P_1}\left[\mathbf{F}_{\langle 1,\mathbf{y}_1,\mathbf{x}\rangle}\right] - \frac{|\boldsymbol{\theta}_1|}{{\sigma_1}^2} \ , \\ \frac{\partial \mathcal{L}_2}{\partial \boldsymbol{\theta}_2} &= \tilde{E}\left[\mathbf{F}_{\langle 2,\mathbf{y}_2,\mathbf{x}\rangle}\right] - E_{P_2}\left[\mathbf{F}_{\langle 2,\mathbf{y}_2,\mathbf{x}\rangle}\right] - \frac{|\boldsymbol{\theta}_2|}{{\sigma_2}^2} \ . \end{aligned} \tag{12}$$

These calculations are performed by the ordinary F-B on G_1 and G_2, respectively. Using the chain rule of differentiation derived from the functional relations illustrated in Figure 1, the remaining term $\frac{\partial L_2}{\partial \boldsymbol{\theta}_1}$

Algorithm 1 Gradient-based optimization of the model parameters

Input: $\boldsymbol{\theta}_1,\, \boldsymbol{\theta}_2$

Output: $\arg\max_{\langle \boldsymbol{\theta}_1, \boldsymbol{\theta}_2 \rangle} \mathcal{L}$

1: **while** $\boldsymbol{\theta}_1$ or $\boldsymbol{\theta}_2$ changes significantly **do**
2: calculate Z_1 by (2), $\bar{\mathbf{h}}_1$ by (3) with the F-B on G_1, and then $\mathcal{L}_1$ by (8)
3: calculate $\mathbf{f}_{\langle 2,\mathbf{x} \rangle}$ according to their definitions
4: calculate Z_2 by (7) with the F-B on G_2, and then $\mathcal{L}_2$ by (9) and $\mathcal{L}$ by (10)
5: calculate $\frac{\partial \mathcal{L}_1}{\partial \boldsymbol{\theta}_1}$ and $\frac{\partial \mathcal{L}_2}{\partial \boldsymbol{\theta}_2}$ by (12) with the F-B on G_1 and G_2, respectively
6: calculate $\frac{\partial \mathcal{L}}{\partial \mathbf{f}_{\langle 1,\mathbf{x} \rangle}}$ by (16) with the F-B on G_2, $\frac{\partial \mathbf{f}_{\langle 1,\mathbf{x} \rangle}}{\partial \bar{\mathbf{h}}_1}$, and them $\frac{\partial \mathcal{L}_2}{\partial \bar{\mathbf{h}}_1} = \frac{\partial \mathcal{L}}{\partial \mathbf{f}_{\langle 1,\mathbf{x} \rangle}} \cdot \frac{\partial \mathbf{f}_{\langle 1,\mathbf{x} \rangle}}{\partial \bar{\mathbf{h}}_1}$
7: calculate $\frac{\partial \mathcal{L}_2}{\partial \boldsymbol{\theta}_1}$ by (18) with Algorithm 2
8: $\langle \boldsymbol{\theta}_1, \boldsymbol{\theta}_2 \rangle \leftarrow$ **update-parameters**$\Big(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2, \mathcal{L}, \frac{\partial \mathcal{L}}{\partial \boldsymbol{\theta}_1}, \frac{\partial \mathcal{L}}{\partial \boldsymbol{\theta}_2}\Big)$
9: **end while**

in (11) can be decomposed as follows;

$$\frac{\partial \mathcal{L}_2}{\partial \boldsymbol{\theta}_1} = \frac{\partial \mathcal{L}_2}{\partial \mathbf{f}_{\langle 2,\mathbf{x} \rangle}} \cdot \frac{\partial \mathbf{f}_{\langle 2,\mathbf{x} \rangle}}{\partial \boldsymbol{\theta}_1} = \frac{\partial \mathcal{L}_2}{\partial \mathbf{f}_{\langle 2,\mathbf{x} \rangle}} \cdot \frac{\partial \mathbf{f}_{\langle 2,\mathbf{x} \rangle}}{\partial \bar{\mathbf{h}}_1} \cdot \frac{\partial \bar{\mathbf{h}}_1}{\partial \boldsymbol{\theta}_1} \ . \tag{13}$$

Note that Leibniz's notation here denotes a Jacobian with the index sets omitted in the numerator and the denominator, for example,

$$\frac{\partial \mathbf{f}_{\langle 2,\mathbf{x} \rangle}}{\partial \bar{\mathbf{h}}_1} \stackrel{\text{def}}{=} \left\{ \frac{\partial f_{\langle 2,k_2,e_2,\mathbf{x} \rangle}}{\partial h_{\langle 1,k'_1,e_1 \rangle}} \right\}_{k_2 \in \mathcal{K}_2, e_2 \in E_2, k'_1 \in \mathcal{K}'_1, e_1 \in E_1} \tag{14}$$

And also recall that dot operators here stand for the inner product with respect to the index sets commonly omitted in both operands, for example,

$$\frac{\partial \mathcal{L}_2}{\partial \mathbf{f}_2} \cdot \frac{\partial \mathbf{f}_2}{\partial \bar{\mathbf{h}}_1} = \sum_{k_2 \in \mathcal{K}_2, e_2 \in E_2} \frac{\partial \mathcal{L}_2}{\partial f_{\langle 2,k_2,e_2,\mathbf{x} \rangle}} \cdot \frac{\partial f_{\langle 2,k_2,e_2,\mathbf{x} \rangle}}{\partial \bar{\mathbf{h}}_1} \ . \tag{15}$$

We describe the manipulation of each factor in the right side of (13) in turn. Noting $\frac{\partial f_{\langle 2,k_2,e_2,\mathbf{x} \rangle}}{\partial f_{\langle 2,\grave{k}_2,\grave{e}_2,\mathbf{x} \rangle}} = \delta_{k_2=\grave{k}_2} \delta_{e_2=\grave{e}_2}$, each element of the first factor of (13) $\frac{\partial \mathcal{L}_2}{\partial \mathbf{f}_{\langle 2,\mathbf{x} \rangle}}$ can be transformed as follows;

$$\frac{\partial \mathcal{L}_2}{\partial f_{\langle 2,k_2,e_2,\mathbf{x} \rangle}} = \theta_{\langle 2,k_2 \rangle} \sum_{\langle \hat{\mathbf{x}}, \hat{\mathbf{y}}_2 \rangle \in \mathcal{D}} \big(\delta_{e_2 \in \hat{\mathbf{y}}_2} - P_2(e_2 | \hat{\mathbf{x}}; \boldsymbol{\theta}_1, \boldsymbol{\theta}_2) \big) \ . \tag{16}$$

$P_2(e_2|\hat{\mathbf{x}}; \boldsymbol{\theta}_1, \boldsymbol{\theta}_2)$, the marginal probability on e_2, can be obtained as a by-product of the F-B for (12).

As described in the previous section, it is assumed that the values of the second factor $\frac{\partial \mathbf{f}_{\langle 2,\mathbf{x} \rangle}}{\partial \bar{\mathbf{h}}_1}$ is guaranteed to exists for any given $\boldsymbol{\theta}_1$, and the procedure for calculating them is fixed in advance. The procedure for some of concrete features is exemplified in the previous section.

From the definition of $\bar{\mathbf{h}}_1$ (3), each element of the third factor of (13) $\frac{\partial \bar{\mathbf{h}}_1}{\partial \boldsymbol{\theta}_1}$ becomes

$$\frac{\partial \bar{h}_{\langle 1,k'_1,e_1 \rangle}}{\partial \theta_{\langle 1,k_1 \rangle}} = h_{\langle 1,k'_1,e_1 \rangle} \mathrm{Cov}_{P_1(\mathbf{y}_1|\mathbf{x})} \big[\delta_{e_1 \in \mathbf{y}_1},\, F_{\langle 1,k_1,\mathbf{y}_1,\mathbf{x} \rangle} \big] \ . \tag{17}$$

There exists efficient dynamic programming to calculate the covariance value (17) (without goint into that detail because it is very similar to the one shown later in this paper), and of course we can run such dynamic programming for $^\forall k'_1 \in \mathcal{K}'_1,\ e_1 \in E_1$. However, the size of the Jacobian $\frac{\partial \bar{\mathbf{h}}_1}{\partial \boldsymbol{\theta}_1}$ is equal to $|\mathcal{K}'_1| \times |E_1| \times |\mathcal{K}_1|$. Since it is too large in many tasks likely to arise in practice, we should avoid to calculate all the elements of this Jacobian in a straightforward way. Instead of such naive computation, if the values of $\frac{\partial \mathcal{L}_2}{\partial \mathbf{f}_{\langle 2,\mathbf{x} \rangle}}$ and $\frac{\partial \mathbf{f}_{\langle 2,\mathbf{x} \rangle}}{\partial \bar{\mathbf{h}}_1}$ are obtained, then we can compute $\frac{\partial \mathcal{L}_2}{\partial \bar{\mathbf{h}}_1} = \frac{\partial \mathcal{L}_2}{\partial \mathbf{f}_{\langle 2,\mathbf{x} \rangle}} \cdot \frac{\partial \mathbf{f}_{\langle 2,\mathbf{x} \rangle}}{\partial \bar{\mathbf{h}}_1}$, and from (13)

and (17),

$$\frac{\partial \mathcal{L}_2}{\partial \boldsymbol{\theta}_1} = \frac{\partial \mathcal{L}_2}{\partial \bar{\mathbf{h}}_1} \cdot \frac{\partial \bar{\mathbf{h}}_1}{\partial \boldsymbol{\theta}_1} = E_{P_1(\mathbf{y}_1|\mathbf{x})}\left[H'_{\langle 1,\mathbf{y}_1\rangle}\mathbf{F}_{\langle 1,\mathbf{y}_1,\mathbf{x}\rangle}\right] - E_{P_1(\mathbf{y}_1|\mathbf{x})}\left[H'_{\langle 1,\mathbf{y}_1\rangle}\right] E_{P_1(\mathbf{y}_1|\mathbf{x})}\left[\mathbf{F}_{\langle 1,\mathbf{y}_1,\mathbf{x}\rangle}\right] \quad , \tag{18}$$

where $H'_{\langle 1,\mathbf{y}_1\rangle} \stackrel{\text{def}}{\equiv} \sum_{e_1 \in \mathbf{y}_1} \frac{\partial \mathcal{L}_2}{\partial \bar{\mathbf{h}}_{\langle 1,e_1\rangle}} \cdot \mathbf{h}_{\langle 1,e_1\rangle}$. In other words, $\frac{\partial \mathcal{L}_2}{\partial \theta_{\langle 1,k_1\rangle}}$ becomes the covariance between the k_1-th input feature for L_1 and the hypothetical feature $h'_{\langle 1,e_1\rangle} \stackrel{\text{def}}{\equiv} \frac{\partial \mathcal{L}_2}{\partial \bar{\mathbf{h}}_{\langle 1,e_1\rangle}} \cdot \mathbf{h}_{\langle 1,e_1\rangle}$.

The final problem is to derive an efficient way to compute the first term of (18). The second term of (18) can be calculated by the ordinary F-B because it consists of the marginals of arc features. There are two derivations of the algorithm for calculating the first term. We describe briefly the both derivations.

One is a variant of the F-B on the expectation semi-ring proposed in Li and Eisner (2009). First, the F-B is generalized to the expectation semi-ring with respect to the hypothetical feature $h'_{\langle 1,e_1\rangle}$, and by summing up the marginals of the feature vectors $\mathbf{f}_{\langle 1,e_1,\mathbf{x}\rangle}$ on all the arcs under the distribution of the semi-ring, then we obtain the expectation of the feature vector $\mathbf{f}_{\langle 1,e_1,\mathbf{x}\rangle}$ on the semi-ring potential. This expectation is equal to the first term of (18). [1]

Another derivation is to apply the automatic differentiation (AD)(Wengert, 1964; Corliss et al., 2002) on the F-B calculating $E_{P_1}\left[\mathbf{F}_{\langle 1,\mathbf{y}_1,\mathbf{x}\rangle}\right]$. It exploits the fact that $\frac{\partial}{\partial \lambda} E_{P'_1}\left[\mathbf{F}_{\langle 1,\mathbf{y}_1,\mathbf{x}\rangle}\right]\Big|_{\lambda=0}$ is equal to the first term of (18), where $\lambda \in \mathbb{R}$ is a dummy parameter, and $P'_1(\mathbf{y}_1|\mathbf{x}) \stackrel{\text{def}}{\equiv} \frac{1}{Z_1}\exp\left(\boldsymbol{\theta}_1 \cdot \mathbf{F}_{\langle 1,\mathbf{y}_1,\mathbf{x}\rangle} + \lambda H'_{\langle 1,\mathbf{y}_1\rangle}\right)$. It is easy to derive the F-B for calculating the value $E_{P'_1}\left[\mathbf{F}_{\langle 1,\mathbf{y}_1,\mathbf{x}\rangle}\right]\Big|_{\lambda=0}$. AD transforms this F-B into another algorithm for calculating the differentiation w.r.t. λ evaluated at the point $\lambda = 0$. This transformation is achieved in an automatic manner, by replacing all appearances of λ in the F-B with a dual number $\lambda + \varepsilon$. The dual number is a variant of the complex number, with a kind of the imaginary unit ε with the property $\varepsilon^2 = 0$. Like the usual complex numbers, the arithmetic operations and the exponential function are generalized to the dual numbers, and the ordinary F-B is also generalized to the dual numbers. The imaginary part of the resulting values is equal to the needed differentiation. [2] Anyway, these two derivations lead to the same algorithm, and the resulting algorithm is shown as Algorithm 2.

The final line in the loop of Algorithm 1 can be implemented by various optimization routines and line search algorithms.

The time and space complexity to compute the objective and gradient values for given parameter vectors $\boldsymbol{\theta}_1, \boldsymbol{\theta}_2$ is the same as that for that for Bunescu (2008), up to a constant factor. Because the calculation of the objective function is essentially the same as that for Bunescu (2008), and in gradient computation, the time complexity of Algorithm 1 is the same as that for the ordinary F-B (up to a constant factor), and the proposed optimization procedure is only required to store additional scalar values $h'_{\langle 1,e_1\rangle}$ on each G_1's arc.

4 Experiment

We examined effectiveness of the method proposed in this paper on a real task. The task is to annotate the POS tags and to perform base-phrase chunking on English sentences.

Base-phrase chunking is a task to classify continuous subsequences of words into syntactic categories. This task is performed by annotating a chunking label on each word (Ramshaw and Marcus, 1995). The types of chunking label consist of "Begin-*Category*", which represents the beginning of a chunk, "Inside-*Category*", which represents the inside of a chunk, and "Other." Usually, POS labeling runs first before base-phrase chunking is performed. Therefore, this task is a typical interesting case where a sequence labeling depends on the output from other sequence labelers.

The data used for our experiment consist of English sentences from the Penn Treebank project (Marcus et al., 1993) consisting of 10948 sentences and 259104 words. We divided them into two groups, training data consisting of 8936 sentences and 211727 words and test data consisting of 2012

[1] For the detailed description, see Li and Eisner (2009) and its references.

[2] For example, Berz (1992) gives a detailed description of the reason why the dual number is used for this purpose.

Algorithm 2 Forward-backward Algorithm for Calculating Feature Covariances

Input: $\mathbf{f}_{\langle 1,\mathbf{x}\rangle}$, $\phi_{e_1} \stackrel{\text{def}}{\equiv} \exp\left(\boldsymbol{\theta}_1 \cdot \mathbf{f}_{\langle 1,e_1,\mathbf{x}\rangle}\right)$, $h'_{e_1} \stackrel{\text{def}}{\equiv} \frac{\partial \mathcal{L}_2}{\partial \mathbf{h}_{\langle 1,e_1\rangle}} \cdot \mathbf{h}_{\langle 1,e_1\rangle}$

Output: $q_{k_1} = \mathrm{Cov}_{P(\mathbf{y}_1|\mathbf{x})}\left[H'_{\langle 1,\mathbf{y}_1\rangle},\, F_{\langle 1,k_1,\mathbf{y}_1,\mathbf{x}\rangle}\right] \qquad \left(^\forall k_1 \in \mathcal{K}_1\right)$

for $^\forall v_1 \in \mathrm{src}(G_1)$, $\alpha_{v_1} \leftarrow 1$, $\alpha'_{v_1} \leftarrow 1$
for all $v_1 \in V_1$ in a topological order **do**
  $\mathrm{prev} \leftarrow \{x \in V_1 \mid (x, v_1) \in E_1\}$
  $\alpha_{v_1} \leftarrow \sum_{x \in \mathrm{prev}} \phi_{(x,v_1)} \alpha_x$, $\alpha'_{v_1} \leftarrow \sum_{x \in \mathrm{prev}} \phi_{(x,v_1)} \left(h'_{(x,v_1)} \alpha_x + \alpha'_x\right)$
end for
$Z_1 \leftarrow \sum_{x \in \mathrm{snk}(G_1)} \alpha_x$
for $^\forall v_1 \in \mathrm{snk}(G_1)$, $\beta_{v_1} \leftarrow 1$, $\beta'_{v_1} \leftarrow 1$
for all $v_1 \in V_1$ in a reverse topological order **do**
  $\mathrm{next} \leftarrow \{x \in V_1 \mid (v_1, x) \in E_1\}$
  $\beta_{v_1} \leftarrow \sum_{x \in \mathrm{next}} \phi_{(v_1,x)} \beta_x$, $\beta'_{v_1} \leftarrow \sum_{x \in \mathrm{next}} \phi_{(v_1,x)} \left(h'_{(v_1,x)} \beta_x + \beta'_x\right)$
end for
for $^\forall k_1 \in \mathcal{K}_1$, $q_{k_1} \leftarrow 0$
for all $(u_1, v_1) \in E_1$ **do**
  $p \leftarrow \phi_{(u_1,v_1)} \left(\alpha_{u_1} \beta'_{v_1} + \alpha'_{u_1} \beta_{v_1}\right) / Z_1$
  for $^\forall k_1 \in \mathcal{K}_1$, $q_{k_1} \leftarrow q_{k_1} + p f_{\langle 1,k_1,e_1,\mathbf{x}\rangle}$
end for

sentences and 47377 words. The number of the POS label types is equal to 45. The number of the label types used in base-phrase chunking is equal to 23.

We compare the proposed method to two existing sequence labeling methods as baselines. The POS labeler is the same in all the three methods used in this experiment. This labeler is a simple CRF and learned by ordinary optimization procedure. One baseline method is the 1-best pipeline method. A simple CRF model is learned for the chunking labeling, on the input sentences and the most likely POS label sequences predicted by the already learned POS labeler. We call this method "CRF + CRF." The other baseline method has a CRF model for the chunking labeling, which uses the marginalized features offered by the POS labeler. However, the parameters of the POS labeler are fixed in the training of the chunking model. This method corresponds to the method proposed in Bunescu (2008). We call this baseline "CRF + CRF-MF" ("MF" for "marginalized features"). The proposed method is the same as "CRF + CRF-MF", except that the both labelers are jointly trained by the procedure described in Section 3. We call this proposed method "CRF + CRF-BP" ("BP" for "back propagation").

	CRF + CRF	CRF + CRF-MF	CRF +CRF-BP
POS labeling	95.6	(95.6)	95.8
Base-phrase chunking	92.1	92.7	**93.1**

Table 2: Experimental result (F-measure)

In "CRF + CRF-BP," the objective function for joint learning (10) is not guaranteed to be convex, so optimization procedure is sensible to the initial configuration of the model parameters. In this experiment, we set the parameter values learned by "CRF + CRF-MF" as the initial values for the training of the "CRF + CRF-BP" method. Feature templates used in this experiment are listed in Table 1. Although we only described the formalization and optimization procedure of the models with arc features, We use node features in the experiment.

Table 2 shows the result of the methods we men-

Table 1: List of feature templates. All node features are combined with the corresponding node label (POS or chunking label) feature. All arc features are combined with the feature of the corresponding arc label pair. † features are instantiated on each time slice in five character window. ‡ features are not used in POS labeler, and marginalized as output features for "CRF + CRF-MF" and "CRF + CRF-BP."

tioned. In Table 2, bold numbers indicate significant improvement over the baseline models with $\alpha = 0.05$. From Table 2, the proposed method significantly outperforms two baseline methods on chunking performance. Although the improvement on POS labeling performance by the proposed method "CRF + CRF-BP" is not significant, it might show that optimization procedure provides some form of backward information propagation in comparison to "CRF + CRF-MF."

5 Conclusions

In this paper, we adopt the method to weight features on an upper sequence labeling stage by the marginalized probabilities estimated by the model on lower stages. We also point out that the model on an upper stage is considered to depend on the model on lower stages indirectly. In addition, we propose optimization procedure that enables the joint optimization of the multiple models on the different level of stages. We perform an experiment on a real-world task, and our method significantly outperforms existing methods.

We examined the effectiveness of the proposed method only on one task in comparison to just a few existing methods. In the future, we hope to compare our method to other competing methods like joint learning approaches in terms of both accuracy and computational efficiency, and perform extensive experiments on various tasks.

Abstract

In this paper we present a fully unsupervised syntactic class induction system formulated as a Bayesian multinomial mixture model, where each word type is constrained to belong to a single class. By using a mixture model rather than a sequence model (e.g., HMM), we are able to easily add multiple kinds of features, including those at both the type level (morphology features) and token level (context and alignment features, the latter from parallel corpora). Using only context features, our system yields results comparable to state-of-the art, far better than a similar model without the one-class-per-type constraint. Using the additional features provides added benefit, and our final system outperforms the best published results on most of the 25 corpora tested.

1 Introduction

Research on unsupervised learning for NLP has become widespread recently, with part-of-speech induction, or syntactic class induction, being a particularly popular task.[1] However, despite a recent proliferation of syntactic class induction systems (Biemann, 2006; Goldwater and Griffiths, 2007; Johnson, 2007; Ravi and Knight, 2009; Berg-Kirkpatrick et al., 2010; Lee et al., 2010), careful comparison indicates that very few systems perform better than some much simpler and quicker methods dating back ten or even twenty years (Christodoulopoulos et al., 2010). This fact suggests that we should consider which features of the older systems led to their success, and attempt to combine these features with some of the machine learning methods introduced by the more recent systems. We pursue this strategy here, developing a system based on Bayesian methods where the probabilistic model incorporates several insights from previous work.

Perhaps the most important property of our model is that it is *type-based*, meaning that all tokens of a given word type are assigned to the same cluster. This property is not strictly true of linguistic data, but is a good approximation: as Lee et al. (2010) note, assigning each word type to its most frequent part of speech yields an upper bound accuracy of 93% or more for most languages. Since this is much better than the performance of current unsupervised syntactic class induction systems, constraining the model in this way seems likely to improve performance by reducing the number of parameters in the model and incorporating useful linguistic knowledge. Both of the older systems discussed by Christodoulopoulos et al. (2010), i.e., Clark (2003) and Brown et al. (1992), included this constraint and achieved very good performance relative to token-based systems. More recently, Lee et al. (2010) presented a new type-based model, and also reported very good results.

A second property of our model, which distinguishes it from the type-based Bayesian model of Lee et al. (2010), is that the underlying probabilistic model is a *clustering model*, (specifically, a multinomial mixture model) rather than a sequence model (HMM). In this sense, our model is more closely re-

[1] The task is more commonly referred to as part-of-speech induction, but we prefer the term syntactic class induction since the induced classes may not coincide with part-of-speech tags.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 638–647,
Edinburgh, Scotland, UK, July 27–31, 2011.

lated to several non-probabilistic systems that cluster context vectors or lower-dimensional representations of them (Redington et al., 1998; Schütze, 1995; Lamar et al., 2010). Sequence models are by far the most common method of supervised part-of-speech tagging, and have also been widely used for unsupervised part-of-speech tagging both with and without a dictionary (Smith and Eisner, 2005; Haghighi and Klein, 2006; Goldwater and Griffiths, 2007; Johnson, 2007; Ravi and Knight, 2009; Lee et al., 2010). However, systems based on context vectors have also performed well in these latter scenarios (Schütze, 1995; Lamar et al., 2010; Toutanova and Johnson, 2007) and present a viable alternative to sequence models.

One advantage of using a clustering model rather than a sequence model is that the features used for clustering need not be restricted to context words. Additional types of features can easily be incorporated into the model and inference procedure using the same general framework as in the basic model that uses only context word features. In particular, we present two extensions to the basic model. The first uses *morphological features*, which serve as cues to syntactic class and seemed to partly explain the success of two best-performing systems analysed by Christodoulopoulos et al. (2010). The second extension to our model uses *alignment features* gathered from parallel corpora. Previous work suggests that using parallel text can improve performance on various unsupervised NLP tasks (Naseem et al., 2009; Snyder and Barzilay, 2008).

We evaluate our model on 25 corpora in 20 languages that vary substantially in both syntax and morphology. As in previous work (Lee et al., 2010), we find that the one-class-per-type restriction boosts performance considerably over a comparable token-based model and yields results that are comparable to state-of-the-art even without the use of morphology or alignment features. Including morphology features yields the best published results on 14 or 15 of our 25 corpora (depending on the measure) and alignment features can improve results further.

2 Models

Our model is a multinomial mixture model with Bayesian priors over the mixing weights θ and multinomial class output parameters ϕ. The model is defined so that all observations associated with a single word type are generated from the same mixing component (syntactic class). In the basic model, these observations are token-level features; the morphology model adds type-level features as well. We begin by describing the simplest version of our model, where each word token is associated with a single feature, for example its left context word (the word that occurs to its left in the corpus). We then show how to generalise the model to multiple token-level features and to type-level features.

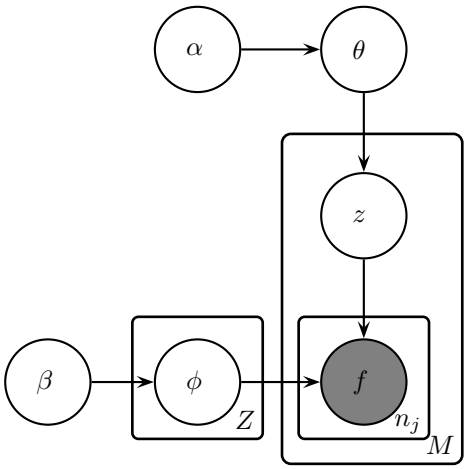

Figure 1: Plate diagram of the basic model with a single feature per token (the observed variable f). M, Z, and n_j are the number of word types, syntactic classes z, and features (= tokens) per word type, respectively.

2.1 Basic model

In the basic model, each word token is represented by a single feature such as its left context word. These features are the observed data; the model explains the data by assuming that it has been generated from some set of latent syntactic classes. The ith class is associated with a multinomial parameter vector ϕ_i that defines the distribution over features generated from that class, and with a mixing weight θ_i that defines the prior probability of that class. θ and ϕ_i are drawn from symmetric Dirichlet distributions with parameters α and β respectively.

The generative story goes as follows: First, generate the prior class probabilities θ. Next, for each

word type $j = 1 \ldots M$, choose a class assignment z_j from the distribution θ. For each class $i = 1 \ldots Z$, choose an output distribution over features ϕ_i. Finally, for each token $k = 1 \ldots n_j$ of word type j, generate a feature f_{jk} from ϕ_{z_j}, the distribution associated with the class that word type j is assigned to. The model is illustrated graphically in Figure 1 and is defined formally as follows:

$$\begin{aligned} \theta \,|\, \alpha &\sim \text{Dirichlet}(\alpha) \\ z_j \,|\, \theta &\sim \text{Multinomial}(\theta) \\ \phi_i \,|\, \beta &\sim \text{Dirichlet}(\beta) \\ f_{jk} \,|\, \phi_{z_j} &\sim \text{Multinomial}(\phi_{z_j}) \end{aligned}$$

In addition to the variables defined above, we will use F to refer to the number of different possible values a feature can take on (so that ϕ is a $Z \times F$ matrix). Thus, one way to think of the model is as a vector-based clustering system, where word type j is associated with a $1 \times F$ vector of feature counts representing the features of all n_j tokens of j, and these vectors are clustered into similar classes. The difference from other vector-based syntactic class induction systems is in the method of clustering. Here, we define a Gibbs sampler that samples from the posterior distribution of the clusters given the observed features; other systems have used various standard distance-based vector clustering methods. Some systems also include dimensionality reduction (Schütze, 1995; Lamar et al., 2010) to reduce the size of the context vectors; we simply use the F most common words as context features.

2.2 Inference

At inference time we want to sample a syntactic class assignment $\mathbf{z}$ from the posterior of the model. We use a collapsed Gibbs sampler, integrating out the parameters θ and ϕ and sampling from the following distribution:

$$P(\mathbf{z}|\mathbf{f}, \alpha, \beta) \propto P(\mathbf{z}|\alpha)P(\mathbf{f}|\mathbf{z}, \beta). \quad (1)$$

Rather than sampling the joint class assignment $P(\mathbf{z}|\mathbf{f}, \alpha, \beta)$ directly, the sampler iterates over each word type j, resampling its class assignment z_j given the current assignments $\mathbf{z}_{-j}$ of all other word types. The posterior over z_j can be computed as

$$\begin{aligned} &P(z_j \,|\, \mathbf{z}_{-j}, \mathbf{f}, \alpha, \beta) \\ &\quad \propto \; P(z_j \,|\, \mathbf{z}_{-j}, \alpha, \beta) P(\mathbf{f}_j \,|\, \mathbf{f}_{-j}, \mathbf{z}, \alpha, \beta) \quad (2) \end{aligned}$$

where $\mathbf{f}_j$ are the features associated with word type j (one feature for each token of j). The first (prior) factor is easy to compute due to the conjugacy between the Dirichlet and multinomial distributions, and is equal to

$$P(z_j = z \,|\, \mathbf{z}_{-j}, \alpha) = \frac{n_z + \alpha}{n_\cdot + Z\alpha} \quad (3)$$

where n_z is the number of types in class z and $n_\cdot$ is the total number of word types in all classes. All counts in this and the following equations are computed with respect to $\mathbf{z}_{-j}$ (e.g., $n_\cdot = M - 1$).

Computing the second (likelihood) factor is slightly more complex due to the dependencies between the different variables in $\mathbf{f}_j$ that are induced by integrating out the ϕ parameters. Consider first a simple case where word type j occurs exactly twice in the corpus, so $\mathbf{f}_j$ contains two features. The probability of the first feature f_{j1} is equal to

$$P(f_{j1} = f \,|\, z_j = z, \mathbf{z}_{-j}, \mathbf{f}_{-j}, \beta) = \frac{n_{f,z} + \beta}{n_{\cdot,z} + F\beta} \quad (4)$$

where $n_{f,z}$ is the number of times feature f has been seen in class z, $n_{\cdot,z}$ is the total number of feature tokens in the class, and F is the number of different possible features.

The probability of the second feature f_{j2} can be calculated similarly, except that it is conditioned on f_{j1} in addition to the other variables, so the counts for previously observed features must include the counts due to f_{j1} as well as those due to $\mathbf{f}_{-j}$. Thus, the probability is

$$\begin{aligned} &P(f_{j2} = f \,|\, f_{j1}, z_j = z, \mathbf{z}_{-j}, \mathbf{f}_{-j}, \beta) \\ &\qquad = \frac{n_{f,z} + \delta(f_{j1}, f_{j2}) + \beta}{n_{\cdot,z} + 1 + F\beta} \quad (5) \end{aligned}$$

where δ is the Kronecker delta function, equal to 1 if its arguments are equal and 0 otherwise.

Extending this example to the general case, the probability of a sequence of features $\mathbf{f}_j$ is computed using the chain rule, where the counts used in each factor are incremented as necessary for each additional conditioning feature, yielding the following expression:

$$\begin{aligned} &P(\mathbf{f}_j \,|\, \mathbf{f}_{-j}, z_j = z, \mathbf{z}_{-j}, \beta) \\ &\qquad = \frac{\prod_{k=1}^{F} \prod_{i=0}^{n_{jk}-1} (n_{jk,z} + i + \beta)}{\prod_{i=0}^{n_j-1} (n_{\cdot,z} + i + F\beta)} \quad (6) \end{aligned}$$

where n_{jk} is the number of instances of feature k in word type j.[2]

2.3 Extended models

We can extend the model above in two different ways: by adding more features at the word token level, or by adding features at the type level. To add more token-level features, we simply assume that each word token generates multiple features, one feature from each of several different kinds.[3] For example, the left context word might be one kind of feature and the right context word another. We assume conditional independence between the generated features given the syntactic class, so each kind of feature t has its own output parameters $\phi^{(t)}$. A plate diagram of the model with T kinds of features is shown in Figure 2 (a type-level feature is also included in this diagram, as described below).

Due to the independence assumption between the different kinds of features, the basic Gibbs sampler is easy to extend to this case by simpling multiplying in extra factors for the additional kinds of features, with the prior (Equation 3) unchanged. The likelihood becomes:

$$P(\mathbf{f}_j^{(1)}, \ldots, \mathbf{f}_j^{(T)} \mid \mathbf{f}_{-j}^{(1\ldots T)}, z_j = z, \mathbf{z}_{-j}, \beta) = \prod_{t=1}^{T} P(\mathbf{f}_j^{(t)} \mid \mathbf{f}_{-j}^{(t)}, z_j = z, \mathbf{z}_{-j}, \beta) \quad (7)$$

where each factor in the product is computed using Equation 6.

In addition to monolingual context features, we also explore the use of alignment features for those languages where we have parallel corpora. These features are extracted for language ℓ by word-aligning ℓ to another language ℓ' (details of the alignment procedure are described in Section 3.1). The features used for each token e in ℓ are the left and right context words of the word token that is aligned to e (if there is one). As with the monolingual context features, we use only the F most frequent words in ℓ' as possible features.

[2]One could approximate this likelihood term by assuming independence between all n_j feature tokens of word type j. This is the approach taken by Lee et al. (2010).

[3]We use the word *kind* here to avoid confusion with *type*, which we reserve for the type-token distinction, which can apply to features as well as words.

Note that this model with multiple context features is deficient: it can generate data that are inconsistent with any actual corpus, because there is no mechanism to constrain the left context word of token e_i to be the same as the right context word of token e_{i-1} (and similarly with alignment features). However, deficient models have proven useful in other unsupervised NLP tasks (Klein and Manning, 2002; Toutanova and Johnson, 2007). In particular, Toutanova and Johnson (2007) demonstrate good performance on unsupervised part-of-speech tagging (using a dictionary) with a Bayesian model similar to our own. If we remove the part of their model that relies on the dictionary (the morphological ambiguity classes), their model is equivalent to our own, without the restriction of one class per type. We use this token-based version of our model as a baseline in our experiments.

The final extension to our model introduces type-level features, specifically morphology features. The model is illustrated in Figure 2. We assume conditional independence between the morphology features and other features, so again we can simply multiply another factor into the likelihood during inference. There is only one morphological feature per type, so this factor has the form of Equation 4. Since frequent words will have many token-level features contributing to the likelihood and only one morphology feature, the morphology features will have a greater effect for infrequent words (as appropriate, since there is less evidence from context and alignments). As with the other kinds of features, we use only a limited number F_m of morphology features, as described below.

3 Experiments

3.1 Experimental setup

We evaluate our models using an increasing level of complexity, starting with a model that uses only monolingual context features. We use the $F = 100$ most frequent words as features, and consider two versions of this model: one with two kinds of features (one left and one right context word) and one with four (two context words on each side).

For the model with morphology features we ran the unsupervised morphological segmentation system Morfessor (Creutz and Lagus, 2005) to get a

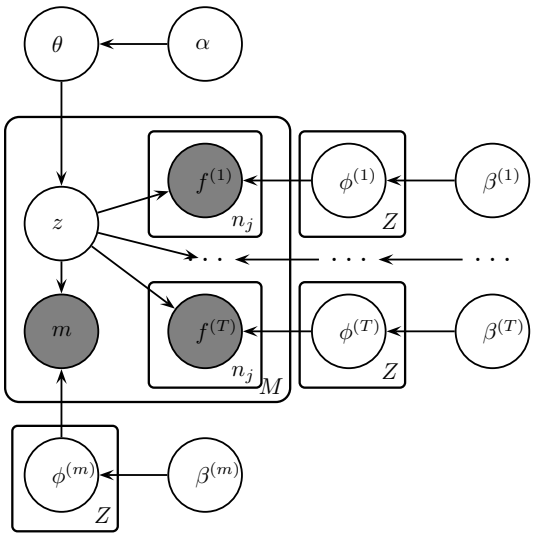

Figure 2: Plate diagram of the extended model with T kinds of token-level features ($f^{(t)}$ variables) and a single kind of type-level feature (morphology, m).

segmentation for each word type in the corpus. We then extracted the suffix of each word type[4] and used it as a feature type. This process yielded on average $F_m = 110$ morphological feature types[5]. Each word type generates at most one of these possible features. If there are overlapping possibilities (e.g. -ingly and -y) we take the longest possible match.

We also explore the idea of extending the morphology feature space beyond suffixes, by including features like capitalisation and punctuation. Specifically we use the features described in Haghighi and Klein (2006), namely *initial-capital*, *contains-hyphen*, *contains-digit* and we add an extra feature *contains-punctuation*.

For the model with alignment features, we follow (Naseem et al., 2009) in using only bidirectional alignments: using Giza++ (Och and Ney, 2003), we get the word alignments in both directions between all possible language pairs in our parallel corpora (i.e., alternating the source and target languages within each pair). We then use only those alignments that are found in both directions. As discussed above, we use two kinds of alignment features: the left and right context words of the aligned token in the other language. The feature space is set to the $F = 100$ most frequent words in that language.

Instead of fixing the hyperparameters α and β, we used the Metropolis-Hastings sampler presented by Goldwater and Griffiths (2007) to get updated values based on the likelihood of the data with respect to those hyperparameters[6]. In order to improve convergence of the sampler, we used simulated annealing with a sigmoid-shaped cooling schedule from an initial temperature of 2 down to 1. Preliminary experiments indicated that we could achieve better results by cooling even further (approximating the MAP solution rather than a sample from the posterior), so for all experiments reported here, we ran the sampler for a total of 2000 iterations, with the last 400 of these decreasing the temperature from 1 to 0.66.

Finally, we investigated two different initialisation techniques: First, we use random class assignments to word types (referred to as method 1) and second, we assign each of the Z most frequent word types to a separate class and then randomly distribute the rest of the word types to the classes (method 2).

3.2 Datasets

Although unsupervised systems should in principle be language- and corpus-independent, most part-of-speech induction systems (especially in the early literature) have been developed on English. Whether because English is simply an easier language, or because of bias introduced during development, these systems' performance is considerably worse in other languages (Christodoulopoulos et al., 2010)

Since we aim to use our system mostly on non-English corpora, and ones that are significantly smaller than the large English treebank corpora, we developed our models using one of the languages of the MULTEXT-East corpus (Erjavec, 2004), namely Bulgarian. The other languages in the corpus were used during development as a source of word alignments, but otherwise were only used for testing final versions of our models. Since none of the authors speak any of the languages in the MULTEXT col-

[4]Since Morfessor yields multiple affixes for each word we concatenated all the suffixes into a single suffix.

[5]There was large variance in the number of feature types for each language ranging from 11 in Chinese to more than 350 in German and Czech.

[6]For simplicity, we tied the β parameters for the two or four kinds of context features to the same value, and similarly the β parameters for the two kinds of alignment features.

lection, we also used the Penn Treebank WSJ corpus (Marcus et al., 1993) for development. Following Christodoulopoulos et al. (2010) we created a smaller version of the WSJ corpus (referred to as wsj-s) to approximate the size of the corpora in MULTEXT-East. For comparison to other systems, we also used the full WSJ at test time.

For further testing, we used the remaining MULTEXT languages, as well as the languages of the CONNL-X (Buchholz and Marsi, 2006) shared task. This dataset contains 13 languages, 4 of which are freely available (Danish, Dutch, Portuguese and Swedish) and 9 that are used with permission from the creators of the corpora (Arabic[7], Bulgarian[8], Czech[9], German[10], Chinese[11], Japanese[12], Slovene[13], Spanish[14], Turkish[15]). Following Lee et al. (2010) we used only the training sections for each language.

Finally, to widen the scope of our system, we generated two more corpora in French[16] and Ancient Greek[17], extracting the gold standard parts of speech from the respective dependency treebanks.

3.3 Baselines

We chose three baselines for comparison. The first is the basic k-means clustering algorithm, which we applied to the same feature vectors we extracted for our system (context + extended morphology), using a Euclidean distance metric. This provides a very simple vector-based clustering baseline. The second baseline is a more recent vector-based syntactic class induction method, the SVD approach of (Lamar et al., 2010), which extends Schütze (1995)'s original method and, like ours, enforces a one-class-per-tag restriction. As a third baseline we use the system of Clark (2003) since it is a type-level system that models morphology and has produced very good results on multilingual corpora.

4 Results and Analysis

4.1 Development results

Tables 1 and 2 present the results from development runs, which were used to decide which features to incorporate in the final system. We used V-Measure (Rosenberg and Hirschberg, 2007) as our primary evaluation score, but also present many-to-one matching accuracy (M-1) scores for better comparison with previously published results. We chose V-Measure (VM) as our evaluation score because it is less sensitive to the number of classes induced by the model (Christodoulopoulos et al., 2010), allowing us to develop our models without using the number of classes as a parameter. We fixed the number of classes in all systems to 45 during development; note however that the gold standard tag set for Bulgarian contains only 12 tags, so the results in Table 1 (especially the M-1 scores) are not comparable to previous results. For results using the number of gold-standard tags refer to Table 4.

The first conclusion that can be drawn from these results is the large difference between the token- and type-based versions of our system, which confirms that the one-class-per-type restriction is helpful for unsupervised syntactic class induction. We also see that for both languages, the performance of the model using 4 context words (± 2 on each side) is worse than the 2 context words model. We therefore used only two context words for all of our additional test languages (below).

We can clearly see that morphological features are helpful in both languages; however the extended features of Haghighi and Klein (2006) seem to help only on the English data. This could be due to the fact that Bulgarian has a much richer morphology and thus the extra features contribute little to the overall performance of the model.

The contribution of the alignment features on the Bulgarian corpus (aligned with English) is less significant than that of morphology but when combined, the two sets of features yield the best performance. This provides evidence in favor of using multiple features.

Finally, initialisation method 2 does not yield

consistent improvements over the standard random initialisation—if anything, it seems to perform worse. We therefore use only method 1 in the remaining experiments.

4.2 Overall results

Table 3 presents the results on our parallel corpora. We tested all possible combinations of two languages to align, and present both the average score over all alignments, and the score under the best choice of aligned language.[18] Also shown are the results of adding morphology features to the basic model (context features only) and to the best alignment model for each language. In accord with our development results, adding morphology to the basic model is generally useful. The alignment results are mixed: on the one hand, choosing the best possible language to align yields improvements, which can be improved further by adding morphological features, resulting in the best scores of all models for most languages. On the other hand, without knowing which language to choose, alignment features do not help on average. We note, however, that three out of the seven languages have English as their best-aligned pair (perhaps due to its better overall scores), which suggests that in the absence of other knowledge, aligning with English may be a good choice.

The low average performance of the alignment features is disappointing, but there are many possible variations on our method for extracting these features that we have not yet tested. For example, we used only bidirectional alignments in an effort to improve alignment precision, but these alignments typically cover less than 40% of tokens. It is possible that a higher-recall set of alignments could be more useful.

We turn now to our results on all 25 corpora, shown in Table 4 along with corpus statistics, baseline results, and the best published results for each language (when available). Our system, including morphology features in all cases, is listed as BMMM (Bayesian Multinomial Mixture Model). We do not include alignment features for the MULTEXT languages since these features only yielded improvements for the oracle case where we know which aligned language to choose. Nevertheless, our MULTEXT scores mostly outperform all other systems. Overall, we acheive the highest published results on 14 (VM) or 15 (M-1) of the 25 corpora.

One surprising discovery is the high performance of the k-means clustering system. Despite its simplicity, it is competitive with the other systems and in a few cases even achieves the best published results.

5 Conclusion

We have presented a Bayesian model for syntactic class induction that has two important properties. First, it is type-based, assigning the same class to every token of a word type. We have shown by

[18] The choice of language was based on the same test data, so the 'best-language' results should be viewed as oracle scores.

Lang.	BASE		ALIGNMENTS		
	base	**+morph**	**Avg.**	**Best**	**+morph**

Table 4: Final results on 25 corpora in 20 languages, with the number of induced classes equal to the number of gold standard tags in all cases. **k-means** and **SVD2** models could not produce a clustering in the Czech CoNLL corpus due its size. Best published results are from *Christodoulopoulos et al. (2010), †Berg-Kirkpatrick et al. (2010) and ‡Lee et al. (2010). The latter two papers do not report VM scores. No best published results are shown for the MULTEXT languages; Christodoulopoulos et al. (2010) report results based on 45 tags suggesting that **clark** performs best on these corpora.

comparison with a token-based version of the model that this restriction is very helpful. Second, it is a clustering model rather than a sequence model. This property makes it easy to incorporate multiple kinds of features into the model at either the token or the type level. Here, we experimented with token-level context features and alignment features and type-level morphology features, showing that morphology features are helpful in nearly all cases, and alignment features can be helpful if the aligned language is properly chosen. Our results even without these extra features are competitive with state-of-the-art; with the additional features we achieve the best published results in the majority of the 25 corpora tested.

Since it is so easy to add extra features to our model, one direction for future work is to explore other possible features. For example, it could be useful to add dependency features from an unsupervised dependency parser. We are also interested in improving our morphology features, either by considering other ways to extract features during preprocessing (for example, including prefixes or not concatenating together all suffixes), or by developing a joint model for inducing both morphology and syntactic classes simultaneously. Finally, our model could be extended by replacing the standard mixture model with an infinite mixture model (Rasmussen, 2000) in order to induce the number of syntactic classes automatically.

Abstract

Responding to the need for semantic lexical resources in natural language processing applications, we examine methods to acquire noun compounds (NCs), e.g., *orange juice*, together with suitable fine-grained semantic interpretations, e.g., *squeezed from*, which are directly usable as paraphrases. We employ bootstrapping and web statistics, and utilize the relationship between NCs and paraphrasing patterns to jointly extract NCs and such patterns in multiple alternating iterations. In evaluation, we found that having one compound noun fixed yields both a higher number of semantically interpreted NCs and improved accuracy due to stronger semantic restrictions.

1 Introduction

Noun compounds (NCs) such as *malaria mosquito* and *colon cancer tumor suppressor protein* are challenging for text processing since the relationship between the nouns they are composed of is implicit. NCs are abundant in English and understanding their semantics is important in many natural language processing (NLP) applications. For example, a question answering system might need to know whether *protein acting as a tumor suppressor* is a good paraphrase for *tumor suppressor protein*. Similarly, a machine translation system facing the unknown noun compound *Geneva headquarters* might translate it better if it could first paraphrase it as *Geneva headquarters of the WTO*. Given a query for *"migraine treatment"*, an information retrieval system could use paraphrasing verbs like *relieve* and *prevent* for query expansion and result ranking.

Most work on noun compound interpretation has focused on two-word NCs. There have been two general lines of research: the first one derives the NC semantics from the semantics of the nouns it is made of (Rosario and Hearst, 2002; Moldovan et al., 2004; Kim and Baldwin, 2005; Girju, 2007; Séaghdha, 2009; Tratz and Hovy, 2010), while the second one models the relationship between the nouns directly (Vanderwende, 1994; Lapata, 2002; Kim and Baldwin, 2006; Nakov and Hearst, 2006; Nakov and Hearst, 2008; Butnariu and Veale, 2008).

In either case, the semantics of an NC is typically expressed by an abstract relation like CAUSE (e.g., *malaria mosquito*), SOURCE (e.g., *olive oil*), or PURPOSE (e.g., *migraine drug*), coming from a small fixed inventory. Some researchers however, have argued for a more fine-grained, even infinite, inventory (Finin, 1980). Verbs are particularly useful in this respect and can capture elements of the semantics that the abstract relations cannot. For example, while most NCs expressing MAKE, can be paraphrased by common patterns like *be made of* and *be composed of*, some NCs allow more specific patterns, e.g., *be squeezed from* for *orange juice*, and *be topped with* for *bacon pizza*.

Recently, the idea of using fine-grained paraphrasing verbs for NC semantics has been gaining popularity (Butnariu and Veale, 2008; Nakov, 2008b); there has also been a related shared task at SemEval-2010 (Butnariu et al., 2010). This interest is partly driven by practicality: verbs are directly usable as paraphrases. Still, abstract relations remain dominant since they offer a more natural generalization, which is useful for many NLP applications.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 648–658,
Edinburgh, Scotland, UK, July 27–31, 2011.

One good contribution to this debate would be a direct study of the relationship between fine-grained and coarse-grained relations for NC interpretation. Unfortunately, the existing datasets do not allow this since they are tied to one particular granularity; moreover, they only contain a few hundred NCs. Thus, our objective is to build a large-scale dataset of hundreds of thousands of NCs, each interpreted (1) by an abstract semantic relation and (2) by a set of paraphrasing verbs. Having such a large dataset would also help the overall advancement of the field.

Since there is no universally accepted abstract relation inventory in NLP, and since we are interested in NC semantics from both a theoretical and a practical viewpoint, we chose the set of abstract relations proposed in the theory of Levi (1978), which is dominant in theoretical linguistics and has been also used in NLP (Nakov and Hearst, 2008).

We use a two-step algorithm to jointly harvest NCs and patterns (verbs and prepositions) that interpret them for a given abstract relation. First, we extract NCs using a small number of seed patterns from a given abstract relation. Then, using the extracted NCs, we harvest more patterns. This is repeated until no new NCs and patterns can be extracted or for a pre-specified number of iterations. Our approach combines pattern-based extraction and bootstrapping, which is novel for NC interpretation; however, such combinations have been used in other areas, e.g., named entity recognition (Riloff and Jones, 1999; Thelen and Riloff, 2002; Curran et al., 2007; McIntosh and Curran, 2009).

The remainder of the paper is organized as follows: Section 2 gives an overview of related work, Section 3 motivates our semantic representation, Sections 4, 5, and 6 explain our method, dataset and experiments, respectively, Section 7 discusses the results, Section 8 provides error analysis, and Section 9 concludes with suggestions for future work.

2 Related Work

As we mentioned above, the implicit relation between the two nouns forming a noun compound can often be expressed overtly using verbal and prepositional paraphrases. For example, *student loan* is "loan given to a student", while *morning tea* can be paraphrased as "tea in the morning".

Thus, many NLP approaches to NC semantics have used verbs and prepositions as a fine-grained semantic representation or as features when predicting coarse-grained abstract relations. For example, Vanderwende (1994) associated verbs extracted from definitions in an online dictionary with abstract relations. Lauer (1995) expressed NC semantics using eight prepositions. Kim and Baldwin (2006) predicted abstract relations using verbs as features. Nakov and Hearst (2008) proposed a fine-grained NC interpretation using a distribution over Web-derived verbs, prepositions and coordinating conjunctions; they also used this distribution to predict coarse-grained abstract relations. Butnariu and Veale (2008) adopted a similar fine-grained verb-centered approach to NC semantics. Using a distribution over verbs as a semantic interpretation was also carried out in a recent challenge: SemEval-2010 Task 9 (Butnariu et al., 2009; Butnariu et al., 2010).

In noun compound interpretation, verbs and prepositions can be seen as patterns connecting the two nouns in a paraphrase. Similar pattern-based approaches have been popular in information extraction and ontology learning. For example, Hearst (1992) extracted hyponyms using patterns such as *X, Y, and/or other Zs*, where *Z* is a hypernym of *X* and *Y*. Berland and Charniak (1999) used similar patterns to extract meronymy (part-whole) relations, e.g., *parts/NNS of/IN wholes/NNS* matches *basements of buildings*. Unfortunately, matches are rare, which makes it difficult to build large semantic inventories. In order to overcome data sparseness, pattern-based approaches are often combined with bootstrapping. For example, Riloff and Jones (1999) used a multi-level bootstrapping algorithm to learn both a semantic lexicon and extraction patterns, e.g., *owned by X* extracts COMPANY and *facilities in X* extracts LOCATION. That is, they learned semantic lexicons using extraction patterns, and then, alternatively, they extracted new patterns using these lexicons. They also introduced a second level of bootstrapping to retain the most reliable examples only. While the method enables the extraction of large lexicons, its quality degrades rapidly, which makes it impossible to run for too many iterations. Recently, Curran et al. (2007) and McIntosh and Curran (2009) proposed ways to control degradation using simultaneous learning and weighting.

Bootstrapping has been applied to noun compound extraction as well. For example, Kim and Baldwin (2007) used it to produce a large number of semantically interpreted noun compounds from a small number of seeds. In each iteration, the method replaced one component of an NC with its synonyms, hypernyms and hyponyms to generate a new NC. These new NCs were further filtered based on their semantic similarity with the original NC. While the method acquired a large number of noun compounds without significant semantic drifting, its accuracy degraded rapidly after each iteration. More importantly, the variation of the sense pairs was limited since new NCs had to be semantically similar to the original NCs.

Recently, Kozareva and Hovy (2010) combined patterns and bootstrapping to learn the selectional restrictions for various semantic relations. They used patterns involving the coordinating conjunction *and*, e.g., "* *and John fly to* *", and learned arguments such as *Mary/Tom* and *France/New York*. Unlike in NC interpretation, it is not necessary for their arguments to form an NC, e.g., *Mary France* and *France Mary* are not NCs. Rather, they were interested in building a semantic ontology with a predefined set of semantic relations, similar to YAGO (Suchanek et al., 2007), where the pattern *work for* would have arguments like *a company/UNICEF*.

3 Semantic Representation

Inspired by (Finin, 1980), Nakov and Hearst (2006) and (Nakov, 2008b) proposed that NC semantics is best expressible using paraphrases involving verbs and/or prepositions. For example, *bronze statue* is a statue that *is made of, is composed of, consists of, contains, is of, is, is handcrafted from, is dipped in, looks like* bronze. They further proposed that selecting one such paraphrase is not enough and that multiple paraphrases are needed for a fine-grained representation. Finally, they observed that not all paraphrases are equally good (e.g., *is made of* is arguably better than *looks like* or *is dipped in* for MAKE), and thus proposed that the semantics of a noun compound should be expressed as a *distribution* over multiple possible paraphrases. This line of research was later adopted by SemEval-2010 Task 9 (Butnariu et al., 2010).

It easily follows that the semantics of abstract relations such as MAKE that can hold between the nouns in an NC can be represented in the same way: as a distribution over paraphrasing verbs and prepositions. Note, however, that some NCs are paraphrasable by more specific verbs that do not necessarily support the target abstract relation. For example, *malaria mosquito*, which expresses CAUSE, can be paraphrased using verbs like *carry*, which do not imply direct causation. Thus, while we will be focusing on extracting NCs for a particular abstract relation, we are interested in building semantic representations that are specific for these NCs and do not necessarily apply to *all* instances of that relation.

Traditionally, the semantics of a noun compound have been represented as an abstract relation drawn from a small closed set. Unfortunately, no such set is universally accepted, and mapping between sets has proven challenging (Girju et al., 2005). Moreover, being both abstract and limited, such sets capture only part of the semantics; often multiple meanings are possible, and sometimes none of the pre-defined ones suits a given example. Finally, it is unclear how useful these sets are since researchers have often fallen short of demonstrating practical uses.

Arguably, verbs have more expressive power and are more suitable for semantic representation: there is an infinite number of them (Downing, 1977), and they can capture fine-grained aspects of the meaning. For example, while both *wrinkle treatment* and *migraine treatment* express the same abstract relation TREATMENT-FOR-DISEASE, fine-grained differences can be revealed using verbs, e.g., *smooth* can paraphrase the former, but not the latter.

In many theories, verbs play an important role in NC derivation (Levi, 1978). Moreover, speakers often use verbs to make the hidden relation between the noun in a noun compound overt. This allows for simple extraction and for straightforward use in NLP tasks like textual entailment (Tatu and Moldovan, 2005) and machine translation (Nakov, 2008a).

Finally, a single verb is often not enough, and the meaning is better approximated by a collection of verbs. For example, while *malaria mosquito* expresses CAUSE (and is paraphrasable using *cause*), further aspects of the meaning can be captured with more verbs, e.g., *carry*, *spread*, *be responsible for*, *be infected with*, *transmit*, *pass on*, etc.

4 Method

We harvest noun compounds expressing some target abstract semantic relation (in the experiments below, this is Levi's MAKE$_2$), starting from a small number of initial seed patterns: paraphrasing verbs and/or prepositions. Optionally, we might also be given a small number of noun compounds that instantiate the target abstract relation. We then learn more noun compounds and patterns for the relation by alternating between the following two bootstrapping steps, using the Web as a corpus. First, we extract more noun compounds that are paraphrasable with the available patterns (see Section 4.1). We then look for new patterns that can paraphrase the newly-extracted noun compounds (see Section 4.2). These two steps are repeated until no new noun compounds can be extracted or until a pre-determined number of iterations has been reached. A schematic description of the algorithm is shown in Figure 1.

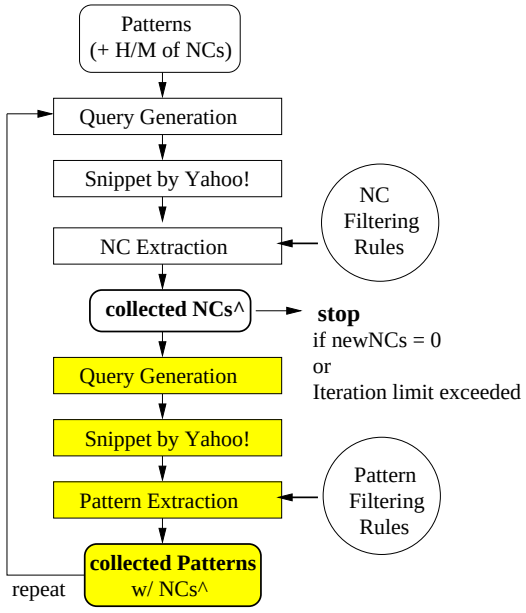

Figure 1: Our bootstrapping algorithm.

4.1 Bootstrapping Step 1: Noun Compound Extraction

Given a list of patterns (verbs and/or prepositions), we mine the Web to extract noun compounds that match these patterns. We experiment with the following three bootstrapping strategies for this step:

- **Loose bootstrapping** uses the available patterns and imposes no further restrictions.
- **Strict bootstrapping** requires that, in addition to the patterns themselves, some noun compounds matching each pattern be made available as well. A pattern is only instantiated in the context of either the head or the modifier of a noun compound that is known to match it.
- **NC-only strict bootstrapping** is a stricter version of *strict bootstrapping*, where the list of patterns is limited to the initial seeds.

Below we describe each of the sub-steps of the NC extraction process: query generation, snippet harvesting, and noun compound acquisition & filtering.

4.1.1 Query Generation

We generate generalized exact-phrase queries to be used in a Web search engine (we use *Yahoo!*):

`"* that PATTERN *"`	(*loose*)
`"HEAD that PATTERN *"`	(*strict*)
`"* that PATTERN MOD"`	(*strict*)

where `PATTERN` is an inflected form of a verb, `MOD` and `HEAD` are inflected forms the modifier and the head of a noun compound that is paraphrasable by the pattern, `that` is the word *that*, and `*` is the search engine's star operator.

We use the first pattern for *loose bootstrapping* and the other two for both *strict bootstrapping* and *NC-only strict bootstrapping*.

Note that the above queries are generalizations of the actual queries we use against the search engine. In order to instantiate these generalizations, we further generate the possible inflections for the verbs and the nouns involved. For nouns, we produce singular and plural forms, while for verbs, we vary not only the number (singular and plural), but also the tense (we allow present, past, and present perfect). When inflecting verbs, we distinguish between active verb forms like *consist of* and passive ones like *be made from* and we treat them accordingly. Overall, in the case of *loose bootstrapping*, we generate about 14 and 20 queries per pattern for active and passive patterns, respectively, while for *strict bootstrapping* and *NC-only strict bootstrapping*, the instantiations yield about 28 and 40 queries for active and passive patterns, respectively.

For example, given the seed *be made of*, we could generate "⋆ that were made of ⋆". If we are further given the NC *orange juice*, we could also produce "juice that was made of ⋆" and "⋆ that is made of oranges".

4.1.2 Snippet Extraction

We execute the above-described instantiations of the generalized queries against a search engine as exact phrase queries, and, for each one, we collect the snippets for the top 1,000 returned results.

4.1.3 NC Extraction and Filtering

Next, we process the snippets returned by the search engine and we acquire potential noun compounds from them. Then, in each snippet, we look for an instantiation of the pattern used in the query and we try to extract suitable noun(s) that occupy the position(s) of the ⋆.

For *loose bootstrapping*, we extract two nouns, one from each end of the matched pattern, while for *strict bootstrapping* and for *NC-only strict bootstrapping*, we only extract one noun, either preceding or following the pattern, since the other noun is already fixed. We then lemmatize the extracted noun(s) and we form NC candidates from the two arguments of the instantiated pattern, taking into account whether the pattern is active or passive.

Due to the vast number of snippets we have to process, we decided not to use a syntactic parser or a part-of-speech (POS) tagger[1]; thus, we use heuristic rules instead. We extract "phrases" using simple indicators such as punctuation (e.g., comma, period), coordinating conjunctions[2] (e.g., *and, or*), prepositions (e.g., *at, of, from*), subordinating conjunctions (e.g., *because, since, although*), and relative pronouns (e.g., *that, which, who*). We then extract the nouns from these phrases, we lemmatize them using WordNet, and we form a list of NC candidates.

While the above heuristics work reasonably well in practice, we perform some further filtering, removing all NC candidates for which one or more of the following conditions are met:

1. the candidate NC is one of the seed examples or has been extracted on a previous iteration;
2. the head and the modifier are the same;
3. the head or the modifier are not both listed as nouns in WordNet (Fellbaum, 1998);
4. the candidate NC occurs less than 100 times in the *Google Web 1T 5-gram corpus*[3];
5. the NC is extracted less than N times (we tried 5 and 10) in the context of the pattern for all instantiations of the pattern.

4.2 Bootstrapping Step 2: Pattern Extraction

This is the second step of our bootstrapping algorithm as shown on Figure 1. Given a list of noun compounds, we mine the Web to extract patterns: verbs and/or prepositions that can paraphrase each NC. The idea is to turn the NC's pre-modifier into a post-modifying relative clause and to collect the verbs and prepositions that are used in such clauses. Below we describe each of the sub-steps of the NC extraction process: query generation, snippet harvesting, and NC extraction & filtering.

4.2.1 Query Generation

The process of extraction starts with exact-phrase queries issued against a Web search engine (again *Yahoo!*) using the following generalized pattern:

"HEAD THAT? ⋆ MOD"

where MOD and HEAD are inflected forms of NC's modifier and head, respectively, THAT? stands for *that*, *which*, *who* or the empty string, and ⋆ stands for 1-6 instances of search engine's star operator.

For example, given *orange juice*, we could generate queries like "juice that ⋆ oranges", "juices which ⋆ ⋆ ⋆ ⋆ ⋆ ⋆ oranges", and "juices ⋆ ⋆ ⋆ orange".

4.2.2 Snippet Extraction

The same as in Section 4.1.2 above.

[1] In fact, POS taggers and parsers are unreliable for Web-derived snippets, which often represent parts of sentences and contain errors in spelling, capitalization and punctuation.

[2] Note that filtering the arguments using such indicators indirectly subsumes the pattern "X PATTERN Y and" proposed in (Kozareva and Hovy, 2010).

[3] http://www.ldc.upenn.edu/Catalog/CatalogEntry.jsp?catalogId=LDC2006T13

4.2.3 Pattern Extraction and Filtering

We split the extracted snippets into sentences, and filter out all incomplete ones and those that do not contain (a possibly inflected version of) the target nouns. We further make sure that the word sequence following the second mentioned target noun is non-empty and contains at least one non-noun, thus ensuring the snippet includes the entire noun phrase. We then perform shallow parsing, and we extract all verb forms, and the following preposition, between the target nouns. We allow for adjectives and participles to fall between the verb and the preposition but not nouns; we further ignore modal verbs and auxiliaries, but we retain the passive *be*, and we make sure there is exactly one verb phrase between the target nouns. Finally, we lemmatize the verbs to form the patterns candidates, and we apply the following pattern selection rules:

1. we filter out all patterns that were provided as initial seeds or were extracted previously;
2. we select the top 20 most frequent patterns;
3. we filter out all patterns that were extracted less than N times (we tried 5 and 10) and with less than M NCs per pattern (we tried 20 and 50).

5 Target Relation and Seed Examples

As we mentioned above, we use the inventory of abstract relations proposed in the popular theoretical linguistics theory of Levi (1978). In this theory, noun compounds are derived from underlying relative clauses or noun phrase complement constructions by means of two general processes: predicate deletion and predicate nominalization. Given a two-argument predicate, *predicate deletion* removes that predicate, but retains its arguments to form an NC, e.g., *pie made of apples* $\rightarrow$ *apple pie*. In contrast, *predicate nominalization* creates an NC whose head is a nominalization of the underlying predicate and whose modifier is either the subject or the object of that predicate, e.g., *The President refused General MacArthur's request.* $\rightarrow$ *presidential refusal*.

According to Levi, predicate deletion can be applied to abstract predicates, whose semantics can be roughly approximated using five paraphrasing verbs (CAUSE, HAVE, MAKE, USE, and BE) and four prepositions (IN, FOR, FROM, and ABOUT).

Typically, in predicate deletion, the modifier is derived from the object of the underlying relative clause; however, the first three verbs also allow for it to be derived from the subject. Levi expresses the distinction using indexes. For example, *music box* is MAKE_1 (object-derived), i.e., the *box makes music*, while *chocolate bar* is MAKE_2 (subject-derived), i.e., *the bar is made of chocolate* (note the passive).

Due to time constraints, we focused on one relation of Levi's, MAKE_2, which is among the most frequent relations an NC can express and is present in some form in many relation inventories (Warren, 1978; Barker and Szpakowicz, 1998; Rosario and Hearst, 2001; Nastase and Szpakowicz, 2003; Girju et al., 2005; Girju et al., 2007; Girju et al., 2009; Hendrickx et al., 2010; Tratz and Hovy, 2010).

In Levi's theory, MAKE_2 means that the head of the noun compound is made up of or is a product of its modifier. There are three subtypes of this relation (we do not attempt to distinguish between them):

(a) the modifier is a unit and the head is a configuration, e.g., *root system*;

(b) the modifier represents a material and the head is a mass or an artefact, e.g., *chocolate bar*;

(c) the head represents human collectives and the modifier specifies their membership, e.g., *worker teams*.

There are 20 instances of MAKE_2 in the appendix of (Levi, 1978), and we use them all as *seed NCs*. As *seed patterns*, we use a subset of the human-proposed paraphrasing verbs and prepositions corresponding to these 20 NCs in the dataset in (Nakov, 2008b), where each NC is paraphrased by 25-30 annotators. For example, for *chocolate bar*, we find the following list of verbs (the number of annotators who proposed each verb is shown in parentheses):

> be made of (16), contain (16), be made from (10), be composed of (7), taste like (7), consist of (5), be (3), have (2), melt into (2), be manufactured from (2), be formed from (2), smell of (2), be flavored with (1), sell (1), taste of (1), be constituted by (1), incorporate (1), serve (1), contain (1), store (1), be made with (1), be solidified from (1), be created from (1), be flavoured with (1), be comprised of (1).

Seed NCs: bronze statue, cable network, candy cigarette, chocolate bar, concrete desert, copper coin, daisy chain, glass eye, immigrant minority, mountain range, paper money, plastic toy, sand dune, steel helmet, stone tool, student committee, sugar cube, warrior castle, water drop, worker team
Seed patterns: be composed of, be comprised of, be inhabited by, be lived in by, be made from, be made of, be made up of, be manufactured from, be printed on, consist of, contain, have, house, include, involve, look like, resemble, taste like

Table 1: Our seed examples: 20 noun compounds and 18 verb patterns.

As we can see, the most frequent patterns are of highest quality, e.g., *be made of (16)*, while the less frequent ones can be wrong, e.g., *serve (1)*. Therefore, we filtered out all verbs that were proposed less than five times with the 20 seed NCs. We further removed the verb *be*, which is too general, thus ending up with 18 seed patterns. Note that some patterns can paraphrase multiple NCs: the total number of seed NC-pattern pairs is 84.

The seed NCs and patterns are shown in Table 1. While some patterns, e.g., *taste like* do not express the target relation MAKE$_2$, we kept them anyway since they were proposed by several human annotators and since they do express the fine-grained semantics of some particular instances of that relation; thus, we thought they might be useful, even for the general relation. For example, *taste like* has been proposed 8 times for *candy cigarette*, 7 times for *chocolate bar*, and 2 times for *sugar cube*, and thus it clearly correlates well with some seed examples, even if it does not express MAKE$_2$ in general.

6 Experiments and Evaluation

Using the NCs and patterns in Table 1 as initial seeds, we ran our algorithm for three iterations of *loose bootstrapping* and *strict bootstrapping*, and for two iterations of *NC-only strict bootstrapping*. We only performed up to three iterations because of the huge number of noun compounds extracted for *NC-only strict bootstrapping* (which we only ran for two iterations) and because of the low number of new NCs extracted by *loose bootstrapping* on iteration 3. While we could have run *strict bootstrapping* for more iterations, we opted for a comparable number of iterations for all three methods.

Examples of noun compounds that we have extracted are *bronze bell* (be made of, be made from) and *child team* (be composed of, include). Example patterns are *be filled with* (cotton bag, water cup) and *use* (water sculpture, wood statue).

Limits (see 4.2.3)	**Extracted & Retained** NCs	Patterns	Patt.+NC
Loose Bootstrapping			
N=5, M=50	1,662 / 61.67	12 / 65.83	1,337
N=10, M=20	590 / 61.52	9 / 65.56	316
Strict Bootstrapping			
N=5, M=50	25,375 / 67.42	16 / 71.43	9,760
N=10, M=20	16,090 / 68.27	16 / 78.98	5,026
NC-only Strict Bootstrapping			
N=5	205,459 / 69.59	–	–
N=10	100,550 / 70.43	–	–

Table 2: Total number and accuracy in % for NCs, patterns and NC-pattern pairs extracted and retained for each of the three methods over all iterations.

Tables 2 and 3 show the overall results. As we mentioned in section 4.2.3, at each iteration, we filtered out all patterns that were extracted less than N times or with less than M NCs. Note that we only used the 10 most frequent NCs per pattern as NC seeds for NC extraction in the next iteration of *strict bootstrapping* and *NC-only strict bootstrapping*. Table 3 shows the results for two value combinations of (N;M): (5;50) and (10;20). Note also that if some NC was extracted by several different patterns, it was only counted once. Patterns are subject to particular NCs, and thus we show (1) the number of patterns extracted with all NCs, i.e., unique NC-pattern pairs, (2) the accuracy of these pairs,[4] and (3) the number of unique patterns retained after filtering, which will be used to extract new noun compounds on the second step of the current iteration.

[4]One of the reviewers suggested that evaluating the accuracy of NC-pattern pairs could potentially conceal some of the drift of our algorithm. For example, while *water cup* / *be filled with* is a correct NC-pattern pair, *water cup* is incorrect for MAKE$_2$; it is probably an instance of Levi's FOR. Thus, the same bootstrapping technique evaluated against a fixed set of semantic relations (which is the more traditional approach) could arguably show bootstrapping going "off the rails" more quickly than what we observe here. However, our goal, as stated in Section 3, is to find NC-specific paraphrases, and our evaluation methodology is more adequate with respect to this goal.

Limits (see 4.2.3)	Seeds Patt.	Seeds NCs	Iteration 1 Patt.	Iteration 1 NCs	Iteration 2 Patterns	Iteration 2 NCs	Iteration 3 Patterns	Iteration 3 NCs
Loose Bootstrapping								
N=5, M=50	–	18	–	1,144 / 63.11	1,136 / 64.44 / 9	390 / 58.72	201 / 70.00 / 3	128 / 57.03
N=10, M=20	–	18	–	502 / 61.55	294 / 62.50 / 8	78 / 60.26	22 / 90.00 / 1	10 / 70.00
Strict Bootstrapping								
N=5, M=50	20	18	–	7,011 / 70.65	5,312 / 74.00 / 10	11,214 / 67.15	4,448 / 60.00 / 6	7,150 / 64.69
N=10, M=20	20	18	–	4,826 / 71.26	2,838 / 79.38 / 10	7,371 / 67.26	2,188 / 78.33 / 6	3,893 / 66.48
NC-only Strict Bootstrapping								
N=5	20	18	–	7,011 / 70.65	–	198,448 / 69.55	–	–
N=10	20	18	–	4,826 / 71.26	–	95,524 / 70.59	–	–

Table 3: *Evaluation results for up to three iterations.* For NCs, we show the number of unique NCs extracted and their accuracy in %. For patterns, we show the number of unique NC-pattern pairs extracted, their accuracy in %, and the number of unique patterns retained and used to extract NCs on the second step of the current iteration. The first column shows the pattern filtering thresholds used (see Section 4.2.3 for details).

The above accuracies were calculated based on human judgments by an experienced, well-trained annotator. We also hired a second annotator for a small subset of the examples.

For NCs, the first annotator judged whether each NC is an instance of MAKE$_2$. All NCs were judged, except for iteration 2 of *NC-only strict bootstrapping*, where their number was prohibitively high and only the most frequent noun compounds extracted for each modifier and for each head were checked: 9,004 NCs for N=5 and 4,262 NCs for N=10.

For patterns, our first annotator judged the correctness of the unique NC-pattern pairs, i.e., whether the NC is paraphrasable with the target pattern. Given the large number of NC-pattern pairs, the annotator only judged patterns with their top 10 most frequent NCs. For example, if there were 5 patterns extracted, then the NC-pattern pairs to be judged would be no more than $5 \times 10 = 50$.

Our second annotator judged 340 random examples: 100 NCs and 20 patterns with their top 10 NCs for each iteration. The Cohen's kappa (Cohen, 1960) between the two annotators is .66 (85% initial agreement), which corresponds to substantial agreement (Landis and Koch, 1977).

7 Discussion

Tables 2 and 3 show that fixing one of the two nouns in the pattern, as in *strict bootstrapping* and *NC-only strict bootstrapping*, yields significantly higher accuracy (χ^2 test) for both NC and NC-pattern pair extraction compared to *loose bootstrapping*.

The accuracy for *NC-only strict bootstrapping* is a bit higher than for *strict bootstrapping*, but the actual differences are probably smaller since the evaluation of the former on iteration 2 was done for the most frequent NCs, which are more accurate.

Note that the number of extracted NCs is much higher with the strict methods because of the higher number of possible instantiations of the generalized query patterns. For *NC-only strict bootstrapping*, the number of extracted NCs grows exponentially since the number of patterns does not diminish as in the other two methods. The number of extracted patterns is similar for the different methods since we select no more than 20 of them per iteration.

Overall, the accuracy for all methods decreases from one iteration to the next since errors accumulate; still, the degradation is slow. Note also the exception of *loose bootstrapping* on iteration 3.

Comparing the results for N=5 and N=10, we can see that, for all three methods, using the latter yields a sizable drop in the number of extracted NCs and NC-pattern pairs; it also tends to yield a slightly improved accuracy. Note, however, the exception of *loose bootstrapping* for the first two iterations, where the less restrictive N=5 is more accurate.

As a comparison, we implemented the method of Kim and Baldwin (2007), which generates new semantically interpreted NCs by replacing either the head or the modifier of a seed NC with suitable synonyms, hypernyms and sister words from WordNet, followed by similarity filtering using `WordNet::Similarity` (Pedersen et al., 2004).

Rep.	Iter. 1	Iter. 2	Iter. 3	All
Syn.	11/81.81	3/66.67	0	14/78.57
Hyp.	27/85.19	35/77.14	33/66.67	95/75.79
Sis.	381/82.05	1,736/69.33	17/52.94	2,134/75.12
All	419/82.58	1,774/71.68	50/62.00	2,243/**75.47**

Table 4: Number of extracted noun compounds and accuracy in % for the method of Kim and Baldwin (2007). The abbreviations *Syn.*, *Hyp.*, and *Sis.* indicate using synonyms, hypernyms, and sister words, respectively.

The results for three bootstrapping iterations using the same list of 20 initial seed NCs as in our previous experiments, are shown in Table 4. We can see that the overall accuracy of their method is slightly better than ours. Note, however, that our method acquired a much larger number of NCs, while allowing more variety in the NC semantics. Moreover, for each extracted noun compound, we also generated a list of fine-grained paraphrasing verbs.

8 Error Analysis

Below we analyze the errors of our method.

Many problems were due to wrong POS assignment. For example, on Step 2, because of the omission of *that* in "*the statue has such high quality gold (that) demand is ...*", *demand* was tagged as a noun and thus extracted as an NC modifier instead of *gold*. The problem also arose on Step 1, where we used WordNet to check whether the NC candidates were composed of two nouns. Since words like *clear*, *friendly*, and *single* are listed in WordNet as nouns (which is possible in some contexts), we extracted wrong NCs such as *clear cube*, *friendly team*, and *single chain*. There were similar issues with verb-particle constructions since some particles can be used as nouns as well, e.g., *give back, break down*.

Some errors were due to semantic transparency issues, where the syntactic and the semantic head of a target NP were mismatched (Fillmore et al., 2002; Fontenelle, 1999). For example, from the sentence "*This wine is made from a range of white grapes.*", we would extract *range* rather than *grapes* as the potential modifier of *wine*.

In some cases, the NC-pattern pair was correct, but the NC did not express the target relation, e.g., while *contain* is a good paraphrase for *toy box*, the noun compound itself is not an instance of MAKE$_2$.

There were also cases where the pair of extracted nouns did not make a good NC, e.g., *worker work* or *year toy*. Note that this is despite our checking that the candidate NC occurred at least 100 times in the *Google Web 1T 5-gram corpus* (see Section 4.1.3). We hypothesized that such bad NCs would tend to have a low collocation strength. We tested this hypothesis using the Dice coefficient, calculated using the *Google Web 1T 5-gram corpus*. Figure 2 shows a plot of the NC accuracy vs. collocation strength for *strict bootstrapping* with N=5, M=50 for all three iterations (the results for the other experiments show a similar trend). We can see that the accuracy improves slightly as the collocation strength increases: compare the left and the right ends of the graph (the results are mixed in the middle though).

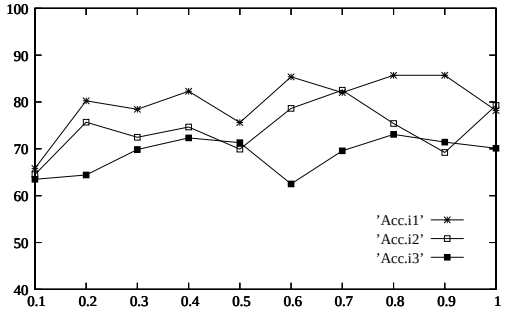

Figure 2: NC accuracy vs. collocation strength.

9 Conclusion and Future Work

We have presented a framework for building a very large dataset of noun compounds expressing a given target abstract semantic relation. For each extracted noun compound, we generated a corresponding fine-grained semantic interpretation: a frequency distribution over suitable paraphrasing verbs.

In future work, we plan to apply our framework to the remaining relations in the inventory of Levi (1978), and to release the resulting dataset to the research community. We believe that having a large-scale dataset of noun compounds interpreted with both fine- and coarse-grained semantic relations would be an important contribution to the debate about which representation is preferable for different tasks. It should also help the overall advancement of the field of noun compound interpretation.

Abstract

In the last few years, the interest of the research community in micro-blogs and social media services, such as Twitter, is growing exponentially. Yet, so far not much attention has been paid on a key characteristic of micro-blogs: the high level of information redundancy. The aim of this paper is to systematically approach this problem by providing an operational definition of redundancy. We cast redundancy in the framework of Textual Entailment Recognition. We also provide quantitative evidence on the pervasiveness of redundancy in Twitter, and describe a dataset of redundancy-annotated tweets. Finally, we present a general purpose system for identifying redundant tweets. An extensive quantitative evaluation shows that our system successfully solves the redundancy detection task, improving over baseline systems with statistical significance.

1 Introduction

Micro-blogs and social media services, such as Twitter, have experienced an exponential growth in the last few years. The interest of the research community and the industry in these services has followed a similar trend. Web companies such as Google, Yahoo, and Bing are integrating more and more social content to their sites. At the same time, the computational linguistic community is getting increasingly interested in studying social and linguistic properties of Twitter and other micro-blogs (Java et al., 2007; Krishnamurthy et al., 2008; Kwak et al., 2010; Zhao et al., 2007; Popescu and Pennacchiotti, 2010; Petrović et al., 2010; Lin et al., 2010; Liu et al., 2010; Ritter et al., 2010). Yet, so far, not much attention has been paid on a key characteristic of micro-blogs: the high level of information redundancy. Users often post messages with the same, or very similar, content, especially when reporting or commenting on news and events. For example, the following two tweets are part of a large set of redundant tweets issued during the 2010 winter Olympics:

(example 1)

t_1 : *"Swiss ski jumper Simon Ammann takes first gold of Vancouver"*

t_2 : *"Swiss (Suisse) get the Gold on Normal Hill ski jump. #Vancouver2010"*

By performing an editorial study (described later in the paper) we discovered that a large part of event-related tweets are indeed redundant.

Detecting information redundancy is important for various reasons. First, most applications based on Twitter share the goal of providing tweets that are both *informative* and *diverse*, with respect to an initial user information need. For example, Twitter search engines should ideally select the most informative and diverse set of tweets in return to a user query. Similarly, a news web portal that attaches tweets to a given news article should attach those tweets that provide the broadest and most diverse set of information, opinions, and updates about the news item. To keep a high level of diversity, redundant tweets should be removed from the set of tweets displayed to the user. Figure 1 shows an example of a Twitter search engine where redundant tweets are

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 659–669,
Edinburgh, Scotland, UK, July 27–31, 2011.

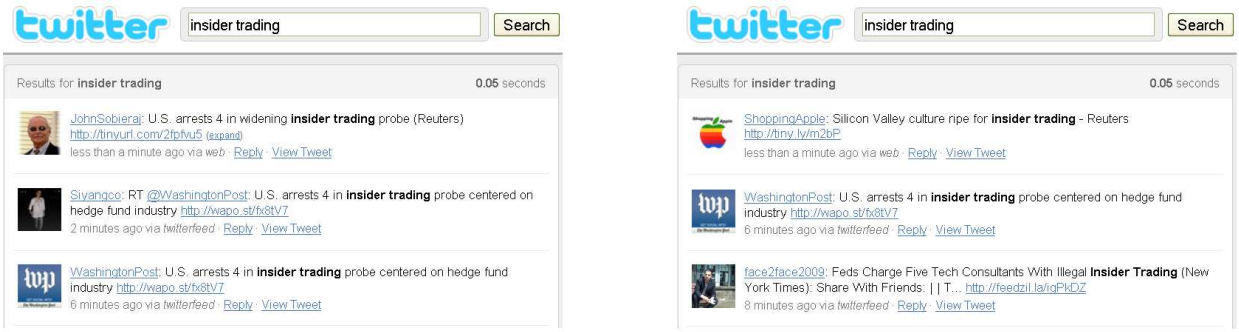

Figure 1: Twitter search: actual Twitter results and desired results after redundancy reduction.

present (left) and where they are discarded (right).

Also, from a computational linguistic point of view, the high redundancy in micro-blogs gives the unprecedented opportunity to study classical tasks such as text summarization (Haghighi and Vanderwende, 2009), textual entailment recognition (Dagan et al., 2006) and paraphrase detection (Dolan et al., 2004) on very large corpora characterized by an original and emerging linguistic style, pervaded with ungrammatical and colloquial expressions, abbreviations, and new linguistic forms.

The aim of this paper is to formally define, for the first time, the problem of redundancy in micro-blogs and to systematically approach the task of automatic redundancy detection. Note that we focus on linguistic redundancy, i.e. tweets that convey the same information with different wordings, and ignore the more trivial issue of detecting retweets, which can be considered the most basic expression of redundancy.

The main contributions of this paper are the following:

- We formally define the problem of redundancy detection in micro-blogs within the framework of Textual Entailment theory;
- We report results from an editorial study and provide quantitative evidence of the pervasiveness of redundancy in Twitter;
- We present a set of simple and effective machine learning models for solving the task of redundancy detection;
- We provide promising experimental results that show that these models outperform baseline approaches with statistical significance, and we report a qualitative evaluation revealing the advantages of the proposed model.

The rest of the paper is organized as follows. First, we shortly describe related work in Section 2. Next, we provide our operational definition of redundancy and introduce our editorial study and dataset in Section 3. In Section 4 we describe our models for redundancy detection. In Section 5 we provide a quantitative and qualitative evaluation of our models. In Section 6 we conclude the paper with final observations and future work.

2 Related Work

So far, most research on **Twitter** has focused on its network structure, the social behavior of its users (Java et al., 2007; Krishnamurthy et al., 2008; Kwak et al., 2010), ranking tweets by relevance for web search (Ramage et al., 2010; Duan et al., 2010), and the analysis of time series for extracting trending news, events and facts (Zhao et al., 2007; Popescu and Pennacchiotti, 2010; Petrović et al., 2010; Lin et al., 2010). Only few studies have specifically focused on the linguistic content analysis of tweets, e.g. (Davidov et al., 2010; Barbosa and Feng, 2010). To date, our paper most closely relates to works on semantic role labeling (SRL) on social media (Liu et al., 2010) and conversation modeling (Ritter et al., 2010).

Liu et al. (2010) present a self-learning SRL system for news tweets, with the goal of addressing low performance caused by the noise and the unstructured nature of the data. The authors first cluster together tweets that refer to the same news. Then, for each cluster, they identify the tweets that are

well-formed (i.e. copy-pasted from news), and induce role mappings between well-formed and noisy tweets in the same cluster by performing word alignment. In our paper we are also interested in aligning and grouping tweets, although our goal is to detect redundancy, not to perform SRL.

On a different ground, Ritter et al. (2010) propose a probabilistic model to discover dialogue acts in Twitter conversations and to classify tweets in a conversation according to those acts. (A conversation is defined as a set of tweets in the same reply thread.) The authors define 10 major dialogue acts for Twitter, including status, question, response and reaction, and automatically build a probabilistic transition graph for such acts. In our paper, we also aim at classifying tweets, but our interest is in information redundancy instead of acts.

In the computational linguistic literature, **redundancy detection** is studied in multi-document summarization, where the overall document is used to select the most informative sentences or snippets (Haghighi and Vanderwende, 2009). Since tweets are short and tweet sets cannot be considered documents, these methods are hard to apply. A more convenient setting is paraphrase detection (Dolan et al., 2004) and textual entailment recognition (Dagan et al., 2006) (RTE).

In RTE the task is to recognize if a text called the *text* T (typically one or two sentences long) entails another text called the *hypothesis* H. Many approaches have been proposed for this task, mostly based on machine learning. Three main classes of features have been so far explored in RTE: distance/similarity feature spaces (Corley and Mihalcea, 2005; Newman et al., 2005; Haghighi et al., 2005; Hickl et al., 2006), entailment trigger feature spaces (de Marneffe et al., 2006; MacCartney et al., 2006), and pair content feature spaces (Zanzotto et al., 2009). Distance/similarity feature spaces are more suitable to the paraphrase detection task because they model the similarity between the two texts. On the other hand, entailment trigger and content feature spaces model complex relations between the texts, taking into account first-order entailment rules, i.e. entailment rules with variables.

In this paper, one of our goals is to explore RTE techniques and features that are usually used for classical texts, and check if they can be successfully adapted to the unstructured, and oftentimes ungrammatical, Twitter language.

3 Redundancy in Twitter

We formally define two tweets as **redundant** if they either convey the same information (*paraphrase*) or if the information of one tweet subsumes the information of the other (*textual entailment*). For example, the pair in *(example 1)* is redundant. The first tweet subsumes (i.e. 'textually entails') the other; both tweets state that Switzerland won a Gold Medal at the Vancouver winter Olympics, but the first one also specifies the name of the athlete. The following pair is, instead, non-redundant, because the two tweets convey different information, and they do not subsume each other:

(example 2)

t_1 : *"Goal! Iniesta scores for #ESP and they have one hand on the #worldcup"*

t_2 : *"this will be a hard final #Esp vs Ned #worldcup"*

Our definition of redundancy is grounded on, and inspired by, the theory of Textual Entailment, to which we refer the reader for further details (Dagan et al., 2006).

3.1 Quantifying redundancy

How pervasive is redundancy in Twitter? In order to answer this question we performed an initial editorial study where human editors were asked to annotate pairs of tweets as being either redundant or non-redundant. The editorial study also serves as a test bed for evaluating our redundancy detection models, as discussed in Section 5.

In the study we focus on 'informative' tweets, i.e. tweets that describe or comment on relevant events/facts. Indeed, these are the types of tweets for which redundancy is a critical issue, especially in view of real applications, e.g. to present a diverse set of tweets for a given news article. Other types of tweets, such as status updates, self-promotions, and personal messages are of less interest in this context.

Dataset extraction. The study is performed on an automatically built dataset of informative tweets. The most critical issue for extracting the dataset is to pre-process tweets and to discard those that are

not informative. This is not an easy task: a recent study (Pear-Analytics, 2009) estimates that only 4% of all tweets are factual news, and only 37% are conversations with content. The rest are spam, status updates and other types of uninformative content. In order to retain only informative tweets we first extract *buzzy snapshots* (Popescu and Pennacchiotti, 2010). A snapshot is defined as a set of tweets that explicitly mention a specific topic within a specified time period. A buzzy snapshot is defined as a snapshot with a large number of tweets, compared to previous time periods. For example, given the topic 'Haiti earthquake', the snapshot composed by the tweets mentioning 'Haiti earthquake' on January 12th, 2010, will constitute a buzzy snapshot, since in previous days the topic was not mentioned often.

We use two different topic lists: a *celebrity list* containing about 104K celebrity names, crawled from Wikipedia, including actors, musicians, politicians, and athletes; and an *event list* composed of 398 hashtags related to 8 major events that happened between January and July 2010, and listed in Wikipedia: [1] the earthquake in Haiti, the winter Olympics, the earthquake in Chile, the death of the Polish president, the volcano eruption in Iceland, the oil spill in the Gulf of Mexico, the Greek financial crisis, and the FIFA world cup.

We extract buzzy snapshots for the above two topic lists by following the method described in (Popescu and Pennacchiotti, 2010): we consider time periods of one day, and call buzzy the snapshots that mention a given topic α times more than the average over the previous 2 days. We set α to 20 and 5 respectively for the celebrity list and the event list. We further exclude irrelevant and spam snapshots by removing those that have: fewer than 10 tweets; more than 50% of tweets non-English; and an average token overlap between tweets of more than 80%, usually corresponding to spam threads.

The extraction is performed on a Twitter corpus containing all tweets posted between July 2009 and August 2010. In all, we extract 972 snapshots for the celebrity list, containing 205,885 tweets (i.e. average of 212 tweets per snapshot); and 674 snapshots for the event list, containing 393,965 tweets (584 tweets per snapshot).

[1] Hashtags are keywords prefixed by '#', that are used by the Twitter community to mark the topic of a tweet. We collected our set of hashtags by semi-automatically inspecting the Twitter stream in the days the major events happened.

redundant	**367**	**(29.5%)**
entailment	195	(15.7%)
paraphrase	172	(13.5%)
non-redundant	**875**	**(70.5%)**
related	541	(43.6%)
unrelated	334	(26.9%)

Table 1: Results of the redundancy editorial study.

The above two final snapshot corpora (i.e. the 972 celebrities' snapshots and 674 events' snapshots) can be considered a good representation of event descriptions and comments on Twitter, thus forming our initial set of 'informative' tweets. From these two corpora, we extract the final tweet-pair dataset by randomly sampling 1500 pairs of tweets contained in the same snapshot. Tweet-pairs that contain retweets are excluded.

Dataset annotation. The main editorial task consisted of annotating tweet-pairs as either redundant or non-redundant. We also asked editors to characterize the specific linguistic relation between the two tweets of a pair. We consider four relations: *entailment* (the first tweet entails the second or vice versa), *paraphrase*, *contradiction* (the tweets contradict each other), and *related* (the tweets are about the same topic, e.g. the Haiti earthquake, but are in none of the previous relations). Tweets that were about different topics were labeled *unrelated*. Annotators were asked to base their decisions on the parts of the tweets that contained information relevant to the selected topic, e.g. the earthquake in Haiti. These parts were marked in the corpus. Focusing on these parts is in line with potential applications of tweet redundancy detection as tweets are firstly grouped around a topic. Note that pairs that fall under the entailment or paraphrase relation are redundant, while unrelated, related, and contradictory tweets are non-redundant.

The annotation was performed in a three stage process, since tweets are sometimes hard to understand and hence to annotate (misspellings, usage of slang and abbreviations, lack of discourse context). In the first step, the 1500 pairs were independently annotated by a pool of 20 trained editors, super-

vised by an expert lead. In the second step, the annotations were checked by three highly trained experts with background in computational linguistics: each pair was independently checked by two experts. Average kappa agreement in this second step is $kappa = 0.63$ (corresponding to 'good agreement'). In a final step, discordances between the two experts were resolved by the third expert. Unclear and unresolved pairs after the three stages were discarded from the dataset, leaving a final set of 1242 pairs. [2]

Annotation Results. Table 1 reports the results of our study. Among the 1242 tweet-pairs, 367 (30%) are redundant and 875 (70%) are non-redundant. This shows that redundancy is indeed a pervasive phenomenon in Twitter, and a critical issue that has to be solved in order to provide clean and diverse social content. Most cases of redundancy correspond to tweets that report the same fact using different wording, occasionally adding irrelevant personal comments and sentiments (e.g. 'Johnny Depp died' vs. 'OMG, I am so sad that Johnny Depp is dead').

4 Redundancy detection models

The task of **redundancy detection** in Twitter is a tweet-pair classification problem. Given two tweets t_1 and t_2, the goal is to classify the pair (t_1, t_2) as being either redundant or non-redundant.

In this section we describe different models for redundancy detection, inspired by existing work in RTE. We adopt a machine learning approach where a Support Vector Machine (SVM) is trained on a manually annotated training set to classify incoming test examples as either redundant or non-redundant. An evaluation of the different models adopting for training and testing the dataset described in Section 3, is presented in Section 5.

4.1 Bag-of-word model (BOW)

The bag-of-word model is the most simple approach for detecting redundancy. It is used as a **baseline** in our experiment. The simple intuition of the model is that if two tweets t_1 and t_2 have a high lexical overlap, then they are likely to express the same information – i.e. they are likely to be redundant. In this model, the SVM is trained using a single feature that computes the cosine similarity between the bag-of-word vectors of the two tweets. The bag-of-word vector is built using a classical *tf*idf* weighting schema over the set of tokens of the pair. This a very simple baseline as SVM is only learning thresholds using this single feature.

The bag-of-word model is of course a naive approach, since in many cases redundant tweets can have very different lexical content (e.g. the following two tweets: "Farrah Fawcett left out of Oscar memorial", "No Farrah Fawcett's memory at the Academy Awards"), and non-redundant tweets can have similar lexical content (e.g. the tweets: "Johnny Deep is dead", "Johnny Deep is not dead").

4.2 WordNet-based bag-of-word model (WBOW)

The second **baseline** model was first defined in (Corley and Mihalcea, 2005) and since then has been used by many RTE systems. The model extends BOW by measuring similarity at the semantic level, instead of the lexical level.

For example, consider the tweet pair: "Oscars forgot Farrah Fawcett", "Farrah Fawcett snubbed at Academy Awards". This pair is redundant, and, hence, should be assigned a very high similarity. Yet, BOW would assign a low score, since many words are not shared across the two tweets. WBOW fixes this problem by matching 'Oscar'-'Academy Awards' and 'forgot'-'snubbed' at the semantic level. To provide these matches, WBOW relies on specific word similarity measures over WordNet (Miller, 1995), that allow synonymy and hyperonymy matches: in our experiments we specifically use Jiang&Conrath similarity (Jiang and Conrath, 1997).

In practice, we implement WBOW by using the text similarity measure defined in (Corley and Mihalcea, 2005) as the single feature in the SVM classifier that, as in BOW, learns the threshold on this single feature.

4.3 Lexical content model (LEX)

This model and the next ones (SYNT and FOR) explicitly model the content of a tweet pair $P =$

[2] At this time, the Twitter^{TM} Terms of Use do not allow publication of the annotated dataset. Should the Terms of Use change, the dataset will become available for download at *http://art.uniroma2.it/zanzotto/datasets*.

(t_1, t_2) as a whole. This is a radically different approach with respect to the similarity-based models explored so far, where the content of t_1 and t_2 were treated independently (i.e. each tweet with its own bag of words), and the SVM used as the single feature the similarity between the two tweets.

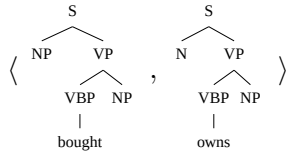
In the LEX model we represent the content of the tweet pair in a double bag-of-word vector space. Each pair $P = (t_1, t_2)$ is represented by two bag-of-word vectors, $(\vec{t_1}, \vec{t_2})$. Within this space, we can then define a specific similarity measure between pairs using a kernel function in the SVM learning algorithm. Given two pairs of tweets $P^{(a)}$ and $P^{(b)}$, the LEX kernel function is defined as follows:

$$K_{LEX}(P^{(a)}, P^{(b)}) = cos(t_1^{(a)}, t_1^{(b)}) + cos(t_2^{(a)}, t_2^{(b)})$$

where $cos(\cdot, \cdot)$ is the cosine similarity between the two vectors. The LEX feature space is simple and can be extremely effective in modeling the content of tweet pairs. Yet, in principle, it doesn't model the relations among words in the tweet. Different content feature spaces are then needed to capture these relations.

4.4 Syntactic content model (SYNT)

The SYNT model represents a tweet pair using pairs of syntactic tree fragments from t_1 and t_2. Each feature is a pair $< fr_1, fr_2 >$, where fr_1 and fr_2 are syntactic tree fragments (see figure below). As defined in (Collins and Duffy, 2002), a syntactic tree fragment fr_i is active in t_i when fr_i is a subtree of the syntactic interpretation of t_i. Therefore, these features represent ground rules connecting the left-hand sides and the right-hand sides of the tweet pair: each feature is active for a pair (t_1, t_2) when the left-hand side fr_1 is activated by the syntactic analysis of t_1 and the right-hand side fr_2 is activated by t_2. As an example consider the feature:



This feature is active for the pair of tweets ("*GM bought Opel*","*GM owns Opel*") since the syntactic analysis of the pair matches the feature (given that the two tweets are correctly syntactically analyzed). This feature space models the relations between words syntactically. Therefore it overcomes the limitations of the LEX feature space. But it also introduces a new limitation: the above feature is in fact also active for the tweet pair ("*GM bought Opel*","*Opel owns GM*"). This pair is extremely different from the previous one, thus possibly misleading the classifier.

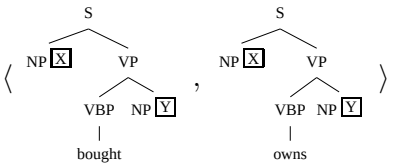
This feature space is not represented explicitly, but it is encoded in a kernel function. Given two pairs of tweets $P^{(a)}$ and $P^{(b)}$, the SYNT kernel function is defined as follows:

$$K_{SYNT}(P^{(a)}, P^{(b)}) = K(t_1^{(a)}, t_1^{(b)}) + K(t_2^{(a)}, t_2^{(b)})$$

where $K(\cdot, \cdot)$ is the tree kernel function described in (Collins and Duffy, 2002).

4.5 Syntactic first-order rule content model (FOR)

The FOR model overcomes the limitations of SYNT, by enriching the space with features representing first-order relations between the two tweets of a pair. Each feature represents a rule with variables, i.e. a first order rule that is activated by the tweet pairs if the variables are unified. This feature space has been introduced in (Zanzotto and Moschitti, 2006) and shown to improve over the ones above. Each feature $< fr_1, fr_2 >$ is a pair of syntactic tree fragments augmented with variables. The feature is active for a tweet pair (t_1, t_2) if the syntactic interpretations of t_1 and t_2 can be unified with $< fr_1, fr_2 >$. For example, consider the following feature:



This feature is active for the pair ("*GM bought Opel*","*GM owns Opel*"), with the variable unification X = "*GM*" and Y = "*Opel*". On the contrary, this feature is not active for the pair ("*GM bought Opel*","*Opel owns GM*") as there is no possibility of unifying the two variables. Efficient algorithms for the computation of the related kernel functions can

be found in (Moschitti and Zanzotto, 2007; Zanzotto and Dell'Arciprete, 2009).

5 Experimental Evaluation

In this section we present an evaluation of the different redundancy detection models. First, we define the experimental setup in Section 5.1. Then, we analyze the results of the experiments in Section 5.2.

5.1 Experimental Setup

We experiment with the redundancy detection dataset described in Section 3. We randomly divide the corpus into two sets: 50% for training and 50% for testing. The training set contains 185 positive tweet-pairs and 416 negative pairs. The test set contains 182 positive pairs and 466 negatives.

We evaluate the performance of the SVM models using the following feature combinations: LEX+BOW, LEX+WBOW, SYNT+BOW, SYNT+WBOW, FOR+BOW, FOR+WBOW. We compare to the system baselines BOW and WBOW. [3]

The performance of the different models is computed using the Area Under the ROC curve (AROC) applied to the classification score returned by the SVM. The ROC curve allows us to study the behavior of the classifier in detail, and also provides a powerful way to compare among systems when the dataset is unbalanced (as in our case).

To determine the statistical significance of the difference in the performance of the systems we analyzed, we use the model described in (Yeh, 2000) as implemented in (Padó, 2006).

We pre-process the dataset with the following tools: the Charniak Parser (Charniak, 2000) for parsing sentences, the WordNet similarity package (Pedersen et al., 2004) for computing WBOW and for linking the two tweets in a pair, and SVM-light (Joachims, 1999), extended with the syntactic first-order rule kernels described in (Moschitti and Zanzotto, 2007) for creating the SYNT and the FOR feature spaces. We used the Charniak syntactic parser without any specific adaptation to the Twitter language.

Model	AROC
BOW	0.592
WBOW	0.578
LEX + BOW	0.725 †
LEX + WBOW	0.728 †
SYNT + BOW	0.736 †
SYNT + WBOW	0.737 †
FOR + BOW	0.739 †
FOR + WBOW	**0.747** † ‡

Table 2: Experimental results of the different systems. † indicates statistical significance ($p < 0.01$) with respect to the two baseline methods BOW and WBOW. ‡ indicates statistical significance ($p < 0.1$) with respect to FOR + BOW

5.2 Experimental Results

Table 2 reports the results of the experiment. The first and most important result is that models using content features (LEX, SYNT, and FOR) along with similarity features (BOW and WBOW) outperform the two baseline models using only similarity features with statistical significance, up to more than 15% AROC points.

At first glance, WordNet similarities are not useful: the performance of the WBOW model is indeed comparable and statistically insignificant with respect to the pure token based model BOW. This seems to be intuitive as the language of the tweets can be far from proper English, i.e. it may contain many out-of-dictionary words that are not present in WordNet, thus impairing the similarity measure used by WBOW.

This trend is also confirmed in the case of content-based systems like LEX and SYNT. Using BOW or WBOW in combination with these features has the same effect on the final performance. Only the FOR features are positively affected by the WordNet-based distance. This may be explained by the fact that in the FOR+WBOW system, the WordNet similarity is also used to link words in the two tweets of a pair. This increases the possibility of finding reasonable and useful first-order rules. In the quali-

[3] Note that other feature combinations would not add value, as BOW and WBOW are interchangeable, and the same stands for LEX, SYNT and FOR.

tative analysis that follows, we show some examples that support this intuition.

On the other hand, syntax plays a key role for detecting redundancy. The two syntax based models SYNT and FOR outperform the lexical based models LEX between 1 and 2 AROC points. This is surprising, since the Charniak parser used in the experiments has not been adapted to the Tweet language, and therefore could have produced many interpretation errors, thus impairing the use of syntax. This seems to suggest that if the interpretations of the part-of speech tags of the unknown words is correct, the syntax of tweets is reasonably similar to the syntax of the generic English language.

The best performing model is FOR+WBOW: first-order rules successfully emerge in tweets and are positively exploited by the learning system. In the next section we report examples that support this observation.

5.3 Qualitative analysis

The experimental results reported in the previous section show that first-order syntactic rules in combination with the WordNet-based bag-of-word (FOR+WBOW) are highly effective in detecting redundancy. In this section, we briefly analyze some tweet pairs where the differences between this model and the BOW and WBOW models are evident.

Table 3 reports examples of tweet pairs, along with their ranking position in the test set, according to the SVM score, with respect to different models. The first column represents the editorial gold standard (gs) for the tweet pairs we considered: either redundant (R) or non-redundant (N). Since we feed the classifiers with 'redundant' as the positive class [4], a classifier is better than another if it ranks redundant tweet pairs (R) higher than non-redundant ones (N). The second, the third, and the fourth columns represent the rank given by WBOW+FOR, WBOW, and BOW respectively. The fifth column is the tweet-pair identifier in our dataset (id). The last two columns are the two tweets in each pair.

The table reports interesting examples where redundant pairs have very little lexical similarity while the non-redundant pairs have a high lexical similarity. These are all examples where BOW and WBOW should typically fail, while FOR+WBOW could capture important syntactic first-order rules to overcome the limitations of the pure similarity-based models.

As a first example, both BOW and WBOW fail to assign a high rank (i.e. low rank number) to the redundant pair *o165*: in fact, 'died' does not lexically match 'rip', nor are these two words related in WordNet. In contrast, FOR+WBOW assigns a high rank to this pair, since it may be able to apply the rule $<$*X died*, *rip X*$>$ that was most probably acquired from examples in the training set (the hoax of somebody's death is pervasive in Twitter, and it is therefore likely to fire the abovementioned rule in our dataset if enough examples are available).

The third and the fourth pairs (*o130* and *o21*) show some commonalities [5] . According to the WordNet similarity measure we used, 'recognize' and 'snub' are highly related as well as 'forget' and 'snub'. Hence, the two tokens are linked as similar. For *o130*, the triggering syntactic rule is $<$(S (NP *X*) (VP *Y*),(VP (V *Y*) (NP *X*)$>$ where *X* and *Y* are variables. For *o21*, the rule is: $<$(VP (V *X*) (NP *Y*),(VP (V *X*) (NP *Y*)$>$.

For the non-redundant pairs (N) at the bottom of the table, the first-order rules are less intuitive. Yet, it is clear why these pairs have high lexical similarity (and therefore are ranked high by BOW and WBOW): The two tweets in the pair *oe387* share 'volcanic', 'ash', and the hashtag '#ashtag'. Tweets in *oe64* share 'Icelandic' and 'eruption' but they are describing different facts. Tweets in the pair *oe43* are similar since they are sharing the three hashtags '#bpoil', '#bp', and '#oilspill'. This example shows that hashtags alone are not very indicative and useful for detecting redundancy in Twitter.

6 Conclusions

In this paper we introduced the notion of linguistic redundancy in micro-blogs and the task of tweet redundancy detection. We also presented an editorial study showing that redundancy is pervasive in Twitter, and that methods for its detection will be key in

[4] This is just a convention. Results would be the same by taking non-redundant pairs as the positive class.

[5] In o130, the common topic is 'farrah fawcett': "farrah fawcett not recognized at the Oscars memorial?" and "snubbed farrah fawcett. #oscars" are used by the annotators to make the decision.

the future for the development of accurate Twitter-based applications. In the second part of the paper we presented some promising models for redundancy detection that show encouraging results when compared to typical lexical baselines. Even with the ungrammaticalities used in tweets, syntactic feature spaces are effective in modeling redundancy, especially when used in first-order rules.

In future work we plan to improve our system by adapting existing linguistic tools and resources to Twitter (e.g. syntactic parsers). We also plan to investigate the use of semantic roles and contextual information to improve the models. For example, the tweets that other users post about the same topic of the target-pair may be of some help. Finally, we are investigating the integration of our models into real applications such a the enrichment of news articles with related and *diverse* content from social media.

Abstract

We address the creation of cross-lingual textual entailment corpora by means of crowdsourcing. Our goal is to define a cheap and replicable data collection methodology that minimizes the manual work done by expert annotators, without resorting to preprocessing tools or already annotated monolingual datasets. In line with recent works emphasizing the need of large-scale annotation efforts for textual entailment, our work aims to: *i)* tackle the scarcity of data available to train and evaluate systems, and *ii)* promote the recourse to crowdsourcing as an effective way to reduce the costs of data collection without sacrificing quality. We show that a complex data creation task, for which even experts usually feature low agreement scores, can be effectively decomposed into simple subtasks assigned to non-expert annotators. The resulting dataset, obtained from a pipeline of different jobs routed to Amazon Mechanical Turk, contains more than 1,600 aligned pairs for each combination of texts-hypotheses in English, Italian and German.

1 Introduction

Cross-lingual Textual Entailment (CLTE) has been recently proposed by (Mehdad et al., 2010; Mehdad et al., 2011) as an extension of Textual Entailment (Dagan and Glickman, 2004). The task consists of deciding, given a text (T) and an hypothesis (H) *in different languages*, if the meaning of H can be inferred from the meaning of T. As in other NLP applications, both for monolingual and cross-lingual TE, the availability of large quantities of annotated data is an enabling factor for systems development and evaluation. Until now, however, the scarcity of such data on the one hand, and the costs of creating new datasets of reasonable size on the other, have represented a bottleneck for a steady advancement of the state of the art.

In the last few years, monolingual TE corpora for English and other European languages have been created and distributed in the framework of several evaluation campaigns, including the RTE Challenge[1], the Answer Validation Exercise at CLEF[2], and the Textual Entailment task at EVALITA[3]. Despite the differences in the design of the tasks, all the released datasets were collected through similar procedures, always involving expensive manual work done by expert annotators. Moreover, in the data creation process, large amounts of hand-crafted T-H pairs often have to be discarded in order to retain only those featuring full agreement, in terms of the assigned entailment judgements, among multiple annotators. The amount of discarded pairs is usually high, contributing to increase the costs of creating textual entailment datasets[4].

The issues related to the shortage of datasets and the high costs for their creation are more evident

[1] http://www.nist.gov/tac/2011/RTE/

[2] http://nlp.uned.es/clef-qa/ave/

[3] http://www.evalita.it/2009/tasks/te

[4] For instance, in the first five RTE Challenges, the average effort needed to create 1,000 pairs featuring full agreement among 3 annotators was around 2.5 person-months. Typically, around 25% of the original pairs had to be discarded during the process, due to low inter-annotator agreement (Bentivogli et al., 2009).

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 670–679,
Edinburgh, Scotland, UK, July 27–31, 2011.

in the CLTE scenario, where: *i)* the only dataset currently available is an English-Spanish corpus obtained by translating the RTE-3 corpus (Negri and Mehdad, 2010), and *ii)* the application of the standard methods adopted to build RTE pairs requires proficiency in multiple languages, thus significantly increasing the costs of the data creation process.

To address these issues, in this paper we devise a cost-effective methodology to create cross-lingual textual entailment corpora. In particular, we focus on the following problems:

(1) Is it possible to collect T-H pairs minimizing the intervention of expert annotators? To address this question, we explore the feasibility of crowdsourcing the corpus creation process. As a contribution beyond the few works on TE/CLTE data acquisition, we define an effective methodology that: *i)* does not involve experts in the most complex (and costly) stages of the process, *ii)* does not require preprocessing tools, and *iii)* does not rely on the availability of already annotated RTE corpora.

(2) How can we guarantee good quality of the collected data at a low cost? We address the quality control issue through the decomposition of a complex task (*i.e.* creating and annotating entailment pairs) into smaller sub-tasks. Complex tasks are usually hard to explain in a simple way understandable to non-experts, difficult to accomplish, and not suitable for the application of the quality-check mechanisms provided by current crowdsourcing services. Our "divide and conquer" solution represents the first attempt to address a complex task involving content *generation* and *labelling* through the definition of a cheap and reliable pipeline of simple tasks which are easy to define, accomplish, and control.

(3) Can we adapt such methodology to collect cross-lingual T-H pairs? We tackle this question by separating the problem of creating and annotating TE pairs from the issues related to the multilingual dimension. Our solution builds on the assumption that entailment annotations can be projected across aligned T-H pairs in different languages. In this case, a complex multilingual task is reduced to a sequence of simpler subtasks where the most difficult one, the generation of entailment pairs, is entirely monolingual. Besides ensuring cost-effectiveness, our solution allows us to overcome the problem of finding workers that are proficient in multiple languages. Moreover, since the core monolingual tasks of the process are carried out by manipulating English texts, we are able to address the very large community of English speaking workers, with a considerable reduction of costs and execution time. Finally, as a by-product of our method, the acquired pairs are fully aligned for all language combinations, thus enabling meaningful comparisons between scenarios of different complexity (monolingual TE, and CLTE between close or distant languages).

We believe that, in the same spirit of recent works promoting large-scale annotation efforts around entailment corpora (Sammons et al., 2010; Bentivogli et al., 2010), the proposed approach and the resulting dataset[5] will contribute to meeting the strong need for resources to develop and evaluate novel solutions for textual entailment.

2 Related Works

Crowdsourcing services, such as Amazon Mechanical Turk[6] (MTurk) and CrowdFlower[7], have been recently used with success for a variety of NLP applications (Callison-Burch and Dredze, 2010). The idea is that the acquisition and annotation of large amounts of data needed to train and evaluate NLP tools can be carried out in a cost-effective manner by defining simple Human Intelligence Tasks (HITs) routed to a crowd of non-expert workers (aka "Turkers") hired through on-line marketplaces.

As regards textual entailment, the first work exploring the use of crowdsourcing services for data *annotation* is described in (Snow et al., 2008), which shows high agreement between non-expert annotations of the RTE-1 dataset and existing gold standard labels assigned by expert labellers.

Focusing on the actual *generation* of monolingual entailment pairs, (Wang and Callison-Burch, 2010) experiments the use of MTurk to collect facts and counter facts related to texts extracted from an existing RTE corpus annotated with named entities. Taking a step beyond the task of annotating exist-

[5]The CLTE corpora described in this paper will be made freely available for research purposes through the website of the funding EU Project CoSyne (http://www.cosyne.eu/).

[6]https://www.mturk.com/

[7]Although MTurk is directly accessible only to US citizens, the CrowdFlower service (http://crowdflower.com/) provides an interface to MTurk for non-US citizens.

ing datasets, and showing the feasibility of involving non-experts also in the generation of TE pairs, this approach is more relevant to our objectives. However, at least two major differences with our work have to be remarked. First, they still use available RTE data to obtain a monolingual TE corpus, whereas we pursue the more ambitious goal of generating from scratch aligned CLTE corpora for different language combinations. To this aim, we do not resort to already annotated data, nor language-specific preprocessing tools. Second, their approach involves qualitative analysis of the collected data only *a posteriori*, after manual removal of invalid and trivial generated hypotheses. In contrast, our approach integrates quality control mechanisms at all stages of the data collection/annotation process, thus minimizing the recourse to experts to check the quality of the collected material.

Related research in the CLTE direction is reported in (Negri and Mehdad, 2010), which describes the creation of an English-Spanish corpus obtained from the RTE-3 dataset by translating the English hypotheses into Spanish. Translations have been crowdsourced adopting a methodology based on translation-validation cycles, defined as separate HITs. Although simplifying the CLTE corpus creation problem, which is recast as the task of translating already available annotated data, this solution is relevant to our work for the idea of combining gold standard units and "validation HITS" as a way to control the quality of the collected data at runtime.

3 Quality Control of Crowdsourced Data

The design of data acquisition HITs has to take into account several factors, each having a considerable impact on the difficulty of instructing the workers, the quality and quantity of the collected data, the time and overall costs of the acquisition. A major distinction has to be made between jobs requiring data *annotation*, and those involving content *generation*. In the former case, Turkers are presented with the task of labelling input data referring to a fixed set of possible values (*e.g.* making a choice between multiple alternatives, assigning numerical scores to rank the given data). In the latter case, Turkers are faced with creative tasks consisting in the production of textual material (*e.g.* writing a correct translation, or a summary of a given text).

The ease of controlling the quality of the acquired data depends on the nature of the job. For annotation jobs, quality control mechanisms can be easily set up by calculating Turkers' agreement, by applying voting schemes, or by adding hidden gold units to the data to be annotated[8]. In contrast, the quality of the results of content generation jobs is harder to assess, due to the fact that multiple valid results are acceptable (*e.g.* the same content can be expressed, translated, or summarized in different ways). In such situations the standard quality control mechanisms are not directly applicable, and the detection of errors requires either costly manual verification at the end of the acquisition process, or more complex and creative solutions integrating HITs for quality check.

Most of the approaches to content generation proposed so far rely on *post hoc* verification to filter out undesired low-quality data (Mrozinski et al., 2008; Mihalcea and Strapparava, 2009; Wang and Callison-Burch, 2010). The few solutions integrating validation HITs address the translation of single sentences, a task that is substantially different from ours (Negri and Mehdad, 2010; Bloodgood and Callison-Burch, 2010). Compared to sentence translation, the task of creating CLTE pairs is both harder to explain without recurring to notions that are difficult to understand to non-experts (*e.g.* "semantic equivalence", "unidirectional entailment"), and harder to execute without mastering these notions. To tackle these issues the "divide and conquer" approach described in the next section consists in the decomposition of a difficult *content generation* job into easier subtasks that are: *i)* self-contained and easy to explain, *ii)* easy to execute without any NLP expertise, and *iii)* suitable for the integration of a variety of runtime control mechanisms (regional qualifications, gold units, "validation HITs") able to ensure a good quality of the collected material.

[8]Both MTurk and CrowdFlower provide means to check workers' reliability, and weed out untrusted ones without money waste. These include different types of qualification mechanisms, the possibility of giving work only to known trusted Turkers (only with MTurk), and the possibility of adding hidden gold standard units in the data to be annotated (offered as a built-in mechanism only by CrowdFlower).

4 CLTE Corpus Creation Methodology

Our approach builds on a pipeline of HITs routed to MTurk's workforce through the CrowdFlower interface. The objective is to collect aligned T-H pairs for different language combinations, reproducing an RTE-like annotation style. However, our annotation is not limited to the standard RTE framework, where only unidirectional entailment from T to H is considered. As a useful extension, we annotate any possible entailment relation between the two text fragments, including: *i)* bidirectional entailment (*i.e.* semantic equivalence between T and H), *ii)* unidirectional entailment from T to H, and *iii)* unidirectional entailment from H to T. The resulting pairs can be easily used to generate not only standard RTE datasets[9], but also general-purpose collections featuring multi-directional entailment relations.

4.1 Data Acquisition and Annotation

We collect large amounts of CLTE pairs carrying out the most difficult part of the process (the creation of entailment-annotated pairs) at a monolingual level. Starting from a set of parallel sentences in *n* languages, (*e.g.* L1, L2, L3), *n* entailment corpora are created: *one* monolingual (L1/L1), and *n-1* cross-lingual (L1/L2, and L1/L3).

The monolingual corpus is obtained by modifying the sentences only in one language (L1). Original and modified sentences are then paired and annotated to form an entailment dataset for L1. The CLTE corpora are obtained by combining the modified sentences in L1 with the original sentences in L2 and L3, and projecting to the multilingual pairs the annotations assigned to the monolingual pairs.

In principle, only two stages of the process require crowdsourcing multilingual tasks, but do not concern entailment annotations. The first one, at the beginning of the process, aims to obtain a set of parallel sentences to start with, and can be done in different ways (*e.g.* crowdsourcing the translation of a set of sentences). The second one, at the end of the process, consists of translating the modified L1 sentences into other languages (*e.g.* L2) in order to extend the corpus to cover new language combinations (*e.g.* L2/L2, L2/L3).

The execution of the two "multilingual" stages is not strictly necessary but depends on: *i)* the availability of parallel sentences to start the process, and *ii)* the actual objectives in terms of language combinations to be covered[10].

As regards the first stage, in this work we started from a set of 467 English/Italian/German aligned sentences extracted from parallel documents downloaded from the Cafebabel European Magazine[11]. Concerning the second multilingual stage, we performed only one round of translations from English to Italian to extend the *3* combinations obtained without translations (ENG/ENG, ENG/ITA, and ENG/GER) with the new language combinations ITA/ITA, ITA/ENG, and ITA/GER.

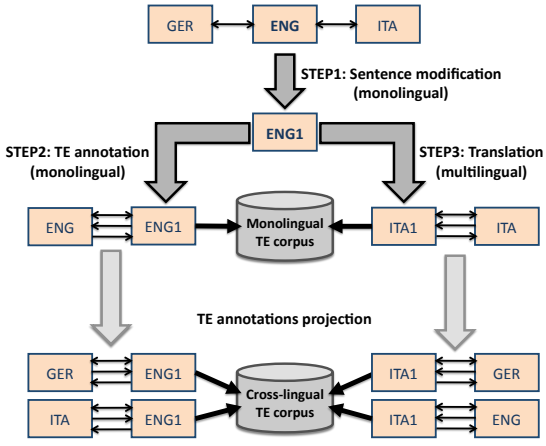

Figure 1: Corpus creation process.

The main steps of our corpus creation process, depicted in Figure 1, can be summarized as follows:

Step1: Sentence modification. The original English sentences (ENG) are modified through (monolingual) *generation* HITs asking Turkers to: *i)* preserve the meaning of the original sentences using different surface forms, or *ii)* slightly change their meaning by adding or removing content. Our assumption, in line with (Bos et al., 2009), is that

[9] With the positive examples drawn from bidirectional and unidirectional entailments from T to H, and the negative ones drawn from unidirectional entailments from H to T.

[10] Starting from parallel sentences in *n* languages, the *n* corpora obtained without recurring to translations can be augmented, by means of translation HITs, to create the full set of language combinations. Each round of translation adds 1 monolingual corpus, and *n-1* CLTE corpora.

[11] http://www.cafebabel.com/

another way to think about entailment is to consider whether one text *T1* adds new information to the content of another text *T*: if so, then *T* is entailed by *T1*.

The result of this phase is a set of texts (ENG1) that can be of three types:

1. Paraphrases of the original ENG texts, that will be used to create bidirectional entailment pairs (ENG↔ENG1);

2. More specific sentences (the outcome of content addition operations), used to create ENG←ENG1 unidirectional entailment pairs;

3. More general sentences (the outcome of content removal operations), used to create ENG→ENG1 unidirectional entailment pairs.

Step2: TE Annotation. Entailment pairs composed of the original sentences (ENG) and the modified ones (ENG1) are used as input of (monolingual) *annotation* HITs asking Turkers to decide which of the two texts contains more information. As a result, each ENG/ENG1 pair is annotated as an example of uni-/bidirectional entailment, and stored in the monolingual English corpus. Since the original ENG texts are aligned with the ITA and GER texts, the entailment annotations of ENG/ENG1 pairs can be projected to the other language pairs and the ITA/ENG1 and GER/ENG1 pairs are stored in the CLTE corpus. The possibility of projecting TE annotations is based on the assumption that the semantic information is mostly preserved during the translation process. This particularly holds at the denotative level (i.e. regarding the truth values of the sentence) which is crucial to semantic inference. At other levels (e.g. lexical) there might be slight semantic variations which, however, are very unlikely to play a crucial role in determining entailment relations.

Step3: Translation. The modified sentences (ENG1) are translated into Italian (ITA1) through (multilingual) *generation* HITs reproducing the approach described in (Negri and Mehdad, 2010). As a result, three new datasets are produced by automatically projecting annotations: the monolingual ITA/ITA1, and the cross-lingual ENG/ITA1 and GER/ITA1.

Since the solution adopted for sentence translation does not present novelty factors, the remainder of this paper will omit further details on it. Instead, the following sections will focus on the more challenging tasks of sentence modification and TE annotation.

4.2 Crowdsourcing Sentence Modification and TE Annotation

Sentence modification and TE annotation have been decomposed into a pipeline of simpler monolingual English sub-tasks. Such pipeline, depicted in Figure 2, involves several types of generation/annotation HITs designed to be easily understandable to non-experts. Each HIT consists of: *i)* a set of instructions for a specific task (*e.g.* paraphrasing a text), *ii)* the data to be manipulated (*e.g.* an English sentence), and *iii)* a test to check workers' reliability. To cope with the quality control issues discussed in Section 3, such tests are realized using gold standard units, either hidden in the data to be annotated (annotation HITs) or defined as test questions that workers must correctly answer (generation HITs). Moreover, regional qualifications are applied to all HITs. As a further quality check, all the annotation HITs consider Turkers' agreement as a way to filter out low quality results (only annotations featuring agreement among 4 out of 5 workers are retained). The six HITs defined for each subtask can be described as follows:

1. Paraphrase (generation). Modify an English text (ENG), in order to produce a semantically equivalent variant (ENG1). As a reliability test, before creating the paraphrase workers are asked to judge if two English sentences contain the same information.

2. Grammaticality (annotation). Decide if an English sentence is grammatically correct. This validation HIT represents a quality check of the output of each generation task (*i.e.* paraphrasing, and add/remove information HITs).

3. Bidirectional Entailment (annotation). Decide whether two English sentences, the original ENG and the modified ENG1, contain the same information (*i.e.* are semantically equivalent).

4a. Add Information (generation). Modify an English text to create a more specific one by adding content. As a reliability test, before generating the

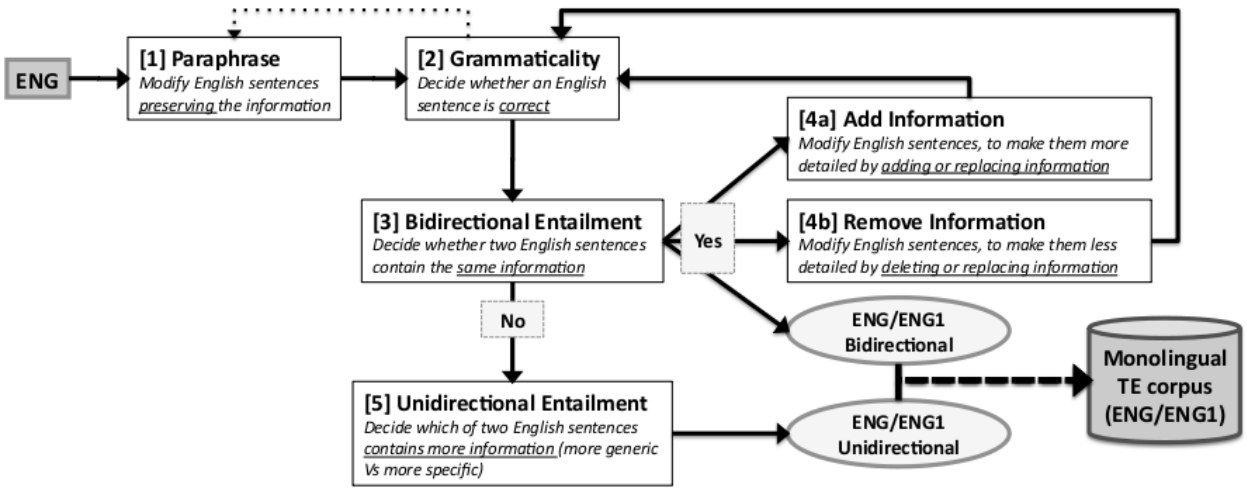

Figure 2: Sentence modification and TE annotation pipeline.

new sentence workers are asked to judge which of two given English sentences is more detailed.

4b. Remove Information (generation). Modify an English text to create a more general one by removing part of its content. As a reliability test, before generating the new sentence workers are asked to judge which of two given English sentences is less detailed.

5. Unidirectional Entailment (annotation). Decide which of two English sentences (the original ENG, and a modified ENG1) provides more information.

These HITs are combined in an iterative process that alternates text generation, grammaticality check, and entailment annotation steps. As a result, for each original ENG text we obtain multiple ENG1 variants of the three types (paraphrases, more general texts, and more specific texts) and, in turn, a set of annotated monolingual (ENG/ENG1) TE pairs.

As described in Section 4.1, the resulting monolingual English TE corpus (ENG/ENG1) is used to create the following mono/cross-lingual TE corpora:

- ITA/ENG1, and GER/ENG1 (by projecting TE annotations)
- ITA/ITA1, GER/ITA1, and ENG/ITA1 (by translating the ENG1 texts into Italian, and projecting TE annotations)

5 The Resulting CLTE Corpora

This section provides a quantitative and qualitative analysis of the results of our corpus creation methodology, focusing on the collected ENG-ENG1 monolingual dataset. It has to be remarked that, as an effect of the adopted methodology, all the observations and the conclusions drawn hold for the collected CLTE corpora as well.

5.1 Quantitative Analysis

Table 1 provides some details about each step of the pipeline shown in Figure 2. For each HIT the table presents: *i)* the number of items (sentences, or pairs of sentences) given in input, *ii)* the number of items (sentences or annotations) produced as output, *iii)* the number of items discarded when the agreement threshold was not reached, *iv)* the number of entailment pairs added to the corpus, *v)* the time (days and hours) required by the MTurk workforce to complete the job, and *vi)* the cost of the job.

In **HIT-1** (Paraphrase) 1,414 paraphrases were collected asking three different meaning-preserving modifications of each of the 467 original sentences[12]. From a practical point of view, such redundancy aims to ensure a sufficient number of grammatically correct and semantically equivalent modified sentences. From a theoretical point of view,

[12]Often, crowdsourced jobs return a number of output items that is slightly larger than required, due to the labour distribution mechanism internal to MTurk.

HIT	# Input items	# Output items	# Discarded items	# Pairs to corpus	MTurk time	Cost ($)
1. Paraphrase	467	1,414			5d+10.5h	45.48
2. Grammaticality	1,414	1,326	88 (6.22%)		1d+15h	56.88
3. Bidirectional Ent.	1,326	1,213 (yes=1,205 no=8)	113 (8.52%)	301	3d+2h	53.47
4a. Add Info	452	916			3d	37.02
4b. Remove Info	452	923			2d+22h	29.73
2. Grammaticality	1,839	1,749	90 (4.89%)		2d+5h	64.37
3. Bidirectional Ent.	1,749	1,438 (yes=148 no=1,290)	311 (17.78%)	148	3d+20.5h	70.52
5. Unidirectional Ent.	1,298	1,171	127 (9.78%)	1,171 (491 + 680)	8.5h	78.24
TOTAL			721	**1,620**	**22d+11h**	**435.71**

Table 1: The monolingual dataset creation pipeline.

collecting many variants of a small pool of original sentences aims to create pairs featuring different entailment relations with similar superficial forms. This, in principle, should allow to obtain a dataset which requires TE systems to focus more on deeper semantic phenomena than on the surface realization of the pairs.

The collected paraphrases were sent as input to **HIT-2** (Grammaticality). After this validation HIT, the number of acceptable paraphrases was reduced to 1,326 (with 88 discarded sentences, corresponding to 6.22% of the total).

The retained paraphrases were paired with their corresponding original sentences, and sent to **HIT-3** (Bidirectional Entailment) to be judged for semantic equivalence. The pairs marked as bidirectional entailments (1,205) were divided in three groups: 25% of the pairs (301) were directly stored in the final corpus, while the ENG1 paraphrases of the remaining 75% (904) were equally distributed to the next modification steps.

In both **HIT-4a** (Add Information) and **HIT-4b** (Remove information) two new modified sentences were asked for each of the 452 paraphrases received as input. The sentences collected in these generation tasks were respectively 916 and 923.

The new modified sentences were sent back to **HIT-2** (Grammaticality) and **HIT-3** (Bidirectional Entailment). As a result 1,438 new pairs were created; out of these, 148 resulted to be bidirectional entailments and were stored in the corpus.

Finally, the 1,298 entailment pairs judged as non-bidirectional in the two previously completed HIT-3 (8+1,290) were given as input to **HIT-5** (Unidirectional Entailment). The pairs which passed the agreement threshold were classified according to the judgement received, and stored in the corpus as unidirectional entailment pairs.

The analysis of Table 1 allows to formulate some considerations. First, the percentage of discarded items confirms the effectiveness of decomposing complex generation tasks into simpler subtasks that integrate validation HITs and quality checks based on non-experts' agreement. In fact, on average, around 9.5% of the generated items were discarded without experts' intervention[13]. Second, the amount of discarded items gives evidence about the relative difficulty of each HIT. As expected, we observe lower rejection rates, corresponding to higher inter-annotator agreement, for grammaticality HITs (5.55% on average) than for more complex entailment-related tasks (12.02% on average).

Looking at costs and execution time, it is hard to draw definite conclusions due to several factors that influence the progress of the crowdsourced jobs (*e.g.* the fluctuations of Turkers' performances, the time of the day at which jobs are posted, the difficulty to set the optimal cost for a given HIT[14]). On the one hand, as expected, the more creative "Add Info" task proved to be more demanding than the "Remove Info": even though it was paid more,

[13]Moreover, it is worthwhile noticing that around 20% of the collected items were automatically rejected (and not paid) due to failures on the gold standard controls created both for generation and annotation tasks.

[14]The payment for each HIT was set on the basis of a previous feasibility study aimed at determining the best trade-off between cost and execution time. However, replicating our approach would not necessarily result in the same costs.

it still took little more time to be completed. On the other hand, although the "Unidirectional Entailment" task was expected to be more difficult and thus rewarded more than the "Bidirectional Entailment" one, in the end it took notably less time to be completed. Nevertheless, the overall figures (435 USD, and about 22.5 days of MTurk work to complete the process)[15] clearly demonstrate the effectiveness of the approach. Even considering the time needed for an expert to manage the pipeline (*i.e.* one week to prepare gold units, and to handle the I/O of each HIT), these figures show that our methodology provides a cheaper and faster way to collect entailment data in comparison with the RTE average costs reported in Section 1.

As regards the amount of data collected, the resulting corpus contains 1,620 pairs with the following distribution of entailment relations: *i)* 449 bidirectional entailments, *ii)* 491 ENG→ENG1 unidirectional entailments, and *iii)* 680 ENG←ENG1 unidirectional entailments.

It must be noted that our methodology does not lead to the creation of pairs where some information is provided in one text and not in the other, and viceversa, as Example 1 shows:

Example 1.
ENG: New theories were emerging in the field of psychology.
ENG1: New theories were rising, which announced a kind of veiled racism.

These negative examples in both directions represent a natural extension of the dataset, relevant also for specific application-oriented scenarios, and their creation will be addressed in future work.

Besides the achievement of our primary objectives, the adopted approach led to some interesting by-products. First, the generated corpora are perfectly suitable to produce entailment datasets similar to those used in the traditional RTE evaluation framework. In particular, considering any possible entailment relation between two text fragments, our annotation subsumes the one proposed in RTE campaigns. This allows for the cost-effective generation of RTE-like annotations from the acquired corpora by combining ENG↔ENG1 and ENG→ENG1 pairs to form 940 positive examples (449+491), keeping the 680 ENG←ENG1 as negative examples. Moreover, by swapping ENG and ENG1 in the unidirectional entailment pairs, 491 additional negative examples and 680 positive examples can be easily obtained.

Finally, the output of HITs 1-2-3 in Table 1 represents *per se* a valuable collection of 1,205 paraphrases. This suggests the great potential of crowdsourcing for paraphrase acquisition.

5.2 Qualitative Analysis

Through manual verification of more than 50% of the corpus (900 pairs), a total number of 53 pairs (5.9%) were found incorrect. The different errors were classified as follows:

Type 1: Sentence modification errors. Generation HITs are a minor source of errors, being responsible for 10 problematic pairs. These errors are either introduced by generating a false statement (Example 2), or by forming a not fully understandable, awkward, or non-natural sentence (Example 3).

Example 2.
ENG: Kosovo was the subject of major riots in 1989.
ENG1: The Russian city of Kosovo was the subject of ...

Example 3.
ENG: Balat is the Kurdish-Armenian district of Instanbul.
ENG1: Balat is a place, which is the Kurdish-Armenian ...

Type 2: TE annotation errors. The notion of containing more/less information, used in the "Unidirectional Entailment" HIT, can mostly be applied straightforwardly to the entailment definition. However, the concept of "more/less detailed", which generally works for factual statements, in some cases is not applicable. In fact, the MTurk workers have regularly interpreted the instructions about the amount of information as concerning the quantity of concepts contained in a sentence. This is not always corresponding to the actual entailment relation between the sentences. As a consequence, 43 pairs featuring wrong entailment annotations were encountered. These errors can be classified as follows:

a) 13 pairs, where the added/removed information changes the meaning of the sentence. In these cases, the modified sentence was judged more/less specific

[15] Although by projecting annotations the ENG1/ITA and ENG1/GER CLTE corpora came for free, the ITA1/ITA, ITA1/ENG, and ITA1/GER combinations created by crowdsourcing translations added 45 USD and approximately 5 days to these figures.

than the original one, leading to unidirectional entailment annotation. On the contrary, in terms of the standard entailment definition, the correct annotation is "no entailment" (as in Example 4, which was annotated as ENG→ENG1):

Example 4.
ENG: If you decide to live in Bulgaria, you have to like difficulties because they are not difficulties, they are challenges.
ENG1: You have to like difficulties as they are not difficulties, they are challenges.

b) 10 pairs where the incorrect annotation is due to a coreference problem, as in:

Example 5.
ENG: John Smith is the new CEO of the company.
ENG1: He is the new CEO of the company.

These pairs were labelled as unidirectional entailments (in the example above ENG→ENG1), under the assumption that a proper name is more specific and informative than a pronoun. However, adhering to the TE definition, co-referring expressions are equivalent, and their realization does not play any role in the entailment decision. This implies that the correct entailment annotation is "bidirectional".

c) 9 pairs where the sentences are semantically equivalent, but contain a piece of information which is explicit in one sentence, and implicit in the other. In these cases, Turkers judged the sentence containing the explicit mention as more specific, and thus the pair was annotated as unidirectional entailment.

Example 6.
ENG: I hear the click of the trigger and the burst of bullets reach me immediately.
ENG1: I hear the trigger and the burst of bullets reach me instantly.

In Example 6, the expression *"the trigger"* in ENG1 implicitly means *"the click of the trigger"*, making the two sentences equivalent, and the entailment bidirectional (instead of ENG→ENG1).

d) 7 pairs where the information removed from or added to the sentence is not relevant to the entailment relation. In these cases, the modified sentence was judged less/more specific than the original one (and thus considered as unidirectional entailment), even though the correct judgement is "bidirectional", as in:

Example 7.
ENG: At the same time, AKP is struggling with its approach to the EU.
ENG1: AKP is struggling with its approach to the European Union.

e) 4 pairs where the added/removed information concerns universally quantified general statements, about which the interpretation of "more/less specific" given by Turkers resulted in the wrong annotation.

Example 8.
ENG: I think the success of multicultural couples depends on the size of the cultural gap between the two partners
ENG1: I believe the success of the couples depends on the size of the cultural gap between the 2 partners.

In Example 8, the additional information (*"multicultural"*) restricts the set to which it refers (*"couples"*) making ENG entailed by ENG1, and not vice versa as resulted from Turkers' annotation.

In light of this analysis, we conclude that the sentence modification methodology proved to be successful, as the low number of Type 1 errors shows. Considering that the most expensive phase in the creation of a TE dataset is the generation of the pairs, this is a significant achievement. Differently, the entailment assessment phase appears to be more problematic, accounting for the majority of errors. As shown by Type 2 errors, this is due to a partial misalignment between the instructions given in our HITs, and the formal definition of textual entailment. For this reason, further experimentation will explore different ways to instruct workers (*e.g.* asking to consider proper names and pronouns as equivalent) in order to reduce the amount of errors produced. As a final remark, considering that in the creation of a TE dataset the manual check of the annotated pairs represents a minor cost, even the involvement of experts to filter out wrong annotations would not decrease the cost-effectiveness of the proposed methodology.

6 Conclusions

There is an increasing need of annotated data to develop new solutions to the Textual Entailment problem, explore new entailment-related tasks, and set up experimental frameworks targeting real-world applications. Following the recent trends promoting annotation efforts that go beyond the established RTE Challenge framework (unidirectional entailment between monolingual T-H pairs), in this

paper we addressed the multilingual dimension of the problem. Our primary goal was the creation of large-scale collections of entailment pairs for different language combinations. Besides that, we considered cost effectiveness and replicability as additional requirements. To achieve our objectives, we developed a "divide and conquer" methodology based on crowdsourcing. Our approach presents several key innovations with respect to the related works on TE data acquisition. These include the decomposition of a complex content generation task in a pipeline of simpler subtasks accessible to a large crowd of non-experts, and the integration of quality control mechanisms at each stage of the process. The result of our work is the first large-scale dataset containing both monolingual and cross-lingual corpora for several combinations of texts-hypotheses in English, Italian, and German. Among the advantages of our method it is worth mentioning: *i)* the full alignment between the created corpora, *ii)* the possibility to easily extend the dataset to new languages, and *iii)* the feasibility of creating general-purpose corpora, featuring multi-directional entailment relations, that subsume the traditional RTE-like annotation.

Acknowledgments

This work has been partially supported by the EC-funded project CoSyne (FP7-ICT-4-24853). The authors would like to thank Emanuele Pianta for the helpful discussions, and Giovanni Moretti for the valuable support in the creation of the CLTE dataset.

Abstract

Metaphor is ubiquitous in text, even in highly technical text. Correct inference about textual entailment requires computers to distinguish the literal and metaphorical senses of a word. Past work has treated this problem as a classical word sense disambiguation task. In this paper, we take a new approach, based on research in cognitive linguistics that views metaphor as a method for transferring knowledge from a familiar, well-understood, or concrete domain to an unfamiliar, less understood, or more abstract domain. This view leads to the hypothesis that metaphorical word usage is correlated with the degree of abstractness of the word's context. We introduce an algorithm that uses this hypothesis to classify a word sense in a given context as either literal (denotative) or metaphorical (connotative). We evaluate this algorithm with a set of adjective-noun phrases (e.g., in *dark comedy*, the adjective *dark* is used metaphorically; in *dark hair*, it is used literally) and with the TroFi (Trope Finder) Example Base of literal and nonliteral usage for fifty verbs. We achieve state-of-the-art performance on both datasets.

1 Introduction

Metaphor is a natural consequence of our ability to reason by analogy (Gentner et al., 2001). It is so common in our daily language that we rarely notice it (Lakoff and Johnson, 1980). Identifying metaphorical word usage is important for reasoning about the implications of text.

Past work on the problem of distinguishing literal and metaphorical senses has approached it as a classical word sense disambiguation (WSD) task (Birke and Sarkar, 2006). Here, we take a different approach to the problem. Lakoff and Johnson (1980) argue that metaphor is a method for transferring knowledge from a concrete domain to an abstract domain. Therefore we hypothesize that the degree of abstractness in a word's context is correlated with the likelihood that the word is used metaphorically. This hypothesis is the basis for our algorithm for distinguishing literal and metaphorical senses.

Consider the following sentences:

L: He *shot down* my plane.
$\rightarrow C_1$: He *fired at* my plane.
$\nrightarrow A_1$: He *refuted* my plane.

M: He *shot down* my argument.
$\nrightarrow C_2$: He *fired at* my argument.
$\rightarrow A_2$: He *refuted* my argument.

The literal sense of *shot down* in L invokes knowledge from the domain of war. The metaphorical usage of *shot down* in M transfers knowledge from the concrete domain of war to the abstract domain of debate (Lakoff and Johnson, 1980).

The entailments of L and M depend on the intended senses of *shot down*. L entails the concrete *fired at* in C_1 (because, in order to literally shoot something down, you must first fire at it) but not the abstract *refuted* in A_1 (except perhaps as a joke). On the other hand, M entails *refuted* in A_2 but not *fired at* in C_2 (except perhaps as a novel metaphor).

In semiotics, Danesi (2003) argues that metaphor transfers *associations* from the source domain to the target domain. The metaphorical usage of *shot down* in M carries associations of violence and destruc-

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 680–690,
Edinburgh, Scotland, UK, July 27–31, 2011.

tion that are not conveyed by A_2.

To make correct inferences about textual entailment, computers must be able to distinguish the literal and metaphorical senses of a word. Since recognizing textual entailment (RTE) is a core problem for NLP, with applications in Question Answering, Information Retrieval, Information Extraction, and Text Summarization, it follows that distinguishing literal and metaphorical senses is a problem for a wide variety of NLP tasks. The ability to recognize metaphorical word usage is a core requirement in the Intelligence Advanced Research Projects Activity (IARPA) Metaphor Program (Madrigal, 2011).[1]

Our approach to the problem of distinguishing literal and metaphorical senses is based on an algorithm for calculating the degree of abstractness of words. For instance, *plane* in L is rated 0.36396 (relatively concrete), whereas *argument* in M is rated 0.64617 (relatively abstract), which suggests that the verb *shot down* is used literally in L, whereas it is used metaphorically in M. Our abstractness rating algorithm is similar to Turney and Littman's (2003) algorithm for rating words according to their semantic orientation.

To classify a word usage as literal or metaphorical, based on the context, we use supervised learning with logistic regression. The abstractness rating algorithm is used to generate feature vectors from a word's context and training data is used to learn a logistic regression model that relates degrees of abstractness to the classes *literal* and *metaphorical*.

We evaluate our algorithm with three experiments. The first experiment involves one hundred adjective-noun phrases labeled *denotative* (literal) or *connotative* (metaphorical or nonliteral) by five annotators, according to the sense of the adjective.[2] For instance, *deep snow* is labeled *denotative* and *deep appreciation* is labeled *connotative*. The algorithm is able to predict the labels of the annotators with an average accuracy of 79%.

The next two experiments use the TroFi (Trope Finder) Example Base of literal and nonliteral usage for fifty verbs.[3] The fifty verbs occur in 3,737 sentences from The 1987-89 Wall Street Journal (WSJ) Corpus Release 1. In each sentence, the target verb is labeled *L* (literal) or *N* (nonliteral), according to the sense of the verb that is invoked by the sentence. A subset of twenty-five of the fifty verbs was used by Birke and Sarkar (2006).

In our second experiment, we duplicate the setup of Birke and Sarkar (2006) so that we can compare our results with theirs. In particular, a separate model is learned for each individual verb. We achieve an average f-score of 63.9%, compared to Birke and Sarkar's (2006) 64.9%.

In the third experiment, we train the algorithm on the twenty-five new verbs that were not used by Birke and Sarkar (2006) and then we test it on the old verbs. That is, the algorithm is tested with verbs that it has never seen before. The training verbs are merged to build a single model, instead of building a separate model for each individual verb. In this experiment, the average f-score is 68.1%.

The next section presents our algorithm for calculating the degree of abstractness of words. In Section 3, we review related work. The experiments are described in Section 4. We discuss the results of the experiments in Section 5 and conclude in Section 6.

2 Abstractness and Concreteness

Concrete words refer to things, events, and properties that we can perceive directly with our senses, such as *trees*, *walking*, and *red*.[4] Abstract words refer to ideas and concepts that are distant from immediate perception, such as *economics*, *calculating*, and *disputable*. In this section, we describe an algorithm that can automatically calculate a numerical rating of the degree of abstractness of a word on a scale from 0 (highly concrete) to 1 (highly abstract). For example, the algorithm rates *purvey* as 1, *donut* as 0, and *immodestly* as 0.5.

The algorithm is a variation of Turney and Littman's (2003) algorithm that rates words according to their semantic orientation. Positive semantic orientation indicates praise (*honest*, *intrepid*) and negative semantic orientation indicates criticism (*disturbing*, *superfluous*). The algorithm calculates the semantic orientation of a given word by comparing it to seven positive words and seven nega-

[1] See http://www.iarpa.gov/solicitations_metaphor.html.

[2] The labeled phrases are available from Yair Neuman.

[3] Available at http://www.cs.sfu.ca/ anoop/students/jbirke/.

[4] The word *red* has an abstract political sense, but our abstractness rating algorithm does not distinguish word senses. The more frequent concrete sense of *red* dominates, resulting in an abstractness rating of 0.24984 (highly concrete).

tive words that are used as paradigms of positive and negative semantic orientation:

Positive paradigm words: *good, nice, excellent, positive, fortunate, correct,* and *superior*.
Negative paradigm words: *bad, nasty, poor, negative, unfortunate, wrong,* and *inferior*.

Likewise, here we calculate the abstractness of a given word by comparing it to twenty abstract words and twenty concrete words that are used as paradigms of abstractness and concreteness.

Turney and Littman (2003) experimented with two measures of semantic similarity, pointwise mutual information (PMI) (Church and Hanks, 1989) and latent semantic analysis (LSA) (Landauer and Dumais, 1997). These measures take a pair of words as input and generate a numerical similarity rating as output. The semantic orientation of a given word is calculated as the sum of its similarity with the positive paradigm words minus the sum of its similarity with the negative paradigm words. Likewise, here we calculate the abstractness of a given word by the sum of its similarity with twenty abstract paradigm words minus the sum of its similarity with twenty concrete paradigm words. We then use a linear normalization to map the calculated abstractness value to range from 0 to 1.

Our algorithm for calculating abstractness uses a form of LSA to measure semantic similarity. This is described in detail in Section 2.1. Although Turney and Littman (2003) manually selected their fourteen paradigm words, here we use a supervised learning algorithm to choose our forty paradigm words, as explained in Section 2.2.

The MRC Psycholinguistic Database Machine Usable Dictionary (Coltheart, 1981) includes 4,295 words rated with degrees of abstractness by human subjects in psycholinguistic experiments.[5] The ratings range from 158 (highly abstract) to 670 (highly concrete). Table 1 gives some examples.

We used half of the 4,295 MRC words to train our supervised learning algorithm and the other half to validate the algorithm. On the testing set, the algorithm attains a correlation of 0.81 with the dictionary ratings. This indicates that the algorithm agrees well with human judgements of the degrees of abstractness of words.

Abstract Words	Rating	Concrete Words	Rating
as	158	ape	654
of	180	grasshopper	660
apt	183	tomato	662
however	186	milk	670

Table 1: Examples of abstract and concrete words from the MRC Dictionary (Coltheart, 1981).

2.1 Measuring Semantic Similarity

The variation of LSA that we use here is similar to Rapp's (2003) work. We modeled our similarity measure on Rapp's due to the high score of 92.5% that he achieved on a set of 80 multiple-choice synonym questions from the Test of English as a Foreign Language (TOEFL). The core idea is to represent words with vectors and calculate the similarity of two words by the cosine of the angle between the two corresponding vectors. The values of the elements in the vectors are derived from the frequencies of the words in a large corpus of text. This general approach is known as a Vector Space Model (VSM) of semantics (Salton et al., 1975).

We began with a corpus of 5×10^{10} words (280 gigabytes of plain text) gathered from university websites by a webcrawler.[6] We then indexed this corpus with the Wumpus search engine (Büttcher and Clarke, 2005).[7] We selected our vocabulary from the terms (words and phrases) in the WordNet lexicon.[8] By querying Wumpus, we obtained the frequency of each WordNet term in our corpus. We selected all WordNet terms with a frequency of 100 or more in our corpus. This resulted in a set of 114,501 terms. Next we used Wumpus to search for up to 10,000 phrases per term, where a phrase consists of the given term plus four words to the left of the term and four words to the right of the term. These phrases were used to build a word–context frequency matrix $\mathbf{F}$ with 114,501 rows and 139,246 columns. A row vector in $\mathbf{F}$ corresponds to a term in WordNet and the columns in $\mathbf{F}$ correspond to contexts (the words to the left and right of a given term in a given phrase) in which the term appeared.

The columns in $\mathbf{F}$ are unigrams (single words) in WordNet with a frequency of 100 or more in the corpus. A given unigram is represented by two

[6] Collected by Charles Clarke at the University of Waterloo.
[7] Wumpus is available at http://www.wumpus-search.org/.
[8] WordNet is available at http://wordnet.princeton.edu/.

columns, one marked *left* and one marked *right*. Suppose r is the term corresponding to the i-th row in $\mathbf{F}$ and c is the term corresponding to the j-th column in $\mathbf{F}$. Let c be marked *left*. Let f_{ij} be the cell in the i-th row and j-th column of $\mathbf{F}$. The numerical value in the cell f_{ij} is the number of phrases found by Wumpus in which the center term was r and c was the unigram closest to r on the left side of r. That is, f_{ij} is the frequency with which r was found in the context c in our corpus.

A new matrix $\mathbf{X}$, with the same number of rows and columns as in $\mathbf{F}$, was formed by calculating the Positive Pointwise Mutual Information (PPMI) of each cell in $\mathbf{F}$ (Turney and Pantel, 2010). The function of PPMI is to emphasize cells in which the frequency f_{ij} is statistically surprising, and hence particularly informative. This matrix was then smoothed with a truncated Singular Value Decomposition (SVD), which decomposes $\mathbf{X}$ into the product of three matrices $\mathbf{U}_k\mathbf{\Sigma}_k\mathbf{V}_k^\mathsf{T}$. Finally, the terms were represented by the matrix $\mathbf{U}_k\mathbf{\Sigma}_k^p$, which has 114,501 rows (one for each term) and k columns (one for each latent contextual factor). The semantic similarity of two terms is given by the cosine of the two corresponding rows in $\mathbf{U}_k\mathbf{\Sigma}_k^p$. For more detail, see Turney and Pantel (2010).

There are two parameters in $\mathbf{U}_k\mathbf{\Sigma}_k^p$ that need to be set. The parameter k controls the number of latent factors and the parameter p adjusts the weights of the factors, by raising the corresponding singular values in $\mathbf{\Sigma}_k^p$ to the power p. The parameter k is well-known in the literature on LSA, but p is less familiar. The use of p was suggested by Caron (2001). Based on our past experience, we set k to 1000 and p to 0.5. We did not explore any alternative settings of these parameters for measuring abstractness.

2.2 Measuring Abstractness

Now that we have $\mathbf{U}_k\mathbf{\Sigma}_k^p$, all we need in order to measure abstractness is some paradigm words. We used the MRC Psycholinguistic Database Machine Usable Dictionary (Coltheart, 1981) to guide our search for paradigm words. We split the 4,295 MRC words into 2,148 for training (searching for paradigm words) and 2,147 for testing (evaluation of the final set of paradigm words). We began with an empty set of paradigm words and added words from the 114,501 rows of $\mathbf{U}_k\mathbf{\Sigma}_k^p$, one word at a time, alternating between adding a word to the concrete paradigm words and then adding a word to the abstract paradigm words. At each step, we added the paradigm word that resulted in the highest Pearson correlation with the ratings of the training words. This is a form of greedy forward search without backtracking. We stopped the search after forty paradigm words were found, in order to prevent overfitting of the training data.

Table 2 shows the forty paradigm words and the order in which they were selected. At each step, the correlation increases on the training set, but eventually it must decrease on the testing set. After forty steps, the training set Pearson correlation was 0.8600. At this point, we stopped the search for paradigm words and calculated the testing set Pearson correlation, which was 0.8064. This shows a small amount of overfitting of the training data. The testing set Spearman correlation was 0.8216.

For another perspective on the performance of the algorithm, we measured its accuracy on the testing set, by creating a binary classification task from the testing data. We calculated the median of the ratings of the 2,147 words in the test set. Every word with an abstractness above the median was assigned to the class 1 and every word with an abstractness below the median was assigned to the class 0. We then used the algorithm to guess the rating of each word in the test set, calculated the median guess, and likewise assigned the guesses to classes 1 and 0. The guesses were 84.65% accurate.

After generating the paradigm words with the training set and evaluating them with the testing set, we then used them to assign abstractness ratings to every term in the matrix. The result of this is that we now have a set of 114,501 terms (words and phrases) with abstractness ratings ranging from 0 to 1.[9] Based on the testing set performance, we estimate these 114,501 ratings would have a Pearson correlation of 0.81 with human ratings and an accuracy of 85% on binary (*abstract* or *concrete*) classification.

We chose to limit the search to forty paradigm words based on our past experience with semantic orientation (Turney and Littman, 2003). To validate this choice, we allowed the algorithm to continue

[9] The 114,501 rated terms are available from Peter Turney.

Concrete Paradigm Words			Abstract Paradigm Words		
Order	Word	Correlation	Order	Word	Correlation

39	usa	0.8585	40	lumbus	0.8600

Table 2: The forty paradigm words and the Pearson correlation on the training set.

searching until one hundred paradigm words were found. This resulted in a training set Pearson correlation of 0.8963, but the testing set correlation was only 0.8097, which shows a significant amount of overfitting of the training data. Although the testing set correlation is slightly higher with one hundred paradigm words, we chose to base the following experiments on the forty paradigm words, because the difference between 0.8064 and 0.8097 is not significant, and the gap between the training and testing correlation (0.8963 versus 0.8097) indicates a problematic amount of overfitting. Furthermore, the execution time of the algorithm increases as the paradigm set increases.

We generated abstractness ratings for a large vocabulary of 114,501 words in order to maximize the variety of text genres and the range of applications for which our list of abstractness ratings would be useful. As a consequence of this large vocabulary, many of the words in Table 2 are rare and obscure; however, the measure of quality of the algorithm is the correlation with the testing set (0.81), not the familiarity of the words in the table. We include the table here so that other researchers can experiment with these paragidm words. The table may give some insight into the internal functioning of the algorithm, but the main output of the algorithm is the list of 114,501 words with abstractness ratings, not the list of paradigm words in Table 2.

3 Related Work

Here we discuss related work on metaphor and then work on measuring abstractness. As far as we know, our approach is the first in computational linguistics to bring these two themes together, although the connection is well-known in cognitive linguistics (Lakoff and Johnson, 1980) and cognitive psychology (Gentner et al., 2001).

3.1 Metaphor

The most closely related work is Birke and Sarkar's (2006) research on distinguishing literal and nonliteral usage of verbs. A later paper (Birke and Sarkar, 2007) provides more detail on their active learning system, briefly mentioned in the earlier paper. Birke and Sarkar (2006; 2007) treat the problem as a classical word sense disambiguation task (Navigli, 2009). A model is learned for each verb indepen-

dently from the other verbs. This approach cannot handle a new verb without additional training.

Hashimoto and Kawahara (2009) discuss work on a similar problem, distinguishing idiomatic usage from literal usage. They also approach this as a classical word sense disambiguation task. Idioms are somewhat different from metaphors, in that the meaning of an idiom (e.g., *kick the bucket*) is often difficult to derive from the meanings of the component words, unlike most metaphors.

Nissim and Markert (2003) use supervised learning to distinguish metonymic usage from literal usage. They take a classical WSD approach, learning a separate model for each target word. As with Birke and Sarkar (2006; 2007) and Hashimoto and Kawahara (2009), the core idea is to learn to classify word usage from similarity of context. Unlike these approaches, our algorithm generalizes beyond the specific semantic content of the context, paying attention only to the degrees of abstractness of the context.

Martin (1992) presents a knowledge-based approach to interpreting metaphors. This approach requires complex hand-coded rules, which are specific to a given domain (e.g., interpreting metaphorical questions from computer users, such as, "How can I *kill* a process?", in an online help system). The knowledge base cannot handle words that are not hand-coded in its rules and a new set of rules must be constructed for each new application domain.

Dolan (1995) describes an algorithm for extracting metaphors from a dictionary. Some suggestive examples are given, but the algorithm is not evaluated in any systematic way.

Mason (2004) takes a corpus-based approach to metaphor. His algorithm is based on a statistical approach to discovering the selectional restrictions of verbs. It then uses these restrictions to discover metaphorical mappings, such as, "Money flows like a liquid." Although the system can discover some metaphorical mappings, it was not designed to distinguish literal and metaphorical usages of words.

3.2 Abstractness

Changizi (2008) uses the hypernym hierarchy in WordNet to calculate the abstractness of a word. A word near the top of the hierarchy is considered abstract and a word near the bottom is considered concrete. It seems to us that the WordNet hypernym hierarchy captures the general–specific continuum, which might not be the same as the abstract–concrete continuum. It would be interesting to see how much correspondence there is between Changizi's measure of abstractness and the ratings in the MRC Psycholinguistic Database Machine Usable Dictionary (Coltheart, 1981). Also, note that adjectives and adverbs are outside of WordNet's hypernym hierarchy, and thus cannot be rated by Changizi's algorithm.

Xing et al. (2010) also use WordNet, but in a different way. They define the *concreteness* of a word sense (a WordNet synset) to be 1 if the given word sense is a hyponym of *physical entity* in the WordNet hypernym hierarchy; otherwise the *concreteness* is 0. We believe that, although physical entities are concrete, so are *redness* and *walking*, which are not hyponyms of *physical entity*. The category *physical entity* only partially captures concreteness.

4 Experiments

In the following experiments, we use the abstractness ratings of Section 2.2 to generate features for supervised machine learning. The learning algorithm we apply is logistic regression (Le Cessie and Van Houwelingen, 1992), as implemented in Weka (Witten and Frank, 2005).[10] In all experiments, we used the Weka parameter settings $R = 0.2$ (for robust ridge regression) and $M = -1$ (for unlimited iterations).

4.1 Adjectives

For this experiment, we selected five adjectives, *dark*, *deep*, *hard*, *sweet*, and *warm*. For each of the five adjectives, we identified twenty word pairs in which the first word is the adjective and the second word is a noun. These pairs were identified through the Corpus of Contemporary American English (COCA)[11] (Davies, 2009) by seeking the nouns that follow each adjective in the corpus and sorting the candidate adjective-noun pairs by frequency. We required a minimum pointwise mutual information (PMI) of 3 between the adjective and the noun. In some of the pairs, the adjective was

[10] Weka is available at http://www.cs.waikato.ac.nz/ml/weka/.

[11] Available at http://www.americancorpus.org/.

used in a denotative (literal) sense (*dark hair*) and in others it was used in a connotative (nonliteral) sense (*dark humor*). Table 3 gives some examples.

Adjective-Noun Pairs	Noun Abstractness
dark glasses	0.26826
dark chocolate	0.28211
dark energy	0.66207
dark mood	0.61858

Table 3: Some examples of adjective-noun pairs and the abstractness rating of the noun.

In this experiment, we used the abstractness rating of the noun (the context) to predict whether the adjective (the target) was used in a metaphorical or literal sense. Table 3 supports this idea, but it is easy to find counterexamples. Although *dark mood* is metaphorical, *bad mood* is literal. The difference is that *dark* has an abstractness rating of 0.43356 (relatively concrete), whereas *bad* has an abstractness rating of 0.63326 (relatively abstract). Metaphor results when a concrete word is imported into an abstract context (Lakoff and Johnson, 1980). Ideally, we should be comparing the abstractness of the target to the abstractness of the context. However, in our data, the target words are mostly concrete; thus we can focus on the context and ignore the target. We discuss this point further in Section 5.

Five judges, undergraduate students in psychology, were asked to judge whether the use of the adjective is a denotation or a connotation. The instructions were as follows:

> *Denotation* is the most direct or specific meaning of a word or expression while *connotation* is the meaning suggested by the word that goes beyond its literal meaning. For instance, the meaning of *bitter* is denotative in *bitter lemon* and connotative in *bitter relations*. In each of the following pairs, you will be asked to judge whether (1) the meaning of the first word is *denotative* or *connotative* and (2) to what extent it is denotative or connotative on a scale ranging from 1 to 4.

The judges were blind to the research hypothesis. Each judge received a booklet with the items organized by the groups of adjectives and presented in a random order. Overall, each subject was asked to evaluate one hundred pairs. Interjudge reliability was high, with Cronbach's Alpha equal to 0.95.

Our feature vectors for each pair contained only one element, the abstractness rating of the noun in the pair. We used logistic regression with ten-fold cross-validation to predict each judge's *denotative* and *connotative* labels. The results are summarized in Table 4. On average, we were able to predict a judge's labels with 79% accuracy.

Judge	Accuracy	Majority
1	0.730	0.590
2	0.810	0.570
3	0.840	0.560
4	0.790	0.510
5	0.780	0.520
Average	0.790	0.550

Table 4: The accuracy of logistic regression at predicting the labels of each judge.

Table 4 also shows the size of the majority class (the most common label) for each judge. For all of the judges, the accuracy was significantly greater than the size of the majority class (Fisher Exact test, 95% confidence level). The results support our hypothesis that the abstractness of the context is predictive of whether an adjective is used in a literal or metaphorical sense.

4.2 Known Verbs

For this experiment, we used the TroFi (Trope Finder) Example Base of literal and nonliteral usage for fifty verbs.[12] To compare our results with Birke and Sarkar's (2006) results, we use the same subset of twenty-five of the fifty verbs. These twenty-five verbs appear in 1,965 sentences, manually labeled *L* (literal) or *N* (nonliteral), according to the sense of the target verb. The verbs also appeared in some sentences labeled *U* (unannotated), but we ignored these sentences (although they could be useful for semi-supervised learning).

The label *nonliteral* is intended to be a broad category that includes *metaphorical* as a special case. Other types of nonliteral usage include *idiomatic* and *metonymical*, but it seems that most of the *nonliteral* cases in TroFi are in fact *metaphorical*, and

[12] Available at http://www.cs.sfu.ca/ anoop/students/jbirke/.

hence our hypothesis about the correlation of abstract context with metaphorical sense is appropriate for classifying the TroFi sentences.

Two examples of sentences from TroFi follow. Both contain the target verb *absorb*. The first sentence is *literal* and the second is *nonliteral*.

***L*:** An Energy Department spokesman says the sulfur dioxide might be simultaneously recoverable through the use of powdered limestone, which tends to *absorb* the sulfur.

***N*:** He said that MMWEC will have to *absorb* only $4 million in additional annual costs now paid by the Vermont utilities.

To generate feature vectors for the sentences, we first applied the OpenNLP part-of-speech tagger to the sentences.[13] We then looked for each word in our list of 114,501 abstractness ratings (Section 2.2). If the word was not found in the list, we applied the Morpha morphological analyzer to identify the stem of the word (e.g., the stem of *managing* is *manage*) (Minnen et al., 2001).[14] We then looked for the stem in our list. If it was still not found, we skipped it.

For each sentence, we created a vector with five features:

1. the average abstractness ratings of all nouns, excluding proper nouns
2. the average abstractness ratings of all proper nouns
3. the average abstractness ratings of all verbs, excluding the target verb
4. the average abstractness ratings of all adjectives
5. the average abstractness ratings of all adverbs

When there were no words for a given part of speech, we set the average to a default value of 0.5. Two examples of feature vectors follow, corresponding to the two TroFi sentences above.

***L*:** $\langle 0.3873, 0.5397, 0.6375, 0.2641, 0.5835 \rangle$

***N*:** $\langle 0.6120, 0.3726, 0.6699, 0.5612, 0.5000 \rangle$

The intuition here is that the weight of each context word, in predicting the class of the target verb, may depend on the part of speech of the context word. We leave it to the logistic regression algorithm to determine the appropriate weighting, based on the training data. (See Table 7 in the next section.)

Following Birke and Sarkar's (2006) approach, we treated each group of sentences for a given target verb as a separate learning problem. For each verb, we used ten-fold cross-validation to learn and test logistic regression models. To measure the performance of the models, we used three different scores, macro-averaged accuracy and two forms of macro-averaged f-score.

Birke and Sarkar (2006) explain their scoring as follows:

> *Literal recall* is defined as *(correct literals in literal cluster / total correct literals)*. *Literal precision* is defined as *(correct literals in literal cluster / size of literal cluster)*. If there are no literals, *literal recall* is 100%; *literal precision* is 100% if there are no nonliterals in the literal cluster and 0% otherwise. The *f-score* is defined as *(2 · precision · recall) / (precision + recall)*. Nonliteral precision and recall are defined similarly. Average precision is the average of literal and nonliteral precision; similarly for average recall. For overall performance, we take the f-score of average precision and average recall.

The overall score is a macro-average, in which each verb has equal weight, regardless of how many sentences it appears in.

Every verb in TroFi has at least one *literal* usage and one *nonliteral* usage, so there is no issue with the definition of recall as 100% when there are no literals or no nonliterals. However, we believe that the definition of precision as 100% when no sentence is assigned to the literal or nonliteral cluster gives too high a score to the trivial algorithm of always guessing the majority class. The minority class will then always have a precision of 100%. Therefore we use a modified f-score in which the precision of a class is 0% if the algorithm never guesses that class. We refer to Birke and Sarkar's (2006) score as *f-score (0/0 = 1)* and to our own score as *f-score (0/0 = 0)*.

Table 5 summarizes our results. *Concrete-Abstract* refers to our own algorithm. *Birke-Sarkar*

[13] Available at http://incubator.apache.org/opennlp/.

[14] Available at http://www.informatics.susx.ac.uk/research/groups/nlp/carroll/morph.html.

refers to the best result reported by Birke and Sarkar (2006), using a form of active learning. *Majority Class* is the simple strategy of always guessing the majority class. *Probability Matching* is the strategy of randomly guessing each class with a probability equal to the size of the class.

Algorithm	Accuracy	F-score (0/0=0)	F-score (0/0=1)
Concrete-Abstract	0.734	0.631	0.639
Birke-Sarkar	*NA*	*NA*	0.649
Majority Class	**0.697**	**0.408**	0.629
Probability Matching	**0.605**	**0.500**	**0.500**

Table 5: The performance with known verbs.

We used a paired t-test to evaluate the statistical significance of the results in Table 5. The numbers are in bold font when the performance of an algorithm is significantly below the performance of Concrete-Abstract. In no case is any score significantly above the performance of Concrete-Abstract, at the 95% confidence level. *NA* indicates scores that were not calculated by Birke and Sarkar (2006).

4.3 Unknown Verbs

For the final experiment, we again used the TroFi Example Base, but with a different experimental setup. Instead of ten-fold cross-validation, we used the twenty-five verbs in Birke and Sarkar (2006) for testing (we call these the *old* verbs) and the other twenty-five verbs (the *new* verbs) for training. The twenty-five old (testing) verbs appear in 1,965 sentences and the twenty-five new (training) verbs appear in 1,772 sentences. For this experiment, we no longer learn a separate logistic regression model for each verb. All of the 1,772 training sentences are used together to learn a single logistic regression model, which is then evaluated on the testing sentences.

Table 6 summarizes our results. Since the testing set is exactly the same as in Section 4.2, we can compare the performance directly with the performance in the preceding section and with Birke and Sarkar's (2006) results.

Again, we used a paired t-test to evaluate the statistical significance of the results in Table 6. The numbers are in bold font when the performance of an algorithm is significantly below the performance of Concrete-Abstract. In no case is any score significantly above the performance of Concrete-Abstract, at the 95% confidence level.

Algorithm	Accuracy	F-score (0/0=0)	F-score (0/0=1)
Concrete-Abstract	0.686	0.673	0.681
Birke-Sarkar	*NA*	*NA*	0.649
Majority Class	0.697	**0.408**	**0.629**
Probability Matching	**0.605**	**0.500**	**0.500**

Table 6: The performance with unknown verbs.

Table 7 shows the coefficients in the logistic regression model that was learned on the training data. The items numbered from 1 to 5 are the five features described in Section 4.2. The sixth item is the constant term in the regression equation. We see that the abstractness of the nouns (excluding proper nouns) has the largest weight in predicting whether the target verb is in class *N*.

	Feature	Coefficient
1	AvgNounAbs	11.4117
2	AvgPropAbs	0.7250
3	AvgVerbAbs	-0.5528
4	AvgAdjAbs	1.1478
5	AvgAdvAbs	-0.2013
6	Intercept	-5.9436

Table 7: The logistic regression coefficients for class *N*.

5 Discussion

It is a strength of our approach that it can classify verbs that it has never seen before, as we see in Section 4.3. The feature vectors in all three experiments are based only on the context; the target adjective or verb is not used in the vectors. This avoids the need for gathering training data on every verb or adjective for which we want to determine whether it is being used metaphorically or literally, since the algorithm is not sensitive to the specific target word.

On the other hand, the performance might improve if the target word were included in the feature vectors. If metaphor is a method for transferring knowledge from concrete domains to abstract domains, then it follows that highly abstract target words will tend to be used literally in most contexts. For instance, the highly abstract verb *epitomize* (with an abstractness rating of 0.85861) is perhaps almost always used in a literal sense. There-

fore it would seem that the abstractness rating of the target word could be a useful clue for determining whether the sense is literal or metaphorical.

We experimented with including the abstractness rating of the target word as a feature, but the impact on performance was not significant for either the adjectives or the verbs. We hypothesize that this may be due to the relatively narrow range in the abstractness of the adjectives and verbs in our data. The abstractness ratings of the adjectives vary from 0.43356 for *dark* to 0.56637 for *hard*. The abstractness ratings of the fifty verbs range from 0.28756 for *plant* to 0.71628 for *lend*, but 80% of the verbs lie in the range from 0.41879 for *fly* to 0.59912 for *rest*. It seems possible that the abstractness rating of the target word would be useful with a dataset in which the target's abstractness varied substantially.

In future work, we would like to gather data for target words with a wider range of abstractness. We expect that such data would show some benefit to including information on the abstractness of the target word in the feature vector.

We also expect that a hybrid of classical word sense disambiguation, such as Birke and Sarkar's (2006) algorithm, with abstractness ratings would perform better than either approach alone. Abstractness may provide a good rough estimate of whether a word usage is literal or metaphorical, but it seems likely that knowledge of the specific target word in question will be required for a highly precise answer. This is another worthwhile topic for future research.

Currently there is no algorithm that identifies what kind of concepts and relations are grafted from the source domain to the target domain by metaphorical inference. The algorithm presented in this paper may be used within a constraints-based model of metaphor (Neuman and Nave, 2009) to address this challenge.

Recently there has been some interest in *visualness*, *picturability*, and *imagability*, the degree to which a word is associated with visual imagery (Deschacht and Moens, 2007). Although Xing et al. (2010) use the term *concreteness* in their work, their research is concerned with predicting the difficulty of queries for image retrieval. It could be argued that Xing et al. should be trying to capture *imagability*, not *concreteness*.

The MRC Psycholinguistic Database (Coltheart, 1981) includes words rated for *imagability*. Our algorithm for rating the abstractness of words (Section 2) could easily be trained with the MRC imagability ratings instead of the abstractness ratings. In future work, it would be interesting to evaluate imagability ratings on the TroFi Example Base. It would also be worthwhile to see whether our algorithm can be adapted for image retrieval (Xing et al., 2010) and image annotation (Deschacht and Moens, 2007).

6 Conclusion

Metaphor is ubiquitous, yet recognizing textual entailment is a challenge when words are used metaphorically. An algorithm for distinguishing metaphorical and literal senses of a word will facilitate correct textual inference, which will improve the many NLP applications that depend on textual inference.

We have introduced a new algorithm for measuring the degree of abstractness of a word. Inspired by research in cognitive linguistics (Lakoff and Johnson, 1980), we hypothesize that the degree of abstractness of the context in which a given word appears is predictive of whether the word is used in a metaphorical or literal sense. This hypothesis is supported by three experiments.

A strength of this approach to the problem of distinguishing metaphorical and literal senses is that it readily generalizes to new words, outside of the training data. We do not claim that abstractness is a complete solution to the problem, but it may be a valuable component in any practical system for processing metaphorical text.

Abstract

Decision trees have been applied to a variety of NLP tasks, including language modeling, for their ability to handle a variety of attributes and sparse context space. Moreover, forests (collections of decision trees) have been shown to substantially outperform individual decision trees. In this work, we investigate methods for combining trees in a forest, as well as methods for diversifying trees for the task of syntactic language modeling. We show that our tree interpolation technique outperforms the standard method used in the literature, and that, on this particular task, restricting tree contexts in a principled way produces smaller and better forests, with the best achieving an 8% relative reduction in Word Error Rate over an n-gram baseline.

1 Introduction

Language Models (LMs) are an essential part of NLP applications that require selection of the most fluent word sequence among multiple hypotheses. The most prominent applications include Automatic Speech Recognition (ASR) and Machine Translation (MT).

Statistical LMs formulate the problem as the computation of the model's probability to generate the word sequence $w_1, w_2, \ldots, w_m$ (denoted as w_1^m), assuming that higher probability corresponds to more fluent hypotheses. LMs are often represented in the following generative form:

$$p(w_1^m) = \prod_{i=1}^{m} p(w_i|w_1^{i-1})$$

Note the context space for this function, w_1^{i-1} is arbitrarily long, necessitating some independence assumption, which usually consists of reducing the relevant context to $n-1$ immediately preceding tokens:

$$p(w_i|w_1^{i-1}) \approx p(w_i|w_{i-n+1}^{i-1}) \quad (1)$$

These distributions are typically estimated from observed counts of n-grams w_{i-n+1}^{i} in the training data. The context space is still far too large[1]; therefore, the models are recursively smoothed using lower order distributions. For instance, in a widely used n-gram LM, the probabilities are estimated as follows:

$$\tilde{p}(w_i|w_{i-n+1}^{i-1}) = \rho(w_i|w_{i-n+1}^{i-1}) + \gamma(w_{i-n+1}^{i-1}) \cdot \tilde{p}(w_i|w_{i-n+2}^{i-1}) \quad (2)$$

where ρ is a *discounted* probability[2].

Note that this type of model is a simple Markov chain lacking any notion of syntax. It is widely accepted that languages do have some structure. Moreover, it has been shown that incorporating syntax into a language model can improve its performance (Bangalore, 1996; Heeman, 1998; Chelba and Jelinek, 2000; Filimonov and Harper, 2009). A straightforward way of incorporating syntax into a language model is by assigning a *tag* to each word and modeling them *jointly*; then to obtain the proba-

[1] $O(|V|^{n-1})$ in n-gram model with typical order $n = 3 \ldots 5$, and a vocabulary size of $|V| = 10^4 \ldots 10^6$.

[2] We refer the reader to (Chen and Goodman, 1996) for a survey of the discounting methods for n-gram models.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 691–699,
Edinburgh, Scotland, UK, July 27–31, 2011.

bility of a word sequence, the tags must be marginalized out:

$$p(w_1^m) = \sum_{t_1 \ldots t_m} p(w_1^m t_1^m) = \sum_{t_1 \ldots t_m} \prod_{i=1}^{m} p(w_i t_i | w_1^{i-1} t_1^{i-1})$$

An independence assumption similar to Eq. 1 can be made:

$$p(w_i t_i | w_1^{i-1} t_1^{i-1}) \approx p(w_i t_i | w_{i-n+1}^{i-1} t_{i-n+1}^{i-1}) \quad (3)$$

A primary goal of our research is to build strong syntactic language models and provide effective methods for constructing them to the research community. Note that the tags in the context of the joint model in Eq. 3 exacerbate the already sparse problem in Eq. 1, which makes the probability estimation particularly challenging. We utilize decision trees for joint syntactic language models to cluster context because of their strengths (reliance on information theoretic metrics to cluster context in the face of extreme sparsity and the ability to incorporate attributes of different types[3]), and at the same time, unlike log-linear models (Rosenfeld et al., 1994), computationally expensive probability normalization does not have to be postponed until runtime.

In Section 2, we describe the details of the syntactic decision tree LM. Construction of a single-tree model is difficult due to the inevitable greediness of the tree construction process and its tendency to overfit the data. This problem is often addressed by interpolating with lower order decision trees. In Section 3, we point out the inappropriateness of backoff methods borrowed from n-gram models for decision tree LMs and briefly describe a generalized interpolation for such models. The generalized interpolation method allows the addition of any number of trees to the model, and thus raises the question: what is the best way to create diverse decision trees so that their combination results in a stronger model, while at the same time keeping the total number of trees in the model relatively low for computational practicality. In Section 4, we explore and evaluate a variety of methods for creating different trees. To support our findings, we evaluate several of the models on an ASR rescoring task in Section 5. Finally, we discuss our findings in Section 6.

[3]For example, morphological features can be very helpful for modeling highly inflectional languages (Bilmes and Kirchhoff, 2003).

2 Joint Syntactic Decision Tree LM

A decision tree provides us with a clustering function $\Phi(w_{i-n+1}^{i-1} t_{i-n+1}^{i-1}) \rightarrow \{\Phi^1, \ldots, \Phi^N\}$, where N is the number of clusters, and clusters Φ^k are disjoint subsets of the context space. The probability estimation for a joint decision tree model is approximated as follows:

$$p(w_i t_i | w_{i-n+1}^{i-1} t_{i-n+1}^{i-1}) \approx p(w_i t_i | \Phi(w_{i-n+1}^{i-1} t_{i-n+1}^{i-1})) \quad (4)$$

In the remainder of this section, we briefly describe the techniques that we use to construct such a decision tree Φ and to estimate the probability distribution for the joint model in Eq. 4.

2.1 Decision Tree Construction

We use recursive partitioning to grow decision trees. In this approach, a number of alternative binary splits of the training data associated with a node are evaluated using some *metric*, the best split is chosen, checked against a *stopping rule* (which aims at preventing overfitting to the training data and usually involves a heldout set), and then the two partitions become the child nodes if the stopping rule does not apply. Then the algorithm proceeds recursively into the newly constructed leaves.

Binary splits are often referred to as *questions* about the context because a binary partition can be represented by a binary function that decides whether an element of context space belongs to one partition or the other. We utilize univariate questions where each question partitions the context on one attribute, e.g., w_{i-2} or t_{i-1}. The questions about words and tags are constructed differently:

- The questions q about the words are in the form $q(x) \equiv w_{i+x} \in S$, where x is an integer between $-n+1$ and -1, and $S \subset V$ is a subset of the word vocabulary V. To construct the set S, we take the set of words S_o *observed* at the offset x in the training data associated with the

current node and split it into two complementary subsets $S \cup \bar{S} = S_o$ using the Exchange algorithm (Martin et al., 1998). Because the algorithm is greedy and depends on the initialization, we construct 4 questions per word position using different random initializations of the Exchange algorithm.

Since we need to account for words that were not observed in the training data, we utilize the structure depicted in Figure 1. To estimate the probability at the backoff node (B in Figure 1), we can either use the probability from its grandparent node A or estimate it using a lower order tree (see Section 3), or combine the two. We have observed no noticeable difference between these methods, which suggests that only a small fraction of probability is estimated from these nodes; therefore, for simplicity, we use the probability estimated at the backoff node's grandparent.

- To create questions about tags we create a hierarchical clustering of all tags in the form of a binary tree. This is done beforehand, using the Minimum Discriminating Information algorithm (Zitouni, 2007) with the entire training data set. In this tree, each leaf is an individual tag and each internal node is associated with the subset of tags that the node dominates. Questions about tags are constructed in the form $q(x, k) \equiv t_{i+x} \in T_k$, where k is a node in the tag tree and T_k is the subset of tags associated with that node. The rationale behind constructing tag questions in this form is that it enables a more efficient decoding algorithm than standard HMM decoding (Filimonov and Harper, 2009).

Questions are evaluated in two steps. First the context attribute x is selected using a metric similar to information gain ratio proposed by (Quinlan, 1986):

$$\mathcal{M} = 1 - \frac{H(w_i) - H(w_i|x)}{H(x)} = 1 - \frac{I(x; w_i)}{H(x)}$$

where x is one of the context attributes, e.g., w_{i-2} or t_{i-1}. Then, among the questions about attribute x, we select the question that maximizes the entropy reduction.

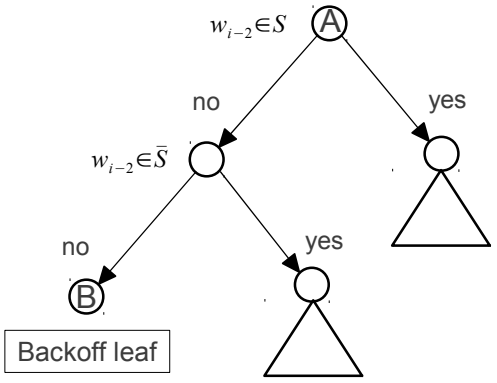

Figure 1: A fragment of the decision tree with a backoff node. $S \cup \bar{S}$ is the set of words observed in the training data at the node A. To account for unseen words, we add the backoff node B.

Instead of dedicating an explicit heldout set for the stopping criterion, we utilize a technique similar to cross validation: the training data set is partitioned into four folds, and the best question is required to reduce entropy on each of the folds.

Note that the tree induction algorithm can also be used to construct trees without tags:

$$p(w_i|w_{i-n+1}^{i-1}) \approx p(w_i|\Phi(w_{i-n+1}^{i-1}))$$

We refer to this model as the *word-tree* model. By comparing syntactic and word-tree models, we are able to separate the effects of decision tree modeling and syntactic information on language modeling by comparing both models to an n-gram baseline.

2.2 In-tree Smoothing

A decision tree offers a hierarchy of clusterings that can be exploited for smoothing. We can interpolate the observed distributions at leaves recursively with their parents, as in (Bahl et al., 1990; Heeman, 1998):

$$\tilde{p}_k(w_i t_i) = \lambda_k p_{ML}(w_i t_i) + (1 - \lambda_k)\tilde{p}_{k'}(w_i t_i) \quad (5)$$

where p_{ML} is the observed distribution at node k and k' is the parent of k. The coefficients λ_k are estimated using an EM algorithm.

We can also combine $p(w_i t_i|\Phi(w_{i-n+1}^{i-1} t_{i-n+1}^{i-1}))$ with lower order decision trees, i.e.,

$p(w_i t_i|\Phi(w_{i-n+2}^{i-1} t_{i-n+2}^{i-1}))$, and so on up until $p(w_i t_i)$ which is a one-node tree (essentially a unigram model). Although superficially similar to backoff in n-gram models, lower order decision trees differ substantially from lower order n-gram models and require different interpolation methods. In the next section, we discuss this difference and present a generalized interpolation that is more suitable for combining decision tree models.

3 Interpolation with Backoff Tree Models

In this section, for simplicity of presentation, we focus on the equations for word models, but the same equations apply equally to joint models (Eq. 3) with trivial transformations.

3.1 Backoff Property

Let us rewrite the interpolation Eq. 2 in a more generic way:

$$\tilde{p}(w_i|w_1^{i-1}) = \rho_n(w_i|\Phi_n(w_1^{i-1})) + \gamma(\Phi_n(w_1^{i-1})) \cdot \tilde{p}(w_i|BO_{n-1}(w_1^{i-1})) \quad (6)$$

where, ρ_n is a *discounted* distribution, Φ_n is a clustering function of order n, and $\gamma(\Phi_n(w_1^{i-1}))$ is the backoff weight chosen to normalize the distribution. BO_{n-1} is the *backoff* clustering function of order $n-1$, representing a reduction of context size. In the case of an n-gram model, $\Phi_n(w_1^{i-1})$ is the set of word sequences where the last $n-1$ words are w_{i-n+1}^{i-1}. Similarly, $BO_{n-1}(w_1^{i-1})$ is the set of sequences ending with w_{i-n+2}^{i-1}. In the case of a decision tree model, the same backoff function is typically used, but the clustering function can be arbitrary.

The intuition behind Eq. 6 is that the backoff context $BO_{n-1}(w_1^{i-1})$ allows for a more robust (but less informed) probability estimation than the context cluster $\Phi_n(w_1^{i-1})$. More precisely:

$$\forall_{w_1^{i-1},W} : W \in \Phi_n(w_1^{i-1}) \Rightarrow W \in BO_{n-1}(w_1^{i-1}) \quad (7)$$

that is, every word sequence W that belongs to a context cluster $\Phi_n(w_1^{i-1})$, belongs to the same backoff cluster $BO_{n-1}(w_1^{i-1})$ (hence has the same backoff distribution). For n-gram models, Property 7 trivially holds since $BO_{n-1}(w_1^{i-1})$ and $\Phi_n(w_1^{i-1})$ are defined as sets of sequences ending with w_{i-n+2}^{i-1} and w_{i-n+1}^{i-1}, with the former clearly being a superset of the latter. However, when Φ can be arbitrary, e.g., a decision tree, the property is not necessarily satisfied. Figure 2 illustrates cases when the Property 7 is satisfied (a) and violated (b).

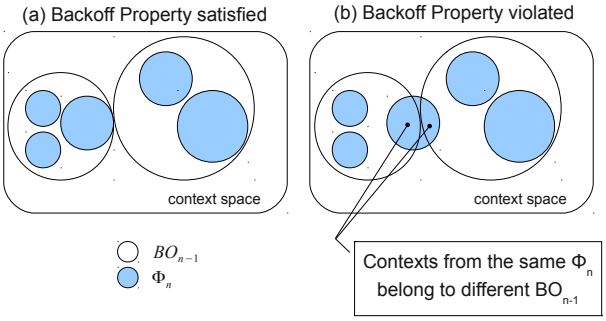

Figure 2: Backoff Property

Let us consider what happens when we have two context sequences W and W' that belong to the same cluster $\Phi_n(W) = \Phi_n(W')$ but different backoff clusters $BO_{n-1}(W) \neq BO_{n-1}(W')$. For example: suppose we have $\Phi(w_{i-2}w_{i-1}) = (\{\text{on}\}, \{\text{may,june}\})$ and two corresponding backoff clusters: $BO' = (\{\text{may}\})$ and $BO'' = (\{\text{june}\})$. Following *on*, the word *may* is likely to be a month rather than a modal verb, although the latter is more frequent and will dominate in BO'. Therefore we have much less faith in $\tilde{p}(w_i|BO')$ than in $\tilde{p}(w_i|BO'')$ and would like a much smaller weight γ assigned to BO'. However this would not be possible in the backoff scheme in Eq. 6, thus we will have to settle on a compromise value of γ, resulting in suboptimal performance.

Hence arbitrary clustering (an advantage of decision trees) leads to a violation of Property 7, which is likely to produce a degradation in performance *if* backoff interpolation Eq. 6 is used.

3.2 Generalized Interpolation

Recursive linear interpolation similar to Jelinek-Mercer smoothing for n-gram models (Jelinek and Mercer, 1980) has been applied to decision tree models:

$$\tilde{p}_n(w_i|w_{i-n+1}^{i-1}) = \lambda_n(\phi_n) \cdot p_n(w_i|\phi_n) + (1 - \lambda_n(\phi_n)) \cdot \tilde{p}_{n-1}(w_i|w_{i-n+2}^{i-1}) \quad (8)$$

where $\phi_n \equiv \Phi_n(w_{i-n+1}^{i-1})$, and $\lambda_n(\phi_n) \in [0, 1]$ are assigned to each cluster and are optimized on a held-out set using EM. $p_n(w_i|\phi_n)$ is the probability distribution at the cluster ϕ_n in the tree of order n. This interpolation method is particularly useful as, unlike count-based discounting methods (e.g., Kneser-Ney), it can be applied to already smoothed distributions p_n.

In (Filimonov and Harper, 2011), we observed that because of the violation of Property 7 in decision tree models, the interpolation method of Eq. 8 is not appropriate for such models. Instead we proposed the following generalized form of linear interpolation:

$$\tilde{p}_n(w_i|w_{i-n+1}^{i-1}) = \frac{\sum_{m=1}^{n} \lambda_m(\phi_m) \cdot p_m(w_i|\phi_m)}{\sum_{m=1}^{n} \lambda_m(\phi_m)} \quad (9)$$

Note that the recursive interpolation of Eq. 8 can be represented in this form with the additional constraint $\sum_{m=1}^{n} \lambda_m(\phi_m) = 1$, which is not required in the generalized interpolation of Eq. 9; thus, the generalized interpolation, albeit having the same number of parameters, has more degrees of freedom. We also showed that the recursive interpolation Eq. 8 is a special case of Eq. 9 that occurs when the Property 7 holds.

4 From Backoff Trees to Forest

Note that, in Eq. 9, individual trees do not have explicit higher-lower order relations, they are treated as a collection of trees, i.e., as a forest. Naturally, to benefit from the forest model, its trees must differ in *some* way. Different trees can be created based on differences in the training data, differences in the tree growing algorithm, or some non-determinism in the way the trees are constructed.

(Xu, 2005) used randomization techniques to produce a large forest of decision trees that were combined as follows:

$$p(w_i|w_{i-n+1}^{i-1}) = \frac{1}{M} \sum_{m=1}^{M} p_m(w_i|w_{i-n+1}^{i-1}) \quad (10)$$

where M is the number of decision trees in the forest (he proposed $M = 100$) and p_m is the m-th tree model[4]. Note that this type of interpolation assumes that each tree model is "equal" a priori and therefore is only appropriate when the tree models are grown in the same way (particularly, using the same order of context). Note that Eq. 10 is a special case of Eq. 9 when all parameters λ are equal.

(Xu, 2005) showed that, although each individual tree is a fairly weak model, their combination outperforms the n-gram baseline substantially. However, we find this approach impractical for online application of any sizable model: In our experiments, fourgram trees have approximately 1.8 million leaves and the tree structure itself (without probabilities) occupies nearly 200MB of disk space after compression. It would be infeasible to apply a model consisting of more than a handful of such trees without distributed computing of some sort. Therefore, we pose the following question: If we can afford to have only a handful of trees in the model, what would be best approach to construct those trees?

In the remainder of this section, we will describe the experimental setup, discuss and evaluate different ways of building decision tree forests for language modeling, and compare combination methods based on Eq. 9 and Eq. 10 (when Eq. 10 is applicable).

4.1 Experimental Setup

To train our models we use 35M words of WSJ 94-96 from LDC2008T13. The text was converted into speech-like form, namely numbers and abbreviations were verbalized, text was downcased, punctuation was removed, and contractions and possessives were joined with the previous word (i.e., *they 'll* becomes *they'll*). For the syntactic modeling, we used tags comprised of the POS tags of the word and it's head. Parsing of the text for tag extraction occurred after verbalization of numbers and abbreviations but

[4]Note that (Xu, 2005) used lower order models to estimate p_m.

before any further processing; we used a latent variable PCFG parser as in (Huang and Harper, 2009). For reference, we include an n-gram model with modified interpolated KN discounting. All models use the same vocabulary of approximately 50k words.

Perplexity numbers reported in Tables 1, 2, 3, and 4 are computed on WSJ section 23 (tokenized in the same way)[5].

In Table 1, we show results reported in (Filimonov and Harper, 2011), which we use as the baseline for further experiments. We constructed two sets of decision trees (a joint syntactic model and a word-tree model) as described in Section 2. Each set was comprised of a fourgram tree with backoff trigram, bigram, and unigram trees. We combined these trees using either Eq. 8 or Eq. 9. The λ parameters in Eq. 8 were estimated using EM by maximizing likelihood of a heldout set (we utilized 4-way cross-validation); whereas, the parameters in Eq. 9 were estimated using L-BFGS because the denominator in Eq. 9 makes the maximization step problematic.

4.2 Random Forest

(Xu, 2005) evaluated a variety of randomization techniques that can be used to build trees. He used a word-only model, with questions constructed using the Exchange algorithm, similar to our model. He tried two methods of randomization: selecting the positions in the history for question construction by a Bernoulli trials[6], and random initialization of the Exchange algorithm. He found that when the Exchange algorithm was initialized randomly, the Bernoulli trial parameter did not matter; however, when the Exchange algorithm was initialized deterministically; lower values for the Bernoulli trial parameter r yielded better overall forest performance. We implemented a similar method, namely, initializing the Exchange algorithm randomly and using $r = 0.1$ for Bernoulli trials[7].

There is a key difference between the two randomization methods. Since we do not have an a priori preference for choosing initializations for the Exchange algorithm, by using random initializations it is *hoped* that due to the greedy nature of the algorithm, the constructed trees, while being "undegraded,"[8] will be sufficiently different so that their combination improves over an individual tree. By introducing Bernoulli trials, on the other hand, there is a choice to purposely *degrade* the quality of individual trees in the hope that additional diversity would enable their combination to compensate for the loss of quality in individual trees.

Another way of introducing randomness to the tree construction without apparent degradation of individual tree quality is through varying the data, e.g., using different folds of the training data (see Section 2.1).

Let us take a closer look at the effect of different types of randomization on individual trees and their combinations. In the first set of experiments, we compare the performance of a single undegraded fourgram tree[9] with forests of fourgram trees grown randomly with Bernoulli trials. Having only same-order trees in a forest allows us to apply interpolation of Eq. 10 (used in (Xu, 2005)) and compare with the interpolation method presented in Eq. 9. By comparing forests of different sizes with the baseline from Table 1, we are able to evaluate the effect of randomization in decision tree growing and assess the importance of the lower order trees.

The results are shown in Table 2. Note that, while an undegraded syntactic tree is better than the word tree, the situation is reversed when the trees are grown randomly. This can be explained by the fact that the joint model has a much higher dimensionality of the context space, and therefore is much more sensitive to the clustering method.

As we increase the number of random trees in the forest, the perplexity decreases as expected, with the interpolation method of Eq. 9 showing improvement of a few percentile points over Eq. 10. Note that in the case of the word-tree model, it takes 4 random decision trees to reach the performance of a single undegraded tree, while in the joint model, even

[5]This section was not used for training the parser or for the LM training.

[6]In this method, positions in the history are ignored with probability $1 - r$, where r is the Bernoulli trials parameter.

[7]Note that because in the joint model, the question about tags are deterministic, we use a lower value of r than (Xu, 2005) to increase randomness.

[8]Here and henceforth, by "undegraded" we mean "according to the algorithm described in Section 2."

[9]Since each tree has a smooth distribution based on Eq. 5, lower order trees are not strictly required.

		Eq. 8		Eq. 9 (generalized)	
order	n-gram	word-tree	syntactic	word-tree	syntactic
2-gram	261.0	257.8	214.3	258.1	214.6
3-gram	174.3 (33.2%)	168.7 (34.6%)	156.8 (26.8%)	168.4 (34.8%)	155.3 (27.6%)
4-gram	161.7 (7.2%)	164.0 (2.8%)	156.5 (0.2%)	155.7 (7.5%)	147.1 (5.3%)

Table 1: Perplexity results on PTB WSJ section 23. Percentage numbers in parentheses denote the reduction of perplexity relative to the lower order model of the same type.

	word-tree		syntactic	
	Eq. 10	Eq. 9	Eq. 10	Eq. 9
1 × undgr	204.9		189.1	
1 × rnd	250.2		289.9	
2 × rnd	229.5	221.5	244.6	240.9
3 × rnd	227.5	214.5	226.2	220.0
4 × rnd	219.5	205.0	219.5	212.2
5 × rnd	200.9	184.1	216.5	209.0
baseline	N/A	155.7	N/A	147.1

Table 2: Perplexity numbers obtained using fourgram trees only. Note that "undgr" and "rnd" denote undegraded and randomly grown trees with Bernoulli trials, respectively, and the number indicates the number of trees in the forest. Also "baseline" refers to the fourgram models with lower order trees (from Table 1, Eq. 9).

	word-tree		syntactic	
# trees	Exchng.	+data	Exchng.	+data
1	204.9		189.1	
2	185.9	186.5	174.5	173.7
3	179.5	179.9	168.8	167.2
4	176.2	176.4	165.1	164.0
5	173.7	172.0	163.0	162.0
baseline	155.7		147.1	

Table 3: Perplexity numbers obtained using fourgram trees produced using random initialization of the Exchange algorithm (Exchng. columns) and, additionally, variations in training data folds (+data columns). Note that "baseline" refers to the fourgram models with lower order trees (from Table 1). All models use the interpolation method of Eq. 9.

5 trees are much worse than a single decision tree constructed without randomization. Finally, compare the performance of single undegraded fourgram trees in Table 2 with fourgram models in Table 1, which are constructed with lower order trees: both word-tree and joint models in Table 1 have over 20% lower perplexity compared to the corresponding models consisting of a single fourgram tree.

In Table 3, we evaluate forests of fourgram trees produced using randomizations without degrading the tree construction algorithm. That is, we use random initializations of the Exchange algorithm and, additionally, variations in the training data fold. All forests in this table use the interpolation method of Eq. 9. Note that, while these perplexity numbers are substantially better than trees produced with Bernoulli trials in Table 2, they are still significantly worse than the baseline model from Table 1.

These results suggest that, while it is beneficial to combine *different* decision trees, we should introduce differences to the tree construction process without degrading the trees when introducing randomness, especially for joint models. In addition, lower order trees seem to play an important role for high quality model combination.

4.3 Context-Restricted Forest

As we have mentioned above, combining higher and lower order decision trees produces much better results. A lower order decision tree is grown from a lower order context space, i.e., the context space where we purposely ignore some attributes. Note that in this case, rather than *randomly* ignoring contexts via Bernoulli trials at every node in the decision tree, we discard some context attributes upfront in a principled manner (i.e., most distant context) and then grow the decision tree without degradation.

Since the joint model, having more context attributes, affords a larger variety of different contexts, we use this model in the remaining experiments.

In Table 4, we present the perplexity numbers for our standard model with additional trees. We denote context-restricted trees by their Markovian or-

Model	size	PPL
1w1t + 2w2t + 3w3t + 4w4t (*)	294MB	147.1
(*) + 4w3t + 3w2t	579MB	143.5
(*) + 4w3t + 3w4t	587MB	144.9
(*) + 4w3t + 3w4t + 3w2t + 2w3t	699MB	**140.7**
(*) + 1 × bernoulli-rnd	464MB	149.7
(*) + 2 × bernoulli-rnd	632MB	150.4
(*) + 3 × bernoulli-rnd	804MB	151.1
(*) + 1 × data-rnd	484MB	147.0
(*) + 2 × data-rnd	673MB	145.0
(*) + 3 × data-rnd	864MB	145.2

Table 4: Perplexity results using the standard syntactic model with additional trees. "bernoulli-rnd" and "data-rnd" indicate fourgram trees randomized using Bernoulli trials and varying training data, respectively. The second column shows the combined size of decision trees in the forest.

ders (words w and tags t independently), so 3w2t indicates a decision tree implementing the probability function: $p(w_i t_i | w_{i-1} w_{i-2} t_{i-1})$. The fourgram joint model presented in Table 1 has four trees and is labeled with the formula "1w1t + 2w2t + 3w3t + 4w4t" in Table 4. The randomly grown trees (denoted "bernoulli-rnd") are grown utilizing the full context 4w4t using the methods described in Section 4.2. All models utilize the generalized interpolation method described in Section 3.2.

As can be seen in Table 4, adding undegraded trees consistently improves the performance of an already strong baseline, while adding random trees only increases the perplexity because their quality is worse than undegraded trees'. Trees produced by data randomization (denoted "data-rnd") also improve the performance of the model; however, the improvement is not greater than that of additional lower order trees, which are considerably smaller in size.

5 ASR Rescoring Results

In order to verify that the improvements in perplexity that we observe in Tables 1 and 4 are sufficient for an impact on a task, we measure Word Error Rate (WER) of our models on an Automatic Speech Recognition (ASR) rescoring task using the Wall Street Journal corpus (WSJ) for evaluation. The test set consists of 4,088 utterances of WSJ0. We optimized the weights for the combination of acoustic and language model scores on a separate development set comprised of 1,243 utterances from Hub2 5k closed vocabulary and the WSJ1 5k open vocabulary sets.

Model	PPL	WER
n-gram	161.7	7.81%
1w1t + 2w2t + 3w3t + 4w4t (Eq.8)	156.5	7.57%
1w1t + 2w2t + 3w3t + 4w4t (*)	147.1	7.32%
(*) + 4w3t + 3w4t + 3w2t + 2w3t	140.7	**7.20%**

Table 5: Perplexity and WER results. Note that the last two rows are syntactic models using the interpolation method of Eq. 9.

The ASR system used to produce lattices is based on the 2007 IBM Speech transcription system for the GALE Distillation Go/No-go Evaluation (Chen et al., 2006). The acoustic models are state-of-the-art discriminatively trained models which are trained on Broadcast News (BN) Hub4 acoustic training data. Lattices were produced using a trigram LM trained on the same data as the models we evaluate, then 1,000 best unique hypotheses were extracted from the lattices. WER of the 1-best hypothesis on the test set is 8.07% and the oracle WER is 3.54%.

In Table 5, we present WER results along with the corresponding perplexity numbers from Tables 1 and 4 for our lowest perplexity syntactic model, as well as the baselines (modified KN n-gram model and standard decision tree models using interpolation methods of Eq. 8 and Eq. 9). The interpolation method of Eq. 9 substantially improves performance over the interpolation method of Eq. 8, reducing WER by 0.25% absolute ($p < 10^{-5}$). Adding four trees utilizing context restricted in different ways further reduces WER by 0.12%, which is also a statistically significant ($p < 0.025$) improvement over the baseline models labeled (*). Altogether, the improvements over the n-gram baseline add up to 0.61% absolute (8% relative) WER reduction.

6 Conclusion

In this paper, we investigate various aspects of combining multiple decision trees in a single language model. We observe that the generalized interpola-

tion (Eq. 9) for decision tree models proposed in (Filimonov and Harper, 2011) is in fact a forest interpolation method rather than a backoff interpolation because, in Eq. 9, models do not have explicit higher-lower order relation as they do in backoff interpolation (Eq. 6). Thus, in this paper we investigate the question of how to construct decision trees so that their combination results in improved performance (under the assumption that computational tractability allows only a handful of decision trees in a forest). We compare various techniques for producing forests of trees and observe that methods that diversify trees by introducing random degradation of the tree construction algorithm perform more poorly (especially with joint models) than methods in which the trees are constructed without degradation and with variability being introduced via parameters that are inherently arbitrary (e.g., training data fold differences or initializations of greedy search algorithms). Additionally, we observe that simply restricting the context used to construct trees in different ways, not only produces smaller trees (because of the context reduction), but the resulting variations in trees also produce forests that are *at least* as good as forests of larger trees.

7 Acknowledgments

We would like to thank Ariya Rastrow for providing word lattices for the ASR rescoring experiments.

Abstract

Augmented and alternative communication (AAC) devices enable users with certain communication disabilities to participate in everyday conversations. Such devices often rely on statistical language models to improve text entry by offering word predictions. These predictions can be improved if the language model is trained on data that closely reflects the style of the users' intended communications. Unfortunately, there is no large dataset consisting of genuine AAC messages. In this paper we demonstrate how we can crowdsource the creation of a large set of fictional AAC messages. We show that these messages model conversational AAC better than the currently used datasets based on telephone conversations or newswire text. We leverage our crowdsourced messages to intelligently select sentences from much larger sets of Twitter, blog and Usenet data. Compared to a model trained only on telephone transcripts, our best performing model reduced perplexity on three test sets of AAC-like communications by 60–82% relative. This translated to a potential keystroke savings in a predictive keyboard interface of 5–11%.

1 Introduction

Users with certain communication disabilities rely on augmented and alternative communication (AAC) devices to take part in everyday conversations. Often these devices consist of a predictive text input method coupled with text-to-speech output. Unfortunately, the text entry rates provided by AAC devices are typically low, between 0.5 and 16 words-per-minute (Trnka et al., 2009).

As a consequence, researchers have made numerous efforts to increase AAC text entry rates by employing a variety of improved language modeling techniques. Examples of approaches include adapting the language model to recently used words (Wandmacher et al., 2008; Trnka, 2008), using syntactic information (Hunnicutt, 1989; Garay-Vitoria and González-Abascal, 1997), using semantic information (Wandmacher and Antoine, 2007; Li and Hirst, 2005), and modeling topics (Lesher and Rinkus, 2002; Trnka et al., 2006). For a recent survey, see Garay-Vitoria and Abascal (2006).

While such language model improvement techniques are undoubtedly helpful, certainly they can all benefit from starting with a long-span language model trained on large amounts of closely matched data. For AAC devices this means closely modeling everyday face-to-face communications. However, a long-standing problem in the field is the lack of good data sources that adequately model such AAC communications. Due to privacy-reasons and other ethical concerns, there is no large dataset consisting of genuine AAC messages. Therefore, previous research has used transcripts of telephone conversations or newswire text. However, these data sources are unlikely to be an ideal basis for AAC language models.

In this paper we show that it is possible to significantly improve conversational AAC language modeling by first crowdsourcing the creation of a fictional collection of AAC messages on the Amazon Mechanical Turk microtask market. Using a care-

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 700–711,
Edinburgh, Scotland, UK, July 27–31, 2011.

fully designed microtask we collected 5890 messages from 298 unique workers. As we will see, word-for-word these fictional AAC messages are better at predicting AAC test sets than a wide-range of other text sources. Further, we demonstrate that Twitter, blog and Usenet data outperform telephone transcripts or newswire text.

While our crowdsourced AAC data is better than other text sources, it is too small to train high-quality long-span language models. We therefore investigate how to use our crowdsourced collection to intelligently select AAC-like sentences from Twitter, blog and Usenet data. We compare a variety of different techniques for doing this intelligent selection. We find that the best selection technique is the recently proposed cross-entropy difference method (Moore and Lewis, 2010). Using this method, we build a compact and well-performing mixture model from the Twitter, blog and Usenet sentences most similar to our crowdsourced data.

We evaluate our mixture model on four different test sets. On the three most AAC-like test sets, we found substantial reductions in not only perplexity but also in potential keystroke savings when used in a predictive keyboard interface. Finally, to aid other AAC researchers, we have publicly released our crowdsourced AAC collection, word lists and best-performing language models[1].

2 Crowdsourcing AAC-like Messages

As we mentioned in the introduction, there are unfortunately no publicly available sources of genuine conversational AAC messages. We conjectured we could create surrogate data by asking workers on Amazon Mechanical Turk to imagine they were a user of an AAC device and having them invent things they might want to say. While crowdsourcing is commonly used for simple human computation tasks, such as labeling images and transcribing audio, it is an open research question whether we can leverage workers' creativity to invent plausible and useful AAC-like messages. In this section, we describe our carefully constructed microtask and compare how well our collected messages correspond to communications from actual AAC users.

[1] http://www.aactext.org/imagine/

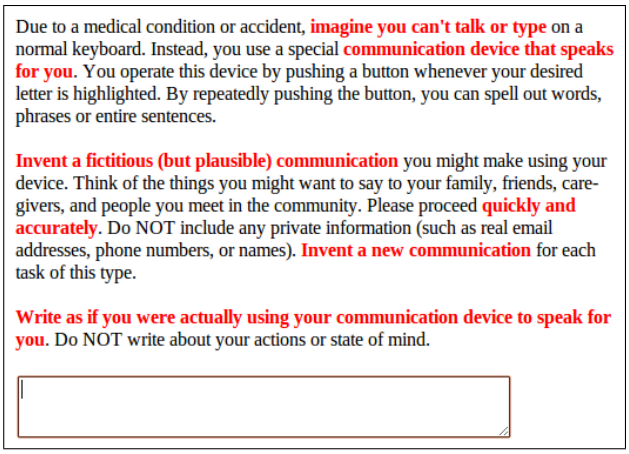

Figure 1: The interface for HITs of type 1 in our crowdsourced data collection.

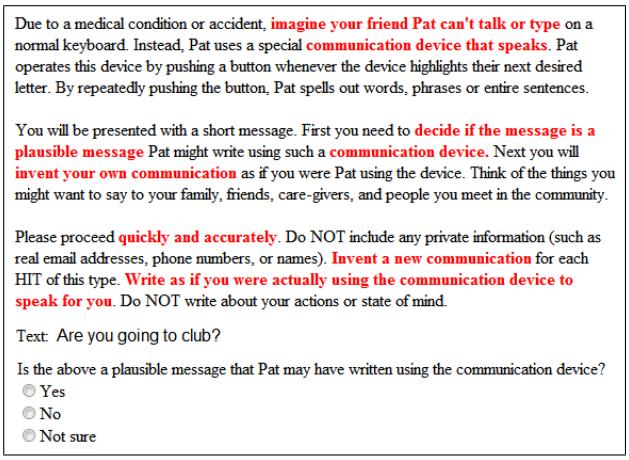

Figure 2: The interface for HITs of type 2 in our crowdsourced data collection.

2.1 Collection Tasks

To collect our data, we used two different types of human intelligence tasks (HITs). In type 1, the workers were told to imagine that due to an accident or medical condition they had to use a communication device to speak for them. Workers were asked to invent a plausible communication. Workers were prevented from pasting text. After several pilot experiments, we arrived at the instructions shown in figure 1.

In type 2, a worker first judged the plausibility of a communication written by a previous worker (figure 2). After judging, the worker was asked to "invent a completely new communication" as if the worker was the AAC user. Workers were prevented from pasting text or typing the identical text as the one just judged. The same communication

was judged by three separate workers. In this work we did not make use of these judgments.

2.2 Data Cleaning

While most workers produced plausible and often creative communications, some workers entered obvious garbage. These workers were identified by a quick visual scan of the submitted communications. We rejected the work of 9% of the workers in type 1 and 4% of the workers in type 2. After removing these workers, we had 2481 communications from type 1 and 4440 communications from type 2.

After combining the data from all accepted HITs, we conducted further semi-automatic data cleaning. We first manually reviewed communications sorted by worker. We removed workers whose text was non-fluent English or not plausible (e.g. some workers entered news headlines or proverbs). Identical communications from the same worker were removed. We removed communications with an out-of-vocabulary (OOV) rate of over 20% with respect to a large word list of 330K words obtained from human-edited dictionaries[2]. We also removed communications that were all in upper case, contained common texting abbreviations (e.g. "plz", "ru", "2day"), communications over 80 characters, and communications with excessive letter repetitions (e.g. "yippeeee"). After cleaning, we had 5890 messages from 298 unique workers.

2.3 Results

Tables 1 and 2 show some example communications obtained in each HIT type. Sometimes, but not always, type 2 resulted in the worker writing a similar communication as the one judged. This is a mixed blessing. While it may reduce the diversity of communications, we found that workers were more eager to accept HITs of type 2. The average HIT completion time was also shorter, 24 seconds in type 2 versus 36 seconds in type 1. While we initially paid $0.04/HIT for both types, we found in subsequent rounds that we could pay $0.02/HIT for type 2. We also had to reject less work in type 2 and qualitatively found the communications to be more AAC-like. Since workers had to imagine themselves in a very unfamiliar situation, it appears that providing a concrete example was helpful to workers.

[2]We combined Wiktionary, Webster's dictionary provided by Project Gutenberg, the CMU pronouncing dictionary and GNU aspell.

Is the dog friendly?
Can I have some water please?
I need to start making a shopping list soon.
What I would really like right now is a plate of fruit.
Who will drive me to the doctor's office tomorrow?

Table 1: Example communications from type 1.

Can you bring my slippers?
I am cold, is there another blanket.
How did Pam take the news?
Bring the fuzzy slippers here.
Did you have breakfast?
why are you so late?
I am pretty hungry, can we go eat?
I had bacon eggs and hashbrowns for breakfast.

Table 2: Example communications from type 2. The text in bold is the message workers judged. It is followed in plain text by the workers' new messages.

3 Comparison of Training Sources

In this section, we compare the predictive performance of language models trained on our Turk AAC data with models trained on other text sources. We use the following training sets:

- NEWS – Newspaper articles from the CSR-III (Graff et al., 1995) and Gigaword corpora (Graff, 2003). 60M sentences, 1323M words.
- WIKIPEDIA – Current articles and discussion threads from a snapshot of Wikipedia (January 3, 2008). 24M sentences, 452M words.
- USENET – Messages from a Usenet corpus (Shaoul and Westbury, 2009). 123M sentences, 1847M words.
- SWITCHBOARD – Transcripts of 2217 telephone conversations from the Switchboard corpus (Godfrey et al., 1992). Due to its conversational style, this corpus has been popular for AAC language modeling (Lesher and Rinkus, 2002; Trnka et al., 2009). 0.2M sentences, 2.6M words.
- BLOG – Blog posts from the ICWSM corpus (Burton et al., 2009). 25M sentences, 387M words.

- TWITTER – We collected Twitter messages via the streaming API between December 2010 and March 2011. We used the free Twitter stream which provides access to 5% of all tweets. Twitter may be particularly well suited for modeling AAC communications as tweets are short typed messages that are often informal person-to-person communications. Twitter has previously been proposed as a candidate for modeling conversations, see for example Ritter et al. (2010). 7M sentences, 55M words.
- TURKTRAIN – Communications from 80% of the workers in our crowdsourced collection. 4981 sentences, 24860 words.

WIKIPEDIA, USENET, BLOG and TWITTER all consisted of raw text that required significant filtering to eliminate garbage, spam, repeated messages, XML tags, non-English text, etc. Given the large amount of data available, our approach was to throw away any text that did not appear to be a sensible English sentence. For example, we eliminated any sentence having a large number of words not in our 330K word list.

3.1 Test Sets

We evaluated our models on the following test sets:

- COMM – Sentences written in response to hypothetical communication situations collected by Venkatagiri (1999). We removed nine sentences containing numbers. This set is used throughout the paper. 251 sentences, 1789 words.
- SPECIALISTS – Context specific phrases suggested by AAC specialists[3]. This set is used throughout the paper. 952 sentences, 3842 words.
- TURKDEV – Communications from 10% of the workers in our crowdsourced collection (disjoint from TURKTRAIN and TURKTEST). This set will be used for initial evaluations and also to tune our models. 551 sentences, 2916 words.
- TURKTEST – Communications from 10% of the workers in our crowdsourced collection (disjoint from TURKTRAIN and TURKDEV). This set is used only in the final evaluation section. 563 sentences, 2721 words.

[3] http://aac.unl.edu/vocabulary.html

Test set	Sentence
COMM	I love your new haircut.
COMM	How many children do you have?
SPECIALISTS	Are you sure you don't mind?
SPECIALISTS	I'll keep an eye on that for you
SWITCHTEST	yeah he's a good actor though
SWITCHTEST	what did she have like

Table 3: Examples from three of our test sets.

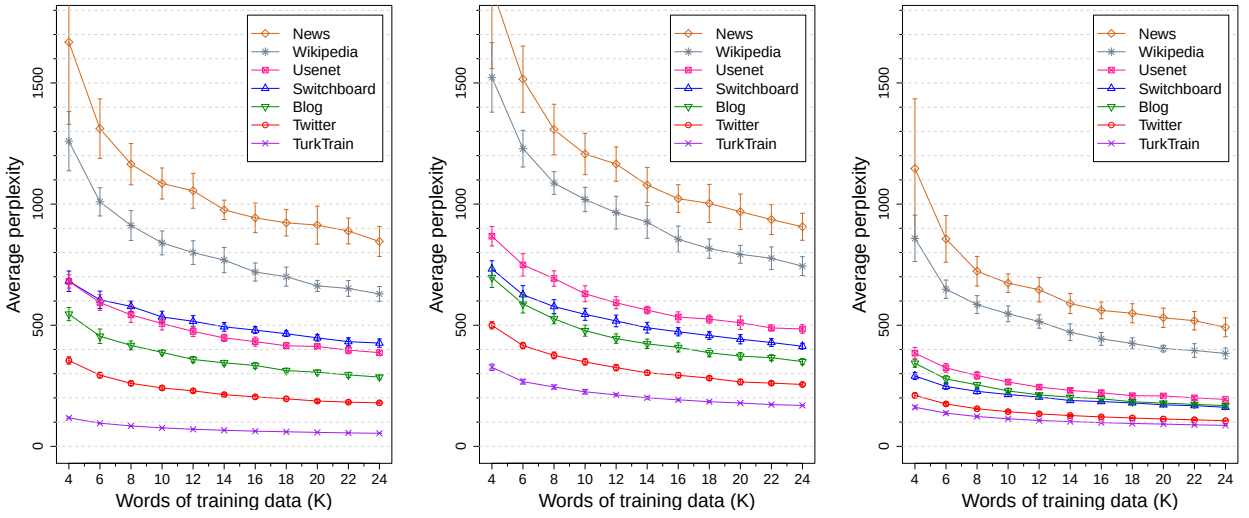
- SWITCHTEST – Transcripts of three Switchboard conversations (disjoint from the SWITCHBOARD training set). This is the same set used in Trnka et al. (2009). We dropped one sentence containing a dash. This set is only used in the final evaluation section. 59 sentences, 508 words.

TURKDEV and TURKTEST contain text similar to table 1 and 2. Table 3 shows some examples from the other three test sets. Sentences in COMM tended to be richer in vocabulary and subject matter than those in SPECIALISTS. The SPECIALISTS sentences tended to be general phrases that avoided mentioning specific situations, proper names, etc. Sentences in SWITCHTEST exhibited phenomena typical of human-to-human voice conversations (filler words, backchannels, interruptions, etc).

3.2 Language Model Training

All language models were trained using the SRILM toolkit (Stolcke, 2002). All models used interpolated modified Kneser-Ney smoothing (Kneser and Ney, 1995; Chen and Goodman, 1998). In this section, we trained 3-gram language models with no count-cutoffs. All text was converted to lowercase and we removed punctuation except for apostrophes. We believe punctuation would likely slow down a user's conversation for only a small potential advantage (e.g. improving text-to-speech prosody).

All models used a vocabulary of 63K words including an unknown word. We obtained our vocabulary by taking all words occurring in TURKTRAIN and all words occurring four or more times in the TWITTER training set. We restricted our vocabulary to words from our large list of 330K words. This restriction prevented the inclusion of common misspellings prevalent in many of our training sets. Our 63K vocabulary resulted in low OOV



(a) TURKDEV test set (b) COMM test set (c) SPECIALISTS test set

Figure 3: Perplexity of language models trained on the same amount of data from different sources. The perplexity is the average of 20 models trained on random subsets of the training data (one standard deviation error bars).

rates for all test sets: COMM 0%, SPECIALISTS 0.05%, TURKDEV 0.1%, TURKTEST 0.07%, and SWITCHTEST 0.8%.

3.3 Small Training Size Experiment

We trained language models on each dataset, varying the number of training words from 4K to 24K (the limit of the TURKTRAIN set). For each dataset and training amount, we built 20 different models by choosing sentences from the full training set at random. We computed the mean and standard deviation of the per-word perplexity of the set of 20 models.

As shown in figure 3, word-for-word the TURKTRAIN data was superior for our three most AAC-like test sets. Thus it appears our crowdsourcing procedure was successful at generating AAC-like data. TWITTER was consistently the second best. BLOG, USENET and SWITCHBOARD also performed well.

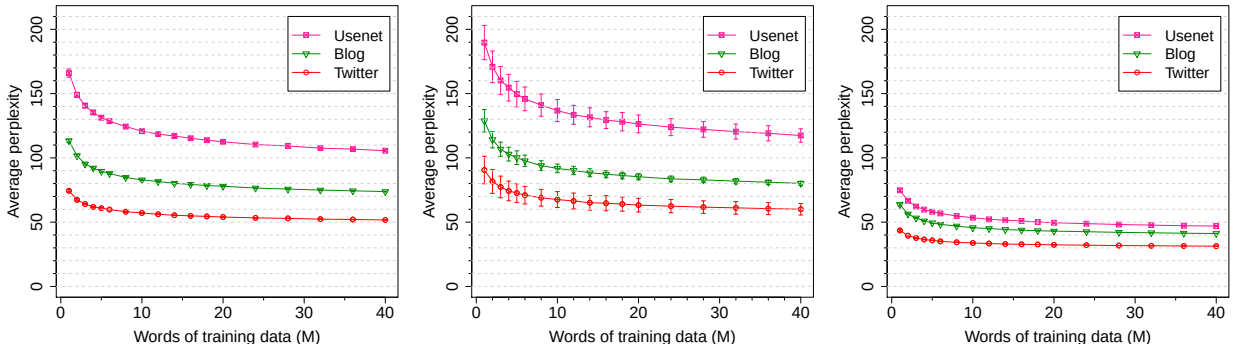
3.4 Large Training Size Experiment

The previous experiment used a small amount of training data. We selected the best three datasets having tens of millions of words of training data: USENET, BLOG, and TWITTER. As in the previous experiment, we computed the mean and standard deviation of the per-word perplexity of a set of 20 models. Increasing the amount of training data substantially reduced perplexity compared to our small TURKTRAIN collection (figure 4). Tweets were clearly well suited for modeling AAC-like text as 3M words of TWITTER data was better than 40M words of BLOG data.

3.5 Comparison with Real AAC Data

Beukelman et al. (1984) analyzed the communications made by five nonspeaking adults over 14 days. All users were experienced using a tape-typewriter AAC device. Beukelman gives a ranked list of the top 500 words, the frequency of the top 20 words, and statistics calculated on the communications.

For the top 10 words in Beukelman's AAC user data, we computed the probability of each word in our various datasets (figure 5). As shown, some words such as "to" and "a" occur with similar frequency across all datasets. Some words such as "the" are overrepresented in data such as news text. Other words such as "I" and "you" are much more variable. Our Turk data has the closest matching frequency for the most popular word "I". Interestingly, our Turk data shows a much higher probability for "you" than the AAC data. We believe this resulted from the situation we asked workers to imagine (i.e. communicating via a letter-at-a-time scanning interface). Workers presumed in such a situation they would need to ask others to do many tasks. We observed many requests in the data such as "Can



(a) TURKDEV test set (b) COMM test set (c) SPECIALISTS test set

Figure 4: Perplexity of language models trained on increasing amounts of data from three different training sources. Results on the TURKDEV, COMM and SPECIALISTS test sets.

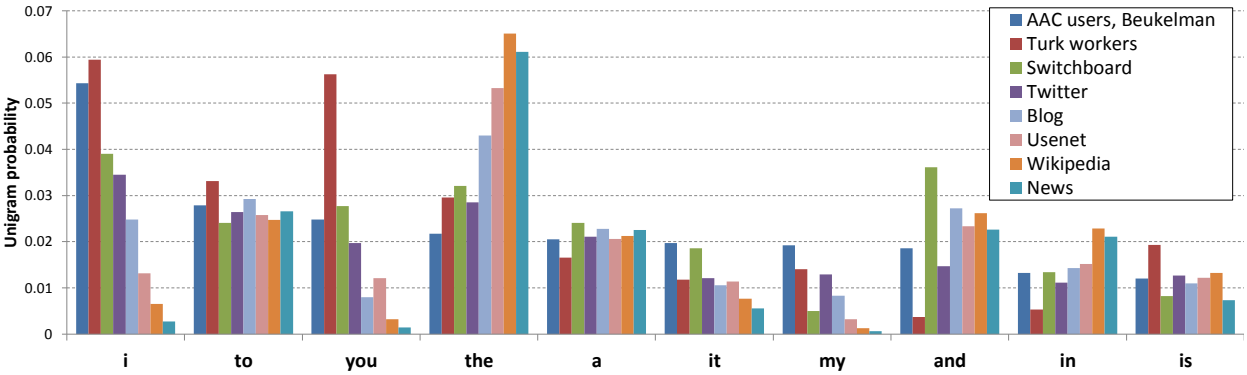


Figure 5: The unigram probabilities of the top 10 words reported by Beukelman et al. (1984).

you change my sheets?" and "Can you walk the dog for me?"

Beukelman reports 33% of all communications could be made using only the top 500 words. The same 500 words allowed writing of 34% of our Turk communications. Other datasets exhibited much lower percentages. Note that this is at least partially due to the longer sentences present in some datasets. Unfortunately, Beukelman does not report the average communication length. Our Turk communications were 5.0 words on average. The next shortest dataset was TWITTER with 7.5 words per communication. Despite their short average length, only 10% of Tweets could be written using the top 500 words.

Beukelman reports that 80% of words in the AAC users' communications were in the top 500 words. 81% of the words in our crowdsourced data were in this word list. For comparison, only 65% of words in our TWITTER data were in the 500 word vocabulary. While our TURKTRAIN set contains only 2141 unique words, this may in fact be good since it has been argued that rare words have received too much attention in AAC (Baker et al., 2000).

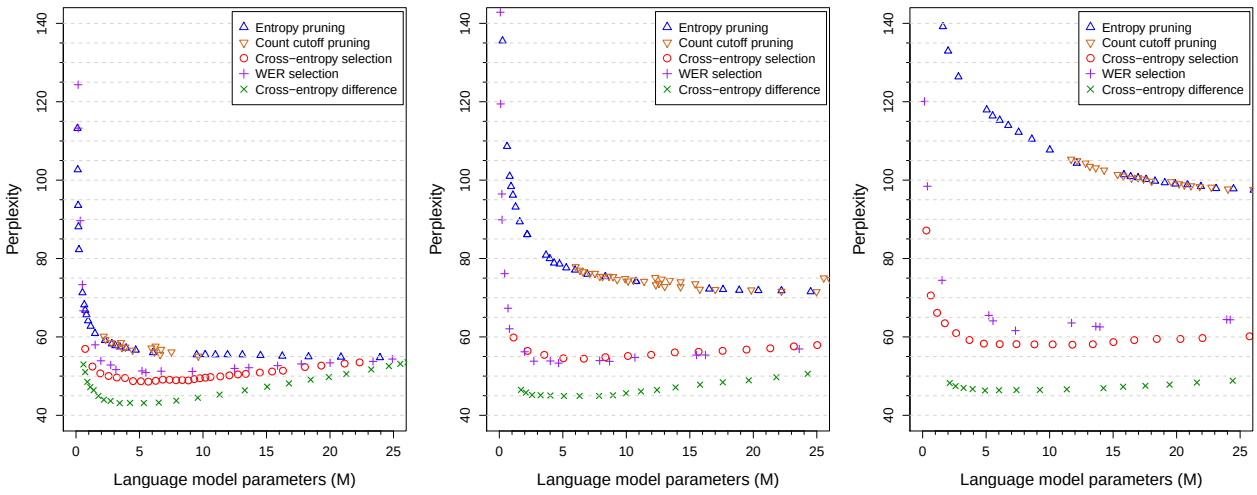
4 Using Large Datasets Effectively

In the previous section, we found our crowdsourced data was good at predicting AAC-like test sets. However, in order to build a good long-span language model, we would require millions of such communications. Crowdsourcing such a large collection would be prohibitively expensive. Therefore, we instead investigated how to use our crowdsourced data to intelligently select AAC-like data from other large datasets. For large datasets, we used TWITTER, BLOG and USENET as they were both large and well-matched to AAC data.

4.1 Selecting AAC-like Data

For each training sentence, we calculated three values:

- WER – The minimum word error rate between the training sentence and one of the crowdsourced



(a) TWITTER (b) BLOG (c) USENET

Figure 6: Perplexity on TURKDEV using different data selection and pruning techniques.

communications. This is the minimum number of words that must be inserted, substituted or deleted to transform the training sentence into a TURKTRAIN sentence divided by the number of words in the TURKTRAIN sentence. For example, the training sentence "I didn't sleep well Monday night either" was given a WER of 0.33 because two word-changes transformed it into a message written by a worker: "I didn't sleep well last night".

- Cross-entropy, in-domain – The average per-word cross-entropy of the training sentence under a 3-gram model trained on TURKTRAIN.
- Cross-entropy, background – The average per-word cross-entropy of the training sentence under a 3-gram model trained on a random portion of the training set. The random portion was the same size as TURKTRAIN.

We used these values to limit training to only AAC-like sentences. We tried three different selection methods. In *WER selection*, only sentences below a threshold on the word error rate were kept in the training data. This tends to find variants of existing communications in our Turk collection.

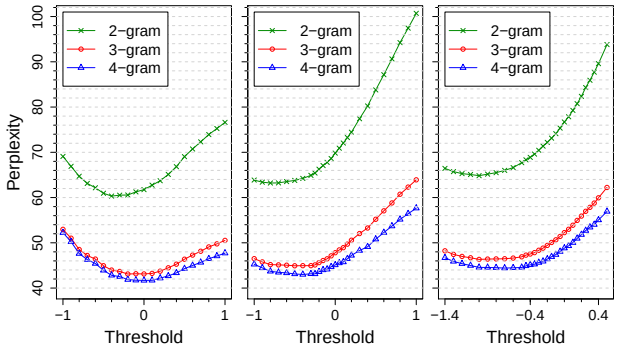
In *cross-entropy selection*, we used only sentences below a threshold on the per-word cross-entropy with respect to a TURKTRAIN language model. This is equivalent to placing a threshold on the perplexity. Previously this technique has been used to improve language models based on web data (Bulyko et al., 2007; Gao et al., 2002) and to construct domain-specific models (Lin et al., 1997).

In *cross-entropy difference selection*, a sentence's score is the in-domain cross-entropy minus the background cross-entropy (Moore and Lewis, 2010). This technique has been used to supplement European parliamentary text (48M words) with newswire data (3.4B words) (Moore and Lewis, 2010). We were curious how this technique would work given our much smaller in-domain set of 24K words.

4.2 Data Selection and Pruning

We built models selecting sentences below different thresholds on the WER, in-domain cross-entropy, or cross-entropy difference. For comparison, we also pruned our models using conventional count-cutoff and entropy pruning (Stolcke, 1998). During entropy pruning, we used a Good-Turing estimated model for computing the history marginals as the lower-order Kneser-Ney distributions are unsuitable for this purpose (Chelba et al., 2010).

We calculated the perplexity of each model on three test sets. We also tallied the number of model parameters (all n-gram probabilities plus all backoff weights). On TURKDEV, cross-entropy difference selection performed the best for all models sizes and for all training sets (figure 6). We also found cross-



(a) TWITTER (b) BLOG (c) USENET

Figure 7: Perplexity on TURKDEV varying the cross-entropy difference threshold.

entropy difference was the best on COMM, reducing perplexity by 10–20% relative compared to cross-entropy selection. Results on SPECIALISTS showed that WER and both forms of cross-entropy selection performed similarly. All three data selection methods were superior to count-cutoff or entropy pruning. We use cross-entropy difference selection for the remainder of this paper.

4.3 Model Order and Optimal Thresholds

We created 2-gram, 3-gram and 4-gram models on TWITTER, BLOG, and USENET using a range of cross-entropy difference thresholds. 4-gram models slightly outperformed 3-gram models (figure 7). The optimal threshold for 4-gram models were as follows: TWITTER 0.0, BLOG -0.4, and USENET -0.7. These thresholds resulted in using 20% of TWITTER, 5% of BLOG, and 1% of USENET.

4.4 Mixture Model

We created a mixture model using linear interpolation from the TWITTER, USENET and BLOG 4-gram models created with each set's optimal threshold. The mixture weights were optimized with respect to TURKDEV using SRILM. The final mixture weights were: TWITTER 0.42, BLOG 0.29, and USENET 0.29. Our final 4-gram mixture model had 43M total parameters and a compressed disk size of 316 MB.

5 Evaluation

In this section, we compare our mixture model against baseline models. We show performance with respect to usage in a typical AAC text entry interface based on word prediction.

5.1 Predictive Text Entry

Many AAC communication devices use word predictions. In a word prediction interface users type letters and the interface offers word completions based on the prefix of the current word and often the prior text. By selecting one of the predictions, the user can potentially save keystrokes as compared to typing out every letter of each word.

We assume a hypothetical predictive keyboard interface that displays five word predictions. Our keyboard makes predictions based on up to three words of prior context. Our keyboard predicts words even before the first letter of a new word is typed. As a user types letters, predictions are limited to words consistent with the typed letters. If the system makes a correct prediction, we assume it takes only one keystroke to enter the word and any following space.

We only predict words in our 63K word vocabulary (empty prediction slots are possible). We display a word even if it was already a proposed prediction for a shorter prefix of the current word. The first word in a sentence is conditioned on the sentence-start pseudo-word. If an out-of-vocabulary word is typed, the word is replaced in the language model's context with the unknown pseudo-word.

We evaluate our predictive keyboard using the common metric of keystroke savings (KS):

$$KS = \left(1 - \left(\frac{k_p}{k_a}\right)\right) \times 100\%,$$

where k_p is the number of keystrokes required with word predictions and k_a is the number of keystrokes required without word prediction.

5.2 Predictive Performance Experiment

We compared our mixture model using cross-entropy difference selection with three baseline models trained on all of TWITTER, SWITCHBOARD and TURKTRAIN. The baseline models were unpruned 4-gram models trained using interpolated modified Kneser-Ney smoothing. They had 72M, 5M, and 129K parameters respectively.

As shown in table 4, our mixture model performed the best on the three most AAC-like test sets (COMM, SPECIALISTS, and TURKTEST). The

LM	Test set	PPL	KS
Mixture	**COMM**	**47.9**	**62.5%**
Twitter	COMM	55.9	60.9%
Switchboard	COMM	151.1	54.4%
Turk	COMM	165.9	52.7%
Mixture	**SPECIALISTS**	**25.7**	**63.1%**
Twitter	SPECIALISTS	27.3	61.9%
Switchboard	SPECIALISTS	64.5	57.7%
Turk	SPECIALISTS	85.9	52.8%
Mixture	**TURKTEST**	**31.2**	**62.0%**
Twitter	TURKTEST	42.3	59.3%
Switchboard	TURKTEST	172.5	50.6%
Turk	TURKTEST	51.0	57.6%
Mixture	SWITCHTEST	174.3	52.8%
Twitter	SWITCHTEST	142.6	54.9%
Switchboard	**SWITCHTEST**	**79.2**	**58.8%**
Turk	SWITCHTEST	642.5	42.9%

Table 4: Perplexity (PPL) and keystroke savings (KS) of different language models on four test sets. The bold line shows the best performing language model on each test set.

mixture model provided substantial increases in keystroke savings compared to a model trained solely on Switchboard. The mixture model also performed better than simply training a model on a large amount of Twitter data. The model trained on only 24K words of Turk data did surprisingly well given its extremely limited training data.

Our Switchboard model performed the best on SWITCHTEST with a keystroke savings of 58.8%. For comparison, past work reported a keystroke savings of 55.7% on SWITCHTEST using a 3-gram model trained on Switchboard (Trnka et al., 2009). While our mixture model performed less well on SWITCHTEST (52.8%), it is likely the other three test sets better represent AAC communications.

5.3 Larger Mixture Model Experiment

Our mixture language model used the best thresholds with respect to TURKDEV. This resulted in throwing away most of the training data. This might be suboptimal in practice if an AAC user's communications are somewhat different or more diverse than the language generated by the Turk workers.

We trained a series of mixture models in which we varied the cross-entropy difference thresholds

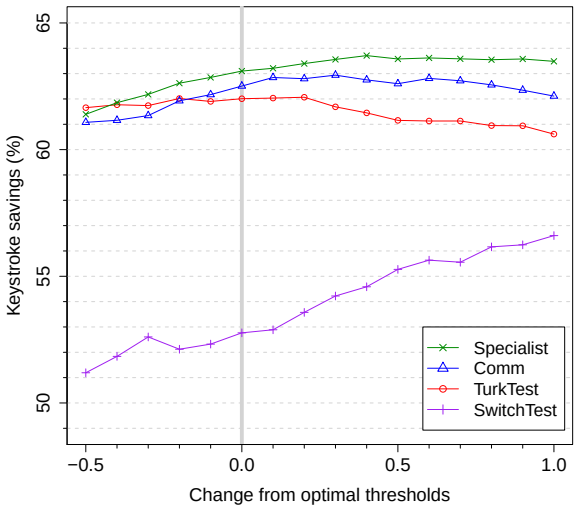


Figure 8: Keystroke savings on mixture models varying a constant added to the optimal thresholds with respect to TURKDEV.

by adding a constant to all three thresholds. The mixture weights for each new model were optimized with respect to TURKDEV. Using somewhat larger models did improve keystroke savings for all test sets except for TURKTEST (figure 8). However, using too large thresholds eventually hurt performance except on SWITCHTEST. Performance on SWITCHTEST steadily increased from 52.8% to 56.6%. These gains however came at the cost of bigger models. The model using +1.0 of the optimal thresholds had 384M parameters and a compressed size of 3.0 GB.

6 Discussion

Given the ethical implications of collecting messages from actual AAC users, it is unlikely that a large corpus of genuine AAC messages will ever be available to researchers. An important finding in this paper is that crowdsourcing can be an effective way to obtain surrogate data for improving AAC language models. Another finding is that Twitter provides a continuous stream of large amounts of very AAC-like data. Twitter also has the advantage of allowing models to be continually updated to reflect current events, new vocabulary, etc.

6.1 Limitations and Implications

We collected data from a large number of workers, some of whom may have written only a single com-

munication. This may have resulted in more messages about simple situations and perceived needs which could differ from true AAC usage.

Our data does not contain long-term two-sided conversations. Thus it may not be as useful for evaluating techniques that adapt to past messages or that use the conversation partner's communications.

We asked workers to imagine they were using a scanning-style AAC device. We believe this led workers to presume they would require assistance in many routine physical tasks. Our workers were (presumably) without cognitive or language impairments. Thus our collection is more representative of one subgroup of AAC communicators (scanning users with normal cognitive function and language skills). By modifying the situation given to workers, it is likely we can expand our collection to better represent other groups of AAC users, such as those using predictive keyboards or eye-trackers. However, obtaining data representative of users with cognitive or language impairments via crowdsourcing would probably be difficult.

While we were unable to obtain real AAC messages for testing, we believe the COMM and SPECIALIST test sets provide a good indication of the real-world potential for our methods. Our collected Turk data was compared with reported data from actual AAC users (though this comparison was necessarily coarse-grained). We hope that by releasing our data and models it may be possible for those privy to real AAC communications to validate and report about the techniques described in this paper.

We evaluated our models in terms of perplexity and keystrokes savings within the auspices of a predictive keyboard. Further work is needed to investigate how our numeric gains translate to real-world benefits to users. However, past work indicates more accurate predictions do in fact yield improvements in human performance (Trnka et al., 2009).

Finally, while the predictive keyboard is a commonly studied interface, it is not appropriate for all AAC users. Eye-tracker users may prefer an interface such as Dasher (Ward and MacKay, 2002). Single-switch users may prefer an interface such as Nomon (Broderick and MacKay, 2009). Any AAC interface based on word- or letter-based predictions stands to benefit from the methods described in this paper.

7 Conclusions

In this paper we have shown how workers' creativity on a microtask crowdsourcing market can be used to create fictional but plausible AAC communications. We have demonstrated that these messages model conversational AAC better than the currently used datasets based on telephone conversations or newswire text. We used our new crowdsourced dataset to intelligently select sentences from Twitter, blog and Usenet data.

We compared a variety of different techniques for intelligent training data selection. We found that even for our small amount of in-domain data, the recently proposed cross-entropy difference method was consistently the best (Moore and Lewis, 2010). Finally, compared to a model trained only on Switchboard, our best performing model reduced perplexity by 60-82% relative on three AAC-like test sets. This translated to a potential keystroke savings in a predictive keyboard interface of 5–11%.

In conclusion, we have shown how to create long-span AAC language models using openly available resources. Our models significantly outperform models trained on the commonly used data sources of telephone transcripts and newswire text. To aid other researchers, we have publicly released our crowdsourced AAC collection, word lists and best-performing models. We hope complementary techniques such as topic modeling and language model adaptation will provide additive gains to those obtained by training models on large amounts of AAC-like data. We plan to use our models to design and test new interfaces that enable faster communication for AAC users.

Abstract

The last decade has seen many interesting applications of Question Answering (QA) technology. The Jeopardy! quiz show is certainly one of the most fascinating, from the viewpoints of both its broad domain and the complexity of its language. In this paper, we study kernel methods applied to syntactic/semantic structures for accurate classification of Jeopardy! definition questions. Our extensive empirical analysis shows that our classification models largely improve on classifiers based on word-language models. Such classifiers are also used in the state-of-the-art QA pipeline constituting Watson, the IBM Jeopardy! system. Our experiments measuring their impact on Watson show enhancements in QA accuracy and a consequent increase in the amount of money earned in game-based evaluation.

1 Introduction

Question Answering (QA) is an important research area of Information Retrieval applications, which requires the use of core NLP capabilities, such as syntactic and semantic processing for a more effective user experience. While the development of most existing QA systems are driven by organized evaluation efforts such as TREC (Voorhees and Dang, 2006), CLEF (Giampiccolo et al., 2007), and NTCIR (Sasaki et al., 2007), there exist efforts that leverage data from popular quiz shows, such as Who Wants to be a Millionaire (Clarke et al., 2001; Lam et al., 2003) and Jeopardy! (Ferrucci et al., 2010), to demonstrate the generality of the technology.

Jeopardy! is a popular quiz show in the US which has been on the air for 27 years. In each game, three contestants compete for the opportunity to answer 60 questions in 12 categories of 5 questions each. Jeopardy! questions cover an incredibly broad domain, from science, literature, history, to popular culture. We are drawn to Jeopardy! as a test bed for open-domain QA technology due to its broad domain, complex language, as well as the emphasis on accuracy, confidence, and speed during game play.

While the vast majority of Jeopardy! questions are factoid questions, we find several other types of questions in the Jeopardy! data, which can benefit from specialized processing in the QA system. The additional processing in these questions complements that of the factoid questions to achieve improved overall QA performance. Among the various types of questions handled by the system are *definition questions* shown in the examples below:

(1) GON TOMORROW*: It can be the basket below a hot-air balloon or a flat-bottomed boat used on a canal* (answer: gondola);

(2) I LOVE YOU, "MIN"*: Overbearing* (answer: domineering);

(3) INVEST*: From the Latin for "year", it's an investment or retirement fund that pays out yearly* (answer: an annuity)

where the upper case text indicates the Jeopardy! category for each question[1].

Several characteristics of this class of questions warrant special processing: first, the clue (question)

[1]A Jeopardy! category indicates a theme is common among its 5 questions.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 712–724,
Edinburgh, Scotland, UK, July 27–31, 2011.

often aligns well with dictionary entries, making dictionary resources potentially effective. Second, these clues often do not indicate an answer type, which is an important feature for identifying correct answers in factoid questions (in the examples above, only (3) provided an answer type, "fund"). Third, definition questions are typically shorter in length than the average factoid question. These differences, namely the shorter clue length and the lack of answer types, make the use of a specialized machine learning model potentially promising for improving the overall system accuracy. The first step for handling definitions is, of course, the automatic separation of definitions from other question types, which is not a simple task in the Jeopardy! domain. For instance, consider the following example which is a variation of (3) above:

(4) INVEST*: From the Latin for "year", an annuity is an investment or retirement fund that pays out this often* (answer: yearly)

Even though the clue is nearly identical to (3), the clue does *not* provide a definition for the answer *yearly*, although at first glance we may have been misled. The source of complexity is given by the fact that Jeopardy! clues are not phrased in interrogative form as questions typically are. This complicates the design of definition classifiers since we cannot directly use either typical structural patterns that characterize definition/description questions, or previous approaches, e.g. (Ahn et al., 2004; Kaisser and Webber, 2007; Blunsom et al., 2006). Given the complexity and the novelty of the task, we found it useful to exploit the kernel methods technology. This has shown state-of-the-art performance in Question Classification (QC), e.g. (Zhang and Lee, 2003; Suzuki et al., 2003; Moschitti et al., 2007) and it is very well suited for engineering feature representations for novel tasks.

In this paper, we apply SVMs and kernel methods to syntactic/semantic structures for modeling accurate classification of Jeopardy! definition questions. For this purpose, we use several levels of linguistic information: word and POS tag sequences, dependency, constituency and predicate argument structures and we combined them using state-of-the-art structural kernels, e.g. (Collins and Duffy, 2002; Shawe-Taylor and Cristianini, 2004; Moschitti, 2006). The extensive empirical analysis of several advanced models shows that our best model, which combines different kernels, improves the F1 of our baseline model by 67% relative, from 40.37 to 67.48. Surprisingly, with respect to previous findings on standard QC, e.g. (Zhang and Lee, 2003; Moschitti, 2006), the Syntactic Tree Kernel (Collins and Duffy, 2002) is not effective whereas the exploitation of partial tree patterns proves to be essential. This is due to the different nature of Jeopardy! questions, which are not expressed in the usual interrogative form.

To demonstrate the benefit of our question classifier, we integrated it into our Watson by coupling it with search and candidate generation against specialized dictionary resources. We show that in end-to-end evaluations, Watson with kernel-based definition classification and specialized definition question processing achieves statistically significant improvement compared to our baseline systems.

In the reminder of this paper, Section 2 describes Watson by focusing on the problem of definition question classification, Section 3 describes our models for such classifiers, Section 4 presents our experiments on QC, whereas Section 5 shows the final impact on Watson. Finally, Section 6 discusses related work and Section 7 derives the conclusions.

2 Watson: The IBM Jeopardy! System

This section gives a quick overview of Watson and the problem of classification of definition questions, which is the focus of this paper.

2.1 Overview

Watson is a massively parallel probabilistic evidence-based architecture for QA (Ferrucci et al., 2010). It consists of several major stages for underlying sub-tasks, including analysis of the question, retrieval of relevant content, scoring and ranking of candidate answers, as depicted in Figure 1. In the rest of this section, we provide an overview of Watson, focusing on the task of answering definitional questions.

Question Analysis: The first stage of the pipeline, it applies several analytic components to identify key characteristics of the question (such as answer

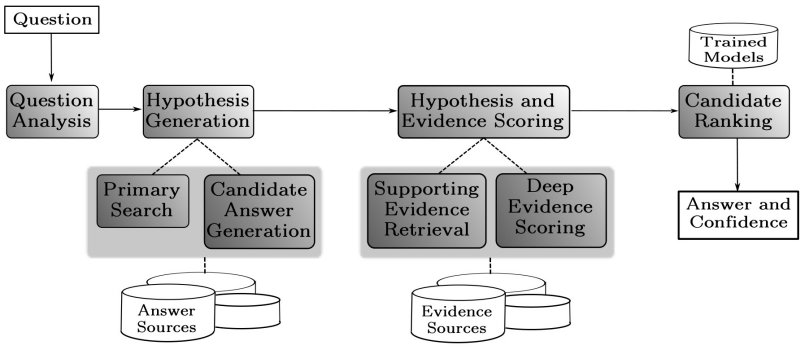

Figure 1: Overview of Watson

type, question classes, etc.) used by later stages of the Watson pipeline. Various general purpose NLP components, such as a parser and named entity detector, are combined with task-specific modules for this analysis.

The task-specific analytics include several QC components, which determine if the question belongs to one or more broad "question classes". These question classes can influence later stages of the Watson pipeline. For instance, a question detected as an *abbreviation* question can invoke specialized candidate generators to produce possible expansions of the abbreviated term in the clue. Similarly, the question classes can impact the methods for answer scoring and the machine learning models used for ranking candidate answers. The focus of this paper is on the *definition* class, which is described in the next section.

Hypothesis Generation: Following question analysis, the Watson pipeline searches its document collection for relevant documents and passages that are likely to contain the correct answer to the question. This stage of the pipeline generates search queries based on question analysis results, and obtains a ranked list of documents and passages most relevant to the search queries. A variety of candidate generation techniques are then applied to the retrieved results to produce a set of candidate answers.

Information obtained from question analysis can be used to influence the search and candidate generation processes. The question classes detected during question analysis can focus the search towards specific subsets of the corpus. Similarly, during candidate generation, strategies used to generate the set of candidate answers are selected based on the detected question classes.

Hypothesis and Evidence Scoring: A wide variety of answer scorers are then used to gather evidence supporting each candidate answer as the correct answer to the given question. The scorers include both context dependent as well as context independent scorers, relying on various structured and unstructured resources for their supporting evidence.

Candidate Ranking: Finally, machine learning models are used to weigh the gathered evidence and rank the candidate answers. The models generate a ranked list of answers each with an associated confidence. The system can also choose to refrain from answering a question if it has low confidence in all candidates. This stage of the pipeline employs several machine learning models specially trained to handle various types of questions. These models are trained using selected feature sets based on question classes and candidate answers are "routed" to the appropriate model according to the question classes detected during question analysis.

2.2 Answering Definition Questions

Among the many question classes that Watson identifies and leverages for special processing, of particular interest for this paper is the class we refer to as *definition* questions. These are questions whose clue texts contain one or more definitions of the correct answer. For instance, in example (3), the main clause in the question corresponds to a dictionary definition of the correct answer (*annuity*). Looking up this definition in dictionary resources could enable us to answer this question correctly and with high confidence. This suggests that special process-

ing of such definition questions could allow us to hone in on the correct answer through processes different from those used for other types of questions.

This paper explores strategies for definition question processing to improve overall question answering performance. A key challenge we have to address is that of accurate recognition of such questions. Given an input question the Watson question analysis stage uses a definition question recognizer to detect this specific class of questions. We explore several approaches for recognition, including a rule based approach and a variety of statistical models.

Questions that are recognized as definition questions invoke search processes targeted towards dictionary-like sources in our system. We use a variety of such sources, such as standard English dictionaries, Wiktionary, WordNet, etc. After gathering supporting evidence for candidate answers extracted from these sources, our system routes the candidates to definition-specific candidate ranking models, which have been trained with selected feature sets.

The following sections present a description and evaluation of our approach for identifying and answering definition questions.

3 Kernel Models for Question Classification

Previous work (Zhang and Lee, 2003; Suzuki et al., 2003; Blunsom et al., 2006; Moschitti et al., 2007) as shown that syntactic structures are essential for QC. Given the novelty of both the domain and the type of our classification items, we rely on kernel methods to study and design effective representations. Indeed, these are excellent tools for automatic feature engineering, especially for unknown tasks and domains. Our approach consists of using SVMs and kernels for structured data applied to several types of structural lexical, syntactic and shallow semantic information.

3.1 Tree and Sequence Kernels

Kernel functions are implicit scalar products between data examples (i.e. questions in our case) in the very high dimensional space of substructures, where each of the latter is a component of the implicit vectors associated with the examples.

Although several kernels for structured data have been developed (see Section 6), the main distinctions in terms of feature spaces is given by the following three different kernels:

• Sequence Kernels (SK); we implemented the discontinuous string kernels described in (Shawe-Taylor and Cristianini, 2004). This allows for representing a string of symbols in terms of its possible substrings with gaps, i.e. an arbitrary number of symbols can be skipped during the generation of a substring. The symbols we used in the sequential descriptions of questions are words and part-of-speech tags (in two separate sequences). Consequently, all possible multiwords with gaps are features of the implicitly generated vector space.

• Syntactic Tree Kernel (STK) (Collins and Duffy, 2002) applied to constituency parse trees. This generates all possible tree fragments as features with the conditions that sibling nodes from the original trees cannot be separated. In other words, substructures are composed by atomic building blocks corresponding to nodes along with all their direct children. These, in case of a syntactic parse tree, are complete production rules of the associated parser grammar[2].

• Partial Tree Kernel (PTK) (Moschitti, 2006) applied to both constituency and dependency parse trees. This generates all possible tree fragments, as above, but sibling nodes can be separated (so they can be part of different tree fragments). In other words, a fragment is any possible tree path, from whose nodes other tree paths can depart. Consequently, an extremely rich feature space is generated. Of course, PTK subsumes STK but sometimes the latter provides more effective solutions as the number of irrelevant features is smaller as well.

When applied to sequences and tree structures, the kernels discussed above produce many different kinds of features. Therefore, the design of appropriate syntactic/semantic structures determines the representational power of the kernels. Hereafter, we show the models we used.

3.2 Syntactic Semantic Structures

We applied the above kernels to different structures. These can be divided in sequences of words (WS) and part of speech tags (PS) and different kinds of trees. For example, given the non-definition Jeopardy! question:

(5) GENERAL SCIENCE*: When hit by electrons, a phosphor gives off electromagnetic energy in this form.* (answer: light or photons),

we use the following sequences:

WS: [when][hit][by][electrons][,][a][phosphor][gives][off][electromagnetic][energy][in][this][form]

PS: [wrb][vbn][in][nns][,][dt][nn][vbz][rp][jj][nn][in][dt][nn]

Additionally, we use constituency trees (CTs), see Figure 2 and dependency structures converted into the dependency trees (DTs), e.g. shown in Figure 3. Note that, the POS-tags are central nodes, the grammatical relation label is added as a father node and all the relations with the other nodes are described by means of the connecting edges. Words are considered additional children of the POS-tag nodes (in this case the connecting edge just serves to add a lexical feature to the target POS-tag node).

Finally, we also use predicate argument structures generated by verbal and nominal relations according to PropBank (Palmer et al., 2005) and NomBank (Meyers et al., 2004). Given the target sentence, the set of its predicates are extracted and converted into a forest, then a fake root node, PAS, is used to connect these trees. For example, Figure 4 illustrates a Predicate Argument Structures Set (PASS) encoding two relations, *give* and *hit*, as well as the nominalization *energy* along with all their arguments.

4 Experiments on Definition Question Classification

In these experiments, we study the role of kernel technology for the design of accurate classification of definition questions. We build several classifiers based on SVMs and kernel methods. Each classifier uses advanced syntactic/semantic structural features and their combination. We carry out an extensive comparison in terms of F1 between the different models on the Jeopardy! datasets.

4.1 Experimental Setup

Corpus: the data for our QC experiments consists of a randomly selected set of 33 Jeopardy! games[3]. These questions were manually annotated based on whether or not they are considered definitional. This resulted in 306 definition and 4964 non-definition clues. Each test set is stored in a separate file consisting of one line per question, which contains tab-separated clue information and the Jeopardy! category, e.g. INVEST in example (4).

Tools: for SVM learning, we used the SVMLight-TK software[4], which includes structural kernels in SVMLight (Joachims, 1999)[5]. For generating con-

[2]From here the name syntactic tree kernels

[3]Past Jeopardy! games can be downloaded from http://www.j-archive.com.

[4]Available at `http://dit.unitn.it/~moschitt`

[5]`http://svmlight.joachims.org`

stituency trees, we used the Charniak parser (Charniak, 2000). We also used the syntactic–semantic parser by Johansson and Nugues (2008) to generate dependency trees (Mel'čuk, 1988) and predicate argument trees according to the PropBank (Palmer et al., 2005) and NomBank (Meyers et al., 2004) frameworks.

Baseline Model: the first model that we used as a baseline is a rule-based classifier (RBC). The RBC leverages a set of rules that matches against lexical and syntactic information in the clue to make a binary decision on whether or not the clue is considered definitional. The rule set was manually developed by a human expert, and consists of rules that attempt to identify roughly 70 different constructs in the clues. For instance, one of the rules matches the parse tree structure for "It's X or Y", which will identify example (1) as a definition question.

Kernel Models: we apply the kernels described in Section 3 to the structures extracted from Jeopardy! clues. In particular, we design the following models: BOW, i.e. linear kernel on bag-of-words from the clues; WSK, PSK and CSK, i.e. SK applied to the word and POS-tag sequences from the clues, and the word sequence taken from the question categories, respectively; STK-CT, i.e. STK applied to CTs of the clue; PTK-CT and PTK-DT, i.e. PTK applied to CTs and DTs of the clues, respectively; PASS, i.e. PTK applied to the Predicate Argument Structure Set extracted from the clues; and RBC, i.e. a linear kernel applied to the vector only constituted by the 1/0 output of RBC.

Learning Setting: there is no particular parameterization. Since there is an imbalance between positive and negative examples, we used a Precision/Recall trade-off parameter in SVM-Light-TK equal to 5.[6]

Measures: the performance is measured with Precision, Recall and F1-measure. We estimated them by means of Leave-One-Out[7] (LOO) on the question set.

4.2 Results and Discussion

Table 1 shows the performance obtained using different kernels (feature spaces) with SVMs. We note that: first, RBC has good Recall but poor Precision. This is interesting since, on one hand, these results validate the complexity of the task: in order to capture the large variability of the positive examples, the rules developed by a skilled human designer are unable to be sufficiently precise to limit the recognition to those examples. On the other hand, RBC, being a rather different approach from SVMs, can be successfully exploited in a joint model with them.

Kernel Space	Prec.	Rec.	F1
RBC	28.27	70.59	**40.38**
BOW	47.67	46.73	47.20
WSK	47.11	50.65	48.82
STK-CT	50.51	32.35	39.44
PTK-CT	47.84	57.84	**52.37**
PTK-DT	44.81	57.84	50.50
PASS	33.50	21.90	26.49
PSK	39.88	45.10	42.33
CSK	39.07	77.12	**51.86**

Table 1: Kernel performance using leave-one-out cross-validation.

Second, BOW yields better F1 than RBC but it does not generalize well since its F1 is still low. When n-grams are also added to the model by means of WSK, the F1 improves by about 1.5 absolute points. As already shown in (Zhang and Lee, 2003; Moschitti et al., 2007), syntactic structures are needed to improve generalization.

Third, surprisingly with respect to previous work, STK applied to CT[8] provides accuracy lower than BOW, about 8 absolute points. The reason is due to the different nature of the Jeopardy! questions: large syntactic variability reduces the probability of finding general and well formed patterns, i.e. structures generated by entire production rules. This suggests that PTK, which can capture patterns derived from partial production rules, can be more effective. Indeed, PTK-CT achieves the highest F1, outperforming WSK also when used with a different syntactic paradigm, i.e. PTK-DT.

Next, PSK and PASS provide a lower accuracy but they may be useful in kernel combinations as they can complement the information captured by the other models. Interestingly, CSK alone is rather effective for classifying definition questions. We be-

[6] We have selected 5 as a reasonable value, which kept balanced Precision and Recall on a validation set.

[7] LOO applied to a corpus of N instances consists in training on $N-1$ examples and testing on the single held-out example. This process is repeated for all instances.

[8] Applying it to DT does not make much sense as already pointed out in (Moschitti, 2006).

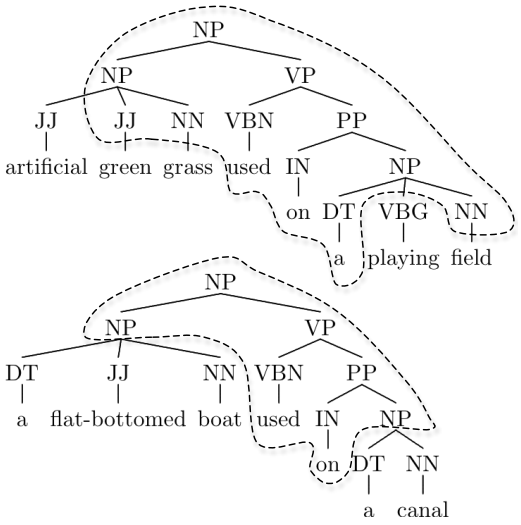

Figure 5: Similarity according to PTK and STK

lieve this is because definition questions are sometimes clustered into categories such as 4-LETTER WORDS or BEGINS WITH "B".

Moreover, we carried out qualitative error analysis on the PTK and STK outcome, which supported our initial hypothesis. Let us consider the bottom tree in Figure 5 in the training set. The top tree is a test example correctly classified by PTK but incorrectly classified by STK. The dashed line in the top tree contains the largest subtree matched by PTK (against the bottom tree), whereas the dashed line in the bottom tree indicates the largest subtree matched by STK (against the top tree). As the figure shows, PTK can exploit a larger number of partial patterns.

Finally, the above points suggest that different kernels produce complementary information. It is thus promising to experiment with their combinations. The joint models can be simply built by summing kernel functions together. The results are shown in Table 2. We note that: (i) CSK complements the WSK information, achieving a substantially better result, i.e. 62.95; (ii) PTK-CT+CSK performs even better than WSK+CSK (as PTK outperforms WSK); and (iii) adding RBC improves further on the above combinations, i.e. 68.11 and 67.32, respectively. This evidently demonstrates that RBC captures complementary information. Finally, more complex kernels, especially the overall kernel summation, do not seem to improve the performance. This is also confirmed by the PASS results derived in (Moschitti et al., 2007) on TREC QC.

Kernel Space	Prec.	Rec.	F1
WSK+CSK	70.00	57.19	62.95
PTK-CT+CSK	69.43	60.13	64.45
PTK-CT+WSK+CSK	68.59	62.09	**65.18**
CSK+RBC	47.80	74.51	58.23
PTK-CT+CSK+RBC	59.33	74.84	65.79
BOW+CSK+RBC	60.65	73.53	66.47
PTK-CT+WSK+CSK+RBC	67.66	66.99	**67.32**
PTK-CT+PASS+CSK+RBC	62.46	71.24	66.56
WSK+CSK+RBC	69.26	66.99	**68.11**
ALL	61.42	67.65	64.38

Table 2: Performance of Kernel Combinations using leave-one-out cross-validation.

5 Experiments on the Jeopardy System

Since the kernel-based classifiers perform substantially better than RBC, we incorporate the PTK-CT+WSK+CSK model[9] into Watson for definition classification and evaluated the QA performance against two baseline systems. For the end-to-end experiments, we used Watson's English Slot Grammar parser (McCord, 1980) to generate the constituency trees. The component level evaluation shows that we achieved comparable performance as previously discussed with ESG.

5.1 Experimental Setup

We integrated the classifier into the question analysis module, and incorporated additional components to search against dictionary resources and extract candidate answers from these search results when a question is classified as definitional. In the final machine learning models, a separate model is trained for definition questions to enable scoring tailored to the specific characteristics of those questions.

Based on our manually annotated gold standard, less than 10% of Jeopardy! questions are classified as definition questions. Due to their relatively low frequency we conduct two types of evaluations. The first is *definition-only evaluation*, in which we apply our definition question classifier to identify a large

[9]Since we aim to compare a purely statistical approach to the rule-based approach, we did not experiment with the model that uses RBC as a feature in our end-to-end experiments.

set of definition questions and evaluate the end-to-end system's performance on this large set of questions. These results enable us to draw statistically significant conclusions about our approach to addressing definition questions.

The second type of evaluation is *game-based evaluation*, which assesses the impact of our definition question processing on Watson performance while preserving the natural distribution of these question types in Jeopardy! data. Game-based evaluations situate the system's performance on definition questions relative to other types of questions, and enable us to gauge the component's contributions in a game-based setting.

For both evaluation settings, three configurations of Watson are used as follows:

- the **NoDef** system, in which Watson is configured without definition classification and processing, thereby treating all definition questions as regular factoid questions;
- the **StatDef** system, which leverages the statistical classifier and subsequent definition specific search and candidate generation components as described above; and
- the **RuleDef** system, in which Watson adopts RBC and employs the same additional definition search and candidate generation components as the StatDef system.

For the definition-only evaluation, we selected all questions recognized as definitional by the statistical classifier from roughly 1000 unseen games (60000 questions), resulting in a test set of 1606 questions. Due to the size of the initial set, it is impractical to manually create a gold standard for measuring Precision and Recall of the classifier. Instead, we compare the StatDef system against the NoDef on these 1606 questions using two metrics: accuracy, defined as the percentage of questions correctly answered, and p@70, the system's Precision when answering only the top 70% most confident questions. P@70 is an important metric in Jeopardy! game play as well as in real world applications where the system may refrain from answering a question when it is not confident about any of its answers. Since RBC identifies significantly more definition questions, we started with an initial set of roughly 300 games, from which the RBC identified 1875 questions as definitional. We compared the RuleDef system's performance on these questions against the NoDef baseline using the accuracy and p@70 metrics.

	NoDef	**StatDef**	**NoDef**	**RuleDef**
# Questions	1606	1606	1875	1875
Accuracy	63.76%	65.57%	56.64%	57.51%
P@70	82.22%	84.53%	72.73%	74.87%

Table 3: Definition-Only Evaluation Results

For the game-based evaluation, we randomly selected 66 unseen Jeopardy! games, consisting of 3546 questions after excluding audio/visual questions.[10] We contrast the StatDef system performance against that of NoDef and RuleDef along several dimensions: accuracy and p@70, described above, as well as earnings, the average amount of money earned for each game.

5.2 Definition-Only Evaluation

For the definition-only evaluation, we compared the StatDef system against the NoDef system on a set of 1606 questions that the StatDef system classified as definitional. The results are shown in the first two columns in Table 3. To contrast the gain obtained by the StatDef system against that achieved by the RuleDef system, we ran the RuleDef system over the 1875 questions identified as definitional by the rule-based classifier. We contrast the RuleDef system performance with that of the NoDef system, as shown in the last two columns in Table 3.

Our results show that based on both evaluation metrics, StatDef improved upon the NoDef baseline more than RuleDef improved on the same baseline system. Furthermore, for the accuracy metric where all samples are paired and independent, the difference in performance between the StatDef and NoDef systems is statistically significant at $p<0.05$, while that between the RuleDef and NoDef systems is not.

5.3 Game-Based Evaluation

The game-based evaluation was carried out on 66 unseen games (roughly 3500 questions). Of these

[10] Audio/visual questions are those accompanied by either an image or an audio clip. The text portions of these questions are often insufficient for identifying the correct answers.

	# Def Q's	Accuracy	P@70	Earnings
NoDef	0	69.71%	86.79%	$24,818
RuleDef	480	69.23%	86.31%	$24,397
StatDef	131	69.85%	87.19%	$25,109

Table 4: Game-Based Evaluation Results

questions, the StatDef system classified 131 of them as definitional while the RuleDef system identified 480 definition questions. Both systems were compared against the NoDef system using the accuracy, p@70, and earnings metric computed over all questions, as shown in Table 4.

Our results show that even though in the definition-only evaluation both the RuleDef and StatDef systems outperformed the NoDef baseline, in our game-based evaluation, the RuleDef system performed *worse* than the NoDef baseline. The lowered performance is due to the fact that the Precision of the RBC is much lower than that of the statistical classifier, and the special definition processing applied to questions that are erroneously classified as definitional was harmful. Our evaluation of this false positive set showed that its accuracy dropped by 6% compared to the NoDef system. On the other hand, the StatDef system outperformed the two other systems, and its accuracy improvement upon the RuleDef system is statistically significant at $p<0.05$.

6 Related Work

Our paper studies the use of advanced representation for QC in the Jeopardy! domain. As previously mentioned Jeopardy! questions are stated as affirmative sentences, which are different from the typical QA questions. For the design of our models, we have carefully taken into account previous work. This shows that semantics and syntax are essential to retrieve precise answers, e.g (Hickl et al., 2006; Voorhees, 2004; Small et al., 2004).

We focus on definition questions, which typically require more complex processing than factoid questions (Blair-Goldensohn et al., 2004; Chen et al., 2006; Shen and Lapata, 2007; Bilotti et al., 2007; Moschitti et al., 2007; Surdeanu et al., 2008; Echihabi and Marcu, 2003). For example, language models were applied to definitional QA in (Cui et al., 2005) to learn soft pattern models based on bigrams. Other related work, such as (Sasaki, 2005; Suzuki et al., 2002), was also very tied to bag-of-words features. Predicate argument structures have been mainly used for reranking (Shen and Lapata, 2007; Bilotti et al., 2007; Moschitti et al., 2007; Surdeanu et al., 2008).

Our work and methods are similar to (Zhang and Lee, 2003; Moschitti et al., 2007), which achieved the state-of-the-art in QC by applying SVMs along with STK-CT. The results were derived by experimenting with a TREC dataset[11](Li and Roth, 2002), reaching an accuracy of 91.8%. However, such data refers to typical instances from QA, whose syntactic patterns can be easily generalized by STK. In contrast, we have shown that STK-CT is not effective for our domain, as it presents very innovative elements: questions in affirmative and highly variable format. Thus, we employed new methods such as PTK, dependency structures, multiple sequence kernels including category information and many combinations.

Regarding the use of Kernel Methods, there is a considerably large body of work in Natural Language Processing, e.g. regarding syntactic parsing (Collins and Duffy, 2002; Kudo et al., 2005; Shen et al., 2003; Kudo and Matsumoto, 2003; Titov and Henderson, 2006; Toutanova et al., 2004), named entity recognition and chunking (Cumby and Roth, 2003; Daumé III and Marcu, 2004), relation extraction (Zelenko et al., 2002; Culotta and Sorensen, 2004; Bunescu and Mooney, 2005; Zhang et al., 2005; Bunescu, 2007; Nguyen et al., 2009a), text categorization (Cancedda et al., 2003), word sense disambiguation (Gliozzo et al., 2005) and semantic role labeling (SRL), e.g. (Kazama and Torisawa, 2005; Che et al., 2006a; Moschitti et al., 2008).

However, ours is the first study on the use of several combinations of kernels applied to several structures on very complex data from the Jeopardy! domain.

7 Final Remarks and Conclusion

In this paper we have experimented with advanced structural kernels applied to several kinds of syntactic/semantic linguistic structures for the classification of questions in a new application domain, i.e. Jeopardy!. Our findings are summarized hereafter:

[11]Available at `http://cogcomp.cs.illinois.edu/Data/QA/QC/`

First, it should be noted that basic kernels, such as STK, PTK and SK, when applied to new representations, i.e. syntactic/semantic structures, constitute new kernels. Thus structural representations play a major role and, from this perspective, our paper makes a significant contribution.

Second, the experimental results show that the higher variability of Jeopardy! questions prevents us from achieving generalization with typical syntactic patterns even if they are derived by powerful methods such as STK. In contrast, partial patterns, such as those provided by PTK applied to constituency (or dependency) trees, prove to be effective.

In particular, STK has been considered as the best kernel for exploiting syntactic information in constituency trees, e.g. it is state-of-the-art in: QC (Zhang and Lee, 2003; Moschitti et al., 2007; Moschitti, 2008); SRL, (Moschitti et al., 2008; Moschitti et al., 2005; Che et al., 2006b); pronominal coreference resolution (Yang et al., 2006; Versley et al., 2008) and Relation Extraction (Zhang et al., 2006; Nguyen et al., 2009b). We showed that, in the complex domain of Jeopardy!, STK surprisingly provides low accuracy whereas PTK is rather effective and greatly outperforms STK. We have also provided an explanation of such behavior by means of error analysis: in contrast with traditional question classification, which focuses on basic syntactic patterns (e.g. "what", "where", "who" and "how"). Figure 5 shows that PTK captures partial patterns that are important for more complex questions like those in Jeopardy!

Third, we derived other interesting findings for NLP related to this novel domain, e.g.: (i) the impact of dependency trees is similar to the one of constituency trees. (ii) A simple computational representation of shallow semantics, i.e. PASS (Moschitti, 2008), does not work in Jeopardy!. (iii) Sequence kernels on category cues, i.e., higher level of lexical semantics, improve question classification. (iv) RBC jointly used with statistical approaches is helpful to tackle the Jeopardy! complexity.

Next, our kernel models improve up to 20 absolute percent points over n-grams based approaches, reaching a significant accuracy of about 70%. Watson, exploiting such a classifier, improved previous versions using RBC and no definition classification both in definition-only evaluations and in game-based evaluations.

Finally, we point out that:

- Jeopardy! has a variety of different special question types that are handled differently. We focus on kernel methods for definition question for two reasons. First, their recognition relies heavily on parse structures and is therefore more amenable to the approach proposed in the paper than the recognition of other question types. Second, definition is by far the most frequent special question type in Jeopardy!; therefore, we can obtain sufficient data for training and testing.

- We were unable to address the whole QC problem using a statistical model due to the lack of sufficient training data for most special question classes. Furthermore, we focused only on the definition classification and its impact on system performance due to space reasons.

- Our RBC has a rather imbalanced trade-off between Precision and Recall. This may not be the best operating point, but the optimal point is difficult to obtain empirically for an RBC, which is a strong motivation of the work in this paper. We experimented with tuning the trade-off between Precision and Recall with the RBC, but since RBC uses hand-crafted rules and does not have a parameter for that, ultimately the statistical approach proved more effective.

In future work, we plan to extend the current research by investigating models capable of exploiting predicate argument structures for question classification and answer reranking. The use of syntactic/semantic kernels is a promising research direction (Basili et al., 2005; Bloehdorn and Moschitti, 2007a; Bloehdorn and Moschitti, 2007b). In this perspective kernel learning is a very interesting research line, considering the complexity of representation and classification problems in which our kernels operate.

Acknowledgements

This work has been supported by the IBM's Open Collaboration Research (OCR) awards program. We are deeply in debt with Richard Johansson, who produced the earlier syntactic/semantic representations of the Jeopardy! questions from the text format.

Abstract

Multiword expressions (MWE), a known nuisance for both linguistics and NLP, blur the lines between syntax and semantics. Previous work on MWE identification has relied primarily on surface statistics, which perform poorly for longer MWEs and cannot model discontinuous expressions. To address these problems, we show that even the simplest parsing models can effectively identify MWEs of arbitrary length, and that Tree Substitution Grammars achieve the best results. Our experiments show a 36.4% F1 absolute improvement for French over an n-gram surface statistics baseline, currently the predominant method for MWE identification. Our models are useful for several NLP tasks in which MWE pre-grouping has improved accuracy.

1 Introduction

Multiword expressions (MWE) have long been a challenge for linguistic theory and NLP. There is no universally accepted definition of the term, but MWEs can be characterized as "idiosyncratic interpretations that cross word boundaries (or spaces)" (Sag et al., 2002) such as *traffic light*, or as "frequently occurring phrasal units which are subject to a certain level of semantic opaqueness, or non-compositionality" (Rayson et al., 2010).

MWEs are often opaque fixed expressions, although the degree to which they are fixed can vary. Some MWEs do not allow morphosyntactic variation or internal modification (e.g., *in short*, but **in shorter* or **in very short*). Other MWEs are "semi-fixed," meaning that they can be inflected or undergo internal modification. The type of modification is often limited, but not predictable, so it is not possible to enumerate all variants (Table 1).

French				English			
à			terme	in the		near	term
à		court	terme	in the		short	term
à	très	court	terme	in the	very	short	term
à		moyen	terme	in the		medium	term
à		long	terme	in the		long	term
à	très	long	terme	in the	very	long	term

Table 1: Semi-fixed MWEs in French and English. The French adverb *à terme* 'in the end' can be modified by a small set of adjectives, and in turn some of these adjectives can be modified by an adverb such as *très* 'very'. Similar restrictions appear in English.

Merging known MWEs into single tokens has been shown to improve accuracy for a variety of NLP tasks: dependency parsing (Nivre and Nilsson, 2004), constituency parsing (Arun and Keller, 2005), sentence generation (Hogan et al., 2007), and machine translation (Carpuat and Diab, 2010). Most experiments use gold MWE pre-grouping or language-specific resources like WordNet. For unlabeled text, the best MWE identification methods, which are based on surface statistics (Pecina, 2010), suffer from sparsity induced by longer n-grams (Ramisch et al., 2010). A dilemma thus exists: MWE knowledge is useful, but MWEs are hard to identify.

In this paper, we show the effectiveness of statistical parsers for MWE identification. Specifically, Tree Substitution Grammars (TSG) can achieve a 36.4% F1 absolute improvement over a state-of-the-art surface statistics method. We choose French, which has pervasive MWEs, for our experiments. Parsing models naturally accommodate discontinuous MWEs like phrasal verbs, and provide syntactic subcategorization. By contrast, surface statistics methods are usually limited to binary judgements for contiguous n-grams or dependency bigrams.

MWI	*interj.*	4	2	0.50	0.02
		19,462	4,093	21.0%	100.0%

Table 3: Frequency distribution of the 11 MWE subcategories in the FTB (training set). MWEs account for 7.08% of the bracketings and 13.0% of the tokens in the treebank. Only 21% of the MWEs occur once ("single").

We first introduce a new instantiation of the French Treebank that, unlike previous work, does not use gold MWE pre-grouping. Consequently, our experimental results also provide a better baseline for parsing raw French text.

2 French Treebank Setup

The corpus used in our experiments is the French Treebank (Abeillé et al. (2003), version from June 2010, hereafter FTB). In French, there is a linguistic tradition of lexicography which compiles lists of MWEs occurring in the language. For example, Gross (1986) shows that dictionaries contain about 1,500 single-word adverbs but that French contains over 5,000 multiword adverbs. MWEs occur in every part-of-speech (POS) category (e.g., noun *trousse de secours* 'first-aid kit'; verb *faire main-basse* [do hand-low] 'seize'; adverb *comme dans du beurre* [as in butter] 'easily'; adjective *'à part entière'* 'wholly').

The FTB explicitly annotates MWEs (also called *compounds* in prior work). We used the subset of the corpus with functional annotations, not for those annotations but because this subset is known to be more consistently annotated. POS tags for MWEs are given not only at the MWE level, but also internally: most tokens that constitute an MWE also have a POS tag. Table 2 compares this part of the FTB to the WSJ portion of the Penn Treebank.

2.1 Preprocessing

The FTB requires significant pre-processing prior to parsing.

Tokenization We changed the default tokenization for numbers by fusing adjacent digit tokens. For example, *500 000* is tagged as an MWE composed of two words *500* and *000*. We made this *500000* and retained the MWE POS, although we did not mark the new token as an MWE. For consistency, we used one token for punctuated numbers like "17,9".

MWE Tagging We marked MWEs with a flat bracketing in which the phrasal label is the MWE-level POS tag with an "MW" prefix, and the preterminals are the internal POS tags for each terminal. The resulting POS sequences are not always unique to MWEs: they appear in abundance elsewhere in the corpus. However, some MWEs contain normally ungrammatical POS sequences (e.g., adverb *à la va vite* 'in a hurry': P D V ADV [at the goes quick]), and some words appear only as part of an MWE, such as *insu* in *à l'insu de* 'to the ignorance of'.

Labels We augmented the basic FTB label set—which contains 14 POS tags and 19 phrasal tags—in two ways. First, we added 16 finer-grained POS tags for punctuation.[1] Second, we added the 11 MWE

[1] Punctuation tag clusters—as used in the WSJ—did not improve accuracy. Enriched tag sets like that of Crabbé and Candito (2008) could also be investigated and compared to our results since Evalb is insensitive to POS tags.

labels shown in Table 3, resulting in 24 total phrasal categories.

Corrections Historically, the FTB suffered from annotation errors such as missing POS and phrasal tags (Arun and Keller, 2005). We found that this problem has been largely resolved in the current release. However, 1,949 tokens and 36 MWE spans still lacked tags. We restored the labels by first assigning each token its most frequent POS tag elsewhere in the treebank, and then assigning the most frequent MWE phrasal category for the resulting POS sequence.[2]

Split We used the 80/10/10 split described by Crabbé and Candito (2008). However, they used a previous release of the treebank with 12,531 trees. 3,391 trees have been added to the present version. We appended these extra trees to the training set, thus retaining the same development and test sets.

2.2 Comparison to Prior FTB Representations

Our pre-processing approach is simple and automatic[3] unlike the three major instantiations of the FTB that have been used in previous work:

Arun-Cont and Arun-Exp (Arun and Keller, 2005): Two instantiations of the full 20,000 sentence treebank that differed principally in their treatment of MWEs: (1) Cont, in which the tokens of each MWE were concatenated into a single token (*en moyenne* $\rightarrow$ *en_moyenne*); (2) Exp, in which they were marked with a flat structure. For both representations, they also gave results in which coordinated phrase structures were flattened. In the published experiments, they mistakenly removed half of the corpus, believing that the multi-terminal (per POS tag) annotations of MWEs were XML errors (Schluter and Genabith, 2007).

MFT (Schluter and Genabith, 2007): Manual revision to 3,800 sentences. Major changes included coordination raising, an expanded POS tag set, and the correction of annotation errors. Like Arun-Cont, MFT contains concatenated MWEs.

FTB-UC (Candito and Crabbé, 2009): An instantiation of the functionally annotated section that makes a distinction between MWEs that are "syntactically regular" and those that are not. Syntactically regular MWEs were given internal structure, while all other MWEs were concatenated into single tokens. For example, nouns followed by adjectives, such as *loi agraire* 'land law' or *Union monétaire et économique* 'monetary and economic Union' were considered syntactically regular. They are MWEs because the choice of adjective is arbitrary (*loi agraire* and not **loi agricole*, similarly to 'coal black' but not *'crow black' for example), but their syntactic structure is not intrinsic to MWEs. In such cases, FTB-UC gives the MWE a conventional analysis of an NP with internal structure. Such analysis is indeed sufficient to recover the meaning of these semantically compositional MWEs that are extremely productive. On the other hand, the FTB-UC loses information about MWEs with non-compositional semantics.

Almost all work on the FTB has followed Arun-Cont and used gold MWE pre-grouping. As a result, most results for French parsing are analogous to early results for Chinese, which used gold word segmentation, and Arabic, which used gold clitic segmentation. Candito et al. (2010) were the first to acknowledge and address this issue, but they still used FTB-UC (with some pre-grouped MWEs). Since the syntax and definition of MWEs is a contentious issue, we take a more agnostic view—which is consistent with that of the FTB annotators—and leave them tokenized. This permits a data-oriented approach to MWE identification that is more robust to changes to the status of specific MWE instances.

To set a baseline prior to grammar development, we trained the Stanford parser (Klein and Manning, 2003) with no grammar features, achieving 74.2% labeled F1 on the development set (sentences ≤ 40 words). This is lower than the most recent results obtained by Seddah (2010). However, the results are not comparable: the data split was different, they made use of morphological information, and more importantly they concatenated MWEs. The focus of

[2] 73 of the unlabeled word types did not appear elsewhere in the treebank. All but 11 of these were nouns. We manually assigned the correct tags, but we would not expect a negative effect by deterministically labeling all of them as nouns.

[3] We automate tree manipulation with Tregex/Tsurgeon (Levy and Andrew, 2006). Our pre-processing package is available at http://nlp.stanford.edu/software/lex-parser.shtml.

our work is on models and data representations that enable MWE identification.

3 MWEs in Lexicon-Grammar

The MWE representation in the FTB is close to the one proposed in the Lexicon-Grammar (Gross, 1986). In the Lexicon-Grammar, MWEs are classified according to their global POS tags (noun, verb, adverb, adjective), and described in terms of the sequence of the POS tags of the words that constitute the MWE (e.g., "N de N" *garde d'enfant* [guard of child] 'daycare', *pied de guerre* [foot of war] 'at the ready'). In other words, MWEs are represented by a flat structure. The Lexicon-Grammar distinguishes between units that are fixed and have to appear as is (*en tout et pour tout* [in all and for all] 'in total') and units that accept some syntactic variation such as admitting the insertion of an adverb or adjective, or the variation of one of the words in the expression (e.g., a possessive as in 'from the top of one's hat'). It also notes whether the MWE displays some selectional preferences (e.g., it has to be preceded by a verb or by an adjective).

Our FTB instantiation is largely consistent with the Lexicon-Grammar. Recall that we defined different MWE categories based on the global POS. We now detail three of the categories.

MWN The MWN category consists of proper nouns (1a), foreign common nouns (1b), as well as common nouns. The common nouns appear in several syntactically regular sequences of POS tags (2). Multiword nouns allow inflection (singular vs. plural) but no insertion.

(1) a. *London Sunday Times, Los Angeles*
b. *week - end, mea culpa, joint - venture*

(2) a. N A: *corps médical* 'medical staff', *dette publique* 'public debt'
b. N P N: *mode d'emploi* 'instruction manual'
c. N N: *numéro deux* 'number two', *maison mère* [house mother] 'headquarters', *grève surprise* 'sudden strike'
d. N P D N: *impôt sur le revenu* 'income tax', *ministre de l'économie* 'finance minister'

MWA Multiword adjectives appear with different POS sequences (3). They include numbers such as *vingt et unième* '21st'. Some items in (3b) allow internal variation: some adverbs or adjectives can be added to both examples given (*à <u>très</u> haut risque*, *de <u>toute</u> dernière minute*).

(3) a. P N: *d'antan* [from before] 'old', *en question* 'under discussion'
b. P A N: *à haut risque* 'high-risk', *de dernière minute* [from the last minute] 'at the eleventh hour'
c. A C A: *pur et simple* [pure and simple] 'straightforward', *noir et blanc* 'black and white'

MWV Multiword verbs also appear in several POS sequences (4). All verbs allow number and tense inflections. Some MWVs containing a noun or an adjective allow the insertion of a modifier (e.g., *donner grande satisfication* 'give great satisfaction'), whereas others do not. When an adverb intervenes between the main verb and its complement, the FTB marks the two parts of the MWV discontinuously (e.g., [MWV [V prennent]] [ADV déjà] [MWV [P en] [N cause]] 'already take into account').

(4) a. V N: *avoir lieu* 'take place', *donner satisfaction* 'give satisfaction'
b. V P N: *mettre en place* 'put in place', *entrer en vigueur* 'to come into effect'
c. V P ADV: *mettre à mal* [put at bad] 'harm', *être à même* [be at same] 'be able'
d. V D N P N: *tirer la sonnette d'alarme* 'ring the alarm bell', *avoir le vent en poupe* 'to have the wind astern'

4 Parsing Models

We develop two parsers for French with the goal of improving MWE identification. The first is a manually-annotated grammar that we incorporate into the Stanford parser. Manual annotation results in human interpretable grammars that can inform future treebank annotation decisions. Moreover, the grammar can be used as the base distribution in our second model, a Probabilistic Tree Substitution Grammar (PTSG) parser. PTSGs learn parameters for tree

Feature	States	Tags	F1	ΔF1
—	4325	31	74.21

markPart	4511	217	77.73	+0.31
markVN	5986	217	78.32	+0.59
markCoord	7361	217	78.45	+0.13
markDe	7521	233	79.11	+0.66
markP	7523	235	79.34	+0.23
markMWE	7867	235	79.23	−0.11

Table 4: Effects on grammar size and labeled F1 for each of the manual state splits (development set, sentences $\leq$ 40 words). *markMWE* decreases overall accuracy, but increases both the number of correctly parsed trees (by 0.30%) and per category MWE accuracy.

fragments larger than basic CFG rules. PTSG rules may also be lexicalized. This means that commonly observed collocations—some of which are MWEs—can be stored in the grammar.

4.1 Stanford Parser

We configure the Stanford parser with settings that are effective for other languages: selective parent annotation, lexicon smoothing, and factored parsing. We use the head-finding rules of Dybro-Johansen (2004), which we find to yield an approximately 1.0% F1 development set improvement over those of Arun (2004). Finally, we include a simple unknown word model consisting entirely of surface features:

- Nominal, adjectival, verbal, adverbial, and plural suffixes
- Contains a digit or punctuation
- Is capitalized (except the first word in a sentence)
- Consists entirely of capital letters
- If none of the above, add a one- or two-character suffix

Combined with the grammar features, this unknown word model yields 97.3% tagging accuracy on the development set.

4.1.1 Grammar Development

Table 4 lists the symbol refinements used in our grammar. Most of the features are POS splits as many phrasal tag splits did not lead to any improvement. Parent annotation of POS tags (*tagPA*) captures information about the external context. *markInf* and *markPart* accomplish a finite/nonfinite distinction: they respectively specify whether the verb is an infinitive or a participle based on the type of the grandparent node. *markVN* captures the notion of verbal distance as in Klein and Manning (2003).

We opted to keep the COORD phrasal tag, and to capture parallelism in coordination, we mark COORD with the type of its child (NP, AP, VPinf, etc.). *markDe* identifies the preposition *de* and its variants (*du*, *des*, *d'*) which is very frequent and appears in several different contexts. *markP* identifies prepositions which introduce PPs modifying a noun. Marking other kinds of prepositional modifiers (e.g., verb) did not help. *markMWE* adds an annotation to several MWE categories for frequently occuring POS sequences. For example, we mark MWNs that occur more than 600 times (e.g., "N P N" and "N N").

4.2 DP-TSG Parser

A shortcoming of CFG-based grammars is that they do not explicitly capture idiomatic usage. For example, consider the two utterances:

(5) a. He [$_{\text{MWV}}$ kicked the bucket] .
b. He [$_{\text{VP}}$ kicked [$_{\text{NP}}$ the pail]] .

The examples in (5) may be equally probable and receive the same analysis under a PCFG; words are generated independently. However, recall that in our representation, (5a) should receive a flat analysis as MWV, whereas (5b) should have a conventional analysis of the verb *kicked* and its two arguments.

An alternate view of parsing is one in which new utterances are built from previously observed fragments. This is the original motivation for data oriented parsing (DOP) (Bod, 1992), in which "idiomaticity is the rule rather than the exception" (Scha, 1990). If we have seen the collocation *kicked the bucket* several times before, we should store that whole fragment for later use.

We consider a variant of the non-parametric PTSG model of Cohn et al. (2009) in which tree fragments are drawn from a Dirichlet process (DP) prior.[4] The DP-TSG can be viewed as a DOP model with Bayesian parameter estimation. A PTSG is a 5-tuple $\langle V, \Sigma, R, \diamondsuit, \boldsymbol{\theta} \rangle$ where $c \in V$ are non-terminals;

[4]Similar models were developed independently by O'Donnell et al. (2009) and Post and Gildea (2009).

α_c	DP concentration parameter for each $c \in V$
$P_0(e\|c)$	CFG base distribution
$\boldsymbol{x}$	Set of non-terminal nodes in the treebank
$\mathcal{S}$	Set of sampling sites (one for each $x \in \boldsymbol{x}$)
S	A block of sampling sites, where $S \subseteq \mathcal{S}$
$\boldsymbol{b} = \{b_s\}_{s \in \mathcal{S}}$	Binary variables to be sampled ($b_s = 1 \rightarrow$ frontier node)
$\boldsymbol{z}$	Latent state of the segmented treebank
m	Number of sites $s \in S$ s.t. $b_S = 1$
$\boldsymbol{n} = \{n_{c,e}\}$	Sufficient statistics of $\boldsymbol{z}$
$\Delta n^{S:m}$	Change in counts by setting m sites in S

Table 5: DP-TSG model notation. For consistency, we largely follow the notation of Liang et al. (2010). Note that $\boldsymbol{z} = (\boldsymbol{b}, \boldsymbol{x})$, and as such $z = \langle c, e \rangle$.

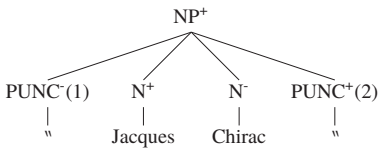

Figure 1: Example of two conflicting sites of the same type. Define the *type* of a site $t(\boldsymbol{z}, s) \stackrel{\text{def}}{=} (\Delta n^{s:0}, \Delta n^{s:1})$. Sites (1) and (2) above have the same type since $t(\boldsymbol{z}, s_1) = t(\boldsymbol{z}, s_2)$. However, the two sites *conflict* since the probabilities of setting b_{s_1} and b_{s_2} both depend on counts for the tree fragment rooted at NP. Consequently, sites (1) and (2) are not exchangeable: the probabilities of their assignments depend on the order in which they are sampled.

$t \in \Sigma$ are terminals; $e \in R$ are elementary trees;[5] $\diamondsuit \in V$ is a unique start symbol; and $\theta_{c,e} \in \boldsymbol{\theta}$ are parameters for each tree fragment. A PTSG derivation is created by successively applying the substitution operator to the leftmost *frontier node* (denoted by c^+). All other nodes are *internal* (denoted by c^-).

In the supervised setting, DP-TSG grammar extraction reduces to a segmentation problem. We have a treebank T that we segment into the set R, a process that we model with Bayes' rule:

$$p(R \mid T) \propto p(T \mid R)\, p(R) \tag{1}$$

Since the tree fragments completely specify each tree, $p(T \mid R)$ is either 0 or 1, so all work is performed by the prior over the set of elementary trees.

The DP-TSG contains a DP prior for each $c \in V$ (Table 5 defines further notation). We generate $\langle c, e \rangle$ tuples as follows:

$$\theta_c | c, \alpha_c, P_0(\cdot|c) \sim DP(\alpha_c, P_0)$$
$$e | \theta_c \sim \theta_c$$

The data likelihood is given by the latent state $\boldsymbol{z}$ and the parameters $\boldsymbol{\theta}$: $p(\boldsymbol{z}|\boldsymbol{\theta}) = \prod_{z \in \boldsymbol{z}} \theta_{c,e}^{n_{c,e}(\boldsymbol{z})}$. Integrating out the parameters, we have:

$$p(\boldsymbol{z}) = \prod_{c \in V} \frac{\prod_e (\alpha_c P_0(e|c))^{\overline{n_{c,e}(\boldsymbol{z})}}}{\alpha_c^{\overline{n_{c,\cdot}(\boldsymbol{z})}}} \tag{2}$$

where $x^{\overline{n}} = x(x+1)\ldots(x+n-1)$ is the rising factorial. (§A.1 contains ancillary details.)

Base Distribution The base distribution P_0 is the same maximum likelihood PCFG used in the Stanford parser.[6,7] After applying the manual state splits, we perform simple right binarization, collapse unary rules, and replace rare words with their signatures (Petrov et al., 2006).

For each non-terminal type c, we learn a stop probability $s_c \sim \text{Beta}(1, 1)$. Under P_0, the probability of generating a rule $A^+ \rightarrow B^-\ C^+$ composed of non-terminals is

$$P_0(A^+ \rightarrow B^-\ C^+) = p_{\text{MLE}}(A \rightarrow B\ C) s_B (1 - s_C) \tag{3}$$

For lexical insertion rules, we add a penalty proportional to the frequency of the lexical item:

$$P_0(c \rightarrow t) = p_{\text{MLE}}(c \rightarrow t) p(t) \tag{4}$$

where $p(t)$ is equal to the MLE unigram probability of t in the treebank. Lexicalizing a rule makes it very specific, so we generally want to avoid lexicalization with rare words. Empirically, we found that this penalty reduces overfitting.

Type-based Inference Algorithm To learn the parameters $\boldsymbol{\theta}$ we use the collapsed, block Gibbs sampler of Liang et al. (2010). We sample binary variables b_s associated with each non-terminal node/site in the treebank. The key idea is to select a block of exchangeable sites S of the same *type* that do not *conflict* (Figure 1). Since the sites in S are exchangeable, we can set $\boldsymbol{b}_S$ randomly so long as we know m, the number of sites with $b_s = 1$. Because this algorithm is a not a contribution of this paper, we refer the reader to Liang et al. (2010).

[5] We use the terms *tree fragment* and *elementary tree* interchangeably.

[6] The Stanford parser is a product model, so the results in §5.1 include the contribution of a dependency parser.

[7] Bansal and Klein (2010) also experimented with symbol refinement in an all-fragments (parametric) TSG for English.

After each Gibbs iteration, we sample each s_c directly using binomial-Beta conjugacy. We re-sample the DP concentration parameters α_c with the auxiliary variable procedure of West (1995).

Decoding We compute the rule score of each tree fragment from a single grammar sample as follows:

$$\theta_{c,e} = \frac{n_{c,e}(\boldsymbol{z}) + \alpha_c P_0(e|c)}{n_{c,\cdot}(\boldsymbol{z}) + \alpha_c} \quad (5)$$

To make the grammar more robust, we also include all CFG rules in P_0 with zero counts in $\boldsymbol{n}$. Scores for these rules follow from (5) with $n_{c,e}(\boldsymbol{z}) = 0$.

For decoding, we note that the derivations of a TSG are a CFG parse forest (Vijay-Shanker and Weir, 1993). As such, we can use a Synchronous Context Free Grammar (SCFG) to translate the 1-best parse to its derivation. Consider a unique tree fragment e_i rooted at X with frontier γ, which is a sequence of terminals and non-terminals. We encode this fragment as an SCFG rule of the form

$$[X \rightarrow \gamma \ , \ X \rightarrow i, Y_1, \ldots, Y_n] \quad (6)$$

where $Y_1, \ldots, Y_n$ is the sequence of non-terminal nodes in γ.[8] During decoding, the input is rewritten as a sequence of tree fragment (rule) indices $\{i, j, k, \ldots\}$. Because the TSG substitution operator always applies to the leftmost frontier node, we can deterministically recover the monolingual parse with top-down re-writes of $\diamondsuit$.

The SCFG formulation has a practical benefit: we can take advantage of the heavily-optimized SCFG decoders for machine translation. We use `cdec` (Dyer et al., 2010) to recover the Viterbi derivation under a DP-TSG grammar sample.

5 Experiments

5.1 Standard Parsing Experiments

We evaluate parsing accuracy of the Stanford and DP-TSG models (Table 6). For comparison, we also include the Berkeley parser (Petrov et al., 2006).[9] For the DP-TSG, we initialized all b_s with fair coin tosses and ran for 400 iterations, after which likelihood stopped improving.

[8] This formulation is due to Chris Dyer.

[9] Training settings: right binarization, no parent annotation, six split-merge cycles, and random initialization.

	Leaf Ancestor		Evalb			
	Corpus	Sent	LP	LR	F1	EX%
PA-PCFG	0.793	0.812	68.1	67.0	67.6	10.5
DP-TSG	0.823	0.842	75.6	76.0	75.8	15.1
Stanford	0.843	0.861	77.8	79.0	78.4	17.5
Berkeley	**0.880**	**0.891**	**82.4**	**82.0**	**82.2**	**21.4**

Table 6: Standard parsing experiments (test set, sentences $\leq$ 40 words). All parsers exceed 96% tagging accuracy. Berkeley and DP-TSG results are the average of three independent runs.

We report two different parsing metrics. *Evalb* is the standard labeled precision/recall metric.[10] *Leaf Ancestor* measures the cost of transforming guess trees to the reference (Sampson and Babarczy, 2003). It was developed in response to the non-terminal/terminal ratio bias of Evalb, which penalizes flat treebanks like the FTB. The range of the score is between 0 and 1 (higher is better). We report micro-averaged (whole corpus) and macro-averaged (per sentence) scores.

In terms of parsing accuracy, the Berkeley parser exceeds both Stanford and DP-TSG. This is consistent with previous experiments for French by Seddah et al. (2009), who show that the Berkeley parser outperforms other models. It also matches the ordering for English (Cohn et al., 2010; Liang et al., 2010). However, the standard baseline for TSG models is a simple parent-annotated PCFG (PA-PCFG). For English, Liang et al. (2010) showed that a similar DP-TSG improved over PA-PCFG by 4.2% F1. For French, our gain is a more substantial 8.2% F1.

5.2 MWE Identification Experiments

Table 7 lists overall and per-category MWE identification results for the parsing models. Although DP-TSG is less accurate as a general parsing model, it is more effective at identifying MWEs.

The predominant approach to MWE identification is the combination of lexical association measures (surface statistics) with a binary classifier (Pecina, 2010). A state-of-the-art, language independent package that implements this approach for higher order n-grams is `mwetoolkit` (Ramisch et al., 2010).[11] In Table 8 we compare DP-TSG to both

[10] Available at http://nlp.cs.nyu.edu/evalb/ (v.20080701).

Model	F1
`mwetoolkit` All	15.4
PA-PCFG	32.6
`mwetoolkit` Filter	34.7
PA-PCFG+Features	63.1
DP-TSG	**71.1**

Table 8: MWE identification F1 of the best parsing model vs. the `mwetoolkit` baseline (test set, sentences ≤ 40 words). PA-PCFG+Features includes the grammar features in Table 4, which is the CFG from which the TSG is extracted. For `mwetoolkit`, *All* indicates the inclusion of all n-grams in the training corpus. *Filter* indicates prefiltering of the training corpus by removing rare n-grams (see §A.2 for details).

`mwetoolkit` and the CFG from the which the TSG is extracted. The TSG-based parsing model outperforms `mwetoolkit` by 36.4% F1 while providing syntactic subcategory information.

6 Discussion

Automatic learning methods run the risk of producing uninterpretable models. However, the DP-TSG model learns useful generalizations over MWEs. A sample of the rules is given in Table 9. Some specific sequences like "[MWN [coup de N]]" are part of the grammar: such rules can indeed generate quite a few MWEs, e.g., *coup de pied* 'kick', *coup de coeur*, *coup de foudre* 'love at first sight', *coup de main* 'help', *coup d'état*, *coup de grâce* (note that only some of these MWEs are seen in the training data). For MWV, "V de N" as in *avoir de cesse* 'give no peace', *perdre de vue* [lose from sight] 'forget', *prendre de vitesse* [take from speed] 'outpace'), is learned. For prepositions, the grammar stores full subtrees of MWPs, but can also generalize the structure of very frequent sequences: "en N de" occurs in many multiword prepositions (e.g., *en compagnie de*, *en face de*, *en matière de*, *en terme de*, *en cours de*, *en faveur de*, *en raison de*, *en fonction de*). The TSG grammar thus provides a categorization of MWEs consistent with the Lexicon-Grammar. It also learns verbal phrases which contain discontinuous MWVs due to the insertion of an adverb or negation such as "[VN [MWV va] [MWADV d'ailleurs] [MWV bon train]]" [go indeed well], "[VN [MWV a] [ADV jamais] [MWV été question d']]" [has never been in question].

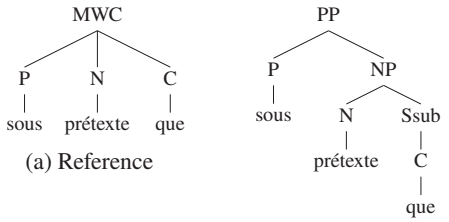
(a) Reference (b) DP-TSG

Figure 2: Example of an MWE error for *tour de passe-passe* 'magic trick'. (dev set)

A significant fraction of errors for MWNs occur with adjectives that are not recognized as part of the MWE. For example, since *établissements privés* 'private corporation' is unseen in the training data, it is not found. Sometimes the parser did not recognize the whole structure of an MWE. Figure 2 shows an example where the parser only found a subpart of the MWN *tour de passe-passe* 'magic trick'.

Other DP-TSG errors are due to inconsistencies in the FTB annotation. For example, *sous prétexte que*

configuration details.



(a) Reference

(b) Reference

Figure 3: Example of an inconsistent FTB annotation for *sous prétexte que* 'on the pretext of'.

'on the pretext of' is tagged as both MWC and as a regular PP structure (Figure 3). However, the parser always assigns a MWC structure, which is a better analysis than the gold annotation. We expect that more consistent annotation would help the DP-TSG more than the CFG-based parsers.

The DP-TSG is not immune to false positives: in *Le marché national, fait-on remarquer, est enfin en régression* ... 'The national economy, people at last note, is going down' the parser tags *marché national* as MWN. As noted, the boundary of what should and should not count as an MWE can be fuzzy, and it is therefore hard to assess whether or not this should be an MWE. The FTB does not mark it as one.

There are multiple examples were the DP-TSG found the MWE whereas Stanford (its base distribution) did not, such as in Figure 4. Note that the "N P N" structure is quite frequent for MWNs, but the TSG correctly identifies the MWADV in *emplois à domicile* [jobs at home] 'homeworking'.

7 Related Work

There is a voluminous literature on MWE identification. Here we review closely related syntax-based methods.[12] The linguistic and computational attractiveness of lexicalized grammars for modeling idiosyncratic constructions in French was identified by Abeillé (1988) and Abeillé and Schabes (1989). They manually developed a small Tree Adjoining Grammar (TAG) of 1,200 elementary trees and 4,000 lexical items that included MWEs. The classic statistical approach to MWE identification, Xtract (Smadja, 1993), used an incremental parser in the third stage of its pipeline to identify predicate-argument relationships. Lin (1999) applied information-theoretic measures to automatically-extracted dependency relations to find MWEs. To our knowledge, Wehrli (2000) was the first to use syntactically annotated corpora to improve a parser for MWE identification. He proposed to rank analyses of a symbolic parser based on the presence of collocations, although details of the ranking function were not provided.

The most similar work to ours is that of Nivre and Nilsson (2004), who converted a Swedish corpus into two versions: one in which MWEs were left as tokens, and one in which they were merged. On the first version, they showed that a deterministic dependency parser could identify MWEs at 71.1% F1, albeit without subcategory information. On the second version—which simulated perfect MWE identification—they showed that labeled attachment improved by about 1%.

Recent statistical parsing work on French has included Stochastic Tree Insertion Grammars (STIGs), which are related to TAGs, but with a restricted adjunction operation.[13] Seddah et al. (2009) and Seddah (2010) showed that STIGs underperform CFG-based parsers on the FTB. In their experiments, MWEs were concatenated.

[12] See Seretan (2011) for a comprehensive survey of syntax-based methods for MWE identification. For an overview of n-gram methods like `mwetoolkit`, see Pecina (2010).

[13] TSGs differ from TAGs and STIGs in that they do not include an adjunction operator.

8 Conclusion

The main result of this paper is that an existing statistical parser can achieve a 36.4% F1 absolute improvement for MWE identification over a state-of-the-art n-gram surface statistics package. Parsers also provide syntactic subcategorization, and do not require pre-filtering of the training data. We have also demonstrated that TSGs can capture idiomatic usage better than a PCFG. While the DP-TSG, which is a relatively new parsing model, still lags state-of-the-art parsers in terms of overall labeling accuracy, we have shown that it is already very effective for other tasks like MWE identification. We plan to improve the DP-TSG by experimenting with alternate parsing objectives (Cohn et al., 2010), lexical representations, and parameterizations of the base distribution. A particularly promising base distribution is the latent variable PCFG learned by the Berkeley parser. However, initial experiments with this distribution were negative, so we leave further development to future work.

We chose French for these experiments due to the pervasiveness of MWEs and the availability of an annotated corpus. However, MWE lists and syntactic treebanks exist for many of the world's major languages. We will investigate automatic conversion of these treebanks (by flattening MWE bracketings) for MWE identification.

A Appendix

A.1 Notes on the Rising Factorial

The rising factorial—also known as the ascending factorial or Pochhammer symbol—arises in the context of samples from a Dirichlet process (see Prop. 3 of Antoniak (1974) for details). For a positive integer n and a complex number x, the rising factorial $x^{\overline{n}}$ is defined[14] by

$$\begin{aligned} x^{\overline{n}} &= x(x+1)\dots(x+n-1) \\ &= \prod_{j=1}^{n}(x+j-1) \end{aligned} \tag{7}$$

The rising factorial can be generalized to a complex number α with the gamma function:

$$x^{\overline{\alpha}} = \frac{\Gamma(x+\alpha)}{\Gamma(x)} \tag{8}$$

where $x^{\overline{0}} \equiv 1$.

In our type-based sampler, we computed (7) directly in a dynamic program. We found that (8) was prohibitively slow for sampling.

A.2 `mwetoolkit` Configuration

We configured `mwetoolkit`[15] with the four standard lexical features: the maximum likelihood estimator, Dice's coefficient, pointwise mutual information (PMI), and Student's t-score. We added the POS sequence for each n-gram as a single feature. We removed the web counts features to make the experiments comparable. To compensate for the absence of web counts, we computed the lexical features using the gold lemmas from the FTB instead of using an automatic lemmatizer.

Since MWE n-grams only account for a small fraction of the n-grams in the corpus, we filtered the training and test sets by removing all n-grams that occurred once. To further balance the proportion of MWEs, we trained on all valid MWEs plus 10x randomly selected non-MWE n-grams. This proportion matches the fraction of MWE/non-MWE tokens in the FTB. Since we generated a random training set, we reported the average of three independent runs.

We created feature vectors for the training n-grams and trained a binary Support Vector Machine (SVM) classifier with Weka (Hall et al., 2009). Although `mwetoolkit` defaults to a linear kernel, we achieved higher accuracy on the development set with an RBF kernel.

The FTB is sufficiently large for the corpus-based methods implemented in `mwetoolkit`. Ramisch et al. (2010)'s experiments were on Genia, which contains 18k sentences and 490k tokens, similar to the FTB. Their test set had 895 sentences, smaller than ours. They reported 30.6% F1 for their task against an Xtract baseline, which only obtained 7.3% F1. These results are comparable in magnitude to our FTB results.

Acknowledgments We thank Marie Candito, Chris Dyer, Dan Flickinger, Percy Liang, Carlos Ramisch, Djamé Seddah, and Val Spitkovsky for their helpful comments. The first author is supported by a National Defense Science and Engineering Graduate (NDSEG) fellowship.

[14] We adopt the notation of Knuth (1992).

[15] We re-implemented `mwetoolkit` in Java for compatibility with Weka and our pre-processing routines.

Abstract

We present the first algorithms to automatically identify explicit discourse connectives and the relations they signal for Arabic text. First we show that, for Arabic news, most adjacent sentences are connected via explicit connectives in contrast to English, making the treatment of explicit discourse connectives for Arabic highly important. We also show that explicit Arabic discourse connectives are far more ambiguous than English ones, making their treatment challenging. In the second part of the paper, we present supervised algorithms to address automatic discourse connective identification and discourse relation recognition. Our connective identifier based on gold standard syntactic features achieves almost human performance. In addition, an identifier based solely on simple lexical and automatically derived morphological and POS features performs with high reliability, essential for languages that do not have high-quality parsers yet. Our algorithm for recognizing discourse relations performs significantly better than a baseline based on the connective surface string alone and therefore reduces the ambiguity in explicit connective interpretation.

1 Introduction

The automatic detection of discourse relations, such as causal, contrast or temporal relations, is useful for many applications such as automatic summarization (Marcu, 2000), question answering (Girju, 2003), sentiment analysis (Somasundaran et al., 2008) and readability assessment (Pitler and Nenkova, 2008). This task has recently seen renewed interest due to the growing availability of large-scale corpora annotated for discourse relations, such as the Penn Discourse Treebank (Prasad et al., 2008a).

In the Penn Discourse Treebank (PDTB), local discourse relations (also called *senses*) such as CAUSAL or CONTRAST are annotated. They hold between two text segments (so-called *arguments*) that express abstract entities such as events, facts and propositions. Annotated discourse relations can be signalled explicitly by so-called *discourse connectives* (Marcu, 2000; Webber et al., 1999; Prasad et al., 2008a) or hold implicitly between adjacent sentences in the same paragraph, i.e. are not signalled by a specific surface string. In Ex. 1, the connective *while* indicates an explicit CONTRAST between the attitudes of John and Richard. In Ex. 2, the connective *while* indicates an explicit TEMPORAL relation. In Ex. 3, an implicit CAUSAL relation between the first and second sentence holds. We indicate discourse connectives and the two arguments they relate via annotated square brackets.

(1) [John liked adventure,]$_{Arg2}$ [while]$_{DC}$[Richard was cautious]$_{Arg2}$

(2) [The children were crying loudly]$_{Arg1}$[while]$_{DC}$,[their mother was cooking]$_{Arg2}$

(3) [I cannot eat any dessert.]$_{Arg1}$ [I have eaten far too much already.]$_{Arg2}$

Although similar corpora for other languages are being developed such as for Hindi (Prasad et al., 2008b), Turkish (Zeyrek and Webber, 2008), Chinese (Xue, 2005) and, by ourselves, for Arabic (Al-

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 736–747,
Edinburgh, Scotland, UK, July 27–31, 2011.

Saif and Markert, 2010), efforts in the automated recognition of discourse connectives, arguments and relations have so far almost exclusively centered on English.

In contrast we present the first models for discourse relations for Arabic, focusing on explicit connectives. This focus is partially justified by the fact that this first study for a new language should center on the superficially more straightforward case and that no annotations for implicit relations are yet available for Arabic. More importantly, however, we make two essential claims (Section 4). Firstly, Arabic discourse connectives are more ambiguous than their English counterparts, i.e cases such as *while* which can signal different relations dependent on context (see Example 1 and 2) are far more frequent. This makes their treatment more *challenging*. Secondly, discourse relations between adjacent sentences in Arabic tend to be expressed via an explicit connective, at least for the news genre, i.e. cases such as Example 3 are rarer. This makes the treatment of explicit connectives *essential*.

We tackle two tasks for explicit Arabic connectives in this paper, which are further discussed in Section 2. Discourse connective recognition needs to distinguish between discourse usage of potential connectives and non-discourse usage (such as the use of *while* as a noun). We show in Section 5 that we can distinguish discourse- and non-discourse usage for potential connectives in Arabic with very high reliability, even without parsed data, a fact that is important for languages with fewer high quality NLP tools available. We then present an algorithm for relation identification in Section 6 that shows small but significant gains over assigning the most frequent relation for each connective. We discuss future work and conclude in Section 7.

2 The Tasks

The handling of explicit connectives can be split into three tasks (Pitler and Nenkova, 2009). The first task of *discourse connective recognition* distinguishes between the *discourse usage and non-discourse usage* of potential connectives. Whereas some potential connectives such as the Arabic connective لكن */lkn/but* almost always have discourse usage, this is not true for all potential connectives.[1] Thus, the discourse usage of Arabic رغبة */rġbh/desire* needs to be distinguished from its use as a noun. Conjunctions such as و */w/and,* او */āw/or* can have discourse usage or just conjoin two non-abstract entities as in عمر و ساره */ʕmr w sārh/Omar and Sarah.*

The second task is *discourse connective interpretation* where a discourse connective in context is assigned a discourse relation. Again, some connectives are largely unambiguous in this respect. For example, لكن */lkn/but* signals almost always a CONTRAST relation. However, there are connectives where this is not the case, such as منذ */mnḏ/since* which has a CAUSAL and a TEMPORAL sense.

The third task is argument identification which identifies the arguments' position and extent. In this paper we tackle Task 1 and Task 2 for Arabic in a supervised machine learning framework.

3 Related work

Annotated Discourse Corpora and Linguistic Background. Discourse relations are widely studied in theoretical linguistics (Halliday and Hasan, 1976; Hobbs, 1985), where also different relation taxonomies have been derived (Hobbs, 1985; Knott and Sanders, 1998; Mann and Thompson, 1988; Marcu, 2000). Different inventories have been used in English corpora annotated for discourse relations (Hobbs, 1985; Prasad et al., 2008a; Carlson et al., 2002) which also differ in other respects (such as whether they prescribe a tree structure for discourse annotation). However, the annotation level of existing Arabic corpora has not yet included the discourse layer, making our work the first to address this problem for Arabic on a larger scale.

Automatic discourse parsing: explicit relations. There is no work on discourse connective recognition, interpretation and argument assignment for Arabic, so that we break entirely new ground here. However, the two tasks we explore (discourse connective recognition and discourse connective disambiguation) have been tackled for English.[2] (Pitler

[1] Arabic examples contain in order: the Arabic right-to-left script, the transliteration (standards ISO/R 233 and DIN 31635) and the English translation (if possible).

[2] There is also substantial work on argument identification (Wellner and Pustejovski, 2007; Elwell and Baldridge, 2008)

and Nenkova, 2009) use gold standard syntactic features as well as the connective surface string in a supervised model for discourse connective recognition. They achieve very high results with this approach. We will (i) show that similar features work well for Arabic (ii) take into account Arabic-specific morphological properties that improve results further and (iii) present a robust version of this approach that does not rely on full parsing or gold standard syntactic annotations.

With regard to discourse connective interpretation, (Miltsakaki et al., 2005) concentrate on disambiguating the three connectives *since, while, when* only, using a very small set of features indicating tense and temporal markers in arguments. They achieve good improvements over a "most frequent relation per connective" baseline. A more comprehensive study on all discourse connectives in the PDTB (Pitler et al., 2008; Pitler and Nenkova, 2009) reveals that most connectives are not ambiguous in English. Using syntactic features of the connective, they achieve only a very small improvement over a "most frequent relation per connective baseline" for which significance tests are not given. We will show that for Arabic, discourse connectives are more highly ambiguous with regard to the relations they convey. We will present a supervised learning model that uses a wider feature set and that achieves small but significant improvements over the most frequent relation per connective baseline.

Automatic discourse parsing: implicit relations. Implicit relations have excited substantial interest for English. This includes work in the framework of RST (Soricut and Marcu, 2003; duVerle and Prendinger, 2009; Marcu and Echihabi, 2002), SDRT (Baldridge and Lascarides, 2005), GraphBank (Wellner et al., 2006), the PDTB (Blair-Goldensohn et al., 2007; Pitler et al., 2009; Lin et al., 2009; Wang et al., 2010; Zhou et al., 2010; Louis and Nenkova, 2010) or framework-independent (Sporleder and Lascarides, 2008).[3] The task is challenging as implicits behave substantially differently from explicits (Sporleder and Lascarides, 2008) and often need world knowledge (Lin et al., 2009). However, features/approaches that have shown improvement over a baseline are word pairs (Sporleder and Lascarides, 2008), production rules and syntactic trees (Wang et al., 2010; Lin et al., 2009) as well as language modelling (Zhou et al., 2010). As we only deal with explicit connectives this work is not directly comparable to ours, although we do explore some of the suggested features for improving explicit connective disambiguation.

4 An Arabic Discourse Corpus

We annotate news articles from the Arabic Penn Treebank (Part 1 v2.0) (Maamouri and Bies, 2004) for explicitly marked discourse relations. This is the first discourse-annotated corpus for Arabic, whose initial development stages we have described in (Al-Saif and Markert, 2010). We summarize this previous work and extend it by including agreement studies for arguments in Sections 4.1 and 4.2. In Sections 4.3, 4.4 and 4.5. we then present a corpus study on the corpus which shows our major claim as to the importance and high levels of ambiguity of Arabic discourse connectives.

4.1 Annotation Principles

We overall follow the annotation principles in the Penn Discourse Treebank for explicit connectives (for example, arguments can occur at any distance from the connectives). The relation set we use is a more coarse-grained version of the PDTB relations with two relations added — BACKGROUND and SIMILARITY — that we found in our Arabic news texts. The final, hierarchically organized, relation set of 17 discourse relations is shown in Fig 1.

Further adaptations necessary for Arabic are the inclusion of clitics as connectives such as ل*/l/for,* ب */b/by,with* and ف */f/then* . In addition, differently to English, prepositions were included as connectives as these are frequently used to express discourse relations in Arabic. In these cases, normally argument 2 is the so-called *Al-Masdar*.[4] Typical examples are وصول */wṣwl/arrival* from the verb وصل */wṣ/to arrive* and محاولة */mḥāwlh/attempt* from the verb حاول

but we do not discuss this work in depth here.

[3] Some work does not make the distinction between implicit and explicit and/or treats them in a joint framework (Soricut and Marcu, 2003; Wellner et al., 2006; Wang et al., 2010).

[4] The medieval Arabic grammar schools, the Basra and Kufa, debated whether the noun (almasdar) or the verb is the most basic element of language (Ryding, 2005).

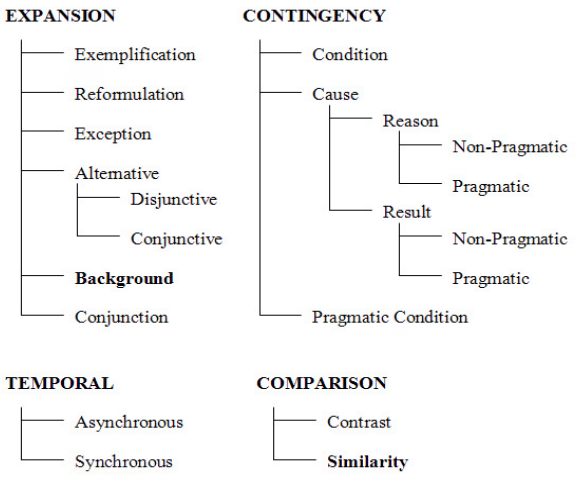

Figure 1: Discourse relations for Arabic

/ḥāwl/to try. Al-Masdar is formed using morphological patterns well-known in the Arabic grammatical tradition: major Arabic grammars list around 60 patterns although some other references also claim that the patterns are many more as well as more unpredictable (Abdl al latif et al., 1997; Wright, 2008; Ryding, 2005). Al-Masdar forms do not fit into one grammatical or morphological category in English: they might correspond to a gerund, a nominalization or a noun which is not a nominalization. Some examples are listed in Table 1.

Table 1: A list of Al-MaSdar patterns, examples and their English correspondence

Root	Pattern	MaSdar	Translation
سبح */sbḥ*	فعالة */fʿalh*	سباحة */sbaḥh*	swimming
نفذ */nfḏ*	تفعيل */tfʿyl*	تنفيذ */tnfyḏ*	execution
دفع */dfʿ*	فعال */fʿāl*	دفاع */dfāʿ*	defence
زرع */zrʿ*	فعالة */fʿālh*	زراعة */zrāʿh*	agriculture
حرب */ḥrb*	فعل */fʿl*	حرب */ḥrb*	war

An example of Al-MaSdar as argument of a discourse relation is Ex. 4, where تبليغ*/tblyġ/informing* is the *Al-MaSdar* form of بلغ*/blġ/inform*.

[We went to the police station]$_{Arg1}$ [for]$_{DC}$ [informing about the loss of the company’s official documents.]$_{Arg2}$

4.2 Agreement Studies

The occurrences of a precompiled list of 107 potential discourse connectives were annotated independently by 2 native Arabic speakers on 537 news texts. Agreement was measured for the distinction of discourse vs. non-discourse usage, relation assignment and argument assignment.

Agreement for the classification tasks of discourse connective recognition and relation assignment was measured using kappa (Siegel and Castellan, 1956). Argument agreement was measured by `agr`, a directional measure (Wiebe et al., 2005). It measures the word overlap between the text spans of two judges (ann1 and ann2). `agr(ann1||ann2)` measures the proportion of words ann1 annotated that were also annotated by ann2.

$$agr(ann1||ann2) = \frac{|ann1\ matching\ ann2|}{|ann1|}$$

Discourse connective recognition proved to be highly reliable with percentage agreement of 0.95 and a kappa of 0.88 on the 23,331 occurrences of the 107 potential discourse connectives. 5586 of the potential connectives were agreed on by both annotators to have discourse usage and agreement for relations and argument assignment was measured on these. As shown in Table 2, kappa on all 17 relations was low with 0.57 — it turned out that this was due to the frequent, almost rhetorical use of the connective و */w/and* at the beginning of paragraphs, which is a genre convention for Arabic news that normally does not convey a specific discourse relation. Disregarding such occurrences of و*/w/and*, kappa rises to good agreement: 0.69 for fine-grained relations and 0.75 when measuring agreement between the 4 major relations EXPANSION, CONTINGENCY, COMPARISON and TEMPORAL.

Argument agreement on the 5586 agreed connectives is shown in Table 3. We report high word overlap via `agr` (over 90%) for Arg2, which is the argument syntactically attached to the connective, and lesser but still substantial agreement for Arg1.

Table 2: Inter-annotator reliability for discourse relation assignment

4.3 Gold standard

We produced a unified gold standard. First, we automatically corrected easily made annotator mistakes. With regard to argument extent, we automatically corrected mistakes such as the erroneous inclusion of punctuation marks at the end of clauses/sentences or not including all obligatory complements in a verb phrase argument. The latter relied on the syntactic annotation in the ATB. Second, with regard to discourse relation assignment, we automatically assigned EXPANSION.CONJUNCTION to all disagreed instances of و /*w*/*and* at BOP.[5] A further disambiguation study is necessary for و /*w*/*and* at BOP, which is beyond the scope of this paper.

Finally, an adjudicator not initially involved in annotation reconciled the remaining disagreements at all levels and included annotations for 5 new potential discourse connective types not in our initial connective list but commented on by the annotators during annotation. 3 news files were removed from the corpus — they contained no actual news reports but just a list of headlines.

The final discourse treebank we use has 6328 annotated explicit connectives in 534 files. 68 connective types were found, rising to 80 connective types if we include all modified forms of a connective as distinct types such as بالرغم من/*bālrġm mn,* رغم ان /*rġm ān* as modified forms of رغم /*rġm/although.*

Most discourse connectives were only annotated with a single relation but 5% were annotated with two or more relations (as also allowed in the PDTB). These statistics are summarised in Table 4.

Files	534
Total tagged tokens	126,046 (125KB)
Sentences	3607
Paragraphs	3312
Discourse connectives (tokens)	6328
Distinct connective (types) including modifed form connectives	68 80
Clitic discourse connectives (tokens)	4779 (76%)
Non-clitic discourse connectives (tokens)	1549 (24%)
Relations types (17 single, 38 combined)	55
Single relations (tokens)	6039 (95%)
Combined relations (tokens)	289 (5%)

Table 4: Statistics of the final gold standard corpus

4.4 Importance of explicitly signalled relations

We compared the number of relations between 2 adjacent sentences that were explicitly signalled in English vs. the ones that were explicitly signalled in Arabic, using the PDTB and our corpus (both containing texts of the news genre). Out of a total 44,470 adjacent sentence pairs in the PDTB, 5355

[5] Other instances of و /*w*/*and* are not treated this way.

(12%) were linked by an explicit connective.[6] In contrast, out of the 3073 adjacent sentence pairs in our corpus, 2140 (70%) were linked by an explicit connective, 948 (30%) were linked via non-*wa* connectives. Thus, for our corpus, modeling of explicit connectives is primary: intrasentential relations tend to be marked by connectives anyway in both English and Arabic, and our corpus shows that this is true for most local intersentential relations as well.

4.5 Ambiguity for Arabic discourse connectives

We investigate the ambiguity of Arabic connectives with regard to their sense at class level (4 relations) as well as the more fine-grained level (all 17 relations). We restrict our investigation to the connective occurrences that were annotated with a single relation (6039 tokens) and also exclude و */w/and* at the beginning of paragraph, leaving 3813 tokens.[7] Of 80 connective types, 52 were unambiguous at the class level and 47 at the fine-grained level. However, many of the most frequent connectives are highly ambiguous. If we just assign the most frequent reading to each of the 3813 connectives, we achieve an accuracy of 82.7% at the class-level and 74.3% at the more fine-grained level for relation assignment, leaving a substantial error margin. This contrasts with the English PDTB, where at the class-level 92% can be achieved with this simple method and 85% at the second-level.[8]

5 Discourse Connective Recognition

We distinguished discourse vs. non-discourse usage for all potential connectives in the 534 gold standard files. As headers and footers in the news files never contained true discourse connectives, we disregarded these, leaving 20,312 potential discourse connectives of which 6328 are actual connectives.

[6]Connections between subclauses or phrases in different, adjacent sentences were included in the count.

[7]We automatically assigned CONJUNCTION to many occurrences of و */w/and* at BOP (Section 4.3) so that it is not sensible to include these occurrences in a study of human-assigned ambiguity.

[8]The second level in the PDTB with its 16 relations corresponds approximately to our fine-grained inventory. This comparison can only be appropriate due to slight differences in the lower-grained relation inventory.

5.1 Features

Apart from the surface string of the potential connective *Conn*, we use the following features. Features are either extracted from raw files tokenized by white space only (M2) or from raw files tokenized by white space and tagged by the Stanford tagger[9] (Models M3, M4) or from the Arabic Treebank (ATB) gold standard part-of-speech and parse annotation (models M5-M9). The syntactic features (Syn) are inspired by (Pitler and Nenkova, 2009). Lexical/POS patterns of surrounding words, clitic features and Al-Masdar are novel.

Surface Features (SConn). These include the position of the potential connective (sentence-initial, medial or final). The *type* of the potential connective is `Simple` when the potential connective is a single token not attached to other tokens, `PotClitic` when it is attached. Potential connectives containing more than one token have `MoreThanToken` type.

Models where we use ATB or automated tagging (M3-M9) distinguish further between potential clitics that are assigned a POS and ones that are not. Models that use ATB annotation also distinguish between potential connectives that correspond to a phrase in the ATB (`MorethanToken_Phrase`) and the ones that do not (`MorethanToken_NonPhrase`).

Lexical features of surrounding words (Lex). We encode the surface strings of the three words before and after the connective, recording position. These features are especially useful for languages where no accurate parser or tagger is available as lexical patterns can capture discourse and non-discourse usage. For instance, if a potential connective is followed by ان */ān/* it most likely has a discourse function (see Ex. 5).

(5) ان الاطفال يمكن [ان يصابوا بالارهاق]$_{Arg1}$[و]$_{DC}$ [ان يشعروا بالنعاس]$_{Arg2}$ خلال الدراسة اذا لم يناموا جيدا

[*ān ālāṭfāl ymkn [ān yṣābwā bālārhāq*]$_{Arg1}$[*w*]$_{DC}$[*ān yšʕrwā bālnʕās*]$_{Arg2}$ *ẖlāl āldrāsh āḏā lm ynāmwā ğydā*

[Children might be tired]$_{Arg1}$ [and]$_{DC}$ [feel sleepy]$_{Arg2}$ during school time if they did not sleep well

[9]`http://nlp.stanford.edu/software/tagger.shtml`

Part of Speech features (POS). We include the pos tag of the potential connective via the ATB/Stanford Tagger. For potential connectives that consist of more than one token, we combined its ordered POS tags. Thus, the potential connective في حال */fy ḥāl/in case* with its tags (fy PREP)(Hal NOUN)) will receive the pos PREP#NOUN. If a potential connective does not receive a separate POS tag in the ATB/tagger, the value "NONE" is assigned. This allows to distinguish clitics from letters at the start of a word. We also record the POS of the three words before/after the connective (ATB/Stanford Tagger). Similar to lexical patterns, these can capture discourse and non-discourse usage. For instance, if a potential connective is soon followed by a modal, it is more likely to have a discourse function.

Syntactic category of related phrases (Syn). We record the syntactic category of the parent of the potential connective in ATB. For example, it is rare that cases where the parent of the potential connective is an adjective phrase, correspond to discourse-usage. A typical example of a non-discourse usage of و*/w/and* (المدرسة كبيرة و جميلة */ālmdrsh kbyrh w ğmylh/ the school is very large and beautiful*) illustrates this. Unlike English, parents in Arabic often are noun phrases as nominalisations are frequent arguments of prepositional connectives. We also encode the Left sibling category and right sibling category of the connective. For discourse connectives, the right sibling is normally S, SBAR, VP or an NP (if the connective is a preposition).

Al-Masdar feature. Potential connectives followed by Al-Masdar are more likely to have discourse usage (see Section 4.1). Especially prepositions with discourse usage are normally attached to Al-masdar such as in لمحادثة */lmḥādṯh/for contacting* or باجراء */bāğrāʔ/by processing*. Al-Masdar information is not included in the ATB so we constructed a binary Al-Masdar feature from (tagged) text by examining the first noun after the potential connective. We developed an algorithm to judge such a noun as Al-Masdar or not. This algorithm uses a stemmer for Arabic and then determines whether the stem is al-Masdar by a combination of surface-based rules to check whether the stem corresponds to one of the known Al-Masdar patterns.

5.2 Results and Discussion

We used the implementation JRip of the rule-based classifier Ripper in the machine learning tool WEKA with its default settings. We used 10-fold cross-validation throughout. Significance tests are reported using the McNemar test at the significance level of 1%. A most frequent category baseline would assign all potential connectives as *not connective*, achieving an accuracy of 68.9% as only 6328 of our potential 20,312 connectives actually have discourse usage. We built several models using different features. The results are shown in Table 5.

A simple model M1 that only uses the connective string improves significantly over the baseline with 75.7% accuracy but a kappa of only 0.48, showing that this is not a reliable strategy. Models M2-M4 do not rely on gold standard annotation or parsing (in contrast to the models for English in (Pitler and Nenkova, 2009)). Using only surface and lexical features that can be extracted from white-space tokenized raw files in addition to the connective string (M2), gains a substantial improvement over using the connective string alone. This is further improved by using POS tags of connectives and surrounding words with an automatic tagger (M3) and by including the Al-Masdar feature (M4), thus making good use of the morphological properties of Arabic. All differences are statistically significant (M1 $<$ M2 $<$ M3 $<$ M4). The final model is reliable (kappa 0.70), an encouraging result given the absence of parsing and important for resource-scarce languages.

With ATB gold standard tokenisation, tagging and parsing, our models (not surprisingly) improve further showing the same pattern of (M1 $<$ M5 $<$ M6 $<$ M7) with all differences being significant. The final best model achieves highly reliable results (accuracy 92.4%, kappa 0.82). We also conclude that syntactic features are more useful than lexical patterns as model M8 (syntax with no lexical patterns) achieves equally good results as M6. Our models also manage to generalise well over individual connectives. If we leave out the connective string (M9), we still achieve a highly reliable result.

6 Discourse Relation Recognition

When disambiguating the relation that discourse connectives signal, we assume that the arguments of

	Features	Acurr	K
	Baseline (not conn)	68.9	0
M1	Conn only	75.7	0.48
Tokenization by white space + auto tagger			
M2	Conn+ SConn+Lex	85.6	0.62
M3	Conn+ SConn+Lex+POS	87.6	0.69
M4	Conn+SConn+Lex+POS+Masdar	88.5	0.70
ATB-based features			
M5	Conn+SConn+Lex	86.2	0.65
M6	Conn+SConn+Lex+Syn/POS	91.2	0.79
M7	Conn+SConn+Lex+Syn/POS+Masdar	92.4	0.82
M8	Conn+SConn+Syn	91.2	0.79
M9	SConn+Lex+Syn+Masdar	91.2	0.79

Table 5: Performance of different models for identifying discourse connectives.

the connective are known. This is well-established for PDTB relation recognition (Wang et al., 2010; Lin et al., 2009; Miltsakaki et al., 2005). Our models predict single relations on two datasets: (i) all instances of connectives signalling single relations (Set `All`, 6039 instances) (2) all instances apart from the connective و */w/and* at beginning of paragraph as they are affected by the auto-correction process (Set `no-wa-atBOP`, 3813 instances). We use 10-fold cross-validation and JRip as well as a McNemar test at the 5% level for significance tests.

6.1 Features

Whereas some of the features we use have been used for English implicit relation recognition (Lin et al., 2009; Wang et al., 2010; Pitler et al., 2009) , they are new for Arabic and not widely used for explicit connectives. All features are extracted from the ATB gold standard parses.

Connective features. This includes the connective string *Conn*. In addition, we also use the surface connective features and POS of connective described in Section 5. We also use the syntactic path to the connective as a novel feature.

Words and POS of arguments. The words and pos tags of the first three words in Arg1 and Arg2 are used to catch patterns in arguments. For example, when the first word of Arg2 is قد */qd/might/may* or كان */kān/had*, the relation is likely to be EXPANSION.BACKGROUND or EXPANSION.CONJUNCTION. We also measure word overlap between the arguments, hoping to catch relations such as COMPARISON.SIMILARITY.

Masdar. This feature states whether the first or second word in Arg 2 is an Al-Masdar. Many prepositional connectives followed by an Al-Masdar indicate a CONTINGENCY.CAUSE relation (see Ex. 4)

Tense and Negation. Each argument is assigned its tense as one of *perfect, imperfect, future or none*. We also indicate whether the tense of Arg1 or 2 are the same and whether a negation is part of Arg 1 or 2. Inspired by (Miltsakaki et al., 2005), we stipulate that tense is useful for recognizing temporal and causal relations. For example, the arguments of the relation TEMPORAL.SYNCHRONOUS are likely to have the same tense. In contrast, arg1_tense is more likely to be prior to arg2_tense for TEMPORAL.ASYNCHRONOUS and CAUSE relations.

Length, Distance and Order Features. We use the length of arguments (in words), word distance between a connective and its arguments (-1; for arguments in order Arg1_Conn_Arg2_Arg1), tree distance of connective and arguments (0 if connective and an argument are in the same tree) and a binary feature of whether Arg1 and Arg2 are in different sentences. A nominal feature encodes one of the three orders Arg1_Conn_Arg2, Conn_Arg2_Arg1 and Arg1_Conn_Arg2_Arg1, the latter being frequent in Arabic for TEMPORAL.ASYNCHRONOUS relations.

Argument Parent. We record the syntactic parent of each Argument. However, not every argu-

ment corresponds to a complete tree in the ATB — in these cases we extract the category of the parent shared by the first and last word in the argument.

Production Rules. We use all non-lexical production rules that occur more than 10 times in the arguments as binary features. This was inspired by (Lin et al., 2009) who use production rules to good effect for implicit relations in English.

6.2 Results

Table 6 shows the results for fine-grained (17 relations) classification. The baseline of assigning the most frequent relation EXPANSION.CONJUNCTION to every connective performs with an accuracy of 52.5% on Set `All` and 35% on set `no-wa-atBOP`. If we use a model that relies on the discourse connective alone (M1) we achieve results of 77.2%/74.3%, respectively. As noted in Section 4.5 this is substantially lower than what the same model can achieve for English. Including connective and argument features (apart from production rules) in M2, leads to a small but significant improvement.[10] Further incorporation of production rules does not improve the results (M3). In Table 7, we show the results at the class-level (4 relations). Here using additional features over the connective string does not lead to significant improvements.

6.3 Discussion and Error Analysis

We concentrate our discussion on fine-grained classification excluding wa at BOP.

Our improvements in M2 over the connective-only classifier (M1) are in two main areas. First, our model performs generalisation, i.e. outputs some rules that do not use the connective string at all. These achieve a somewhat surprising improvement of M2 over M1 for *u*nambiguous connectives which are too rare to classify via the connective string. In those cases, they either (i) have not been seen in the training data before and are therefore not classifiable when seen first time in the test set or (ii) have been seen in the training data too rarely for the rule-based classifier to develop a rule judged to be more reliable than the default EXPANSION.CONJUNCTION classification. Our data includes 47 unambiguous connective types, accounting for 574 of the 3813 tokens. 30 of these 47 types are so rare that we found mistakes in the connective-only classification, including الا */ālā*/except (2), عقب */ʿqb*(2),طالما */ṭā-lmā*(2), برغم*/brġm*(1). For 14 of these 30 connectives, model M2 was able to use generalised rules to improve relation assignment.[11] These rules involve mainly connective surface and POS features. Thus, sentence-start adverbials consisting of more than one token such as بيد ان */byd ān*(6) and غير ان */ġyr ān*(6) were correctly classified as CONTRAST.

Table 7: Performance of different models for identifying class-level discourse relations on two datasets.

[10] Our corpus includes some texts on similar topics where some sentences are (almost) repeated in different texts. To investigate whether our improvements are due to this repetition, we also performed an experiment excluding all repeated instances of feature vectors from the corpus. The results are almost the same and, most importantly, M2 again improves significantly over M1.

[11] For the other 16 connectives neither of the models was able to classify them correctly.

This advantage of our model over the connective-only model might disappear if in a larger corpus more instances of those connectives are found and are still unambiguous. Therefore, we are more interested in how our classifier does on truly ambiguous connectives (33 connective types accounting for 3239 tokens of 3813 overall tokens). We conducted a separate significance test on ambiguous connectives only and found that M2 improves over M1 classification significantly at the 1% level. How well we do on individual connectives depends on their frequency and on their level of ambiguity. If connectives are ambiguous and of low frequency (لو /*lw*, انما /*ānmā*, حال /*ḥāl*/) both M1 and M2 do perform badly on them. If connectives are frequent (10 or more occurrences) and have relatively low ambiguity (majority reading accounts for more than 70% of instances), the overall performance of M1 and M2 with regard to accuracy is also similar, often both using just the connective string. On the other hand, if connectives are frequent and have high ambiguity (i.e. no such clear majority reading), then M2 normally improves (often substantially) on M1. Examples of such connectives are كما /*kmā*, فيما /*fymā*and اثر /*āṯr*. Most of the successful rules use tense in some form, either via part of speech of verbs or via comparing the tense in the two arguments. This, for example, led to a successful recognition of all 9 instances of `Similarity` in the connective kmA (whose majority relation is `Expansion.Conjunction` in 40 out of 65 occurrences). The connective ف */f/then* is distinguished into EXPANSION.EXEMPLIFICATION, CONTINGENCY.CAUSE.RESULT and CONTINGENCY.CAUSE.REASON readings, depending on the lexemes around it, the parents of its arguments, and whether its argument 2 is tensed or not. Thus, nontensed arguments are most often nominalisations leading to a reason reading, whereas a verb phrase as argument 2 and a sentence as argument 1 often is a result reading. However, it is worth reporting that in cases of very high ambiguity, M2 is still far from perfect such as for connectives f ف /*f*/and اثر /*āṯr*.

Some improvements again come from generalised rules: there are some very high-coverage and high precision generalised rules that reduce dependency on the connective string. For example, clitic prepositions (such as ل /*l*/for) can without any further information be clearly classified as `Contingency.Cause.Reason.NonPragmatic` covering 494 occurrences with only 26 mistakes. These are cases where the following argument is normally Al-Masdar.

Our analysis leads us to the following strategy for follow-on work. First of all, a larger corpus is necessary to get more examples for low frequency connectives. Secondly, experiments with different classifiers are worthwhile to conduct to see how our improvements generalise. Third, the most mileage is in further improvements on frequent, ambiguous connectives such as ف /*f*, منذ /*mnḏ*and او /*āw*. This can be achieved with, on the one hand, training connective-specific classifiers on larger data sets but will, on the other hand, also need a wider feature base. From our corpus study, we think that lexico-semantic features such as word pairs and semantic classes of verbal/nominalised arguments are the most promising.

7 Conclusions and Future Work

We have presented the first study on the automatic detection and disambiguation of Arabic discourse connectives. A corpus study showed that these are highly frequent and more ambiguous than their English counterparts. Our automatic algorithms achieve very good results on discourse connective identification, using Arabic morphological properties to good effect. It is particular promising that we do not need parsed data to identify discourse usage of potential connectives reliably. Our algorithm for discourse connective interpretation beats the challenging baseline of assigning the most frequent relation per connective. In future, we will explore further features for connective disambiguation as well as connective-specific classification, combined with semi-supervised algorithms to alleviate data sparseness. We will also develop algorithms for argument identification.

Classifying Sentences as Speech Acts in Message Board Posts

Abstract

This research studies the text genre of message board forums, which contain a mixture of expository sentences that present factual information and conversational sentences that include communicative acts between the writer and readers. Our goal is to create sentence classifiers that can identify whether a sentence contains a speech act, and can recognize sentences containing four different speech act classes: *Commissives*, *Directives*, *Expressives*, and *Representatives*. We conduct experiments using a wide variety of features, including lexical and syntactic features, speech act word lists from external resources, and domain-specific semantic class features. We evaluate our results on a collection of message board posts in the domain of veterinary medicine.

1 Introduction

In the 1990's, the natural language processing community shifted much of its attention to corpus-based learning techniques. Since then, most of the text corpora that have been annotated and studied are collections of *expository text* (e.g., news articles, scientific literature, etc.). The intent of expository text is to present or explain information to the reader. In recent years, there has been a growing interest in text genres that originate from Web sources, such as weblogs and social media sites (e.g., tweets). These text genres offer new challenges for NLP, such as the need to handle informal and loosely grammatical text, but they also pose new opportunities to study discourse and pragmatic phenomena that are fundamentally different in these genres.

Message boards are common on the WWW as a forum where people ask questions and post comments to members of a community. They are typically devoted to a specific topic or domain, such as finance, genealogy, or Alzheimer's disease. Some message boards offer the opportunity to pose questions to domain experts, while other communities are open to anyone who has an interest in the topic.

From a natural language processing perspective, message board posts are an interesting hybrid text genre because they consist of both expository text and conversational text. Most obviously, the conversations appear as a thread, where different people respond to each other's questions in a sequence of posts. Studying the conversational threads, however, is not the focus of this paper. Our research addresses the issue of conversational pragmatics within individual message board posts.

Most message board posts contain both expository sentences as well as speech acts. The person posting a message (*the "writer"*) often engages in speech acts with the readers. The writer may explicitly greet the readers (*"Hi everyone!"*), request help from the readers (*"Anyone have a suggestion?"*), or commit to a future action (*"I promise I will report back soon."*). But most posts contain factual information as well, such as general knowledge or personal history describing a situation, experience, or predicament.

Our research goals are twofold: (1) to distinguish between expository sentences and speech act sentences in message board posts, and (2) to clas-

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 748–758,
Edinburgh, Scotland, UK, July 27–31, 2011.

sify speech act sentences into four types: *Commissives*, *Directives*, *Expressives*, and *Representatives*, following Searle's original taxonomy (Searle, 1976). Speech act classification could be useful for many applications. Information extraction systems could benefit from filtering speech act sentences (e.g., promises and questions) so that facts are only extracted from the expository text. Identifying *Directive* sentences could be used to summarize the questions being asked in a forum over a period of time. *Representative* sentences could be extracted to highlight the conclusions and beliefs of domain experts in response to a question.

In this paper, we present sentence classifiers that can identify speech act sentences and classify them as *Commissive*, *Directive*, *Expressive*, and *Representative*. First, we explain how each speech act class is manifested in message board posts, which can be different from how they occur in spoken dialogue. Second, we train classifiers to identify speech act sentences using a variety of lexical, syntactic, and semantic features. Finally, we evaluate our system on a collection of message board posts in the domain of veterinary medicine.

2 Related Work

There has been relatively little work on applying speech act theory to written text genres, and most of the previous work has focused on email classification. Cohen et al. (2004) introduced the notion of "email speech acts" defined as specific verb-noun pairs following a pre-designed ontology. They approached the problem as a document classification task. Goldstein and Sabin (2006) adopted this notion of email acts (Cohen et al., 2004) but focused on verb lexicons to classify them. Carvalho and Cohen (2005) presented a classification scheme using a dependency network, capturing the sequential correlations with the context emails using transition probabilities from or to a target email. Carvalho and Cohen (2006) later employed N-gram sequence features to determine which N-grams are meaningfully related to different email speech acts with a goal towards improving their earlier email classification based on the writer's intention.

Lampert et al. (2006) performed speech act classification in email messages following a verbal response modes (VRM) speech act taxonomy. They also provided a comparison of VRM taxonomy with Searle's taxonomy (Searle, 1976) of speech act classes. They evaluated several machine learning algorithms using syntactic, morphological, and lexical features. Mildinhall and Noyes (2008) presented a stochastic speech act model based on verbal response modes (VRM) to classify email intentions.

Some research has considered speech act classes in other means of online conversations. Twitchell and Jr. (2004) and Twitchell et al. (2004) employed speech act profiling by plotting potential dialogue categories in a radar graph to classify conversations in instant messages and chat rooms. Nastri et al. (2006) performed an empirical analysis of speech acts in the away messages of instant messenger services to achieve a better understanding of the communication goals of such services. Ravi and Kim (2007) employed speech act profiling in online threaded discussions to determine message roles and to identify threads with questions, answers, and unanswered questions. They designed their own speech act categories based on their analysis of student interactions in discussion threads.

The work most closely related to ours is the research of Jeong et al. (2009) on semi-supervised speech act recognition in both emails and forums. Like our work, their research also classifies individual sentences, as opposed to entire documents. However, they trained their classifier on spoken telephone (SWBD-DAMSL corpus) and meeting (MRDA corpus) conversations and mapped the labelled dialog act classes of these corpora to 12 dialog act classes that they found suitable for email and forum text genres. These dialog act classes (addressed as speech acts by them) are somewhat different from Searle's original speech act classes. They also used substantially different types of features than we do, focusing primarily on syntactic subtree structures.

3 Classifying Speech Acts in Message Board Posts

3.1 Speech Act Class Definitions

Searle's (Searle, 1976) early research on *speech acts* was seminal work in natural language processing that opened up a new way of thinking about con-

versational dialogue and communication. Our goal was to try and use Searle's original speech act definitions and categories as the basis for our work to the greatest extent possible, allowing for some interpretation as warranted by the WWW message board text genre.

For the purposes of defining and evaluating our work, we created detailed annotation guidelines for four of Searle's speech act classes that commonly occur in message board posts: *Commissives*, *Directives*, *Expressives*, and *Representatives*. We omitted the fifth of Searle's original speech act classes, *Declarations*, because we virtually never saw declarative speech acts in our data set.[1] The data set used in our study is a collection of message board posts in the domain of veterinary medicine. We designed our definitions and guidelines to reflect language use in the text genre of message board posts, trying to be as domain-independent as possible so that these definitions should also apply to message board texts representing other topics. However, we give examples from the veterinary domain to illustrate how these speech act classes are manifested in our data set.

Commissives: A *Commissive speech act* occurs when the speaker commits to a future course of action. In conversation, common Commissive speech acts are promises and threats. In message boards, these types of Commissives are relatively rare. However, we found many statements where the main purpose was to confirm to the readers that the writer would perform some action in the future. For example, a doctor may write *"I plan to do surgery on this patient tomorrow"* or *"I will post the test results when I get them later today"*. We viewed such statements as implicit commitments to the reader about intended actions. We also considered decisions not to take an action as Commissive speech acts (e.g., *"I will not do surgery on this cat because it would be too risky."*). However, statements indicating that an action will not occur because of circumstances beyond the writer's control were considered to be factual statements and not speech acts (e.g., *"I cannot do an ultrasound because my machine is broken."*).

Directives: A *Directive speech act* occurs when the speaker expects the listener to do something as a response. For example, the speaker may ask a question, make a request, or issue an invitation. Directive speech acts are common in message board posts, especially in the initial post of each thread when the writer explicitly requests help or advice regarding a specific topic. Many Directive sentences are posed as questions, so they are easy to identify by the presence of a question mark. However, the language in message board forums is informal and often ungrammatical, so many Directives are posed as a question but do not end in a question mark (e.g., *"What do you think."*). Furthermore, many Directive speech acts are not stated as a question but as a request for assistance. For example, a doctor may write *"I need your opinion on what drug to give this patient."* Finally, some sentences that end in question marks are rhetorical in nature and do not represent a Directive speech act, such as *"Can you believe that?"*.

Expressives: An *Expressive speech act* occurs in conversation when a speaker expresses his or her psychological state to the listener. Typical cases are when the speaker thanks, apologizes, or welcomes the listener. Expressive speech acts are common in message boards because writers often greet readers at the beginning of a post (*"Hi everyone!"*) or express gratitude for help from the readers (*"I really appreciate the suggestions."*). We also found Expressive speech acts in a variety of other contexts, such as apologies.

Representatives: According to Searle, a *Representative speech act* commits the speaker to the truth of an expressed proposition. It represents the speaker's belief of something that can be evaluated to be true or false. These types of speech acts were less common in our data set, but some cases did exist. In the veterinary domain, we considered sentences to be a Representative speech act when a doctor explicitly confirmed a diagnosis or expressed their suspicion or hypothesis about the presence (or absence) of a disease or symptom. For example, if a doctor writes that *"I suspect the patient has pancreatitis."* then this represents the doctor's own proposition/belief about what the disease might be.

Many sentences in our data set are stated as fact but could be reasonably inferred to be speech acts. For example, suppose a doctor writes *"The cat has*

[1] Searle defines Declarative speech acts as statements that bring about a change in status or condition to an object by virtue of the statement itself. For example, a statement declaring war or a statement that someone is fired.

pancreatitis.". It would be reasonable to infer that the doctor writing the post diagnosed the cat with pancreatitis. And in many cases, that is true. However, we saw many posts where that inference would have been wrong. For example, the following sentence might say *"The cat was diagnosed by a previous vet but brought to me due to new complications"* or *"The cat was diagnosed with it 8 years ago as a kitten in the animal shelter"*. Consequently, we were very conservative in labelling sentences as Representative speech acts. Any sentence presented as fact was not considered to be a speech act. A sentence was only labelled as a Representative speech act if the writer explicitly expressed his belief.

3.2 Features for Speech Act Classification

To create speech act classifiers, we designed a variety of lexical, syntactic, and semantic features. We tried to capture linguistic properties associated with speech act expressions as well as discourse properties associated with individual sentences and the message board post as a whole. We also incorporated speech act word lists that were acquired from external resources, and used two types of semantic features to represent semantic entities associated with the veterinary domain. Except for the semantic features, all of our features are domain-independent so should be able to recognize speech act sentences across different domains. We experimented with domain-specific semantic features to test our hypothesis that Commissive speech acts can be associated with domain-specific semantic entities.

For the purposes of analysis, we partition the feature set into three groups: *Lexical and Syntactic (LexSyn) Features*, *Speech Act Clue Features*, and *Semantic Features*. Unless otherwise noted, all of the features had binary values indicating the presence or absence of that feature.

3.2.1 Lexical and Syntactic Features

We designed a variety of features to capture lexical and syntactic properties of words and sentences. We described the feature set below, with the features categorized based on the type of information that they capture.

Unigrams: We created bag-of-word features representing each unigram in the training set. Numbers were replaced with a special # token.

Personal Pronouns: We defined three features to look for the presence of a 1st person pronoun, 2nd person pronoun, and 3rd person pronoun. We included the subjective, objective, and possessive form of each pronoun (e.g., *he*, *him*, and *his*).

Tense: Speech acts such as Commissives can be related to tense. We created three features to identify verb phrases that occur in the *past*, *present*, or *future* tense. To recognize tense, we followed the rules defined by Allen (1995).

Tense + Person: We created four features that require the presence of a first person subjective pronoun (I, we) within a two word window on the left of a verb phrase matching one of four tense representations: *past*, *present*, *future*, and *present progressive* (a subset of the more general *present* tense representation).

Modals: One feature indicates whether the sentence contains a modal (*may*, *must*, *shall*, *will*, *might*, *should*, *would*, *could*).

Infinitive VP: One feature looks for an infinitive verb phrase ('to' followed by a verb) that is preceded by a first person pronoun (I, we) within a three word window on the left. This feature tries to capture common Commissive expressions (e.g., *"I definitely plan to do the test tomorrow."*).

Plan Phrases: Commissives are often expressed as a plan, so we created a feature that recognizes four types of plan expressions: *"I am going to"*, *"I am planning to"*, *"I plan to"*, and *"My plan is to"*.

Sentence contains Early Punctuation: One feature checks for the following punctuation marks within the first three tokens of the sentence: , : ! This feature was designed to recognize greetings, such as: *"Hi,"* , or *"Hiya everyone !"*.

Sentence begins with Modal/Verb: One feature checks if a sentence begins with a modal or verb. The intuition is to capture interrogative and imperative sentences, since they are likely to be Directives.

Sentence begins with WH Question: One feature checks if a sentence begins with a WH question word (Who, When, Where, What, Which, What, How).

Neighboring Question: One feature checks whether the following sentence contains a question mark '?'. We observed that in message boards, *Directives* often occur in clusters.

Sentence Position: Four binary features represent the relative position of the sentence in the post. One feature indicates whether it is the first sentence, one feature indicates whether it is the last sentence, one feature indicates whether it is the second to last sentence, and one feature indicates whether the sentence occurs in the bottom 25% of the message. The motivation for these features is that Expressives often occur at the beginning and end of the post, and Directives tend to occur toward the end.

Number of Verbs: One feature represents the number of verbs in the sentence using four possible values: 0, 1, 2, >2. Some speech acts classes (e.g., Expressives) may occur with no verbs, and rarely occur in long, complex sentences.

3.2.2 Speech Act Word Clues

We collected speech act word lists (mostly verbs) from two external sources. In Searle's original paper (Searle, 1976), he listed words that he considered to be indicative of speech acts. We discarded a few that we considered to be overly general, and we added a few additional words. We also collected a list of speech act verbs published in (Wierzbicka, 1987). The details for these *speech act clue lists* are given below. Our system recognized all derivations of these words.

Searle Keywords: We created one feature for each speech act class. The Representative keywords were: (*hypothesize*, *insist*, *boast*, *complain*, *conclude*, *deduce*, *diagnose*, and *claim*). We discarded 3 words from Searle's list (*suggest*, *call*, *believe*) and added 2 new words, *assume* and *suspect*. The Directive keywords were: (*ask*, *order*, *command*, *request*, *beg*, *plead*, *pray*, *entreat*, *invite*, *permit*, *advise*, *dare*, *defy*, *challenge*). We added the word *please*. The Expressives keywords were: (*thank*, *apologize*, *congratulate*, *condole*, *deplore*, *welcome*). We added the words *appreciate* and *sorry*. Searle did not provide any hint on possible indicator words for Commissives, so we manually defined five likely Commissive keywords: (*plan*, *commit*, *promise*, *tomorrow*, *later*).

Wierzbicka Verbs: We created one feature that included 228 speech act verbs listed in the book *"English speech act verbs: a semantic dictionary"* (Wierzbicka, 1987)[2].

3.2.3 Semantic Features

All of the previous features are domain-independent and should be useful for identifying speech acts sentences across many domains. However, we hypothesized that semantic entities may correlate with speech acts within a particular domain. For example, consider medical domains. Representative speech acts may involve diagnoses and hypotheses regarding diseases and symptoms. Similarly, Commissive speech acts may reveal a doctor's plan or intention regarding the administration of drugs or tests. Thus, it may be beneficial for a classifier to know whether a sentence contains certain semantic entities. We experimented with two different sources of semantic information.

Semantic Lexicon: Basilisk (Thelen and Riloff, 2002) is a bootstrapping algorithm that has been used to induce semantic lexicons for terrorist events (Thelen and Riloff, 2002), biomedical concepts (McIntosh, 2010), and subjective/objective nouns for opinion analysis (Riloff et al., 2003). We ran Basilisk over our collection of 15,383 veterinary message board posts to create a semantic lexicon for veterinary medicine. As input, Basilisk requires seed words for each semantic category. To obtain seeds, we parsed the corpus using a noun phrase chunker, sorted the head nouns by frequency, and manually identified the 20 most frequent nouns belonging to four semantic categories: DISEASE/SYMPTOM, DRUG, TEST, and TREATMENT.

However, the induced TREATMENT lexicon was of relatively poor quality so we did not use it. The DISEASE/SYMPTOM lexicon appeared to be of good quality, but it did not improve the performance of our speech act classifiers. We suspect that this is due to the fact that diseases were not distinguised from symptoms in our lexicon.[3] Representative speech acts are typically associated with disease diagnoses

[2] `openlibrary.org/b/OL2413134M/English_speech_act_verbs`

[3] We induced a single lexicon for diseases and symptoms because it is difficult to draw a clear line between them semantically. A veterinary consultant explained to us that the same term (e.g., diabetes) may be considered a symptom in one context if it is secondary to another condition (e.g., pancreatitis) but a disease in a different context if it is the primary diagnosis.

and hypotheses, rather than individual symptoms.

In the end, we only used the DRUG and TEST semantic lexicon in our classifiers. We used all 1000 terms in the DRUG lexicon, but only used the top 200 TEST words because the quality of the lexicon seemed questionable after that point.

Semantic Tags: We also used bootstrapped contextual semantic taggers (Huang and Riloff, 2010) that had been previously trained for the domain of veterinary medicine. These taggers assign semantic class labels to noun phrase instances based on the surrounding context in a sentence. The taggers were trained on 4,629 veterinary message board posts using 10 seed words for each semantic category (see (Huang and Riloff, 2010) for details). To ensure good precision, only tags that have a confidence value ≥ 1.0 were used. Our speech act classifiers used the tags associated with two semantic categories: DRUG and TEST.

3.3 Classification

To create our classifiers, we used the Weka (Hall et al., 2009) machine learning toolkit. We used Support Vector Machines (SVMs) with a polynomial kernel and the default settings supplied by Weka. Because a sentence can include multiple speech acts, we created a set of binary classifiers, one for each of the four speech act classes. All four classifiers were applied to each sentence, so a sentence could be assigned multiple speech act classes.

4 Evaluation

4.1 Data Set

Our data set consists of message board posts from the Veterinary Information Network (VIN), which is a web site (www.vin.com) for professionals in veterinary medicine. Among other things, VIN hosts message board forums where veterinarians and other veterinary professionals can discuss issues and pose questions to each other. Over half of the small animal veterinarians in the U.S. and Canada use the VIN web site.

We obtained 15,383 VIN message board threads representing three topics: cardiology, endocrinology, and feline internal medicine. We did basic cleaning, removing html tags and tokenizing numbers. We then applied the Stanford part-of-speech tagger (Toutanova et al., 2003) to each sentence to obtain part-of-speech tags for the words. For our experiments, we randomly selected 150 message board threads from this collection. Since the goal of our work was to study speech acts in sentences, and not the conversational dialogue between different writers, we used only the initial post of each thread. These 150 message board posts contained a total of 1,956 sentences, with an average of 13.04 sentences per post. In the next section, we explain how we manually annotated each sentence in our data set to create gold standard speech act labels.

4.2 Gold Standard Annotations

To create training and evaluation data for our research, we asked two human annotators to manually label sentences in our message board posts. Identifying speech acts is not always obvious, even to people, so we gave them detailed annotation guidelines describing the four speech act classes discussed in Section 3.1. Then we gave them the same set of 50 message board posts from our collection to annotate independently. Each annotator was told to assign one or more speech act classes to each sentence (COM, DIR, EXP, REP), or to label the sentence as having no speech acts (NONE). The vast majority of sentences had either no speech acts or at most one speech act, but a small number of sentences contained multiple types of speech acts.

We measured the inter-annotator agreement of the two human judges using the kappa (κ) score (Carletta, 1996). However, kappa agreement scores are only applicable to labelling schemes where each instance receives a single label. Therefore we computed kappa agreement in two different ways to look at the results from two different perspectives. In the first scheme, we discarded the small number of sentences that had multiple speech act labels and computed kappa on the rest.[4] This produced a kappa score of .95, suggesting extremely high agreement. However, over 70% of the sentences in our data set have no speech act at all, so NONE was by far the most common label. Consequently, this agreement score does not necessarily reflect how consistently the judges agreed on the four speech act classes.

[4]Of the 594 sentences in these 50 posts, only 22 sentences contained multiple speech act classes.

In the second scheme, we computed kappa for each speech act category independently. For each category C, the judges were considered to be in agreement if both of them assigned category C to the sentence or if neither of the judges assigned category C to the sentence. Table 1 shows the κ agreement scores using this approach.

Speech Act	Kappa (κ) score
Expressive	.97
Directive	.94
Commissive	.81
Representative	.77

Table 1: Inter-annotator (κ) agreement

Inter-annotator agreement was very high for both the Expressive and Directive classes. Agreement was lower for the Commissive and Representative classes, but still relatively good so we felt comfortable that we had high-quality annotations.

To create our final data set, the two judges adjudicated their disagreements on this set of 50 posts. We then asked each annotator to label an additional (different) set of 50 posts each. All together, this gave us a gold standard data set consisting of 150 annotated message board posts. Table 2 shows the distribution of speech act labels in our data set. 71% of the sentences did not include any speech acts. These were usually expository sentences containing factual information. 29% of the sentences included one or more speech acts, so nearly $\frac{1}{3}$ of the sentences were conversational in nature. Directive and Expressive speech acts are by far the most common, with nearly 26% of all sentences containing one of these speech acts. Commissive and Representative speech acts are less common, each occurring in less than 3% of the sentences.[5]

4.3 Experimental Results

4.3.1 Speech Act Filtering

For our first experiment, we created a *speech act filtering classifier* to distinguish sentences that contain one or more speech acts from sentences that do not contain any speech acts. Sentences labelled as having one or more speech acts were positive instances, and sentences labelled as NONE were negative instances. Speech act filtering could be useful for many applications, such as information extraction systems that only seek to extract facts. For example, information may be posed as a question (in a Directive) rather than a fact, information may be mentioned as part of a future plan (in a Commissive) that has not actually happened yet, or information may be stated as a hypothesis or suspicion (in a Representative) rather than as a fact.

Speech Act	# sentences	distribution
None	1397	71.42%
Directive	311	15.90%
Expressive	194	9.92%
Representative	57	2.91%
Commissive	51	2.61%

Table 2: Speech act class distribution in our data set.

We performed 10-fold cross validation on our set of 150 annotated message board posts. Initially, we used all of the features defined in Section 3.2. However, during the course of our research we discovered that only a small subset of the lexical and syntactic features seemed to be useful, and that removing the unnecessary features improved performance. So we created a subset of *minimal lexsyn features*, which will be described in Section 4.3.2. For speech act filtering, we used the *minimal lexsyn features* plus the speech act clues and semantic features.[6]

Class	P	R	F
Speech Act	.86	.83	.84
No Speech Act	.93	.95	.94

Table 3: Precision, Recall, F-measure for speech act filtering.

Table 3 shows the performance for speech act filtering with respect to Precision (P), Recall (R), and F-measure score (F).[7] The classifier performed well, recognizing 83% of the speech act sentences with 86% precision, and 95% of the expository (no

[5]These numbers do not add up to 100% because some sentences contain multiple speech acts.

[6]This is the same feature set used to produce the results for row E of Table 4.

[7]We computed an F1 score with equal weighting of precision and recall.

	Features	Commissives			Directives			Expressives			Representatives		
		P	R	F	P	R	F	P	R	F	P	R	F

speech act) sentences with 93% precision.

4.3.2 Speech Act Categorization

BASELINES

Our next set of experiments focused on labelling sentences with the four specific speech act classes: *Commissive*, *Directive*. *Expressive*, and *Representative*. To assess the difficulty of identifying each speech act category, we created several simple baselines using our intuitions about each category.

For Commissives, we created a heuristic to capture the most obvious cases of future tense (because Commissive speech acts represent a writer's commitment toward a future course of action). For example, the presence of the phrases 'I will' and 'I shall' were hypothesized by Cohen et al. (2004) to be useful bigram clues for Commissives. This baseline looks for future tense verb phrases with a 1st person pronoun within one or two words preceding the verb phrase. The **Com** baseline row of Table 4 shows the results for this heuristic, which obtained 8% recall with 45% precision. The heuristic applied to only 9 sentences in our test set, 4 of which contained a Commissive speech act.

Directive speech acts are often questions, so we created a baseline system that labels all sentences containing a question mark as a Directive. The **Dir** baseline row of Table 4 shows that 97% of sentences with a question mark were indeed Directives.[8] But only 73% of the Directive sentences contained a question mark. The remaining 27% of Directives did not contain a question mark and generally fell into two categories. Some sentences asked a question but the writer ended the sentence with a period (e.g., *"Has anyone seen this before."*). And many directives were expressed as requests rather than questions (e.g., *"Let me know if anyone has a suggestion."*).

For Expressives, we implemented two baselines. **Exp** baseline 1 simply looks for an exclamation mark, but this heuristic did not work well (18% recall with 58% precision) because exclamation marks were often used for general emphasis (e.g., *"The owner is frustrated with cleaning up urine!"*). **Exp** baseline 2 looks for the presence of four common expressive words (*appreciate*, *hi*, *hello*, *thank*), including morphological variations of *appreciate* and *thank*. This baseline produced very good results, 86% recall with 97% precision. Obviously a small set of common expressions account for most of the Expressive speech acts in our corpus. However, the word "hi" did produce some false hits because it was used as a shorthand for "high", usually when reporting test results (e.g., *"hi calcium"*).

[8] 235 sentences contained a question mark, and 227 of them were Directives.

Finally, as a baseline for the Representative class we simply looked for the words *diagnose(d)* and *suspect(ed)*. The **Rep** baseline row of Table 4 shows that this heuristic was 100% accurate, but only produced 5% recall (matching 3 of the 57 Representative sentences in our test set).

CLASSIFIER RESULTS

The bottom portion of Table 4 shows the results for our classifiers. As we explained in Section 3.3, we created one classifier for each speech act category, and all four classifiers were applied to each sentence. So a sentence could receive anywhere from 0-4 speech act labels indicating how many different types of speech acts appeared in the sentence. We trained and evaluated each classifier using 10-fold cross-validation on our gold standard data set.

The *Unigram (U)* row shows the performance of classifiers that use only unigram features. For Directives, we see a 2% F-score improvement over the baseline, which reflects a recall gain of 11% but a corresponding precision loss of 10%. The unigrams are clearly helpful in identifying many Directive sentences that do not end in a question mark, but at some cost to accuracy. For Expressives, the unigram classifier achieves an F score of 92%, identifying slightly more Expressive sentences than the baseline with the same level of precision. For Commissives and Representatives, the unigram classifiers performed susbtantially better than their corresponding baseline systems, but performance is still relatively weak.

Row A (*U+ all lexsyn*) in Table 4 shows the results using unigram features plus all of the lexical and syntactic features described in Section 3.2.1. The lexical and syntactic features dramatically improve performance on Commissives, increasing F score from 27% to 40%, and they produce a 2% recall gain for Representatives but with a corresponding loss of precision.

However, we observed that only a few of the lexical and syntactic features had much impact on performance. We experimented with different subsets of the features and obtained even better performance when using just 10 of them, which we will refer to as the *minimal lexsyn* features. The *minimal lexsyn* feature set consists of the 4 Tense+Person features, the Early Punctuation feature, the Sentence begins with Modal/Verb feature, and the 4 Sentence Position features. Row B shows the results using unigram features plus only these *minimal lexsyn* features. Precision improves for Commissives by an additional 7% and Representatives by 2% when using only these lexical and syntactic features. Consequently, we use the *minimal lexsyn* features for the rest of our experiments.

Row C shows the results of adding the speech act clue words (see Section 3.2.2) to the feature set used in Row B. The speech act clue words produced an additional recall gain of 3% for Expressives and 2% for Representatives, although performance on Commissives dropped 2% in both recall and precision.

Rows D and E show the results of adding the semantic features. We added one semantic category at a time to measure the impact of them separately. Row D adds two semantic features for the TEST category, one from the Basilisk lexicon and one from the semantic tagger. The TEST semantic features produced an F-score gain of 5% for Commissives, improving recall by 4% and precision by 7%. Row E adds two semantic features for the DRUG category. The DRUG features produced an additional F-score gain of 2% for Commissives, improving recall by 4% with a slight drop in precision.

4.4 Analysis

Together, the TEST and DRUG semantic features dramatically improved the classifier's ability to recognize Commissive speech acts, increasing its F score from 41% $\rightarrow$ 48%. This result demonstrates that in the domain of veterinary medicine, some types of semantic entities are associated with speech acts. Our intuition behind this result is that commitments are usually related to future actions. In veterinary medicine, TESTS and DRUGS are associated with actions performed by doctors. Doctors help their patients by prescribing or administering drugs and by conducting tests. So these semantic entities may serve as a proxy to implicitly represent actions that the doctor has done or may do. In future work, explicitly recognizing actions and events many be a worthwhile avenue to further improve results.

We achieved good success at identifying both Directives and Expressives, although simple heuristics also perform well on these categories. We showed that training a Directive classifier can help to iden-

tify Directive sentences that do not end with a question mark, although at the cost of some precision.

The Commissive speech act class benefitted the most from the rich feature set. Unigrams are clearly not sufficient to identify Commissive sentences. Many different types of clues seem to be important for recognizing these sentences. The improvements obtained from adding semantic features also suggests that domain-specific semantics can be useful for recognizing some speech acts. However, there is still ample room for improvement, illustrating that speech act classification is a challenging problem.

Representative speech acts were by far the most difficult to recognize. We believe that there are several reasons for their low performance. First, Representatives were sparse in the data set, occurring in only 2.91% of the sentences. Consequently, the classifier had relatively few positive training instances. Second, Representatives had the lowest inter-annotator agreement, indicating that human judges had difficulty recognizing these speech acts too. The judges often disagreed about whether a hypothesis or suspicion was the writer's own belief or whether it was stated as a fact reflecting general medical knowledge. The message board text genre is especially challenging in this regard because the writer is often presumed to be expressing his/her beliefs even when the writer does not explicitly say so. Finally, our semantic features could not distinguish between diseases and symptoms. Access to a resource that can reliably identify disease terms could potentially improve performance in this domain.

5 Conclusions

Our goal was to identify speech act sentences in message board posts and to classify the sentences with respect to four categories in Searle's (1976) speech act taxonomy. We achieved good results for speech act filtering and the identification of Directive and Expressive speech act sentences. We found that Representative and Commissive speech acts are much more difficult to identify, although the performance of our Commissive classifier substantially improved with the addition of lexical, syntactic, and semantic features. Except for the semantic class information, our feature set is domain-independent and could be used to recognize speech act sentences in message boards for any domain. Furthermore, our features only rely on part-of-speech tags and do not require parsing, which is of practical importance for text genres such as message boards that are littered with ungrammatical text, typos, and shorthand notations.

In future work, we believe that segmenting sentences into clauses may help to train classifiers more precisely. Ultimately, we would like to identify the speech act expressions themselves because some sentences contain speech acts as well as factual information. Extracting the speech act expressions and clauses from message boards and similar text genres could provide better tracking of questions and answers in web forums and be used for summarization.

Learning Local Content Shift Detectors from Document-level Information

Richárd Farkas
Institute for Natural Language Processing
University of Stuttgart
farkas@ims.uni-stuttgart.de

Abstract

Information-oriented document labeling is a special document multi-labeling task where the target labels refer to a specific information instead of the topic of the whole document. These kind of tasks are usually solved by looking up indicator phrases and analyzing their local context to filter false positive matches. Here, we introduce an approach for machine learning *local content shifters* which detects irrelevant local contexts using just the original document-level training labels. We handle content shifters in general, instead of learning a particular language phenomenon detector (e.g. negation or hedging) and form a single system for document labeling and content shift detection. Our empirical results achieved 24% error reduction – compared to supervised baseline methods – on three document labeling tasks.

1 Introduction

There are special document multi-labeling tasks where the target labels refer to a specific piece of information extractable from the document instead of the overall topic of the document. In these kinds of tasks the target information is usually an attribute or relation related to the target entity (usually a person or an organisation) of the document in question, but the task is to assign class labels at the document (entity) level. For example, the smoking habits of the patients are frequently discussed in the textual parts of clinical notes (Uzuner et al., 2008). In this case the task is to find specific information in the text – i.e. the patient in question is a smoker, past smoker, non-smoker – but at the end an application has to assign labels to the documents(patients). Similarly, the soccer club names where a sportsman played for are document(sportman)-level labels in Wikipedia articles expressed by the Wikipedia categories. The target information in these tasks is usually just mentioned in the document and much of the document is irrelevant for this information request in contrast to standard document classification tasks where the goal is to identify the topics of the whole document. On the other hand, they are not a standard information extraction task as the task is to assign class labels to documents, and the training dataset contains labels just at this level. These special tasks lie somewhere between information extraction and document classification and require special approaches to solve them. We will call them *Information-oriented document labeling* throughout this paper. There are several application areas where information-oriented document labels are naturally present in an enormous amount like clinical records, Wikipedia categories and user-generated tags of news.

Previous evaluation campaigns (Uzuner et al., 2008; Pestian et al., 2007; Uzuner, 2009) demonstrated that information-oriented document labeling can be effectively performed by looking up *indicator phrases* which can be gathered by hand, by corpus statistics or in a hybrid way. However these campaigns also highlighted that the analysis of the *local context* of the indicator phrases is crucial. For instance, in the smoking habit detection task there are a few indicator words (e.g. *smokes*, *cigarette*) and the local context of their occurrences in texts should

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 759–770,
Edinburgh, Scotland, UK, July 27–31, 2011.

be analysed to see whether their semantic was radically changed (e.g. they are negated or in a past tense), for instance:

> *The patient has a 20 pack-year smoking history.*
>
> *The patient denies any smoking history.*
>
> *He has a greater than 100 pack year smoking history and quit 9 to 10 years ago.*

We propose a simple but efficient approach for information-oriented document labeling tasks by addressing the automatic detection of language phenomena for a particular task which alters the sense or information content of the indicator phrase's occurrences. For example, they may be logical modifiers (e.g. negation) or modal modifiers (e.g. auxiliaries like *might* and *can*); they may refer to a subject which differs from the target entity of the task (e.g. clinical notes usually contain information about the family history of the patient); or the semantic content of the shifter may change the role of the target span of a text (e.g. a sportsman can play *for* or *against* a particular team). We call these phenomena *content shifters* and the task of identifying them *content shift detection (CSD)*.

Existing CSD approaches focus on a particular class of language phenomena (especially negation or hedging) and use hand-crafted rules (Chapman et al., 2007) or a supervised learning approach that exploits corpora manually annotated at the token-level for a particular type of content shifter (Morante et al., 2009). Moreover higher level applications (like document labeling and information extraction) use a separate CSD module which is developed independently from the target task. We argue that the nature of content shifters is domain and task dependent, so training corpora (at the token-level) are required for content shifters which are important for a particular task but the construction of such training corpora is expensive. Here, we propose an alternative approach which uses only document-level labels.

The input of our system is a training corpus labeled on the document level (e.g. a clinical dataset consisting clinical notes and meta-data about patients). Our approach extracts indicator phrases and trains a CSD jointly. We focus on local content shifters and we analyse just the sentences of indicator phrase occurrences. Our chief assumption is that CSD can be learnt by exploiting the false positive occurrences of indicator phrases in the training dataset. We show that our method performs significantly better than standard document classifiers (which were designed for a slightly different task).

The chief contributions of our work are that (i) we handle the CSD problem in general, so we detect all content shifters instead of focusing on one particular language phenomenon, (ii) we form a single framework for joint CSD and document labeling, (iii) moreover our approach does not require a dedicated annotated training dataset for content shifters.

2 Related Work

Information-oriented document classification tasks were first highlighted in the clinical domain where medical reports contain useful information about the patient in question, but labels are only available at the document (patient) level. The field of clinical NLP has been studied extensively since the 1990s (Larkey and Croft, 1995), but the most recent results are related to the shared task challenges organized relatively recently (Pestian et al., 2007; Uzuner et al., 2008; Uzuner, 2009). For example the first I2B2 challenge in 2006 (Uzuner et al., 2008) focused on the smoking habits of the patient, the CMC challenge in 2007 (Pestian et al., 2007) dealt with the problem of automatically constructing ICD coding systems and the second I2B2 challenge (Uzuner, 2009) addressed the classification of discharge summaries according to the question "Who's obese and what co-morbidities do they have?". These challenges were dominated by entirely or partly rule-based systems that solved the tasks using indicator phrase lookup and incorporated explicit mechanisms for detecting speculation and negation.

Another domain for information-oriented document classification might be Wikipedia, which contains rich information about entities like persons, places or organisations. Some items of information are available about these entities in the form of categories and infoboxes assigned to articles. Automatic document labeling methods can be trained based on these assignments (Schönhofen, 2006), but these labels do not refer to the main theme of the article but

to a certain type of information.

Existing content shift detection approaches focus on a particular class of language phenomena, especially on negation and hedge recognitions. Available tools work mainly on clinical and biological domains. The first systems were fully hand-crafted (Light et al., 2004; Friedman et al., 1994; Chapman et al., 2007) without any empirical evaluation on a dedicated corpus. Recently, there have been several corpora published with manual sentence-, event- or token-level annotation for negation, certainty and factuality in the biological (Medlock and Briscoe, 2007; Vincze et al., 2008), newswire (Strassel et al., 2008; Sauri and Pustejovsky, 2009) and encyclopedical (Farkas et al., 2010) domains.

Exploiting these corpora, machine learning models were also developed. Solving the sentence-level task, Medlock and Briscoe (2007) used single words as input features in order to classify sentences from biological articles as speculative or non-speculative. Szarvas (2008) extended their methodology to use n-gram features and a semi-supervised selection of the keyword features. Ganter and Strube (2009) proposed an approach for the automatic detection of sentences containing uncertainty based on Wikipedia weasel tags and syntactic patterns. For in-sentence negation and speculation detection, Morante et al. (2009) developed scope – i.e. content shifted text spans – detectors for negation and speculation following a supervised sequence labeling approach, while Özgür and Radev (2009) developed a rule-based system that exploits syntactic patterns. The goal of the CoNLL 2010 Shared Task (Farkas et al., 2010) was to develop linguistic scope detectors as well. The participants usually followed a supervised sequence labeling approach or used a rule-based system that exploits syntactic patterns. The approach of classifying identified events into whether they fall under negation or speculation was followed by Sauri and Pustejovsky (2009) and the participants of the BioNLP'09 Shared Task (Kim et al., 2009). Here the systems investigated the syntax path between the event trigger and a cue word (which came from a small lexicon) (Kilicoglu and Bergler, 2009; Aramaki et al., 2009).

Our approach differs from the previous works fundamentally. We deal with the two tasks (information-oriented document classification and content shift detection) together and introduce a co-learning approach for them. Our approach handles content shifters in a data-driven and generalized way i.e. it is not specialized for a certain class of language phenomena. Instead it tries to recognize task-specific syntactic and semantic patterns which are responsible for semantic changes or irrelevance. In addition, we have no access to a gold-standard sentence-level or in-sentence-level annotation but exploit document-level ones.

3 Tasks and Datasets

Before introducing our approach in detail we describe three tasks and datasets which were used in our experiments in order to give an insight into the challenges of the information-oriented document labeling tasks. Table 1 summarizes the key statistical figures (the number of documents in the corpora, the size of the label sets along with the average number of tokens and label assignments per document) of the datasets used for the experimental evaluations.

Table 1: The datasets used in our experiments.

	CMC	Obes	Soccer
domain	clinical	clinical	encycl.
|train|	978	730	4850
|eval|	976	507	1736
#token/d	25	1387	389
#labels	45	16	12
#label/d	1.24	4.37	1.23

The CMC ICD Coding Dataset was originally prepared for a shared task challenge organized by the Computational Medicine Center (CMC) in Cincinatti, Ohio in 2007 (Pestian et al., 2007). It contains radiology reports along with document-level International Classification of Diseases (ICD) codes given by three human experts. ICD is a coding of diseases, signs, symptoms and abnormal findings. In our experiments we used the train/evaluation split of the shared task. The ICD coding guide states that negative or uncertain diagnosis should not be coded in any case.

The corpus contains very short documents. For instance, the document

HISTORY: Left lower chest pain. Rule-out

pneumonia. IMPRESSION: Normal chest.

has one label *786.50 (cough)* as *486 (pneumonia)* is ruled out.

The main conclusion of the shared task in 2007 was that simple rule-based systems generally outperform bag-of-words-based machine learning models. The rules were extracted from ICD guidelines and/or from the training corpus using simple statistical measures, then they were checked or extended manually. Several systems of the challenge employed a negation and speculation detection submodule. The (manually highly fine-tuned) top systems of the CMC shared task achieved an F-measure of 88-89 (Pestian et al., 2007; Farkas and Szarvas, 2008).

The I2B2 Obesity Dataset was also the subject of a clinical natural language processing shared task. The challenge in 2008 focused on analyzing clinical discharge summary texts and addressed the following question: "Who is obese and what co-morbidities do they have?" (Uzuner, 2009). Target diseases (document labels) included obesity and its 15 most frequent co-morbidities exhibited by patients. In our experiments, we used the same train/evaluation split as that of the shared task. Here a special aspect of the corpus is that the documents are semi-structured, i.e. they contain headings like *discharge medications* and *admit diagnosis*. By pasting the given heading to the beginning of each sentence, we incorporated it into the local context. The top performing systems of the shared task employed mostly hand-crafted rules for indicator selection and for negation and uncertainty detection as well. They achieved an F-measure[1] of 96-97 (Uzuner, 2009; Solt et al., 2009).

Wikipedia Soccer Dataset. We constructed a corpus based on Wikipedia articles and categories[2]. The categories assigned to Wikipedia articles can be regarded as labels (for example, the labels of *David Beckham* in the Wikipedia are *English people*, *expatriate soccer player*, *male model* and *A.C. Milan player*, *Manchester United player*). Based on the categories of Wikipedia, classifiers can be trained to tag unlabeled texts or even add missing category assignments to Wikipedia (Schönhofen, 2006).

For a case study we focused on learning English soccer clubs that a given sportsman played for. Note that this task is an information-oriented document labeling task as the clubs for which a sportsman played are usually just mentioned (especially for smaller clubs) in the article of a player. The Wikipedia category *Footballers in England by club* contains 408 subcategories (for the present and past). We selected the best known clubs (where the category label for the club is assigned to more than 500 player pages). Each article referring to a player having a category assignment to these clubs was downloaded and the textual parts were extracted. Then a random 3:1 train:evaluation split of the document set was used.

4 Document-labeling with CSD

We introduce here an iterative solution which selects indicator phrases and trains a content shift detector at the same time. Our focus will be on *multi-label document classification* tasks where multiple class labels can be assigned to a single document. In this study we will not deal with the modeling of inter-label dependencies, so binary (positive versus negative) and multi-class document classifications (where exactly one label has to be assigned to a single document) can be regarded as special cases of this multi-label classification problem. Our resulting multi-label model is then a set of binary classifiers – "assign a label" classifiers for each class label – and the final prediction on a document is simply the union of the labels forecasted by the individual classifiers.

Our key assumption in the multi-label environment is that while indicator phrases have to be selected on a per class basis, the content shifters can be learnt in a class-independent (aggregated) way i.e. we can assume that within one task, each class label belongs to a given semantic domain (determined by the task), thus the content shifters for their indicator phrases are the same. This approach provides an adequate amount of training samples for content shift detector learning.

[1] Using the definitions of the challenge, the evaluation metric applied here is the micro F-measure of the textual task on the YES versus every other class.

[2] The dataset is available as the supplementary material.

Table 2: Example feature representation of local contexts of *Arsenal*. The prefix NP stands for the lemma features from the deepest noun phrase; D,DR and DEP marks the lemmas, roles and their combination in the dependency path, respectively; SUBJ and SUBJD denote the lemmas and dependency roles on the "subject path", respectively.

His brother, Paul had a long career at Newcastle. (sentenceId=1, indicator=Newcastle)	
bag-of-word features	syntax-based features
he, brother, Paul, have, a, long, career, at	NP#a, NP#long, NP#career, NP#at D#career, D#have, DR#prepat, DR#dobj, DEP#career#prepat, DEP#have#dobj SUBJ#brother, SUBJ#Paul, SUBJ#he, SUBJD#he#poss
He was born in Gosforth, Newcastle and played for Arsenal. (sentenceId=2, indicator=Arsenal)	
bag-of-word features	syntax-based features
he, be, bear, in, Gosforth, Newcastle, and, play, for	D#play, DR#prepfor, DEP#play#prepfor SUBJ#he

4.1 Learning Content Shift Detectors

The key idea behind our approach is that a training corpus for task-specific content shifter learning can be automatically generated by exploiting the occurrences of indicators in various contexts. The local context of an indicator is assumed to have altered if it yields a false positive document-level prediction. More precisely, a training dataset can be constructed for learning a content shift detector in a way that the instances are the local contexts of each occurrence of indicator phrases in the training document set. The instances of this content shifter training dataset are then labeled as `non-altered` when the indicated label is among the gold-standard labels of the document in question or is labeled as `altered` otherwise. On this dataset, arbitrary binary classification models (S) can be trained.

As a feature representation of a local context of an indicator phrase, the bag-of-words of the sentence instance (excluding the indicator phrase itself) was used at the beginning. Our preliminary experiments showed that the tokens of the sentence after the indicator played a negligible role, hence we represented contexts just by tokens before the indicator.

Features concerning the syntactic context of the given indicator were also investigated. For this, we extended the feature set with features derived from the constituent and dependency parses of the sentence[3]. First, the deepest noun phrase which includes the indicator phrase was identified, then all lemmas from its subtree were gathered. From the dependency parse, the lemmas and dependency labels on the directed path from the indicator to the root node (main path) were extracted. The directed paths branching from this main path starting with `subject` dependency were also used for feature extraction (note that these walk in opposite direction to that of the main path). The intuition of the latter was that the subject of the given information – as it can differ from the target entity of extraction – is of great importance. We note that we recognize the in-sentence subject and employing a co-reference module would probably increase the value of these features.

Table 2 exemplifies the feature representation of local contexts of the *Newcastle* and *Arsenal* indicators for the Wikipedia soccer task. In both sentences, a naive system would extract *Newcastle* as false positives. We want to learn content shifters from them along with the true positive match of *Arsenal* in sentence 2. From the first example the CSD could learn even that the bag-of-word contains *brother* or the `SUBJ=`*brother*. However, in the second example, the bag-of-word representation is not sufficient to learn that the local context of *Newcastle* is `altered` because it is the subset of the bag-of-word representation of *Arsenal*'s `non-altered` local context. In this case the syntactic context representation can help and in our CSD `DEP=`*play#prepfor* gets high weight for the `non-altered` class.

[3]We parse only the sentences which contain indicator phrase which makes these features computable in reasonable time even on bigger document sets.

4.2 Co-learning of Indicator Selection and CSD

If document labels are available at training time, an iterative approach can be used to learn the local content shift detector and the indicator phrases as well. The training phase of this procedure (see Algorithm 1) has two outputs, namely the set of indicator phrases for each label I and the content shift detector S which is a binary function for determining whether the sense of an indicator in a particular local context is being altered. Good indicator phrases are those that identify the class label in question when they are present. In each step of the iteration we select indicator phrases $I[l]$ for each label l based on the actual state of the document set D'. Using these $I[l]$s we train a CSD S. Then we apply it to the original dataset D and we delete each local context from the documents which was predicted to be altered by S.

Algorithm 1 Co-learning of labels and CSD

Input: L class labels, D labeled training documents
  $D' \leftarrow D$
  repeat
    for all $l \in L$ **do**
      $I[l] \leftarrow$ indicatorSelection(D', l)
    end for
    $S \leftarrow$ learnCSD(D', I)
    $D' \leftarrow$ removeAlteredParts(D, S)
  until convergence
  return I, S

The indicator selection and content shifter learning phases can form an iterative process. The better the selected indicators are, the better the content shift detectors can be learnt. By applying the content shift detector to each token of the documents, each part of the texts lying within the scope of a content shifter can be removed[4]. By using such a cleaned training document set (D'), better indicators can be selected. These steps can be repeated until some convergence criterion is reached. In our experiments we simply used a fixed iteration number to gain an insight into the behavior of the approach.

[4]In our first experiments introduced here, we removed the parts of the documents classified as altered. Instead of removing these parts they may be marked and then different features may be extracted from them.

Algorithm 2 Document labeling with CSD

Input: d document, I indicator sets, S CSD
  pred $\leftarrow \emptyset$
  for all $l \in L$ **do**
    for all $o \in$ occurrences($d, I[l]$) **do**
      if not altered(o, S) **then**
        pred $\leftarrow$ pred $\cup\, l$
      end if
    end for
  end for
  return pred

The prediction procedure of the approach (see Algorithm 2) then looks for occurrences of the indicator phrases in the text and checks whether they are altered in a certain local context. A non-altered indicator directly assigns a class label without any global consistency check on assigned labels.

We note here, that the local relationship among tokens (i.e. the local context) may be taken into account by incorporating this information directly into the feature space of a document classifier (as an alternative of our co-learning procedure), but the number of features would exponentially increase and submodels for each indicator phrases should be learnt which would made such a classification task intractable.

4.3 Indicator Phrase Selection

Indicator phrases are sequences of tokens whose presence implies the positive class. We aimed to extract phrases with the length of 1,2 or 3 (and we used exact matching after lemmatisation). There are several possible ways of developing indicator selection algorithms. One way is to treat it as a special feature selection procedure where the goal is to select a set of features (uni-, bi-, trigrams of a bag-of-word model) which achieves high recall along with moderate precision as false positives are expected to be eliminated by the local CSD in our two-step approach. Indicator selectors can be even derived from most classifiers which are based on feature weighting (like MaxEnt and AvgPerceptron) or feature ranking (like rule-based classifiers)[5] as well. However indicator selection is not the focus of this

[5]A derivation is more complicated or unfeasible for example-based classifiers like SVMs.

Table 3: Results obtained for local content shift detection in a precision/recall/F-measure format.

		CMC	Obesity	Soccer
Trained	BoW	90.7 / 60.7 / 72.7	82.1 / 35.4 / 49.4	75.0 / 70.6 / 72.7
	BoW+syntactic	88.3 / 60.2 / 71.6	84.4 / 33.3 / 47.8	81.0 / 78.9 / 79.9
Hand-crafted	CSSDB	94.7 / 53.3 / 68.2	42.0 / 57.9 / 48.7	36.8 / 9.8 / 15.5
	in-sentence	80.7 / 65.2 / 72.2	70.5 / 40.5 / 51.5	N/A

work.

For our experiments, a feature evaluation-based greedy algorithm was employed to select the set of indicators from the pool of token uni- and bigrams. The aim of the the indicator selection here is to cover each positive documents while introducing a relatively small amount of false positives. The greedy algorithm iteratively selects the 1-best phrase according to a feature evaluation metric based on the actual state of covered documents and adds it to the indicator phrase set. The process is iterated while the score – in terms of the applied feature evaluation metric – of the 1-best phrase is above a threshold t. The quality of the selected indicator set is highly dependent on the stopping threshold t, but as individual feature evaluation functions are very fast and the number of good indicators is usually low (4-5), the whole greedy indicator selection is fast, hence t can be fine-tuned without overfitting on the training sets employing a cross-validation procedure. As a feature evaluation metric we employed $p(+|f)$ the probability of the positive class "+" conditioned on the presence of a feature f because preliminary experiments did not show any significant advances for more complex metrics.

5 Experiments

Experiments were carried out on the three datasets introduced in Section 3 with local content shift detection as an individual task and also to investigate its added value to information-oriented document labeling.

In our experiments, we applied the sentence splitter and lemmatizer implementation of the MorphAdorner package[6] and the Stanford tokenizer and lexicalized PCFG parser (Klein and Manning, 2003)[7].

5.1 Content Shifter Learning Results

In order to evaluate content shift detection as an individual task, a set of indicator phrases have to be fixed as an input to the CSD. We used manually collected indicator phrases for each label for each dataset. We utilized the terms of Farkas and Szarvas (2008) and Farkas et al. (2009) collected for the CMC and Obesity datasets, respectively and club names for the Soccer dataset in our first branch of experiments. Note that the clinical term sets here have been manually fine-tuned as they were developed for participating systems of the shared tasks of the corpora.

Based on the occurrences of these fixed indicator phrases, CSD **train**ing datasets were built from the local contexts of the three datasets and binary classification was carried out by using MaxEnt. Table 3 shows the results achieved by the learnt CSDs using the bag-of-word feature representation (row 1) along with the ones obtained by the feature set that was extended with syntactic patterns (raw 2). Here, the precision/recall/F-measure values measure how many false positive matches of the indicator phrases can be recognized (the F-measure of the `altered` class), i.e. here, the true positives are local contexts of an indicator phrase which do not indicate a document label in the evaluation set and the local content shift detector predicted it to be `altered`.

For comparison purposes, we employed **manually developed CSDs** which were fine-tuned for the medical shared task datasets. Row 3 of Table 3 (we refer to it as *content shifted sentence detection baseline (CSSDB)* later on) shows the results archived by the method which predicts every sentence to be `altered` which contain any *cue phrases* for negation, modality and different experiencer. Note that off-the-shelf tools are available just for these types of content shifters. We collected cue phrases for such a content shifted sentence detection from the

[6] `morphadorner.northwestern.edu/`

[7] The JAVA implementation of the entire framework and dataset adapters can be found as the supplementary material

works of Chapman et al. (2007), Light et al. (2004) and Vincze et al. (2008) and from the experiments of Farkas and Szarvas (2008) and Farkas et al. (2009).

For the CMC and Obesity tasks, hand-crafted in-sentence CSDs were also available (Farkas and Szarvas, 2008; Farkas et al., 2009), i.e. they apply heuristics – which usually tries to recognise clause boundaries – for determining the scope of a negaton/modality cue. This CSD is more fine-grained than the sentence-level one as here a part of a sentence can be detected as `altered` while other parts as `non-altered`. The results of these detectors – two different CSDs, both highly fine-tuned for the corresponding shared task – are listed in the last row of Table 3.

On the CMC dataset, our machine learning approach identified mostly negation and speculation expressions as **content shifters**; the top weighted features for the positive class of the MaxEnt model were *no, without, may* and *vs*. They can filter out false positive matches like

Hyperinflated without focal pneumonia..

On the Obesity dataset, similar content shifters were learnt along with references to family members (like the terms *mother* and *uncle*, and the *family history* header). The significance of these types of content shifters may be illustrated by the following sentence:

History of hypertension in mother and sister.

The soccer task highlighted totally different content shifters which is also the reason for the poor performance of CSSDB. The mention of a club name which the person in question did not play for (false positives) is usually a rival club, club of an unsuccessful negotiation or club which was managed by the footballer after his retirement. For example:

His last game was against Chelsea at Stamford Bridge.

He was a coach at United during his son's playing career.

Summing up, the machine learnt CSDs proved to be competitive with the manually fine-tuned CSD on the three datasets. Table 3 shows that learnt CSDs were able to eliminate a significant amount of false positive indicator phrase matches on each of the three datasets. The hand-crafted CSDs developed for the medical texts certainly work poorly (an F-score of 15.5) on the Soccer dataset as content shifters different from negation, hedge and experiencer are useful there. On the other hand, the content shifters could be learnt on this dataset by our CSD approach (achieving F-score of 79.9). In the clinical corpora, the features from the syntactic parses just confused the system, but they proved to be useful on the Soccer corpus. Here, the dependency parse achieved improvements in terms of both precision and recall (the number of true positives increased by 137) which can be mainly attributed to the prepositions *against* and *over*. The reason why it did not advance on the clinical corpora is probably the domain difference between the training corpus of the parsers and the target texts, i.e. the parsers trained on the Wall Street Journal could not build adequate dependency parses on clinical notes.

As a final comparison we investigated the manually annotated BioScope corpus (Vincze et al., 2008) as a CSD. The CMC corpus is included in the BioScope corpus where text spans in the in-sentence scope of speculation and negation were annotated. We used this manual annotation as an oracle CSD and got an F-measure of 75.2 (which is significantly higher than the scores 72.2 and 72.7 archived by the hand-crafted and trained CSD respectively). This score can be regarded as an upper bound for the amount of false positive indicator matches that can be fixed by local speculation and negation detectors. The remaining false positives are not covered by the linguistically motivated annotations of BioScope, i.e. false positives recognizable by domain knowledge (e.g. coding symptoms should be omitted when a certain diagnosis that is connected with the symptom in question is present in the document) are not marked.

Our **error analysis** revealed that most of the errors of the learnt CSDs is due to the lack of semantic link between lexical units. For instance, on the Soccer dataset it could learn that the token *coach* occuring in the sentence in question indicates an `altered` content, but it was not able to recognise this for *trainer*. The reason for that is simple, the ratio of occurrences of *trainer*:*coach* is 5:95 in the

Table 4: Results obtained by document multi-labeling algorithms in a precision/recall/F-measure format.

rowID				CMC	Obesity	Soccer
1	Baseline	SVM	with CSSDB	87.7 / 76.7 / 81.8	90.0 / 81.3 / 85.4	92.2 / 75.1 / 82.8
2		MaxEnt		92.2 / 72.2 / 81.0	91.4 / 87.6 / 89.4	92.2 / 77.4 / 84.2
3		PART		83.9 / 80.6 / 82.2	87.3 / 86.4 / 86.8	81.2 / 77.0 / 79.0
4	Indicator Selection	without CSD		78.0 / 85.1 / 81.4	89.2 / 93.6 / 91.3	84.4 / 83.7 / 84.1
5		with CSSDB		79.0 / 84.1 / 81.4	94.8 / 86.6 / 91.1	85.2 / 85.5 / 85.3
6		with learnt CSD		83.1 / 83.2 / 83.2	91.7 / 92.9 / 92.3	91.7 / 85.2 / **88.3**
7		after 3 iterations		82.4 / 86.8 / **84.6**	92.6 / 95.4 / **94.0**	92.5 / 84.0 / 88.0
8		after 10 iterations		82.4 / 86.8 / 84.6	92.7 / 95.4 / 94.0	92.5 / 84.0 / 88.0
9	Baseline	MaxEnt with learnt CSD		89.9 / 77.0 / 83.0	91.9 / 90.4 / 91.1	95.0 / 78.7 / 86.1

training corpus. Increasing the training size may be a simple way to overcome this shortcoming. Note that increasing the number of labels (e.g. introducing more soccer clubs in the Soccer task) would also directly increase the size of training dataset as we use the occurrences of the indicator phrases belonging to each of the labels for training a CSD. The solution for the rare cases would require the explicit handling of semantic relatedness (by utilising existing semantic resources or trying to automatically identify task-specific relations).

5.2 Document Labeling Results

The second branch of experiments investigated the added value of CSDs in information-oriented document labeling tasks. Table 4 summarizes the results we got on the three datasets using the micro-averaged $F_{\beta=1}$ of assigned labels (positive class).

As **baseline** systems we trained binary SVMs with a linear kernel, MaxEnts and PARTs – a rule-learner classification algorithm (Frank and Witten, 1998) – for each label using the bag-of-word representation of the documents (implementations of SVMligth (Joachims, 1999), MALLET (McCallum, 2002) and WEKA (Witten and Frank, 1999) were used). The first two learners are popular choices for document classification, while the third is similar to our simple indicator selection procedure. We did not tuned the parameters of the classifiers, we used the default ones everywhere.

To have a fair comparison, we applied to preprocessing steps on dataset of these document classifiers. First, we removed from the training and evaluation raw documents which were predicted to be `altered` by CSSDB. Second, as our indicator selection phrase can be regarded as a special feature selection method, we carried out an Information Gain-based feature selection (keeping the 500 best-rated features proved to be the best solution) on the bag-of-word representation of the documents. The effect of these two preprocessing steps varied among datasets. It improved the F-score of the MaxEnt baseline document classifier by 20%, 2% and 3% on the Obesity, CMC and Soccer datasets, respectively (the F-measures of Table 4 are the values we got by employing pre-processing).

The **indicator selection** results presented in the rows 4-8 of Table 4 made use of the $p(+|f)$-based indicator selector with a five-fold-cross-validated stopping threshold t (introduced in Section 4.3). Row 4 contains the results of using the selected indicators without any CSD. Indicator selection with the CSSDB was applied for the 5th row. Rows 6-8 of Table 4 show the results obtained after one, three and ten iterations of the full learning algorithm (see Algorithm 1). For training the CSD, we employed MaxEnt as a binary classifier for detecting `altered` local contexts and we used the basic BoW feature representation for the clinical tasks while the extended (BoW+syntactic) one for the Soccer dataset.

In the final experiment (the last row of Table 4)) we investigated whether the learnt content shift detector can be applied as a general "**document cleaner**" tool. For this, we trained the baseline MaxEnt document classifier with feature selection on documents from which the text spans predicted to be `altered` by the learnt CSD in the tenth iteration were removed. This means that the systems

used in row 2 and row 9 differ only in the applied document cleaner pre-processing steps (the first one applied the CSSDB while the latter one employed the the learnt CSD).

The difference between the best baseline and the indicator selector with learnt CSD and between the best baseline and the document classifier with learnt CSD were statistically significant[8] on each dataset. The difference between the predictions after the 1st and 3rd iterations were statistically significant on the CMC and the Obesity corpora but not significant on the Soccer dataset. The difference between the 3th and 10th iterations were not significant in either case. Our co-learning method which integrated the document-labeling and CSD tasks significantly outperformed the baseline approaches – which use separate document cleaning and document labeling steps – on the three datasets.

On the clinical domains the automatically selected indicators were disease names, symptom names (e.g. *high blood pressure*), their spelling variants, synonyms (like *hypertension*) and their abbreviations (e.g *htn*). On the soccer domain club names, synonyms (like *The Saints*) and stadium names (e.g. *Old Trafford*) were selected. A label was indicated by 3-4 indicator phrases.

Note that in these information-oriented document multi-labeling tasks simple indicator selection-based document labelers alone achieved results comparable to the bag-of-words-based classifiers. The learnt content shift detectors led to an average improvement of 3.6% in the F-measure (i.e. a 24% error reduction). The effect of further iterations is various. As Table 4 shows, three iterations brought an increase on the CMC and Obesity datasets but not on the Soccer corpus. After a few iterations the set of indicator phrases and the content shift detector did not change substantially. The results achieved by the MaxEnt document classifier employing the ”cleaned” training documents (last row of Table 4) are significantly better (an average improvement of 1.9% in the F-measure and 12% error reduction) than those by the CSSDB (row 2) but the indicator selector approach performed even better.

[8] According to McNemar's test with P-value of 0.001

6 Conclusions

In this paper, we dealt with information-oriented document labeling tasks and investigated machine learning approaches for local content shift detectors from document-level labels. We demonstrated experimentally that a significant amount of false positive matches of indicator phrases can be recognized by trained content shift detectors. Our trained CSD does not use any task or domain specific knowledge and exploits the false and true positive matches of indicator phrases, i.e. it uses only document-level annotation. This task-independent approach achieved competitive results with CSDs which were manually fine-tuned for particular datasets. The empirical results also support the idea of generalized local CSD (false positive removal) opposite to developing independent CSD for particular language phenomena (like negation and speculation).

A co-learning framework for training local content shift detectors and indicator selection was introduced as well. Our method integrates document classification and CSD learning, which are traditionally used as independent submodules of applications. Experiments on three information-oriented document-labeling datasets – from two application areas – with simple indicator selection and syntactic parse-based content shifter learning were performed and the results show a clear improvement over the bag-of-word-based document classification baseline approaches.

However, the proposed content shift detector learning approach is tailored for information-oriented document labeling tasks, i.e. it performs well when not too many and reliable indicator phrases are present. In the future, we plan to investigate and extend the framework for the general document classification task where many indicators with complex relationships among them determine the labels of a document but local content shifters can play an important role.

Abstract

In this paper, we present a new ranking scheme, collaborative ranking (*CR*). In contrast to traditional non-collaborative ranking scheme which solely relies on the strengths of isolated queries and one stand-alone ranking algorithm, the new scheme integrates the strengths from multiple collaborators of a query and the strengths from multiple ranking algorithms. We elaborate three specific forms of collaborative ranking, namely, micro collaborative ranking (MiCR), macro collaborative ranking (MaCR) and micro-macro collaborative ranking (MiMaCR). Experiments on entity linking task show that our proposed scheme is indeed effective and promising.

1 Introduction

Many natural language processing tasks can be formalized as a ranking problem, namely to rank a collection of candidate "objects" with respect to a "query". For example, intensive studies were devoted to parsing in which multiple possible parsing trees or forests are ranked with respect to a sentence (Collins, 2000; Charniak and Johnson, 2005; Huang, 2008), machine translation in which multiple translation hypotheses are ranked with respect to a source sentence (Och, 2002; Shen et al., 2005), anaphora resolution in which multiple antecedents are ranked with respect to an anaphora (Yang et al., 2008), and question answering in which multiple possible answers are ranked with respect to a question (Ravichandran et al., 2003). Previous studies mainly focused on improving the ranking performance using one stand-alone learning algorithm on isolated queries.

Although a wide range of learning algorithms (unsupervised, supervised or semi-supervised) is available, each with its strengths and weaknesses, there is not a learning algorithm that can work best on all types of data. In such a situation, it would be desirable to build a "collaborative" model by integrating multiple models. Such an idea forms the basis of ensemble methodology and it is well-known that ensemble methods (e.g., bagging, boosting) can improve the performance of many problems, in which classification is the most intensively studied (Rokach, 2009). The other situation is related with isolated queries handled by learning algorithms. The single query may not be formulated with the best terms or the query itself may not contain comprehensive information required for a high-performance ranking algorithm. Therefore, techniques of query expansion or query reformulation can be introduced and previous research has shown the effectiveness of those techniques in such applications as information retrieval and question answering (Manning et al., 2008; Riezler et al., 2007). Nevertheless, previous research normally considers query reformulation as a new query for the ranking system, it would be more desirable to form a larger-scale "collaborative" group for the query and make a unified decision based on the group.

Inspired from human collaborative learning in which two or more people form a group and accomplish work together, we propose a new ranking scheme, *collaborative ranking*, which aims to imitate human collaborative learning and enhance system ranking performance. The main idea is to seek collaborations for each query from two levels:

(1) query-level: search a group of query collaborators, and make the joint decision from the group together with the query using a stand-alone ranking algorithm.

(2) ranker-level: design a group of multiple rankers, and make the joint decision from the entire group on a single query.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 771–781,
Edinburgh, Scotland, UK, July 27–31, 2011.

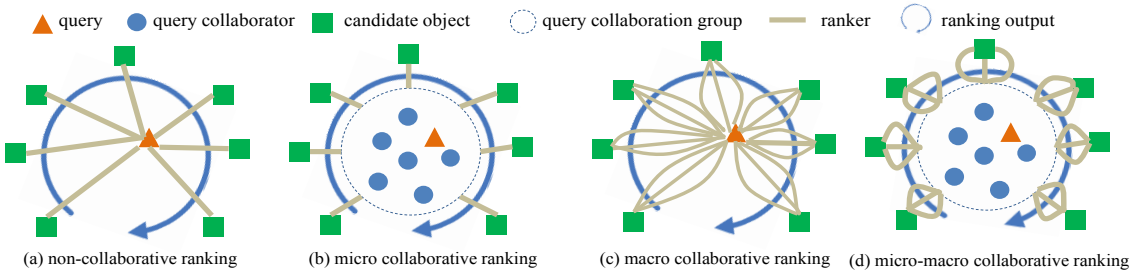

Figure 1: Non-collaborative ranking and three collaborative ranking approaches.

Figure 1 presents an intuitive illustration of four ranking approaches, including the traditional non-collaborative ranking and three collaborative ranking forms: micro collaborative ranking (MiCR), macro collaborative ranking (MaCR), and micro-macro collaborative ranking (MiMaCR).

Compared with the traditional non-collaborative ranking that only leverages the information contained in a single query and only applies one ranking function (Figure 1 (a)), the three collaborative ranking approaches have the following advantages:

(1)MiCR (corresponding to query-level collaboration[1]) leverages the information contained in the collaborators of a query. Figure 1 (b) demonstrates that 6 query collaborators together with the query form a query collaboration group.

(2)MaCR (corresponding to ranker-level collaboration[2]) integrates the strengths from two or more rankers. Figure 1 (c) demonstrates an example of 3 rankers.

(3)MiMaCR combines the advantages from MiCR and MaCR as shown in Figure 1 (d).

In this paper, we will show the efficacy of collaborative ranking on the entity linking task defined in the Knowledge Base Population (KBP) track (Ji et al., 2010) at Text Analysis Conference (TAC). Each query in the task is associated with a name string and its context document. Traditional approaches for entity linking only made use of the lexical or document level information contained in the query, however, it may not be sufficient for the task. The intuition why query-level collaboration may work is that it leverages more comprehensive information about the entity mention from multiple "collaborators" (related documents containing the name string). Furthermore, previous work on this task mainly focused on comparing one ranking algorithm with the others, however, each ranking algorithm has its own strengths, and therefore, ranker-level collaboration can potentially improve the performance. Last, the combination of query-level and ranker-level collaboration can lead to further performance gains.

[1]Query is normally expressed by small-scale data structure, so called micro.

[2]Ranker is normally implemented by large-scale algorithm, so called macro.

2 Non-collaborative Ranking

Let q denote a query. Let $o^{(q)} = \left\{o_1^{(q)}, \ldots, o_{n^{(q)}}^{(q)}\right\}$ denote the object set associated with q, where $n^{(q)}$ denotes the size of the $o^{(q)}$. The goal of non-collaborative ranking is to seek a ranking function f such that it computes ranking scores for the candidates in the object set, i.e., $y^{(q)} = f(o^{(q)}) = \left\{y_1^{(q)}, \ldots, y_{n^{(q)}}^{(q)}\right\}$.

Earlier studies on non-collaborative ranking mainly explored unsupervised approaches, e.g., vector space model, link based algorithm such as PageRank (Page et al., 1998). Unsupervised approaches are based on well-established statistical and probability theory, nevertheless, they suffer from some drawbacks, for example, it is hard to tune parameters. Recently, supervised approaches (named "learning to rank") that automatically learn ranking functions from training data become the focus of ranking research. In the literature, supervised approaches are categorized into three classes, namely, pointwise, pairwise, and listwise. We summarize a comparison of the three approaches in Table 1. We use the following notations in the table.

Let $\mathcal{Q} = \{q_1, \ldots, q_N\}$ denote the set of N queries in the training data, each query q_i is associated with a set of objects $o^{(q_i)} = \left\{o_1^{(q_i)}, \ldots, o_{n^{(q_i)}}^{(q_i)}\right\}$ and a set of ground-truth ranking scores $y^{(q_i)} =$

	pointwise	pairwise	listwise
approach overview	common: 1) use training samples; 2) learn the best ranking function by minimizing a given loss function; 3) apply the ranking function at ranking step		
	transform ranking to regression or classification on single objects	transform ranking to classification on object pairs	ranking by learning from lists of objects
training set	$\{\left(x_j^{(q_i)}, y_j^{(q_i)}\right)\}_{j=1,\ldots,n^{(q_i)};\ i=1,\ldots,N}$	$\{\left(x_j^{(q_i)}, x_k^{(q_i)}, y\right)\}_{j=1,\ldots,n^{(q_i)};k=1,\ldots,n^{(q_i)};\ k\neq j;\ i=1,\ldots,N}$ $y=\begin{cases}+1\ if\ x_j^{(q_i)} > x_k^{(q_i)}\\ -1\ if\ x_j^{(q_i)} \leq x_k^{(q_i)}\end{cases}$	$\{(x^{(q_i)}, y^{(q_i)})\}_{i=1,\ldots,N}$
loss function	pointwise loss, e.g., square loss(Chen et al., 2009)	pairwise loss, e.g., hinge loss(Zhang, 2004), exponential loss(Bartlett et al., 2003), logistic loss(Lin, 2002)	listwise loss, e.g., cross entropy loss(Cao et al., 2007),cosine loss(Qin et al., 2007)
pros and cons	pros: classification is well studied cons:1) only consider one object at a time ignoring relationship among objects	pros: classification is well studied cons:1) only consider pairwise orders; 2) biased towards lists with more objects	pros: fully consider relationship among objects cons: 1) less well studied in theory
selected algorithms	Discriminative model for IR (Nallapati, 2004); McRank (Li et al., 2007)	SVM Ranking(Joachims, 2002); RankBoost(Freund et al., 2003); RankNet(Burges et al., 2005)	ListNet (Cao et al., 2007); RankCosine(Qin et al., 2007); ListMLE (Xia et al., 2008)

Table 1: Comparison of pointwise, pairwise and listwise ranking approaches.

$\left\{y_1^{(q_i)}, \ldots, y_{n^{(q_i)}}^{(q_i)}\right\}$. Let $x_j^{(q_i)} = \varphi(q_i, o_j^{(q_i)})$ denote a feature vector associated with each query-object pair $(q_i, o_j^{(q_i)})$.

3 Collaborative Ranking

3.1 Micro Collaborative Ranking(MiCR)

Micro collaborative ranking is characterized by integrating joint strengths from multiple query collaborators and the query itself. It is based on the following assumptions:

• Expandability: Query is expandable, that is, it is able to find potential collaborators.

• Redundancy: Collaborators and query may share redundant information.

• Diversity: Collaborators exhibit multifaceted information that may complement the information contained in the query.

• Robustness: Noisy collaborators are allowable, and they could be put under control.

Let $cq^{(q)} = \{cq_1, \ldots, cq_k\}$ be the k collaborators of a query q. For each object $o_j^{(q)}$ associated with q, we form $k+1$ feature vectors $x_j^{(q)} = \varphi(q, o_j^{(q)}), x_j^{(cq_1)} = \varphi(cq_1, o_j^{(cq_1)}), \ldots, x_j^{(cq_k)} = \varphi(cq_k, o_j^{(cq_k)})$. Let f be a ranking function which is obtained by either an unsupervised or supervised approach. There are two important steps that distinguish MiCR from traditional non-collaborative ranking approaches:

• Step (1): searching the best k collaborators of q.

• Step (2): simulating the interaction of k collaborators at the ranking step.

Solutions for step (1) can vary from case to case. In our case study presented later, we transform the collaborator searching problem into a clustering problem. Collaborators of a query are then formed by members (excluding the query) in a cluster which contains the query and k is the size of the cluster minus one.

We transform the problem of step (2) into solving a function g_1 such that a ranking score $y_j^{(q)}$ can be computed for each object $o_j^{(q)}$. One approach to computing g_1 is to firstly compute the ranking scores of collaborators and query using the ranking function f and then combine those ranking scores in some way (Formula 1). The other approach is to learn a supervised ranking function f' which takes collaborators and query as input (Formula 2).

$$y_j^{(q)} = g_1(f\left(x_j^{(q)}\right), f\left(x_j^{(cq_1)}\right), \ldots, f\left(x_j^{(cq_k)}\right)) \quad (1)$$

$$y_j^{(q)} = g_1(\bullet) = f'\left(x_j^{(q)}, x_j^{(cq_1)}, \ldots, x_j^{(cq_k)}\right) \quad (2)$$

We present three specific forms of g_1 in Formula 1, namely, max, min, and weighted. We can also define a special case of weighted, called "average" in which $w_0 = w_1 \ldots = w_k = 1/(k+1)$.

- max: $y_j^{(q)} = \max(f\left(x_j^{(q)}\right), \ldots, f\left(x_j^{(cq_k)}\right))$
- min: $y_j^{(q)} = \min(f\left(x_j^{(q)}\right), \ldots, f\left(x_j^{(cq_k)}\right))$
- weighted: $y_j^{(q)} = w_0 f\left(x_j^{(q)}\right) + \sum_{i=1}^{k} w_i f\left(x_j^{(cq_i)}\right)$

We will discuss three supervised versions of g_1 (Formula 2) in section 4.4. A general algorithm for MiCR is presented in Algorithm 1.

Algorithm 1 MiCR Algorithm.

Input:
a query q; a set of objects $o^{(q)}$; a function g_1
Output:
a set of ranking scores $y^{(q)}$

```
Search k collaborators of q:
cq^(q) = {cq_1, ..., cq_k}.
for j = 1; j <= n^(q); j++ do
    Form k + 1 feature vectors: x_j^(q), x_j^(cq_1), ..., x_j^(cq_k).
    Compute function y_j^(q) = g_1(•).
end for
return y^(q)
```

3.2 Macro Collaborative Ranking(MaCR)

Macro collaborative ranking is characterized by integrating joint strengths from multiple rankers. It is based on the following assumptions:

- Independence: Each ranker can make its own ranking decisions.
- Diversity: Each ranker has its own strengths in making ranking decisions.
- Collaboration: Rankers in the group could collaborate to make a consensus decision under some mechanism.

Let $x_j^{(q)} = \varphi(q, o_j^{(q)})$ be the feature vector formed from the pair consisting of query q and an associated object $o_j^{(q)}$. Let $\mathcal{F}^* = \{f_1, \ldots, f_m\}$ be m existing ranking functions. We transform the computation of collaboration among rankers into solving the following composite function g_2:

$$y_j^{(q)} = g_2(f_1\left(x_j^{(q)}\right), \ldots, f_m\left(x_j^{(q)}\right)) \quad (3)$$

Similar with MiCR, g_2 can be expressed by max, min, weighted (average) respectively:

- max: $y_j^{(q)} = \max\{f_i\left(x_j^{(q)}\right)\}_{i=1}^{m}$
- min: $y_j^{(q)} = \min\{f_i\left(x_j^{(q)}\right)\}_{i=1}^{m}$
- weighted: $y_j^{(q)} = \sum_{i=1}^{m} w_i f_i\left(x_j^{(q)}\right)$

It is worth noting that max and min can be useful only if the ranking scores produced by various rankers can be compared to each other directly, however, in practice, this can hardly be true.

A special form of ranking problem is that only the best object is required as output. In this case, we have another version of g_2 which is called voting:

- voting: $y_j^{(q)} = \sum_{i=1}^{m} \text{sign}(f_i\left(x_j^{(q)}\right))$

in which $sign(\bullet)$ is an indicator function

$$sign(\bullet) = \begin{cases} 1 & \text{if } f_i \text{ outputs } o_j^{(q)} \text{ as the best object} \\ 0 & \text{otherwise} \end{cases}$$

A general algorithm for MaCR is presented in Algorithm 2.

Algorithm 2 MaCR Algorithm.

Input:
a query q; a set of objects $o^{(q)}$; a set of m ranking functions $\mathcal{F}^*$; a composite function g_2
Output:
a set of ranking scores $y^{(q)}$

```
for j = 1; j <= n^(q); j++ do
    Form a feature vector x_j^(q).
    Compute ranking scores: f_1(x_j^(q)), ..., f_m(x_j^(q)).
    Compute composite function: y_j^(q) = g_2(•).
end for
return y^(q)
```

3.3 Micro-Macro Collaborative Ranking (MiMaCR)

The above two ranking approaches can be further integrated into a joint model which is named Micro-Macro Collaborative Ranking (MiMaCR). In order to compute query-level and ranker-level collaboration jointly, we solve the following complex composite function g_3:

$$y_j^{(q)} = g_2(g_1(\bullet)) \quad (4)$$

in which, for each object $o_j^{(q)}$, firstly we compute m micro-ranking scores using m ranking functions on query-level collaborators:

$$m \begin{cases} g_1(f_1\left(x_j^{(q)}\right), f_1\left(x_j^{(cq_1)}\right), \ldots, f_1\left(x_j^{(cq_k)}\right)) \\ \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \\ g_1(f_m\left(x_j^{(q)}\right), f_m\left(x_j^{(cq_1)}\right), \ldots, f_m\left(x_j^{(cq_k)}\right)) \end{cases}$$

and secondly, we compute a macro-ranking score using g_2.

We can similarly define g_1 and g_2 as those in MiCR and MaCR. A general algorithm for MiMaCR is presented in Algorithm 3.

Algorithm 3 MiMaCR Algorithm.

Input:

a query q; a set of objects $o^{(q)}$; a set of ranking functions $\mathcal{F}^*$; functions g_1, g_2

Output:

a set of ranking scores $y^{(q)}$

1: Search k collaborators of q: $cq^{(q)} = \{cq_1, \ldots, cq_k\}$.
2: **for** $j = 1; j <= n^{(q)}; j++$ **do**
3: Form $k+1$ feature vectors: $x_j^{(q)}, x_j^{(cq_1)}, \ldots, x_j^{(cq_k)}$.
4: Compute m micro-ranking scores using $\mathcal{F}^*$ and g_1.
5: Compute the macro-ranking score using g_2.
6: **end for**
7: **return** $y^{(q)}$

4 A Case Study on Entity Linking

To demonstrate the efficacy of our collaborative ranking scheme, we apply it to the entity linking task defined in the TAC-KBP2010 program (Ji et al., 2010) because there is a large amount of training and evaluation data available and various non-collaborative ranking approaches have been proposed, as summarized in (McNamee and Dang, 2009; Ji et al., 2010).

4.1 Task Definition

The entity linking task aims to align a textual mention of a named entity (person,organization or geo-political) to an appropriate entry in a knowledge base (KB), which may or may not contain the entity. More formally, given a large corpus $\mathcal{C}$, let $q = (q.id, q.string, q.text)$ denote a query in the task which is a triple consisting of query id ($q.id$), name string ($q.string$) and context document ($q.text \in \mathcal{C}$). Let $o^{(q)} = \left\{o_1^{(q)}, \ldots, o_{n^{(q)}}^{(q)}\right\}$ denote the candidate KB entries associated with the query. Each KB entry is a tuple consisting of KB id, KB title, KB infobox (a set of attribute-value pairs that summarize or highlight the key features of the concept or subject of this entry) and KB text. The goal is to rank the KB entries and determine whether the top entry id should be considered as the answer, otherwise NIL should be returned.

A specific example of the task is as follows, given a name string "Michael Jordan" and its context document "...England Youth International goalkeeper *Michael Jordan*...". From the name string, we retrieve a set of candidate KB entries including "Michael Jordan (mycologist)", "Michael Jordan (footballer)", etc. The entity linking system should return the id of "Michael Jordan (footballer)" as the answer, rather than the id of "Michael Jordan" who is most well known as a basketball player.

4.2 General Framework

A general framework of entity linking consists of two crucial components, one for candidate generation, the other for candidate ranking, as shown in Figure 2. In this paper, we developed the first component by following the procedures described in (Chen et al., 2010) which extensively leveraged resources mined from Wikipedia. The performance of the first component is 96.8% measured by recall (the percentage of queries in which the candidates cover the true answer). We then focus on the second component.

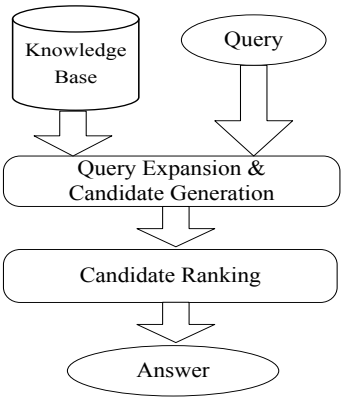

Figure 2: A general framework of entity linking system.

4.3 Baseline Rankers

We developed 8 baseline rankers, including 4 unsupervised rankers (f_1, f_2, f_3, f_4) and 4 supervised rankers(f_5, f_6, f_7, f_8).

•Naive (f_1): since the answer for each query can either be a KB id or NIL, the naive ranker simply outputs NIL for all queries.

•Entity (f_2): f_2 is defined as weighted combination of entity similarities in three types (person, organization and geo-political). Name entities are extracted from $q.text$ and KB text respectively using Stanford NER toolkit[3]. The formulas to compute entity similarities are defined in (Yoshida et al., 2010).

•Tfidf (f_3): f_3 is defined as cosine similarity between $q.text$ and KB text using tfidf weights.

•Profile (f_4): f_4 is defined as profile similarity between $q.text$ and KB text (Chen et al., 2010). We used a slot filling toolkit (Chen et al., 2011) to generate the profile (attribute-value pairs) for each query.

•Maxent (f_5): a pointwise ranker implemented using OpenNLP Maxent toolkit[4] which is based on maximum entropy model.

•SVM (f_6): a pointwise ranker implemented using SVM^{light} (Joachims, 1999).

•SVM ranking (f_7): a pairwise ranker implemented using SVM^{rank} (Joachims, 2006).

•ListNet (f_8): a listwise ranker presented in (Cao et al., 2007).

The four supervised rankers apply exactly the same set of features except that SVM ranking (f_7) needs to double expand the feature vector. The features are categorized into three levels, surface features (Dredze et al., 2010; Zheng et al., 2010), document features (Dredze et al., 2010; Zheng et al., 2010), and profiling features (entity slots that are extracted by the slot filling toolkit (Chen et al., 2011)).

4.4 MiCR for Entity Linking

We convert the collaborator searching problem into a clustering problem, i.e., for a given query q in the task, we retrieve at most $K = 300$ documents from the large corpus $\mathcal{C}$, each of which contains $q.string$; we then apply a clustering algorithm to generate clusters over the documents, and form query collaborators (excluding $q.text$) from the cluster that contains $q.text$.

We experimented the following two clustering approaches:

(1)*agglomerative clustering*: it iteratively merges clusters from singleton documents until a stop threshold is reached. Document similarity is defined as cosine similarity using tfidf weights. We applied group-average linking strategy to merge clusters (Manning et al., 2008).

(2)*graph-based clustering*: it iteratively partitions clusters from one single cluster until a stop threshold is reached. Document similarity is similarly defined as agglomerative clustering. We selected normalized spectral clustering as our clustering algorithm (Shi and Malik, 2000).

We first selected f_3 as our basic ranking function, and investigated whether the ranker can benefit from query collaborators formed by either agglomerative clustering or graph clustering. We implemented three versions of composite function g_1 (*max*, *min* and *average*), and experimented their performance using three unsupervised rankers f_2, f_3, f_4 respectively.

Last, we implemented three supervised versions of g_1 (Maxent, SVM and ListNet respectively) by adding cluster-level features and retraining the models in three supervised rankers f_5, f_6, f_8 respectively. Cluster-level features include maximum, minimum, average tfidf/entity similarities between the candidate and the query collaboration group.

4.5 MaCR for Entity Linking

We implemented two versions of composite function g_2, *average* and *voting*. Furthermore, we investigated how the performance can be affected by incrementally adding more rankers into the ranker set $\mathcal{F}^*$. To do so, we first sorted the 8 rankers according to their performance on the *development* set from the highest to the lowest, and starting with the highest performance ranker, we added one ranker at a time, until we have all the 8 rankers. It is worth noting that, when there are even number of rankers in the set $\mathcal{F}^*$, "ties" could take place using *voting* function. In order to break the ties, we rank the candidate higher if it is output as the answer from a higher performance ranker.

4.6 MiMaCR for Entity Linking

We investigated how the final performance can be boosted by jointly computing micro-ranking scores and macro-ranking score.

5 Experiments

5.1 Data and Evaluation Metric

We used TAC-KBP2009 evaluation data as our training (75%) and development set (25%), and used TAC-KBP2010 evaluation data as our blind testing set (shown in Table 2).

Corpus	Queries			
	PER	ORG	GPE	Total
Training&Dev	627	2710	567	3904
Testing	750	750	750	2250

Table 2: Training, development and testing corpus.

The reference KB consists of 818,741 entries which are extracted from an October 2008 dump of English Wikipedia. The source text corpus (denoted as $\mathcal{C}$ in section 4.1) consists of 1,777,888 documents in 5 genres (mostly Newswire and Web Text).

We used the official evaluation metric for TAC-KBP2010 entity linking task, that is, micro-averaged accuracy. It is computed by

$$\textit{micro-averaged accuracy} = \frac{\#\textit{correct answers}}{\#\textit{queries}}$$

An answer is considered as correct if the system output (either a KB entry id or NIL) exactly matches the key.

5.2 Performance of 8 Baseline Rankers

Table 3 shows the performance of the 8 baseline rankers in 4 columns: *Overall* for all queries, *PER* for person queries, *ORG* for organization queries, and *GPE* for geo-political queries. Each column is further split into *All*, *KB* (for Non-NIL queries) and *NIL* (for NIL queries). It shows that all the four supervised rankers perform better than the four unsupervised rankers. Naive ranker obtains the lowest overall micro-average accuracy (54.5%) but the highest NIL accuracy (100%). Among the four unsupervised rankers, *profile* ranker performs the best, which clearly shows that the extracted attributes of entities are effective for disambiguating confusable names. For example, our data analysis shows that the attribute value of "*per:alternative-name*" from the context document is particularly useful if a person query is only mentioned by its last name. The attribute "*per:title*" is another important indicator to discriminate one person from the other. For geo-political queries, if the query is a city name, attribute "*gpe:state*" is useful to distinguish cities with the same name but in different states or provinces. Among the four supervised rankers, ListNet outperforms SVM ranking and then SVM ranking outperforms the two pointwise rankers. It may confirm previous research findings that listwise ranking is superior to pairwise ranking and pairwise ranking is superior to pointwise ranking (Cao et al., 2007; Zheng et al., 2010). The best baseline ranker (ListNet) obtains an absolute overall accuracy gain of 26.6% over the naive ranker.

5.3 Impact of MiCR

To study the impact of MiCR, we first select f_3 (*tfidf* ranker) as our ranking function. Figure 3 shows the performance of applying different query collaborator searching strategies (graph or agglomerative clustering) and different versions of g_1 (average, max and min respectively). We intentionally adjust the meaning of threshold (x-axis) for both graph clustering and agglomerative clustering, such that at threshold 0, both clustering algorithms generate the largest number of clusters (i.e., each document is a cluster), and at threshold 1, they generate only one cluster. We now take the *average* function (Figure 3 (a)) into considerations, as graph clustering algorithm gradually partitions from one cluster (corresponding to threshold 1) to more clusters, the number of query collaborators gradually reduces, meanwhile, the accuracy gradually increases and reaches the highest (73.6%) at threshold of 0.45, which clearly shows that removing noisy collaborators in the query collaboration group can improve the performance. As the threshold continues dropping below 0.45, the number of query collaborators reduces and the performance significantly drops until it reaches the baseline performance of *tfidf* ranker (68.3%). It clearly shows that maintaining a controllable number of query collaborators can improve the performance. For the agglomerative clustering, it is the other story. As it continues merging from singleton clusters (corresponding to threshold 0) to one single cluster, the performance continues increasing until in the end it reaches the highest accuracy of 72.6%. However, unlike graph clustering, a peak never appears in the middle which implies that agglomerative clustering is inferior to graph clustering.

	Overall (%)			PER (%)			ORG (%)			GPE (%)		
	All	KB	NIL	All	KB	NIL	All	KB	NIL	All	KB	NIL
Naive	54.5	0.0	**100**	70.8	0.0	**100**	59.7	0	**100**	33.0	0	**100**
Entity	65.6	48.6	79.7	82.1	52.1	94.5	68.4	46.2	83.3	46.1	48.5	41.3
Tfidf	68.3	45.0	87.7	83.6	54.3	95.7	66.2	45.9	80.0	54.9	40.3	84.6
Profile	75.0	58.7	88.6	90.8	82.2	94.4	73.3	62.7	80.4	61.0	46.1	91.1
Maxent	77.4	72.3	81.6	86.5	**82.6**	94.4	73.3	62.7	80.4	61.0	**71.5**	72.1
SVM	78.1	**73.0**	82.3	91.1	81.7	94.9	78.7	**70.0**	84.6	64.4	71.1	51.0
SVM Rank	80.3	66.7	91.7	**91.3**	76.3	97.6	77.3	59.7	89.1	72.3	66.7	83.8
ListNet	**81.1**	69.7	90.6	90.8	77.6	96.2	**79.0**	64.0	89.1	**73.5**	69.7	81.4

Table 3: Comparison of 8 baseline rankers.

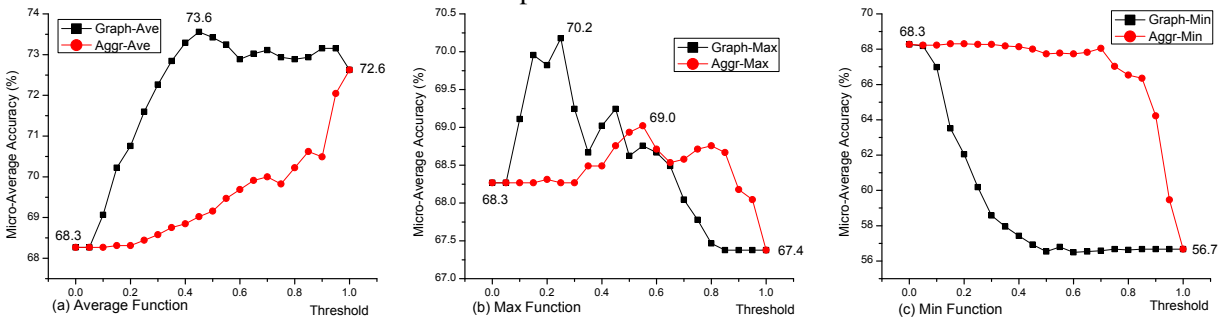

Figure 3: MiCR: comparison of average, max, and min functions combined with Graph and Agglomerative (Aggr)-based query collaborator searching strategies (*tfidf* ranker).

The *max* function (Figure 3 (b)) leverages the strengths from the strongest collaborator in the group, which can potentially improve KB accuracy, but meanwhile hurt NIL accuracy. As shown in the figure, as more collaborators join in the group, the performance increases first for both graph and agglomerative clustering, however, it starts to deteriorate when arriving at a threshold, and in the end, the performance drops even lower than the baseline of tfidf ranker.

The *min* function (Figure 3 (c)) leverages the strengths from the weakest collaborator in the group, which can potentially improve NIL accuracy, but meanwhile hurt KB accuracy. Our data analysis shows that the gain in NIL accuracy can not afford the larger loss in non-NIL accuracy, therefore, the performance continues dropping as the threshold increases. Min function is a counter example showing that searching query collaborators can not always lead to benefits.

To summarize so far, the best strategy for *tfidf* ranker in MiCR approach is *graph-ave* (applying graph clustering and using average function) which obtains overall accuracy gain of 5.3% over the baseline (68.3%). We further validate the performance of *graph-ave* using f_2, f_4 ranking functions, for *entity* ranker, we obtain accuracy gain of 6.3%, and for *profile* ranker, we obtain accuracy gain of 3.0%.

We then experiment the three supervised g_1 functions (ListNet, Maxent, and SVM respectively) using graph clustering as the query collaborator searching strategy. Figure 6 shows that ListNet, Maxent, SVM rankers obtain accuracy gain of 1.4%, 4.6%, 4.2% respectively over the baselines (corresponding to those points at threshold 0).

5.4 Impact of MaCR

Figure 4 shows that the MaCR approach obtains absolute accuracy gain of 1.3% (*voting* function) and 0.5% (*average* function) over the best baseline ranker (81.1%) when we add the 7th ranker (*entity* ranker). The improvement of *voting* function is statistically significant at a 99.6% confidence level by conducting Wilcoxon Matched-Pairs Signed-Ranks Test on the 10 folds of the testing set. However, the improvement of average function is not significant at the 0.05 level which implies that *average* is inferior to *voting*. We observe that the performance drops

when there are even number of rankers in the ranker set using voting function, which implies that our tie breaking strategy is not very effective.

We also experimented the *voting* function on the top 10 KBP2009 entity linking systems (each system performance is shown in the table embedded in Figure 5, and experiment is similarly done as described in section 4.5). Figure 5 shows that it can obtain absolute accuracy gain of 4.7% over the top entity linking system (82.2%). The reasons why we achieve relative smaller gains using our own ranker set are as follows: (1) we use the same candidate object set for all rankers, while different KBP2009 systems may use their own set of objects. (2) our top 4 supervised rankers apply almost the same set of features, while different KBP2009 systems may apply more diversified features. Therefore, diversity is a highly important factor that makes MaCR approach effective.

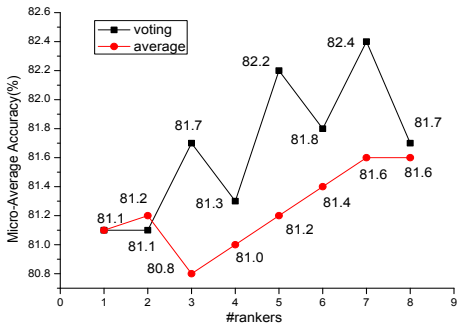

Figure 4: MaCR: comparison of voting and average.

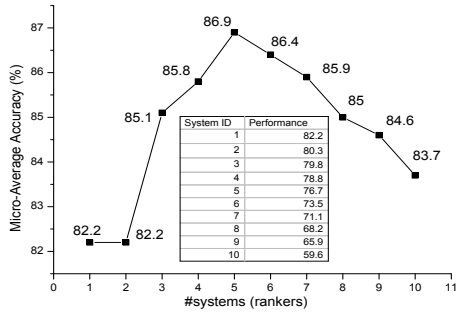

Figure 5: MaCR: applying voting function to the top 10 KBP2009 entity linking systems.

5.5 Impact of MiMaCR

We applied the following settings in our MiMaCR approach: selecting graph clustering as the query collaborator searching strategy, including five rankers (tfidf, entity, Maxent, SVM and ListNet) in the ranker set, using *average* function to compute micro-ranking scores for the tfidf and entity ranker, using the three corresponding supervised versions of g_1 to compute micro-ranking scores for Maxent, SVM and ListNet respectively, and finally applying *voting* function to compute the macro-ranking score. In Figure 6, the curve of "MiMaCR" shows how the performance of MiMaCR is affected by the threshold in graph clustering. We obtain the best micro-average accuracy of 83.7% at threshold 0.3, which is 2.6 % higher than the best baseline ranker (81.1%). The improvement is statistically significant at a 98.6% confidence level by conducting Wilcoxon Matched-Pairs Signed-Ranks Test on the 10 folds of the testing set. The score reported here is on par with the second best in the KBP2010 evaluation.

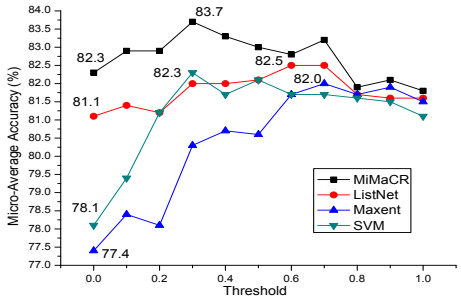

Figure 6: MiMaCR: Comparison of MiMaCR and three supervised versions of g_1 (ListNet, Maxent, and SVM respectively).

6 Related Work

In the literature of information retrieval, query expansion is a useful technique that involves the process of reformulating a query, and as a consequence, is capable to extend the ability of a query and improve the retrieval performance. Various approaches for query expansion have been proposed, as summarized in (Manning et al., 2008). The MiCR presented in this paper is superior to query expansion in two aspects, firstly, we leverage more information contained in multiple query collaborators; secondly, we place great emphasis on interactions among members in the query collaboration group.

In the literature of machine learning, there has been a considerable amount of research on ensemble-based classification, which is to build a predictive classification model by integrating multiple classifiers. A comprehensive survey is presented in (Rokach, 2009). In contrast, ensemble-based ranking has only recently attracted research interests (Hoi and Jin, 2008; Wei et al., 2010). Although the MaCR presented here is in essence ensemble-based

ranking, we extend it to MiMaCR which integrates the strengths from both MiCR and MaCR.

It is worth noting that "collaborative ranking" presented here should be distinguished from "collaborative filtering" in that "collaborative filtering" uses the known preferences of a group of users to generate personalized recommendations while "collaborative ranking" leverages query collaborators and ranker collaborators to enhance the overall ranking performance.

There has been an increasing amount of research on entity linking, especially through KBP2009 and KBP2010. Various unsupervised or supervised approaches have been proposed, as summarized in (McNamee and Dang, 2009; Ji et al., 2010). However, most of the previous research mainly focused on one or two ranking algorithms on isolated queries. In this paper, we have extended the work by systematically studying the possibility of performance enhancement through query-level collaboration and ranker-level collaboration.

7 Conclusions

We presented a new ranking scheme called *collaborative ranking* with three specific forms, MiCR, MaCR and MiMaCR and demonstrated its effectiveness on entity linking task. However, our scheme is not restricted to this specific task and it is generally applicable to many other other applications such as question answering. In MiCR, effective searching of query collaborators and active interplay among members in the query collaboration group are two key factors that make MiCR successful. In MaCR, diversity is a highly important factor to make it successful. Overall, MiMaCR can bootstrap the performance to its maximum if integrating MiCR and MaCR properly. However, the better performance is at the expense of much more computations.

Abstract

Disambiguating named entities in natural-language text maps mentions of ambiguous names onto canonical entities like people or places, registered in a knowledge base such as DBpedia or YAGO. This paper presents a robust method for collective disambiguation, by harnessing context from knowledge bases and using a new form of coherence graph. It unifies prior approaches into a comprehensive framework that combines three measures: the prior probability of an entity being mentioned, the similarity between the contexts of a mention and a candidate entity, as well as the coherence among candidate entities for all mentions together. The method builds a weighted graph of mentions and candidate entities, and computes a dense subgraph that approximates the best joint mention-entity mapping. Experiments show that the new method significantly outperforms prior methods in terms of accuracy, with robust behavior across a variety of inputs.

1 Introduction

1.1 Motivation

Web pages, news articles, blog postings, and other Internet data contain mentions of named entities such as people, places, organizations, etc. Names are often ambiguous: the same name can have many different meanings. For example, given a text like "They performed Kashmir, written by Page and Plant. Page played unusual chords on his Gibson.", how can we tell that "Kashmir" denotes a song by Led Zeppelin and not the Himalaya region (and that Page refers to guitarist Jimmy Page and not to Google founder Larry Page, and that Gibson is a guitar model rather than the actor Mel Gibson)?

Establishing these mappings between the mentions and the actual entities is the problem of *named-entity disambiguation (NED)*.

If the possible meanings of a name are known upfront - e.g., by using comprehensive gazetteers such as GeoNames (`www.geonames.org`) or knowledge bases such as DBpedia (Auer07), Freebase (`www.freebase.com`), or YAGO (Suchanek07), which have harvested Wikipedia redirects and disambiguation pages - then the simplest heuristics for name resolution is to choose the most prominent entity for a given name. This could be the entity with the longest Wikipedia article or the largest number of incoming links in Wikipedia; or the place with the most inhabitants (for cities) or largest area, etc. Alternatively, one could choose the entity that uses the mention most frequently as a hyperlink anchor text. For the example sentence given above, all these techniques would incorrectly map the mention *"Kashmir"* to the Himalaya region. We refer to this suite of methods as a *popularity-based (mention-entity) prior*.

Key to improving the above approaches is to consider the *context* of the mention to be mapped, and compare it - by some *similarity measure* - to contextual information about the potential target entities. For the example sentence, the mention "Kashmir" has context words like "performed" and "chords" so that we can compare a bag-of-words model against characteristic words in the Wikipedia articles of the different candidate entities (by measures such as cosine similarity, weighted Jaccard distance, KL divergence, etc.). The candidate entity with the highest similarity is chosen. Alternatively, labeled training data can be harnessed to learn a multi-way classifier, and additional features like entire phrases, part-of-speech tags, dependency-parsing paths, or nearby

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 782–792,
Edinburgh, Scotland, UK, July 27–31, 2011.

hyperlinks can be leveraged as well. These methods work well for sufficiently long and relatively clean input texts such as predicting the link target of a Wikipedia anchor text (Milne08). However, for short or more demanding inputs like news, blogs, or arbitrary Web pages, relying solely on context similarity cannot achieve near-human quality. Similarity measures based on syntactically-informed distributional models require minimal context only. They have been developed for common nouns and verbs (Thater10), but not applied to named entities.

The key to further improvements is to jointly consider multiple mentions in an input and aim for a *collective assignment* onto entities (Kulkarni09). This approach should consider the *coherence* of the resulting entities, in the sense of semantic relatedness, and it should combine such measures with the context similarity scores of each mention-entity pair. In our example, one should treat "Page", "Plant" and "Gibson" also as named-entity mentions and aim to disambiguate them together with "Kashmir".

Collective disambiguation works very well when a text contains mentions of a sufficiently large number of entities within a thematically homogeneous context. If the text is very short or is about multiple, unrelated or weakly related topics, collective mapping tends to produce errors by directing some mentions towards entities that fit into a single coherent topic but do not capture the given text. For example, a text about a football game between "Manchester" and "Barcelona" that takes place in "Madrid" may end up mapping either all three of these mentions onto football clubs (i.e., Manchester United, FC Barcelona, Real Madrid) or all three of them onto cities. The conclusion here is that none of the prior methods for named-entity disambiguation is robust enough to cope with such difficult inputs.

1.2 Contribution

Our approach leverages recently developed knowledge bases like YAGO as an entity catalog and a rich source of entity types and semantic relationships among entities. These are factored into new measures for the similarity and coherence parts of collectively disambiguating all mentions in an input text. For similarity, we also explore an approach that leverages co-occurrence information obtained from large, syntactically parsed corpora (Thater10).

We cast the joint mapping into the following graph problem: mentions from the input text and candidate entities define the node set, and we consider weighted edges between mentions and entities, capturing context similarities, and weighted edges among entities, capturing coherence. The goal on this combined graph is to identify a dense subgraph that contains exactly one mention-entity edge for each mention, yielding the most likely disambiguation. Such graph problems are NP-hard, as they generalize the well-studied Steiner-tree problem. We develop a greedy algorithm that provides high-quality approximations, and is customized to the properties of our mention-entity graph model.

In addition to improving the above assets for the overall disambiguation task, our approach gains in robustness by using components selectively in a self-adapting manner. To this end, we have devised the following multi-stage procedure.

- For each mention, we compute popularity priors and context similarities for all entity candidates as input for our tests.
- We use a threshold test on the prior to decide whether popularity should be used (for mentions with a very high prior) or disregarded (for mentions with several reasonable candidates).
- When both the entity priors and the context similarities are reasonably similar in distribution for all the entity candidates, we keep the best candidate and remove all others, fixing this mention *before* running the coherence graph algorithm.

We then run the coherence graph algorithm on all the mentions and their remaining entity candidates. This way, we restrict the coherence graph algorithm to the critical mentions, in situations where the goal of coherence may be misleading or would entail high risk of degradation.

The paper makes the following novel contributions: 1) a framework for combining popularity priors, similarity measures, and coherence into a robust disambiguation method; 2) new measures for defining mention-entity similarity; 3) a new algorithm for computing dense subgraphs in a mention-entity graph, which produces high-quality mention-entity mappings; 4) an empirical evaluation on a demanding corpus (based on additional annotations for the dataset of the CoNLL 2003 NER task), with signifi-

cant improvements over state-of-the-art opponents.

2 State of the Art

Recognizing named entities (NER tagging) in natural-language text has been extensively addressed in NLP research. The output is labeled noun phrases. However, these are not yet canonical entities, explicitly and uniquely denoted in a knowledge repository. Approaches that use Wikipedia for explicit disambiguation date back to (Bunescu06) and have been further pursued by (Cucerzan07; Han09; Milne08; Nguyen08; Mihalcea07). (Bunescu06) defined a similarity measure that compared the context of a mention to the Wikipedia categories of an entity candidate. (Cucerzan07; Milne08; Nguyen08) extended this framework by using richer features for the similarity comparison. (Milne08) additionally introduced a supervised classifier for mapping mentions to entities, with learned feature weights rather than using the similarity function directly. (Milne08) introduced a notion of semantic relatedness between a mention's candidate entities and the unambiguous mentions in the textual context. The relatedness values are derived from the overlap of incoming links in Wikipedia articles. (Han09) considered another feature: the relatedness of common noun phrases in a mention's context, matched against Wikipedia article names. While these features point towards semantic coherence, the approaches are still limited to mapping each mention separately. Nonetheless, this line of feature-rich similarity-driven methods achieved very good results in experiments, especially for the task of predicting Wikipedia link targets for a given href anchor text. On broader input classes such as news articles (called "wikification in the wild" in (Milne08)), the precision was reported to be about 75 percent.

The first work with an explicit collective-learning model for joint mapping of all mentions has been (Kulkarni09). This method starts with a supervised learner for a similarity prior, and models the pairwise coherence of entity candidates for two different mentions as a probabilistic factor graph with all pairs as factors. The MAP (maximum a posteriori) estimator for the joint probability distribution of all mappings is shown to be an NP-hard optimization problem, so that (Kulkarni09) resorts to approximations and heuristics like relaxing an integer linear program (ILP) into an LP with subsequent rounding or hill-climbing techniques. The experiments in (Kulkarni09) show that this method is superior to the best prior approaches, most notably (Milne08). However, even approximate solving of the optimization model has high computational costs.

Coreference resolution is the task of mapping mentions like pronouns or short phrases to a preceding, more explicit, mention. Recently, interest has arisen in cross-document coreference resolution (Mayfield09), which comes closer to NED, but does not aim at mapping names onto entities in a knowledge base. Word sense disambiguation (McCarthy09; Navigli09) is the more general task of mapping content words to a predefined inventory of word senses. While the NED problem is similar, it faces the challenges that the ambiguity of entity names tends to be much higher (e.g., mentions of common lastnames or firstname-only).

Projects on automatically building knowledge bases (Doan08) from natural-language text include KnowItAll (Banko07), YAGO and its tool SOFIE (Suchanek09; Nakashole11), StatSnowball (Zhu09), ReadTheWeb (Carlson10), and the factor-graph work by (Wick09). Only SOFIE maps names onto canonical entities; the other projects produce output with ambiguous names. SOFIE folds the NED into its MaxSat-based reasoning for fact extraction. This approach is computationally expensive and not intended for online disambiguation of entire texts.

3 Framework

Mentions and Ambiguity: We consider an input text (Web page, news article, blog posting, etc.) with mentions (i.e., surface forms) of named entities (people, music bands, songs, universities, etc.) and aim to map them to their proper entries in a knowledge base, thus giving a disambiguated meaning to entity mentions in the text. We first identify noun phrases that potentially denote named entities. We use the Stanford NER Tagger (Finkel05) to discover these and segment the text accordingly.

Entity Candidates: For possible entities (with unique canonical names) that a mention could denote, we harness existing knowledge bases like DBpedia or YAGO. For each entity they provide a set of short names (e.g., "Apple" for `Apple Inc.` and para-

phrases (e.g., "Big Apple" for `New York City`). In YAGO, these are available by the `means` relation, which in turn is harvested from Wikipedia disambiguation pages, redirects, and links.

Popularity Prior for Entities: Prominence or popularity of entities can be seen as a probabilistic prior for mapping a name to an entity. The most common way of estimating this are the Wikipedia-based frequencies of particular names in link anchor texts referring to specific entities, or number of inlinks.

Context Similarity of Mentions and Entities: The key for mapping mentions onto entities are the contexts on both sides of the mapping. We consider two different approaches. First, for each mention, we construct a context from all words in the entire input text. This way, we can represent a mention as a set of (weighted) words or phrases that it co-occurs with. Second, we alternatively consider similarity scores based on syntactically-parsed contexts, based on (Thater10). On the entity side of the mapping, we associate each entity with characteristic keyphrases or salient words, precomputed from Wikipedia articles and similar sources. For example, `Larry Page` would have keyphrases like "Stanford", "search engine", etc., whereas `Jimmy Page` may have keyphrases "Gibson guitar", "hard rock", etc. Now we can define and compute *similarity* measures between a mention and an entity candidate, e.g., the weighted word overlap, the KL divergence, n-gram-based measures, etc. In addition, we may use syntactic contextualization techniques, based on dependency trees, that suggest phrases that are typically used with the same verb that appears with the mention in the input text (Thater10).

Coherence among Entities: On the entity side, each entity has a context in the underlying knowledge base(s): other entities that are connected via semantic relationships (e.g., `memberOf`) or have the same semantic type (e.g., `rock musician`). An asset that knowledge bases like DBpedia and YAGO provide us with is the same-as cross-referencing to Wikipedia. This way, we can quantify the coherence between two entities by the number of incoming links that their Wikipedia articles share. When we consider candidate entities for different mentions, we can now define and compute a notion of *coherence* among the corresponding entities, e.g., by the overlap among their related entities or some form of type distance. Coherence is a key asset because most texts deal with a single or a few semantically related topics such as rock music or Internet technology or global warming, but not everything together.

Overall Objective Function: To aim for the best disambiguation mappings, our framework combines prior, similarity, and coherence measures into a combined objective function: for each mention m_i, $i = 1..k$, select entity candidates e_{j_i}, one per mention, such that

$$\alpha \cdot \sum_{i=1..k} \text{prior}(m_i, e_{j_i}) +$$
$$\beta \cdot \sum_{i=1..k} \text{sim}(\text{cxt}(m_i), \text{cxt}(e_{j_i})) +$$
$$\gamma \cdot \text{coh}(e_{j_1} \in \text{cnd}(m_1) \ldots e_{j_k} \in \text{cnd}(m_k)) = \max!$$

where $\alpha + \beta + \gamma = 1$, $\text{cnd}(m_i)$ is the set of possible meanings of m_i, cxt( ) denotes the context of mentions and entities, respectively, and coh( ) is the coherence function for a set of entities.

Section 4 gives details on each of these three components. For robustness, our solution selectively enables or disables the three components, based on tests on the mentions of the input text; see Section 5.

4 Features and Measures

4.1 Popularity Prior

As mentioned above, our framework supports multiple forms of popularity-based priors, but we found a model based on Wikipedia link anchors to be most effective: For each surface form that constitutes an anchor text, we count how often it refers to a particular entity. For each name, these counts provide us with an estimate for a probability distribution over candidate entities. For example, "Kashmir" refers to `Kashmir` (the region) in 90.91% of all occurrences and in 5.45% to `Kashmir (Song)`.

4.2 Mention-Entity Similarity

Keyphrase-based Similarity: On the **mention side**, we use all tokens in the document (except stopwords and the mention itself) as context. We experimented with a distance discount to discount the weight of tokens that are further away, but this did not improve the results for our test data.

On the **entity side**, the knowledge base knows authoritative sources for each entity, for example, the

corresponding Wikipedia article or an organizational or individual homepage. These are the inputs for an offline data-mining step to determine characteristic *keyphrases* for each entity and their statistical weights. We describe this only for Wikipedia as input corpus, the approach extends to other inputs. As keyphrase candidates for an entity we consider its corresponding Wikipedia article's link anchors texts, including category names, citation titles, and external references. We extended this further by considering also the titles of articles linking to the entity's article. All these phrases form the keyphrase set of an entity: $KP(e)$.

For each word w that occurs in a keyphrase, we compute a *specificity weight* with regard to the given entity: the **MI** (mutual information) between the entity e and the keyword w, calculating the joint probabilities for MI as follows:

$$p(e,w) = \frac{\left|w \in \left(KP(e) \cup \bigcup_{e' \in IN_e} KP(e')\right)\right|}{N}$$

reflecting if w is contained in the keyphrase set of e or any of the keyphrase sets of an entity linking to e, $IN(e)$, with N denoting the total number of entities. The joint probabilities for the cases $p(e,\bar{w})$, $p(\bar{e},w)$, $p(\bar{e},\bar{w})$ are calculated accordingly.

Keyphrases may occur only partially in an input text. For example, the phrase "Grammy Award winner" associated with entity `Jimmy Page` may occur only in the form "Grammy winner" near some mention "Page". Therefore, our algorithm for the similarity of mention m with regard to entity e computes partial matches of e's keyphrases in the text. This is done by matching individual words and rewarding their proximity in an appropriate score. To this end we compute, for each keyphrase, the shortest window of words that contains a maximal number of words of the keyphrase. We refer to this window as the phrase's *cover* (cf. (Taneva11)). For example, matching the text "winner of many prizes including the Grammy" results in a cover length of 7 for the keyphrase "Grammy award winner". By this rationale, the score of partially matching phrase q in a text is set to:

$$score(q) = z \left(\frac{\sum_{w \in cover} weight(w)}{\sum_{w \in q} weight(w)} \right)^2$$

where $z = \frac{\#\ matching\ words}{length\ of\ cover(q)}$ and $weight(w)$ is either the **MI** weight (defined above) or the collection-wide **IDF** weight of the keyphrase word w. Note that the second factor is squared, so that there is a superlinear reduction of the score for each word that is missing in the cover.

For the similarity of a mention m to candidate entity e, this score is aggregated over all keyphrases of e and all their partial matches in the text, leading to the *similarity score*

$$simscore(m,e) = \sum_{q \in KP(e)} score(q)$$

Syntax-based Similarity: In addition to surface features of words and phrases, we leverage information about the immediate syntactic context in which an entity mention occurs. For example, in the sentence "Page played unusual chords", we can extract the fact that the mention "Page" is the subject of the verb "play". Using a large text corpus for training, we collect statistics about what kinds of entities tend to occur as subjects of "play", and then rank the candidate entities according to their compatibility with the verb.

Specifically, we employ the framework of (Thater10), which allows us to derive vector representations of words in syntactic contexts (such as being the subject of a particular verb). We do not directly apply this model to derive contextualized representations of entity mentions, as information about specific proper names is very sparse in corpora like GigaWord or Wikipedia. Instead, we consider a set of *substitutes* for each possible entity e, which we take as its context $\text{cxt}(e)$. For this, we use the WordNet synsets associated with the entity's YAGO types and all their hypernyms. For each substitute, we compute a standard distributional vector and a contextualized vector according to (Thater10). Syntax-based similarity between $\text{cxt}(e)$ and the context $\text{cxt}(m)$ of the mention is then defined as the sum of the scalar-product similarity between these two vectors for each substitute. This results in high similarity if the syntactic contextualization only leads to small changes of the vectors, reflecting the compatibility of the entity's substitutes.

In our example, we compute a vector for "guitarist" as subject of "play", and another one for "entrepreneur" in the same context. The former is more

compatible with the given context than the latter, leading to higher similarity for the entity `Jimmy Page`.

4.3 Entity-Entity Coherence

As all entities of interest are registered in a knowledge base (like YAGO), we can utilize the *semantic type system*, which is usually a DAG of classes. The simples measure is the distance between two entities in terms of `type` and `subclassOf` edges.

The knowledge bases also provide same-as cross-referencing to Wikipedia, amd we quantify the coherence between two entities by the number of *incoming links* that their Wikipedia articles share. This approach has been refined by Milne and Witten (Milne08), taking into account the total number N of entities in the (Wikipedia) collection:

$$mw\_coh(e_1, e_2) = 1 - \frac{\log\left(\max(|IN_{e_1}|, |IN_{e_2}|)\right) - \log(|IN_{e_1} \cap IN_{e_2}|)}{\log(|N|) - \log\left(\min(|IN_{e_1}|, |IN_{e_2}|)\right)}$$

if > 0 and else set to 0.

5 Graph Model and Algorithms

5.1 Mention-Entity Graph

From the popularity, similarity, and coherence measures discussed in Section 4, we construct a weighted, undirected graph with mentions and candidate entities as nodes. As shown in the example of Figure 1, the graph has two kinds of edges:

- A mention-entity edge is weighted with a similarity measure or a combination of popularity and similarity measure. Our experiments will use a linear combination with coefficients learned from withheld training data.
- An entity-entity edge is weighted based on Wikipedia-link overlap, or type distance, or some combination along these lines.

Our experiments will focus on anchor-based popularity, keyphrase-based and/or syntactic similarity, and link-based coherence (mw_coh). The mention-entity graph is dense on the entities side and often has hundreds or thousands of nodes, as the YAGO knowledge base offers many candidate entities for common mentions (e.g., country names that could also denote sports teams, common lastnames, firstnames, etc.).

5.2 Graph Algorithm

Given a mention-entity graph, our goal is to compute a *dense subgraph* that would ideally contain all mention nodes and exactly one mention-entity edge for each mention, thus disambiguating all mentions. We face two main challenges here. The first is how to specify a notion of density that is best suited for capturing the coherence of the resulting entity nodes. The seemingly most natural approach would be to measure the density of a subgraph in terms of its total edge weight. Unfortunately, this will not work robustly for the disambiguation problem. The solution could be dominated by a few entity nodes with very high weights of incident edges, so the approach could work for prominent targets, but it would not achieve high accuracy also for the long tail of less prominent and more sparsely connected entities. We need to capture the weak links in the collective entity set of the desired subgraph. For this purpose, we define the *weighted degree* of a node in the graph to be the total weight of its incident edges. We then define the density of a subgraph to be equal to the minimum weighted degree among its nodes. Our goal is to compute a subgraph with maximum density, while observing constraints on the subgraph structure.

The second critical challenge that we need to face is the computational complexity. Dense-subgraph problems are almost inevitably NP-hard as they generalize the Steiner-tree problem. Hence, exact algorithms on large input graphs are infeasible.

To address this problem, we adopt and extend an approximation algorithm of (Sozio10) for the problem of finding strongly interconnected, size-limited groups in social networks. The algorithm starts from the full mention-entity graph and iteratively removes the entity node with the smallest weighted degree. Among the subgraphs obtained in the various steps, the one maximizing the minimum weighted degree will be returned as output. To guarantee that we arrive at a coherent mention-entity mapping for all mentions, we enforce each mention node to remain connected to at least one entity. However, this constraint may lead to very suboptimal results.

For this reason, we apply a pre-processing phase to prune the entities that are only remotely related to the mention nodes. For each entity node, we compute the distance from the set of all mention nodes in terms

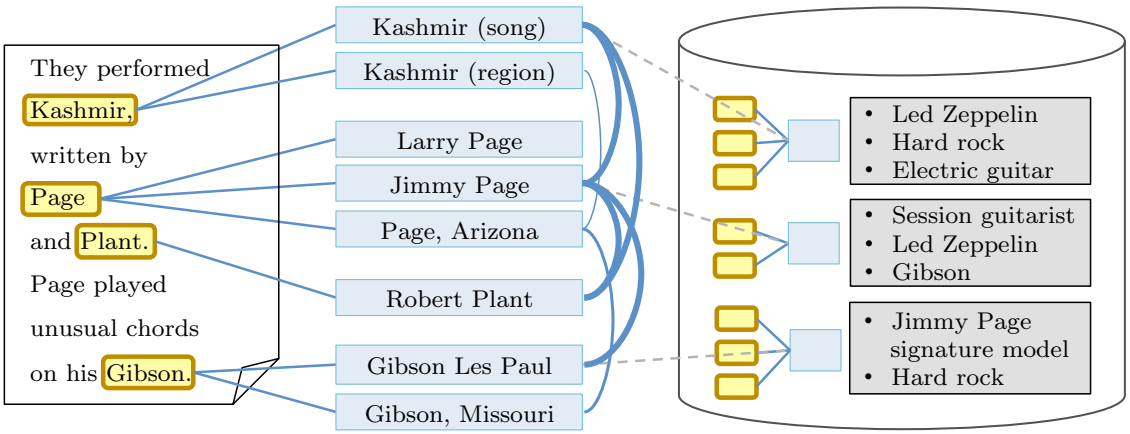

Figure 1: Mention-Entity Graph Example

of the sum of the corresponding squared shortest-path distances. We then restrict the input graph to the entity nodes that are closest to the mentions. An experimentally determined good choice for the size of this set is five times the number of the mention nodes. Then the iterative greedy method is run on this smaller subgraph. Algorithm 1 summarizes this procedure, where an `entity` is `taboo` if it is the last candidate for a mention it is connected to.

Algorithm 1: Graph Disambiguation Algorithm

Input: weighted graph of mentions and entities
Output: result graph with one edge per mention
begin
  pre–processing phase;
  foreach `entity` **do**
    calculate distance to all mentions;
  keep the closest ($5\times$ `mentions_count`) `entities`, drop the others;
  main loop;
  while *graph has* `non-taboo entity` **do**
    determine `non-taboo entity` node with lowest weighted degree, remove it and all its incident edges;
    if *minimum weighted degree increased* **then**
      set `solution` to current graph;
  post–processing phase;
  process `solution` by local search or full enumeration for best configuration;

The output of the main loop would often be close to the desired result, but may still have more than one mention-entity edge for one or more mentions. At this point, however, the subgraph is small enough to consider an exhaustive enumeration and assessment of all possible solutions. This is one of the options that we have implemented as post-processing step. Alternatively, we can perform a faster local-search algorithm. Candidate entities are randomly selected with probabilities proportional to their weighted degrees. This step is repeated for a prespecified number of iterations, and the best configuration with the highest total edge-weight is used as final solution.

5.3 Robustness Tests

The graph algorithm generally performs well. However, it may be misled in specific situations, namely, if the input text is very short, or if it is thematically heterogeneous. To overcome these problems, we introduce two *robustness tests* for individual mentions and, depending on the tests' outcomes, use only a subset of our framework's features and techniques.

Prior test: Our first test ensures that the popularity prior does not unduly dominate the outcome if the true entities are dominated by false alternatives. We check, for each mention, whether the popularity prior for the most likely candidate entity is above some threshold ρ, e. g. above 90% probability. If this is not the case, then the prior is completely disregarded for computing the mention-entity edge weights. Otherwise, the prior is combined with the context-based similarity computation to determine edge weights.

We never rely solely on the prior.

Coherence test: As a test for whether the coherence part of our framework makes sense or not, we compare the popularity prior and the similarity-only measure, on a per-mention basis. For each mention, we compute the $L1$ distance between the popularity-based vector of candidate probabilities and the similarity-only-based vector of candidate probabilities:

$$\sum_{i=1..k} |\text{prior}(m, e_i) - \text{simscore}(m, e_i)|$$

This difference is always between 0 and 2. If it exceeds a specified threshold λ (e.g., 1), the disagreement between popularity and similarity-only indicates that there is a situation that coherence may be able to fix. If, on the other hand, there is hardly any disagreement, using coherence as an additional aspect would be risky for thematically heterogeneous texts and should better be disabled. In that case, we choose an entity for the mention at hand, using the combination of prior and similarity. Only the winning entity is included in the mention-entity graph, all other candidates are omitted for the graph algorithm. The robustness tests and the resulting adaptation of our method are fully automated.

6 Experiments

6.1 Setup

System: All described methods are implemented in a prototype system called AIDA (Accurate Online Disambiguation of Named Entities). We use the Stanford NER tagger (Finkel05) to identify mentions in input texts, the YAGO2 knowledge base (Hoffart11) as a repository of entities, and the English Wikipedia edition (as of 2010-08-17) as a source of mining keyphrases and various forms of weights. The graph algorithm makes use of Webgraph (Boldi04).

Datasets: There is no established benchmark for NED. The best prior work (Kulkarni09)) compiled its own hand-annotated dataset, sampled from online news. Unfortunately, this data set is fairly small (102 short news articles, about 3,500 proper noun mentions). Moreover, its entity annotations refer to an old version of Wikipedia. To avoid unfair comparisons, we created our own dataset based on CoNLL 2003 data, extensively used in prior work on NER tagging (Sang03).

articles	1,393
mentions (total)	34,956
mentions with no entity	7,136
words per article (avg.)	216
mentions per article (avg.)	25
distinct mentions per article (avg.)	17
mentions with candidate in KB (avg.)	21
entities per mention (avg)	73
initial annotator disagreement (%)	21.1

Table 1: *CoNLL* Dataset Properties

This consists of proper noun annotations for 1393 Reuters newswire articles. We hand-annotated all these proper nouns with corresponding entities in YAGO2. Each mention was disambiguated by two students and resolved by us in case of conflict. This data set is referred to as *CoNLL* in the following and fully available at `http://www.mpi-inf.mpg.de/yago-naga/aida/`. Table 1 summarizes properties of the dataset.

Methods under comparison: Our framework includes many variants of prior methods from the literature. We report experimental results for some of them. AIDA's parameters were tuned by line-search on 216 withheld development documents. We found the following to work best:

- threshold for prior test: $\rho = 0.9$
- weights for popularity, similarity, coherence: $\alpha = 0.43$, $\beta = 0.47$, $\gamma = 0.10$
- initial number of entites in graph: $5 \cdot \#mentions$
- threshold for coherence test: $\lambda = 0.9$

We checked the sensitivity of the hyper-parameter settings and found the influence of variations to be small, e. g. when varying λ within the range [0.5,1.3], the changes in precision@1.0 are within 1%.

The baseline for our experiments is the collective-inference method of (Kulkarni09), which outperforms simpler methods (such as (Milne08)). We refer to this method as *Kul_CI*. Since program code for this method is not available, we re-implemented it using the LP solver CPLEX for the optimization problem with subsequent rounding, as described in (Kulkarni09). In addition, we compare against (our re-implementation of) the method of (Cucerzan07),

	Our Methods							Competitors				
	sim-k	prior sim-k	prior sim-s	sim-k sim-s	r-prior sim-k	r-prior sim-k coh	r-prior sim-k r-coh	prior	Cuc	Kul_s	Kul_sp	Kul_CI
Macro P@1.0	76.53	75.75	71.43	76.40	80.71	80.73	**81.91**	71.24	43.74	58.06	76.74	76.74
Micro P@1.0	76.09	70.72	66.09	76.13	79.57	81.77	**81.82**	65.84	51.03	63.42	72.31	72.87
MAP	66.98	83.99	85.97	67.00	85.91	**89.05**	87.31	86.63	40.06	63.90	86.50	85.44

Table 2: Experimental results on *CoNLL* (all values in %)

referred to as *Cuc*. For all methods, weights for combining components were obtained by training a SVM classifier on 946 withheld *CoNLL* training documents.

Performance measures: The key measures in our evaluation are *precision* and *recall*. We consider the precision-recall curve, as there is an inherent trade-off between the two measures. Precision is the fraction of mention-entity assignments that match the ground-truth assignment. Recall is the fraction of the ground-truth assignments that our method(s) could compute. Both measures can aggregate over of all mentions (across all texts) or over all input texts (each with several mentions). The former is called micro-averaging, the latter macro-averaging.

As we use a knowledge base with millions of entities, we decided to neglect the situation that a mention may refer to an unknown entity not registered in the knowledge base. We consider only mention-entity pairs where the ground-truth gives a known entity, and thus ignore roughly 20% of the mentions without known entity in the ground-truth. This simplifies the calculation of aggregated precision-recall measures like (interpolated) MAP (mean average precision):

$$\text{MAP} = \frac{1}{m} \sum_{i=1..m} \text{precision@}\frac{i}{m}$$

where precision@$\frac{i}{m}$ is the precision at a specific recall level. This measure is equivalent to the area under the precision-recall curve.

For constructing the precision-recall curve, we sort the mention-entity pairs in descending order of confidence, so that x% recall refers to the x% with the highest confidence. We use each method's mention-entity similarity for the confidence values.

6.2 Results

The results of AIDA vs. the collective-inference method of (Kulkarni09) and the entity disambiguation method of (Cucerzan07) on 229 test documents are shown in Table 2[1]. The table includes variants of our framework, with different choices for the similarity and coherence computations. The shorthand notation for the combinations in the table is as follows: *prior*: popularity prior; *r-prior*: popularity prior with robustness test; *sim-k*: keyphrase based similarity measure; *sim-s*: syntax-based similarity; *coh*: graph coherence; *r-coh*: graph coherence with robustness test.

The shorthand names for competitors are: *Cuc*: (Cucerzan07) similarity measure; *Kul_s*: (Kulkarni09) similarity measure only; *Kul_sp*: Kul_s combined with plus popularity prior; *Kul_CI*: Kul_sp combined with coherence. All coherence methods use the Milne-Witten inlink overlap measure mw_coh.

The most important measure is macro/micro precison@1.0, which corresponds to the overall correctness of the methods for all mentions that are assigned to an entity in the ground-truth data. Our *sim-k* precision is already very good. Combining it with the syntax-based similarity improves micro-averaged precision@1.0, but the macro-averaged results are a bit worse. Thus, the more advanced configurations of AIDA did not use syntax-based similarity. Unconditionally combining *prior* and *sim-k* degrades the quality, but including the prior robustness test (*r-prior sim-k*) improves the results significantly. The precision for our best method, the prior- and coherence-tested Keyphrase-based mention-entity similarity (*r-prior sim-k r-coh*), significantly outperforms all competitors (with a p-value of a paired t-test < 0.01). Our macro-averaged precision@1.0 is 81.91%, whereas *Kul_CI* only achieves 76.74%. Even *r-prior sim-k*, without any coherence, significantly outperforms

[1] 2 of the 231documents in the original test set could not be processed by *Kul_CI* due to memory limitations. All results are given for the subset, for the sake of comparability. Results for the complete set are available on our website.

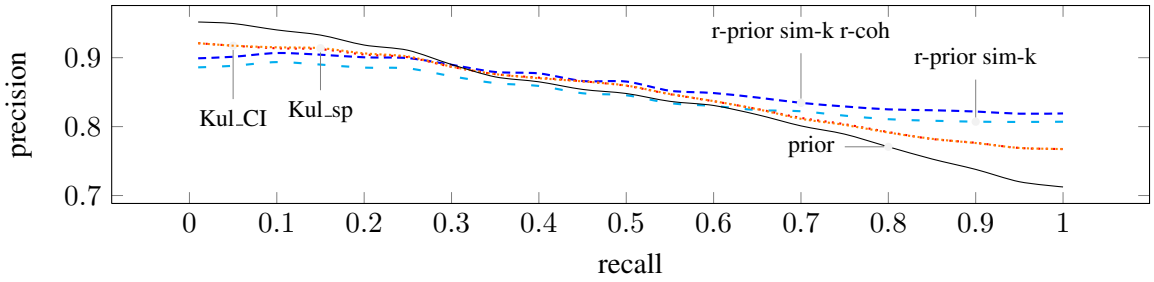

Figure 2: Experimental results on *CoNLL*: precision-recall curves

Kul_CI (with coherence) with a p-value of < 0.01. In micro-average precision@1.0, the differences are even higher, showing that we perform better throughout all documents.

The macro-averaged precision-recall curves in Figure 2 show that the best AIDA method performs particularly well in the tail of high recall values. The MAP underlines the robustness of our best methods.

The high MAP for the *prior* method is because we rank by mention-entity edge weight; for *prior* this is simply the prior probability. As the prior is most probably correct for mentions with a very high prior for their most popular entity (by definition), the initial ranking of the prior is very good, but drops more sharply. We believe that the main difficulty in named entity disambiguation lies exactly in the "long tail" of not-so-prominent entities.

We also tried the (Milne08) web service on a subset of our test collection, but this was obviously geared for Wikipedia linkage and performed poorly.

6.3 Discussion

Our keyphrase-based similarity measure performs better than the *Kul_s* measure, which is a combination of 4 different entity contexts (abstract tokens, full text tokens, inlink anchor tokens, inlink anchor tokens + surrounding tokens), 3 similarity measures (Jaccard, dot product, and tf.idf cosine similarity), and the popularity prior. Adding the prior to our similarity measure by linear combination degrades the performance. We found that our measure already captures a notion of popularity because popular entities have more keyphrases and can thus accumulate a higher total score. The popularity should only be used when one entitiy has a very high probability, and introducing the robustness test for the prior achieved this, improving on both our similarity and *Kul_sp*.

Unconditionally adding the notion of coherence among entities improves the micro-average precision, but not the macro-average. Investigating potential problems, we found that the coherence can be led astray when parts of the document form a coherent cluster of entities, and other entities are then forced to be coherent to this cluster. To overcome this issue, we introduced the coherence robustness test, and the results with *r-coh* show that it makes sense to fix an entity for a mention when the prior and similarity are in reasonable agreement. Adding this coherence test leads to a signigicant (p-value < 0.05) improvement over the non-coherence based measures in both micro- and macro-average precision. Our experiments showed that when adding this coherence test, around $\frac{2}{3}$ of the mentions are solved using local similarity only and are assigned an entity before running the graph algorithm. In summary, we observed that the AIDA configuration with *r-prior*, keyphrase-based *sim-k*, and *r-coh* significantly outperformed all competitors.

7 Conclusions and Future Work

The AIDA system provides an integrated NED method using popularity, similarity, and graph-based coherence, and includes robustness tests for self-adaptive behavior. AIDA performed significantly better than state-of-the-art baselines. The system is fully implemented and accessible online (`http://www.mpi-inf.mpg.de/yago-naga/aida/`). Our future work will consider additional semantic properties between entities (types, memberOf/partOf, etc.) for further enhancing the coherence algorithm.

Abstract

Most NLP systems use tokenization as part of preprocessing. Generally, tokenizers are based on simple heuristics and do not recognize multi-word units (MWUs) like *hot dog* or *black hole* unless a precompiled list of MWUs is available. In this paper, we propose a new cascaded model for detecting MWUs of arbitrary length for tokenization, focusing on noun phrases in the physics domain. We adopt a classification approach because – unlike other work on MWUs – tokenization requires a completely automatic approach. We achieve an accuracy of 68% for recognizing non-compositional MWUs and show that our MWU recognizer improves retrieval performance when used as part of an information retrieval system.

1 Introduction

Most NLP systems use tokenization as part of preprocessing. Generally, tokenizers are based on simple heuristics and do not recognize multi-word units (MWUs) like *hot dog* or *black hole*. Our long-term goal is to build MWU-aware tokenizers that are used as part of the standard toolkit for NLP preprocessing alongside part-of-speech and named-entity tagging.

We define an MWU as a sequence of words that has properties that cannot be inferred from the component words (cf. e.g. Manning and Schütze (1999, Ch. 5), Sag et al. (2002)). The most important of these properties is non-compositionality, the fact that the meaning of a phrase cannot be predicted from the meanings of its component words. For example, a *hot dog* is not a hot animal but a sausage in a bun and a *black hole* in astrophysics is a region of space with special properties, not a dark cavity.

The correct recognition of MWUs is an important building block of many NLP tasks. For example, in information retrieval (IR) the query *hot dog* should not retrieve documents that only contain the words *hot* and *dog* individually, outside of the phrase *hot dog*.

In this study, we focus on noun phrases in the physics domain. For specialized domains such as physics, adaptable and reliable MWU recognition is of particular importance because comprehensive and up-to-date lists of MWUs are not available and would have to be created by hand. We chose noun phrases because domain-specific terminology is commonly encoded in noun phrase MWUs; other types of phrases – e.g., verb constructions – rarely give rise to fixed domain-specific multi-word sequences that should be treated as a unit.

We cast the task of MWU tokenization as *semantic head recognition* in this paper. The importance of syntactic heads for many NLP tasks is generally accepted. For example, in coreference resolution identity of syntactic heads is predictive of coreference; in parse disambiguation, the syntactic head of a noun phrase is a powerful feature for resolving attachment ambiguities. However, in all of these cases, the syntactic head is only an approximation of the information that is really needed; the underlying assumption made when using the syntactic head as a substitute for the entire phrase is that the syntactic head is representative of the phrase. This is not the case when the phrase is non-compositional.

We define the *semantic head* of a noun phrase as the non-compositional part of a phrase. Semantic heads would serve most NLP tasks better than syntactic heads. For example, a coreference resolution system is misled if it looks at syntactic heads to de-

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 793–803,
Edinburgh, Scotland, UK, July 27–31, 2011.

termine possible coreference of *a hot dog ... the dog* in *I first ate a hot dog and then fed the dog*. This is not the case for a system that makes the decision based on the semantic heads *hot dog* of *a hot dog* and *dog* of *the dog*.

The specific NLP application we evaluate in this paper is information retrieval. We will show that semantic head recognition improves the performance of an information retrieval system.

We introduce a cascaded classification framework for recognizing semantic heads that allows us to treat noun phrases of arbitrary length. We use a number of previously proposed features for recognizing non-compositionality and semantic heads. In addition, we compare three features that measure contextual similarity.

Our main contributions in this paper are as follows. First, we introduce the notion of semantic head, in analogy to syntactic head, and propose semantic head recognition as a new component of NLP preprocessing. Second, we develop a cascaded classification framework for semantic head recognition. Third, we investigate the utility of contextual similarity for detecting non-compositionality and show that it significantly enhances a baseline semantic head recognizer. However, we also identify a number of challenges of using contextual similarity in high-confidence semantic head recognition. Fourth, we show that our approach to semantic head recognition improves the performance of an IR system.

Section 2 discusses previous work. In Section 3 we introduce semantic heads and present our cascaded model for semantic head recognition. In Section 4, we describe our data and three different measures of contextual similarity. Section 5 introduces the classifier and its features. Section 6 presents classification results and discussion. Section 7 describes the information retrieval experiments. In Section 8 we present our conclusions.

2 Related Work

While there is a large number of publications on MWUs and collocation extraction, the general problem of automatic MWU detection for the specific purpose of tokenization has not been investigated before to our knowledge.

The classic approach to identifying collocations and MWUs is to apply statistical association measures (AMs) to n-grams extracted from a corpus – often combined with various linguistic heuristics and other filters, resulting in candidate lists. Choueka (1988) and the XTRACT system (Smadja, 1993) are well-known examples of this approach.

More recent approaches such as Pecina (2010) and Ramisch et al. (2010) combine classifiers with association measures. Although our approach is classification-based as well, our data set has a more realistic size than Pecina (2010)'s (1 billion words vs 1.5 million words) and we work on noun phrases of arbitrary length (instead of just bigrams). The `mwetoolkit`[1] by Ramisch et al. (2010) aims to be a software package for lexicographers and its features are limited to a small set of association measures that do not consider marginal frequencies. Neither of these two studies includes evaluation in the context of an application.

Lin (1999) defines a decision criterion for non-compositional phrases based on the change in the mutual information of a phrase when substituting one word for a similar one based on an automatically constructed thesaurus. The method reaches 15.7% precision and 13.7% recall.

In terms of the extraction of domain-specific MWUs, cross-language methods have been proposed that make use of the fact that an MWU in one language might be expressed as a single word in another. Caseli et al. (2009) utilize word alignments in a parallel corpus; Attia et al. (2010) exploit the links between article names of different-language Wikipedias to search for many-to-one translations. We did not pursue a cross-language approach because we strive for a self-contained method of MWU recognition that operates on a single textual resource.

Non-compositionality and distributional semantics. In recent years, a number of studies have investigated the relationship between distributional semantics and non-compositionality. These studies compute the similarity between words and phrases represented as semantic vectors in a word space model. A semantic vector of a word is the accumulation of the particular contexts in which the word

[1] `http://sourceforge.net/projects/mwetoolkit/`

appears. The underlying idea is similar to Lin's: the meaning of a non-compositional phrase somehow deviates from what one would expect given the semantic vectors of parts of the phrase. The standard measure to compare semantic vectors is cosine similarity. The questions that arise are (i) which vectors to compare, (ii) how to combine the vectors of the parts and (iii) from what point on a certain dissimilarity indicates non-compositionality. To our knowledge, there are no generally accepted answers to these questions.

Regarding (i), Schone and Jurafsky (2001) compare the semantic vector of a phrase p and the vectors of its component words in two ways: one includes the contexts of p in the construction of the semantic vectors of the parts and one does not. Regarding (ii), they suggest weighted or unweighted sums of the semantic vectors of the parts.

Baldwin et al. (2003) investigate semantic decomposability of noun-noun compounds and verb constructions. They address (i) by comparing the semantic vectors of phrases with the vectors of their parts *individually* to detect meaning changes; e.g., they compare *vice president* to *vice* and *president*.

We propose a new method that compares phrases with their alternative phrases, in the spirit of Lin (1999)'s substitution approach (see Section 4.3). Our rationale is that context features should be based on contexts that are syntactically similar to the phrase in question.

With respect to (iii), the above-mentioned studies use ad hoc thresholds to separate compositional and non-compositional phrases but do not offer a principled decision criterion.[2] In contrast, we train a statistical classifier to learn a decision criterion.

There is a larger body of work concerning non-compositionality which revolves around the problem of literal (compositional) vs. non-literal (non-compositional) usage of idiomatic verb constructions like *to break the ice* or *to spill the beans*. Some studies approach the problem with semantic vector comparisons in the style of Schone and Jurafsky (2001), e.g Katz and Giesbrecht (2006) and Cook et al. (2007). Other approaches use word-alignment (e.g. Moirón and Tiedemann (2006)) or a combination of heuristic and linguistic features (e.g. Diab and Bhutada (2009), Li and Sporleder (2010)). Even though there is some methodological overlap between our approach and some of the verb-oriented studies, we believe that verb constructions have properties that are quite different from noun phrases. For example, our definition of alternative vector relies on the fact that most noun phrase MWUs are fixed and exhibit no syntactic variability. In contrast, verb constructions are often discontinuous.

The motivation for most work on MWU detection is lexicography, terminology extraction or the creation of machine-readable dictionaries. Our motivation – tokenization in a preprocessing setting – is different from this earlier work.

3 Semantic Heads and Cascaded Model

We cast the task of MWU tokenization as *semantic head recognition* in this paper. We define the semantic head of a noun phrase as the *largest non-compositional part of the phrase that contains the syntactic head*. For example, *black hole* is the semantic head of *unusual black hole* and *afterglow* is the semantic head of *bright optical afterglow*; in the latter case syntactic and semantic heads coincide.

Semantic heads would serve most NLP tasks better than syntactic heads. The attachment ambiguity of the last noun phrase in *he bought the hot dogs in a packet* can be easily resolved for the semantic head *hot dogs* (food is often in a packet), but not as easily for the syntactic head *dogs* (dogs are usually not in packets). Indeed, we will show in Section 7 that semantic head recognition improves the performance of an IR system.

The semantic head is either a single noun or a non-compositional noun phrase. In the latter case, the modifier(s) introduce(s) a non-compositional, unpredictable shift of meaning; *hot* shifts the meaning of *dog* from live animal to food. In contrast, the compositional meaning shift caused by *small* in *small dog* is transparent. The semantic head always contains the syntactic head; for compositional phrases, syntactic head and semantic head are identical.

To determine the semantic head of a phrase, we use a cascaded classification approach. The cascade

[2] Lin (1999) uses a well-defined criterion but his approach is not based on vector similarity.

(1)		*neutron*	**star**	
(2)	*unusual*	black	**hole**	
(3)	*bright*	optical	**afterglow**	
(4)		*small*	**moment**	of inertia

Figure 1: Example phrases with modifiers. Peripheral elements are set in italics, syntactic heads in bold.

comes into play in all aspects of our study: the rating experiments with human subjects, data extraction, feature design and classification itself.

We need a cascade because we want to recognize the semantic head in noun phrases of arbitrary length. The starting point is a phrase of length n: $p = w_1 \dots w_n$. We distinguish between the syntactic head of a phrase and the remaining words, the modifiers. Figure 1 shows phrases of varying syntactic complexity. The syntactic head is marked in bold. The model accommodates pre-nominal modifiers as in examples (1) through (3) and post-nominal modifiers like PPs in example (4).

Among the modifiers, there is a distinguished element, the *peripheral element* u (italicized in the examples). The remaining words are called the *rest* v. We can now represent any phrase p as $p = uv$.[3] The element u is always the outermost modifier. *of*-PPs are treated as a single modifier and they take precedence over pre-nominal modification because this analysis is dominant in our gold standard data. This means that in the phrase *small moment of inertia*, *small* (and not *of inertia*) is the peripheral element u.

Cascaded classification then operates as shown in Figure 2. In each iteration, the classifier decides whether the relation between the current peripheral element u and the rest v is compositional (C) or non-compositional (NC). If the relation is NC, processing stops and uv is returned as the semantic head of p. If the relation is compositional, u is discarded and classification continues with v as the new input phrase, which again is represented in the form $u'v'$. In case there is no more peripheral element u, i.e. the new v is a single word, it is returned as the semantic head of p.

Table 1 shows two examples. For the fully compositional phrase *bright optical afterglow*, the process runs all the way down to the syntactic head *afterglow* which is also the semantic head. In the second case, the process stops earlier, in step 2, because the classifier finds that the relation between *moment* and *of inertia* is NC. This means that the semantic head of *small moment of inertia* is *moment of inertia*.

[3] We use the abstract representation $p = uv$ even though u can appear after v in the surface form of p.

function $recognize\_semantic\_head(p)$
  $u \leftarrow peripheral(p)$
  $v \leftarrow rest(p)$
  while $decision(u, v) \neq NC$ **do**
    $u \leftarrow peripheral(v)$
    if $u = \emptyset$ **then**
      return v
    $v \leftarrow rest(v)$
  return uv

Figure 2: Cascaded classification of p

step	u	v	decision
1	*bright*	optical **afterglow**	C
2	*optical*	**afterglow**	C
3	$\emptyset$	**afterglow**	
1	*small*	**moment** of inertia	C
2	*of inertia*	**moment**	NC

Table 1: Cascaded decision processes

4 Corpus and Feature Definitions

4.1 Candidate phrases

As our corpus, we use the iSearch collection, a one billion word collection of documents from the physics domain (Lykke et al., 2010). We tokenized the collection by splitting on white space and adding sentence boundaries and part-of-speech tags to the output. With part-of-speech information, the identification of MWU candidates is easy, fast and reliable.

We extracted all noun phrases from the collection that consist of a head noun with up to four modifiers – almost all domain-specific terminology in our collection is captured by this pattern. The pre-nominal modifiers can be nouns, proper nouns, adjectives or cardinal numbers.

The baseline accuracy of a classifier that always chooses compositionality is very high ($> 90\%$) for

	$V = v$	$V \neq v$	
$U = u$	O_{11}	O_{12}	$= R_1$
$U \neq u$	O_{21}	O_{22}	$= R_2$
	$= C_1$	$= C_2$	$= N$

Table 2: 2-by-2 contingency tables with observed and marginal frequencies

phrases of the type *[noun] of the/a [noun] (sg.)* (e.g. *rest of the paper*) and *[noun] of [noun] (pl.)* (e.g. *series of papers*). We therefore restrict postnominal modifiers to prepositional phrases with the word *of* followed by a non-modified, indefinite, singular noun, e.g., *speed of light* or *moment of inertia*.

Out of all phrases extracted with part-of-speech patterns, we keep only the ones that appear more often than 50 times because it is hard to compute reliable features for less frequent phrases. All experiments were carried out with lemmatized word forms. We refer to lemmas as words if not noted otherwise.

4.2 Association measures

Statistical association measures are frequently used for MWU detection and collocation extraction (e.g. Schone and Jurafsky (2001), Evert and Krenn (2001), Pecina (2010)).

We use all measures used by Schone and Jurafsky (2001) that can be derived from a phrase's contingency table. These measures are Student's t-score, z-score, χ^2, pointwise mutual information (MI), Dice coefficient, frequency, log-likelihood (G^2) and symmetric conditional probability.

We define the AMs in Table 3 based on the notation for the contingency table shown in Table 2 (cf. Evert (2004)). O_{ij} is observed frequency and $E_{ij} = \frac{R_i C_j}{N}$ expected frequency.

The AMs are designed to deal with two random variables U and V that traditionally represent single words. In our model, we use U to represent peripheral elements u and V for rests v.

association measure	formula
student's t-score (am_t)	$\frac{O_{11}-E_{11}}{\sqrt{O_{11}}}$
z-score (am_z)	$\frac{O_{11}-E_{11}}{\sqrt{E_{11}}}$
chi-square (am_{χ^2})	$\sum_{i,j} \frac{(O_{ij}-E_{ij})^2}{E_{ij}}$
pointwise mutual information (am_{MI})	$\log \frac{O_{11}}{E_{11}}$
Dice coefficient (am_D)	$\frac{2O_{11}}{R_1+C_1}$
frequency (am_f)	O_{11}
log-likelihood (am_{G^2})	$2\sum_{i,j} O_{ij} \log \frac{O_{ij}}{E_{ij}}$
symmetric conditional probability (am_{scp})	$\frac{{O_{11}}^2}{R_1 C_1}$

Table 3: Association measures

4.3 Word space model

As our baseline, we use two methods of comparing semantic vectors: *sj1* and *sj2*, both introduced by Schone and Jurafsky (2001). They experimented with variants of sj1 and sj2, but found no large differences. In addition, we introduce our own approach *alt*.

Method sj1 compares the semantic vector of a phrase p with the sum of the vectors of its parts. Method sj2 is like sj1, except the contexts of p are not part of the semantic vectors of the parts. Method alt compares the semantic vector of a phrase with its alternative vector. In the definitions below, s represents a vector similarity measure, $w(p)$ a general semantic vector of a phrase p and $w^*(w_i)$ the semantic vector of a part w_i of a phrase p that does not include the contexts of occurrences of w_i that were part of p itself.

sj1 $s(w(\textit{black hole}),\ w(\textit{black}) + w(\textit{hole}))$

sj2 $s(w(\textit{black hole}),\ w^*(\textit{black}) + w^*(\textit{hole}))$

alt $s(w(\textit{black hole}), \sum_u w(u,\ \textit{hole}));\ u \neq \textit{black}$

For the third comparison, we build the *alternative vector* as follows. For a phrase $p = uv$ with peripheral element u and rest v, we call the phrase

$p' = u'v$ an *alternative phrase* if the rest v is the same and $u' \neq u$. E.g., *giant star* is an alternative phrase of *neutron star* and *isolated neutron star* is an alternative of *young neutron star*. The alternative vector of p is then the semantic vector that is computed from the contexts of all of p's alternative phrases. The alternative vector is a representation of the contexts of v except for those modified by u. This technique bears resemblance to the substitution approach of Lin (1999). The difference is that he relies on a similarity thesaurus for substitution and monitors the change in mutual information for each substitution individually whereas we substitute with general alternative modifiers and combine the alternative contexts into one vector for comparison.

Previous work has compared the semantic vector of a phrase with the vectors of its components. Our approach is more "head-centric" and only compares phrases in the same syntactic configuration. Our question is: Is the typical context of the head *hole* if it occurs with a modifier that is not *black* different from when it occurs with the modifier *black*?

We used a bag-of-words model and a window of ± 10 words for contexts to create semantic vectors. We only kept the content words in the window which we defined as words that are tagged as either a noun, verb, adjective or adverb. To add information about the variability of syntactic contexts in which phrases occur, we add the words immediately before and after the phrase with positional markers (-1 and $+1$, respectively) to the vector. These words were not subject to the content-word filter. The dimensionality of the vectors is then $3V$ where V is the size of the vocabulary: V dimensions each for bag-of-words, left and right syntactic contexts. We did not include vectors for the stop word *of* for sj1 and sj2.

4.4 Non-compositionality judgments

Since the domain of the corpus is physics, highly specialized vocabulary had to be judged. We employed domain experts as raters (one engineering and two physics graduate students).

In line with the cascaded model, the raters where asked to identify the semantic head of each candidate phrase. If at least two raters agreed on a semantic head of a phrase we made this choice the semantic head in the gold standard. The final gold standard comprises 1560 phrases.

We computed raw agreement of each rater with the gold standard as the percentage of correctly recognized semantic heads – this is the task that the classifier addresses. Agreement is quite high at 86.5%, 88.3% and 88.5% for the three raters. In addition, we calculated chance-corrected agreement with Cohen's κ on the first decision task against the gold standard (see Section 6). As expected, agreement decreases, but is still substantial at 74.0%, 78.2% and 71.8% for the three raters.

5 Classifier

We use the Stanford maximum entropy classifier for our experiment.[4] We randomly split the data into a training set of 1300 and a held-out test set of 260 pairs.

We use the eight AMs and the cosine similarities sim_{sj1}, sim_{sj2} and sim_{alt} described in Section 4.3 as features for the classifier. Cosine similarity should be small if a phrase is non-compositional and large if it is compositional. In other words, if the contexts of the candidate phrase are too dissimilar to the contexts of the sum of its parts or to the alternative phrases, then we suspect non-compositionality.

Feature values are binned into 5 bins. We applied a log transformation to the four AMs with large values: am_f, am_{G^2}, am_{χ^2} and am_z. For our application there is little difference between statistical significance at $p < .001$ and $p < .00001$. The log transformation reduces the large gap in magnitude between high significance and very high significance. If co-occurrence of u and v in uv is below chance, then we set the association scores to 0 since this is an indication of compositionality (even if it is highly significant).

Since AMs have been shown to be correlated (e.g. Pecina (2010)), we first perform feature selection on the AM features. We tested accuracy of all $2^r - 1$ non-empty combinations of the $r = 8$ AM features on the task of deciding whether the first decision during the classification of a phrase was C or NC. We then selected those AM features that were part of at least one top 10 result in each fold. Those features were am_t, am_f and am_{scp}.

The main experiment combines these three se-

[4] http://nlp.stanford.edu/software/classifier.shtml

lected AM features with all possible subsets of context features. We train on the 1300-element training set and test on the 260-element test set.

6 Results and Discussion

We ran three evaluation modes: *dec-1st*, *dec-all*, and *semh*. Mode *dec-1st* only evaluates the first decision for each phrase; the baseline in this case is .554 since 55.4% of the first decisions are C. In mode *dec-all*, we evaluate all decisions that were made in the course of recognizing the semantic head. This mode emphasizes the correct recognition of semantic heads in phrases where multiple correct decisions in a row are necessary. We define the confidence for multi-decision classification as the product of the confidence values of all intermediate decisions. There is no obvious baseline for *dec-all* because the number of decisions depends on the classifier – a classifier whose first decision on a four-word phrase is NC makes one decision, another one may make three. The mode *semh* evaluates how many semantic heads were recognized correctly. This mode directly evaluates the task of semantic head recognition. The baseline for *semh* is the tokenizer that always returns the syntactic head; this baseline is .488.[5] Table 4 shows 8×3 runs, corresponding to the three modes tested on the AM features (am_t, am_f, and am_{scp}) and the eight possible subsets of the three context features.

For all modes, the best result is achieved with base AMs combined with the sim_{alt} feature; the accuracies are .692, .703 and .680. The improvements over the baselines (for *dec-1st* and *semh*) are statistically significant at $p < .01$ (binomial test, $n = 260$).

For *semh*, accuracy without any context features is .603; this is significantly better than the .488 baseline ($p < .01$). Performance with only the base AM features is significantly lower than the best context feature experiment (.680) at $p < .01$ and significantly lower than the worst context feature experiment (.653) at $p < .1$. However, the differences between the context feature runs are not significant.

When the semantic head recognizer processes a phrase, there are four possible results. Result r_{semh}: the semantic head is correctly recognized and it is distinct from the syntactic head. Result r_{synth}: the semantic head is correctly recognized and it is identical to the syntactic head. Result r_+: the semantic head is not correctly recognized because the cascade was stopped too early, i.e., a compositional modifier that should have been removed was kept. Result r_-: the semantic head is not correctly recognized because the cascade was stopped too late, i.e., a modifier causing a non-compositional meaning shift was removed. Table 5 shows the distribution of result types. It shows that r_+ is the more common error: the classifier more often regards compositional relations as non-compositional than vice versa.

type	freq	definition
r_{semh}	92	sem. head correct ($\neq$ synt. head)
r_{synth}	85	sem. head correct (= synt. head)
r_+	48	sem. head too long
r_-	35	sem. head too short
all	260	

Table 5: Distribution of result types

Table 6 shows the top 20 classifications where the semantic head was not the same as the syntactic head sorted by confidence in descending order. In the third column "phrase ..." we list the candidates with semantic heads in bold. The columns to the right show the predicted semantic head and the feature values. All five errors in the list are of type r^+.

Two r^+ phrases are *schematic view* and *many others*. The two phrases are clearly compositional and the classifier failed even though the context feature points in the direction of compositionality with a value greater than .5. It can be argued that *many others* is a trivial example that does not require complex machinery to be identified as compositional, e.g. by using a stop list. We included it in the analysis since we want to be able to process arbitrary phrases without additional hand-crafted resources.

Another incorrect classification occurs with the phrase *massive star birth*[6] for which *star birth* was annotated as the semantic head. Here we have a case where the peripheral element *massive* does not mod-

[5] The baseline could be improved with simple heuristics, e.g. "uv contains capital letter" $\rightarrow NC$. However, this feature only results in a 2% improvement compared to the baseline.

[6] i.e. the birth of a massive star, a certain type of star with very high mass

mode	baseline	context feature	context feature subsets

Table 4: Performance for base AM features plus context feature subsets. A '•' indicates the use of the corresponding context feature.

ify the syntactic head *birth* but *massive star* is itself a complex modifier. In the test set, 5% of the phrases exhibit structural ambiguities of this type. Our system cannot currently deal with this phenomenon.

The remaining r^+ phrases are *peculiar velocity* and *local group*. However, Wikipedia lists both phrases with an individual entry defining the former as *the true velocity of an object, relative to a rest frame*[7] and the latter as *the group of galaxies that includes Earth's galaxy, the Milky Way*[8]. Both definitions provide evidence for non-compositionality since the velocity is not peculiar (as in strange) and the scope of *local* is not clear without further knowledge. Arguably, in these cases our method chose a justifiable semantic head, but the raters disagreed.[9]

For NLP preprocessing, it is acceptable to sacrifice recall and only make high-confidence decisions on semantic heads. A tokenizer that reliably detects a subset of MWUs is better than one that recognizes none. However, our attempts to use the sim_{alt} recognizer (bold in Table 4) in this way were not successful. Precision is .680 for confidence $>$ .7 and does not exceed .770 for higher confidence values.

To understand this effect, we analyzed the distribution of sim_{alt} scores. Surprisingly, moderate similarity between .4 and .6 is a more reliable indicator for NC than low similarity $<$ .3. Our intuition for using distributional semantics in Section 2 was that low similarity indicates non-compositionality. This does not seem to hold for the lowest similarity values possibly because they are often extreme cases in terms of distribution and frequency and then give rise to unreliable decisions. This means that the context features enhance the overall performance of the classifier, but they are unreliable and do not support the high-confidence decisions we need in NLP preprocessing.

For comparison, the classifier that only uses AM features achieves 90% precision at 14% recall with confidence $>$ .7 – although it has lower overall accuracy than the sim_{alt} recognizer. We are still in the process of analyzing these results and decided to use the AM-only recognizer for the IR experiment because it has more predictable performance.

In summary, the results show that, for the recognition of semantic heads, basic AMs offer a significant improvement over the baseline. We have shown that some wrong decisions are defensible even though the gold standard data suggests otherwise. Context features further increase performance significantly, but surprisingly, they are not of clear benefit for a high-confidence classifier that is targeted towards recognizing a smaller subset of semantic heads with high confidence.

7 Information Retrieval Experiment

Typically, IR systems do not process non-compositional phrases as one semantic entity, missing out on potentially important information captured by non-compositionality. This section illustrates one way of adjusting the retrieval process so that non-compositional phrases are processed as semantic entities that may enhance retrieval performance. The underlying hypothesis is that, given

[7] http://en.wikipedia.org/wiki/Peculiar_velocity

[8] http://en.wikipedia.org/wiki/Local_group

[9] Further evidence that *local group* is non-compositional is the fact that one of the domain experts annotated the phrase as non-compositional but was overruled by the other two.

a query that contains a non-compositional phrase, boosting the retrieval weight of documents that contain this phrase will improve overall retrieval performance.

We do this boosting using Indri's[10] combination of the language modeling and inference network approaches (Metzler and Croft, 2004), which allows assigning different degrees of belief to different parts of the query. This belief can be drawn from any suitable external evidence of relevance. In our case, this source of evidence is the knowledge that certain query terms constitute a non-compositional phrase. Under this approach, and using the *#weight* and *#combine* operators for combining beliefs, the relevance of a document D to a query Q is computed as the probability that D generates Q, $P(Q|D)$:

$$P(Q|D) = \prod_{t \in Q} P(t|D)^{\frac{w_t}{W}} \qquad (W = \sum_{t \in Q} w_t) \quad (1)$$

where t is a term and w_t is the belief weight assigned to t. The higher w_t is, the higher the rank of documents containing t. In this work, we distinguish between two types of query terms: terms occurring in non-compositional phrases (Q_{nc}), and the remaining query terms (Q_c). Terms $t \in Q_{nc}$ receive belief weight w_{nc} and terms $t \in Q_c$ belief weight w_c, ($w_{nc} + w_c = 1$ and $w_{nc}, w_c \in [0, 1]$). To boost the ranking of documents containing non-compositional phrases, we increase w_{nc} at the expense of w_c. We estimate $P(t|D)$ in Eq. 1 using Dirichlet smoothing (Zhai and Lafferty, 2002).

We use Indri for indexing and retrieval without removing stopwords or stemming. This choice is motivated by two reasons: (i) We do not have a domain-specific stopword list or stemmer. (ii) Baseline performance is higher when keeping stopwords and without stemming, rather than without stopwords and with stemming.

We use the iSearch collection discussed in Section 4. It comprises 453,254 documents and a set of 65 queries with relevance assessments. To match documents to queries without any treatment of non-compositionality (baseline run), we use the Kullback-Leibler language model with Dirichlet smoothing (KL-Dir) (Zhai and Lafferty, 2002). We applied the preprocessing described

Table 7: IR performance without considering non-compositionality (*baseline*), versus boosting real and pseudo non-compositionality (*real NC, pseudo* NC_i).

in Section 4 to the queries and identified non-compositional phrases with the base AM classifier from Section 5. Our approach for boosting the weight of these non-compositional phrases uses the same retrieval model enhanced with belief weights as described in Eq. 1 (real NC run). In addition, we include five runs that boost the weight of pseudo non-compositional phrases that were created randomly from the query text (pseudo NC runs). These pseudo non-compositional phrases have exactly the same length as the observed non-compositional phrases for each query. We measure retrieval performance in terms of mean average precision (MAP), precision at 20 (P20), and recall (REC, number of relevant documents retrieved – total is 2878). For each evaluation measure separately, we tune the following parameters and report the best performance: (i) the smoothing parameter μ of the KL-Dir retrieval model ($\mu \in \{100, 500, 800, 1000, 2000, 3000, 4000, 5000, 8000, 10000\}$, following Zhai and Lafferty (2002)); (ii) the belief weights $w_{nc}, w_c \in \{0.1, \ldots, 0.9\}$ in steps of 0.1 while preserving $w_{nc} + w_c = 1$ at all times.

Table 7 displays retrieval performance of our approach against the baseline and five runs with pseudo non-compositional phrases. We see a 9.61% improvement in the number of relevant retrieved documents over the baseline. MAP and P20 also show improvements. Our approach is better than any of the 5 random runs on all three metrics – the probability of getting such a good result by chance is $\frac{1}{2^5} < .05$, and thus the improvements are statistically significant. On doing a query-wise analysis of MAP scores, we find that large improvements over the baseline occur when a non-compositional phrase aligns with what the user is looking for. The system seems to retrieve more relevant documents in that case. E.g., the improvement in MAP is 0.0977 for query #19. The user was looking for *"articles ... on making tunable vertical cavity surface emitting laser diodes"* and *laser diodes* was one of the non-compositional phrases recognized. On the other hand, a decrease in MAP occurs for non-compositional phrases unrelated to the information need. In query #4 the user is looking for *"protein-protein interaction, the surface charge distribution of these proteins and how this has been investigated with Electrostatic Force Microscopy"* and though non-compositional phrases such as *Force Microscopy* are recognized, these do not reflect the core information need *"The proteins of interest are the Avidin-Biotin and IgG-anti-IgG systems"*.

8 Conclusion

We have presented an approach to improving tokenization in NLP preprocessing that is based on the notion of semantic head. Semantic heads are – in analogy to syntactic heads – the core meaning units of phrases that cannot be further semantically decomposed. To perform semantic head recognition for tokenization, we defined a novel cascaded model and implemented it as a statistical classifier that used previously proposed and new context features. We have shown that the classifier significantly outperforms the baseline and that context features increase performance. We reached an accuracy of 68% and argued that even a semantic head recognizer restricted to high-confidence decisions is useful – because reliably recognizing a subset of semantic heads is better than recognizing none. We showed that context features increase the accuracy of the classifier, but undermine the confidence assessments of the classifier, a result we are still analyzing. Finally, we showed that even in its preliminary current form the semantic head recognizer is able to improve the performance of an IR system.

Abstract

In this paper we present a novel approach to entity linking based on a statistical language model-based information retrieval with query expansion. We use both local contexts and global world knowledge to expand query language models. We place a strong emphasis on named entities in the local contexts and explore a positional language model to weigh them differently based on their distances to the query. Our experiments on the TAC-KBP 2010 data show that incorporating such contextual information indeed aids in disambiguating the named entities and consistently improves the entity linking performance. Compared with the official results from KBP 2010 participants, our system shows competitive performance.

1 Introduction

When people read news articles, Web pages and other documents online, they may encounter named entities which they are not familiar with and therefore would like to look them up in an encyclopedia. It would be very useful if these entities could be automatically linked to their corresponding encyclopedic entries. This task of linking mentions of entities within specific contexts to their corresponding entries in an existing knowledge base is called *entity linking* and has been proposed and studied in the Knowledge Base Population (KBP) track of the Text Analysis Conference (TAC) (McNamee and Dang, 2009). Besides improving an online surfer's browsing experience, entity linking also has potential usage in many other applications such as normalizing entity mentions for information extraction.

The major challenge of entity linking is to resolve name ambiguities. There are generally two types of ambiguities: (1) Polysemy: This type of ambiguities refers to the case when more than one entity shares the same name. E.g. *George Bush* may refer to the 41st President of the U.S., the 43rd President of the U.S., or any other individual who has the same name. Clearly polysemous names cause difficulties for entity linking. (2) Synonymy: This type of ambiguities refers to the case when more than one name variation refers to the same entity. E.g. *Metro-Goldwyn-Mayer Inc.* is often abbreviated as *MGM*. Synonymy affects entity linking when the entity mention in the document uses a name variation not covered in the entity's knowledge base entry.

Intuitively, to disambiguate a polysemous entity name, we should make use of the context in which the name occurs, and to address synonymy, external world knowledge is usually needed to expand acronyms or find other name variations. Indeed both strategies have been explored in existing literature (Zhang et al., 2010; Dredze et al., 2010; Zheng et al., 2010). However, most existing work uses supervised learning approaches that require careful feature engineering and a large amount of training data. In this paper, we take a simpler unsupervised approach using statistical language model-based information retrieval. We use the KL-divergence retrieval model (Zhai and Lafferty, 2001) and expand the query language models by considering both the local contexts within the query documents and global world knowledge obtained from the Web.

Symbol	Description
Q	Query
D_Q	Query document
N_Q	Query name string
E	KB entity node
N_E	KB entity name string
D_E	KB entity disambiguation text
$\mathcal{S}_Q$	Set of alternate query name strings
$N_Q^{l,i}$	Local alternative name strings
N_Q^g	Global alternative name strings
$\mathcal{E}_Q$	Candidate KB entries for Q
θ_Q	Query Language Model
θ_Q^L	KB entry language model using local context from D_Q
θ_Q^G	KB entry language model using global knowledge
θ_Q^{L+G}	KB entry language model using local context and global knowledge
θ_{N_E}	KB entry language model with named entities only
$\theta_{N_E+D_E}$	KB entry language model with named entities and disambiguation text

Table 1: Notation

We evaluate our retrieval method with query expansion on the 2010 TAC-KBP data set. We find that our expanded query language models can indeed improve the performance significantly, demonstrating the effectiveness of our principled and yet simple techniques. Comparison with the official results from KBP participants also shows that our system is competitive. In particular, when no disambiguation text from the knowledge base is used, our system can achieve an overall 85.2% accuracy and 9.3% relative improvement over the best performance reported in KBP 2010.

2 Task Definition and System Overview

Following TAC-KBP (Ji et al., 2010), we define the entity linking task as follows. First, we assume the existence of a Knowledge Base (KB) of entities. Each KB entry E represents a unique entity and has three fields: (1) a name string N_E, which can be regarded as the official name of the entity, (2) an entity type T_E, which is one of {PER, ORG, GPE, UNKNOWN}, and (3) some disambiguation text D_E. Given a query Q which consists of a query name string N_Q and a query document D_Q where the name occurs, the task is to return a single KB entry to which the query name string refers or *Nil* if there is no such KB entry.

It is fairly natural to address entity linking by ranking the KB entries given a query. In this section we present an overview of our system, which consists of two major stages: a candidate selection stage to identify a set of candidate KB entries through name matching, and a ranking stage to link the query entity to the most likely KB entry. In both stages, we consider the query's local context in the query document and world knowledge obtained from the Web. It is important to note that the selection stage is based on string matching where the order of the word matters. It is different from the ranking stage where a probabilistic retrieval model based on bag-of-word representation is used. Our preliminary experiments demonstrate that without the first candidate selection stage the linking process results in low performance.

2.1 Selecting Candidate KB Entries

The first stage of our system aims to filter out irrelevant KB entries and select only a set of candidates that are potentially the correct match to the query. Intuitively, we determine whether two entities are the same by comparing their name strings. We therefore need to compare the query name string N_Q with the name string N_E of each KB entry. However, because of the name ambiguity problem, we cannot expect the correct KB entry to always have exactly the same name string as the query. To address this problem, we use a set of alternative name strings expanded from N_Q and select KB entries whose name

strings match at least one of them. These alternative name strings come from two sources: the query document D_Q and the Web.

First, we observe that some useful alternative name strings come from the query document. For example, a PER query name string may contain only a person's last name but the query document contains the person's full name, which is clearly a less ambiguous name string to use. Similarly, a GPE query name string may contain only the name of a city or town but the query document contains the state or province, which also helps disambiguate the query entity. Based on this observation, we do the following. Given query Q, let $\mathcal{S}_Q$ denote the set of alternative query name strings. Initially $\mathcal{S}_Q$ contains only N_Q. We then use an off-the-shelf NER tagger to identify named entities from the query document D_Q. For PER and ORG queries, we select named entities in D_Q that contain N_Q as a substring. For GPE queries, we select named entities that are of the type GPE, and we then combine each of them with N_Q. We denote these alternative name strings as $\{N_Q^{l,i}\}_{i=1}^{K_Q}$, where l indicates that these name strings come locally from D_Q and K_Q is the total number of such name strings. $\{N_Q^{l,i}\}$ are added to $\mathcal{S}_Q$. Figure 1 and Figure 2 show two example queries together with their $\mathcal{S}_Q$.

Sometimes alternative name strings have to come from external knowledge. For example, one of the queries we have contains the name string "AMPAS," and the query document also uses only this acronym to refer to this entity. But the full name of the entity, "Academy of Motion Pictures Arts and Sciences," is needed in order to locate the correct KB entry. To tackle this problem, we leverage Wikipedia to find the most likely official name. Given query name string N_Q, we check whether the following link exists: `http://en.wikipedia.org/`N_Q. If N_Q is an abbreviation, Wikipedia will redirect the link to the Wikipedia page of the corresponding entity with its official name. So if the link exists, we use the title of the Wikipedia page as another alternative name string for N_Q. We refer to this name string as N_Q^g to indicate that it is a global name variant. N_Q^g is also added to $\mathcal{S}_Q$. Figure 2 shows such an example.

For each name string N in $\mathcal{S}_Q$, we find KB entries whose name strings match N. We take the union of these sets of KB entries and refer to it as $\mathcal{E}_Q$. These are the candidate KB entries for query Q.

Query name string (N_Q): *Mobile*
Query document (D_Q): *The site is near Mount Vernon in the Calvert community on the Tombigbee River, some 25 miles (40 kilometers) north of Mobile. It's on a river route to the Gulf of Mexico and near Mobile's rails and interstates. Along with tax breaks and $400 million (euro297 million) in financial incentives, Alabama offered a site with a route to a Brazil plant that will provide slabs for processing in Mobile.*
Alternative Query Strings ($\mathcal{S}_Q$):
from local context: *Mobile, Mobile Mount Vernon, Mobile Calvert, Mobile River, Mobile Mexico, Mobile Alabama, Mobile Brazil*

Figure 1: An example *GPE* query from TAC 2010.

Query name string (N_Q): *Coppola*
Query document (D_Q): *I had no idea of all these semi-obscure connections, felicia! Alex Greenwald and Claire Oswalt aren't names I'm at all familiar with, but Jason Schwartzman I've heard of. Isn't he Sophia Coppola's cousin? I think I once saw a picture of him sometime ago*
Alternative Query Strings ($\mathcal{S}_Q$):
from local context: *Coppola, Sophia Coppola, Sofia Coppola*
from world knowledge(Wikipedia): *Sofia Coppola*

Figure 2: An example *PER* query from TAC 2010.

2.2 Ranking KB Entries

Given the candidate KB entries $\mathcal{E}_Q$, we need to decide which one of them is the correct match. We adopt the widely-used KL-divergence retrieval model, a statistical language model-based retrieval method proposed by Lafferty and Zhai (2001). Given a KB entry E and query Q, we score E based on the KL-divergence defined below:

$$s(E,Q) = -Div(\theta_Q \| \theta_E) = -\sum_{w \in V} p(w|\theta_Q) \log \frac{p(w|\theta_Q)}{p(w|\theta_E)}. \quad (1)$$

Here θ_Q and θ_E are the query language model and the KB entry language model, respectively. A language model here is a multinomial distribution over words (i.e. a unigram language model). V is the vocabulary and w is a single word.

To estimate θ_E, we follow the standard maximum likelihood estimation with Dirichlet smooth-

ing (Zhai and Lafferty, 2004):

$$p(w|\theta_E) = \frac{c(w,E) + \mu p(w|\theta_C)}{|E| + \mu}, \quad (2)$$

where $c(w,E)$ is the count of w in E, $|E|$ is the number of words in E, θ_C is a background language model estimated from the whole KB, and μ is the Dirichlet prior. Recall that E contains N_E, T_E and D_E. We consider using either N_E only or both N_E and D_E to obtain $c(w,E)$ and $|E|$. We refer to the former estimated θ_E as θ_{N_E} and the latter as $\theta_{N_E+D_E}$.

To estimate θ_Q, typically we can use the empirical query word distribution:

$$p(w|\theta_Q) = \frac{c(w,N_Q)}{|N_Q|}, \quad (3)$$

where $c(w,N_Q)$ is the count of w in N_Q and $|N_Q|$ is the length of N_Q. We call this model the *original* query language model.

After ranking the candidate KB entries in $\mathcal{E}_Q$ using Equation (1), we perform entity linking as follows. First, using an NER tagger, we determine the entity type of the query name string N_Q. Let T_Q denote this entity type. We then pick the top-ranked KB entry whose score is higher than a threshold τ and whose T_E is the same as T_Q. The system links the query entity to this KB entry. If no such entry exists, the system returns *Nil*.

3 Query Expansion

We have shown in Section 2.1 that using the original query name string N_Q itself may not be enough to obtain the correct KB entry, and additional words from both the query document and external knowledge can be useful. However, in the KB entry selection stage, these additional words are only used to enlarge the set of candidate KB entries; they have not been used to rank KB entries. In this section, we discuss how to expand the query language model θ_Q with these additional words in a principled way in order to rank KB entries based on how likely they match the query entity.

3.1 Using Local Contexts

Let us look at the example from Figure 2 again. During the KB entry ranking stage, if we use θ_Q estimated from N_Q, which contains only the word "Coppola," the retrieval function is unlikely to rank the correct KB entry on the top. But if we include the contextual word "Sophia" from the query document when estimating the query language model, KL-divergence retrieval model is likely to rank the correct KB entry on the top. This idea of using contextual words to expand the query is very similar to (pseudo) relevance feedback in information retrieval. We can treat the query document D_Q as our only feedback document.

Many different (pseudo) relevance feedback methods have been proposed. Here we apply the relevance model (Lavrenko and Croft, 2001), which has been shown to be effective and robust in a recent comparative study (Lv and Zhai, 2009). We first briefly review the relevance model. Given a set of (pseudo) relevant documents $\mathcal{D}_r$, where for each $D \in \mathcal{D}_r$ there is a document language model θ_D, we can estimate a feedback language model θ_Q^{fb} as follows:

$$p(w|\theta_Q^{\text{fb}}) \propto \sum_{D \in \mathcal{D}_r} p(w|\theta_D) p(\theta_D) p(Q|\theta_D). \quad (4)$$

For our problem, since we have only a single feedback document D_Q, the equation above can be simplified. In fact, in this case the feedback language model is the same as the document language model of the only feedback document, i.e. θ_{D_Q}.

We then linearly interpolate the feedback language model with the original query language model to form an expanded query language model:

$$p(w|\theta_Q^L) = \alpha p(w|\theta_Q) + (1-\alpha) p(w|\theta_{D_Q}), \quad (5)$$

where α is a parameter between 0 and 1, to control the amount of feedback. The larger α is, the less we rely on the local context. L indicates that the query expansion comes from local context. This θ_Q^L can then replace θ_Q in Equation (1) to rank KB entries.

Special Treatment of Named Entities

Usually the document language model θ_{D_Q} is estimated using the entire text from D_Q. For entity linking, we suspect that named entities surrounding the query name string in D_Q are particularly useful for disambiguation and thus should be emphasized over other words. This can be done by weighting

NE and non-NE words differently. In the extreme case, we can use only NEs to estimate the document language model θ_{D_Q} as follows:

$$p(w|\theta_{D_Q}) = \frac{1}{K_Q}\sum_{i=1}^{K_Q}\frac{c(w, N_Q^{l,i})}{|N_Q^{l,i}|}, \quad (6)$$

where $\{N_Q^{l,i}\}$ are defined in Section 2.

Positional Model

Another observation is that words closer to the query name string in the query document are likely to be more important than words farther away. Intuitively, we can use the distance between a word and the query name string to help weigh the word. Here we apply a recently proposed positional pseudo relevance feedback method (Lv and Zhai, 2010). The document language model θ_{D_Q} now has the following form:

$$p(w|\theta_{D_Q}) = \frac{1}{K_Q}\sum_{i=1}^{K_Q} f(p_i, q)\cdot\frac{c(w, N_Q^{l,i})}{|N_Q^{l,i}|}, \quad (7)$$

where p_i and q are the absolute positions of $N_Q^{l,i}$ and N_Q in D_Q. The function f is Gaussian function defined as follows:

$$f(p, q) = \frac{1}{\sqrt{2\pi\sigma^2}}\exp\Big(\frac{-(p-q)^2}{2\sigma^2}\Big). \quad (8)$$

where variance σ controls the spread of the curve.

3.2 Using Global World Knowledge

Similar to the way we incorporate words from D_Q into the query language model, we can also construct a feedback language model using the most likely official name of the query entity obtained from Wikipedia. Specifically, we define

$$p(w|\theta_{N_Q^g}) = \frac{c(w, N_Q^g)}{|N_Q^g|}. \quad (9)$$

We can then linearly interpolate $\theta_{N_Q^g}$ with the original query language model θ_Q to form an expanded query language model θ_Q^G:

$$p(w|\theta_Q^G) = \alpha p(w|\theta_Q) + (1-\alpha)p(w|\theta_{N_Q^g}). \quad (10)$$

Here G indicates that the query expansion comes from global world knowledge.

Entity Type	%Nil	%non-Nil
GPE	32.8%	67.2 %
ORG	59.5%	40.5 %
PER	71.7%	28.3 %

Table 2: Percentages of Nil and non-Nil queries.

3.3 Combining Local Context and World Knowledge

We can further combine the two kinds of additional words into the query language model as follows:

$$p(w|\theta_Q^{L+G}) = \alpha p(w|\theta_Q) + (1-\alpha)\Big(\beta p(w|\theta_{D_Q}) + (1-\beta)p(w|\theta_{N_Q^g})\Big). \quad (11)$$

Note that here we have two parameters α and β to control the amount of contributions from the local context and from global world knowledge.

4 Experiments

4.1 Experimental Setup

Data Set: We evaluate our system on the TAC-KBP 2010 data set (Ji et al., 2010). The knowledge base was constructed from Wikipedia with 818,741 entries. The data set contains 2250 queries and query documents come from news wire and Web pages. Around 45% of the queries have non-Nil entries in the KB. Some statistics of the queries are shown in Table 2.

Tools: In our experiments, to extract named entities within D_Q and to determine T_Q, we use the Stanford NER tagger[1]. An example output of the NER tagger is shown below:

```
<PERSON>Hugh Jackman<PERSON> is Jacked!!
```

This piece of text comes from a query document where the query name string is "Jackman." We can see that the NER tagger can help locate the full name of the person.

We use the Lemur/Indri[2] search engine for retrieval. It implements the KL-divergence retrieval model as well as many other useful functionalities.

Evaluation Metric: We adopt the *Micro-averaged accuracy* metric, which is the mean accuracy over all queries. It was used in TAC-KBP 2010 (Ji et

[1] http://nlp.stanford.edu/software/CRF-NER.shtml

[2] http://www.lemurproject.org/indri.php

al., 2010) as the official metric to evaluate the performance of entity linking. This metric is simply defined as the percentage of queries that have been correctly linked.

Methods to Compare: Recall that our system consists of a KB entry selection stage and a KB entry ranking stage. At the selection stage, a set $\mathcal{S}_Q$ of alternative name strings are used to select candidate KB entries. We first define a few settings where different alternative name string sets are used to select candidate KB entries:

- **Q** represents the baseline setting which uses only the original query name string N_Q to select candidate KB entries.
- **Q+L** represents the setting where alternative name strings obtained from the query document D_Q are combined with N_Q to select candidate KB entries.
- **Q+G** represents the setting where the alternative name string obtained from Wikipedia is combined with N_Q to select candidate KB entries.
- **Q+L+G** represents the setting as we described in Section 2.1, that is, alternative name strings from both D_Q and Wikipedia are used together with N_Q to select candidate KB entries.

After selecting candidate KB entries, in the KB entry ranking stage, we have four options for the query language model and two options for the KB entry language model. For the query language model, we have (1) θ_Q, the original query language model, (2) θ_Q^L, an expanded query language model using local context from D_Q, (3) θ_Q^G, an expanded query language model using global world knowledge, and (4) θ_Q^{L+G}, an expanded query language model using both local context and global world knowledge. For the KB entry language model, we can choose whether or not to use the KB disambiguation text D_E and obtain θ_{N_E} and $\theta_{N_E+D_E}$, respectively.

4.2 Results and Discussion

First, we compare the performance of KB entry selection stage for all four settings on non-Nil queries. The performance measure recall is defined as

$$recall = \begin{cases} 1, & if\ E\ that\ refers\ to\ Q,\ exists\ in\ \mathcal{E}_Q \\ 0, & otherwise \end{cases}$$

The recall statistics in Table 3 shows that, Q+L+G has the highest recall of the KB candidate entries.

Method	Recall(%)
Q	67.1
Q+L	89.7
Q+G	94.9
Q+L+G	98.2

Table 3: Comparing the effect of candidate entry selection using different methods - KB entry selection stage recall.

Before examining the effect of query expansion in ranking, we now compare the effect of using different sets of alternative query name strings in the candidate KB entry selection stage. For this set of experiments, we fix the query language model to θ_Q and the KB entry language model to θ_{N_E} in the ranking stage.

Table 4 shows the performance of all the settings in terms of micro-averaged accuracy. The results shown in Tables 4, 5 and 6 are based on the optimum parameter settings. We can see that in terms of the overall performance, both Q+L and Q+G give better performance than Q with a 7.7% and a 9.9% relative improvement, respectively. Q+L+G gives the best performance with a 12.8% relative improvement over Q. If we further zoom into the results, we see that for ORG and PER queries, when no correct KB entry exists (i.e. the Nil case), the performance of Q, Q+L, Q+G and Q+L+G is very close, indicating that the additional alternative query name strings do not help. It shows that the alternative query name strings are most useful for queries that do have their correct entries in the KB.

We now further analyze the impact of the expanded query language models θ_Q^L, θ_Q^G and θ_Q^{L+G}. We first analyze the results without using the KB disambiguation text, i.e. using θ_{N_E}. Table 5 shows the comparison between θ_Q and other expanded query language models in terms of micro-averaged accuracy. The results reveal that the expanded query language models can indeed improve the overall performance (the both Nil and non-Nil case) under all settings. This shows the effectiveness of using the principled query expansion technique coupled with KL-divergence retrieval model to rank KB entries.

Method	All				Nil			Non-Nil		
	ALL	GPE	ORG	PER	GPE	ORG	PER	GPE	ORG	PER
Q	0.6916	0.5714	0.6533	0.8495	0.8618	**0.9888**	**0.9963**	0.4294	0.1612	0.4789

	θ_Q^{L+G}	**0.8516**	**0.8278**	**0.7867**	**0.9401**	0.8821	0.9372	0.9814	**0.8012**	**0.5658**	**0.8357**

Table 5: Comparison between the performance of θ_Q and expanded query language models in terms of micro average accuracy. θ_{N_E} was used in ranking.

On the other hand, again we observe that the effects on the Nil and the non-Nil queries are different. While in Table 4 the alternative name strings do not affect the performance much for Nil queries, now the expanded query language models actually hurt the performance for Nil queries. It is not surprising to see this result. When we expand the query language model, we can possibly introduce noise, especially when we use the external knowledge obtained from Wikipedia, which largely depends on what Wikipedia considers to be the most popular official name of a query name string. With noisy terms in the expanded query language model we increase the chance to link the query to a KB entry which is not the correct match. The challenge is that we do not know when additional terms in the expanded query language model are noise and when they are not, because for non-Nil queries we do observe a substantial amount of improvement brought by query expansion, especially with external world knowledge. We will further investigate this research question in the future.

We now further study the impact of using the KB disambiguation text associated with each entry to estimate the KB entry language model used in the KL-divergence ranking function. The results are shown in Table 6 for all the methods on θ_{N_E} vs. $\theta_{N_E+D_E}$ using the expanded query language models. We can see that for all methods the impact of using the KB disambiguation text is very minimal and is observed only for GPE and ORG queries. Table 7 shows an example of the KL-divergence scores for a query, *Mobile* whose context is previously shown in the Figure 1. Without the KB disambiguation text both the KB entry *Mobile Alabama* and the entry *Mobile River* are given the same score, resulting in inaccurate linking in the θ_{N_E} case. But with $\theta_{N_E+D_E}$, *Mobile Alabama* was scored higher, resulting in an accurate linking. However, we observe that such cases are very rare in the TAC 2010 query list and thus the overall improvement observed is minimal.

KB Entry	KB Name	w/o text	w/ text
E0583976	Mobile Alabama	-6.28514	-6.3839
E0183287	Mobile River	-6.28514	-6.69372

Table 7: The KL-divergence scores of KB entities for the query *Mobile*.

Finally, we compare our performance with the highest scores from TAC-KBP 2010 as shown in the Table 8. It is important to note that the highest TAC results shown in the table under each setting are not necessarily obtained by the same team. We can see that our overall performance when KB text is used is competitive compared with the highest TAC score, and is substantially higher than the TAC score when KB text is not used. Lehmann et al. (2010) achieved highest TAC scores. They used a variety of evidence from Wikipedia like disambiguation pages, anchors, expanded acronyms and redirects to build a rich feature set. But as we discussed, building a rich fea-

Method	KB Text	All				Nil			Non-Nil		
		ALL	GPE	ORG	PER	GPE	ORG	PER	GPE	ORG	PER

	$\theta_{N_E+D_E}$	0.6888	0.5607	0.6533	0.8495	0.8618	0.9888	0.9963	0.4135	0.1612	0.4789
Q+L	θ_{N_E}	0.7689	0.7850	0.6533	0.8682	0.9309	0.9888	0.9944	0.7137	0.1612	0.5493
	$\theta_{N_E+D_E}$	**0.7707**	**0.7904**	0.6533	0.8682	**0.9390**	0.9888	0.9944	**0.7177**	0.1612	0.5493
Q+G	θ_{N_E}	0.8160	0.7423	**0.7867**	0.9188	**0.9106**	0.9372	0.9796	0.6600	**0.5658**	0.7653
	$\theta_{N_E+D_E}$	**0.8222**	**0.7450**	0.7827	**0.9387**	0.8902	0.9372	**0.9814**	**0.6740**	0.5559	**0.8310**
Q+L+G	θ_{N_E}	0.8516	0.8278	0.7867	0.9401	**0.8821**	0.9372	0.9814	0.8012	0.5658	0.8357
	$\theta_{N_E+D_E}$	**0.8524**	**0.8291**	**0.7880**	0.9401	0.8740	0.9372	0.9814	**0.8072**	**0.5691**	0.8357

Table 6: Comparing the performance using KB text and without using KB text for all methods using expanded query models in terms of micro average accuracy on 2250 queries. $\theta_{N_E+D_E}$ represents method using KB text and θ_{N_E} represents methods without using KB text.

ture set is an expensive task. Their overall accuracy is 1.5% higher than our model. Table 8 shows that the performance of ORG entities is lower when compared with the TAC results when we used KB text. In our analysis, we observed that, even though some entities like AMPAS are linked correctly, the entities like CCC (Consolidated Contractors Company) failed due to ambiguity in the title. Here, we may benefit by leveraging more global knowledge, i.e, we should expand the N_Q^g with Wikipedia global context entities together with the title to fully benefit from global knowledge. In particular, when KB text is not used, our system outperforms the highest TAC results for all three types of queries.

From the analysis by Ji et al. (2010), overall the participating teams generally performed the best on PER queries and the worst on GPE queries. With our system, we can achieve good performance on GPE queries.

KB Text Usage	Type	Our System	TAC Highest
$\theta_{N_E+D_E}$	All	0.8524	**0.8680**
	GPE	**0.8291**	0.7957
	ORG	0.7880	**0.8520**
	PER	0.9401	**0.9601**
θ_{N_E}	All	**0.8516**	0.7791
	GPE	**0.8278**	0.7076
	ORG	**0.7867**	0.7333
	PER	**0.9401**	0.9001

Table 8: Comparison of the best configuration of our system (Q+L+G with θ_Q^{L+G}) with the TAC-KBP 2010 results in terms of micro-averaged accuracy. $\theta_{N_E+D_E}$ represents the method using KB disambiguation text and θ_{N_E} represents the method without using KB disambiguation text.

4.3 Parameter Sensitivity

In all our experiments, we set the Dirichlet prior μ to 2500 following previous studies. For the threshold τ we empirically set it to -12.0 in all the experiments based on preliminary results. Recall that all the expanded query language models also have a control parameters α. The local context-based models θ_Q^L and θ_Q^{L+G} have an additional parameter σ which controls the proximity weighing. The θ_Q^{L+G} model has another additional parameter β that controls the balance between local context and world knowledge. In this subsection, we study the sensitivity of these parameters. We plot the sensitivity graphs for all the methods that involve α (β set to 0.5) in Figure 3. As we can see, all the curves appear to be stable and α=0.4 appears to work well.

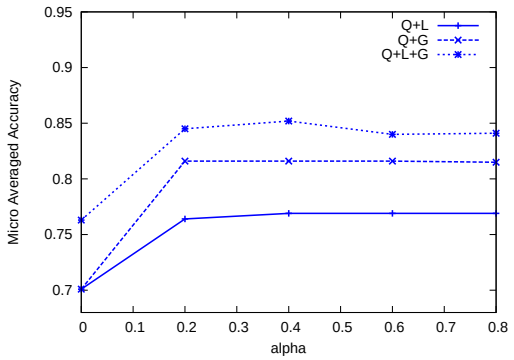

Figure 3: Sensitivity of α in regard to micro-averaged accuracy.

Similarly, we set α=0.4 and examine how β affects micro averaged accuracy. We plot the sensitivity curve for β for the Q+L+G setting with θ_Q^{L+G} in Figure 5. As we can see, the best performance is achieved when β=0.5. This implies that the local

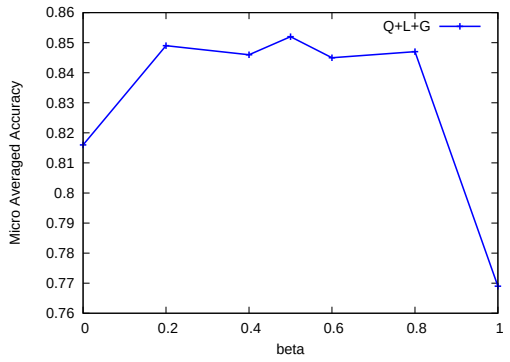

Figure 4: Sensitivity of β in regard to micro-averaged accuracy.

context and the global world knowledge are weighed equally for aiding disambiguation and improving the entity linking performance.

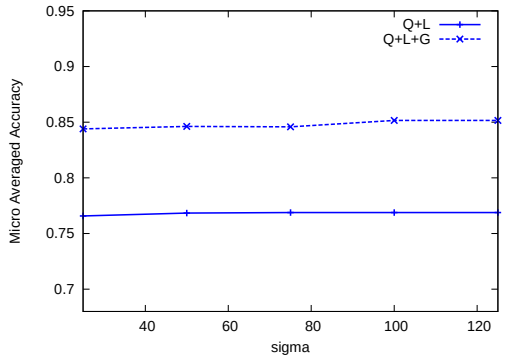

Figure 5: Sensitivity of σ with respect to micro-averaged accuracy.

Furthermore, we systematically test a fixed set of σ values from 25 to 125 with an intervals of 25 and examine how σ affects micro averaged accuracy. We set α=0.4 and β=0.5, which is the best parameter setting as discussed above. We plot the sensitivity curves for the parameter σ for methods that utilize the local context, i.e. θ_Q^L and θ_Q^{L+G}, in Figure 5. We observe that all the curves are stable and 75 $<=$ σ $<=$ 100 appears to work well. We set σ=100 for all our experiments. Moreover, after 100, the graph becomes stable, which indicates that proximity has less impact on the method from this point on. This implies that an equal weighing scheme actually would work the same for these experiments. Part of the reason may be that by using only named entities in the context rather than all words, we have effectively picked the most useful contextual terms. Therefore, positional feedback models do have exhibit much benefit for our problem.

5 Related Work

Bunescu and Pasca (2006) and Cucerzan (2007) explored the entity linking task using Vector Space Models for ranking. They took a classification approach together with the novel idea of exploiting Wikipedia knowledge. In their pioneering work, they used Wikipedia's category information for entity disambiguation. They show that using different background knowledge, we can find efficient approaches for disambiguation. In their work, they took an assumption that every entity has a KB entry and thus the NIL entries are not handled.

Similar to other researchers, Zhang et al. (2010) took an approach of classification and used a two-stage approach for entity liking. They proposed a supervised model with SVM ranking to filter out the candidates and deal with disambiguation effectively. For entity diambiguation they used the contextual comparisons between the Wikipedia article and the KB article. However, their work ignores the possibilities of acronyms in the entities. Also, the ambiguous geo-political names are not handled in their work.

Dredze et al. (2010) took the approach that large number of entities will be unlinkable, as there is a probability that the relevant KB entry is unavailable. Their algorithm for learning NIL has shown very good results. But their proposal for handling the alias name or stage name via multiple lists is not scalable. Unlike their approach, we use the global knowledge to handle the stage names and thus this gives an optimized solution to handle alias names. Similarly, for acronyms we use the global knowledge that aids unabbreviating and thus entity disambiguation. Similar to other approaches, Zheng et al. (2010) took a learning to rank approach and compared list-wise rank model to the pair-wise rank model. They achieved good results on the list-wise ranking approach. They handled acronyms and disambiguity through wiki redirect pages and the anchor texts which is similar to others ideas.

Challenges in supervised learning includes careful feature selection. The features can be selected in ad hoc manner - similarity based or semantic based. Also machine learning approach induces challenges of handling heterogenous cases. Unlike their machine learning approach which requires careful fea-

ture engineering and heterogenous training data, our method is simple as we use simple similarity measures. At the same time, we propose a statistical language modeling approach to the linking problem. Many researchers have proposed efficient ideas in their works. We integrated some of their ideas like world knowledge with our new techniques to achieve efficient entity linking accuracy.

6 Conclusions

In this paper we proposed a novel approach to entity linking based on statistical language model-based information retrieval with query expansion using the local context from the query document as well as world knowledge from the Web. Our model is a simple unsupervised one that follows principled existing information retrieval techniques. And yet it performs the entity linking task effectively compared with the best performance achieved in the TAC-KBP 2010 evaluation.

Currently our model does not exploit world knowledge from the Web completely. World knowledge, especially obtained from Wikipedia, has shown to be useful in previous studies. As our future work, we plan to explore how to further incorporate such world knowledge into our model in a principled way.

Abstract

We address the task of automatic discovery of information extraction template from a given text collection. Our approach clusters candidate slot fillers to identify meaningful template slots. We propose a generative model that incorporates distributional prior knowledge to help distribute candidates in a document into appropriate slots. Empirical results suggest that the proposed prior can bring substantial improvements to our task as compared to a K-means baseline and a Gaussian mixture model baseline. Specifically, the proposed prior has shown to be effective when coupled with discriminative features of the candidates.

1 Introduction

Information extraction (IE) is the task of extracting information from natural language texts to fill a database record following a structure called a *template*. Such templates are usually defined based on the domain of interest. For example, the domain in the Sixth Message Understanding Conference (MUC-6, 1995) is management succession, and the pre-defined template consists of the slots *position*, the *person leaving*, the *person joining*, and the *organization*.

Previous research on IE often requires the predefinition of templates. Template construction is usually done manually by domain experts, and annotated documents are often created to facilitate supervised learning approaches to IE. However, both manual template construction and data annotation are labor-intensive. More importantly, templates and annotated data usually cannot be re-used in new domains due to domain dependency. It is therefore natural to consider the problem of unsupervised template induction and information extraction. This is the topic of this paper.

There have been a few previous attempts to address the unsupervised IE problem (Shinyama and Sekine, 2006; Sekine, 2006; Rosenfeld and Feldman, 2006; Filatova et al., 2006). These approaches have a commonality: they try to cluster candidate slot fillers, which are often nouns and noun phrases, into slots of the template to be constructed. However, most of them have neglected the following important observation: a single document or text segment tends to cover different slots rather than redundantly fill the same slot. In other words, during clustering, candidates within the same text segment should be more likely to be distributed into different clusters.

In this paper, we propose a generative model that incorporates this distributional prior knowledge. We define a prior distribution over the possible label assignments in a document or a text segment such that a more diversified label assignment is preferred. This prior is based on the Poisson distribution. We also compare a number of generative models for generating slot fillers and find that the Gaussian mixture model is the best. We then combine the Poisson-based label assignment prior with the Gaussian mixture model to perform slot clustering. We find that compared with a K-means baseline and a Gaussian mixture model baseline, our combined model with the proposed label assignment prior substantially performs better on two of the three data sets we use for evaluation. We further analyze the results on the third data set and find that the proposed prior will have little effect if there are no good discriminative features to begin with. In summary, we find that

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 814–824,
Edinburgh, Scotland, UK, July 27–31, 2011.

our Poisson-based label assignment prior is effective when coupled with good discriminative features.

2 Related Work

One common approach to unsupervised IE is based on automatic IE pattern acquisition on a cluster of similar documents. For instance, Sudo et al. (2003) and Sekine (2006) proposed different methods for automatic IE pattern acquisition for a given domain based on frequent subtree discovery in dependency parse trees. These methods leveraged heavily on the entity types of candidates when assigning them to template slots. As a consequence, potentially different semantic roles of candidates having the same entity type could become indistinguishable (Sudo et al., 2003; Sekine, 2006). This problem is alleviated in our work by exploiting distributional prior knowledge about template slots, which is shown effective when coupled with discriminative features of candidates. Filatova et al. (2006) also considered frequent subtrees in dependency parse trees, but their goal was to build templates around verbs that are statistically important in a given domain. Our work, in contrast, is not constrained to verb-centric templates. We aim to identify salient slots in the given domain by clustering.

Marx et al. (2002) proposed the cross-component clustering algorithm for unsupervised IE. Their algorithm assigned a candidate from a document to a cluster based on the candidate's feature similarity with candidates from *other documents only*. In other words, the algorithm did not consider a candidate's relationships with other candidates in the same document. Our work is based on a different perspective: we model label assignments for all candidates in the same document with a distributional prior that prefers a document to cover more distinct slots. We show empirically that this prior improves slot clustering results greatly in some cases.

Also related to our work is open domain IE, which aims to perform unsupervised *relation extraction*. TEXTRUNNER (Banko et al., 2007), for example, automatically extracts *all possible relations* between pairs of noun phrases from a given corpus. The main difference between open domain IE and our work is that open domain IE does not aim to induce domain templates, whereas we focus on a single domain with the goal of inducing a template that describes salient information structure of that domain. Furthermore, TEXTRUNNER and related studies on unsupervised relation extraction often rely on highly redundant information on the Web or in large corpus (Hasegawa et al., 2004; Rosenfeld and Feldman, 2006; Yan et al., 2009), which is not assumed in our study.

We propose a generative model with a distributional prior for the unsupervised IE task, where slot fillers correspond to *observations* in the model, and their labels correspond to *hidden variables* we want to learn. In the machine learning literature, researchers have explored the use of similar prior knowledge in the form of *constraints* through model expectation. For example, Graça et al. (2007) proposed to place constraints on the posterior probabilities of hidden variables in a generative model, while Druck et al. (2008) studied a similar problem in a discriminative, semi-supervised setting. These studies model constraints as features, and enforce the constraints through expected feature values. In contrast, we place constraints on label assignments through a probabilistic prior on the distribution of slots. The proposed prior is simple and easy to interpret in a generative model. Nevertheless, it will be interesting to explore how the proposed prior can be implemented within the posterior constraint framework.

3 Problem Overview

In this section, we first formally define our unsupervised IE problem. We then provide an overview of our solution, which is based on a generative model.

3.1 Problem Definition

We assume a collection of documents or short text segments from a certain domain. These documents or text segments describe different events or entities, but they are about the same topic or aspect of the domain. Examples of such collections include a collection of sentences describing the educational background of famous scientists and a collection of aviation incident reports. Our task is to automatically discover an IE template from this collection. The discovered template should contain a set of slots that play different semantic roles in the domain.

Topic: Graduate Student Seminar Lunch
Dates: 13-Apr-95
Time: 12:00 PM - 1:30 PM
PostedBy: Edmund J. Delaney on 5-Apr-95 at 16:24 from andrew.cmu.edu
Abstract:
The last Graduate Student Seminar Series lunch will be held on Thursday, April 13 from noon-1:30 p.m. in room 207, Student Activities Center. Professor Sara Kiesler of SDS will speak on Carving A Successful Research Niche.

Output:

Slot	Slot Filler(s)
Slot 1 (*start time*)	12:00PM
Slot 2 (*end time*)	1:30PM, 1:30 p.m.
Slot 3 (*location*)	room 207, Student Activities Center
Slot 4 (*speaker*)	Professor Sara Kiesler
Slot 4 (*irrelevant information*)	Edmund J. Delaney

Figure 1: An input text from a seminar announcement collection and the discovered IE template. Note that the slots are automatically discovered and the slot names are manually assigned.

To construct such a template, we start with identifying candidate slot fillers, hereafter referred to as *candidates*, from the input text. Then we cluster these candidates with the aim that each cluster will represent a semantically meaningful slot. Figure 1 gives an example of an input text from a collection of seminar announcements and the resulting template discovered from the collection. As we can see, the template contains some semantically meaningful slots such as the *start time*, *end time*, *location* and *speaker* of a seminar. Moreover, it also contains a slot that covers an irrelevant candidate. We call such slots covering irrelevant candidates *garbage slots*.

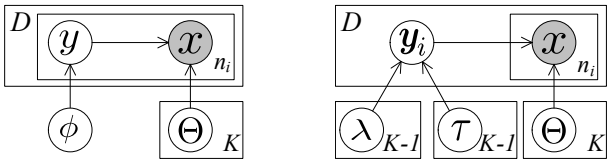
We can make two observations on the mapping from candidates to template slots from real data, such as the text in Figure 1. Firstly, a template slot may be filled by more than one candidate from a single document, although this number has been observed to be small. For example, the template slot *end time* in Figure 1 has two slot fillers: "1:30 PM" from the semi-structured header and "1:30 p.m." from within the abstract. Secondly, a document tends to contain candidates that cover different template slots. We believe that this observation is a consequence of the fact that a document will tend to convey as much information as possible. We further exploit these observations in Section 4.

3.2 A General Solution

Recall that our general solution to the unsupervised IE problem is to cluster candidate slot fillers in order to identify meaningful slots. We leave the details of how to extract the candidates to Section 7.1. In this section, we assume that we have a set of candidates $\boldsymbol{x} = \{x_{i,j}\}$, where $x_{i,j}$ is the j-th candidate from the i-th document in the collection. We cluster these candidates into K groups for a given K.

Let $y_{i,j} \in \{1, \ldots, K\}$ denote the cluster label for $x_{i,j}$ and $\boldsymbol{y}$ denote the set of all the $y_{i,j}$'s. Let $\boldsymbol{x}_i$ and $\boldsymbol{y}_i$ denote the sets of all the $x_{i,j}$'s and the $y_{i,j}$'s in the i-th document respectively. We assume a generative model for $\boldsymbol{x}$ and $\boldsymbol{y}$ as follows. For the i-th document in our collection, we assume that the number of candidates is known and we draw a label assignment $\boldsymbol{y}_i$ according to some distribution parameterized by Λ. Then for the j-th candidate, we generate $x_{i,j}$ from $y_{i,j}$ according to a generative model parameterized by Θ. Since the labels $\boldsymbol{y}$ are hidden, the observed log-likelihood of the parameters given the observations $\boldsymbol{x}$ is

$$\begin{aligned} L(\Lambda, \Theta) &= \log p(\boldsymbol{x}; \Lambda, \Theta) \\ &= \sum_i \log \sum_{\boldsymbol{y}_i} p(\boldsymbol{x}_i, \boldsymbol{y}_i; \Lambda, \Theta) \\ &= \sum_i \log \sum_{\boldsymbol{y}_i} p(\boldsymbol{y}_i; \Lambda) \prod_j p(x_{i,j} | y_{i,j}; \Theta). \quad (1) \end{aligned}$$



(a) A multinomial prior. (b) The proposed Poisson-based prior.

Figure 2: Generative models with different label assignment priors. D denotes the number of documents in the given collection, n_i denotes the number of candidates in the i-th document, and K is the number of slots (clusters).

For a given functional form of $p(\boldsymbol{y}_i; \Lambda)$ and $p(x_{i,j}|y_{i,j}; \Theta)$, the best model parameters can be estimated by maximizing Eq. (1). In the next section, we detail two designs of the prior $p(\boldsymbol{y}_i; \Lambda)$, followed by different generative models for the distribution $p(x_{i,j}|y_{i,j}; \Theta)$ in Section 5. Then we describe the estimation of model parameters in Section 6.

4 Label Assignment Prior

The label assignment prior, $p(\boldsymbol{y}_i; \Lambda)$, models the generation of labels for candidates in a document. In this section, we first describe a commonly used multinomial prior, and then introduce the proposed Poisson-based prior for the unsupervised IE task.

4.1 A Multinomial Prior

Usually, one would assume that the labels for the different candidates in the same document are generated independently, that is, $p(\boldsymbol{y}_i; \Lambda) = \prod_j p(y_{i,j}; \Lambda)$. Under this model, we assume that each $y_{i,j}$ is generated from a multinomial distribution parameterized by $\boldsymbol{\phi}$, where ϕ_y denotes the probability of generating label y. Our objective function in Eq. (1) then becomes:

$$\begin{aligned} L(\Lambda, \Theta) &= \log p(\boldsymbol{x}; \Lambda, \Theta) \\ &= \sum_{i,j} \log \sum_y \phi_y p(x_{i,j}|y; \Theta). \end{aligned} \quad (2)$$

Figure 2(a) depicts a generative model with this multinomial prior in plate notation. Note that the independence assumption on label assignment in this model does not capture our observation that candidates in a document are likely to cover different semantic roles.

4.2 The Proposed Poisson-based Prior

We propose a prior distribution that favors more diverse label assignments. Our proposal takes into consideration the following three observations. Firstly, candidates in the same document are likely to cover different semantic roles. The proposed prior distribution should therefore assign higher probability to a label assignment that covers more distinct slots. Secondly, the same piece of information is not likely to be repeated many times in a document. Our design thus allows a slot to generate multiple fillers in a document, up to a limited number of times. Thirdly, there may exist candidates that do not belong to slots in the extracted template. Therefore, we introduce a *dummy slot* or *garbage slot* to the label set to collect such candidates. Yet, we shall not assume any prior/domain knowledge about candidates generated by the garbage slot as they are essentially irrelevant in the given domain.

We now detail the prior that exploits the above observations. First, we fix the K-th slot (or cluster) in the label set to be the garbage slot. For each of the non-garbage slot $k = 1, \ldots, K-1$, we also fix the maximum number of fillers that can be generated, which we denote by λ_k. There is no λ_K for the garbage slot because the number of fillers is not constrained for this slot. This allows all candidates in a document to be generated by the garbage slot. Let n_i be the number of candidates in the i-th document. Given K, $\{\lambda_k\}_{k=1}^{K-1}$ and n_i, the set of possible label assignments for the i-th document can be generated. We illustrate this with an example. Let $K = 2$ and $\lambda_1 = 1$. The label set is $\{1, 2\}$, where 2 represents the garbage slot. Let the number of candidates be $n_i = 2$. The possible label assignments within this setting are $(1, 2)$, $(2, 1)$ and $(2, 2)$.

The set of possible label assignments for the i-th document is the sample space on which we place the prior distribution $p(\boldsymbol{y}_i; \Lambda)$. We need a prior that gives a higher probability to a more diverse label assignment. For a given $\boldsymbol{y}_i$ for the i-th document, let $n_{i,k}$ be the number of candidates in the document that have been assigned to slot k. That is, $n_{i,k} \stackrel{\text{def}}{=} \sum_{j=1}^{n_i} \mathbf{1}(y_{i,j} = k)$, where $\mathbf{1}(\cdot)$ is the indicator variable. We propose the following distribution based on the Poisson distribution:

$$p(\boldsymbol{y}_i; \Lambda) \stackrel{\text{def}}{=} Z_i^{-1} \prod_{k=1}^{K-1} \text{Poisson}(n_{i,k}; \tau_k), \quad (3)$$

where Z_i is the normalizing constant, and τ_k is the mean parameter of the k-th Poisson distribution, $k = 1, \ldots K-1$. The absence of a factor that depends on $n_{i,K}$ reflects the lack of prior knowledge on the number of garbage slot fillers. Figure 2(b) depicts the proposed generative model with the Poisson-based prior in plate notation.

5 Generating Slot Fillers

Different existing generative models can be used to model the generation of a slot filler given a label, that is, $p(x|y;\Theta)$. We explore four of them for our task, namely, the naive Bayes model, the Bernoulli mixture model, the Gaussian mixture model, and a locally normalized logistic regression model proposed by Berg-Kirkpatrick et al. (2010).

5.1 Multinomial Naive Bayes

In the multinomial naive Bayes model, features of an observation x are assumed to be independent and each generated from a multinomial distribution. We first introduce some notations. Let f denote a feature (e.g. entity type) and $\mathcal{V}_f$ denote the set of possible values for f. Let $x^f \in \mathcal{V}_f$ be the value of feature f in x (e.g. *person*). For a given label y, feature f follows a multinomial distribution parameterized by $\boldsymbol{\psi}_{y,f}$, where $\psi_{y,f,v}$ denotes the probability of feature f taking the value $v \in \mathcal{V}_f$ given label y. The functional form of the conditional probability of x given a label y is then

$$p(x|y;\Theta) = \prod_f p(x^f|y;\Theta) = \prod_f \psi_{y,f,x^f}. \quad (4)$$

5.2 Bernoulli Mixture Model

In the naive Bayes model our features are defined to be categorical. For the Bernoulli mixture model, as well as the Gaussian mixture model and the locally normalized logistic regression model in the next subsections, we first convert each observation x into a binary feature vector $\mathbf{x} \in \{0,1\}^F$ where F is the number of binary features. An example of a binary features is "the entity type is *person*".

We assume that, for a given label y, observations are generated from a multivariate Bernoulli distribution parameterized by $\boldsymbol{\varphi}_{y,f}$, where $\varphi_{y,f,v}$ denotes the probability of feature f taking the value $v \in \{0,1\}$ given label y. The conditional probability of $\mathbf{x}$ given y can then be written as

$$\begin{aligned} p(\mathbf{x}|y;\Theta) &= \prod_f p(x_f = 1|y;\Theta)^{x_f} \cdot p(x_f = 0|y;\Theta)^{1-x_f} \\ &= \prod_f \varphi_{y,f,x^f}. \end{aligned} \quad (5)$$

5.3 Gaussian Mixture Model

In the Gaussian mixture model, we assume that a given label y generates observations with a multivariate Gaussian distribution $\mathcal{N}(\mu_y, \Sigma_y)$, where $\mu_y \in \mathbb{R}^F$ is the mean and $\Sigma_y \in \mathbb{R}^{F \times F}$ is the covariance matrix of the Gaussian. If we assume that the different feature dimensions are independent and have the same variance, that is, $\Sigma_y = \sigma_y^2 I$, where I is the identity matrix, then the conditional density of $\mathbf{x}$ given y is

$$p(\mathbf{x}|y;\Theta) = \frac{1}{(2\pi\sigma_y^2)^{F/2}} \exp\left(-\frac{\|\mathbf{x} - \mu_y\|^2}{2\sigma_y^2}\right). \quad (6)$$

5.4 Locally Normalized Logistic Regression

Berg-Kirkpatrick et al. (2010) proposed a method for incorporating features into generative models for unsupervised learning. Their method models the generation of $\mathbf{x}$ given y as a logistic function parameterized by a weight vector $\mathbf{w}_y$, defined as follows:

$$p(\mathbf{x}|y;\Theta) = \frac{\exp\langle \mathbf{x}, \mathbf{w}_y \rangle}{\sum_{\mathbf{x}'} \exp\langle \mathbf{x}', \mathbf{w}_y \rangle}. \quad (7)$$

$\langle \mathbf{x}, \mathbf{w} \rangle$ denotes the inner product between $\mathbf{x}$ and $\mathbf{w}$. The denominator considers all data points $\mathbf{x}'$ in the data set, thus Eq. (7) gives a probability distribution over data points for a given y.

6 Parameter Estimation

We can apply the Expectation-Maximization (EM) algorithm (Dempster et al., 1977) to maximize the log-likelihood functions under both multinomial prior in Eq. (2) and the proposed Poisson-based prior in Eq. (1). For the multinomial prior, there are standard closed form solutions for the naive Bayes, the Bernoulli mixture and the Gaussian mixture models. For locally normalized logistic regression, model parameters can also be learned via EM, but with a gradient-based M-step (Berg-Kirkpatrick et al., 2010). We leave out the details here and focus on parameter estimation in the proposed generative model with the Poisson-based prior.

We assume that in the Poisson-based prior, the parameters $\{\lambda_k\}_{k=1}^{K-1}$ and $\{\tau_k\}_{k=1}^{K-1}$ are fixed rather than learned in this work. For the distribution $p(x|y;\Theta)$, let $\Theta^{(t-1)}$ and $\Theta^{(t)}$ denote parameter estimates from two consecutive EM iterations. At the t-th iteration, the E-step updates the responsibilities of each label assignment $\boldsymbol{y}_i$ for each document:

$$\begin{aligned}\alpha_{i,\boldsymbol{y}_i} &= p(\boldsymbol{y}_i|\boldsymbol{x_i};\Lambda,\Theta^{(t-1)}) \\ &= \frac{p(\boldsymbol{y}_i;\Lambda)p(\boldsymbol{x}_i|\boldsymbol{y}_i;\Theta^{(t-1)})}{\sum_{\boldsymbol{y}'_i} p(\boldsymbol{y}'_i;\Lambda)p(\boldsymbol{x}_i|\boldsymbol{y}'_i;\Theta^{(t-1)})}, \quad (8)\end{aligned}$$

where α_i is a distribution over all possible label assignments $\boldsymbol{y}_i$'s for the i-th document. The M-step updates the estimates of $\Theta^{(t)}$ based on the current values of α_i's and $\Theta^{(t-1)}$. This is done by maximizing the following objective function:

$$\sum_i \sum_{\boldsymbol{y}_i} \alpha_{i,\boldsymbol{y}_i} \log\Big(p(\boldsymbol{y}_i;\Lambda)\prod_j p(x_{i,j}|y_{i,j};\Theta^{(t-1)})\Big). \quad (9)$$

The exact formulas used in the M-step for updating Θ depend on the functional form of $p(x_{i,j}|y_{i,j};\Theta)$. As an example, we give the formulas for the Gaussian mixture model, in which Θ contains the set of means $\{\mu_k^{(t)}\}_{k=1}^K$ and variances $\{\sigma_k^{(t)}\}_{k=1}^K$. Taking the derivatives of Eq. (9) with respect to μ_k and to σ_k, and then setting the derivations to zero, we can solve for μ_k and for σ_k to get:

$$\mu_k^{(t)} = \frac{\sum_i \sum_{\boldsymbol{y}_i} \alpha_{i,\boldsymbol{y}_i} \sum_j \mathbf{1}(y_{i,j}=k)\mathbf{x}_{i,j}}{\sum_i \sum_{\boldsymbol{y}_i} \alpha_{i,\boldsymbol{y}_i} \sum_j \mathbf{1}(y_{i,j}=k)}, \quad (10)$$

$$\sigma_k^{(t)} = \frac{\sum_i \sum_{\boldsymbol{y}_i} \alpha_{i,\boldsymbol{y}_i} \sum_j \mathbf{1}(y_{i,j}=k)||\mathbf{x}_{i,j}-\mu_k^{(t)}||^2}{F\sum_i \sum_{\boldsymbol{y}_i} \alpha_{i,\boldsymbol{y}_i} \sum_j \mathbf{1}(y_{i,j}=k)}, \quad (11)$$

where $\mathbf{1}(\cdot)$ is the indicator variable. We skip the derivations here due to space limit.

Closed form solutions also exist for the naive Bayes and the Bernoulli mixture models. For locally normalized logistic regression, parameters can be learned with a gradient-based M-step as in the multinomial prior setting. Existing optimization algorithms, such as L-BFGS, can be used for optimizing model parameters in the M-step as discussed in (Berg-Kirkpatrick et al., 2010).

7 Experiments

In this section, we first describe the data sets we used in our experiments, detailing the target slots and candidates in each data set, as well as features we extract for the candidates. We then describe our evaluation metrics, followed by experimental results.

7.1 Data Sets

We use three data sets for evaluating our unsupervised IE task. Note that to speed up computation, we only include documents or text segments containing no more than 10 candidates in our experiments. The first data set contains a set of seminar announcements (Freitag and McCallum, 1999), annotated with four slot labels, namely *stime* (start time), *etime* (end time), *speaker* and *location*. We used as candidates all strings labeled in the annotated data as well as all named entities found by the Stanford NER tagger for CoNLL (Finkel et al., 2005). There are 309 seminar announcements with 2262 candidates in this data set.

The second data set is a collection of paragraphs describing aviation incidents, taken from the Wikipedia article on "List of accidents and incidents involving commercial aircraft" (Wikipedia, 2009). Each paragraph in the article contains one to a few sentences describing an incident. In this domain, we take each paragraph as a separate document, and all hyperlinked phrases in the original Wikipedia article as candidates. For evaluation, we manually annotated the paragraphs of incidents from 2006 to 2009 with five slot labels: the *flight number* (FN), the *airline* (AL), the *aircraft model* (AC), the *exact*

location (LO) of the incident (e.g. airport name), and the *country* (CO) where the incident occurred. The entire data set consists of 564 paragraphs with 2783 candidates. The annotated portion consists of 74 paragraphs with 395 candidates.

The third data set comes from the management succession domain used in the Sixth Message Understanding Conference (MUC-6, 1995). We extract from the original data set all sentences that were tagged with a management succession event, and use as candidates all tagged strings in those sentences. This domain has four target slots, namely *PersonIn* (the person moving into a new position), *PersonOut* (the person leaving a position), *Org* (the corporation's name) and *Post* (the position title). Sentences containing candidates with multiple labels (candidates annotated as both *PersonIn* and *PersonOut*) are discarded. The extracted data set consists of 757 sentences with 2288 candidates.

7.2 Features

To extract features for candidates, we first normalize each word to its lower-case, with digits replaced by the token *digit*. We extract the following features for every candidate: the candidate phrase itself, its head word, the unigram and bigram before and after the candidate in the sentence where it appeared, its entity type (*person*, *location*, *organization*, and *date/time*), as well as features derived from dependency parse trees. Specifically, we first apply the Stanford lexical parser to our data (de Marneffe et al., 2006). Then for each candidate, we follow its dependencies in the corresponding dependency parse tree until we find a relation $r \in \{nsubj, csubj, dobj, iobj, pobj\}$ in which the candidate is the dependent. We then construct a feature (r, v) where v is governor of the relation.

7.3 Evaluation Baseline and Method

We use the standard K-means algorithm (Macqueen, 1967) as a non-generative baseline, since K-means is commonly used for clustering. To evaluate clustering results, we match each slot in the labeled data to the cluster that gives the best F1-measure when evaluated for the slot. We report the precision (P), recall (R) and F1-measure for individual slot labels, as well as the macro- and micro- average results across all labels for each experiment. We conduct 10 trials of experiment on each model and each data set with different random initializations. We report the trials that give the smallest within-cluster sum-of-squares (WCSS) distance for K-means, and those that give the highest log-likelihood of data for all other models. Experimental trials are run until the change in WCSS/log-likelihood between two EM iterations is smaller than 1×10^{-6}. All trials converged within 30 minutes.

All models we evaluate involve a parameter K, which is the number of values that y can take on. The value of K is manually fixed in this study. As noted, we use a garbage slot to capture irrelevant candidates, thus the value of K is set to the number of target slots plus 1 for each data set. We empirically set the adjustable parameters in the proposed prior, and the weight of the regularization term in the locally normalized logistic regression model (Berg-Kirkpatrick et al., 2010), denoted by β. Exact settings are given in the next subsection. Note that the focus of our experiments is on evaluating the effectiveness of the proposed prior. We leave the task of learning the various parameter values to future work.

7.4 Results

Evaluation on existing generative models

We first evaluate the existing generative models described in Section 5 with the multinomial prior. Table 1 summarizes the performance of Naive Bayes (NB), the Bernoulli mixture model (BMM), the Gaussian mixture model (GMM), the locally normalized logistic regression (LNLR) model, and K-means. We only show the F1 measures in the table due to space limit.

We first observe that NB does not perform well for our task. LNLR, which is an interesting contribution in its own right, does not seem to be suitable for our task as well. While NB and LNLR are inferior to K-means for all three data sets, BMM shows mixed results. Specifically, BMM outperforms K-means for aviation incidents, but performs poorly for seminar announcements. GMM and K-means achieve similar results, which is not surprising because K-means can be viewed as a special case of the spherical GMM we used (Duda et al., 2001).

Overall speaking, results show that GMM is the best among the four generative models for the distri-

(a) Results on **seminar announcements**. No macro- and micro-average result is reported for NB and BMM as they merged the *etime* cluster with the *stime* cluster. Numbers in brackets are the respective measures of the *stime* cluster when evaluated for *etime*.

Model	*stime*	*etime*	*speaker*	*location*	Macro-avg	Micro-avg	Parameter

Table 1: Performance summary of the different generative models and K-means in terms of F1.

Data set	Parameter	Value
Seminar announcements	$\{\lambda_k\}_{k=1}^4$	$\{2\}_{k=1}^4$
	$\{\tau_k\}_{k=1}^4$	$\{1\}_{k=1}^4$
Aviation incidents	$\{\lambda_k\}_{k=1}^5$	$\{1\}_{k=1}^5$
	$\{\tau_k\}_{k=1}^5$	$\{1\}_{k=1}^5$
Management succession	$\{\lambda_k\}_{k=1}^4$	{1,2,2,2}
	$\{\tau_k\}_{k=1}^4$	{1,2,2,2}

Table 2: Parameter settings for $p(\boldsymbol{y}_i; \Lambda)$.

bution $p(x|y; \Theta)$. We proceed with incorporating the proposed prior into GMM for further explorations.

Effectiveness of the proposed prior

We evaluate the effectiveness of the proposed prior by combining it with GMM. Specifically, the combined model follows Eq. (1), with $p(\boldsymbol{y}_i; \Lambda)$ computed using the Poisson-based formula in Eq. (3) and $p(x_{i,j}|y_{i,j}; \Theta)$ following Eq. (6) as in GMM.

We empirically determine the parameters used in $p(\boldsymbol{y}_i; \Lambda)$ to maximize data's log-likelihood as noted. Table 2 reports the values of $\{\lambda_k\}_{k=1}^{K-1}$ and $\{\tau_k\}_{k=1}^{K-1}$ for different data sets. Recall that λ_k specifies the *maximum* number of candidates that the k-th slot can generate, and its value is observed to be small in real data. τ_k specifies the *expected* number of candidates that the k-th slot will generate.

Table 3 reports the performance of the combined model ("GMM with prior") on the three data sets, along with results of GMM and K-means for easy comparison. The combined model improves over both GMM and K-means for seminar announcements and aviation incidents, as can be seen from the models' macro- and micro-average performance.

The advantages brought by the proposed prior are mainly reflected in slots that are difficult to cluster under GMM and K-means. Taking seminar announcements as an example, GMM and K-means achieve high precision but low recall for *stime*, and low precision but high recall for *etime*. When examining the clusters produced by these two models, we found one small cluster that contains mostly *stime* fillers (thus high precision but low recall), and another much larger cluster that contains mostly *etime* fillers together with most of the remaining *stime* fillers (thus low precision but high recall for *etime*).

Table 3: Comparison between the combined model (GMM with the proposed prior), GMM and K-means.

This shows that GMM, when used with the multinomial prior, and K-means have difficulties separating candidates from these two slots. In contrast, the combined model improves the recall of *stime* to 68%, as compared to 29.1% achieved by GMM with the multinomial prior and 40.8% by K-means, without sacrificing precision. It also improves the precision of *etime* from 36.2% to 98.3%.

For aviation incidents, the advantage of the proposed prior is reflected in the *location (LO)* and *country (CO)* slots, which may confuse the various models as they both belong to the entity type *location*. The proposed prior improves the precision of these two slots greatly by trying to distribute them into appropriate slots in the clustering process.

The three models achieve very similar performance on management succession events as Table 3(c) shows. Surprisingly, incorporating the Poisson-based prior into GMM does not seem useful in separating *PersonIn* and *PersonOut* slot fillers. To investigate the possible reasons for this, we examine feature values in the centriods of the two clusters learned by the three models.

Tables 4 and 5 respectively list the top-10 features in the *PersonIn* cluster and the *PersonOut* cluster learned by the combined model[1], and their corresponding values in the centriods of the two clusters. The two clusters share 3 of the top-5 features, some

[1]We made similar observations from centriods learned in GMM and K-Means, which are therefore not reported here.

Table 5: Top-10 features in the *PersonOut* cluster, as learned by GMM with the proposed prior.

of them being general context features that might not help characterizing candidates from different slots (e.g. the unigram after the candidate is a comma). Both lists also contain features from dependency parse trees. Note that the "dobj:succeeds" feature in the *PersonIn* cluster is in fact contributed by *PersonOut* slot fillers, while the "nsubj:succeeds" feature in the *PersonOut* cluster is contributed by *PersonIn* slot fillers. Although listed among the top-10, these features have relatively low values in the learned centriods (about 0.1). These observations may suggest that the management succession data set lacks strong, discriminative features for all models to effectively distinguish between *PersonIn* and *PersonOut* candidates in an unsupervised manner.

To conclude, the proposed prior is effective in assigning different but confusing candidate slot fillers into appropriate slots, when there exist reasonable features that can be exploited in the label assignment process. This is evident by the improvements the proposed prior brings to GMM in the seminar announcement and aviation incident data sets.

8 Conclusions

We propose a generative model that incorporates distributional prior knowledge about template slots in a document for the unsupervised IE task. Specifically, we propose a Poisson-based prior that prefers label assignments to cover more distinct slots in the same document. The proposed prior also allows a slot to generate multiple fillers in a document, up to a certain number of times depending on the domain of interest.

We experimented with four existing generative models for the task of clustering slot fillers with a multinomial prior, which assumes that labels are generated independently in a document. We then evaluate the effectiveness of the proposed prior by incorporating it into the Gaussian mixture model (GMM), which is shown to be the best among the four existing models in our experiments. By incorporating the proposed prior into GMM, we can obtain significantly better clustering results on two out of three data sets.

Further improvements to this work are possible. Firstly, we assume that some adjustable parameters in the proposed prior can be manually fixed, such as the number of template slots in the output and the maximum numbers of fillers that can be generated by different slots. We are looking into methods for automatically learning such parameters. This will help improve the applicability of our work to different domains as an unsupervised model. Secondly, we currently consider in the prior a probability distribution over all possible label assignments for every document. This can be computationally expensive if input documents are long, or when we aim to discover large templates with large values of K. An alternative is to consider an approximate solution that evaluates, for instance, only the top few label assignments that are likely to maximize the likelihood of our observations. This remains as an interesting future work of this study.

Abstract

This paper proposes a semi-supervised relation acquisition method that does not rely on extraction patterns (e.g. "*X causes Y*" for causal relations) but instead learns a combination of indirect evidence for the target relation — *semantic word classes* and *partial patterns*. This method can extract long tail instances of semantic relations like causality from rare and complex expressions in a large Japanese Web corpus — in extreme cases, patterns that occur only once in the entire corpus. Such patterns are beyond the reach of current pattern based methods. We show that our method performs on par with state-of-the-art pattern based methods, and maintains a reasonable level of accuracy even for instances acquired from infrequent patterns. This ability to acquire long tail instances is crucial for risk management and innovation, where an exhaustive database of high-level semantic relations like causation is of vital importance.

1 Introduction

Pattern based relation acquisition methods rely on *lexico-syntactic patterns* (Hearst, 1992) for extracting relation instances. These are templates of natural language expressions such as "X causes Y" that signal an instance of some semantic relation (i.e., causality). Pattern based methods (Agichtein and Gravano, 2000; Pantel and Pennacchiotti, 2006b; Paşca et al., 2006; De Saeger et al., 2009) learn many such patterns to extract new instances (word pairs) from the corpus.

However, since extraction patterns are learned using statistical methods that require a certain frequency of observations, pattern based methods fail to capture relations from complex expressions in which the pattern connecting the two words is rarely observed. Consider the following sentence:

> "Curing hypertension alleviates the deterioration speed of the renal function, thereby lowering the risk of causing intracranial bleeding"

Humans can infer that this sentence expresses a causal relation between the underlined noun phrases. But the actual *pattern* connecting them, i.e., "*Curing X alleviates the deterioration speed of the renal function, thereby lowering the risk of causing Y*", is rarely observed more than once even in a 10^8 page Web corpus. In the sense that the term *pattern* implies a recurring event, this expression contains no pattern for detecting the causal relation between *hypertension* and *intracranial bleeding*. This is what we mean by "long tail instances" — words that co-occur infrequently, and only in sparse extraction contexts.

Yet an important application of relation extraction is mining the Web for so-called *unknown unknowns* — in the words of D. Rumsfeld, "things we don't know we don't know" (Torisawa et al., 2010). In knowledge discovery applications like risk management and innovation, the usefulness of relation extraction lies in its ability to find many unexpected remedies for diseases, causes of social problems, and so on. To give an example, our relation extrac-

tion system found a blog post mentioning Japanese automaker Toyota as a hidden cause of Japan's deflation. Several months later the same connection was made in an article published in an authoritative economic magazine.

We propose a semi-supervised relation extraction method that does not rely on direct pattern evidence connecting the two words in a sentence. We argue that the role of binary patterns can be replaced by a combination of two types of *indirect* evidence: *semantic class information* about the target relation and *partial patterns*, which are *fragments* or *subpatterns* of binary patterns. The intuition is this: if a sentence like the example sentence above contains some word X belonging to the class of *medical conditions* and another word Y from the class of *traumas*, and X matches the partial pattern "*... causing X*", there is a decent chance that this sentence expresses a causal relation between X and Y. We show that just using this combination of indirect evidence we can pick up semantic relations with roughly 50% precision, regardless of the complexity or frequency of the expression in which the words co-occur. Furthermore, by combining this idea with a straightforward machine learning approach, the overall performance of our method is on par with state-of-the-art pattern based methods. However, our method manages to extract a large number of instances from sentences that contain no pattern that can be learned by pattern induction methods.

Our method is a two-stage system. Figure 1 presents an overview. In Stage 1 we apply a state-of-the-art pattern based relation extractor to a Web corpus to obtain an initial batch of relation instances. In Stage 2 a supervised classifier is built from various components obtained from the output of Stage 1. Given the output of Stage 1 and access to a Web corpus, the Stage 2 extractor is completely self-sufficient, and the whole method requires no supervision other than a handful of seed patterns to start the first stage extractor. The whole procedure is therefore minimally supervised. Semantic word classes and partial patterns play a crucial role throughout all steps of the process.

We evaluate our method on three relation acquisition tasks (*causation*, *prevention* and *material* relations) using a 600 million Japanese Web page corpus (Shinzato et al., 2008) and show that our system can successfully acquire relations from both frequent and infrequent patterns. Our system extracted 100,000 causal relations with 84.6% precision, 50,000 prevention relations with 58.4% precision and 25,000 material relations with 76.1% precision. In the extreme case, we acquired several thousand word pairs co-occurring only in patterns that appear once in the entire corpus. We call such patterns *single occurrence* (SO) patterns. Word pairs that co-occur only with SO patterns represent the theoretical limiting case of relations that cannot be acquired using existing pattern based methods. In this sense our method can be seen as complementary with pattern based approaches, and merging our method's output with that of a pattern based method may be beneficial.

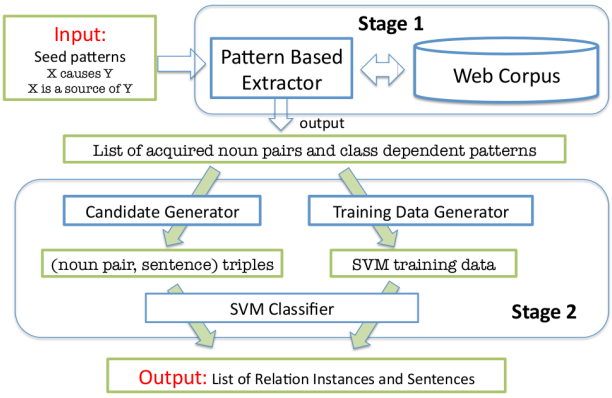

Figure 1: Proposed method: data flow.

2 Stage 1 Extractor

This section introduces our Stage 1 extractor: the pattern based method from (De Saeger et al., 2009), which we call CDP for "*class dependent patterns*". We give a brief overview below, and refer the reader to the original paper for a more comprehensive explanation.

CDP takes a set of *seed patterns* as input, and automatically learns new *class dependent patterns* as paraphrases of the seed patterns. Class dependent patterns are semantic class restricted versions of ordinary lexico-syntactic patterns. Existing methods use class *independent* patterns such as "X causes Y" to learn causal relations between X and Y. Class dependent patterns however place semantic class re-

strictions on the noun pairs they may extract, like "$Y_{accidents}$ *causes* $X_{incidents}$". The *accidents* and *incidents* subscripts specify the semantic class of the X and Y slot fillers.

These class restrictions make it possible to distinguish between multiple senses of highly ambiguous patterns (so-called "generic" patterns). For instance, given the generic pattern "Y *by* X", if we restrict Y and X in to the semantic classes of *injuries* and *accidents* (as in "*death by drowning*"), the class dependent pattern "$Y_{injuries}$ *by* $X_{accidents}$" becomes a valid paraphrase of "X *causes* Y" and can safely be used to extract causal relations, whereas other class dependent versions of the same generic pattern (e.g., "$Y_{products}$ *by* $X_{companies}$", as in "*iPhone by Apple*") may not.

CDP ranks each noun pair in the corpus according to a score that reflects its likelihood of being a proper instance of the target relation, by calculating the semantic similarity of a set of seed patterns to the class dependent patterns this noun pair co-occurs with. The output of CDP is a list of noun pairs ranked by score, together with the highest scoring class dependent pattern each noun pair co-occurs with. This list becomes the input to Stage 2 of our method, as shown in Figure 1. We adopted CDP as Stage 1 extractor because, besides having generally good performance, the class dependent patterns provide the two fundamental ingredients for Stage 2 of our method — the target semantic word classes for a given relation (in the form of the semantic class restrictions attached to patterns), and partial patterns.

To obtain fine-grained semantic word classes we used the large scale word clustering algorithm from (Kazama and Torisawa, 2008), which uses the EM algorithm to compute the probability that a word w belongs to class c, i.e., $P(c|w)$. Probabilistic clustering defines no discrete boundary between members and non-members of a semantic class, so we simply assume w belongs to c whenever $P(c|w) \geq 0.2$. For this work we clustered 10^6 nouns into 500 classes.

Finally, we adopt the structural representation of patterns introduced in (Lin and Pantel, 2001). All sentences in our corpus are dependency parsed, and patterns consist of words on the path of dependency relations connecting two nouns.

3 Stage 2 Extractor

We use CDP as our Stage 1 extractor, and the top N noun pairs along with the class dependent patterns that extract them are given as input to Stage 2, which represents the main contribution of this work. As shown in Figure 1, Stage 2 consists of three modules: a *candidate generator*, a *training data generator* and a *supervised classifier*. The training data generator builds training data for the classifier from the top N output of CDP and sentences retrieved from the Web corpus. This classifier then scores and ranks the candidate relations generated by the candidate relation generator. We introduce each module below.

Candidate Generator This module generates sentences containing candidate word pairs for the target relation from the corpus. It does so using the semantic class restrictions and partial patterns obtained from the output of CDP. The set of all semantic class pairs obtained from the class dependent patterns that extracted the top N results become the target semantic class pairs from which new candidate instances are generated. We extract all sentences containing a word pair belonging to one of the target class pairs from the corpus.

From these sentences we keep only those that contain a trace of evidence for the target semantic relation. For this we decompose the class dependent patterns from the Stage 1 extractor into *partial patterns*. As mentioned previously, patterns consist of words on the path of dependency relations connecting the two target words in a syntactic tree. To obtain partial patterns we split this dependency path into its two constituent branches, each one leading from the leaf word (i.e. variable) to the syntactic head of the pattern. For example, "$X \xleftarrow{\text{subj}}$ *causes* $\xrightarrow{\text{obj}} Y$" is split into two partial patterns "$X \xleftarrow{\text{subj}}$ *causes*" and "*causes* $\xrightarrow{\text{obj}} Y$". These partial patterns capture the predicate structures in binary patterns.[1] We discard partial patterns with syntactic heads other than verbs or adjectives.

The candidate genarator retrieves all sentences from the corpus in which two nouns belonging to one of the target semantic classes co-occur and

[1] In Japanese, case information is encoded in post-positions attached to the noun.

where at least one of the nouns matches a partial pattern. As shown in Figure 1, these sentences and the candidate noun pairs they contain (called *(noun pair, sentence)* triples hereafter) are submitted to the classifier for scoring. Restricting candidate noun pairs by this combination of semantic word classes and partial pattern matching proved to be quite powerful. For instance, in the case of causal relations we found that close to 60% of the *(noun pair, sentence)* triples produced by the candidate generator were correct (Figure 6).

Training Data Generator As shown in Figure 1, the *(noun pair, sentence)* triples used as training data for the SVM classifier were generated from the top results of the Stage 1 extractor and the corpus. We consider the noun pairs in the top N output of the Stage 1 extractor as *true* instances of the target relation (even though they may contain erroneous extractions), and retrieve from the corpus all sentences in which these noun pairs co-occur and that match one of the partial patterns mentioned above. In our experiments we set N to $25,000$. We randomly select positive training samples from this set of *(noun pair, sentence)* triples.

Negative training samples are also selected randomly, as follows. If one member of the target noun pair in the positive samples above matches a partial pattern but the other does not, we randomly replace the latter by another noun found in the same sentence, and generate this new *(noun pair, sentence)* triple as a negative training sample. In the causal relation experiments this approach had about 5% chance of generating *false* negatives — noun pairs contained in the top N results of the Stage 1 extractor. Such samples were discarded. Our experimental results show that this scheme works quite well in practice. We randomly sample M positive and negative samples from the autogenerated training data to train the SVM. M was empirically set to 50,000 in our experiments.

SVM Classifier We used a straightforward feature set for training the SVM classifier. Because our classifier will be faced with sentences containing long and infrequent patterns where the distance between the two target nouns may be quite large, we did not try to represent lexico-syntactic patterns as features but deliberately restricted the feature set to local context features of the candidate noun pair in the target sentence. Concretely, we looked at bigrams and unigrams surrounding both nouns of the candidate relation, as the local context around the target words may contain many telling expressions like "*increase in X*" or "*X deficiency*" which are useful clues for causal relations. Also, in Japanese case information is encoded in post-positions attached to the noun, which is captured by the unigram features.

In addition to these base features, we include the semantic classes to which the candidate noun pair belongs, the partial patterns they match in this sentence, and the infix words inbetween the target noun pair. Note that this feature set is not intended to be optimal beyond the actual claims of this paper, and we have deliberately avoided exhaustive feature engineering so as not to obscure the contribution of semantic classes and partial pattern to our approach. Clearly an *optimal* classifier will incorporate many more advanced features (see GuoDong et al. (2005) for a comprehensive overview), but even without sophisticated feature engineering our classifier achieved sufficient performance levels to support our claims. An overview of the feature set is given in Table 1. The relative contribution of each type of features is discussed in section 4. In preliminary experiments we found a polynomial kernel of degree 3 gave the best results, which suggests the effectiveness of combining different types of indirect evidence.

The SVM classifier outputs *(noun pair, sentence)* triples, ranked by SVM score. To obtain the final output of our method we assign each unique noun pair the maximum score from all *(noun pair, sentence)* triples it occurs in, and discard all other sentences for this noun pair. In section 4 below we evaluate the acquired noun pairs in the context of the sentence that maximizes their score.

4 Evaluation

We demonstrate the effectiveness of semantic word classes and partial pattern matching for relation extraction by showing that the method proposed in this paper performs at the level of other state-of-the-art relation acquisition methods. In addition we demonstrate that our method can successfully extract relation instances from infrequent patterns, and we

Feature type	Description	Number of features
Morpheme features	Unigram and bigram morphemes surrounding both target words.	554,395
POS features	Coarse- and fine-grained POS tags of the noun pair and morpheme features.	2,411
Semantic features	Semantic word classes of the target noun pair.	1000 (500 classes $\times 2$)
Infix word features	Morphemes found inbetween the target noun pair.	94,448
Partial patterns	Partial patterns matching the target noun pair.	86

Table 1: Feature set used in the Stage 2 classifier, and their number for the causal relation experiments.

explore several criteria for what constitutes an infrequent pattern — including the theoretical limiting case of patterns observed only once in the entire corpus. These instances are impossible to acquire by pattern based methods. The ability to acquire relations from extremely infrequent expressions with decent accuracy demonstrates the utility of combining semantic word classes with partial pattern matching.

4.1 Experimental Setting

We evaluate our method on three semantic relation acquisition tasks: *causality*, *prevention* and *material*. Two concepts stand in a *causal relation* when the source concept (the "cause") is directly or indirectly responsible for the subsequent occurrence of the target concept (its "effect"). In a *prevention* relation the source concept directly or indirectly acts to avoid the occurrence of the target concept, and in a *material* relation the source concept is a material or ingredient of the target concept.

For our experiments we used the latest version of the TSUBAKI corpus (Shinzato et al., 2008), a collection of 600 million Japanese Web pages dependency parsed by the Japanese dependency parser KNP[2]. In our implementation of CDP, lexico-syntactic patterns consist of words on the path connecting two nouns in a dependency parse tree. We discard patterns from dependency paths longer than 8 constituent nodes. Furthermore, we estimated pattern frequencies in a subset of the corpus (50 million pages, or 1/12th of the entire corpus) and discarded patterns that co-occur with less than 10 unique noun pairs in this smaller corpus. These restrictions do not apply to the proposed method, which can extract noun pairs connected by patterns of arbitrary length, even if found only once in the corpus. For our purpose we treat dependency paths whose observed frequency is below this threshold as insufficiently frequent to be considered as "patterns". This threshold is of course arbitrary, but in section 4 we show that our results are not affected by these implementation details.

We asked three human judges to evaluate random *(noun pair, sentence)* triples, i.e. candidate noun pairs in the context of some corpus sentence in which they co-occur. If the judges find the sentence contains sufficient evidence that the target relation holds between the candidate nouns, they mark the noun pair correct. To evaluate the performance of each method we use two evaluation criteria: *strict* (all judges must agree the candidate relation is correct) and *lenient* (decided by the judges' majority vote). Over all experiments the interrater agreement (Kappa) ranged between 0.57 and 0.82 with an average of 0.72, indicating substantial agreement (Landis and Koch, 1977).

4.1.1 Methods Compared

We compare our results to two pattern based methods: CDP (the Stage 1 extractor) and *Espresso* (Pantel and Pennacchiotti, 2006a).

Espresso is a popular bootstrapping based method that uses a set of seed instances to induce extraction patterns for the target relation and then acquire new instances in an iterative bootstrapping process. In each iteration Espresso performs pattern induction, pattern ranking and selection using previously acquired instances, and uses the newly acquired patterns to extraction new instances. Espresso computes a reliability score for both instances and patterns based on their pointwise mutual information (PMI) with the top-scoring patterns and instances from the previous iteration.[3] We refer to (Pantel and

[2] http://nlp.kuee.kyoto-u.ac.jp/nl-resource/knp.html

[3] In our implementation of Espresso we found that, despite the many parameters for controlling the bootstrapping process,

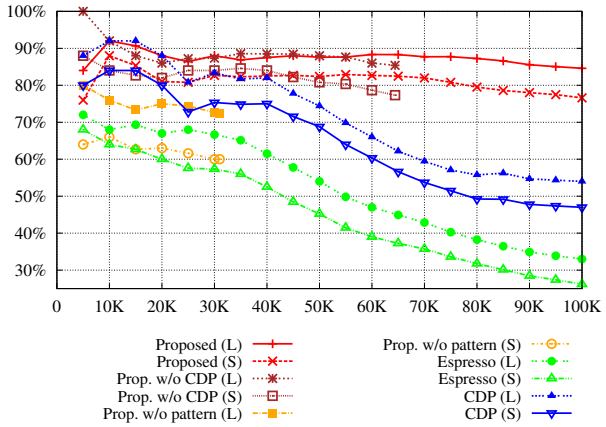

Figure 2: Precision of acquired relations (causality). L and S denote lenient and strict evaluation.

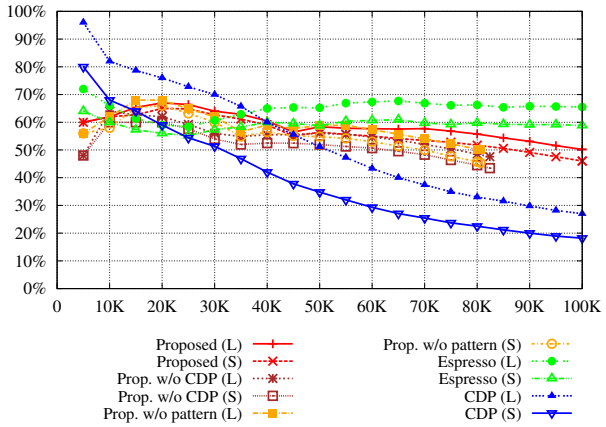

Figure 3: Precision of acquired relations (prevention). L and S denote lenient and strict evaluation.

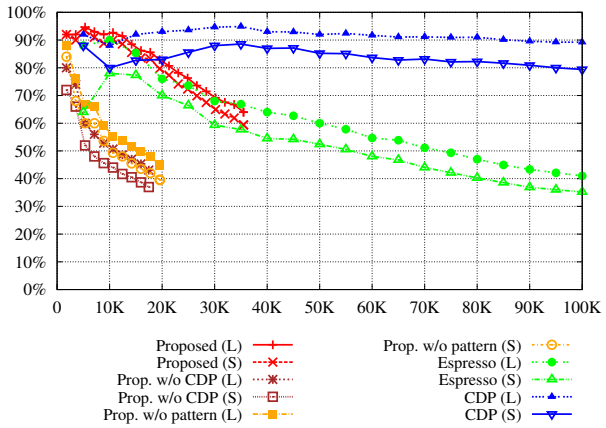

Figure 4: Precision of acquired relations (material). L and S denote lenient and strict evaluation.

Pennacchiotti, 2006a) for a more detailed description.

For all methods compared we rank the acquired noun pairs by their score and evaluated 500 random samples from the top 100,000 results. For noun pairs acquired by CDP and Espresso we select the pattern that extracted this noun pair (in the case of Espresso, the pattern with the highest PMI for this noun pair), and randomly select a sentence in which the noun pair co-occurs with that pattern from our corpus. For the proposed method we evaluate noun pairs in the context of the *(noun pair, sentence)* triple with the highest SVM score.

4.2 Results and Discussion

The performance of each method on the causality, prevention and material relations are shown in Figures 2, 3 and 4 respectively. In the causality experiments (Figure 2) the proposed method performs on par with CDP for the top 25,000 results, both achieving close to 90% precision. But whereas CDP's performance drops from there our method maintains the same high precision throughout (84.6%, lenient). Both our method and CDP outperform Espresso by a large margin.

For the prevention relation (Figure 3), precision is considerably lower for all methods except the top 10,000 of CDP (82% precision, lenient). The proposed method peaks at around 20,000 results (67% precision, lenient) and performance remains more or less constant from there on. The proposed method overtakes CDP's performance around the top 45,000 mark, which suggests that combining the results of both methods may be beneficial.

In the material relations the proposed method slightly outperforms both pattern based methods in the top 10,000 results (92% precision, lenient).

it remains very difficult to prevent *semantic drift* (Komachi et al., 2008) from occurring. One small adjustment to the algorithm stabilized the bootstrapping process considerably and gave overall better results. In the pattern induction step (section 3.2 in (Pantel and Pennacchiotti, 2006a)), Espresso computes a reliability score for each candidate pattern based on the weighted PMI of the pattern with all instances extracted so far. As the number of extracted instances increases this disproportionally favours high frequency (i.e. generic) patterns, so instead of using *all* instances for computing pattern reliability we only use the m most reliable instances from the previous iteration, which were used to extract the candidate patterns of the current iteration ($m = 200$, like the original).

However for this relation our method produced only 35,409 instances. The reason is that the top 25,000 results of CDP were all extracted by just 12 patterns, and these contained many patterns whose syntactic head is not a verb or adjective (like "*Y rich in X*" or "*Y containing X*"). Only 12 partial patterns were obtained, which greatly reduced the output of the proposed method. Taking into account the high performance of CDP for material relations, this suggests that for some relations our method's N and M parameters could use some tuning. In conclusion, in all three relations our method performs at a level comparable to state-of-the-art pattern based methods, which is remarkable given that it only uses indirect evidence.

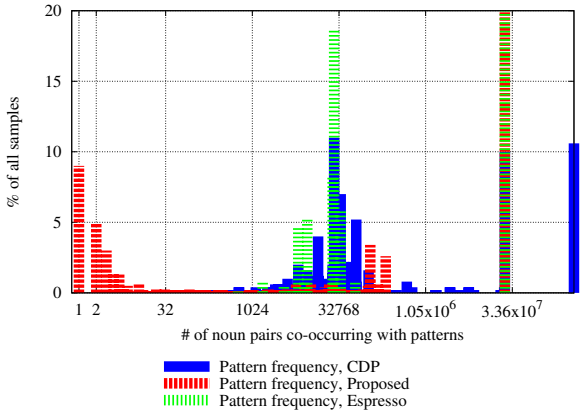

Figure 5: Frequencies of patterns in the evaluation data (causation).

Dealing with Difficult Extractions How does our method handle noun pairs that are difficult to acquire by pattern based methods? The graphs marked "Prop. w/o CDP" (Proposed without CDP) in Figures 2 , 3 and 4 show the number and precision of evaluated samples from the proposed method that do not co-occur in our corpus with any of the patterns that extracted the top N results of the first stage extractor. These graphs show that our method is not simply regenerating CDP's top results but actually extracts many noun pairs that do not co-occur in patterns that are easily learned. Figure 2 shows that roughly two thirds of the evaluated samples are in this category, and that their performance is not significantly worse than the overall result. The same conclusion holds for the prevention results (Figure 3), where over 80% of the proposed method's samples are noun pairs that do not co-occur with easily learnable patterns. Their precision is about 5% worse than all samples from the proposed method. For material relations (Figure 4) about half of all evaluated samples are in this category, but their precision is markedly worse compared to all results.

For genuinely *infrequent* patterns, the graphs marked "Prop. w/o pattern" (Proposed without pattern) in Figures 2 , 3 and 4 show the number and precision of noun pairs evaluated for the proposed method that were acquired from sentences without any discernible pattern. As explained in section 4 above, these constitute noun pairs co-occurring in a sentence in which the path of dependency relations connecting them is either longer than 8 nodes or can extract fewer than 10 noun pairs in 50 million Web pages. Note that in theory it is possible that these noun pairs could not be acquired by pattern based methods due to this threshold — patterns must be able to extract more than 10 different noun pairs in a subset of our corpus, while the proposed method does not have this constraint. So at least in theory, pattern based methods might be able to acquire all noun pairs obtained by our method by lowering this threshold. To see that this is unlikely to be the case, consider Figure 5, which shows the pattern frequency of the patterns induced by CDP and Espresso for the causality experiment. The x-axis represents pattern frequency in terms of the number of unique noun pairs a pattern co-occurs with in our corpus (on a log scale), and the y-axis shows the percentage of samples that was extracted by patterns of a given frequency.[4] Figure 5 shows that for the pattern based methods, the large majority of noun pairs was extracted by patterns that co-occur with several thousand different noun pairs. Extrapolating the original frequency threshold of 10 nounpairs to the size of our entire corpus roughly corresponds to about 120 distinct noun pairs (10 times in 1/12th of the entire corpus). In Figure 5, the histograms for the pattern based methods CDP and Espresso start around 1000 noun pairs, which is far above this new lowerbound.

[4] In the case of CDP we ignore semantic class restrictions on the patterns when comparing frequencies. For Espresso, the most frequent pattern ("Y by X" at the 24,889,329 data point on the x-axis) extracted up to 53.8% of the results, but the graph was cut at 20% for readability.

Causality	〈カテコラミン〉が心拍数の急上昇をもたらすことから、血管内の血行状態の変化が血管内障害につながり、[血栓形成] を促進する。 Because ⟨catecholamine⟩ causes a rapid increase of heart rate, the change of circulation inside the blood vessels leads to blood vessel disorders and promotes [thrombus generation].
	〈頻脈発作〉が始まってキシロカインを静注したところ、患者さんが突然意識をなくして [全身痙攣] を起こしたということです。 When we injected Xylocaine during a ⟨tachycardia seizure⟩, the patient suddenly lost consciousness and fell into a fit of [convulsions].
	その理由としては〈動物性たんぱく質〉を多く取ることで [わきが] の原因物質が増加するからです。 (. . .) The reason is that by taking a lot of ⟨animal proteins⟩ the causative agents of [tragomaschalia] increase.
	* 抗酸化機能を高め、老化や〈生活習慣病〉の原因となる活性化酸素を消去する作用がある [ラドン]。 * [Radon] heightens the (body's) antioxidative function and is effective for eliminating activated oxygen, which is a cause of aging and ⟨lifestyle-related⟩ diseases.
Prevention	マグロのトロ、中トロの部分には、ＤＨＡや〈ＥＰＡ〉が豊富に含まれているので、[神経痛] の予防食材として有効です。 Because the fatty meat of tuna contains DHA and ⟨EPA⟩ in abundance, it is effective for preventing [neuralgia].
	空気の代わりに〈窒素ガス〉を使用すれば [粉塵爆発] の予防になります。 If you use ⟨nitrogen gas⟩ instead of air you may prevent [dust explosions].
	ヨーロッパでは古くから〈クミスクチン〉のお茶は「やせるお茶である」といわれ中性脂肪や [成人病] の予防に良いそうです。 In ancient Europe ⟨orthosiphon aristatus⟩ tea was called a "diet tea", and supposedly it helps preventing triglycerides and [adult diseases].
	*〈幌〉の収納時にスクリーンの間に挟んで、スクリーンの [スリキズ] を防ぐものです。 * (It) is something that prevents [scratches] on the screen if the ⟨calash⟩ gets stuck between the screens during storage.

Table 2: Causality and Prevention relations acquired from Single Occurrence (SO) patterns. ⟨X⟩ and [Y] indicate the relation instance's source and target words, and "*" indicates erroneous extractions.

Thus, pattern based methods naturally tend to induce patterns that are much more frequent than the range of patterns our method can capture, and it is unlikely that this is a result of implementation details like pattern frequency threshold.

The precision of noun pairs in the category "Prop. w/o pattern" is clearly lower than the overall results, but the graphs demonstrate that our method still handles these difficult cases reasonably well. The 500 samples evaluated contained 155 such instances for causality, 403 for prevention and 276 for material. For prevention, the high ratio of these noun pairs helps explain why the overall performance was lower than for the other relations.

Finally, the theoretical limiting case for pattern based algorithms consists of patterns that only co-occur with a single noun pair in the entire corpus (*single occurrence* or SO patterns). Pattern based methods learn new patterns that share many noun pairs with a set of reliable patterns in order to extract new relation instances. If a noun pair that co-occurs with a SO pattern also co-occurs with more reliable patterns there is no need to learn the SO pattern. If that same noun pair does *not* co-occur with any other reliable pattern, the SO pattern is beyond the reach of *any* pattern induction method. Thus, SO patterns are effectively useless for pattern based methods. For the 500 samples evaluated from the causality and prevention relations acquired by our method we found 7 causal noun pairs that co-occur only in SO patterns and 29 such noun pairs for prevention. The precision of these instances was 42.9% and 51.7% respectively. In total we found 8,716 causal noun pairs and 7,369 prevention noun pairs that co-occur only with SO patterns. Table 2 shows some example relations from our causality and prevention experiments that were extracted from SO patterns. To conclude, our method is able to acquire correct relations even from the most extreme infrequent expressions.

Semantic Classes, Partial Patterns or Both? In the remainder of this section we look at how the combination of semantic word classes and partial patterns benefits our method. For each relation we evaluated 1000 random *(noun pair, sentence)* triples satisfying the two conditions from section 3 — matching semantic class pairs and partial patterns. Surprisingly, the precision of these samples was 59% for causality, 40% for prevention and 50.4% for material, showing just how compelling these two types of indirect evidence are in combination.

To estimate the relative contribution of each heuristic we compared our candidate generation method against two baselines. The first baseline evaluates the precision of random noun pairs from

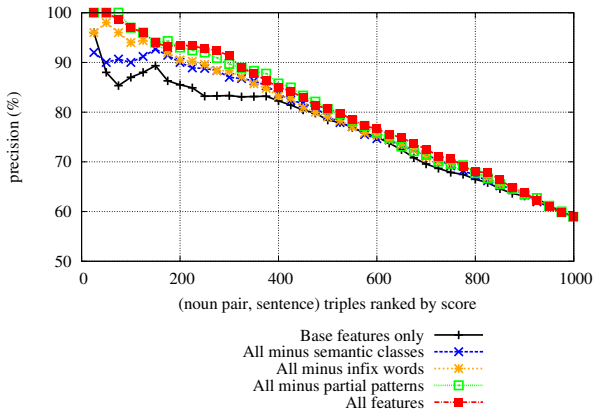

Figure 6: Contribution of feature sets (causality).

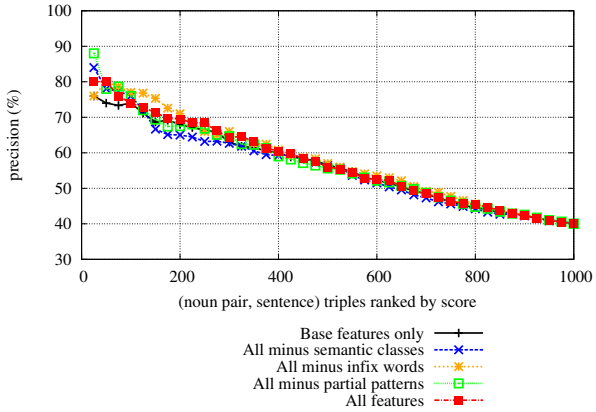

Figure 7: Contribution of feature sets (prevention).

the target semantic classes that co-occur in a sentence. The second baseline does the same for the second heuristic, selecting random sentences containing a noun pair that matches some partial pattern. Evaluating 100 samples for causality and prevention, we found the precision of the semantic class baseline was 16% for causality and 5% for prevention. The pattern fragment baseline gave 9% for causality and 22% for prevention. This is considerably lower than the precision of random samples that satisfy both the semantic class and partial pattern conditions, showing that the combination of semantic classes and partial patterns is more effective than either one individually.

Finally, we investigated the effect of the various feature sets used in the classifier. Figures 6, 7 and 8 show the results for the respective semantic relations. The "Base features" graph shows the performance the unigram, bigram and part-of-speech features. "All features" uses all features in Table 1. The other graphs show the effect of removing one type of features. These graphs suggest that the contribution of the individual feature types (semantic class information, partial patterns or infix words) to the classification performance is relatively minor, but in combination they do give a marked improvement over the base features, at least for some relations like causation and material. In other words, the main contribution of semantic word classes and partial patterns to our method's performance lies not in the final classification step but seems to occur at earlier stages of the process, in the candidate and training data generation steps.

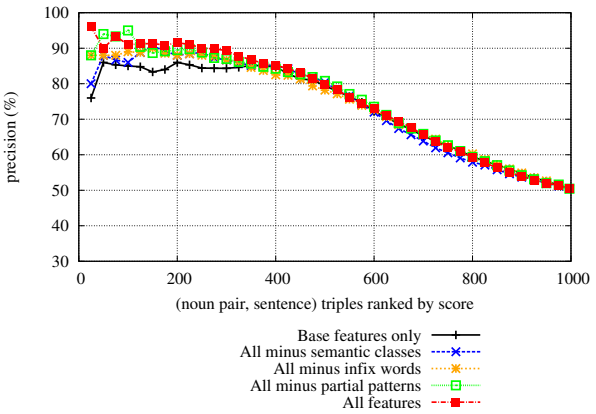

Figure 8: Contribution of feature sets (material).

5 Related Work

Using lexico-syntactic patterns to extract semantic relations was first explored by Hearst (Hearst, 1992), and has inspired a large body of work on semi-supervised relation acquisition methods (Berland and Charniak, 1999; Agichtein and Gravano, 2000; Etzioni et al., 2004; Pantel and Pennacchiotti, 2006b; Paşca et al., 2006; De Saeger et al., 2009), two of which were used in this work.

Some researchers have addressed the sparseness problems inherent in pattern based methods. Downey et al. (2007) starts from the output of the unsupervised information extraction system TextRunner (Banko and Etzioni, 2008), and uses language modeling techniques to estimate the reliability of sparse extractions. Paşca et al. (2006) alle-

viates pattern sparseness by using infix patterns that are generalized using classes of distributionally similar words. In addition, their method employs clustering based semantic similarities to filter newly extracted instances in each iteration of the bootstrapping process. A comparison with our method would have been instructive, but we were unable to implement their method because the original paper contains insufficient detail to allow replication.

There is a large body of research in the *supervised* tradition that does not use explicit pattern representations — kernel based methods (Zelenko et al., 2003; Culotta, 2004; Bunescu and Mooney, 2005) and CRF based methods (Culotta et al., 2006). These approaches are all fully supervised, whereas in our work the automatic generation of candidates and training data is an integral part of the method. An interesting alternative is distant supervision (Mintz et al., 2009), which trains a classifier using an existing database (Freebase) containing thousands of semantic relations, with millions of instances. We believe our method is more general, as depending on external resources like a database of semantic relations limits both the range of semantic relations (i.e., Freebase contains only relations between named entities, and none of the relations in this work) and languages (i.e., no resource comparable to Freebase exists for Japanese) to which the technology can be applied. Furthermore, it is unclear whether distant supervision can deal with noisy input such as automatically acquired relation instances.

Finally, inference based methods (Carlson et al., 2010; Schoenmackers et al., 2010; Tsuchida et al., 2010) are another attempt at relation acquisition that goes beyond pattern matching. Carlson et al. (2010) proposed a method based on inductive logic programming (Quinlan, 1990). Schoenmackers et al. (2010) takes relation instances produced by TextRunner (Banko and Etzioni, 2008) as input and induces first-order Horn clauses, and new instances are infered using a Markov Logic Network (Richardson and Domingo, 2006; Huynh and Mooney, 2008). Tsuchida et al. (2010) generated new relation hypotheses by substituting words in seed instances with distributionally similar words. The difference between these works and ours lies in the treatment of evidence. While the above methods learn inference rules to acquire new relation instances from independent information sources scattered across different Web pages, our method takes the other option of working with all the clues and indirect evidence a single sentence can provide. In the future, a combination of both approaches may prove beneficial.

6 Conclusion

We have proposed a relation acquisition method that is able to acquire semantic relations from infrequent expressions by focusing on the evidence provided by semantic word classes and partial pattern matching instead of direct extraction patterns. We experimentally demonstrated the effectiveness of this approach on three relation acquisition tasks, causality, prevention and material relations. In addition we showed our method could acquire a significant number of relation instances that are found in extremely infrequent expressions, the most extreme case of which are *single occurrence patterns*, which are beyond the reach of existing pattern based methods. We believe this ability is of crucial importance for acquiring valuable long tail instances. In future work we will investigate whether the current framework can be extended to acquire inter-sentential relations.

Abstract

We propose an architecture for expressing various linguistically-motivated features that help identify multi-word expressions in natural language texts. The architecture combines various linguistically-motivated classification features in a Bayesian Network. We introduce novel ways for computing many of these features, and manually define linguistically-motivated interrelationships among them, which the Bayesian network models. Our methodology is almost entirely unsupervised and completely language-independent; it relies on few language resources and is thus suitable for a large number of languages. Furthermore, unlike much recent work, our approach can identify expressions of various types and syntactic constructions. We demonstrate a significant improvement in identification accuracy, compared with less sophisticated baselines.

1 Introduction

Multi-word Expressions (MWEs) are lexical items that consist of multiple orthographic words (e.g., *ad hoc*, *by and large*, *New York*, *kick the bucket*). MWEs are numerous and constitute a significant portion of the lexicon of any natural language (Jackendoff, 1997; Erman and Warren, 2000; Sag et al., 2002). They are a heterogeneous class of constructions with diverse sets of characteristics, distinguished by their idiosyncratic behavior. Morphologically, some MWEs allow some of their constituents to freely inflect while restricting (or preventing) the inflection of other constituents. In some cases MWEs may allow constituents to undergo non-standard morphological inflections that they would not undergo in isolation. Syntactically, some MWEs behave like words while other are phrases; some occur in one rigid pattern (and a fixed order), while others permit various syntactic transformations. Semantically, the compositionality of MWEs is gradual, ranging from fully compositional to idiomatic (Bannard et al., 2003).

Because of their prevalence and irregularity, MWEs must be stored in lexicons of natural language processing applications. Correct handling of MWEs has been proven beneficial for various applications, including information retrieval, building ontologies, text alignment, and machine translation.

We propose a novel architecture for identifying MWEs of various types and syntactic categories in monolingual corpora. Unlike much existing work, which focuses on a particular syntactic construction, our approach addresses MWEs of all types by focusing on the general idiosyncratic properties of MWEs rather than on specific properties of each sub-class thereof. While we only evaluate our methodology on bi-grams, it can in principle be extended to longer MWEs. The architecture uses Bayesian Networks (BN) to express multiple interdependent linguistically-motivated features.

First, we automatically generate a small (training) set of MWE and non-MWE bi-grams (positive and negative instances, respectively). We then define a set of linguistically-motivated features that embody observed characteristics of MWEs. We augment these by features that reflect collocation measures. Finally, we define dependencies among these features, expressed in the structure of a Bayesian Network model, which we then use for classification. This is a directed graph, whose nodes express the features used for classification, and whose edges de-

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 836–845,
Edinburgh, Scotland, UK, July 27–31, 2011.

fine causal relationships among these features. In this architecture, learning does not result in a black box, expressed solely as feature weights. Rather, the structure of the BN allows us to learn the impact of different MWE features on the classification. The result is a new unsupervised method for identifying MWEs of various types in text corpora. It combines statistics with a large array of linguistically-motivated features, organized in an architecture that reflects interdependencies among the features.

The contribution of this work is manifold. First, we show how to generate training material (almost) automatically, so the method is almost completely unsupervised. The methodology we advocate is thus language-independent, requiring relatively few language resources, and is therefore optimal for medium-density languages (Varga et al., 2005). Second, we propose several linguistically-motivated features that can be computed from data and that are demonstrably productive for improving the accuracy of MWE identification. These feature focus on the expression of linguistic idiosyncrasies of various types, a phenomenon typical of MWEs. We propose novel computational modeling of many of these features; in particular, we account for the morphological idiosyncrasy of MWEs using a histogram of the number of inflected forms, in a technique that draws from image processing. Third, we advocate the use of Bayesian Networks as a mechanism for expressing manually-crafted dependencies among features; the use of BN significantly improves the classification accuracy. Finally, we demonstrate the utility of our methodology by applying it to Hebrew.[1] Our evaluation shows that the use of linguistically-motivated features results in reduction of 23% of the errors compared with a collocation baseline; organizing the knowledge in a BN reduces the error rate by additional 8.7%.

After discussing related work in the next section, we describe in Section 3 the methodology we propose, including a detailed discussion of the features and their implementation. Section 4 provides a thorough evaluation of the results. We conclude with suggestions for future research.

[1]To facilitate readability we use a transliteration of Hebrew using Roman characters; the letters used, in Hebrew lexicographic order, are *abgdhwzxTiklmns'pcqršt*.

2 Related Work

Early approaches to MWEs identification concentrated on their collocational behavior (Church and Hanks, 1990). Pecina (2008) compares 55 different association measures in ranking German Adj-N and PP-Verb collocation candidates. He shows that combining different collocation measures using standard statistical classification methods improves over using a single collocation measure. Other results (Chang et al., 2002; Villavicencio et al., 2007) suggest that some collocation measures (especially PMI and Log-likelihood) are superior to others for identifying MWEs.

Soon, however, it became clear that mere co-occurrence measurements are not enough to identify MWEs, and their linguistic properties should be exploited as well (Piao et al., 2005). Hybrid methods that combine word statistics with linguistic information exploit morphological, syntactic and semantic idiosyncrasies to extract idiomatic MWEs.

Ramisch et al. (2008) evaluate a number of association measures on the task of identifying English Verb-Particle Constructions and German Adjective-Noun pairs. They show that adding linguistic information (mostly POS and POS-sequence patterns) to the association measure yields a significant improvement in performance over using pure frequency.

Several works address the *lexical fixedness* or *syntactic fixedness* of (certain types of) MWEs in order to extract them from texts. An expression is considered lexically fixed if replacing any of its constituents by a semantically (and syntactically) similar word generally results in an invalid or literal expression. Syntactically fixed expressions prohibit (or restrict) syntactic variation. For example, Van de Cruys and Villada Moirón (2007) use lexical fixedness to extract Dutch Verb-Noun idiomatic combinations (VNICs). Bannard (2007) uses syntactic fixedness to identify English VNICs. Another work uses both the syntactic and the lexical fixedness of VNICs in order to distinguish them from non-idiomatic ones, and eventually to extract them from corpora (Fazly and Stevenson, 2006).

While these approaches are in line with ours, they require lexical semantic resources (e.g., a database that determines semantic similarity among words) and syntactic resources (parsers) that are unavail-

able for Hebrew (and many other languages). Our approach only requires morphological processing and a bilingual dictionary, which are more readily-available for several languages. Note also that these approaches target a specific syntactic construction, whereas ours is adequate for various types of MWEs.

Several properties of Hebrew MWEs are described by Al-Haj (2010); Al-Haj and Wintner (2010) use them in order to construct an SVM-based classifier that can distinguish between MWE and non-MWE *noun-noun constructions* in Hebrew. The features of the SVM reflect several morphological and morpho-syntactic properties of such constructions. The resulting classifier performs much better than a naïve baseline, reducing over one third of the errors. We rely on some of these insights, as we implement more of the linguistic properties of MWEs. Again, our methodology is not limited to a particular construction: indeed, we demonstrate that our general methodology, trained on automatically-generated, general training data, performs almost as well as the noun-noun-specific approach of Al-Haj and Wintner (2010) on the very same dataset.

Recently, Tsvetkov and Wintner (2010b) introduced a general methodology for extracting MWEs from bilingual corpora, and applied it to Hebrew. The results were a highly accurate set of Hebrew MWEs, of various types, along with their English translations. A major limitation of this work is that it can only be used to identify MWEs in the bilingual corpus, and is thus limited in its scope. We use this methodology to extract both positive and negative instances for our training set in the current work; but we extrapolate the results much further by extending the method to *mono*lingual corpora, which are typically much larger than bilingual ones.

Bayesian Networks have only scarcely been used for classification in natural language applications. For example, BN were used for POS tagging of unknown words (Peshkin et al., 2003); dependency parsing (Savova and Peshkin, 2005); and document classification (Lam et al., 1997; Calado et al., 2003; Denoyer and Gallinari, 2004). Very recently, Ramisch et al. (2010) have used BN for Portuguese MWE identification. The features used for classification were of two kinds: (1) various collocation measures; (2) bi-grams aligned together by an automatic word aligner applied to a parallel (Portuguese-English) corpus. A BN was used to combine the predictions of the various features on the test set, but the structure of the network is not described. The combined classifier resulted in a much higher accuracy than any of the two methods alone. However, the BN does not play any special role in this work, and its structure does not reflect any insights or intuitions on the structure of the problem domain or on interdependencies among features.

We, too, acknowledge the importance of combining different types of knowledge in the hard task of MWE identification. In particular, we also believe that collocation measures are highly important for this task, but cannot completely solve the problem: linguistically-motivated features are mandatory in order to improve the accuracy of the classifier. In this work we focus on various properties of different types of MWEs, and define general features that may accurately apply to some, but not necessarily all of them. An architecture of Bayesian Networks is optimal for this task: it enables us to define weighted dependencies among features, such that certain features are more significant for identifying some class of MWEs, whereas others are more prominent in identifying other classes. As we show below, this architecture results in significant improvements over a more naïve combination of features.

3 Methodology

3.1 Motivation

The task we address is identification of MWEs, of various types and syntactic constructions, in monolingual corpora.[2] Several properties of MWEs make this task challenging: MWEs exhibit idiosyncrasies on a variety of levels, orthographic, morphological, syntactic and of course semantic (Al-Haj, 2010). They are also extremely diverse: for example, on the semantic dimension alone, MWEs cover an entire spectrum, ranging from frozen, fixed idioms to free combinations of words (Bannard et al., 2003).

Such a complex task calls for a combination of multiple approaches, and much research indeed suggests "hybrid" approaches to MWE identification

[2]For simplicity, we focus on bi-grams of tokens (MWEs of length 2) in this work; the methodology, however, is easily extensible to longer n-grams.

(Duan et al., 2009; Weller and Fritzinger, 2010; Ramisch et al., 2010; Hazelbeck and Saito, 2010). We believe that Bayesian Networks provide an optimal architecture for expressing various pieces of knowledge aimed at MWE identification, for the following reasons (Heckerman, 1995):

- In contrast to many other classification methods, BN can learn (and express) causal relationships between features. This facilitates better understanding of the problem domain.
- BN can encode not only statistical data, but also prior domain knowledge and human intuitions, in the form of interdependencies among features. We do indeed use this possibility here.

3.2 Linguistically-motivated Features

Based on the observations of Al-Haj (2010), we define several linguistically-motivated features that are aimed at capturing some of the unique properties of MWEs. While many idiosyncratic properties of MWEs have been previously studied, we introduce novel ways to express those properties as computable features informing a classifier. Note that many of the features we describe below are completely language-independent; others are applicable to a wide range of languages, while few are specific to morphologically-rich languages, and can be exhibited in different ways in different languages. The methodology we advocate, however, is completely universal.

A common theme for all these features is *idiosyncracy*: they are all aimed at locating some linguistic property on which MWEs may differ from non-MWEs. Below we detail these properties, along with the features that we define to reflect them. In all cases, the feature is applied to a *candidate MWE*, defined here as a bi-gram of tokens (all possible bigrams are potential candidates). To compute the features, we use a 46M-token monolingual Hebrew corpus (Itai and Wintner, 2008), which we pre-process as in Tsvetkov and Wintner (2010b). All statistics are computed from this large corpus. Likewise, we compute these features on a small training corpus, which we generate automatically (see Section 3.4).

Orthographic variation Sometimes, MWEs are written with dashes instead of inter-token spaces. We define a binary feature, DASH, whose value is 1 iff the dash character appears in some surface form of the candidate MWE. For example, *xd-cddi* (*one sided*) "unilateral".

Hapax legomena MWEs sometimes include constituents that have no usage outside the particular expression, and are hence not included in lexicons. We define a feature, HAPAX, whose value is a binary vector with 1 in the i-th place iff the i-th word of the candidate is not in the lexicon, and does not occur in other bi-grams at the same location. For example, *hwqws pwqws* "hocus-pocus". In order to filter out potential errors, candidates must occur at least 5 times in the corpus in order for this feature to fire.

Frozen form MWE constituents sometimes occur in one fixed, frozen form. We define a feature, FROZEN, whose value is a binary vector with 1 in the i-th place iff the i-th word of the candidate never inflects in the context of this expression. Example: *bit xwlim* (*house-of sick-people*) "hospital"; the noun *xwlim* must be in the plural in this MWE.

Partial morphological inflection In some cases, MWE constituents undergo a (strict but non-empty) subset of the full inflections that they would undergo in isolation. We capture this property with a technique that has been proven useful in the area of image processing (Jain, 1989, Section 7.3). We compute a histogram of the distribution in the corpus of all the possible surface forms of each constituent of an MWE candidate. Such histograms can compactly represent distributional information on morphological behavior, in the same way that histograms of the distribution of gray levels in a picture are used to represent the picture itself.

Our assumption is that the inflection histograms of non-MWEs are more uniform than the histograms of MWEs, in which some inflections may be more frequent and others may be altogether missing. Of course, restrictions on the histogram may stem from the part of speech of the expression; such constraints are captured by dependencies in the BN structure.

Since each MWE is idiosyncratic in its own way, we do not expect the histograms of MWEs to have some specific pattern, except non-uniformity. We therefore sort the columns of each histogram, thereby losing information pertaining to the specific

inflections, and retaining only information about the idiosyncrasy of the histogram. Offline, we compute the average histogram for positive and negative examples: The average histogram of MWEs is shorter and less uniform than the average histogram of non-MWEs. We define as feature, HIST, the L_1 (Manhattan) distance between the histogram of the candidate and the closest average histogram.

For example, the MWE *bit mepv* (*house-of law*) "court" occurs in the following inflected forms: *bit hmepv* "the court" (75%); *bit mepv* "a court" (15%); *bti hmepv* "the courts" (8%); and *bti mepv* "courts" (2%). The histogram for this candidate is thus $(75, 15, 8, 2)$. In contrast, the non-MWE *txwm mepv* (*domain-of law*) "domain of the law", which is syntactically identical, occurs in nine different inflected forms, and its sorted histogram is $(59, 14, 7, 7, 5, 2, 2, 2, 2)$.

Context We hypothesize that MWEs tend to constrain their (semantic) context more strongly than non-MWEs. We expect words that occur immediately after MWEs to vary less freely than words that immediately follow other expressions. One motivation for this hypothesis is the observation that MWEs tend to be less polysemous than free combinations of words, thereby limiting the possible semantic context in which they can occur.

We define a feature, CONTEXT, as follows. We first compute a histogram of the frequencies of words following each candidate MWE. We trim the tail of the histogram by removing words whose frequency is lower than 0.1% (the expectation is that non-MWEs would have a much longer tail). Offline, we compute the same histograms for positive and negative examples and average them as above. The value of CONTEXT is 1 iff the histogram of the candidate is closer (in terms of L_1 distance) to the positive average.

For example, the histogram of *bit mepv* "court" includes 15 values, dominated by *bit mepv yliwn* "supreme court" (20%) and *bit mepv mxwzi* "district court" (13%), followed by contexts whose frequency ranges between 5% and 0.6%. In contrast, the non-MWE *txwm mepv* "domain-of law" has a much shorter histogram, namely $(12, 11, 6)$: over 70% of the words following this expression occur less than 0.1% and are hence in the trimmed tail.

Syntactic diversity MWEs can belong to various part of speech categories. We define as feature, POS, the category of the candidate, with values obtained by selecting frequent tuples of POS tags. For example, Noun-Noun, PropN-PropN, Noun-Adj, etc.

Translational equivalents Since MWEs are often idiomatic, they tend to be translated in a non-literal way, sometimes to a single word. We use a dictionary to generate word-by-word translations of candidate MWEs to English, and check the number of occurrences of the English literal translation in a large English corpus.[3] Due to differences in word order between the two languages, we create two variants for each translation, corresponding to both possible orders. We expect non-MWEs to have some literal translational equivalent (possibly with frequency that correlates with their frequency in Hebrew), whereas for MWEs we expect no (or few) literal translations. We define a binary feature, TRANS, whose value is 1 iff some literal translation of the candidate occurs more than 5 times in the corpus.

For example, the MWE *htxtn ym* (*marry with*) "marry" is literally translated as *with marry*, *marry with*, *together marry* and *marry together*, none of which occurs in the corpus.

Collocation As a baseline, statistical association measure, we use a heuristic variant of pointwise mutual information (PMI), promoting also collocations whose constituents are frequent (Tsvetkov and Wintner, 2010b). We define a binary feature, PMI, with values (*low* and *high*) reflecting the threshold that maximizes the accuracy of MWE classification in Tsvetkov and Wintner (2010b).

3.3 Feature Interdependencies Expressed as a Bayesian Network

A Bayesian Network (Jensen and Nielsen, 2007) is organized as a graph whose nodes are random variables and whose edges represent interdependencies among those variables. We use a particular type of BN, known as *causal* networks, in which directed edges lead to a variable from each of its direct *causes*. This facilitates the expression of domain knowledge (and intuitions, beliefs, etc.) as structural properties of the network. We use the BN as

[3] We use a 120M-token newspaper corpus.

a classification device: training amounts to computing the joint probability distribution of the training set, whereas classification maximizes the posterior probability of the particular node (variable) being queried.

For MWE identification we define a BN whose nodes correspond to the features described in Section 3.2. In addition, we define a node MWE for the complete classification task. Over these nodes we impose the structure depicted graphically in Figure 1. This structure, which we motivate below, is *manually* defined: it reflects our understanding of the problem domain and is a result of thorough experimentations. That said, it can of course be modified in various ways, and in particular, new nodes can be easily added to reflect additional features.

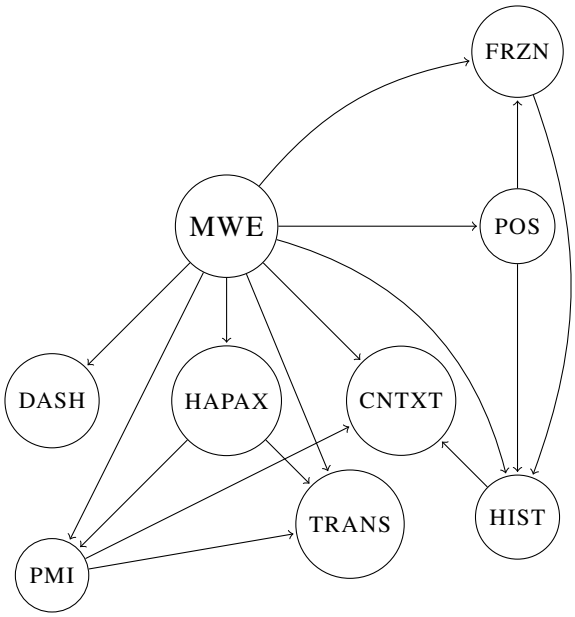

Figure 1: Bayesian Network for MWE identification

All nodes depend on MWE, as all are affected by whether or not the candidate is a MWE. The POS of an expression influences its morphological inflection, hence the edges from POS to HIST and to FROZEN. For example, Hebrew noun-noun constructions allow their constituents to undergo the full inflectional paradigm, but when such a construction is a MWE, inflection is severely constrained (Al-Haj and Wintner, 2010); similarly, when one of the constituents of a MWE is a conjunction, the entire expression is very likely to be frozen.

Hapaxes clearly affect all statistical metrics, hence the edge from HAPAX to PMI, and also the existence of literal translation, since if a word is not in the lexicon, it does not have a translation, hence the edge from HAPAX to TRANS. Also, we assume that there is a correlation between the frequency (and PMI) of a candidate and whether or not a literal translation of the expression exists, hence the edge from PMI to TRANS. The edges from PMI and HIST to CONTEXT are justified by the correlation between the frequency and variability of an expression and the variability of the context in which it occurs.

Once the structure of the network is established, the conditional probabilities of each dependency have to be determined. We compute the conditional probability tables from our training data (see below) using Weka (Hall et al., 2009), and obtain values for $P(X \mid X_1, \ldots, X_k)$ for each variable X and all variables X_i, $1 \leq i \leq k$, such that the graph includes an edge from X_i to X (parents of X). We then perform inference on the network in order to compute $P(X_{mwe} \mid X_1, \ldots, X_k)$, where X_{mwe} corresponds to the node MWE, and $X_1, \ldots, X_k$ are the variables corresponding to all *other* nodes in the network. Using Bayes Rule,

$$P(X_{mwe} \mid X_1, \ldots, X_k) \propto$$
$$P(X_1, \ldots, X_k \mid X_{mwe}) \times P(X_{mwe})$$

We define the prior, $P(X_{mwe})$, to be 0.41: this is the percentage of MWEs in WordNet 1.7 (Fellbaum, 1998). The conditional probabilities $P(X_1, \ldots, X_k \mid X_{mwe})$ are determined by Weka from the conditional probability tables:

$$P(X_1, \ldots, X_k \mid X_{mwe}) = \Pi_{i=1}^{k} P(X_i \mid \mathbf{pa}_i)$$

where k is the number of nodes in the BN (other than X_{mwe}) and $\mathbf{pa}_i$ is the set of parents of X_i.

3.4 Automatic Generation of Training Data

For training we need samples of positive and negative instances of MWEs, each associated with a vector of the values of all features discussed in Section 3.2. We generate this training material automatically. We use a small Hebrew-English bilingual corpus (Tsvetkov and Wintner, 2010a). We word-align the corpus with Giza++ (Och and Ney, 2003), and then apply the (completely unsupervised)

algorithm of Tsvetkov and Wintner (2010b), which extracts MWE candidates from the aligned corpus and re-ranks them using statistics computed from a large monolingual corpus. The core idea behind this method is that MWEs tend to be translated in non-literal ways; in a parallel corpus, words that are 1:1 aligned typically indicate literal translations and are hence unlikely constituents of MWEs.

The result is a set of 134,001 Hebrew bi-gram types (from the bilingual corpus), classified as either 1:1 aligned (implying they are likely *not* MWEs) or unaligned (in which case they may or may not be MWEs). In addition, for each bi-gram we have a PMI score; naturally, higher PMI scores are indicative of MWEs. We thus divide the set into four classes: aligned bi-grams with high PMI score, aligned bi-grams with low PMI score, misaligned with high PMI and misaligned with low PMI. Aligned bi-grams, independently of their PMI score, are more likely non-MWEs; high-PMI misaligned bi-grams are very likely MWEs; and the status of low-PMI misaligned bi-grams is unclear, and must be further investigated. This is summarized in Table 1.

	Misaligned	Aligned
High PMI	MWE	non-MWE
Low PMI	unclear	non-MWE

Table 1: Classification of bi-grams

We set the threshold that separates low PMI from high PMI as in Tsvetkov and Wintner (2010b). The results of this classification is depicted in Table 2.

	Misaligned	Aligned	Total
High PMI	2,203	493	2,696
Low PMI	61,314	69,991	131,305
Total	63,517	70,484	134,001

Table 2: Statistics of the sample space from which the training set is generated

We assume that all bi-grams in the 'Aligned' column are non-MWEs. Additionally, we assume that the 2,203 misaligned bi-grams with high PMI scores are likely MWEs. As for the set of over 61,000 misaligned low-PMI bi-grams, certainly many of them are non-MWEs, but some may be MWEs, and we are interested in including them as positive examples of MWEs with low PMI scores. We therefore manually annotate a sample of 50 MWEs from this particular set (we had to manually go over a few thousands of bi-grams to select this sample). This is the only supervision provided in this work.

The remaining question is how to determine the sizes of samples from each of the other three classes. We use two guidelines: first, we would like the ratio of MWEs to non-MWEs in the training set to be $41 : 59$, reflecting the ratio in WordNet (the prior MWE probability). Second, we would like classification by PMI score only to yield a reasonable baseline; the baseline is defined as the ratio of the sum of high-PMI MWEs plus low-PMI non-MWEs to the size of the training set. We choose 67%, the PMI baseline reported by Al-Haj and Wintner (2010). As a result of these two considerations, we end up with training sets whose sizes are depicted in Table 3. We randomly select from the sample space this many instances for each class. Since much of the procedure of preparing training data is automatic, the results may be somewhat noisy. As Bayesian Network are known to be robust to noisy data, we expect the BN to compensate for this problem.

	MWE	non-MWE	Total
High PMI	300	232	532
Low PMI	50	272	322
Total	350	504	854

Table 3: Sizes of each training set

4 Results and Evaluation

We use the training set described above for training and evaluation: we perform 10-fold cross validation experiments, reporting Precision, Recall, Accuracy and F-measure in three setups: one (SVM) in which we train an SVM classifier[4] with the features described in Section 3.2; one (BN-auto) in which we train a BN but let Weka determine its structure (using the K2 algorithm); and one (BN) in which we train a Bayesian Network whose structure reflects manually-crafted linguistically-motivated knowledge, as depicted in Figure 1. The

[4]We use Weka SMO with the PolyKernel setup; experimentation with several other kernels yielded worse results.

results, along with the PMI baseline figures, are listed in Table 4.

	Accuracy	Prec.	Recall	F-score
PMI	66.98%	0.73	0.67	0.67
BN-auto	71.19%	0.71	0.71	0.71
SVM	74.59%	0.75	0.75	0.75
BN	**76.82%**	**0.77**	**0.77**	**0.77**

Table 4: 10-fold cross validation evaluation results

The linguistically-motivated features defined in Section 3.2 are clearly helpful in the classification task: the accuracy of the SVM, informed by these features, is close to 75%, reducing the error rate of the PMI baseline by 23%. The contribution of the Bayesian Network is also highly significant, reducing almost 7% more errors (8.7% of the errors made by the SVM classifier), or a total of almost 30% error-rate reduction with respect to the baseline. Interestingly, a BN whose structure does not reflect prior knowledge, but is rather learned automatically, performs poorly. It is the combination of linguistically-motivated features with feature interdependencies reflecting domain knowledge that contribute to the best performance.

As a further demonstration of the utility of our approach, we evaluate the algorithm on an additional test set that was used for evaluation in the past (Tsvetkov and Wintner, 2010b; Al-Haj and Wintner, 2010). This is a small annotated corpus, **NN**, of Hebrew noun-noun constructions. The corpus consists of 413 high-frequency bi-grams of the same syntactic construction; of those, 178 are tagged as MWEs (in this case, noun compounds) and 235 as non-MWEs. This corpus consolidates the annotation of three annotators: only instances on which all three agreed were included. Since it includes both positive and negative instances, this corpus facilitates a robust evaluation of precision and recall.

We train a Bayesian Network on the training set described in Section 3.4 and use it to classify the set **NN**. We compare the results of this classifier with a PMI baseline (using the same threshold as above), and also with the classification results reported by Al-Haj and Wintner (2010) (AW); the latter reflects 10-fold cross-validation evaluation using the entire set, so it should be considered an upper bound for any classifier that uses a general training corpus.

The results are depicted in Table 5. They clearly demonstrate that the linguistically-motivated features we define provide a significant improvement in classification accuracy over the baseline PMI measure. Note that our F-score, 0.77, is very close to the best result of 0.79 obtained by Al-Haj and Wintner (2010) as the average of 10-fold cross validation runs, using *only* high-frequency noun-noun constructions for training. We interpret this result as a further proof of the robustness of our architecture.

	Accuracy	Precision	Recall	F-score
PMI	71.43%	0.71	0.71	0.71
BN	**77.00%**	**0.77**	**0.77**	**0.77**
AW	80.77%	0.77	0.81	0.79

Table 5: Evaluation results: noun-noun constructions

Finally, we have used the trained BN to classify the entire set of bi-grams present in the (Hebrew side of the) parallel corpus described in Tsvetkov and Wintner (2010a). Of the 134,000 candidates, only 4,000 are classified as MWEs. We sort this list of potential MWEs by the probability assigned by the BN to the positive value of the variable X_{mwe}. The resulting sorted list is dominated by high-PMI bi-grams, especially proper names, all of which are indeed MWEs. The first non-MWE (false positive) occurs in the 50th place on the list; it is *crpt niqwla* "France Nicolas", which is obviously a sub-sequence of the larger MWE, *neia crpt niqwla srqwzi* "French president Nicolas Sarkozy". Similar sub-sequences are also present, but only five are in the top-100. Such false positives can be reduced when longer MWEs are extracted, as it can be assumed that a sub-sequence of a longer MWE does not have to be identified. Other false positives in the top-100 include some highly frequent expressions, but over 85 of the top-100 are clearly MWEs.

While more careful evaluation is required in order to estimate the rate of true positives in this list, we trust that the vast majority of the positive results are indeed MWEs.

5 Conclusions and future work

We presented a novel architecture for identifying MWEs in text corpora. The main insights we em-

phasize are sophisticated computational encoding of linguistic knowledge that focuses on the idiosyncratic behavior of such expressions. This is reflected in two ways in our work: by defining computable features that reflect different facets of irregularities; and by framing the features as part of a larger Bayesian Network that accounts for interdependencies among them. We also introduce a method for automatically generating a training set for this task, which renders the classification almost entirely unsupervised. The result is a nearly-unsupervised, language-independent classification method that can identify MWEs of various lengths, types and constructions. Evaluation on Hebrew shows significant improvement in the accuracy of the classifier compared with the state of the art.

The modular architecture of BN facilitates easy exploration with more features. We are currently investigating the contribution of various other sources of information to the classification task. For example, Hebrew lacks large-scale lexical semantic resources. However, it is possible to literally translate a MWE candidate to English and rely on the English WordNet for generating synonyms of the literal translation. Such "literal synonyms" can then be back-translated to Hebrew. The assumption is that if a back-translated expression has a high PMI, the original candidate is very likely not a MWE. While such a feature may contribute little on its own, incorporating it in a well-structured BN may improve performance.

While our methodology is applicable to MWEs of any length, we have so far only evaluated it on bigrams. In the future, we intend to extend the evaluation to longer n-grams. We also plan to apply the methodology to languages other than Hebrew.

Abstract

An A-C bilingual dictionary can be inferred by merging A-B and B-C dictionaries using B as pivot. However, polysemous pivot words often produce wrong translation candidates. This paper analyzes two methods for pruning wrong candidates: one based on exploiting the structure of the source dictionaries, and the other based on distributional similarity computed from comparable corpora. As both methods depend exclusively on easily available resources, they are well suited to less resourced languages. We studied whether these two techniques complement each other given that they are based on different paradigms. We also researched combining them by looking for the best adequacy depending on various application scenarios.

1 Introduction

Nobody doubts the usefulness and multiple applications of bilingual dictionaries: as the final product in lexicography, translation, language learning, etc. or as a basic resource in several fields such as Natural Language Processing (NLP) or Information Retrieval (IR), too. Unfortunately, only major languages have many bilingual dictionaries. Furthermore, construction by hand is a very tedious job. Therefore, less resourced languages (as well as less-common language pairs) could benefit from a method to reduce the costs of constructing bilingual dictionaries. With the growth of the web, resources like Wikipedia seem to be a good option to extract new bilingual lexicon (Erdmann et al., 2008), but the reality is that a dictionary is quite different from an encyclopedia. Wiktionary[1] is a promising asset more oriented towards lexicography. However, the presence of less resourced languages in these kinds of resources is still relative -in Wikipedia, too-.

Another way to create bilingual dictionaries is by using the most widespread languages (e.g., English, Spanish, French...) as a bridge between less resourced languages, since most languages have some bilingual dictionary to/from a major language. These pivot techniques allow new bilingual dictionaries to be built automatically. However, as the next section will show, it is no small task because translation between words is not a transitive relation at all. The presence of polysemous or ambiguous words in any of the dictionaries involved may produce wrong translation pairs. Several techniques have been proposed to deal with these ambiguity cases (Tanaka and Umemura, 1994; Shirai and Yamamoto, 2001; Bond et al., 2001; Paik et al., 2004; Kaji et al., 2008; Shezaf and Rappoport, 2010). However, each technique has different performance and properties producing dictionaries of certain characteristics, such as different levels of coverage of entries and/or translations. The importance of these characteristics depends on the context of use of the dictionary. For example, a small dictionary containing the most basic vocabulary and the corresponding most frequent translations can be adequate for some IR and NLP tasks, tourism, or initial stages of language learning. Alternatively, a dictionary which maximizes the vocabulary coverage is more oriented towards advanced users or translation services.

This paper addresses the problem of pruning

Edinburgh, Scotland, UK, July 27–31, 2011.

wrong translations when building bilingual dictionaries by means of pivot techniques. We aimed to come up with a method suitable for less resourced languages. We analyzed two of the approaches proposed in the literature which are not very demanding on resources: Inverse Consultation (IC) (Tanaka and Umemura, 1994) and Distributional Similarity (DS) (Kaji et al., 2008), their strong points and weaknesses, and proposed that these two paradigms be combined. For this purpose, we studied the effect the attributes of the source dictionaries have on the performance of IC and DS-based methods, as well as the characteristics of the dictionaries produced. This could allow us to predict the performance of each method just by looking at the characteristics of the source dictionaries. Finally, we tried to provide the best combination adapted to various application scenarios which can be extrapolated to other languages.

The basis of the pivot technique is dealt with in the next section, and the state of the art in pivot techniques is reviewed in the third section. After that, the analysis of the aforementioned approaches and experiments carried out for that purpose are presented, and a proposal for combining both paradigms is included. The paper ends by drawing some conclusions from the results.

2 Pivot Technique

The basic pivot-oriented construction method is based on assuming the transitive relation of the translation of a word between two languages. Thus:

if p (pivot word) is a translation of s (source word) in the A-B dictionary and t (target word) is a translation of p in the B-C dictionary, we can say that t is therefore a translation of s, or $translation_{A,B}(s) = p$ and $translation_{B,C}(p) = t \rightarrow translation_{A,C}(s) = t$

This simplification is incorrect because it does not take into account word senses. Translations correspond to certain senses of the source words. If we look at figure 1, t (case of t_1 and t_2) can be the translation of p (p_2) for a sense c (c_3) different from the sense for which p (p_2) is the equivalent of s (c_1). This can happen when p pivot word is polysemous.

It could be thought that these causalities are not frequent, and that the performance of this basic approach could be acceptable. Let us analyze a real case. We merged a Basque-English dictionary composed of 17,672 entries and 43,021 pairs with an English-Spanish one composed of 16,326 entries and 38,128 pairs, and obtained a noised Basque-Spanish dictionary comprising 14,000 entries and 104,165 pairs. 10,000 (99,844 pairs) among all the entries have more than one translation. An automatic evaluation shows that 80.32% of these ambiguous entries contain incorrect translation equivalents (80,200 pairs out of 99,844). These results show that a basic pivot-oriented method is very sensitive to the ambiguity level of the source dictionaries. The conclusion is that the transitive relation between words across languages can not be assumed, because of the large number of ambiguous entries that dictionaries actually have. A more precise statement for the transitive property in the translation process would be:

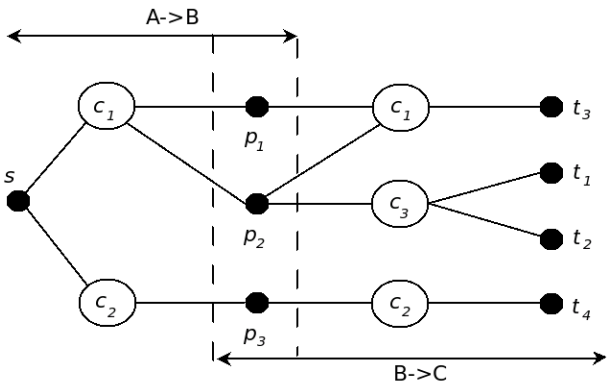

Figure 1: Ambiguity problem of the pivot technique.

if p (pivot word) is a translation of s with respect to a sense c and t is a translation of p with respect to the same sense c we can say that t is a translation of s, or $translation_{A,B}(s_{c_1}) = p$ and $translation_{B,C}(p_{c_2}) = t$ and $c_1 = c_2 \rightarrow translation_{A,C}(s) = t$

Unfortunately, most dictionaries lack comparable information about senses in their entries. So it is not possible to map entries and translation equivalents according to their corresponding senses. As an alternative, most papers try to guide this mapping according to semantic distances extracted from the dictionaries themselves or from external resources

such as corpora.

Another problem inherent in pivot-based techniques consists of missing translations. This consists of pairs of equivalents not identified in the pivot process because there is no pivot word, or else one of the equivalents is not present. We will not be dealing with this issue in this work so that we can focus on the translation ambiguity problem.

3 State of the Art

In order to reject wrong translation pairs, Tanaka et al. (1994) worked with the structure of the source dictionaries and introduced the IC method which measures the semantic distance between two words according to the number of pivot-words they share. This method was extended by using additional information from dictionaries, such as semantic classes and POS information in (Bond et al., 2001; Bond and Ogura, 2007). Sjöbergh (2005) compared full definitions in order to detect words corresponding to the same sense. However, not all the dictionaries provide this kind of information. Therefore, external knowledge needs to be used in order to guide mapping according to sense. István et al. (2009) proposed using WordNet, only for the pivot language (for English in their case), to take advantage of all the semantic information that WordNet can provide. Mausam et. al. (2009) researched the use of multiple languages as pivots, on the hypothesis that the more languages used, the more evidences will be found to find translation equivalents. They used Wiktionary for building a multilingual lexicon. Tsunakawa et al. (2008) used parallel corpora to estimate translation probabilities between possible translation pairs. Those reaching a minimum threshold are accepted as correct translations to be included in the target dictionary. However, even if this strategy achieves the best results in the terminology extraction field, it is not adequate when less resourced languages are involved because parallel corpora are very scarce.

As an alternative, (Kaji et al., 2008; Gamallo and Pichel, 2010) proposed methods to eliminate spurious translations using cross-lingual context or distributional similarity calculated from comparable corpora. In this line of work, (Shezaf and Rappoport, 2010) propose a variant of DS, and show how it outperforms the IC method. In comparison, our work focuses on analyzing the strong and weak points of each technique and aims to combine the benefits of each of them.

Other characteristics of the merged dictionaries like directionality (Paik et al., 2004) also influence the results.

4 Experimental Setup

This work focuses on adequate approaches for less resourced languages. Thus, the assumption for the experimentation is that few resources are available for both source and target languages. The resources for building the new dictionary are two basic (no definitions, no senses) bilingual dictionaries (A-B, B-C) including source (A), target (C) and a pivot language (B), as well as a comparable corpus for the source-target (A-C) language pair. We explored the IC (Tanaka and Umemura, 1994) and DS (Kaji et al., 2008; Gamallo and Pichel, 2010) approaches. In our experiments, the source and target languages are Basque and Spanish, respectively, and English is used for pivot purposes. In any case, the experiments could be conducted with any other language set, so long the required resources are available.

It must be noted that the proposed task is not a real problem because there is a Basque-Spanish dictionary already available. Resources like parallel corpora for that language pair are also available. These dictionaries and pivot language were selected in order to be able to evaluate the results automatically. During the evaluation we also used frequency information extracted from a parallel corpus, but then again, this corpus was not used during the dictionary building process, and therefore, it would not be used in a real application environment.

4.1 Resources

In order to carry out the experiments we used three dictionaries. The two dictionaries mentioned in the previous section (Basque-English $D_{eu \rightarrow en}$ and English-Spanish $D_{en \rightarrow es}$) were used to produce a new Basque-Spanish $D_{eu \rightarrow en \rightarrow es}$ dictionary. In addition, we used a Basque-Spanish $D_{eu \rightarrow es}$ dictionary for evaluation purposes. Its broad coverage is indicative of its suitability as a reference

dictionary. Table 1 shows the main characteristics of the dictionaries. We can observe that the ambiguity level of the entries (average number of translations per source word) is significant. This produces more noise in the pivot process, but it also benefits IC due to the increase in pivot words. As for the directions of source dictionaries, English is taken as target. Like Paik et al. (2004) we obtained the best coverage of pairs in that way.

Dictionary	**#entries**	**#pairs**	**ambiguity level**
$D_{eu \to en}$	17,672	43,021	2.43
$D_{en \to es}$	16,326	38,128	2.33
$D_{eu \to es}$(reference)	57,334	138,579	2.42
$D_{eu \to en \to es}$(noisy)	14,601	104,172	7.13

Table 1: Characteristics of the dictionaries.

Since we were aiming to merge two general dictionaries, the most adequate strategy was to use open domain corpora to compute DS. The domain of journalism is considered to be close to the open domain, and so we constructed a Basque-Spanish comparable corpus composed of news articles (see Table 2). The articles were gathered from the newspaper Diario Vasco (Hereinafter DV) for the Spanish part and from the Berria newspaper for the Basque part. Both publications focus on the Basque Country. In order to achieve a higher comparability degree, some constraints were applied:

- News in both languages corresponded to the same time span, 2006-2010.
- News corresponding to unrelated categories between newspapers were discarded.

Corpus	**#words**	**#docs**
Berria(eu)	40Mw	149,892
DV(es)	77Mw	306,924

Table 2: Characteristics of the comparable corpora.

In addition, as mentioned above, we extracted the frequencies of translation pairs from a Basque-Spanish parallel corpus. The corpus had 295,026 bilingual segments (4 Mw in Basque and 4.7 Mw in Spanish) from the domain of journalism.

5 Pruning Methods

IC and DS a priori suffer different weak points. IC depends on the structure of the source dictionaries. On the other hand, DS depends on a good comparable corpus and translation process. DS is measured more precisely between frequent words because context representation is richer.

The conditions for good performance of both IC and DS are analyzed below. These conditions will then be linked to the required characteristics for the initial dictionaries. In addition, we will measure how divergent the entries solved for each method are.

5.1 Inverse consultation

IC uses the structure of the D_{a-b} and D_{b-c} source dictionaries to measure the similarity of the meanings between source word and translation candidate. The description provided by Tanaka et al. (1994) is summarized as follows. To find suitable equivalents for a given entry, all target language translations of each pivot translation are looked up (e.g., $D_{b \to c}(D_{a \to b}(s))$). This way, all the "equivalence candidates" (ECs) are obtained. Then, each one is looked up in the inverse direction (following the previous example, $D_{c \to b}(t)$) to create a set of words called "selection area" (SA). The number of common elements of the same language between SA and the translations or equivalences (E) obtained in the original direction ($D_{a \to b}(s)$) is used to measure the semantic distance between entries and corresponding translations. The more matches there are, the better the candidate is. If only one inverse dictionary is consulted, the method is called "one time inverse consultation" or IC1. If n inverse dictionaries are consulted, the method is called "n time inverse consultation". As there is no significant difference in performance, we simply implemented IC1. Assuming that each element (x) of these two sets (SA, E) has a weight that is determined by the number of times it appears in the set that belongs (X), this weight is denoted as $\delta(X, x)$. In the same way, the number of common elements between SA and E is denoted as follows:

$$\delta(E, SA) = \sum_{x \in SA} \delta(E, x) \quad (1)$$

IC asks for more than one pivot word between source word s and translation candidate t. In our example:

$$\delta(D_{a\rightarrow b}(s), D_{c\rightarrow b}(t)) > 1 \quad (2)$$

In general, this condition guarantees that pivot words belong to the same sense of the source word (e.g. *iturri→tap→grifo, iturri→faucet→grifo*). Consequently, source word and target word also belong to the same sense.

Conceptually, the IC method is based on the confluence of two evidences. Let us take our dictionaries as examples. If two or more pivot words share a translation t in the $D_{es\rightarrow en}$ dictionary ($|tr(t_c, D_{es\rightarrow en}| > 1$) (e.g. *grifo→tap, grifo→faucet*) we could hypothesize that they are lexical variants belonging to a unique sense c. If an entry s includes those translations ($|tr(s_c, D_{eu\rightarrow en})| > 1$) (e.g. *iturri→tap, iturri→faucet*)) in the $D_{eu\rightarrow en}$ dictionary, we could also hypothesize the same. We can conclude that entry s and candidate t are mutual translations because the hypothesis that *"faucet"* and *"tap"* are lexical variants of the same sense c is contrasted against two evidences. This makes IC highly dependant on the number of lexical variants. Specifically, IC needs several lexical variants in the pivot language per each entry sense in both dictionaries. Assuming that wrong pairs cannot fulfill this requirement (see Formula 2) we can estimate the probabilities of the conditions for solving an ambiguous pair (s, t) where s and $t \in c$, as follows:

(a) $p(|tr(s_c, D_{a\rightarrow b})| > 1)$: Estimated by computing the average coverage of lexical variants in the pivot language for each entry in $D_{a\rightarrow b}$.

(b) $p(|tr(t_c, D_{c\rightarrow b})| > 1)$: Estimated by computing the average coverage of lexical variants in the pivot language for each entry in $D_{c\rightarrow b}$.

(c) $p(|tr(s_c, D_{a\rightarrow b}) \bigcap tr(t_c, D_{c\rightarrow b})| > 1)$: Convergence degree between translations of s and t in $D_{a\rightarrow b}$ and $D_{c\rightarrow b}$ corresponding to c.

So, in order to obtain a good performance with IC, the dictionaries used need to provide a high coverage of lexical variants per sense in the pivot language. If we assume that variants of a sense do not vary considerably between dictionaries, performance of IC in terms of recall would be estimated as follows:

$$R = p(|tr(s_c, D_{a\rightarrow b})| > 1) * p(|tr(t_c, D_{c\rightarrow b})| > 1) \quad (3)$$

We estimated the adequacy of the different dictionaries in the experimental setup according to estimations (a) and (b). Average coverage of lexical variants in the pivot language was calculated for both dictionaries. It was possible because lexical variants in the target language were grouped according to senses in both dictionaries. Only ambiguous entries were analyzed because they are the set of entries which IC must solve. In the $D_{eu\rightarrow en}$ dictionary more than 75% of senses have more than one lexical variant in the pivot language. So, $p(|tr(s_c, D_{eu\rightarrow en})| > 1) = 0.75$. In $D_{es\rightarrow en}$ this percentage (23%) is much lower. So, $p(|tr(t_c, D_{es\rightarrow en})| > 1) = 0.23$. Therefore, $D_{eu\rightarrow en}$ dictionary is more suited to the IC method than $D_{es\rightarrow en}$. As the conditions must be met in the maximum of both dictionaries, performance according to Formula 3 would be: $0.75 * 0.23 = 0.17$. This means that IC alone could solve about 17% of ambiguous entries.

5.2 Distributional Similarity

DS has been used successfully for extracting bilingual terminology from comparable corpora. The underlying idea is to identify as translation equivalents those words which show similar distributions or contexts across two corpora of different languages, assuming that this similarity is proportional to the semantic distance. In other words, establishing an equivalence between cross lingual semantic distance and translation probability. This technique can be used for pruning wrong translations produced in a pivot-based dictionary building process (Kaji et al., 2008; Gamallo and Pichel, 2010).

We used the traditional approach to compute DS (Fung, 1995; Rapp, 1999). Following the "bag-of-words" paradigm, the contexts of a word w

are represented by weighted collections of words. Those words are delimited by a window (± 5 words around w) and punctuation marks. The context words are weighted with regard to w according to the Log-likelihood ratio measure, and the context vector of w is formed. After representing word contexts in both languages, the algorithm computes for each source word the similarity between its context vector and all the context vectors corresponding to words in the target language by means of the cosine measure. To be able to compute the cross-lingual similarity, the context vectors are put in the same space by translating the vectors of the source words into the target language. This is done by using a seed bilingual dictionary. The problem is that we do not have that bilingual dictionary, since that is precisely the one we are trying to build. We propose that dictionaries extracted from our noisy dictionary ($D_{eu \rightarrow en \rightarrow es}$) be used:

- Including the unambiguous entries only
- Including unambiguous entries and selecting the most frequent candidates according to the target language corpus for ambiguous entries
- The dictionary produced by the IC1 method

The second method performed better in the tests we carried out. So, that is the method implemented for the experiments in the next section.

DS calls for several conditions in order to perform well. For solving an ambiguous translation t of a source word s, both context representations must be accurate. The higher their frequency in the comparable corpus, the richer their context representation will be. In addition to context representation, the translation quality of contexts is also a critical factor for the performance of DS. Factors can be formulated as follows if we assume big and highly comparable corpora:

(a) Precision of context representation: this can be estimated by computing the frequency of the words

(b) Precision of translation process: this can be estimated by computing the quality of the seed dictionary

6 Results

In order to evaluate the performance of each pruning method, the quality of the translations was measured according to the average precision and recall of translations per entry with respect to the reference dictionary. As we were not interested in dealing with missing translations, the reference for calculating recall was drawn up with respect to the intersection between the merged dictionary ($D_{eu \rightarrow en \rightarrow es}$) and the reference dictionary ($D_{eu \rightarrow es}$). F-score is the metric that combines both precision and recall.

We also introduced the frequency of use of both entry and pair as an aspect to take into account in the analysis of the results. It is better to deal effectively with frequent words and frequent translations than rare ones. Frequency of use of Basque words and frequency of source-target translation equivalent pairs were extracted respectively from the open domain monolingual corpus and the parallel corpus described in the previous section. Corpora were lemmatized and POS tagged in both cases in order to extract the frequency information of the lemmas.

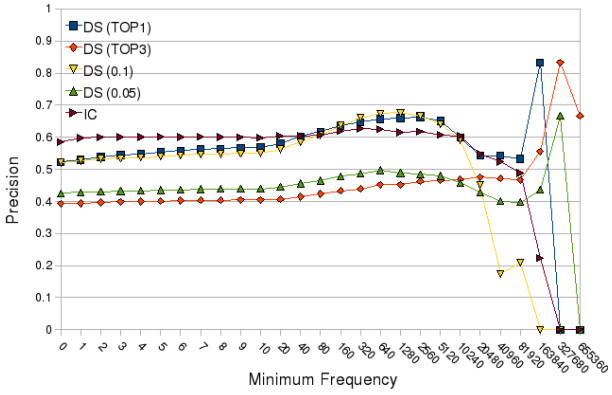

Figure 2: Precision results according to the minimum frequency of entries.

6.1 Inverse Consultation

Results show that IC precision is about 0.6 (See Figure 2). This means that many wrong pairs fulfill IC conditions. After analyzing the wrong pairs by hand, we observed that some of them corresponded to correct pairs not included in the reference dictionary. They are not included in

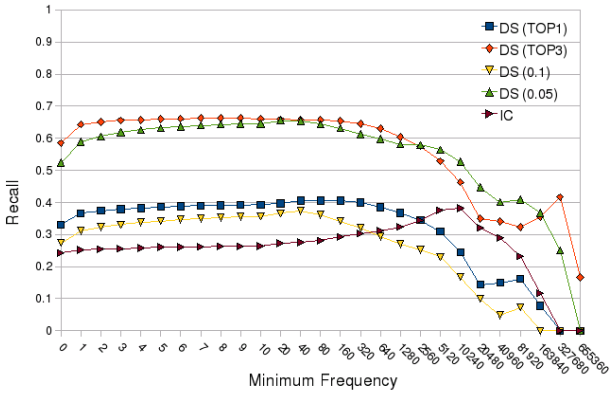

Figure 3: Recall results according to the minimum frequency of entries.

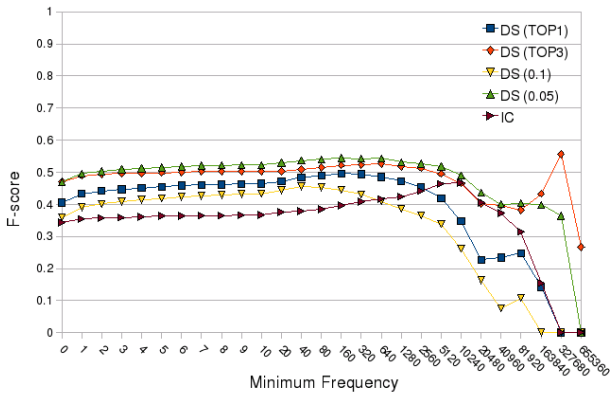

Figure 4: F-score results according to the minimum frequency of entries.

the reference because not all synonyms -or lexical variants- are included in it, only the most common ones. This is an inherent problem in automatic evaluation, and affects all the experiments presented throughout section 6 equally. Other wrong pairs comprise translation equivalents which have the same stem but different gramatical categories (e.g., 'aldakuntza' (noun) *(change, shift)* $\rightarrow$ *'cambiar'* (verb) *(to change, to shift)*). These wrong cases could be filtered if POS information would be available in the source dictionaries.

Precision is slightly better when dealing with frequent words, a maximum of 0.62 is reached when minimum frequency is between 150 and 2,000. Precision starts to decline significantly when dealing

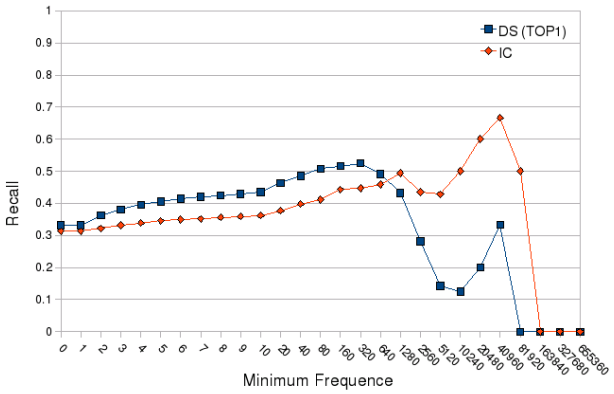

Figure 5: Recall results according to the minimum frequency of translation pairs.

with those entries over a minimum frequency of 10,000. However, only very few entries (234) reach that minimum frequency.

Recall is about 0.2 (See Figure 3), close to the estimation computed in section 5.1. It presents a more marked variability according to the frequency of entries, improving the performance as the frecuency increases. This could be due to the fact that frequent entries tend to have more translation variants (See Table 3). The fact that there are too many candidates to solve would explain why the recall starts to decline when dealing with very frequent entries.

Global performance according to F-score reflects the variability depending on frequency (See Figure 4).

Recall according to frequency of pairs provides information about whether IC selects rare translations or the most probable ones (See Figure 5). It must be noted that this recall is calculated with respect to the translation pairs of the merged dictionary $D_{eu \rightarrow en \rightarrow es}$ which appear in the parallel corpus (see section 4.1). Results (See Figure 5) show that IC deals much better with frequent translation pairs. However, recall for pairs whose frequency is higher than 100 only reaches 0.5. Even if the maximum recall is achieved for pairs whose frequency is above 40,000, it is not significant because they suppose a minimum number (3 pairs). In short, we can conclude that IC often does not find the most probable translation

(e.g. 'usain'→*'olor' (smell)*, 'zulo'→*'agujero' (hole)*,...).

6.2 Distributional Similarity

DS provides an idea of semantic distance. However, in order to determine whether a candidate is a correct translation, a minimum threshold must be established. It is very difficult to establish a threshold manually because its performance depends on the characteristics of the corpora and the seed dictionaries. The threshold can be applied at a global level, by establishing a numeric threshold for all candidates, or at local level by selecting certain top ranked candidates for each entry. The dictionary created by IC or unambiguous pairs can be used as a reference for tuning the threshold in a robust way with respect to the evaluation score such as F-score. In our experiments, thresholds estimated against the dictionary created by IC are very close to those calculated with respect to the whole reference dictionary (see Figure 6).

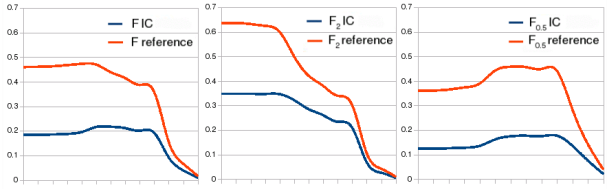

Figure 6: Threshold parameter tuning comparison for different F_n scores. Tuning against dictionary created by IC vs. Reference dictionary.

There is not much variation in performance between local and global thresholds. Precision increases from 0.4 to 0.5 depending on the strictness level of the threshold (See Figure 2), the stricter the better. In all cases, precision is slightly better when dealing with frequent words (frequency $>$ 20). This improvement is more marked with the strictest thresholds (TOP_1, 0.1). However, if global thresholds are used, performance starts to decline significantly when dealing with words whose frequency is above 1,000. So, it seems that local thresholds (TOP_3) perform more consistently with respect to the high frequencies of entries.

Recall (See Figure 3) goes from 0.5 to 0.7 depending on the strictness level of the threshold. It starts declining when frequency is above 50 depending on the type of threshold. In this case, global thresholds seem to perform better because the most frequent entries are handled better. These entries tend to have many translations. Therefore thresholds based on top ranks are too rigid.

There is no significant difference between global and local thresholds in terms of F-Score (See Figure 4). Each threshold type is more stable in precision or recall. So the F-Score is similar for both. Variability of F-Score according to frequency is lower than in precision and recall. As performance peaks on both measures at different points of frequency, the variability is mitigated when measures are combined by F-Score.

We have plotted the recall according to the frequency of pairs calculated from a parallel corpus in order to analyze the performance of DS when dealing with frequent translation pairs (See Figure 5). The performance decreases when dealing with pairs whose frequency is higher than 100. This means that DSs performance is worse when dealing with the most common translation pairs. So it is clear that it is very difficult to represent the contexts of very frequent words correctly.

The results show that DS rankings are worse when dealing with some words above a certain frequency threshold (e.g. 'on' *'good'*, 'berriz' *'again'*, 'buru' *'head'*, 'orain' *'now'*...). Although context representation of frequent words is based on many evidences, high polysemy level related to high frequency leads to a poorer representation. Alternatively we found that some of those frequent words are not very polysemous. Those words do not have strong collocates, that is, they tend to appear freely in contexts, which also leads to poor representation. This low quality representation hampers an accurate computation of semantic distance.

6.3 Comparison between IC and DS

As for average precision, IC provides better results than DS if all entries are taken into account. However, DS tips the scales in its favor if only entries with frequencies above 50 are considered and strict thresholds are used (TOP_1, 0.1).

DS clearly outperforms IC in terms of average recall of translations. Even if strict thresholds are used, DS outperforms IC for all entries whose

frequency is lower than 640.

If average precision and recall are evaluated together by means of F-score, DS outperforms IC (Figure 4). Only when dealing with very frequent entries (frequency $> 8,000$) is ICs performance close to DSs, but these entries make up a very small group (234 entries).

In order to compare the recall with respect to the frequency of translation pairs under the same conditions, we have to select a threshold that provides a similar precision to IC. TOP_1 is the most similar one (see figure 2). As Figure 5 shows, again DS is better than IC. Even if IC's recall clearly surpasses DS's when dealing with frequent translation pairs (frequency $> 2,560$), it only represents a minimal number of pairs (39).

6.4 Combining IC and DS according to different scenarios

In order to see how the methods can complement each other, we calculated the performance for solving ambiguous entries obtained by combining the results of both methods using various alternatives:

- Union: $IC \cup DS$: Pairs obtained by both methods are merged. Duplicated pairs are cleaned.
- Lineal combination (Lcomb): $IC * k + DS * (1 - k)$. Each method provides a value representing the translation score. For IC that value is the number of pivot words (see Formula 1), and the context similarity score in the case of DS. Those values are linearly combined and applied over the noised dictionary.

As mentioned in the first section, one of the goals of the paper was to analyze which method and which combination was best depending on the use case. We have selected some measures which are a good indicator of good performance for different use cases:

- $AvgF$: Average F-score per entry.
- $wAvgF$: Average F-score per entry weighted by the frequency of the entry. Higher frequency increases the weight.
- $AvgF_2$: Average F-score per entry where recall is weighted higher.
- $AvgF_{0.5}$: Average F-score per entry where precision is weighted higher.

For the use cases presented in section 1, some measures will provide richer information than others. On the one hand, if we aim to build small, accurate dictionaries, $AvgF_{0.5}$ would be a better indicator since it attaches more importance to high precision. In addition, if we want the dictionaries to cover the most common entries (e.g., in a basic dictionary for language learners) it is also interesting to look at $wAvgF$ values because greater value is given to finding translations for the most frequent words. On the other hand, if our objective is to build big dictionaries with a high recall, it would be better to look at $AvgF_2$ measure which attaches importance to recall.

Method	$AvgF$	$wAvgF$	$AvgF_2$	$AvgF_{0.5}$
IC	0.34	0.27	0.27	0.46
DS	0.47	0.44	0.64	0.46
Union	**0.52**	**0.49**	0.65	0.49
Lcomb	**0.52**	**0.49**	**0.67**	**0.52**

Table 3: Performance results of methods for ambiguous entries according to different measures.

Table 3 shows the results for the different combinations. The parameters of all methods are optimized for each metric (as explained in section 6.2, see figure 6). In all cases, the combinations surpass the results of both methods separately. There is a reasonable improvement over DS (10.6% for $AvgF$), and an even more startling one over IC (52.9% for $AvgF$). IC only gets anywhere near the other methods when precision is given priority ($AvgF_{0.5}$). There is no significant difference in terms of performance between the two combinations, although Lcomb is slightly better. $wAvgF$ measure is stricter than the others since it takes frequency of entries into account. This is emphasised more in the case of IC where results decrease notably compared with $AvgF$.

7 Conclusions

This paper has analyzed IC and DS, for the task of pruning wrong translations from bilingual dictionaries built by means of pivot techniques. After analyzing their strong and weak points we have showed that IC requires high ambiguity level dictionaries with several lexical variants per entry sense. With an average ambiguity close to 2 translation candidates DS obtains better results. IC is a high precision method, but contrary to our expectations, it seems that it is not much more precise than DS. In addition, DS offers much better recall of translations and entries. As a result, DS performs the best if both precision and recall are taken into account by F-score.

Both methods prune most probable translations for a significant number of frequent entries. DS encounters a problem when dealing with very frequent words due to the difficulty in representing their context. The main reason behind this is the high polysemy level of those words.

Our initial beliefs were that the translations found by each method would diverge to a certain extent. The results obtained when combining the two methods show that although the performance does not increase as much as expected (10.6% improvement over DS), there is in fact some divergence. As for the different use cases proposed, combinations offer the best performance in all cases. IC is indeed the poorer method, although it presents competitive results when precision is given priority.

Future experiments include contrasting these results with other dictionaries and language pairs.

Soft Dependency Constraints for Reordering in Hierarchical Phrase-Based Translation

Abstract

Long-distance reordering remains one of the biggest challenges facing machine translation. We derive soft constraints from the source dependency parsing to directly address the reordering problem for the hierarchical phrase-based model. Our approach significantly improves Chinese–English machine translation on a large-scale task by 0.84 BLEU points on average. Moreover, when we switch the tuning function from BLEU to the LRscore which promotes reordering, we observe total improvements of 1.21 BLEU, 1.30 LRscore and 3.36 TER over the baseline. On average our approach improves reordering precision and recall by 6.9 and 0.3 absolute points, respectively, and is found to be especially effective for long-distance reodering.

1 Introduction

Reordering, especially movement over longer distances, continues to be a hard problem in statistical machine translation. It motivates much of the recent work on tree-based translation models, such as the hierarchical phrase-based model (Chiang, 2007) which extends the phrase-based model (Koehn et al., 2003) by allowing the so-called *hierarchical phrases* containing subphrases.

The hierarchical phrase-based model captures the recursiveness of language without relying on syntactic annotation, and promises better reordering than the phrase-based model. However, Birch et al. (2009) find that although the hierarchical phrase-based model outperforms the phrase-based model in terms of medium-range reordering, it does equally poorly in long-distance reordering due to constraints to guarantee efficiency.

Syntax-based models that use phrase structure constituent labels as non-terminals in their transfer rules, exemplified by that of Galley et al. (2004), produce smarter and syntactically motivated reordering. However, when working with off-the-shelf tools for parsing and alignment, this approach may impose harsh limits on rule extraction and requires serious efforts of optimization (Wang et al., 2010).

An alternative approach is to augment the general hierarchical phrase-based model with soft syntactic constraints. Here, we derive three word-based, complementary constraints from the source dependency parsing, including:

- A dependency orientation feature, trained with maximum entropy on the word-aligned parallel data, which directly models the head-dependent orientation for source words;
- An integer-valued cohesion penalty that complements the dependency orientation feature, and fires when a word is not translated with its head. It measures derivation well-formedness and is used to indirectly help reordering;
- An auxiliary unaligned penalty feature that mitigates search error given the other two features.

We achieve significant improvements in terms of the overall translation quality and reordering behavior. To our knowledge we are the first to use the source dependency parsing to target the reordering problem for hierarchical phrase-based MT.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 857–868,
Edinburgh, Scotland, UK, July 27–31, 2011.

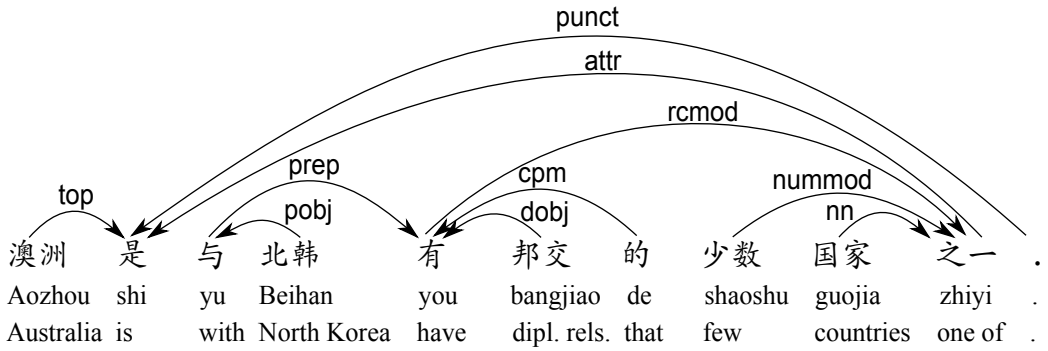

Figure 1: Example dependency parsing generated by the Stanford Parser. The Chinese source sentence and its English translation come from (Chiang, 2007).

2 Three Soft Dependency Constraints

Our features are based on the source dependency parsing, as shown in Figure 1. The basic unit of dependency parsing is a triple consisting of the dependent word, the head word and the dependency relation that connects them. For example, in Figure 1, an arrow labelled prep goes from the word *yu* (English *with*) to the word *you* (English *have*), showing that *yu* is a prepositional modifier of *you*.

We use the Stanford Parser[1] to generate dependency parsing, which automatically extracts dependency relations from phrase structure parsing (de Marneffe et al., 2006).

2.1 Dependency Orientation

Based on the assumption that constituents generally move as a whole (Quirk et al., 2005), we decompose the sentence reordering probability into the reordering probability for each aligned source word with respect to its head, excluding the root word at the top of the dependency hierarchy which does not have a head word. Similarly, Hayashi et al. (2010) also take a word-based reordering approach for HPBMT, but they model *all possible* pairwise orientation from the source side as a general linear ordering problem (Tromble and Eisner, 2009).

To be more specific, we have a maximum entropy orientation classifier that predicts the probability of a source word being translated in a monotone or reversed manner with respect to its head. For example, given the alignment in Figure 2(a), with the alignment points (i_{dep}, j_{dep}) for the source dependent word and (i_{head}, j_{head}) for the source head word, we define two orientation classes as:

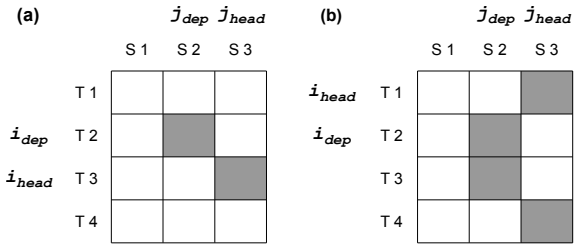

Figure 2: Word alignments to illustrate orientation classification. In (a), monotone (M); in (b), reversed (R).

$$c = \begin{cases} R & \text{if } (j_{dep} - j_{head})(i_{dep} - i_{head}) < 0 \\ M & \text{otherwise} \end{cases} \quad (1)$$

When a source head or dependent word is aligned to multiple target words, as shown in Figure 2(b), we always take the first target word for orientation classification.

The orientation classifier is trained on the large word-aligned parallel corpus. Various features can potentially be used, based on the source and target context as well as syntactic and semantic analysis. The orientation probability is evaluated in the following log-linear equation, where f is the source context, d is the source dependency parsing, e^* is the target context produced so far, a^* is the alignment produced so far and c is the orientation class:

[1] http://nlp.stanford.edu/software/lex-parser.shtml

Word	p(M)	p(R)
Aozhou	0.81	0.19
shi	NA	NA
yu	0.45	0.55
Beihan	0.88	0.12
you	0.12	0.88
bangjiao	0.83	0.17
de	0.58	0.42
shaoshu	0.30	0.70
guojia	0.19	0.81
zhiyi	0.85	0.15
.	1.00	0.00

Table 1: The dependency orientation probabilities for words of the Figure 1 sentence, in both monotone and reversed cases.

$$p(c|f,d,e^*,a^*) = \frac{exp(\sum_{n=1}^{N}\lambda_n h_n(f,d,e^*,a^*,c))}{\sum_{c'\in\{M,R\}} exp(\sum_{n=1}^{N}\lambda_n h_n(f,d,e^*,a^*,c'))} \quad (2)$$

Currently, we only use two kinds of features: (1) the concatenation of the source dependent word with the dependency relation and (2) the concatenation of the source head word with the dependency relation. So for the word *yu* (English *with*) in Figure 1, we extract these features for orientation classification: prep_DEP_*yu* and prep_HEAD_*you*.

We define the dependency orientation feature score for a translation hypothesis as the sum of the log orientation probabilities for each source word. This score is used as one feature in the log-linear formulation of the hierarchical phrase-based model.

Table 1 shows the dependency orientation probabilities for all words in the Figure 1 sentence. Most interestingly, the orientation probabilities for *you* (English *have*) strongly support global reordering of *one of the few countries* with the relative clause *that have diplomatic relations with North Korea*. We find that it is a general trend for long-distance reordering to gain stronger support, since it is often correlated with prominent reordering patterns (such as relative clause and preposition) as well as lexical evidences (such as *"... zhiyi"* (English *"one of ..."*)) for which the reversed orientation takes up the majority of the training cases.

Consider the following rules (both terminals and nonterminals are coindexed):

$$X \rightarrow (\underline{yu_1\ Beihan_2}\ you_3\ bangjiao_4,\ have_3\ dipl._4\ rels._4\ \underline{with_1\ North_2\ Korea_2}) \quad (3)$$

$$X \rightarrow (\underline{yu_1\ Beihan_2}\ you_3\ bangjiao_4,\ \underline{with_1\ North_2\ Korea_2}\ have_3\ dipl._4\ rels._4) \quad (4)$$

According to Table 1, the hypothesis that applies Rule 3 receives a probability of 0.55 for *yu* getting reversed with its head *you*, as well as 0.88 and 0.83 for translating *Beihan* and *bangjiao* in a monotone manner with respect to their heads. Rule 4 is associated with probabilities 0.45, 0.88 and 0.83 for monotone translation of *yu*, *Beihan* and *bangjiao*. Thus our dependency orientation feature is able to trace the difference in ordering the PP *with North Korea* (as underlined) and the VP *have dipl. rels.* down to the orientation of the preposition *yu* (English *with*) with respect to its head *you* (English *have*), and promote Rule 3 which has the right word order.

The word *you* (English *have*) cannot be scored in Rules 3 or 4, since its head word *zhiyi* (English *one of*) is not covered. In this case, we say that the word *you* is unresolved. We carry an unresolved word along in the derivation process until we reach a terminator hypothesis which translates the head word. Then the resulting dependency orientation score is added to the terminator hypothesis. This means that the dependency orientation feature is "stateless", i.e., hypotheses that cover the same source span with the same orientation information will receive the same feature score, regardless of the derivation history. Therefore, Derivation 5 in the following will have the same dependency orientation score as Derivation (Rule) 3, and Derivation 6 will score the same as Derivation (Rule) 4.

5.1 $X \rightarrow (yu_1, with_1)$

5.2 $X \rightarrow (Beihan_1, North_1\ Korea_1)$

5.3 $X \rightarrow (X_1\ X_2, X_1\ X_2)$

5.4 $X \rightarrow (X_1\ you_2\ bangjiao_3,\ have_2\ dipl._3\ rels._3\ X_1)$ (5)

6.1 $X \rightarrow$ (*Beihan*$_1$ *you*$_2$, *North*$_1$ *Korea*$_1$ *has*$_2$)

6.2 $X \rightarrow$ (X_1 *bangjiao*$_2$, X_1 *dipl.*$_2$ *rels.*$_2$)

6.3 $X \rightarrow$ (*yu*$_1$ X_2, *with*$_1$ X_2)

(6)

2.2 Cohesion Penalty

When the dependency orientation for a word is temporarily unavailable ("unresolved"), a cohesion penalty fires. Cohesion penalty counts the total occurrences of unresolved words for a translation hypothesis, which involve newly encountered unresolved words as well as old unresolved words carried on from the derivation history. Therefore, the cohesion penalty is "stateful", i.e., an unresolved word is repeatedly penalized until it gets resolved. Under this definition, the most cohesive derivation translates the entire sentence with one rule, where every word is locally resolved. The least cohesive derivation translates each word individually and glues word translations together. Consulting Figure 1, the cohesion penalty in Derivation 5 is 4, since the word *yu* (English *with*) is unresolved twice (in 5.1 and 5.3), and both *Beihan* (English *North Korea*) and *you* (English *have*) are unresolved once (in 5.2 and 5.4, respectively); the cohesion penalty in Derivation 6 is 5: 2 from *Beihan* (English *North Korea*) (in 6.1 and 6.2) and 3 from *you* (English *have*). As a result, Derivation 5 gets promoted, which echoes with human intuition since Derivation 5 translates syntactic constituents. To sum up, our cohesion penalty provides an integer-valued measure of derivation well-formedness in the hierarchical phrase-based MT. Same as dependency orientation, the cohesion penalty is not applicable to the root word of the sentence.

We propose the cohesion penalty in order to further improve reordering, especially in long-distance cases, since a well-formed derivation at an earlier stage makes it more likely to explore hierarchical rules that perform more reliable reordering. In this respect, the cohesion penalty can be seen as an aid to the glue rule penalty and as an alternative to constituency-based constraints.

Specifically, the glue rule penalty (Chiang, 2007) promotes hierarchical rules. Hierarchical rules whose lexical evidence helps resolve words locally will also be favored by our cohesion penalty feature. However, ignorant of the syntactic structure, the glue rule penalty may penalize a reasonably cohesive derivation such as Derivation 5 and at the same time promote a less cohesive hierarchical translation, such as Derivation 6.

Compared with constituency constraints based on the phrase structure, our cohesion penalty derived from the binary dependency parsing has two different characteristics.

First, our cohesion penalty is by nature more tolerant to some meaningful noncontituent translations. For example, constituency constraints in (Chiang, 2005; Marton and Resnik, 2008; Chiang et al., 2009) would penalize Rule 7 below which is useful for German–English translation (Koehn et al., 2003), and Rule 8 which can be applied to the Figure 1 sentence. Fuzzy constituency constraints can solve this problem with a combination of product categories and slash categories (Chiang, 2010). Yet our cohesion penalty by nature admits these translations as cohesive (with no extra cost from *es* and *Aozhou* since both are locally resolved). Admittedly, our current implementation of the cohesion penalty is blind to some other meaningful nonconstituent collocations, such as neighbouring siblings of a common uncovered head (regulated as the "floating structure" in (Shen et al., 2008)). A concrete example is Rule 9 which is useful for the Figure 1 sentence. To address this problem, another feature can be defined in the same manner to capture how each head word is translated with its children.

$$X \rightarrow (es_1\ gibt_2,\ there_1\ is_2) \quad (7)$$

$$X \rightarrow (Aozhou_1\ shi_2,\ Australia_1\ is_2) \quad (8)$$

$$X \rightarrow (shaoshu_1\ guojia_2,\ few_1\ countries_2) \quad (9)$$

Second, our cohesion penalty can be by nature more discriminative. Compared with the constituency constraints, the cohesion penalty is integer-valued, and can be made sensitive to the depth of each word in the dependency hierarchy (see Section 2.4). Inspired by (Marton and Resnik, 2008; Chiang et al., 2009), the cohesion penalty could also be made sensitive to the dependency relation of each word. However, this drastically increases the number of features and requires a tuning algorithm which scales better to high-dimensional model spaces, such as MIRA (Watanabe et al., 2007; Chiang et al., 2008).

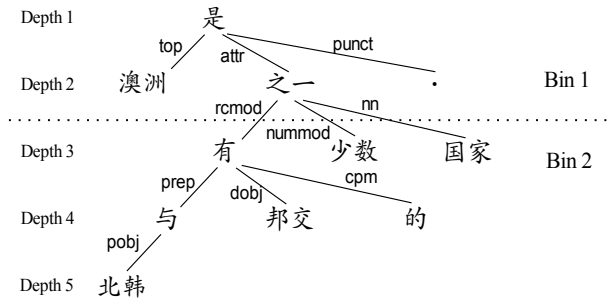

Figure 3: Using 2 bins for the dependency parse tree of the Figure 1 sentence.

2.3 Unaligned Penalty

The dependency orientation and cohesion penalty cannot be applied to unaligned source words. This may lead to search error, such as dropping (i.e., unaligning) key content words that are important for lexical translation and reordering. The problem is mitigated by an unaligned penalty applicable to all words in the dependency hierarchy.

2.4 Grouping Words into Bins

Having defined dependency orientation, cohesion penalty and unaligned penalty, we section the source dependency tree *uniformly by depth*, group words at different depths into bins and only add the feature scores of a word into its respective bin. In this way one feature is split into several sub-features and each can be trained discriminatively by MERT.

There are two motivations for binning. The primary motivation is to distinguish long-distance reordering which is still problematic for the hiero-style model, since local reorderings generally operate at low levels of the tree while high tree levels tend to take more care of long-distance reordering. Parsing accuracy is another concern, yet its impact on feature performance is intricate and our MaxEnt-trained dependency orientation feature also buffers against odd parsing. Using bins, we simply let the tuning process decide how much to trust feature scores coming from different levels of parsing.

We experiment with 1, 2 and 3 bins. An example of binning for the Figure 1 sentence can be found in Figure 3. With 2 bins (hereafter "bin-2"), words at Depth 1 and 2 are grouped into Bin 1, and words at Depth 3, 4, 5 are grouped into Bin 2. As a simple approach, binning does not take into account how the tree levels spread out.

3 Experiments

3.1 General Settings

We used a parallel training corpus with 2.1 million Chinese–English sentence pairs, aligned by GIZA++. The Chinese side was parsed by the Stanford Parser. Then we extracted 33.8 million examples from the parsed Chinese side to discriminatively train 1.1 million features (using the MegaM software[2]) for dependency orientation classification.

We trained three 5-gram language models with modified Kneser-Ney smoothing (Kneser and Ney, 1995): one on the English half of the parallel corpus, one on the Xinhua part of the Gigaword corpus, one on the AFP part, and interpolated them for best fit to the tuning set (Schwenk and Koehn, 2008).

We used NIST MT06 evaluation data (1664 lines) as our tuning set, and tested on NIST MT02 (878 lines), MT05 (1082 lines) and MT08 (1357 lines).

Our baseline system was the Moses implementation of the hierarchical phrase-based model with standard settings (Hoang et al., 2009). When only 1 bin was used, 3 additional features were added to the baseline, one each from the soft dependency constraints. When we used 2 or 3 bins, the additional feature counts doubled or tripled. We preserved terminal alignment alongside nonterminal alignment during the rule extraction and output word alignments together with translated strings. Since the features we currently define are based entirely on the source side, we used preprocessing to speed up decoding of our feature-augmented model. All experiments were tuned with MERT (Och, 2003).

3.2 Using BLEU as the Tuning Metric

As a standard practice, we first used BLEU (Papineni et al., 2002) as the objective function for tuning. Table 2 shows the results of the baseline model as well as our complete feature-augmented model with different bin numbers. With the "bin-2" setting, we get substantial improvement of up to 1.03 BLEU points (on MT02 data), and 0.84 BLEU points on average. Using more than one bin (i.e., differentiating tree depths) is generally beneficial, although the

[2]http://www.umiacs.umd.edu/∼hal/megam/index.html

Setting	BLEU / LRscore / TER			
	MT02	MT05	MT08	Average
baseline	34.01 / 41.85 / 68.93	32.23 / 40.50 / 68.15	28.09 / 37.17 / 66.82	31.44 / 39.84 / 67.97
bin-2	**35.04 / 43.07 / 65.58**	**33.18 / 41.62 / 65.59**	**28.63 / 38.12 / 65.36**	**32.28 / 40.94 / 65.51**
baseline-lr	34.23 / 42.06 / 68.08	32.28 / 40.61 / 67.61	27.99 / 37.27 / 66.98	31.50 / 39.98 / 67.56
bin-2-lr	**35.42 / 43.25 / 64.82**	**33.44 / 41.80 / 64.88**	**29.10 / 38.38 / 64.14**	**32.65 / 41.14 / 64.61**

Table 4: Results for the baseline model and the complete feature-augmented model with 2 bins ("bin-2"), using BLEU and LRscore ("-lr") as the tuning function. The BLEU scores of "bin-2" and "bin-2-lr" are significantly better than baseline ($p < 0.05$), computed by paired bootstrap resampling (Koehn, 2004).

Setting	BLEU			
	MT02	MT05	MT08	Average
baseline	34.01	32.23	28.09	31.44
bin-1	34.20	32.13	28.41	31.58(+.14)
bin-2	**35.04**	**33.18**	**28.63**	**32.28(+.84)**
bin-3	34.35	32.79	28.37	31.84(+.40)

Table 2: Results of the baseline model as well as our complete feature-augmented model with 1, 2 and 3 bins. BLEU is the tuning function.

Setting	BLEU			
	MT02	MT05	MT08	Average
baseline	34.01	32.23	28.09	31.44
dep	34.26	32.58	28.07	31.64(+.20)
dep+coP	34.47	32.81	28.61	31.96(+.52)
dep+coP+unP	35.04	33.18	28.63	32.28(+.84)

Table 3: Contributions of the three soft dependency constraints, with the "bin-2" setting

problem of overfitting sets in when we use 3 bins (with slightly higher tuning BLEU, not shown here).

We also studied the effect of adding features incrementally onto the baseline with the "bin-2" setting, as shown in Table 3. On average, all three features seem to have similar contributions.

3.3 Using LRscore as the Tuning Metric

Since our features are proposed to address the reordering problem and BLEU is not sensitive enough to reordering (especially in long-distance cases), we have also tried tuning with a metric that highlights reordering, i.e., the LRscore (Birch and Osborne, 2010). LRscore is a linear interpolation of a lexical metric and a reordering metric. We interpolated BLEU (as the lexical metric) with the Kendall's tau permutation distance (as the reordering metric). The Kendall's tau permutation distance measures the relative word order difference between the translation output and the reference(s) and is particularly sensitive to long-distance reordering. Testing results in terms of BLEU, LRscore and TER (Snover et al., 2006) are shown in Table 4. Tuned with the LRscore, our feature-augmented model achieves further average improvements (compare "bin-2" and "bin-2-lr") of 0.20 LRscore *as well as* 0.37 BLEU and 0.90 TER. Note that while the BLEU increase can largely be seen as a projection of the LRscore increase back into its lexical component, the consistent TER drop confirms that our improvement is not metric-specific[3]. Altogether the final improvement is 1.21 BLEU, 1.30 LRscore and 3.36 TER on average over the baseline.

However, an important question is how our features affect short, medium and long-distance reorderings. In the next section, we conduct quantitative analysis on reordering precision and recall, as well as qualitative analysis on translation examples.

4 Analysis

4.1 Precision and Recall of Reordering

The key to obtaining precision and recall for reordering is to investigate whether reorderings in the references are reproduced in the translations. We calculate precision as the number of reproduced reorderings divided by the total number of reorderings in the translation, and recall as the number of reproduced reorderings divided by the number of reorder-

[3]One of our reviewers points out that according to the inductive learning theory, it is counter-intuitive to improve on BLEU and TER if we optimize by the LRscore. Yet we do observe some other papers reporting increased TER or other metric scores when BLEU is used for tuning (Carpuat and Wu, 2007; Shen et al., 2008), suggesting that MT evaluation might be too complicated to be characterized just with inductive learning. Similar results based on extensive experiments can also be found in (Birch and Osborne, 2011).

Setting	MT02	MT05	MT08	Average
baseline	37.0	35.3	35.6	36.0
bin-2	42.7	40.8	38.7	40.7 (+4.7)
baseline-lr	37.3	35.0	34.2	35.5 (-0.5)
bin-2-lr	44.1	42.0	42.5	42.9 (+6.9)

Table 5: Overall precision for the test sets.

Setting	MT02	MT05	MT08	Average
baseline	37.5	36.2	33.2	35.6
bin-2	36.8	35.9	31.8	34.8 (-0.8)
baseline-lr	37.0	35.6	32.2	34.9 (-0.7)
bin-2-lr	37.7	36.7	33.2	35.9 (+0.3)

Table 6: Overall recall for the test sets.

ings in the reference. Then we average the precision and recall over all four reference translations.

Details of measuring reproduced reordering can be found in Birch et al. (2008). An important difference in this work is in handling many-to-one and one-to-many alignments, as we only retain the first word alignment for any source or target word which has multiple alignments. This is consistent with our treatment in dependency orientation classification, and results in more reorderings being extracted.

From Table 5 we can see that our features improve precision by an average of 4.7 absolute points when BLEU is used for tuning ("bin-2"). Switching from BLEU to the LRscore ("bin-2-lr"), we gain 2.2 points more and have a total improvement of 6.9 absolute points on average. This is a novel and important finding as we directly show that the quality of reordering has been improved.

From Table 6, we observe a small but consistent increase in recall with the "bin-2-lr" setting, averaging 0.3 absolute points. However, the drop of recall with the "bin-2" setting (by an average 0.8 points from the baseline) is unexpected. It seems that when applying our features alone, we are trading a small drop in recall for a large gain in precision.

In Figure 4 we break down the precision and recall statistics in MT08 by the reordering width on the source side. We find that our features consistently help precision over all word ranges, with more substantial improvement in the medium and long word ranges. When recall is concerned, our model does not help for short ranges of up to Width 4, but improves consistently for longer distance re-

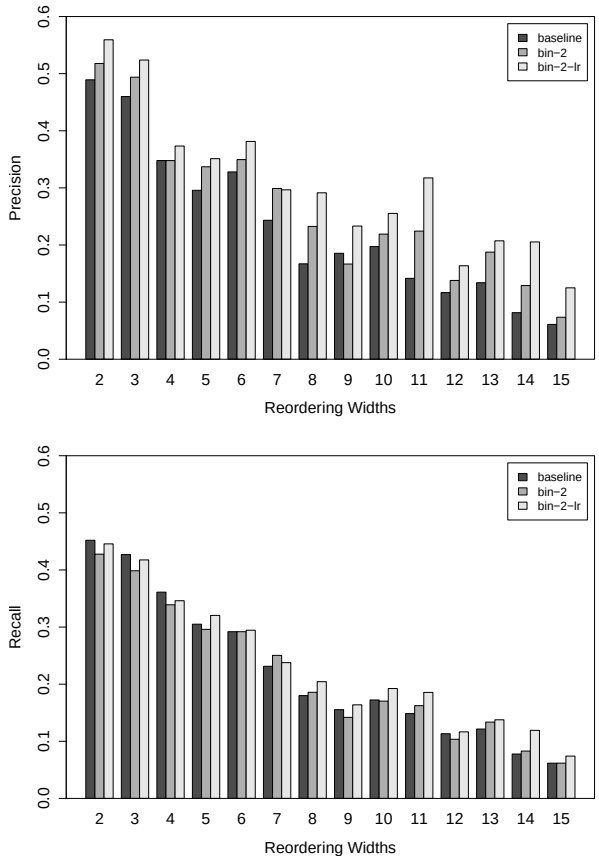

Figure 4: Precision and recall breakdown for the source-side reordering width 2-15 for the NIST MT08 dataset.

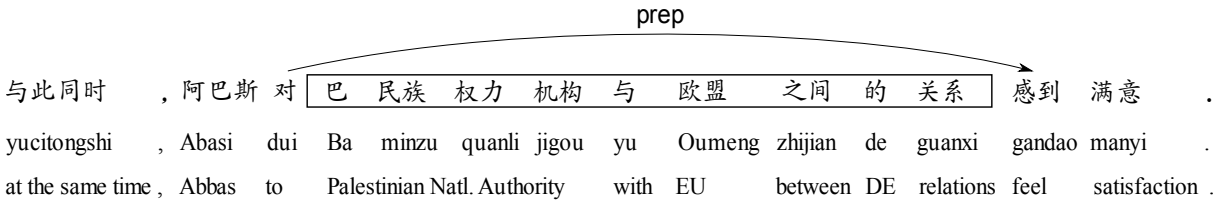
orderings. Once again, it seems that the feature-augmented model is able to benefit from tuning with a metric that is more sensitive to reordering, as the performance of "bin-2-lr" is the best in all reordering statistics.

4.2 Translation Examples

We observe a number of outputs with improved word order and more cohesive derivation, as the one in Figure 5. The baseline translation is fragmented and requires more glue rule applications. Specifically, it fails to translate the boxed area as a whole into "the relations between the palestinian national authority (pna) and the european union (eu)". The key dependency orientation that controls the global reordering is between the prepositional modifier *dui* (English *to*) and its head word, the verb *gandao* (English *feel*). The baseline system translates *dui* (English *to*) as "of the" and misorders the sentence. In contrast, the feature-augmented model "bin-2" cap-



baseline: [at the same time , abbas] [of the] [palestinian [national authority (pna)]] [and] [is satisfied with the [relations] [between [the european union (eu)]]] [.]

bin-2: [at the same time , abbas] [expressed satisfaction with [the relations between the [palestinian [national authority (pna) [and the european union (eu)]]]] .]

Figure 5: Example translations from the NIST MT08 set, output by the baseline model and "bin-2" model. The "-lr" version outputs are quite similar and not shown here. Translation outputs are in lower case.

tures the boxed area as a whole and uses Rule 10 to perform the right global reordering.

$$X \rightarrow (\underline{dui_1\ X_2}\ gandao_3\ manyi_4\ .5\ ,\ expressed_3\ satisfaction_4\ \underline{with_1\ X_2}\ .5\ ) \quad (10)$$

5 Related Work

In recent years, there has been a growing body of research on using dependency for statistical machine translation. Some directly encodes dependency in the translation model (Ding and Palmer, 2005; Quirk et al., 2005; Xiong et al., 2007; Shen et al., 2008; Mi and Liu, 2010), while others use dependency as a soft constraint (Cherry, 2008; Bach et al., 2009a,b; Chang et al., 2009). Among them, Shen et al. (2008) report that just filtering the phrase table by the so-called well-formed target dependency structure does not help, yet adding a target dependency language model improves performance significantly. Our intuitive interpretation is that the target dependency language model capitalizes on two characteristics of the dependency structure: it is based on words and it directly connects head and child. Therefore, the target dependency language model makes good use of the dependency representation as well as the target side training data.

We follow the second line of research, and derive three *word-based* soft constraints from the source dependency parsing. Note that although we reuse the word "cohesion" to name one of the constraints, our work is different from (Cherry, 2008; Bach et al., 2009a,b) which have successfully defined *another* cohesion constraint from the source dependency structure, with the aim of improving reordering in phrase-based MT.

To take a glance, Cherry (2008) and Bach et al. (2009b) define cohesion as translating a source dependency subtree contiguously into the target side without interruption (span or subtree overlapping), following Fox (2002). This span-based cohesion constraint has a different criterion from our word-based cohesion penalty and often leads to opposite conclusions. Bach et al. (2009a) also use cohesion to correlate with the lexicalized reordering model (Tillman, 2004; Koehn et al., 2005), whereas we define an orthogonal dependency orientation feature to explicitly model head-dependent reordering.

The fundamental difference, however, is rooted in the translation model. Their span-based cohesion constraint is implemented as an "interruption check" to encourage finishing a subtree before translating something else. This check is very effective for phrase-based decoding which searches over an entire space within the distortion limit in order to advance a hypothesis. In fact, it constrains reordering for the phrase-based model, as Cherry finds that the cohesion constraint is used "primarily to prevent distortion" and to provide "an intelligent estimate as to when source order must be respected" (Cherry, 2008). However, since the hierarchical phrase-based model *already* conducts principled reordering search with rules through the more constrained chart-decoding, ill-formed derivations exhibit themselves more often as nonconstituent translation than interrupted translation as defined in (Cherry, 2008; Bach et al., 2009a,b) (They do have a non-empty intersection, but neither subsumes the other). There-

fore, our cohesion penalty is better suited for the hierarchical phrase-based model.

To discourage nonconstituent translation, Chiang (2005) has proposed a constituency feature to examine whether a source rule span matches the source constituent as defined by phrase structure parsing. Finer-grained constituency constraints significantly improve hierarchical phrase-based MT when applied on the source side (Marton and Resnik, 2008; Chiang et al., 2009), or on the target side in a more tolerant fashion (Zollmann and Venugopal, 2006). Using both source and target syntax, but relaxing on rule extraction and substitution enables HPBMT to produce more well-formed and syntactically richer derivations (Chiang, 2010). Softening constituency matching with latent syntactic distributions proves to be helpful (Huang et al., 2010). Compared to constituency-based approaches, our cohesion penalty based on the dependency structure naturally supports constituent translations as well as some nonconstituent translations, if not all of them (as discussed in Section 2.2).

Our dependency orientation feature is similar to the order model within dependency treelet translation (Quirk et al., 2005). Yet instead of a head-relative position number for each modifier word, we simply predict the head-dependent orientation which is either monotone or reversed. Our coarser-grained approach is more robust from a machine learning perspective, yet still captures prominent and long-distance reordering patterns observed in Chinese–English (Wang et al., 2007), German–English (Collins et al., 2005), Japanese–English (Katz-Brown and Collins, 2008) and translation from English to a group of SOV languages (Xu et al., 2009). Not committed to specific language pairs, we learn orientation classification from the word-aligned parallel data through maximum entropy training as Zens and Ney (2006) and Chang et al. (2009) for phrase-based translation and Xiong et al. (2006) for the BTG model (Wu, 1996). While Chang et al. (2009) also make use of source dependency, their orientation classification concerns two subsequent phrase pairs in the left-to-right phrase-based decoding (as apposed to each dependent word and its head) and is therefore less linguistically-motivated.

6 Conclusion

We have derived three novel features from the source dependency structure for hierarchical phrase-based MT. They work as a whole to capitalize on two characteristics of the dependency representation: it is directly based on words and it directly connects head and child. The effectiveness of our approach has been demonstrated by a final average improvement of 1.21 BLEU, 1.30 LRscore and 3.36 TER. On average we improve reordering precision and recall by 6.9 and 0.3 absolute points, respectively, over the baseline. Moreover, our approach is found to be especially effective for long-distance reodering.

As mentioned in Section 2.2, the cohesion penalty can be extended to also account for how a head word is translated with its children so that we are not biased towards one form of cohesive nonconstituent translation. All our features can be made sensitive to the dependency relations or even words. This fine-grainedness is especially desirable when we want to reward words for being unaligned or unresolved, such as punctuations and function words in certain context. Word alignment quality is crucial for the performance of our features as well as the LRscore which uses word alignment to compute the permutation distance. As an alternative to GIZA++, we would like to experiment with syntactically informed aligners that better handle function words which often exhibit high alignment ambiguity due to low cross-lingual correspondence.

Finally, since our soft dependency constraints promote reordering without increasing model complexity, further gains can be achieved when combining our approach with orthogonal studies to improve the quantity and quality of hierarchical (reordering) rules, such as relaxing hierarchical rule extraction constraints (Setiawan and Resnik, 2010) and selectively lexicalizing rules with function words (Setiawan et al., 2009).

Acknowledgments

We would like to thank Miles Osborne, Adam Lopez, Barry Haddow, Hieu Hoang, Philip Williams and Michael Auli in the Edinburgh SMT group as well as Kevin Knight, David Chiang and Andrew Dai for inspiring discussions. We appreciate Pichuan Chang, Huihsin Tseng, Richard Zens, Matthew Snover and Nguyen Bach for helping us

understand their brilliant work. Many thanks to the anonymous reviewers for their insightful comments and suggestions. Statistical Machine Translation with Local Language Models

Abstract

Part-of-speech language modeling is commonly used as a component in statistical machine translation systems, but there is mixed evidence that its usage leads to significant improvements. We argue that its limited effectiveness is due to the lack of lexicalization. We introduce a new approach that builds a separate local language model for each word and part-of-speech pair. The resulting models lead to more context-sensitive probability distributions and we also exploit the fact that different local models are used to estimate the language model probability of each word during decoding. Our approach is evaluated for Arabic- and Chinese-to-English translation. We show that it leads to statistically significant improvements for multiple test sets and also across different genres, when compared against a competitive baseline and a system using a part-of-speech model.

1 Introduction

Language models are an important component of current statistical machine translation systems. They affect the selection of phrase translation candidates and reordering choices by estimating the probability that an application of a phrase translation is a fluent continuation of the current translation hypothesis. The size and domain of the language model can have a significant impact on translation quality. Brants et al. (2007) have shown that each doubling of the training data from the news domain (used to build the language model), leads to improvements of approximately 0.5 BLEU points. On the other hand, each doubling using general web data leads to improvements of approximately 0.15 BLEU points.

While large n-gram language models do lead to improved translation quality, they still lack any generalization beyond the surface forms (Schwenk, 2007). Consider example (1), which is a short sentence fragment from the MT09 Arabic-English test set, with the corresponding machine translation output (1.b), from a phrase-based statistical machine translation system, and reference translation (1.c).

(1) a. ... خلفية تصريحات صحافية مثيرة للجدل واتهامهم له ...

b. ... the background of press statements of controversial and accused him ...

c. ... the background of controversial press statements and accused him ...

Clearly, the adjective "controversial" should precede the nouns "press statement", but since the AFP and Xinhua portions of the Gigaword corpus, used to build the language model for the translation system, do not contain this surface n-gram, translations with obviously ungrammatical constructions such as (1.b) can result. For unseen n-grams, one would like to model adjectives as being likely to precede nouns in English, for example.

A straightforward approach to address this is to exploit the part-of-speech (POS) tags of the target words during translation (Kirchhoff and Yang, 2005). Though models exploiting POS information are not expressive enough to model long-distance dependencies, they can account for locally ungrammatical constructions such as (1.b). Several attempts have been made to interpolate POS language models

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 869–879,
Edinburgh, Scotland, UK, July 27–31, 2011.

with surface models. Under constrained data conditions, this can lead to improvements. But once larger amounts of training data are used, the gains obtained from adding POS language models decline substantially. This raises the question of why POS language models are not more effective. We argue that one of the short-comings of previous approaches to using POS language models is that these models are estimated globally, not lexically anchored, and hence rather context insensitive.

In this paper, we introduce a novel approach that builds and uses individual, local POS language models for each word in the vocabulary. Our experiments show that it leads to statistically significant improvements over a competitive baseline, using lexicalized reordering and a sizable 5-gram word language model, as well as a standard 7-gram POS language model approach.

2 Part-of-Speech Language Models

2.1 Background

Typically, POS language models are used like word-based language models. N-grams are extracted from a POS-tagged corpus and an n-gram language model is built from that. While word-based models estimate the probability of a string of m words by Equation 2, POS-based models estimate the probability of string of m POS tags by Equation 3.

$$p(w_1^m) \propto \prod_{i=1}^{m} p(w_i|w_{i-n+1}^{i-1}) \quad (2)$$

$$p(t_1^m) \propto \prod_{i=1}^{m} p(t_i|t_{i-n+1}^{i-1}) \quad (3)$$

where, n is the order of the language model, and w_i^j refers to the sub-sequence of words (or tags) from positions i to j.

Word language models can be built directly from large text corpora, such as LDC's Gigaword corpus, but POS models require texts that are annotated with POS tags. Ideally, one would use manually annotated corpora such as the Penn Treebank (Marcus et al., 1993), but since those tend to be small, most approaches rely on larger corpora which have been automatically annotated by a POS tagger or a parser (Koehn et al., 2008). Though automated annotation inevitably contains errors, it is assumed that this is ameliorated by the increased size of annotated data.

The event space of a language models is of size $|V|^n$, where V is the vocabulary, and n is the order of the language model. The vocabulary of POS models, (typically ranging between 40 and 100 tags), is much smaller than the vocabulary of a word model, which can easily approach a million words. Nevertheless, most POS language modeling approaches apply some form of smoothing to account for unseen events (Bonneau-Maynard et al., 2007).

To deploy POS language models in machine translation, translation candidates need to be annotated with POS tags. Each target phrase $\bar{e}$ in a phrase pair $(\bar{f}, \bar{e})$ can be associated with a number of POS tag sequences $\bar{t}_{\bar{e}}$. Heeman (1998) shows that using the joint probability leads to improved perplexity for POS models. For machine translation one can sum over all possible tag sequences, as in Equation 4.

$$p(\mathbf{e}|\mathbf{f}) = \arg\max_{\mathbf{e}} \sum_{\mathbf{t}} p(\mathbf{e}, \mathbf{t}|\mathbf{f}) \quad (4)$$

Summing over all possible tag sequences has the disadvantage that it requires one to keep this information during decoding. Below, we opt for an approximate solution, where each target phrase is annotated with the most likely POS tag sequence given the source and target phrase: $\bar{t}_{\bar{e}} = \arg\max_{\bar{t}} p(\bar{t}|\bar{e}, \bar{f})$.

2.2 Effectiveness of POS Language Models

Reported results on the effectiveness of POS language models for machine translation are mixed, in particular when translating into languages that are not morphologically rich, such as English. While they rarely seem to hurt translation quality, there does not seem to be a clear consensus that they significantly improve quality either.

Koehn and Hoang (2007) have reported an increase of 0.86 BLEU points for German-to-English translation for small training data. After relaxing phrase-matching to include lemma and morphological information on the source side, POS language models lead to a decrease of -0.42 BLEU points. Supertagging encapsulates more contextual information than POS tags and Birch et al. (2007) report improvements when comparing a supertag language model to a baseline using a word language model

only. Once the baseline incorporates lexicalized distortion (Tillmann, 2004; Koehn et al., 2005), these improvements disappear. Factored language models have not resulted in significant improvements either. Kirchhoff and Yang (2005) report slight improvements when re-ranking the n-best lists of their decoder, which word tri-grams. But these improvements are less than those gained by re-ranking the n-best lists with a 4-gram word language model.

The impact of POS language models depends among other things on the size of the parallel corpus, the size and order of the word language model, and whether lexicalized distortion models are used. To gauge the potential effectiveness of POS language models without taking into consideration all these factors, we isolate the contribution of the language model by simulating machine translation output using English data only (Al-Onaizan and Papineni, 2006; Post and Gildea, 2008). Taking a set of POS-tagged reference translations of the MT04 Arabic-to-English test set, each English sentence is randomly chunked into n-grams of average length three. The chunks of each sentence, with their corresponding POS tags, are randomly reordered. This is repeated 500 times for each sentence in the test set. The smoothed sentence BLEU score (ignoring brevity penalty) is computed for each reordered sentence with respect to all reference translations. The higher the BLEU score, the more well-formed the reordering is. As each reordered sentence only contains words from at least one of the reference translations, the uni-gram precision is always 1.0. The language model probability is then computed for each reordering. Table 1 shows the average correlations between language model probabilities and BLEU scores.

We can see that the surface language model correlates moderately well with BLEU, explaining about 49% ($r^2 = 0.49$) of the variation, whereas the POS language model does not correlate with BLEU at all.[1] On the other hand, local language models alone (as introduced in Section 3) correlate with BLEU only slightly worse than surface models. The highest correlation is seen when they are interpolated with word models. The BLEU scores in Table 1 are computed using the 1-best sentences after reranking. These system-agnostic correlation results look promising for our local models and the end-to-end translation results in Section 5 confirm these initial findings.

LM	Kendall's τ	Pearson r	BLEU[%]
wordLM	0.53	0.71	80.20
POS 7gLM	0.01	0.01	48.44
locLM	0.45	0.62	76.03
λwordLM+$(1-\lambda)$locLM ($\lambda = 0.92$)	0.54	0.73	80.98

Table 1: Correlation between randomly permuted English reference translations and BLEU.

3 Local Language Models

In this section, we introduce a novel approach to language modeling that is more context-sensitive than standard POS language models. Instead of using one global POS language model that is built by using all of a mono-lingual corpus in the target language, we build individual models, or local models, for each word-POS pair using the POS tags surrounding each occurrence of that pair. This adds an aspect of lexicalization that is entirely absent in previous POS language models. The effect is that the resulting n-gram probability distributions of each local model are more biased towards the contextual constraints of each individual word-POS pair. This is similar to the idea of cached language models (Kuhn, 1988), but more fine-grained and with a tighter integration of POS and lexical information.

3.1 Definition of Local Language Models

Each conditional probability of order n in a local model for the word-POS pair $w:t$ is of the form:

$$p_{w:t}(t_n, p_n | t_1 : p_1, \ldots, t_{n-1} : p_{n-1})$$

where t_i refers to POS tags and p_i to positions relative to an occurrence of the pair $(w:t)$. For example, consider the sentence fragment in Figure 1. The conditional local n-gram probabilities (a–d) are generated from the occurrence of the word *told* with POS tag VBD. Probability (c) in Figure 1 estimates that a word with POS tag NN occurs two positions to the right of *told*, given the n-gram history that a noun occurs to its left and a determiner to its right.

[1] Interpolating both models does not lead to further correlation improvements.

position	...	11	12	13	14	15	16	17	...
relative position	...	-3	-2	-1	0	+1	+2	+3	...
word	...	the	new	mayor	told	the	reporter	to	...
POS	...	DT	JJ	NN	VBD	DT	NN	TO	...

(a) $p_{told:\mathrm{VBD}}(\mathrm{NN{:}-1}|\mathrm{DT{:}-3\ JJ{:}-2})$

(b) $p_{told:\mathrm{VBD}}(\mathrm{DT{:}+1}|\mathrm{JJ{:}-2\ NN{:}-1})$

(c) $p_{told:\mathrm{VBD}}(\mathrm{NN{:}+2}|\mathrm{NN{:}-1\ DT{:}+1})$

(d) $p_{told:\mathrm{VBD}}(\mathrm{TO{:}+3}|\mathrm{DT{:}+1\ NN{:}+2})$

Figure 1: Sentence fragment with the tri-gram probabilities (a–d) linked to *told*.

For each local model we use a sliding window considering all n-grams of length n starting n words to the left and ending n words to the right of an occurrence of the word-POS pair of the model at hand.

All local model probabilities are smoothed using Witten-Bell smoothing and interpolation.[2] POS tags are annotated with positional information to distinguish between lower-order estimates such as $p_{told:\mathrm{VBD}}(\mathrm{NN{+}2})$ and $p_{told:\mathrm{VBD}}(\mathrm{NN{+}3})$ both of which can arise when backing off during smoothing. Without positional information, $p_{told:\mathrm{VBD}}(\mathrm{NN})$ only estimates the probability of the tag NN occurring within the proximity of *told*.[3]

A local model of order n contains the conditional probabilities for words occurring at relative positions -1, +1, ...+n. Therefore the probability of a word occurrence is estimated by all local models covering this word's position. Figure 2 shows schematically how overlapping n-gram probabilities interact. E.g., the probability of word w_{i+2} is based on the probability of the local model for w_{i+1}, w_i, w_{i-1}, and w_{i-2} (the last two are not shown in Figure 2 for space reasons). Formally, the conditional probability of a word-POS pair, given its word and POS tag history is defined in Equation 5.

$$p(w_i, t_i \mid w_{i-n+1}^{i-1}, t_{i-n+1}^{i-1}) = p_{w_i:t_i}(t_{i-1}\text{:-1} \mid \langle t_{i-n}\text{:-}n, \ldots, t_{i-2}\text{:-2}\rangle) \cdot \prod_{j=0}^{n-1} p_{w_{i-n+j}:t_{i-n+j}}(t_i\text{:}n-j \mid H_{i,n}[j,\cdot]) \quad (5)$$

[2]The smaller event space of local models often leads to incomplete counts-of-counts, preventing the use of Kneser-Ney smoothing (Chen and Goodman, 1999).

[3]Despite the notational similarities, our approach should not be confused with projected POS models, which use source side POS tags to model reordering (Och et al., 2004).

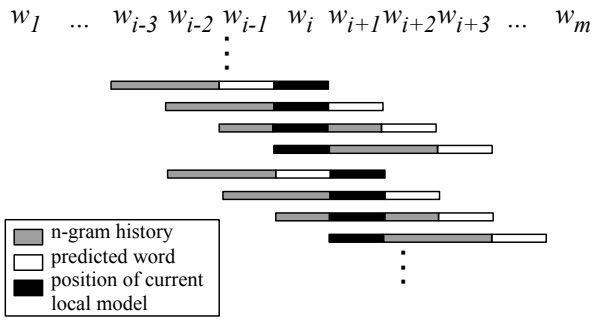

Figure 2: Schema of overlapping local language model applications.

where $H_{i,n}$ is an $n \times n$ matrix specifying the history of the word at position i. Each row j of $H_{i,n}$ represents the history of the conditional probability belonging to the local model associated with position $i-n+j$. Each entry $H_{i,n}[j,k]$ is defined as follows:

$$H_{i,n}[j,k] = \begin{cases} t_{i-n+k}\text{:}k-j & \text{if } j \neq k \\ \epsilon & \text{otherwise} \end{cases}$$

where t_{i-n+k} is the POS tag at position $i-n+k$ and $k-j$ is the relative position with respect to the diagonal of $H_{i,n}$, i.e., the position of the local language model corresponding to row j. $H_{i,n}[j,\cdot]$ is the jth row vector from which the jth entry (the empty element) has been removed. For instance, given the example in Figure 1, $H_{14,3}$ is

$$H_{14,3} = \begin{bmatrix} \epsilon & \mathrm{JJ{:}+1} & \mathrm{NN{:}+2} \\ \mathrm{DT{:}-1} & \epsilon & \mathrm{NN{:}+1} \\ \mathrm{DT{:}-2} & \mathrm{JJ{:}-1} & \epsilon \end{bmatrix}$$

For convenience we assume that the row and column indices are 0-based, i.e., the upper-left entry of a matrix is referred to by $H_{i,n}[0,0]$. In this example, $H_{14,3}[1,\cdot] = \langle \mathrm{DT{:}-1},\ \mathrm{NN{:}+1} \rangle$.

position	0	1	2	3	4	5	6

\end{aligned}
$$

Figure 3: Language model probability computation for the sentence "Cuba frees more dissidents." using our local language modeling approach.

The example in Figure 3 shows word-by-word how tri-gram local language models are used to compute the probability of a whole sentence.

Our local language model approach also bears some resemblance to statistical approaches to modeling subcategorization frames (Manning, 1993). While our approach is more general by considering all words and not just focusing on verbal subcategorization frames, it is also more shallow in the sense that only part-of-speech categories are considered which does not model any contextual relationships on the phrase level.

3.2 Building Local Language Models

To build the local language models, we use the SRILM toolkit (Stolcke, 2002), which is commonly applied in speech recognition and statistical machine translation. While SRILM collects n-gram statistics from all n-grams occurring in a corpus to build a single global language model, we build a language model for each word-POS pair only using the n-grams within the proximity of occurrences for that word-POS pair in a POS-tagged corpus. This results in separate n-gram count files, which are then processed by SRILM to build the individual language models.[4] Charniak's parser (Charniak, 2000) is used to POS tag the corpus.

[4]The pre-processing scripts are available at `http://www.science.uva.nl/~christof/locLM/`.

3.3 Decoder Integration

Several approaches that integrate POS language models have focused on n-best list re-ranking only (Hasan et al., 2006; Wang et al., 2007). Often this is due to the computational (and implementational) complexities of integrating more complex language models with the decoder, although it is expected that a tighter integration with the decoder itself leads to better improvements than n-best list re-ranking.

Integrating our local language modeling approach with a decoder is straightforward. Our baseline decoder already uses SRILM's API for computing word language model probabilities. Since SRILM supports arbitrarily many language models, local language models can be added using the same functionalities of SRILM's API. For the experiments discussed in Section 4, we add about 150,000 local language models to the word model. All local language model probabilities are coupled with the same feature weight. Potentially, improvements could be gained from using separate weights for individual local models, but this would require an optimization procedure such as MIRA (Chiang et al., 2009), which can handle a larger number of features.

During decoding no POS tagging ambiguities are resolved. Each target phrase is associated with its most likely POS tag sequence, given the source and target side of the phrase pair; see Section 2.1.

4 Experimental Setup

Three approaches are compared in our experiments: the baseline system is a phrase-based statistical machine translation system (Koehn et al., 2003), very similar to Moses (Koehn et al., 2007), using a word-based 5-gram language model. The second approach extends the baseline by including a 7-gram POS-based language model. The third approach represents the work described in this paper, extending the baseline by including 4-gram local language models.

Translation quality is evaluated for two language pairs: Arabic-to-English and Chinese-to-English. NIST's MT-Eval test sets are used for both pairs. Only resources allowed under NIST's constrained data conditions are used to train the language, translation, and lexicalized distortion models.

To see whether our local language models result in improvements over a competitive baseline, we designed the baseline to use a large 5-gram word language model and lexicalized distortion modeling, both of which are known to cancel-out improvements gained from POS language models (Birch et al., 2007; Kirchhoff and Yang, 2005). The 5-gram word language model is trained on the Xinhua and AFP sections of the Gigaword corpus (3rd edition, LDC2007T40) and the target side of the bitext. We removed from the training data all documents released during the periods that overlap with the publication dates of the documents included in our development or test data sets. In total, 630 million tokens were used to build the word language model. The language model was trained using SRILM with modified Kneser-Ney smoothing and interpolation (Chen and Goodman, 1999). It is common practice not to include higher-order n-grams that occur fewer than a predefined number of times. Here, we applied rather conservative cut-offs, by ignoring 3-, 4-, and 5-grams that occurred only once. The 7-gram POS and 4-gram local language models were both trained on the POS tagged English side of the bitext and 10M sentences from Gigaword's Xinhua and AFP sections.

The data for building the translation models were primarily drawn from the parallel news resources distributed by the Linguistic Data Consortium (LDC).[5] The Arabic-English bitext consists of 11.4M source and 12.6M target tokens, and the Chinese-English bitext of 10.6M source and 12.3M target tokens. Word alignment was performed running GIZA++ in both directions and generating the symmetric alignments using the 'grow-diag-final-and' heuristics.

All three approaches, including the baseline, use lexicalized distortion, distinguishing between monotone, swap, and discontinuous reordering, all with respect to the previous and next phrase (Koehn et al., 2005). The distortion limit is set to 5 for Arabic-to-English, and 6 for Chinese-to-English. For each source phrase the top 30 translations are considered.

For tuning and testing we use NIST's official MT-Eval test sets. MT04 was used as the development set for both language pairs. Testing was carried out on MT05 to MT09 for Arabic-English and MT05 to MT08 for Chinese-English. NIST did not release a new Chinese-English test set for MT-Eval 2009. Parameter tuning of the decoder was done with minimum error rate training (MERT) (Och, 2003), adapted to BLEU maximization.

As evaluation metrics we used NIST's adaptation of BLEU-4 (Papineni et al., 2001), version 13a, where the brevity penalty is based on the reference translation with the closest length, and translation error rate (TER) version 0.7.25 (Snover et al., 2006). All results reported here are case-insensitive. TER scores are shown as 1-TER.

To see whether the differences between the approaches we compared in our experiments are statistically significant, we apply approximate randomization (Noreen, 1989); Riezler and Maxwell (2005) have shown that approximate randomization is less sensitive to Type-I errors, i.e., less likely to falsely reject the null hypothesis, than bootstrap resampling (Koehn, 2004) in the context of machine translation.

5 Results and Analysis

The Arabic-to-English results are shown in Table 2, and the Chinese-to-English results in Table 3. All results are subdivided by genre following NIST's genre classification. Note that MT06 con-

Table 2: Results for Arabic-to-English translation. Comparison of our approach (**+locLM**, rows 4a/b) to the baseline using a word language model (**wordLM**, rows 1a/b) and a competing approach using a POS-based language model (**+posLM**, rows 2a/b). Results are presented using BLEU[%] (rows 1a–6a) and 1-TER[%] (rows 1b–6b) and broken down by genre: NW=newswire, WB=web, and ALL=NW∪WB. Rows 3a/b, 5a/b, and 6a/b show the relative improvements over the system mentioned to the right of the $>$ sign. Statistically significant improvements/declines (using approximate randomization) at the $p < .01$ level are marked $^{\blacktriangle}$/$^{\blacktriangledown}$ and $^{\triangle}$/$^{\triangledown}$ at the $p < .05$ level.

tains the genres 'broadcast news' and 'newsgroup'. In both tables, the former has been classified under 'newswire' and the latter under 'web'.

The first approach is the baseline system 'wordLM' (rows 1a/b in Tables 2 and 3), which uses a 5-gram word-based language model. The next approach '+posLM' extends the baseline by adding a 7-gram POS language model (rows 2a/b in both tables). Rows 3a/b show the relative improvements over the baseline. The third approach '+locLM' (rows 4a/b) uses local language models in addition to the baseline's word-based model. Note that +locLM does not use the 7-gram POS language model as well. Rows 5a/b show the relative improvements of the local modeling approach over the baseline and rows 6a/b the improvements over the approach using a POS language model.

Let us first take a closer look at the Arabic-to-English results in Table 2. The approach using a POS language model results in statistically significant improvements for only one test set (MT05) and the newswire documents of MT09. The average improvements across all sets and genres are negligible ($+0.07$ BLEU). Our local language modeling approach achieves the highest BLEU scores for all test sets and across all genres. In particular, the improvements of +1.06 BLEU for newswire documents are substantial. With the exception of MT08-WB and MT09-WB all BLEU improvements over the baseline are statistically significant.

When evaluating with 1-TER, local language modeling also achieves the best results, with the exception of MT06, where the POS language model approach performs slightly better.

Turning to the Chinese-English results in Table 3, we see similar improvements in BLEU. The improvements of using a POS language model are negligible ($+0.04$ BLEU). Here as well, local language modeling leads to the best results, with substantial improvements of +0.88 BLEU for web documents.

The major difference between Arabic-English and Chinese-English is the discrepancy between BLEU score improvements and decreases in 1-TER. While we cannot explain this discrepancy, it is worth noting that similar discrepancies between BLEU and TER and Arabic-to-English and Chinese-to-English translation can be found in the literature. The results described in Shen et al. (2009) show a strong correlation between BLEU and 1-TER improvements[6]

[6]Shen et al. (2009) report TER rather than 1-TER scores.

for Arabic-to-English on the MT06 and MT08 sets, but for Chinese-to-English the correlation seems to be much weaker and BLEU improvements of +0.75 can correspond to decreases of up to -0.80 in 1-TER.

One of the motivations of using POS language models in general, and local language models in our case, is to improve the fluency of translations, which should be reflected in increased precision for higher-order n-grams. Table 4 shows that this is the case when comparing local modeling to both word and POS language models for Arabic-to-English translation. The same trend, but to a somewhat weaker degree can be observed for Chinese-to-English.

	Prec-1	Prec-2	Prec-3	Prec-4	BP

Table 4: BLEU n-gram precision ($1 \leq n \leq 4$) and Brevity Penalty (BP) scores over all test sets.

The effectiveness of a POS language model often diminishes with improved translation quality of the base system to which it is added. Naturally, we are interested in the extent that this diminishing effect also holds for our local language models. A full experimental setup, varying all relevant factors, such as language, translation, and distortion model size, and the various meta-parameters, is beyond the scope of this paper. Nevertheless, we can gauge this by taking a closer look at the distribution of improvements within our experiments. Figure 4 shows performance improvements in document-level BLEU for both language pairs. The document-level BLEU score for the baseline system is plotted on the x-axis and improvements are plotted on the y-axis. The dotted line is the linear fit (using least square regression). If the effectiveness of either added model (POS or local) diminishes with increasing translation quality, we would expect a declining regression line. This is not the case for Arabic-to-English translation. Relative improvements for both added models increase as the translation quality of the baseline increases. The slope of both regression fits is almost identical, but the y-intercept is larger for our local modeling approach. Note that the small slope is also due to difference in scale between full BLEU scores and relative improvements. We can observe the opposite for Chinese-to-English translation, where the slope is negative. Both models seem to help more for documents with lower baseline translation quality. For the POS model, the regression line intersects with the neutral line (± 0 improvement) at around 31 BLEU, which is close to the average BLEU score and in line with its negligible improvements (see Ta-

ble 3). For the local language model, the regression line intersects with the neutral line at about 40 BLEU, suggesting that until translation quality improves substantially, local language models could still have a positive impact.

6 Related Work

The main goal of this paper is to show that by tying POS language models to lexical items, we get more accurate distributions for specific words. The work on factored language models (Bilmes and Kirchhoff, 2003) is related to our work to the extent that it also mixes POS tags with lexical information, albeit in a very different manner. Factored language models use more general representations, such as POS tags or stems, only during back-off. Kirchhoff and Yang (2005) applied factored language models to machine translation but the improvements were negligible.

Collins et al. (2005) proposed a discriminative language modeling approach that uses mixtures of POS and surface information and showed that it leads to a reduction in speech recognition word error rates. On the other hand, their approach seems more suited for n-best list re-ranking and it is not clear whether those improvements carry over to machine translation. Li and Khudanpur (2008) adapted this discriminative approach to machine translation re-ranking but used surface forms only.

Wang et al. (2007) and Zheng et al. (2008) use elaborately enriched representations, called *super abstract role values* (Wang and Harper, 2002), which capture contextual dependencies using lexical categories, role labels, and dependency grammar structures. So far their approach has been limited to re-ranking n-best lists only.

7 Conclusion

Though POS language models do not lead to significant improvements over a competitive baseline, we have shown that a competitive phrase-based baseline system can benefit from using POS information by building lexically anchored local models. Our local model approach does not only lead to more context-specific probability distributions, but also takes ad-

vantage of the language model probability of each word being based on all surrounding local models. The evaluations for Arabic- and Chinese-to-English show that local models lead to statistically significant improvements across different test sets and genres. Correlating the translation quality of the baseline with the improvements that result from adding local models, further suggests that these improvements are sustainable and should carry over to improved baseline systems.

Abstract

Although discriminative training guarantees to improve statistical machine translation by incorporating a large amount of overlapping features, it is hard to scale up to large data due to decoding complexity. We propose a new algorithm to generate translation forest of training data in linear time with the help of word alignment. Our algorithm also alleviates the oracle selection problem by ensuring that a forest always contains derivations that exactly yield the reference translation. With millions of features trained on 519K sentences in 0.03 second per sentence, our system achieves significant improvement by 0.84 BLEU over the baseline system on the NIST Chinese-English test sets.

1 Introduction

Discriminative model (Och and Ney, 2002) can easily incorporate non-independent and overlapping features, and has been dominating the research field of statistical machine translation (SMT) in the last decade. Recent work have shown that SMT benefits a lot from exploiting large amount of features (Liang et al., 2006; Tillmann and Zhang, 2006; Watanabe et al., 2007; Blunsom et al., 2008; Chiang et al., 2009). However, the training of the large number of features was always restricted in fairly small data sets. Some systems limit the number of training examples, while others use short sentences to maintain efficiency.

Overfitting problem often comes when training many features on a small data (Watanabe et al., 2007; Chiang et al., 2009). Obviously, using much more data can alleviate such problem. Furthermore, large data also enables us to globally train millions of sparse lexical features which offer accurate clues for SMT. Despite these advantages, to the best of our knowledge, no previous discriminative training paradigms scale up to use a large amount of training data. The main obstacle comes from the complexity of packed forests or n-best lists generation which requires to search through all possible translations of each training example, which is computationally prohibitive in practice for SMT.

To make normalization efficient, contrastive estimation (Smith and Eisner, 2005; Poon et al., 2009) introduce neighborhood for unsupervised log-linear model, and has presented positive results in various tasks. Motivated by these work, we use a *translation forest* (Section 3) which contains both "*reference*" derivations that potentially yield the reference translation and also *neighboring* "*non-reference*" derivations that fail to produce the reference translation.[1] However, the complexity of generating this translation forest is up to $\mathcal{O}(n^6)$, because we still need biparsing to create the reference derivations.

Consequently, we propose a method to fast generate a subset of the forest. The key idea (Section 4) is to initialize a reference derivation tree with maximum score by the help of word alignment, and then traverse the tree to generate the subset forest in linear time. Besides the efficiency improvement, such a forest allows us to train the model without resort-

[1] Exactly, there are no reference derivations, since derivation is a latent variable in SMT. We call them reference derivation just for convenience.

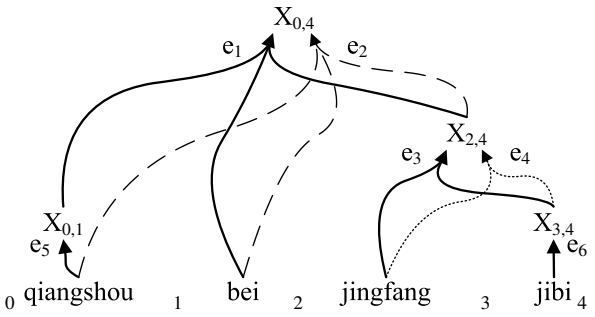
Edinburgh, Scotland, UK, July 27–31, 2011.



hyper-edge		rule
e_1	r_1	$X \Rightarrow \langle X_1$ *bei* X_2, X_1 was $X_2 \rangle$
e_2	r_2	$X \Rightarrow \langle$ *qiangshou bei* X_1, the gunman was $X_1 \rangle$
e_3	r_3	$X \Rightarrow \langle$ *jingfang* X_1, X_1 by the police$\rangle$
e_4	r_4	$X \Rightarrow \langle$ *jingfang* X_1, police $X_1 \rangle$
e_5	r_5	$X \Rightarrow \langle$ *qiangshou*, the gunman$\rangle$
e_6	r_6	$X \Rightarrow \langle$ *jibi*, shot dead$\rangle$

Figure 1: A translation forest which is the running example throughout this paper. The reference translation is "*the gunman was killed by the police*". (1) Solid hyperedges denote a "reference" derivation tree t_1 which exactly yields the reference translation. (2) Replacing e_3 in t_1 with e_4 results a competing non-reference derivation t_2, which fails to swap the order of $X_{3,4}$. (3) Removing e_1 and e_5 in t_1 and adding e_2 leads to another reference derivation t_3. Generally, this is done by deleting a node $X_{0,1}$.

ing to constructing the oracle reference (Liang et al., 2006; Watanabe et al., 2007; Chiang et al., 2009), which is non-trivial for SMT and needs to be determined experimentally. Given such forests, we globally learn a log-linear model using stochastic gradient descend (Section 5). Overall, both the generation of forests and the training algorithm are scalable, enabling us to train millions of features on large-scale data.

To show the effect of our framework, we globally train millions of word level context features motivated by word sense disambiguation (Chan et al., 2007) together with the features used in traditional SMT system (Section 6). Training on 519K sentence pairs in 0.03 seconds per sentence, we achieve significantly improvement over the traditional pipeline by 0.84 BLEU.

2 Synchronous Context Free Grammar

We work on synchronous context free grammar (SCFG) (Chiang, 2007) based translation. The elementary structures in an SCFG are rewrite rules of the form:

$$X \Rightarrow \langle \gamma, \alpha \rangle$$

where γ and α are strings of terminals and nonterminals. We call γ and α as the source side and the target side of rule respectively. Here a rule means a phrase translation (Koehn et al., 2003) or a translation pair that contains nonterminals.

We call a sequence of translation steps as a *derivation*. In context of SCFG, a derivation is a sequence of SCFG rules $\{r_i\}$. *Translation forest* (Mi et al., 2008; Li and Eisner, 2009) is a compact representation of all the derivations for a given sentence under an SCFG (see Figure 1). A *tree* t in the forest corresponds to a derivation. In our paper, tree means the same as derivation.

More formally, a **forest** is a pair $\langle V, E \rangle$, where V is the set of **nodes**, E is the set of **hyperedge**. For a given source sentence $\mathbf{f} = f_1^n$, Each node $v \in V$ is in the form $X_{i,j}$, which denotes the recognition of nonterminal X spanning the substring from the i through j (that is $f_{i+1}...f_j$). Each hyperedge $e \in E$ connects a set of antecedent to a single consequent node and corresponds to an SCFG rule $r(e)$.

3 Our Translation Forest

We use a translation forest that contains both "*reference*" derivations that potentially yield the reference translation and also some neighboring "*non-reference*" derivations that fail to produce the reference translation. Therefore, our forest only represents some of the derivations for a sentence given an SCFG rule table. The motivation of using such a forest is efficiency. However, since this space contains both "good" and "bad" translations, it still provides evidences for discriminative training.

First see the example in Figure 1. The derivation tree t_1 represented by solid hyperedges is a reference derivation. We can construct a non-reference derivation by making small change to t_1. By replacing the e_3 of t_1 with e_4, we obtain a non-reference deriva-

tion tree t_2. Considering the rules in each derivation, the difference between t_1 and t_2 lies in r_3 and r_4. Although r_3 has a same source side with r_4, it produces a different translation. While r_3 provides a swapping translation, r_4 generates a monotone translation. Thus, the derivation t_2 fails to move the subject "police" to the behind of verb "shot dead", resulting a wrong translation "the gunman was police shot dead". Given such derivations, we hope that the discriminative model is capable to explain why should use a reordering rule in this context.

Generally, our forest contains all the reference derivations $\mathcal{RT}$ for a sentence given a rule table, and some neighboring non-reference derivations $\mathcal{NT}$, which can be defined from $\mathcal{RT}$.

More formally, we call two hyperedges e^1 and e^2 are **competing hyperedges**, if their corresponding rules $r(e^1) = \langle \gamma^1, \alpha^1 \rangle$ and $r(e^2) = \langle \gamma^2, \alpha^2 \rangle$:

$$\gamma^1 = \gamma^2 \wedge \alpha^1 \neq \alpha^2 \quad (1)$$

This means they give different translations for a same source side. We use $C(e)$ to represent the set of competing hyperedges of e.

Two derivations $t^1 = \langle V^1, E^1 \rangle$ and $t^2 = \langle V^2, E^2 \rangle$ are **competing derivations** if there exists $e^1 \in E^1$ and $e^2 \in E^2$: [2]

$$V^1 = V^2 \wedge E^1 - e^1 = E^2 - e^2 \\ \wedge e^2 \in C(e^1) \quad (2)$$

In other words, derivations t^1 and t^2 only differ in e^1 and e^2, and these two hyperedges are competing hyperedges. We use $C(t)$ to represent the set of competing derivations of tree t, and $C(t,e)$ to represent the set of competing derivations of t if the competition occurs in hyperedge e in t.

Given a rule table, the set of reference derivations $\mathcal{RT}$ for a sentence is determined. Then, the set of non-reference derivations $\mathcal{NT}$ can be defined from $\mathcal{RT}$:

$$\cup_{t \in \mathcal{RT}} C(t) \quad (3)$$

Overall, our forest is the compact representation of $\mathcal{RT}$ and $\mathcal{NT}$.

[2]The definition of derivation tree is similar to forest, except that the tree contains exactly one tree while forest contains exponentially trees. In tree, the hyperedge degrades to edge.

Algorithm 1 Forest Generation

```
1:  procedure GENERATE(t)
2:      list ← t
3:      for v ∈ t in post order do
4:          e ← incoming edge of v
5:          append C(t, e) to list;

7:              t_n ← OPERATE(t, u)
8:              if t_n ≠ t then
9:                  append t_n to list
10:                 for e' ∈ t_n ∧ e' ∉ t do
11:                     append C(t_n,e') to list
12:                 if SCORE(t) < SCORE(t_n) then
13:                     t ← t_n
14:     return t,list
```

4 Fast Generation

It is still slow to calculate the entire forest defined in Section 3, therefore we use a greedy decoding for fast generating a subset of the forest. Starting form a reference derivation, we try to slightly change the derivation into a new reference derivation. During this process, we collect the competing derivations of reference derivations. We describe the details of local operators for changing a derivation in section 4.1, and then introduce the creation of initial reference derivation with max score in Section 4.2.

For example, given derivation t_1, we delete the node $X_{0,1}$ and the related hyperedge e_1 and e_5. Fixing the other nodes and edges, we try to add a new edge e_2 to create a new reference translation. In this case, if rule r_2 really exists in our rule table, we get a new reference derivation t_3. After constructing t_3, we first collect the new tree and $C(t_3, e_2)$. Then, we will move to t_3, if the score of t_3 is higher than t_2. Notably, if r_2 does not exist in the rule table, we fail to create a new reference derivation. In such case, we keep the origin derivation unchanged.

Algorithm 1 shows the process of generation.[3] The input is a reference derivation t, and the output is a new derivation and the generated derivations.

[3]For simplicity, we list all the trees, and do not compress them into a forest in practice. It is straight to extent the algorithm to get a compact forest for those generated derivations. Actually, instead of storing the derivations, we call the generate function twice to calculate gradient of log-linear model.

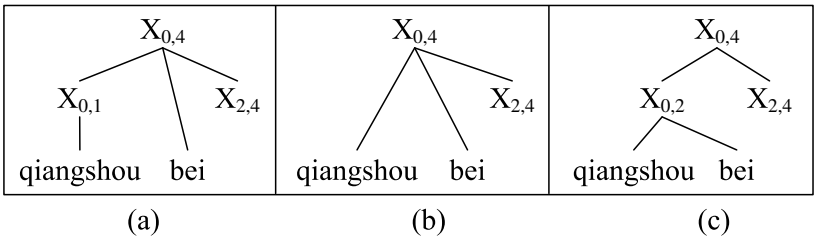

Figure 2: Lexicalize and generalize operators over t_1 (part) in Figure 1. Although here only shows the nodes, we also need to change relative edges actually. (1) Applying lexicalize operator on the non-terminal node $X_{0,1}$ in (a) results a new derivation shown in (b). (2) When visiting *bei* in (b), the generalize operator changes the derivation into (c).

The $list$ used for storing forest is initialized with the input tree (line 2). We visit the nodes in t in post-order (line 3). For each node v, we first append the competing derivations $C(t,e)$ to $list$, where e is incoming edge of v (lines 4-5). Then, we apply operators on the child nodes of v from left to right (lines 6-13). The operators returns a reference derivation t_n (line 7). If it is new (line 8), we collect both the t_n (line 9), and also the competing derivations $C(t_n, e')$ of the new derivation on those edges e' which only occur in the new derivation (lines 10-11). Finally, if the new derivation has a larger score, we will replace the origin derivation with new one (lines 12-13).

Although there is a two-level loop for visiting nodes (line 3 and 6), each node is visited only one time in the inner loops. Thus, the complexity is linear with the number of nodes $\#node$. Considering that the number of source word (also leaf node here) is less than the total number of nodes and is more than $\lceil(\#node+1)/2\rceil$, the time complexity of the process is also linear with the number of source word.

4.1 Lexicalize and Generalize

The function OPERATE in Algorithm 1 uses two operators to change a node: *lexicalize* and *generalize*. Figure 2 shows the effects of the two operators. The **lexicalize** operator works on nonterminal nodes. It moves away a nonterminal node and attaches the children of current node to its parent. In Figure 2(b), the node $X_{0,1}$ is deleted, requiring a more lexicalized rule to be applied to the parent node $X_{0,4}$ (one more terminal in the source side). We constrain the lexicalize operator to apply on pre-terminal nodes whose children are all terminal nodes. In contrast, the **generalize** operator works on terminal nodes and inserts a nonterminal node between current node and its parent node. This operator generalizes over the continuous terminal sibling nodes left to the current node (including the current node). Generalizing the node *bei* in Figure 2(b) results Figure 2(c). A new node $X_{0,2}$ is inserted as the parent of node *qiangshou* and node *bei*.

Notably, there are two steps when apply an operator. Suppose we want to lexicalize the node $X_{0,1}$ in t_1 of Figure 1, we first delete the node $X_{0,1}$ and related edge e_1 and e_5, then we try to add the new edge e_2. Since rule table is fixed, the second step is a process of decoding. Therefore, sometimes we may fail to create a new reference derivation (like r_2 may not exist in the rule table). In such case, we keep the origin derivation unchanged.

The changes made by the two operators are local. Considering the change of rules, the lexicalize operator deletes two rules and adds one new rule, while the generalize operator deletes one rule and adds two new rules. Such local changes provide us with a way to incrementally calculate the scores of new derivations. We use this method motivated by Gibbs Sampler (Blunsom et al., 2009) which has been used for efficiently learning rules. The different lies in that we use the operator for decoding where the rule table is fixing.

4.2 Initialize a Reference Derivation

The generation starts from an initial reference derivation with max score. This requires bi-parsing (Dyer, 2010) over the source sentence $\mathbf{f}$ and the reference translation $\mathbf{e}$. In practice, we may face three problems.

First is efficiency problem. Exhaustive search over the space under SCFG requires $\mathcal{O}(|f|^3|e|^3)$.

To parse quickly, we only visit the tight consistent (Zhang et al., 2008) bi-spans with the help of word alignment $\mathbf{a}$. Only visiting tight consistent spans greatly speeds up bi-parsing. Besides efficiency, adoption of this constraint receives support from the fact that heuristic SCFG rule extraction only extracts tight consistent initial phrases (Chiang, 2007).

Second is degenerate problem. If we only use the features as traditional SCFG systems, the bi-parsing may end with a derivation consists of some giant rules or rules with rare source/target sides, which is called degenerate solution (DeNero et al., 2006). That is because the translation rules with rare source/target sides always receive a very high translation probability. We add a prior score $log(\#rule)$ for each rule, where $\#rule$ is the number of occurrence of a rule, to reward frequent reusable rules and derivations with more rules.

Finally, we may fail to create reference derivations due to the limitation in rule extraction. We create minimum trees for $(\mathbf{f}, \mathbf{e}, \mathbf{a})$ using shift-reduce (Zhang et al., 2008). Some minimum rules in the trees may be illegal according to the definition of Chiang (2007). We also add these rules to the rule table, so as to make sure every sentence is reachable given the rule table. A source sentence is **reachable** given a rule table if reference derivations exists. We refer these rules as **added rules**. However, this may introduce rules with more than two variables and increase the complexity of bi-parsing. To tackle this problem, we initialize the chart with minimum parallel tree from the Zhang et al. (2008) algorithm, ensuring that the bi-parsing has at least one path to create a reference derivation. Then we only need to consider the traditional rules during bi-parsing.

5 Training

We use the forest to train a log-linear model with a latent variable as describe in Blunsom et al.(2008). The probability $p(\mathbf{e}|\mathbf{f})$ is the sum over all possible derivations:

$$p(\mathbf{e}|\mathbf{f}) = \sum_{\mathbf{t} \in \triangle(\mathbf{e},\mathbf{f})} p(\mathbf{t}, \mathbf{e}|\mathbf{f}) \quad (4)$$

where $\triangle(\mathbf{e}, \mathbf{f})$ is the set of all possible derivations that translate $\mathbf{f}$ into $\mathbf{e}$ and $\mathbf{t}$ is one such derivation.[4]

[4]Although the derivation is typically represent as $\mathbf{d}$, we denotes it by t since our paper use tree to represent derivation.

Algorithm 2 Training

procedure TRAIN($\mathcal{S}$)
  Training Data $\mathcal{S} = \{\mathbf{f}^n, \mathbf{e}^n, \mathbf{a}^n\}_{n=1}^N$
  Derivations $\mathcal{T} = \{\}_{n=1}^N$
  for $n = 1$ **to** N **do**
    $t^n \leftarrow$ INITIAL($\mathbf{f}^n, \mathbf{e}^n, \mathbf{a}^n$)
  $i \leftarrow 0$
  for $m = 0$ to M **do**
    for $n = 0$ to N **do**
      $\eta \leftarrow$ LEARNRATE(i)
      $(\Delta L(\mathbf{w}^i, t^n), t^n) \leftarrow$GENERATE($t^n$)
      $\mathbf{w}^i \leftarrow \mathbf{w}^i + \eta \times \Delta L(\mathbf{w}^i, t^n)$
      $i \leftarrow i + 1$
  return $\frac{\sum_{i=1}^{MN} \mathbf{w}^i}{MN}$

This model defines the conditional probability of a derivation $\mathbf{t}$ and the corresponding translation $\mathbf{e}$ given a source sentence $\mathbf{f}$ as:

$$p(\mathbf{t}, \mathbf{e}|\mathbf{f}) = \frac{\exp \sum_i \lambda_i h_i(\mathbf{t}, \mathbf{e}, \mathbf{f})}{Z(\mathbf{f})} \quad (5)$$

where the partition function is

$$Z(\mathbf{f}) = \sum_{\mathbf{e}} \sum_{\mathbf{t} \in \triangle(\mathbf{e},\mathbf{f})} \exp \sum_i \lambda_i h_i(\mathbf{t}, \mathbf{e}, \mathbf{f}) \quad (6)$$

The partition function is approximated by our forest, which is labeled as $\tilde{Z}(\mathbf{f})$, and the derivations that produce reference translation is approximated by reference derivations in $\tilde{Z}(\mathbf{f})$.

We estimate the parameters in log-linear model using maximum a posteriori (MAP) estimator. It maximizes the likelihood of the bilingual corpus $\mathcal{S} = \{\mathbf{f}^n, \mathbf{e}^n\}_{n=1}^N$, penalized using a gaussian prior (L2 norm) with the probability density function $p_0(\lambda_i) \propto \exp(-\lambda_i^2/2\sigma^2)$. We set σ^2 to 1.0 in our experiments. This results in the following gradient:

$$\frac{\partial \mathcal{L}}{\partial \lambda_i} = E_{p(\mathbf{t}|\mathbf{e},\mathbf{f})}[h_i] - E_{p(\mathbf{e}|\mathbf{f})}[h_i] - \frac{\lambda_i}{\sigma^2} \quad (7)$$

We use an online learning algorithm to train the parameters. We implement stochastic gradient descent (SGD) recommended by Bottou.[5] The dynamic learning rate we use is $\frac{N}{(i+i_0)}$, where N is the

[5]http://leon.bottou.org/projects/sgd

number of training example, i is the training iteration, and i_0 is a constant number used to get a initial learning rate, which is determined by calibration.

Algorithm 2 shows the entire process. We first create an initial reference derivation for every training examples using bi-parsing (lines 4-5), and then online learn the parameters using SGD (lines 6-12). We use the GENERATE function to calculate the gradient. In practice, instead of storing all the derivations in a list, we traverse the tree twice. The first time is calculating the partition function, and the second time calculates the gradient normalized by partition function. During training, we also change the derivations (line 10). When training is finished after M epochs, the algorithm returns an averaged weight vector (Collins, 2002) to avoid overfitting (line 13). We use a development set to select total epoch m, which is set as $M = 5$ in our experiments.

6 Experiments

Our method is able to train a large number of features on large data. We use a set of word context features motivated by word sense disambiguation (Chan et al., 2007) to test scalability. A word level context feature is a triple (f, e, f_{+1}), which counts the number of time that f is aligned to e and f_{+1} occurs to the right of f. Triple (f, e, f_{-1}) is similar except that f_{-1} locates to the left of f. We retain word alignment information in the extracted rules to exploit such features. To demonstrate the importance of scaling up the size of training data and the effect of our method, we compare three types of training configurations which differ in the size of features and data.

MERT. We use MERT (Och, 2003) to training 8 features on a small data. The 8 features is the same as Chiang (2007) including 4 rule scores (direct and reverse translation scores; direct and reverse lexical translation scores); 1 target side language model score; 3 penalties for word counts, extracted rules and glue rule. Actually, traditional pipeline often uses such configuration.

Perceptron. We also learn thousands of context word features together with the 8 traditional features on a small data using perceptron. Following (Chiang et al., 2009), we only use 100 most frequent words for word context feature. This setting use CKY decoder to generate n-best lists for training. The complexity of CKY decoding limits the training data into a small size. We fix the 8 traditional feature weights as MERT to get a comparable results as MERT.

	TRAIN	RTRAIN	DEV	TEST
#Sent.	519,359	186,810	878	3,789
#Word	8.6M	1.3M	23K	105K
Avg. Len.	16.5	7.3	26.4	28.0
Lon. Len.	99	95	77	116

Table 1: Corpus statistics of Chinese side, where Sent., Avg., Lon., and Len. are short for sentence, longest, average, and length respectively. RTRAIN denotes the reachable (given rule table without added rules) subset of TRAIN data.

Our Method. Finally, we use our method to train millions of features on large data. The use of large data promises us to use full vocabulary of training data for the context word features, which results millions of fully lexicalized context features. During decoding, when a context feature does not exit, we simply ignore it. The weights of 8 traditional features are fixed the same as MERT also. We fix these weights because the translation feature weights fluctuate intensely during online learning. The main reason may come from the degeneration solution mentioned in Section 4.2, where rare rules with very high translation probability are selected as the reference derivations. Another reason could be the fact that translation features are dense intensify the fluctuation. We leave learning without fixing the 8 feature weights to future work.

6.1 Data

We focus on the Chinese-to-English translation task in this paper. The bilingual corpus we use contains $519,359$ sentence pairs, with an average length of 16.5 in source side and 20.3 in target side, where $186,810$ sentence pairs (36%) are reachable (without added rules in Section 4.2). The monolingual data includes the Xinhua portion of the GIGAWORD corpus, which contains 238M English words. We use the NIST evaluation sets of 2002 (MT02) as our development set, and sets of MT03/MT04/MT05 as test sets. Table 2 shows the statistics of all bilingual corpus.

We use GIZA++ (Och and Ney, 2003) to perform

System	#DATA	#FEAT	MT03	MT04	MT05	ALL
MERT	878	8	33.03	35.12	32.32	33.85
Perceptron	878	2.4K	32.89	34.88	32.55	33.76
Our Method	187K	2.0M	33.64	35.48	32.91*	34.41*
	519K	13.9M	34.19*	35.72*	33.09*	34.69*
Improvement over MERT			+1.16	+0.60	+0.77	+0.84

Table 2: Effect of our method comparing with MERT and perceptron in terms of BLEU. We also compare our fast generation method with different data (only reachable or full data). #Data is the size of data for training the feature weights. * means significantly (Koehn, 2004) better than *MERT* ($p < 0.01$).

word alignment in both directions, and grow-diag-final-and (Koehn et al., 2003) to generate symmetric word alignment. We extract SCFG rules as described in Chiang (2007) and also added rules (Section 4.2). Our algorithm runs on the entire training data, which requires to load all the rules into the memory. To fit within memory, we cut off those composed rules which only happen once in the training data. Here a composed rule is a rule that can be produced by any other extracted rules. A 4-grams language model is trained by the SRILM toolkit (Stolcke, 2002). Case-insensitive NIST BLEU4 (Papineni et al., 2002) is used to measure translation performance.

The training data comes from a subset of the LDC data including LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06. Since the rule table of the entire data is too large to be loaded to the memory (even drop one-count rules), we remove many sentence pairs to create a much smaller data yet having a comparable performance with the entire data. The intuition lies in that if most of the source words of a sentence need to be translated by the added rules, then the word alignment may be highly crossed and the sentence may be useless. We create minimum rules from a sentence pair, and count the number of source words in those minimum rules that are added rules. For example, suppose the result minimum rules of a sentence contain r_3 which is an added rule, then we count 1 time for the sentence. If the number of such source word is more than 10% of the total number, we will drop the sentence pair.

We compare the performances of MERT setting on three bilingual data: the entire data that contains 42.3M Chinese and 48.2M English words; 519K data that contains 8.6M Chinese and 10.6M English words; FBIS (LDC2003E14) parts that contains 6.9M Chinese and 9.1M English words. They produce 33.11/32.32/30.47 BLEU tested on MT05 respectively. The performance of 519K data is comparable with that of entire data, and much higher than that of FBIS data.

6.2 Result

Table 3 shows the performance of the three different training configurations. The training of MERT and perceptron run on MT02. For our method, we compare two different training sets: one is trained on all 519K sentence pairs, the other only uses 186K reachable sentences.

Although the perceptron system exploits 2.4K features, it fails to produce stable improvements over MERT. The reason may come from overfitting, since the training data for perceptron contains only 878 sentences. However, when use our method to learn the word context feature on the 519K data, we significantly improve the performance by 0.84 points on the entire test sets (ALL). The improvements range from 0.60 to 1.16 points on MT03-05. Because we use the full vocabulary, the number of features increased into 13.9 millions, which is impractical to be trained on the small development set. These results confirm the necessity of exploiting more features and learning the parameters on large data. Meanwhile, such results also demonstrate that we can benefits from the forest generated by our fast method instead of traditional CKY algorithm.

Not surprisingly, the improvements are smaller when only use 186K reachable sentences. Sometimes we even fail to gain significant improvement. This verifies our motivation to guarantee all sentence

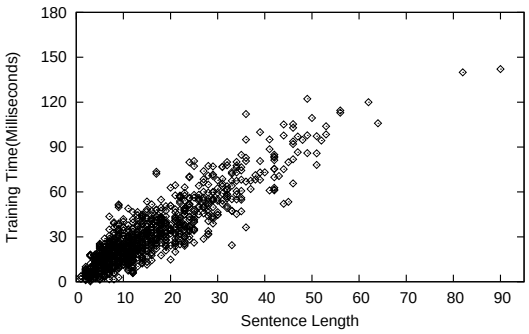

Figure 3: Plot of training times (including forest generation and SGD training) versus sentence length. We randomly select 1000 sentence from the 519K data for plotting.

are reachable, so as to use all training data.

6.3 Speed

How about the speed of our framework? Our method learns in 32 mlliseconds/sentence. Figure 3 shows training times (including forest generation and SGD training) versus sentence length. The plot confirms that our training algorithm scales linearly. If we use n-best lists which generated by CKY decoder as MERT, it takes about 3105 milliseconds/sentence for producing 100-best lists. Our method accelerates the speed about 97 times (even though we search twice to calculate the gradient). This shows the efficiency of our method.

The procedure of training includes two steps. (1) Bi-parsing to initialize a reference derivation with max score. (2) Training procedure which generates a set of derivations to calculate the gradient and update parameters. Step (1) only runs once. The average time of processing a sentence for each step is about 9.5 milliseconds and 30.2 milliseconds respectively.

For simplicity we do not compress the generated derivations into forests, therefore the size of resulting derivations is fairly small, which is about 265.8 for each sentence on average, where 6.1 of them are reference derivations. Furthermore, we use lexicalize operator more often than generalize operator (the ration between them is 1.5 to 1). Lexicalize operator is used more frequently mainly dues to that the reference derivations are initialized with reusable (thus small) rules.

7 Related Work

Minimum error rate training (Och, 2003) is perhaps the most popular discriminative training for SMT. However, it fails to scale to large number of features. Researchers have propose many learning algorithms to train many features: perceptron (Shen et al., 2004; Liang et al., 2006), minimum risk (Smith and Eisner, 2006; Li et al., 2009), MIRA (Watanabe et al., 2007; Chiang et al., 2009), gradient descent (Blunsom et al., 2008; Blunsom and Osborne, 2008). The complexity of n-best lists or packed forests generation hamper these algorithms to scale to a large amount of data.

For efficiency, we only use neighboring derivations for training. Such motivation is same as contrastive estimation (Smith and Eisner, 2005; Poon et al., 2009). The difference lies in that the previous work actually care about their latent variables (pos tags, segmentation, dependency trees, etc), while we are only interested in their marginal distribution. Furthermore, we focus on how to fast generate translation forest for training.

The local operators lexicalize/generalize are use for greedy decoding. The idea is related to "pegging" algorithm (Brown et al., 1993) and greedy decoding (Germann et al., 2001). Such types of local operators are also used in Gibbs sampler for synchronous grammar induction (Blunsom et al., 2009; Cohn and Blunsom, 2009).

8 Conclusion and Future Work

We have presented a fast generation algorithm for translation forest which contains both reference derivations and neighboring non-reference derivations for large-scale SMT discriminative training. We have achieved significantly improvement of 0.84 BLEU by incorporate 13.9M feature trained on 519K data in 0.03 second per sentence.

In this paper, we define the forest based on competing derivations which only differ in one rule. There may be better classes of forest that can produce a better performance. It's interesting to modify the definition of forest, and use more local operators to increase the size of forest. Furthermore, since the generation of forests is quite general, it's straight to

apply our forest on other learning algorithms. Finally, we hope to exploit more features such as reordering features and syntactic features so as to further improve the performance.

Abstract

Models of word alignment built as sequences of links have limited expressive power, but are easy to decode. Word aligners that model the alignment matrix can express arbitrary alignments, but are difficult to decode. We propose an alignment matrix model as a correction algorithm to an underlying sequence-based aligner. Then a greedy decoding algorithm enables the full expressive power of the alignment matrix formulation. Improved alignment performance is shown for all nine language pairs tested. The improved alignments also improved translation quality from Chinese to English and English to Italian.

1 Introduction

Word-level alignments of parallel text are crucial for enabling machine learning algorithms to fully utilize parallel corpora as training data. Word alignments appear as hidden variables in IBM Models 1-5 (Brown et al., 1993) in order to bridge a gap between the sentence-level granularity that is explicit in the training data, and the implicit word-level correspondence that is needed to statistically model lexical ambiguity and word order rearrangements that are inherent in the translation process. Other notable applications of word alignments include cross-language projection of linguistic analyzers (such as POS taggers and named entity detectors,) a subject which continues to be of interest. (Yarowsky et al., 2001), (Benajiba and Zitouni, 2010)

The structure of the alignment model is tightly linked to the task of finding the optimal alignment. Many alignment models are factorized in order to use dynamic programming and beam search for efficient marginalization and search. Such a factorization encourages - but does not require - a sequential (often left-to-right) decoding order. If left-to-right decoding is adopted (and exact dynamic programming is intractable) important right context may exist beyond the search window. For example, the linkage of an English determiner may be considered before the linkage of a distant head noun.

An alignment model that jointly models all of the links in the entire sentence does not motivate a particular decoding order. It simply assigns comparable scores to the alignment of the entire sentence, and may be used to rescore the top-N hypotheses of another aligner, or to decide whether heuristic perturbations to the output of an existing aligner constitute an improvement. Both the training and decoding of full-sentence models have presented difficulties in the past, and approximations are necessary.

In this paper, we will show that by using an existing alignment as a starting point, we can make a significant improvement to the alignment by proposing a series of heuristic perturbations. In effect, we train a model to fix the errors of the existing aligner. From any initial alignment configuration, these perturbations define a multitude of paths to the reference (gold) alignment. Our model learns alignment moves that modify an initial alignment into the reference alignment. Furthermore, the resulting model assigns a score to the alignment and thus could be used in numerous rescoring algorithms, such as top-N rescorers.

In particular, we use the maximum entropy frame-

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 889–898,
Edinburgh, Scotland, UK, July 27–31, 2011.

work to choose alignment moves. The model is symmetric: source and target languages are interchangeable. The alignment moves are sufficiently rich to reach arbitrary phrase to phrase alignments. Since most of the features in the model are not language-specific, we are able to test the correction model easily on nine language pairs; our corrections improved the alignment quality compared to the input alignments in all nine. We also tested the impact on translation and found a 0.48 BLEU improvement on Chinese to English and a 1.26 BLEU improvement on English to Italian translation.

2 Alignment sequence models

Sequence models are the traditional workhorse for word alignment, appearing, for instance, in IBM Models 1-5. This type of alignment model is not symmetric; interchanging source and target languages results in a different aligner. This parameterization does not allow a target word to be linked to more than one source word, so some phrasal alignments are simply not considered. Often the choice of directionality is motivated by this restriction, and the choice of tokenization style may be designed (Lee, 2004) to reduce this problem. Nevertheless, aligners that use this parameterization internally often incorporate various heuristics in order to augment their output with the disallowed alignments - for example, swapping source and target languages to obtain a second alignment (Koehn et al., 2007) with different limitations. Training both directions jointly (Liang et al., 2006) and using posterior probabilities during alignment prediction even allows the model to see limited right context. Another alignment combination strategy (Deng and Zhou, 2009) directly optimizes the size of the phrase table of a target MT system.

Generative models (such as Models 1-5, and the HMM model (Vogel et al., 1996)) motivate a narrative where alignments are selected left-to-right and target words are then generated conditioned upon the alignment and the source words. Generative models are typically trained unsupervised, from parallel corpora without manually annotated word-level alignments.

Discriminative models of alignment incorporate source and target words, as well as more linguistically motivated features into the prediction of alignment. These models are trained from annotated word alignments. Examples include the maximum entropy model of (Ittycheriah and Roukos, 2005) or the conditional random field jointly normalized over the entire sequence of alignments of (Blunsom and Cohn, 2006).

3 Joint Models

An alternate parameterization of alignment is the alignment matrix (Niehues and Vogel, 2008). For a source sentence F consisting of words $f_1 ... f_m$, and a target sentence $E = e_1 ... e_l$, the alignment matrix $A = \{\sigma_{ij}\}$ is an $l \times m$ matrix of binary variables. If $\sigma_{ij} = 1$, then e_i is said to be linked to f_j. If e_i is unlinked then $\sigma_{ij} = 0$ for all j. There is no constraint limiting the number of source tokens to which a target word is linked either; thus the binary matrix allows some alignments that cannot be modeled by the sequence parameterization. All 2^{lm} binary matrices are potentially allowed in alignment matrix models. For typical l and m, $2^{lm} \gg (m+1)^l$, the number of alignments described by a comparable sequence model. This parameterization is symmetric - if source and target are interchanged, then the alignment matrix is transposed.

A straightforward approach to the alignment matrix is to build a log linear model (Liu et al., 2005) for the probability of the alignment A. (We continue to refer to "source" and "target" words only for consistency of notation - alignment models such as this are indifferent to the actual direction of translation.) The log linear model for the alignment (Liu et al., 2005) is

$$p(A|E,F) = \frac{\exp\left(\sum_i \lambda_i \phi_i(A,E,F)\right)}{Z(E,F)} \quad (1)$$

where the partition function (normalization) is given by

$$Z(E,F) = \sum_A \exp\left(\sum_i \lambda_i \phi_i(A,E,F)\right). \quad (2)$$

Here the $\phi_i(A,E,F)$ are feature functions. The model is parameterized by a set of weights λ_i, one for each feature function. Feature functions are often binary, but are not required to be. Feature functions

may depend upon any number of components σ_{ij} of the alignment matrix A.

The sum over all alignments of a sentence pair (2^{lm} terms) in the partition function is computationally impractical except for very short sentences, and is rarely amenable to dynamic programming. Thus the partition function is replaced by an approximation. For example, the sum over all alignments may be restricted to a sum over the n-best list from other aligners (Liu et al., 2005). This approximation was found to be inconsistent for small n unless the merged results of several aligners were used. Alternately, loopy belief propagation techniques were used in (Niehues and Vogel, 2008). Loopy belief propagation is not guaranteed to converge, and feature design is influenced by consideration of the loops created by the features. Outside of the maximum entropy framework, similar models have been trained using maximum weighted bipartite graph matching (Taskar et al., 2005), averaged perceptron (Moore, 2005), (Moore et al., 2006), and transformation-based learning (Ayan et al., 2005).

4 Alignment Correction Model

In this section we describe a novel approach to word alignment, in which we train a log linear (maximum entropy) model of alignment by viewing it as correction model that fixes the errors of an existing aligner. We assume a priori that the aligner will start from an existing alignment of reasonable quality, and will attempt to apply a series of small changes to that alignment in order to correct it. The aligner naturally consists of a *move generator* and a *move selector*.

The move generator perturbs an existing alignment A in order to create a set of candidate alignments $\mathcal{M}_t(A)$, all of which are nearby to A in the space of alignments. We index the set of moves by the decoding step t to indicate that we generate entirely different (even non-overlapping) sets of moves at different steps t of the alignment prediction. Typically the moves affect linkages local to a particular word, e.g. the t'th source word.

The move selector then chooses one of the alignments $A_{t+1} \in \mathcal{M}_t(A_t)$, and proceeds iteratively: $A_{t+2} \in \mathcal{M}_{t+1}(A_{t+1})$, etc. until suitable termination criteria are reached. Pseudocode is depicted in Fig. (1.) In practice, one move for each source and target word is sufficient.

Input: sentence pair E_1 .. E_l, F_1 .. F_m
Input: alignment A
Output: improved alignment A_{final}
  for $t = 1 \rightarrow l$ **do**
    generate moves: $\mathcal{M}_t(A_t)$
    select move:
    $A_{t+1} \leftarrow \text{argmax}_{A \in \mathcal{M}_t(A_t)} p(A|A_t, E, F)$
  $A_{final} \leftarrow A_{l+1}$
  {repeat for source words}

Figure 1: pseudocode for alignment correction

4.1 Move generation

Many different types of alignment perturbations are possible. Here we restrict ourselves to a very simple move generator that changes the linkage of exactly one source word at a time, or exactly one target word at a time. Many of our corrections are similar to those of (Setiawan et al., 2010), although our motivation is perhaps closer to (Brown et al., 1993), who used similar perturbations to approximate intractable sums that arise when estimating the parameters of the generative models Models 3-5, and approach refined in (Och and Ney, 2003). We note that our corrections are designed to improve even a high-quality starting alignment; in contrast the model of (Fossum et al., 2008) considers deletion of links from an initial alignment (union of aligners) that is likely to overproduce links.

From the point of view of the alignment matrix, we consider changes to one row or one column (generically, one slice) of the alignment matrix. At each step t, the move set $\mathcal{M}_t(A_t)$ is formed by choosing a slice of the current alignment matrix A_t, and generating all possible alignments from a few families of moves. Then the move generator picks another slice and repeats. The $m + l$ slices are cycled in a fixed order: the first m slices correspond to source words (ordered according to a heuristic top-down traversal of the dependency parse tree if available), and the remaining l slices correspond to target words, similarly parse-ordered. For each slice we consider the following families of moves, illustrated by rows.

- add link to row i - for one j such that $\sigma_{ij} = 0$,

make $\sigma_{ij} = 1$ (shown here for row $i = 1$.)

	α	β	γ
a	○	○	○
b	○	●	○
c	○	○	○

$\Longrightarrow$

	α	β	γ
a	●	○	○
b	○	●	○
c	○	○	○

- remove one or more links from row i - for some j such that $\sigma_{ij} = 1$, make $\sigma_{ij} = 0$ (shown here for $i = 3$.)

	α	β	γ
a	●	○	○
b	○	●	○
c	○	○	●

$\Longrightarrow$

	α	β	γ
a	●	○	○
b	○	●	○
c	○	○	○

- move a link in row i - for one j and one j' such that $\sigma_{ij} = 1$ and $\sigma_{ij'} = 0$, make $\sigma_{ij} = 0$ and $\sigma_{ij'} = 1$ (shown here for $i = 1$.)

	α	β	γ
a	○	●	○
b	○	●	○
c	○	○	○

$\Longrightarrow$

	α	β	γ
a	●	○	○
b	○	●	○
c	○	○	○

- leave row i unchanged

Similar families of moves apply to column slices (source words.) In practice, perturbations are restricted by a window (typically ± 5 from existing links.) If the given source word is unlinked, we consider adding a link to each target word in a window (± 5 from nearby links.) The window size restrictions mean that some reference alignments are not reachable from the starting point. However, this is unlikely to limit performance - an oracle aligner achieves $97.6\% F$-measure on the Arabic-English training set.

4.2 Move selection

A log linear model for the selection of the candidate alignment at $t+1$ from the set of alignments $\mathcal{M}_t(A_t)$ generated by the move generator at step t takes the form:

$$p(A_{t+1}|E, F, \mathcal{M}_t(A_t)) = \frac{e^{\sum_i \lambda_i \phi_i(A_{t+1}, E, F)}}{Z(E, F, \mathcal{M}_t(A_t))} \quad (3)$$

where the partition function is now given by

$$Z(E, F, \mathcal{M}) = \sum_{A \in \mathcal{M}} e^{\sum_i \lambda_i \phi_i(A, E, F)} \quad (4)$$

and $A_{t+1} \in \mathcal{M}_t(A_t)$ is required for correct normalization. This equation is notationally very similar to equation (1), except that the predictions of the model are restricted to a small set of nearby alignments. For the move generator considered in this paper, the summation in Eq.(4) is similarly restricted, and hence training the model is tractable. The set of candidate alignments $\mathcal{M}_t(A_t)$ typically does not contain the reference (gold) alignment; we model the best alignment among a finite set of alternatives, rather than the correct alignment from among all possible alignments. This is a key difference between our model and (Liu et al., 2005).

Note that if we extended our definition of perturbation to the limiting case that the alignment set included all possible alignments then we would clearly recover the standard log linear model of alignment.

4.3 Training

Since the model is designed to predict perturbation to an alignment, it is trained from a collection of errorful alignments and corresponding reference sequences of aligner moves that reach the reference (gold) alignment. We construct a training set from a collection of sentence pairs and reference alignments for training $(A^{*n}, E^n, F^n)_{n=1}^N$, as well as collections of corresponding "first pass" alignments A_1^n produced by another aligner. For each n, we form a number of candidate alignment sets $\mathcal{M}_t(A_t^n)$, one for each source and target word. For training purposes, the true alignment from the set is taken to be the one identical with A^{*n} in the slice targeted by the move generator at the current step. (A small number of move sets do not have an exact match and are discarded.) Then we form an objective function from the log likelihood of reference alignment, smoothed with a gaussian prior

$$\mathcal{L} = \sum_n \mathcal{L}_n + \sum_i (\lambda_i / \gamma)^2 \quad (5)$$

where the likelihood of each training sample is

$$\mathcal{L}_n = \sum_{\alpha} \log p_1(A_n^0|E, F_n; \mathcal{M}(f_\alpha, A_n^0, E, F_n)) + \sum_{\beta} \log p_1(A_n^0|E, F_n; \mathcal{M}(e_\beta, A_n^0, E, F_n)) \quad (6)$$

The likelihood has a term for each sentence pair and for each decoder step. The model is trained by gradient ascent using the l-BFGS method (Liu and Nocedal, 1989), which has been successfully used for training log linear models (Blunsom and Cohn, 2006) in many natural language tasks, including alignment.

5 Features

A wide variety of features were used in the model. We group the features in three broad categories: link-based, geometrical, and parse-based.

Link-based features are those which decompose into a (linear) sum of alignment matrix elements σ_{ij}. An example link-based feature is one that fires if a source language noun is linked to a target language determiner. Note that this feature may fire more than once in a given sentence pair: as with most features in our model, it is an integer-valued feature that counts the number of times a structure appears in a sentence pair. These features do not capture any correlation between different σ_{ij}. Among the link-based features are those based on Model 1 translation matrix parameters $\tau(e_i|f_j)$ and $\tau(f_j|e_i)$. We bin the model 1 parameters, and form integer-valued features for each bin that count the number of links with $\tau_0 < \tau(e_i|f_j) < \tau_1$.

Geometrical features are those which capture correlation between different σ_{ij} based on adjacency or nearness. They capture the idea that nearby words in one language link to nearby words in the other language - the motivation of HMM-based models of alignment. An example is a feature that counts the number of times that the next word in the source language is linked to the next word in the target language:

$$\phi(A, E, F) = \sum_{ij} \sigma_{ij}\sigma_{i+1,j+1} \quad (7)$$

Parse-based features are those which capture correlation between different σ_{ij}, but use parsing to determine links which are correlated - for example, if a determiner links to the same word as its head noun. As an example, if e_i is the headword of $e_{i'}$, and f_j is the headword of $f_{j'}$, then

$$\phi(A, E, F) = \sum_{ij} \sigma_{ij}\sigma_{i'j'} \quad (8)$$

counts the number of times that a dependency relation in one language is preserved by alignment in the other language. This feature can also be decorated, either lexically, or with part-of-speech tags (as many features in all three categories are.)

5.1 Unsupervised Adaptation

We constructed a heuristic phrase dictionary for unsupervised adapatation. After aligning a large unannotated parallel corpus with our aligner, we enumerate fully lexicalized geometrical features that can be extracted from the resulting alignments - these are entries in a phrase dictionary. These features are tied, and treated as a single real-valued feature that fires during training and decoding phases if a set of hypothesized links matches the geometrical feature extracted from the unannotated data. The value of this real-valued feature is the log of the number of occurrences of the identical (lexicalized) geometrical feature in the aligned unannotated corpus.

6 Results

We design our experiments to validate that a correction model using simple features, mostly non-language-specific, can improve the alignment accuracy of a variety of existing aligners for a variety of language pairs; we do not attempt to exactly match features between comparison aligners - this is unlikely to lead to a robust correction model.

6.1 Arabic-English alignment results

We trained the Arabic-English alignment system on 5125 sentences from Arabic-English treebanks (LDC2008E61, LDC2008E22) that had been annotated for word alignment. Reference parses were used during the training. Results are measured on a 500 sentence test set, sampled from a wide variety of parallel corpora, including various genres. During alignment, only automatically-generated parses (based on the parser of (Ratnaparkhi, 1999)) were available. Alignments on

the training and test sets were decoded with three other aligners, so that the robustness of the correction model to different input alignments could be validated. The three aligners were GIZA++ (Och and Ney, 2003) (with the MOSES (Koehn et al., 2007) postprocessing option `-alignment grow-diag-final-and`) the posterior HMM aligner of (Ge, 2004), a maximum entropy sequential model (ME-seq) (Ittycheriah and Roukos, 2005). ME-seq is our primary point of comparison: it is discriminatively trained (on the same training data,) uses a rich set of features, and provides the best alignments of the three. Three correction models were trained: corr(GIZA++) is trained to correct the alignments produced by GIZA++, corr(HMM) is trained to correct the alignments produced by the HMM aligner, and corr(ME-seq) is trained to correct the alignments produced by the ME-seq model.

In Table (1) we show results for our system correcting each of the aligners as measured in the usual recall, precision, and F-measure.[1] The resulting improvements in F-measure of the alignments produced by our models over their corresponding baselines is statistically significant ($p < 10^{-4}$, indicated by a *.) Statistical significance is tested by a Monte Carlo bootstrap (Efron and Tibshirani, 1986) - sampling with replacement the difference in F-measure of the two system's alignments of the same sentence pair. Both recall and precision are improved, but the improvement in precision is somewhat larger. We also show cross-condition results in which a correction model trained to correct HMM alignments is applied to correct ME-seq alignments. These results show that our correction model is robust to different starting aligners.

6.2 Chinese-English alignment results

Table (2) presents results for Chinese-English word alignments. The training set for the corr(ME-seq) model consisted of approximately 8000 hand-aligned sentences sampled from LDC2006E93 and LDC2008E57. The model was trained to correct the output of the ME-seq aligner, and tested on the same condition. For this language pair, reference parses were not available in our training set, so automatically-generated parses were used for both training and test sets. Results are measured on a 512 sentence test set, sampled from a wide variety of parallel corpora of various genres. We compare performance with GIZA++, and with the ME-seq aligner. Again the resulting improvement over the ME-seq aligner is statistically significant. However, here the improvement in recall is somewhat larger than the improvement in precision.

6.3 Additional language pairs

Table (3) presents alignment results for seven other language pairs. Separate alignment corrector models were trained for both directions of Italian $\leftrightarrow$ English and Portuguese $\leftrightarrow$ English. The training and test data vary by language, and are sampled uniformly from a diverse set of corpora of various genres, including newswire, and technical manuals. Manual alignments for training and test data were annotated. We compare performance with the ME-seq aligner trained on the same training data. As with the Chinese results above, customization and feature development for the language pairs was minimal. In general, machine parses were always available for the English half of the pair. Machine parses were also available for French and Spanish. Machine part of speech tags were available for all language (although character-based heuristic was substituted for Japanese.) Large amounts (up to 10 million sentence pairs) of unaligned parallel text was available for model 1 type features. Our model obtained improved alignment F-measure in all language pairs, although the improvements were small for ES$\rightarrow$EN and FR$\rightarrow$EN, the language pairs for which the baseline accuracy was the highest.

6.4 Analysis

Some of the improvement can be attributed to "look-ahead" during the decoding. For example, the English word "the", which (during Arabic-English alignment) should often be aligned to the same Arabic words to which its headword is linked. The number of errors associated with "the" dropped from 383 (186 false alarms, 197 misses) in the ME-seq model to 137 (60 false alarms and 77 misses) in the current model.

In table 5, we show contributions to performance resulting from various classes of features. The

[1] We do not distinguish sure and possible links in our annotations - under this circumstance, alignment error rate(Och and Ney, 2003) is $1 - F$.

method	Zh-En correct	Zh-En miss	Zh-En fa	Ar-En correct	Ar-En miss	Ar-En fa

GIZA++	139	677	396	132	271	370
ME-seq	71	745	**133**	127	276	191
corr(ME-seq)	**358**	**458**	231	**264**	**139**	**114**

Table 4: Analysis of $2-1$ alignments errors (misses and false alarms) for Zh-En and Ar-En aligners

largest contribution is noted by removing features based on the Model 1 translation matrices. These features contain a wealth of lexical information learned from approximately 7×10^6 parallel sentences - information that cannot be learned from a relatively small amount of word-aligned training data. Geometrical features contribute more than parse-based features, but the contribution from parse-based features is important, and these are more difficult to incorporate into sequential models. We note that all of the comparison aligners had equivalent lexical information.

We show a small improvement from the unsupervised adaptation - learning phrases from the parallel corpus that are not captured by the lexical features based on model 1. The final row in the table shows the result of running the correction model on its own output. The improvement is not statistically significant, but it is important to note the performance is *stable* - a further indication that the model is robust to a wide variety of input alignments, and that our decoding scheme is a reasonable approach to finding the best alignment.

In table 4, we characterize the errors based on the fertility of the source and target words. We focus on the case that exactly one target word is linked to exactly two source words. These are the links that

Table 7: Translation results, En to It

are poorly suited for the HMM and ME-seq models used in this comparison because of the chosen directionality: the source (Arabic, Chinese) words are the states and the target (English) words are the observation. The HMM is able to produce these links only by the use of posterior probabilities, rather than viterbi decoding. The ME-seq model only produces these links because of language-specific post-processing. GIZA++ has an underlying sequential model, but uses both directionalities. The correction model improved performance across all three of these links structures. The single exception is that the number of $2-1$ false alarms increased (Zh-En alignments) but in this case, the first pass ME-seq alignment produced few false alarms because it simply proposed few links of this form. It is also notable that $1-2$ links are more numerous than $2-1$ links, in both language pairs. This is consequence of the choice of directionality and tokenization style.

6.5 Translation Impact

We tested the impact of improved alignments on the performance of a phrase-based translation system (Ittycheriah and Roukos, 2007) for three lan-

guage pairs. Our alignment did not improve the performance of a mature Arabic to English translation system, but two notable successes were obtained: Chinese to English, and English to Italian. It is well known that improved alignment performance does not always improve translation performance (Fraser and Marcu, 2007). A mature machine translation system may incorporate alignments obtained from multiple aligners, or from both directions of an asymmetric aligner. Furthermore, with large amounts of training data (the Gale Phase 4 Arabic English corpus consisting of 8×10^6 sentences,) a machine translation system is subject to a saturation effect: correcting an alignment may not yield a significant improvement because the the phrases learned from the correct alignment have already been acquired in other contexts.

For the Chinese to English translation system (table 6) the training corpus consisted of 11×10^6 sentence pairs, subsampled to 10^6. The test set was NIST MT08 Newswire, consisting of 691 sentences and 4 reference translations. Corpus-level performance (columns 2 and 3) improved when measured by BLEU, but not by TER. Performance on the most difficult sentences (near the 90th percentile, columns 4 and 5) improved on both BLEU and TER (Snover et al., 2006), and the improvement in BLEU was larger for the more difficult sentences than it was overall. Translation performance further improved, by a smaller amount, using both ME-seq and corr(ME-seq) alignments during the training.

The improved alignments impacted the translation performance of the English to Italian translation system (table 7) even more strongly. Here the training corpus consisted of 9.4×10^6 sentence pairs, subsampled to 387000 pairs. The test set consisted of 7899 sentences. Overall performance improved as measured by both TER and BLEU (1.26 points.)

7 Conclusions

A log linear model for the alignment matrix is used to guide systematic improvements to an existing aligner. Our system models arbitrary alignment matrices and allows features that incorporate such information as correlations based on parse trees in both languages. We train models to correct the errors of several existing aligners; we find the resulting models are robust to using different aligners as starting points. Improvements in alignment F-measure, often significant improvements, show that our model successfully corrects input alignments from existing models in all nine language pairs tested. The resulting Chinese-English and English-Italian word alignments also improved translation performance, especially on the English-Italian test, and notably on the particularly difficult subset of the Chinese sentences. Future work will assess its impact on translation for the other language pairs, as well as its impact on other tasks, such as named entity projection.

Abstract

State of the art Tree Structures Prediction techniques rely on bottom-up decoding. These approaches allow the use of context-free features and bottom-up features. We discuss the limitations of mainstream techniques in solving common Natural Language Processing tasks. Then we devise a new framework that goes beyond Bottom-up Decoding, and that allows a better integration of contextual features. Furthermore we design a system that addresses these issues and we test it on Hierarchical Machine Translation, a well known tree structure prediction problem. The structure of the proposed system allows the incorporation of non-bottom-up features and relies on a more sophisticated decoding approach. We show that the proposed approach can find better translations using a smaller portion of the search space.

1 Introduction

Tree Structure Prediction (TSP) techniques have become relevant in many Natural Language Processing (NLP) applications, such as Syntactic Parsing, Semantic Role Labeling and Hierarchical Machine Translation (HMT) (Chiang, 2007). HMT approaches have a higher complexity than Phrase-Based Machine Translation techniques, but exploit a more sophisticated reordering model, and can produce translations with higher Syntactic-Semantic quality.

TSP requires as inputs: a weighted grammar, $\mathbf{G}$, and a sequence of symbols or a set of sequences encoded as a Lattice (Chappelier et al., 1999). The input sequence is often a sentence for NLP applications. Tree structures generating the input sequence can be composed using rules, r, from the weighted grammar, $\mathbf{G}$. TSP techniques return as output a tree structure or a set of trees (forest) that generate the input string or lattice. The output forest can be represented compactly as a weighted hypergraph (Klein and Manning, 2001). TSP tasks require finding the tree, $\mathbf{t}$, with the highest score, or the best-k such trees. Mainstream TSP relies on Bottom-up Decoding (BD) techniques.

With this paper we propose a new framework as a generalization of the CKY-like Bottom-up approach. We also design and test an instantiation of this framework, empirically showing that wider contextual information leads to higher accuracy for TSP tasks that rely on non-local features, like HMT.

2 Beyond Bottom-up Decoding

TSP decoding requires scoring candidate trees, $\mathsf{cost}(\mathbf{t})$. Some TSP tasks require only local features. For these cases $\mathsf{cost}(\mathbf{t})$ depends only on the local score of the rules that compose $\mathbf{t}$:

$$\mathsf{cost}(\mathbf{t}) = \sum_{r_i \in \mathbf{t}} \mathsf{cost}(r_i) \qquad (1)$$

This is the case for Context Free Grammars. More complex tasks need non-local features. Those features can be represented by a non-local factor, $\mathsf{nonLocal}(\mathbf{t})$, into the overall $\mathbf{t}$ score:

$$\mathsf{cost}(\mathbf{t}) = \sum_{r_i \in \mathbf{t}} \mathsf{cost}(r_i) + \mathsf{nonLocal}(\mathbf{t}) \qquad (2)$$

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 899–908,
Edinburgh, Scotland, UK, July 27–31, 2011.

For example, in HMT the Language Model (LM) is a non-local fundamental feature that approximates the adequacy of the translation with the sum of log-probabilities of composing n-grams.

CKY-like BD approaches build candidate trees in a bottom-up fashion, allowing the use of Dynamic Programming techniques to simplify the search space by mering sub-trees with the same state, and also easing application of pruning techniques (such as Cube Pruning, e.g. Chiang (2007), Gesmundo (2010)). For clarity of presentation and following HMT practice, we will henceforth restrict our focus to binary grammars. Standard CKY works by building objects known as $items$ (Hopkins and Langmead, 2009). Each item, ι, corresponds to a candidate sub-tree. Items are built linking a rule instantiation, r, to two sub-items that represents left context, ι_1, and right context, ι_2; formally: $\iota \equiv \langle\ \iota_1 \succ r \prec \iota_2\ \rangle$. An item is a triple that contains a $span$, a $postcondition$ and a $carry$. The span contains the indexes of the starting and ending input words delimiting the continuous sequence covered by the sub-tree represented by the item. The postcondition is a string that represents r's head non-terminal label, telling us which rules may be applied. The carry, κ, stores extra information required to correctly score the non-local interactions of the item when it will be linked in a broader context (for HMT with LM the carry consists of boundary words that will form new n-grams).

Items, $\iota \equiv \langle \iota_1 \succ r \prec \iota_2 \rangle$, are scored according to the following formula:

$$\begin{aligned} \mathsf{cost}(\iota) &= \mathsf{cost}(r) + \mathsf{cost}(\iota_1) + \mathsf{cost}(\iota_2) \\ &+ \mathsf{interaction}(r, \kappa_1, \kappa_2) \end{aligned} \quad (3)$$

Where: $\mathsf{cost}(r)$ is the cost associated to the weighted rule r; $\mathsf{cost}(\iota_1)$ and $\mathsf{cost}(\iota_2)$ are the costs of the two sub-items computed recursively using formula (3); $\mathsf{interaction}(r, \kappa_1, \kappa_2)$ is the interaction cost between the rule instantiation and the two sub-items. In HMT the interaction cost includes the LM score of new n-grams generated by connecting the childrens' sub-spans with terminals of r. Notice that formula (3) is equal to formula (2) for items that cover the whole input sequence.

In many TSP applications, the search space is too large to allow an exhaustive search and therefore pruning techniques must be used. Pruning decisions are based on the score of partial derivations. It is not always possible to compute exactly non-local features while computing the score of partial derivations, since partial derivations miss part of the context. Formula (3) accounts for the interaction between r and sub-items ι_1 and ι_2, but it does not integrate the cost relative to the interaction between the item and the surrounding context. Therefore the item score computed in a bottom-up fashion is an approximation of the score the item has in a broader context. For example, in HMT the LM score for n-grams that partially overlap the item's span cannot be computed exactly since the surrounding words are not known.

Basing pruning decisions on approximated scores can introduce search errors. It is possible to reduce search errors using heuristics based on future cost estimation. In general the estimation of the interaction between ι and the surrounding context is function of the carry, κ. In HMT it is possible to estimate the cost of n-grams that partially overlap ι's span considering the boundary words. We can obtain the heuristic cost for an item, ι, adding to formula (3) the factor, $\mathsf{est}(\kappa)$, for the estimation of interaction with missing context:

$$\mathsf{heuristicCost}(\iota) = \mathsf{cost}(\iota) + \mathsf{est}(\kappa) \quad (4)$$

And use $\mathsf{heuristicCost}(\iota)$ to guide BD pruning decisions. Anyway, even if a good interaction estimation is available, in practice it is not possible to avoid search errors while pruning.

More sophisticated parsing models allow the use of non-bottom-up features within a BD framework. Caraballo and Charniak (1998) present best-first parsing with Figures of Merit that allows conditioning of the heuristic function on statistics of the input string. Corazza et al. (1994), and Klein and Manning (2003) propose an A* parsing algorithm that estimates the upper bound of the parse completion scores using contextual summary features. These models achieve time efficiency and state-of-the-art accuracy for PCFG parsing, but still use a BD framework that doesn't allow the application of a broader class of non-bottom-up contextual features.

In HMT, knowing the sentence-wide context in which a sub-phrase is translated is extremely important. It is obviously important for word choice: as

a simple example consider the translation of the frequent English word "get" into Chinese. The choice of the correct set of ideograms to translate "get" often requires being aware of the presence of particles that can be at any distance within the sentence. In a common English to Chinese dictionary we found 93 different sets of ideograms that could be translations of "get". Sentence-wide context is also important in the choice of word re-ordering: as an example consider the following translations from English to German:

1. EN : *I go home.*
   DE : *Ich gehe nach Hause.*

2. EN : *I say, that I go home.*
   DE : *Ich sage, dass ich nach Hause gehe.*

3. EN : *On Sunday I go home.*
   DE : *Am Sonntag gehe ich nach Hause.*

The English phrase "*I go home*" is translated in German using the same set of words but with different orderings. It is not possible to choose the correct ordering of the phrase without being aware of the context. Thus a bottom-up decoder without context needs to build all translations for "*I go home*", introducing the possibility of pruning errors.

Having shown the importance of contextual features, we define a framework that overcomes the limitations of bottom-up feature approximation.

3 Undirected-CKY Framework

Our aim is to propose a new Framework that overcomes BD limitations allowing a better integration of contextual features. The presented framework can be regarded as a generalization of CKY.

To introduce the new framework let us focus on a detail of CKY BD. The items are created and scored in topological order. The ordering constraint can be formally stated as: *an item covering the span* $[i, j]$ *must be processed after items covering sub spans* $[h, k] | h \geq i, k \leq j$. This ordering constraint implies that full yield information is available when an item is processed, but information about ancestors and siblings is missing. Therefore non-bottom-up context cannot be used because of the ordering constraint. Now let us investigate how the decoding algorithm could change if we remove the ordering constraint.

Removing the ordering constraint would lead to the occurrence of cases in which an item is processed before all child items have been processed. For example, we could imagine to create and score an item, ι, with postcondition X and span $[i, j]$, linking the rule instantiation $r : X \rightarrow AB$ with only the left sub-item, ι_A, while information for the right sub-item, ι_B is still missing. In this case, we can rely on local and partial contextual features to score ι. Afterwards, it is possible to process ι_B using the parent item, ι, as a source of additional information about the parent context and sibling ι_A yield. This approach can avoid search errors in cases where pruning at the parent level can be correctly done using only local and partial yield context, while pruning at the child level needs extra non-bottom-up context to make a better pruning decision. For example, consider the translation of the English sentence "*I run*" into French using the following synchronous grammar:

$$
\begin{aligned}
&r_1 : S \rightarrow X_{\boxed{1}}\, X_{\boxed{2}} \mid X_{\boxed{1}}\, X_{\boxed{2}} \\
&r_2 : X \rightarrow I \mid Je \\
&r_3 : X \rightarrow run \mid course \\
&r_4 : X \rightarrow run \mid courir \\
&r_5 : X \rightarrow run \mid cours \\
&r_6 : X \rightarrow run \mid courons \\
&\vdots
\end{aligned}
$$

Where: r_1 is a $Glue$ rule and boxed indexes describe the alignment; r_2 translates "I" in the corresponding French pronoun; r_3 translates "run" as a noun; remaining rules translate "run" as one of the possible conjugations of the verb "$courir$". Using only bottom-up features it is not possible to resolve the ambiguity of the word "run". If the beam is not big enough the correct translation could be pruned. Anyway a CKY decoder would give the highest score to the most frequent translation. Instead, if we follow a non bottom-up approach, as described in Figure 1, we can: 1) first translate "I"; 2) Then create an item using r_1 with missing right child; 3) finally choose the correct translation for "run" using r_1 to access a wider context. Notice that with this undirected approach it is possible to reach the correct translation using only beam size of

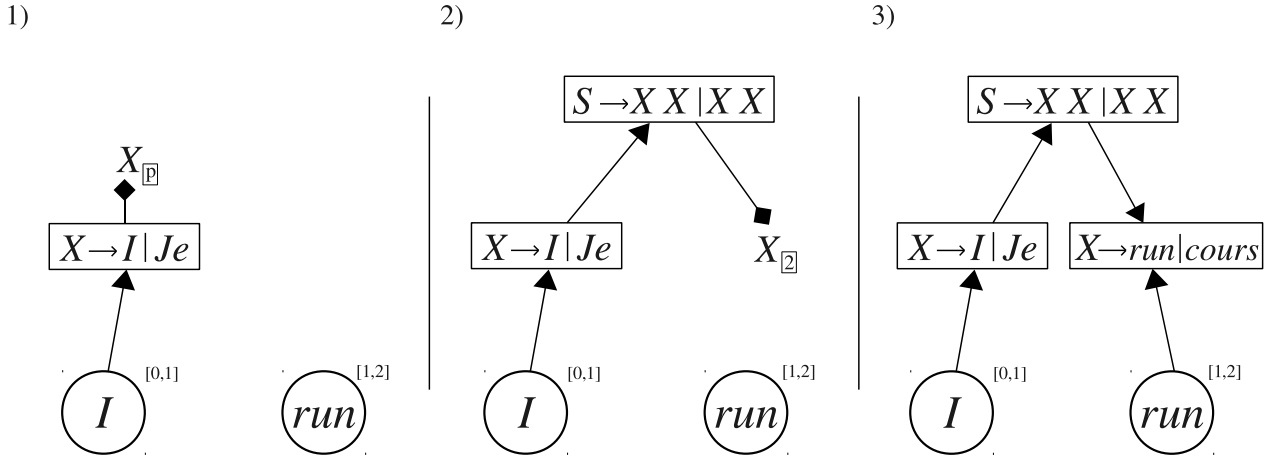

Figure 1: Example of undirected decoding for HMT. The arrows point to the direction in which information is propagated. Notice that the parent link at step 3 is fundamental to correctly disambiguate the translation for "run".

1 and the LM feature.

To formalize Undirected-CKY, we define a generalized item called $undirected\text{-}item$. Undirected-items, $\mathring{\boldsymbol{\imath}}$, are built linking rule instantiations with elements in $\mathcal{L} \equiv \{$left child, right child, parent$\}$; for example: $\mathring{\boldsymbol{\imath}} \equiv \langle \mathring{\boldsymbol{\imath}}_1 \gg r \dot{\vee} \mathring{\boldsymbol{\imath}}_p \rangle$, is built linking r with left child, $\mathring{\boldsymbol{\imath}}_1$, and parent, $\mathring{\boldsymbol{\imath}}_p$. We denote with $\mathcal{L}^+_{\mathring{\boldsymbol{\imath}}}$ the set of links for which the undirected-item, $\mathring{\boldsymbol{\imath}}$, has a connection, and with $\mathcal{L}^-_{\mathring{\boldsymbol{\imath}}}$ the set of missing links. An undirected-item is a triple that contains a span, a carry and an $undirected\text{-}postcondition$. The undirected-postcondition is a set of strings, one string for each of $\mathring{\boldsymbol{\imath}}$'s missing links, $l \in \mathcal{L}^-_{\mathring{\boldsymbol{\imath}}}$. Each string represents the non-terminal related to one of the missing links available for expansion. Bottom-up items can be considered specific cases of undirected-items having $\mathcal{L}^+ = \{$ left child, right child$\}$ and $\mathcal{L}^- = \{$parent$\}$. We can formally describe the steps of the example depicted in Figure 1 with:

$$1)\quad \frac{r_2 : X \rightarrow I|Je\ ,\ terminal : [0,1]}{\mathring{\boldsymbol{\imath}}_1 : [0,1,\{X_{\boxed{1}}\},\kappa_1]}$$

$$2)\quad \frac{r_1 : S \rightarrow X_{\boxed{1}}X_{\boxed{2}}|X_{\boxed{1}}X_{\boxed{2}}\ ,\ \mathring{\boldsymbol{\imath}}_1 : [0,1,\{X_{\boxed{1}}\},\kappa_1]}{\mathring{\boldsymbol{\imath}}_2 : [0,1,\{X_{\boxed{2}}\},\kappa_2)]}$$

$$3)\quad \frac{r_5 : X \rightarrow run|cours, \mathring{\boldsymbol{\imath}}_2 : [\cdots]\ ,\ terminal : [1,2]}{\mathring{\boldsymbol{\imath}}_3 : [0,2,\{\},\kappa_3]}$$

The scoring function for undirected-items can be obtained generalizing formula (3):

$$\begin{aligned} \mathsf{cost}(\mathring{\boldsymbol{\imath}}) &= \mathsf{cost}(r) \\ &+ \sum_{l \in \mathcal{L}^+} \mathsf{cost}(\mathring{\boldsymbol{\imath}}_l) \\ &+ \mathsf{interaction}(r, \mathcal{L}^+) \end{aligned} \tag{5}$$

In CKY, each span is processed separately in topological order, and the best-k items for each span are selected in sequence according to scoring function (4). In the proposed framework, the selection of undirected-items can be done in any order, for example: in a first step selecting an undirected-item for span s_1, then selecting an undirected-item for span s_2, and in a third step selecting a second undirected-item for s_1, and so on. As in agenda based parsing (Klein and Manning, 2001), all candidate undirected-items can be handled with an unique queue. Allowing the system to decide decoding order based on the candidates' scores, so that candidates with higher confidence can be selected earlier and used as context for candidates with lower confidence.

Having all candidates in the same queue introduces comparability issues. In CKY, candidates are comparable since each span is processed separately and each candidate is scored with the estimation of the yield score. Instead, in the proposed framework,

the unique queue contains candidates relative to different nodes and with different context scope. To ensure comparability, we can associate to candidate undirected-items a heuristic score of the full derivation:

$$\mathsf{heuristicCost}(\mathring{\boldsymbol{\imath}}) = \mathsf{cost}(\mathring{\boldsymbol{\imath}}) + \mathsf{est}(\mathring{\boldsymbol{\imath}}) \qquad (6)$$

Where $\mathsf{est}(\mathring{\boldsymbol{\imath}})$ estimates the cost of the missing branches of the derivation as a function of $\mathring{\boldsymbol{\imath}}'s$ partial structure and carry.

In this framework, the queue can be initialized with a candidate for each rule instantiation. These initializing candidates have no context information and can be scored using only local features. A generic decoding algorithm can loop selecting the candidate undirected-item with the highest score, $\mathring{\boldsymbol{\imath}}$, and then propagating its information to neighboring candidates, which can update using $\mathring{\boldsymbol{\imath}}$ as context. In this general framework the link to the parent node is not treated differently from links to children. While in CKY the information is always passed from children to parent, in Undirected-CKY the information can be propagated in any direction, and any decoding order is allowed.

We can summarize the steps done to generalize CKY into the proposed framework: 1) remove the node ordering constraint; 2) define the scoring of candidates with missing children or parent; 3) use a single candidate queue; 4) handle comparability of candidates from different nodes and/or with different context scope; 5) allow information propagation in any direction.

4 Undirected Decoding

In this section we propose Undirected Decoding (UD), an instantiation of the Undirected-CKY framework presented above. The generic framework introduces many new degrees of freedom that could lead to a higher complexity of the decoder. In our actual instantiation we apply constraints on the initialization step, on the propagation policy, and fix a search beam of k. These constraints allow the system to converge to a solution in practical time, allow the use of dynamic programming techniques to merge items with equivalent states, and gives us the possibility of using non-bottom-up features and testing their relevance.

Algorithm 1 Undirected Decoding

```
1:  function decoder (k) : out-forest
2:  Q ← LeafRules();
3:  while |Q| > 0 do
4:     ı̊ ← PopBest (Q);
5:     if CanPop(ı̊) then
6:        out-forest.Add(ı̊);
7:        if ı̊.HasChildrenLinks() then
8:           for all r ∈ HeadRules(ı̊) do
9:              Ĉ ← NewUndirectedItems(r, ı̊);
10:             for all ĉ ∈ Ĉ do
11:                if CanPop(ĉ) then
12:                   Q.Insert(ĉ);
13:                end if
14:             end for
15:          end for
16:       end if
17:    end if
18: end while
```

Algorithm 1 summarizes the UD approach. The beam size, k, is given as input. At $line$ 2 the queue of undirected-item candidates, $\mathbf{Q}$, is initialized with only leafs rules. At $line$ 3 the loop starts, it will terminate when $\mathbf{Q}$ is empty. At $line$ 4 the candidate with highest score, $\mathring{\boldsymbol{\imath}}$, is popped from $\mathbf{Q}$. $line$ 5 checks if $\mathring{\boldsymbol{\imath}}$ is within the beam width: if $\mathring{\boldsymbol{\imath}}$ has a span for which k candidates were already popped, then $\mathring{\boldsymbol{\imath}}$ is dropped and a new iteration is begun. Otherwise $\mathring{\boldsymbol{\imath}}$ is added to the out-forest at $line$ 6. From $line$ 7 to $line$ 10 the algorithm deals with the generation of new candidate undirected-items. $line$ 7 checks if $\mathring{\boldsymbol{\imath}}$ has both children links, if not a new decoding iteration is begun. $line$ 8 loops over the rule instantiations, r, that can use $\mathring{\boldsymbol{\imath}}$ as child. At $line$ 9, the set of new candidates, $\hat{\mathbf{C}}$, is built linking r with $\mathring{\boldsymbol{\imath}}$ and any context already available in the out-forest. Finally, between $line$ 10 and $line$ 12, each element $\hat{\mathbf{c}}$ in $\hat{\mathbf{C}}$ is inserted in $\mathbf{Q}$ after checking that $\hat{\mathbf{c}}$ is within the beam width: if $\hat{\mathbf{c}}$ has a span for which k candidates were already popped it doesn't make sense to insert it in $\mathbf{Q}$ since it will be surely discarded at $line$ 5.

In more detail, the function NewUndirectedItems$(r, \mathring{\boldsymbol{\imath}})$ at $line$ 9 creates new undirected-items linking r using: 1) $\mathring{\boldsymbol{\imath}}$ as child; 2) (optionally) as other child any other undirected-item that has already been inserted in the out-forest and

doesn't have a missing child and matches missing span coverage; 3) and using as parent context the best undirected-item with missing child link that has been incorporated in the out-forest and can expand the missing child link using r. In our current method, only the best possible parent context is used because it only provides context for ranking candidates, as discussed at the end of this section. In contrast, a different candidate is generated for each possible other child in 2), as well as for the case where no other child is included in the undirected-item.

We can make some general observations on the Undirected Decoding Algorithm. Notice that, the **if** statement at $line$ 7 and the way new undirected-items are created at $line$ 9, enforce that each undirected-item covers a contiguous span. An undirected-item that is missing a child link cannot be used as child context but can be used as parent context since it is added to the out-forest at $line$ 6 before the **if** statement at $line$ 7. Furthermore, the **if** statements at $line$ 5 and $line$ 11 check that no more than k candidates are selected for each span, but the algorithm does not require the the selection of exactly k candidates per span as in CKY.

The queue of candidates, $\mathbf{Q}$, is ordered according to the heuristic cost of formula (6). The score of the candidate partial structure is accounted for with factor $\mathsf{cost}(\mathring{\boldsymbol{\imath}})$ computed according to formula (5). The factor $\mathsf{est}(\mathring{\boldsymbol{\imath}})$ accounts for the estimation of the missing part of the derivation. We compute this factor with the following formula:

$$\mathsf{est}(\mathring{\boldsymbol{\imath}}) = \sum_{l \in \mathcal{L}^{-}_{\mathring{\boldsymbol{\imath}}}} \Big(\mathsf{localCost}(\mathring{\boldsymbol{\imath}}, l) + \mathsf{contextEst}(\mathring{\boldsymbol{\imath}}, l) \Big) \tag{7}$$

For each missing link, $l \in \mathcal{L}^{-}_{\mathring{\boldsymbol{\imath}}}$, we estimate the cost of the corresponding derivation branch with two factors: $\mathsf{localCost}(\mathring{\boldsymbol{\imath}}, l)$ that computes the context-free score of the branch with highest score that could be attached to l; and $\mathsf{contextEst}(\mathring{\boldsymbol{\imath}}, l)$ that estimates the contextual score of the branch and its interaction with $\mathring{\boldsymbol{\imath}}$. Because our model is implemented in the Forest Rescoring framework (e.g. Huang and Chiang (2007), Dyer et al. (2010), Li et al. (2009)), $\mathsf{localCost}(\mathring{\boldsymbol{\imath}}, l)$ can be efficiently computed exactly. In HMT it is possible to exhaustively represent and search the context-free-forest (ignoring the LM), which is done in the Forest Rescoring framework before our task of decoding with the LM. We exploit this context-free-forest to compute $\mathsf{localCost}(\mathring{\boldsymbol{\imath}}, l)$: for missing child links the $\mathsf{localCost}(\cdot)$ is the Inside score computed using the $(max,\ +)$ semiring (also known as the Viterbi score), and for missing parent links the $\mathsf{localCost}(\cdot)$ is the corresponding Outside score. The factor $\mathsf{contextEst}(\cdot)$ estimates the LM score of the words generated by the missing branch and their interaction with the span covered by $\mathring{\boldsymbol{\imath}}$. To compute the expected interaction cost we use the boundary words information contained in $\mathring{\boldsymbol{\imath}}$'s carry as done in BD. To estimate the LM cost of the missing branch we use an estimation function, conditioned on the missing span length, whose parameters are tuned on held-out data with gradient descent, using the search score as objective function.

To show that UD leads to better results than BD, the two algorithms are compared in the same search space. Therefore we ensure that candidates embedded in the UD out-forest would have the same score if they were scored from BD. We don't need to worry about differences derived from the missing context estimation factor, $\mathsf{est}(\cdot)$, since this factor is only considered while sorting the queue, $\mathbf{Q}$, according to the $\mathsf{heuristicCost}(\cdot)$. Also, we don't have to worry about candidates that are scored with no missing child and no parent link, because in that case scoring function (3) for BD is equivalent to scoring function (5) for UD. Instead, for candidates that are scored with parent link, we remove the parent link factor from the $\mathsf{cost}(\cdot)$ function when inserting the candidate into the out forest. And for the candidates that are scored with a missing child, we adjust the score once the link to the missing child is created in the out-forest. In this way UD and BD score the same derivation with the same score and can be regarded as two ways to explore the same search space.

5 Experiments

In this section we test the algorithm presented, and empirically show that it produces better translations searching a smaller portion of the search space.

We implemented UD on top of a widely-used HMT open-source system, cdec (Dyer et al., 2010). We compare with cdec Cube Pruning BD. The ex-

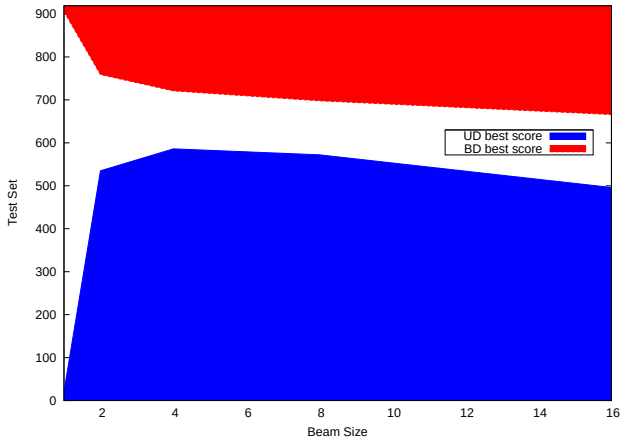

Figure 2: Comparison of the quality of the translations.

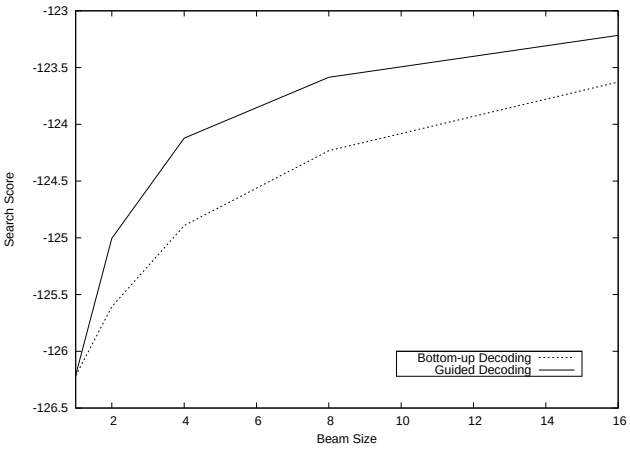

Figure 3: Search score evolution for BD and UD.

periments are executed on the NIST MT03 Chinese-English parallel corpus. The training corpus contains 239k sentence pairs with 6.9M Chinese words and 8.9M English words. We use a hierarchical phrase-based translation grammar extracted using a suffix array rule extractor (Lopez, 2007). The NIST-03 test set is used for decoding, it has 919 sentence pairs. The experiments can be reproduced on an average desktop computer. Since we compare two different decoding strategies that rely on the same training technique, the evaluation is primarily based on search errors rather than on BLEU. We compare the two systems on a variety of beam sizes between 1 and 16.

Figure 2 reports a comparison of the translation quality for the two systems in relation to the beam size. The blue area represents the portion of sentences for which UD found a better translation. The white area represents the portion of sentences for which the two systems found a translation with the same search score. With beam 1 the two systems obviously have a similar behavior, since both the systems stop investigating the candidates for a node after having selected the best candidate immediately available. For beams 2-4, UD has a clear advantage. In this range UD finds a better translation for two thirds of the sentences. With beam 4, we observe that UD is able to find a better translation for 63.76% of the sentences, instead BD is able to find a better translation for only 21.54% of the sentences. For searches that employ a beam bigger than 8, we notice that the UD advantage slightly decreases, and the number of sentences with equivalent translation slowly increases. We can understand this behavior considering that as the beam increases the two systems get closer to exhaustive search. Anyway with this experiment UD shows a consistent accuracy advantage over BD.

Figure 3 plots the search score variation for different beam sizes. We can see that UD search leads to an average search score that is consistently better than the one computed for BD. Undirected Decoding improves the average search score by 0.411 for beam 16. The search score is the logarithm of a probability. This variation corresponds to a relative gain of 50.83% in terms of probability. For beams greater than 8 we see that the two curves keep a monotonic ascendant behavior while converging to exhaustive search.

Figure 4 shows the BLEU score variation. Again we can see the consistent improvement of UD over BD. In the graph we report also the performance obtained using BD with beam 32. BD reaches BLEU score of 32.07 with beam 32 while UD reaches 32.38 with beam 16: UD reaches a clearly higher BLEU score using half the beam size. The difference is even more impressive if we consider that UD reaches a BLEU of 32.19 with beam 4.

In Figure 5 we plot the percentage reduction of the size of the hypergraphs generated by UD compared to those generated by BD. The size reduction grows quickly for both nodes and edges. This is due to the fact that BD, using Cube Pruning, must select k candidates for each node. Instead, UD is not obliged to

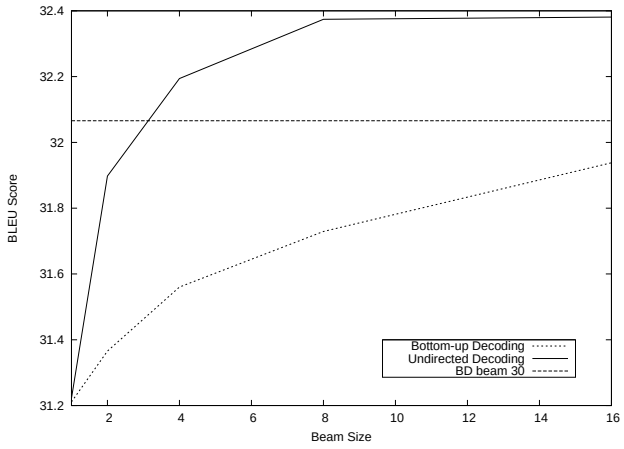

Figure 4: BLEU score evolution for BD and UD.

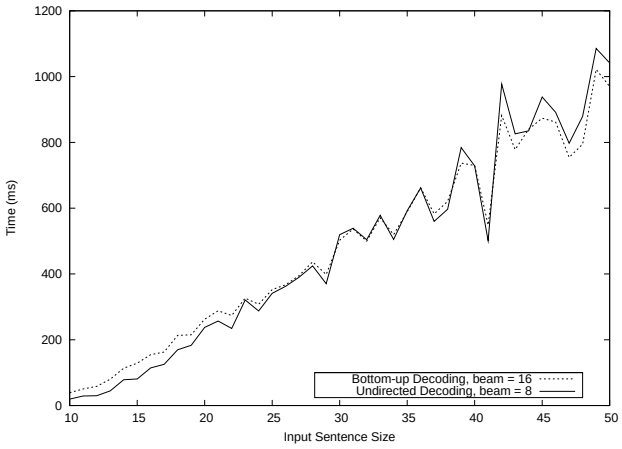

Figure 6: Time comparison between BD and UD.

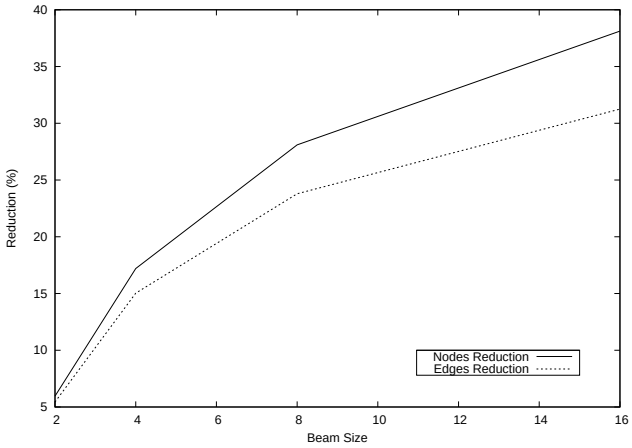

Figure 5: Percentage of reduction of the size of the hypergraph produced by UD.

select k candidates per $\mathbf{f}$-node. As we can see from Algorithm 1, the decoding loop terminates when the queue of candidates is empty, and the statements at $line\ 5$ and $line\ 11$ ensure that no more than k candidates are selected per $\mathbf{f}$-node, but nothing requires the selection of k elements, and some bad candidates may not be generated due to the sophisticated propagation strategy. The number of derivations that a hypergraph represents is exponential in the number of nodes and edges composing the structure. With beam 16, the hypergraphs produced by UD contain on average 4.6k fewer translations. Therefore UD is able to find better translations even if exploring a smaller portion of the search space.

Figure 6 reports the time comparison between BD and UD with respect to sentence length. The sentence length is measured with the number of ideogram groups appearing in the source Chinese sentences. We compare BD with beam of 16 and UD with beam of 8, so that we compare two systems with comparable search score. We can notice that for short sentences UD is faster, while for longer sentences UD becomes slower. To understand this result consider that for simple sentences UD can rely on the advantage of exploring a smaller search space. While, for longer sentences, the amount of candidates considered during decoding grows exponentially with the size of the sentence, and UD needs to maintain an unique queue whose size is not bounded by the beam size k, as for the queues used in BD's Cube Pruning. It may be possible to address this issue with more efficient handling of the queue.

In conclusion we can assert that, even if exploring a smaller portion of the search space, UD finds often a translation that is better than the one found with standard BD. UD's higher accuracy is due to its sophisticated search strategy that allows a more efficient integration of contextual features. This set of experiments show the validity of the UD approach and empirically confirm our intuition about the BD's inadequacy in solving tasks that rely on fundamental contextual features.

6 Future Work

In the proposed framework the link to the parent node is not treated differently from links to child nodes, the information in the hypergraph can be propagated in any direction. Then the Derivation

Hypergraph can be regarded as a non-directed graph. In this setting we could imagine applying message passing algorithms from graphical model theory (Koller and Friedman, 2010).

Furthermore, considering that the proposed framework lets the system decide the decoding order, we could design a system that explicitly learns to infer the decoding order at training time. Similar ideas have been successfully tried: Shen et al. (2010) and Gesmundo (2011) investigate the Guided Learning framework, that dynamically incorporates the tasks of learning the order of inference and training the local classifier.

7 Conclusion

With this paper we investigate the limitations of Bottom-up parsing techniques, widely used in Tree Structures Prediction, focusing on Hierarchical Machine Translation. We devise a framework that allows a better integration of non-bottom-up features. Compared to a state of the art HMT decoder the presented system produces higher quality translations searching a smaller portion of the search space, empirically showing that the bottom-up approximation of contextual features is a limitation for NLP tasks like HMT.

Abstract

Statistical machine translation systems are usually trained on a large amount of bilingual sentence pairs and translate one sentence at a time, ignoring document-level information. In this paper, we propose a cache-based approach to document-level translation. Since caches mainly depend on relevant data to supervise subsequent decisions, it is critical to fill the caches with highly-relevant data of a reasonable size. In this paper, we present three kinds of caches to store relevant document-level information: 1) a dynamic cache, which stores bilingual phrase pairs from the best translation hypotheses of previous sentences in the test document; 2) a static cache, which stores relevant bilingual phrase pairs extracted from similar bilingual document pairs (i.e. source documents similar to the test document and their corresponding target documents) in the training parallel corpus; 3) a topic cache, which stores the target-side topic words related with the test document in the source-side. In particular, three new features are designed to explore various kinds of document-level information in above three kinds of caches. Evaluation shows the effectiveness of our cache-based approach to document-level translation with the performance improvement of 0.81 in BLUE score over Moses. Especially, detailed analysis and discussion are presented to give new insights to document-level translation.

1 Introduction

During last decade, tremendous work has been done to improve the quality of statistical machine translation (SMT) systems. However, there is still a huge performance gap between the state-of-the-art SMT systems and human translators. Bond (2002) suggested nine ways to improve machine translation by imitating the best practices of human translators (Nida, 1964), with parsing the entire document before translation as the first priority. However, most SMT systems still treat parallel corpora as a list of independent sentence-pairs and ignore document-level information.

Document-level information can and should be used to help document-level machine translation. At least, the topic of a document can help choose specific translation candidates, since when taken out of the context from their document, some words, phrases and even sentences may be rather ambiguous and thus difficult to understand. Another advantage of document-level machine translation is its ability in keeping a consistent translation.

However, document-level translation has drawn little attention from the SMT research community. The reasons are manifold. First of all, most of parallel corpora lack the annotation of document boundaries (Tam, 2007). Secondly, although it is easy to incorporate a new feature into the classical log-linear model (Och, 2003), it is difficult to capture document-level information and model it via some simple features. Thirdly, reference translations of a test document written by human translators tend to have flexible expressions in order to avoid producing monotonous texts. This makes the evaluation of document-level SMT systems extremely difficult.

Tiedemann (2010) showed that the repetition and consistency are very important when modeling natural language and translation. He proposed to employ cache-based language and translation models in a phrase-based SMT system for domain

adaptation. Especially, the cache in the translation model dynamically grows up by adding bilingual phrase pairs from the best translation hypotheses of previous sentences. One problem with the dynamic cache is that those initial sentences in a test document may not benefit from the dynamic cache. Another problem is that the dynamic cache may be prone to noise and cause error propagation. This explains why the dynamic cache fails to much improve the performance.

This paper proposes a cache-based approach for document-level SMT using a static cache and a dynamic cache. While such a approach applies to both phrase-based and syntax-based SMT, this paper focuses on phrase-based SMT. In particular, the static cache is employed to store relevant bilingual phrase pairs extracted from similar bilingual document pairs (i.e. source documents similar to the test document and their target counterparts) in the training parallel corpus while the dynamic cache is employed to store bilingual phrase pairs from the best translation hypotheses of previous sentences in the test document. In this way, our cache-based approach can provide useful data at the beginning of the translation process via the static cache. As the translation process continues, the dynamic cache grows and contributes more and more to the translation of subsequent sentences.

Our motivation to employ similar bilingual document pairs in the training parallel corpus is simple: a human translator often collects similar bilingual document pairs to help translation. If there are translation pairs of sentences/phrases/words in similar bilingual document pairs, this makes the translation much easier. Given a test document, our approach imitates this procedure by first retrieving similar bilingual document pairs from the training parallel corpus, which has often been applied in IR-based adaptation of SMT systems (Zhao et al.2004; Hildebrand et al.2005; Lu et al.2007) and then extracting bilingual phrase pairs from similar bilingual document pairs to store them in a static cache.

However, such a cache-based approach may introduce many noisy/unnecessary bilingual phrase pairs in both the static and dynamic caches. In order to resolve this problem, this paper employs a topic model to weaken those noisy/unnecessary bilingual phrase pairs by recommending the decoder to choose most likely phrase pairs according to the topic words extracted from the target-side text of similar bilingual document pairs. Just like a human translator, even with a big bilingual dictionary, is often confused when he meets a source phrase which corresponds to several possible translations. In this case, some topic words can help reduce the perplexity. In this paper, the topic words are stored in a topic cache. In some sense, it has the similar effect of employing an adaptive language model with the advantage of avoiding the interpolation of a global language model with a specific domain language model.

The rest of this paper is organized as follows. Section 2 reviews the related work. Section 3 presents our cache-based approach to document-level SMT. Section 4 presents the experimental results. Session 5 gives new insights on cache-based document-level translation. Finally, we conclude this paper in Section 6.

2 Related work

There are only a few studies on document-level SMT. Representative work includes Zhao et al. (2006), Tam et al. (2007), Carpuat (2009).

Zhao et al. (2006) assumed that the parallel sentence pairs within a document pair constitute a mixture of hidden topics and each word pair follows a topic-specific bilingual translation model. It shows that the performance of word alignment can be improved with the help of document-level information, which indirectly improves the quality of SMT.

Tam et al. (2007) proposed a bilingual-LSA model on the basis of a parallel document corpus and built a topic-based language model for each language. By automatically building the correspondence between the source and target language models, this method can match the topic-based language model and improve the performance of SMT.

Carpuat (2009) revisited the "one sense per discourse" hypothesis of Gale et al. (1992) and gave a detailed comparison and analysis of the "one translation per discourse" hypothesis. However, she failed to propose an effective way to integrate document-level information into a SMT system. For example, she simply recommended some translation candidates to replace some target words in the post-process stage.

In principle, the cache-based approach can be well suited for document-level translation. Basical-

ly, the cache is analogous to "cache memory" in hardware terminology, which tracks short-term fluctuation (Iyer et al., 1999). As the cache changes with different documents, the document-level information should be capable of influencing SMT.

Previous cache-based approaches mainly point to cache-based language modeling (Kuhn and Mori, 1990), which uses a large global language model to mix with a small local model estimated from recent history data. However, applying such a language model in SMT is very difficult due to the risk of introducing extra noise (Raab, 2007).

For cache-based translation modeling, Nepveu et al. (2004) explored user-edited translations in the context of interactive machine translation. Tiedemann (2010) proposed to fill the cache with bilingual phrase pairs from the best translation hypotheses of previous sentences in the test document. Both Nepveu et al. (2004) and Tiedemann (2010) also explored traditional cache-based language models and found that a cache-based language model often contributes much more than a cache-based translation model.

3 Cache-based document-level SMT

Given a test document, our system works as follows:

1) clears the static, topic and dynamic caches when switching to a new test document d_x;
2) retrieves a set of most similar bilingual document pairs dd_s for d_x from the training parallel corpus using the cosine similarity with tf-idf weighting;
3) fills the static cache with bilingual phrase pairs extracted from dd_s;
4) fills the topic cache with topic words extracted from the target-side documents of dd_s;
5) for each sentence in the test document, translates it using cache-based SMT and continuously expands the dynamic cache with bilingual phrase pairs obtained from the best translation hypothesis of the previous sentences.

In this way, our cache-based approach can provide useful data at the beginning of the translation process via the static cache. As the translation process continues, the dynamic cache grows and contributes more and more to the translation of subsequent sentences. Besides, the possibility of choosing noisy/unnecessary bilingual phrase pairs in both the static and dynamic caches is wakened with the help of the topic words in the topic cache. In particular, only the most similar document pair is used to construct the static cache and the topic cache unless specified.

In this section, we first introduce the basic phrase-based SMT system and then present our cache-based approach to achieve document-level SMT with focus on constructing the caches (static, dynamic and topic) and designing their corresponding features.

3.1 Basic phrase-based SMT system

It is well known that the translation process of SMT can be modeled as obtaining the best translation **e** of the source sentence **f** by maximizing following posterior probability (Brown et al., 1993):

$$e_{best} = \arg\max_{e} P(e \mid f) = \arg\max_{e} P(f \mid e) P_{lm}(e) \quad (1)$$

where P(e|f) is a translation model and P_{lm} is a language model.

Our system adopted Moses (a state-of-art phrase-based SMT system) as a baseline, which follows Koehn et al. (2003) and mainly adopts six groups of popular features: 1) two phrase translation probabilities (two directions): $P_{phr}(e|f)$ and $P_{phr}(f|e)$; 2) two word translation probabilities (two directions) : $P_w(e|f)$ and $P_w(f|e)$; 3) one language model (target language): LM(e); 4) one phrase penalty (target language): PP(f); 5) one word penalty (target language):WP(e); 6) a lexicalized reordering model. Besides, the log-linear model as described in (Och and Ney, 2003) is employed to linearly interpolate these features for obtaining the best translation according to the formula (2):

$$e_{best} = \text{argmax} \{ \sum_{m=1}^{M} \lambda_m h_m(e, f) \} \quad (2)$$

where $h_m(e , f)$ is a feature function, and λ_m is the weight of $h_m(e , f)$ optimized by a discriminative training method on a held-out development data.

In principle, a phrase-based SMT system can provide the best phrase segmentation and alignment that cover a bilingual sentence pair. Here, a segmentation of a sentence into K phrases is defined as:

$$(f \sim e) \approx \sum_{i=1}^{K} (f_i, e_i, \sim) \quad (3)$$

where tuple (f_i, e_i) refers to a **phrase pair**, and ~ indicates corresponding alignment information.

3.2 Dynamic Cache

Our dynamic cache is mostly inspired by Tiedemann (2010), which adopts a dynamic cache to store relevant bilingual phrase pairs from the best translation hypotheses of previous sentences in the test document. In particular, a specific feature is incorporated S_{cache} to capture useful document-level information in the dynamic cache:

$$S_{cache}(e_c \mid f_c) = \frac{\sum_{i=1}^{K} I(< e_c, f_c >=< e_i, f_i >) \times e^{-\partial i}}{\sum_{i=1}^{K} I(f_c = f_i)} \quad (4)$$

where $e^{-\partial i}$ is a decay factor to avoid the dependence of the feature's contribution on the cache size. Given $<e_c, f_c>$ an existing phrase pair in the dynamic cache and $<e_i,f_i>$ a phrase pair in a new hypothesis, if ($e_i=e_c \wedge f_i=f_c$) is true (i.e. full matching), function I(.) returns 1 , otherwise 0.

One problem with the dynamic cache in Tiedemann (2010) is that it continuously updates the weight of a phrase pair in the dynamic cache. This may cause noticeable computational burden with the increasing number of phrase pairs in the dynamic cache. In addition, as a source phrase (f_c) may occur many times in the dynamic cache, the weights for related phrase pairs may degrade severely and thus his decoder needs a decay factor, which is difficult to optimize. Finally, Tiedemann (2010) only allowed full matching. This largely lowers down the probability of hitting the dynamic cache and thus much affects its effectiveness.

To overcome above problems, we only employ the bilingual phrase pairs in the dynamic cache to inform the decoder whether one bilingual phrase pair exists in the dynamic cache or not, which is slightly similar to (Nepveu et al, 2004) ,thus avoiding extra computational burden and the fine-tuning of the decay factor. In particular, following new feature is incorporated to better explore the dynamic cache:

$$F_d = \sum_{i=1}^{K} \mathrm{dpairmatch}(e_i, f_i) \quad (5)$$

where $\mathrm{dpairmatch}(e_i, f_i)$

$$= \begin{cases} 1 & (e_i = e_c \wedge f_i = f_c) \\ & \vee (\hat{e}_i = e_c \wedge \hat{f}_i = f_c \wedge \| e_c \| > 3) \\ & \vee (e_i = \hat{e}_c \wedge f_i = \hat{f}_c \wedge \| e_i \| > 3) \\ 0 & \text{other} \end{cases}$$

Here, F_d is called the dynamic cache feature. Assume (e_c,f_c) is a phrase pair in the dynamic cache and (e_i,f_i) is a phrase pair candidate for a new hypothesis. Besides full matching, we introduce a symbol of "^" for sub-phrase, such as $\hat{e}_i$ for a sub-phrase of e_i and $\hat{e}_c$ for a sub-phrase of e_c , to allow partial matching. Finally, F_d measures the overall value of a target candidate f_i by summing over the scores of K phrase pairs.

Obviously, F_d rewards both full matching and partial matching. In order to avoid too much noise, we put some constraints on the number of words in the target phrase of $<e_c,f_c>$ or $<e_i,f_i>$, such as $\| e_i \| > 3$, where " ||| " measures the number of non-blank characters in a phrase. For example, if phrase pair ", 减少||| and reduced" occurs in the cache, phrase pair ",|||and" is not rewarded because such shorter phrase pairs occur frequently and may largely degrade the effect of the cache. In accordance, the dynamic cache only contains phrase pairs whose target phrases contain 4 or more non-blank characters.

3.3 Static Cache

In Tiedemann (2010), initial sentences in a test document fail to benefit from the dynamic cache due to the lack of contents in the dynamic cache at the beginning of the translation process. To overcome this problem, a static cache is included to store relevant bilingual phrase pairs extracted from similar bilingual document pairs in the training parallel corpus. In particular, a static cache feature F_s is designed to capture useful information in the static cache in the same way as the dynamic cache feature, shown in Formula (5).

For this purpose, all the document pairs in the training parallel corpus are aligned at the phrase level using 2-fold cross-validation. That is, we adopt 50% of the training parallel corpus to train a model using Moses and apply the model to enforce phrase alignment of the remaining training data, and vice versa. Here, the enforcement is done by guaranteeing the occurrence of the target phrase candidate of a source phrase in the sentence pair. Besides, all the words pairs trained on the whole training parallel corpus are included in both folds to ensure at least one possible translation. Finally, the phrase pairs in the best translation hypothesis of a sentence pair is retrieved from the decoder. In this way, we can extract a set of phrase pairs for each bilingual document pairs.

Given a test document, we first find a set of similar source documents by computing the Cosine similarity using the TF-IDF weighting scheme and their corresponding target documents, from the training parallel corpus. Then, the phrase pairs ex-

tracted from these similar bilingual document pairs are collected into the static cache. To avoid noise, we filter out those phrase pairs which occur less than two times in the training parallel corpus.

Table 1: Phrase pairs extracted from a document pair with an economic topic

Similar to the dynamic cache, we only consider those phrase pairs whose target phrases contain 4 or more non-blank characters to avoid noise. We do not deliberately remove long phrase pairs. It is possible to use these long phrase pairs if our test document is very similar to one training document pair. Table 1 shows some bilingual phrase pairs extracted from a document pair, which reports a piece of news about "impact on slowdown in US economic growth". Obviously, these phrase pairs are closely related to economics.

3.4 Topic Cache

Both the dynamic and static caches may still introduce noisy/unnecessary bilingual phrase pairs even with constraints on the length of phrases and their occurrence frequency in the training parallel corpus. In order to resolve this problem, this paper adopts a topic cache to store relevant topic words and employs a topic cache feature to weaken those noisy/unnecessary phrase pairs.

Given w_t is a topic word in the topic cache, the topic cache feature F_t is designed as follows:

$$F_t = \sum_{i=1}^{K} \text{topicexist}(e_i, f_i) \quad (6)$$

where $\text{topicexist}(e_i, f_i) = \begin{cases} 1 & (w_t \in e_i) \\ 0 & \text{other} \end{cases}$

Here, the target phrase which contains a topic word w_t will be rewarded. w_t is derived by a topic model, LDA (Latent Dirichlet Allocation). This is different from the previous work (Tam, 2007), which mainly interpolated a topic language model with a general language model and added additional two adaptive lexicon probabilities in his phrase table.

In principle, LDA is a probabilistic model of text data, which provides a generative analog of PLSA (Blei et al., 2003), and is primarily meant to reveal hidden topics in text documents. Like most of the text mining techniques, LDA assumes that documents are made up of words and the ordering of the words within a document is unimportant (i.e. the "bag-of-words" assumption).

Figure 1 shows the principle of LDA, where α is the parameter of the uniform Dirichlet prior on the per-document topic distributions, β is the parameter of the uniform Dirichlet prior on the per-topic word distribution, θ_i is the topic distribution for document i, z_{ij} is the topic for the jth word in document i, and w_{ij} is the specific word. Among all variables, w_{ij} is the only observable variable with all the other variables latent. In particular, K denotes the number of topics considered in the model and φ is a K*V (V is the dimension of the vocabulary) Markov matrix each line of which denotes the word distribution of a topic. The inner plate over z and w illustrates the repeated sampling of topics and words until N words have been generated for document d. The plate surrounding θ illustrates the sampling of a distribution over topics for each document d for a total of M documents. The plate surrounding φ illustrates the repeated sampling of word distributions for each topic z until K topics have been generated.

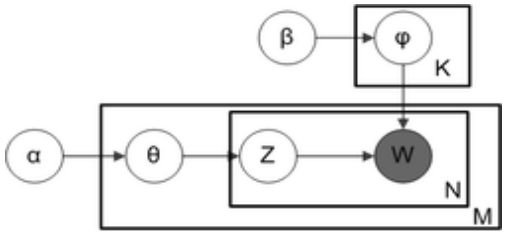

Figure 1: LDA

We use a LDA tool[1] to build a topic model using the target-side documents in the training parallel corpus. Using LDA, we can obtain the topic distribution of each word w, namely $p(z|w)$ for topic z ∈K. Moreover, using the obtained word topic distributions, we can infer the topic distribution of a new document, namely $p(z|d)$ for each topic z ∈K.

Given a test document, we first find the most similar source document from the training data in

[1] http://www.arbylon.net/projects/

the same way as done in the static cache. After that, we retrieve its corresponding target document. Then, the topic of the target document is determined by its major topic, with the maximum $p(z|d)$. Finally, we load some topic words corresponding to this topic z into the topic cache. In particular, our LDA model deploy the setting of K=15, α=0.5 and β=0.1. Besides, only top 1000 topic words are reserved for each topic. Table 2 shows top 10 topic words for five topics.

4 Experimentation

We have systematically evaluated our cache-based approach to document-level SMT on the Chinese-English translation task.

4.1 Experimental Setting

Here, we use SRI language modeling toolkit to train a trigram general language model on English newswire text, mostly from the Xinhua portion of the Gigaword corpus (2007) and performed word alignment on the training parallel corpus using GIZA++(Och and Ney,2000) in two directions. For evaluation, the NIST BLEU script (version 13) with the default setting is used to calculate the Bleu score (Papineni et al. 2002), which measures case-insensitive matching of n-grams with n up to 4. To see whether an improvement is statistically significant, we also conduct significance tests using the paired bootstrap approach (Koehn, 2004)[2]. In this paper, '***', '**', and '*' denote p-values less than or equal to 0.01, in-between (0.01, 0.05), and bigger than 0.05, which mean significantly better, moderately better and slightly better, respectively.

[2] http://www.ark.cs.cmu.edu/MT

In this paper, we use FBIS as the training data, the 2003 NIST MT evaluation test data as the development data, and the 2005 NIST MT test data as the test data. Table 3 shows the statistics of these data sets (with document boundaries annotated).

Corpus		Sentences	Documents
Role	Name		
Train	FBIS	239413	10353
Dev	NIST2003	919	100
Test	NIST2005	1082	100

Table 3: Corpus statistics

In particular, the sizes of the static, topic and dynamic caches are fine-tuned to 2000, 1000 and 5000 items, respectively. For the dynamic cache, we only keep those most recently-visited items, while for the static cache; we always keep the most frequently-occurring items.

4.2 Experimental Results

Table 4 shows the contribution of various caches in our cache-based document-level SMT system. The column of "BLEU_W" means the BLEU score computed over the whole test set and "BLEU_D" corresponds to the average BLEU score over separated documents.

System	BLEU on Dev(%)	BLEU on Test(%)		
		BLEU_W	NIST	BLEU_D
Moses	29.87	25.76	7.784	25.08
Fd	29.90	26.03 (*)	7.852	25.39
Fd+Fs	30.29	26.30 (**)	7.884	25.86
Fd+Ft	30.11	26.24 (**)	7.871	25.74
Fd+Fs+Ft	30.50	26.42 (***)	7.896	26.11
Fd+Fs+Ft with merging	-	26.57 (***)	7.901	26.32

Table 4: Contribution of various caches in our cache-based document-level SMT system. Note that significance tests are done against Moses.

Contribution of dynamical cache (Fd)

Table 4 shows that the dynamic cache slightly improves the performance by 0.27 (*) in BLEU_W. This is similar to Tiedemann (2010). However, detailed analysis indicates that the dynamic cache does have negative effect on about one third of documents, largely due to the instability of the dynamic cache at the beginning of translating a document. Figure 2 shows the distribution of the

BLEU_D difference of 100 test documents (sorted by BLEU_D). It shows that about 55% of test documents benefit from the dynamic cache.

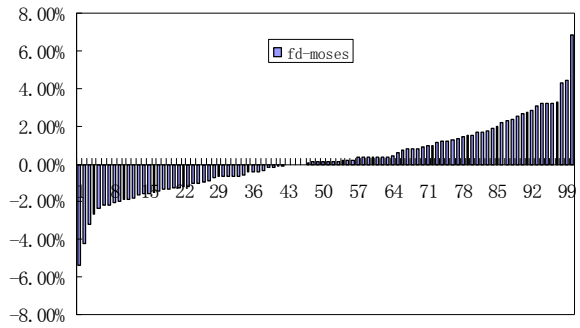

Figure 2: Contribution of employing the dynamic cache on different test documents

Contribution of static cache (Fs)

Table 4 shows that the combination of the static cache with the dynamic cache further improves the performance by 0.27(*) in BLEU_W. This suggests the effectiveness of the static cache in eliminating the instability of the dynamic cache when translating first few sentences of a test document. Together, the dynamic and static caches much improve the performance by 0.54 (**) in BLEU_W over Moses. Figure 3 shows the distribution of the BLEU_D difference of 100 test documents (sorted by BLEU_D), with more positive effect on those borderline documents, compared to Figure 2.

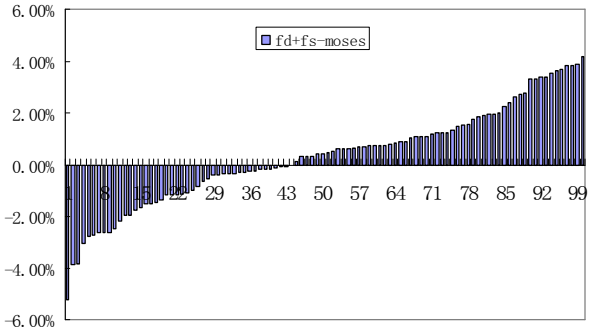

Figure 3: Contribution of combining the dynamic and static cache on different test documents

Contribution of topic cache (Ft)

Table 4 shows that the topic cache has comparable effect on improving the performance as the static cache when combined with the dynamic cache (0.48 vs. 0.54 in BLEU_W). Figure 4 shows the effectiveness of combining the dynamic and topic caches (sorted by BLEU_D).

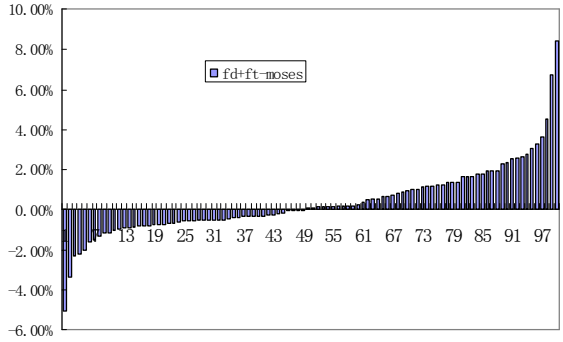

Figure 4: Contribution of combining the dynamic and topic caches

However, detailed analysis shows that the topic cache and the static cache are quite complementary by contributing on different test documents, largely due to that while the static cache tends to keep translation consistent, the topic cache plays like a document-specific language model. This is justified by Table 4 that the combination of the dynamic, static and topic caches significantly improve the performance by 0.66 (***) in BLEU_W, and by Figure 5 that about 75% of test documents benefit from the combination of the three caches (sorted by BLEU_D).

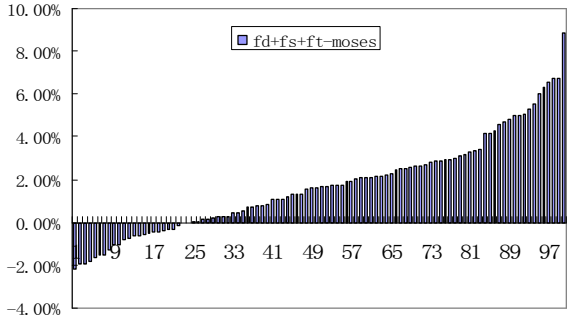

Figure 5: Contribution of combining the three caches

Contribution of merging phrase pairs of similar document pairs

Here, the number of similar documents we adopt is different from previous experiments. In the previous experiments, we only cache bilingual phrase pairs extracted from the most similar document. Here, we merge phrase pairs for several most similar documents (5 at most) which have the same topic.

Table 4 shows that employing this trick can further improve the performance by 0.15 in BLEU_W. As a result, the cache-based approach significantly improve the performance by 0.81 (***) in BLEU_W over Moses.

5 Discussion

In this section, we explore in more depth why the static cache can help the dynamic cache, some constrained factors which impact the effectiveness of our cache-based approach.

Effectiveness of the static cache

We investigate why the static cache affects the performance. Basically, it is difficult for the dynamic cache to capture such similar information in the static cache.

In principle, the static cache can both influence the initial and subsequent sentences; however subsequent ones can be affected by multiple caches. In order to give an insight of the static cache, we evaluate its effectiveness on the first sentence for each test document. Figure 6 shows the contribution of the static cache on translating these first sentences (y-axis shows BLEU value of the first sentence for each test document). It notes that the most BLEU scores of them are zeros because of the length limitation of first sentences.

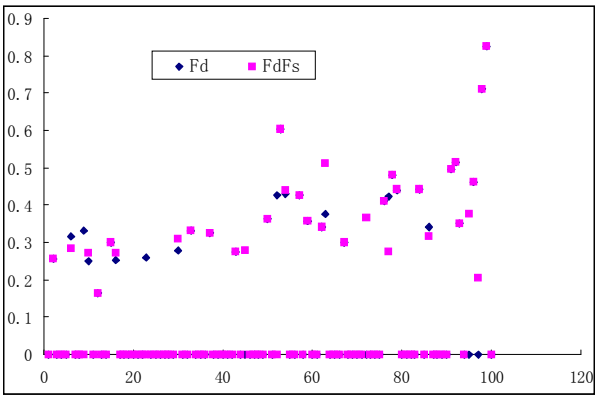

Figure 6: Contribution of the static cache on the first sentence of each test document (i.e. with empty dynamic cache)

Furthermore, we count the hit (matching) frequency of the static cache for each test documents. Since we use 1 or 0 for the static cache feature, it is easy to retrieve its effect for each test document. Our statistics shows that the hit frequency on static cache fluctuates between 5 and 18 for each test document. Without the static cache, the hit frequency of the dynamic cache is 504 on whole test sets, this figure increases to 685 with the static cache. This means that the static cache significantly enlarges the effectiveness of the dynamic cache by including more relevant phrase pairs to the dynamic cache, largely due to the positive impact of the static cache on the initial sentences of each test document.

Size of topic cache

Table 5 shows the impact of the topic cache when the number of the retained topic words for each topic increases from 500 to 2000. It shows that too more topic words actually harm the performance, due to the increase of noise. 1000 topic words seem a lot largely due to that we didn't do stemming for our topic modeling since we hope to introduce some tense information of them in the future.

Number of topic words	BLEU_W
500	26.27
700	26.31
1000	26.42
1500	26.23
2000	26.19

Table 5: Impact of the topic cache size

Influenced translations

In order to explore how our cache-based system impacts on translation results, we manually inspected 5 documents respectively which is improved or degraded in translation quality compared to the baseline Moses output. Those documents have 107 sentences in sum.

The good effectiveness of each kind of cache can be observed by the example 1 and 2 showed in Table 6. Both the example 1 and 2 come from the same document whose "BLEU_D" score exceeds Moses with 8.4 point. The example 1 benefits from the topic cache which contains the item of "action". The example 2 benefits from the static cache which contains a phrase pair of "承诺||| promised to" while Moses use "commitment" for "承诺" , which may be the reason for missing the part of "prime minister" in Moses output. Furthermore, due to the phrase pair of "停火 协议||| the ceasefire agreement" existing in our static cache, our decoder keeps using "ceasefire" to translate "停火" in the whole document while Moses randomly use "ceasefire" or "cease-fire" for this translation.

1	官员 预测 “ 准备 工作 将 会 进行 到 七月 , 然后 再 展开 政治 动作 ”
	Moses: official forecasts said that preparatory work will be carried out in july and then launched a political **maneuver** .

	Reference: On the night of the 17th , nearly 3,000 residents watched a wonderful gala of songs and dances , organized by the municipal government , at Plaza da Armas . Colorful lights lighted up ancient architecture around the plaza . Famous artists including singers and dancers staged performances of national songs and dances of different regions .
4	利马 的 城市 面积 已 从 建城 之 初 的 2.14 平方公里 发展 到 2600 多 平方公里 , 而 人口 也 增加 到 800 万 左右 , 约 占 全国 总人口 的 31% 。
	Moses: at lima 's urban area from the beginning of 2600 **square** to 2.14 million **square kilometers** , while the population has increased to 8 percent of the country 's total , about 31% .
	Ours: lima , the urban area from the beginning of 2600 **square kilometers** to 2.14 million **square kilometers** , but also increased to about 8 million population , the country 's total population of about 31% .
	Reference: The area of Lima city has expanded to more than 2,600 square kilometers from the original 2.14 square kilometers when the city was founded , while the population has increased to around 8 million , roughly accounting for 31% of the nation's total .

Table 6: Positive and negative examples

The example 3 and 4 also come from the same document however whose performance degrades with 2.17 point. We don't think the translation quality for example 4 in our system is worse than Moses. However, the translation quality for example 3 in our system is very bad and especially showed on "re-ordering". We found this sentence did not match any item in our static cache and topic cache. Although this phenomenon also happens in other documents, but this is the most typical negative example among these documents.

Document-specific characteristics

It seems that using the same weight for the whole test sets (all documents) is not very reasonable. Actually, if we can determine those negative documents which are not suitable for the cache-based approach, our cache-based approach may gain much improvement. Tiedemann (2010) explored the correlation to document length, baseline performance and source document repetition. However, it seems that there are no obvious rules to filter out those negative documents. Besides, there may be two more document-specific factors: repetition of the reference text and document style.

Tiedemann (2010) only considered the repetition of the test text in the source side. Since BLEU score is computed against the reference text, the repetition in the reference text may greatly influence the performance of our cache-based approach to document-level SMT. As for document style, it is quite possible that a document may contain several topics. Therefore, it may be useful to track such change over topics and refresh various caches when there is a topic change. We will leave the above issues to the future work.

6 Conclusion

We have shown that our cache-based approach significantly improves the performance with the help of various caches, such as the dynamic, static and topic caches, although the cache-based ap-

proach may introduce some negative impact on BLEU scores for certain documents.

In the future, we will further explore how to reflect document divergence during training and dynamically adjust cache weights according to different documents.

There are many useful components in training documents, such as named entity, event and coreference. In this experiment, we only adopt the flat data in our cache. However, the structured data may improve the correctness of matching and thus effectively avoid noise. We will explore more effective ways to pick up various kinds of useful information from the training parallel corpus to expand our cache-based approach. Besides, we will resort to comparable corpora to enlarge our cache-based approach to document-level SMT.

Abstract

Discriminative training for machine translation has been well studied in the recent past. A limitation of the work to date is that it relies on the availability of high-quality in-domain bilingual text for supervised training. We present an unsupervised discriminative training framework to incorporate the usually plentiful target-language monolingual data by using a rough "reverse" translation system. Intuitively, our method strives to ensure that probabilistic "round-trip" translation from a target-language sentence to the source-language and back will have low expected loss. Theoretically, this may be justified as (discriminatively) minimizing an *imputed empirical risk*. Empirically, we demonstrate that augmenting supervised training with unsupervised data improves translation performance over the supervised case for both IWSLT and NIST tasks.

1 Introduction

Missing data is a common problem in statistics when fitting the parameters θ of a model. A common strategy is to attempt to impute, or "fill in," the missing data (Little and Rubin, 1987), as typified by the EM algorithm. In this paper we develop imputation techniques when θ is to be trained *discriminatively*.

We focus on machine translation (MT) as our example application. A Chinese-to-English machine translation system is given a Chinese sentence x and asked to predict its English translation y. This system employs statistical models $p_\theta(y \mid x)$ whose parameters θ are discriminatively trained using bilingual sentence pairs (x, y). But bilingual data for such supervised training may be relatively scarce for a particular language pair (e.g., Urdu-English), especially for some topics (e.g., technical manuals) or genres (e.g., blogs). So systems seek to exploit additional monolingual data, i.e., a corpus of English sentences y with no corresponding source-language sentences x, to improve estimation of θ. This is our missing data scenario.[1]

Discriminative training of the parameters θ of $p_\theta(y \mid x)$ using monolingual English data is a curious idea, since there is no Chinese input x to translate. We propose an unsupervised training approach, called *minimum imputed risk training*, which is conceptually straightforward: *First guess x (probabilistically) from the observed y using a reverse English-to-Chinese translation model $p_\phi(x \mid y)$. Then train the discriminative Chinese-to-English model $p_\theta(y \mid x)$ to do a good job at translating this imputed x back to y, as measured by a given performance metric.* Intuitively, our method strives to ensure that probabilistic "round-trip" translation from a target-language sentence to the source-language and back again will have low expected loss.

Our approach can be applied in an application scenario where we have (1) enough out-of-domain bilingual data to build two baseline translation systems, with parameters θ for the forward direction, and ϕ for the reverse direction; (2) a small amount

* Zhifei Li is currently working at Google Research, and this work was done while he was a PHD student at Johns Hopkins University.

[1] Contrast this with traditional semi-supervised training that looks to exploit "unlabeled" inputs x, with missing *outputs* y.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 920–929,
Edinburgh, Scotland, UK, July 27–31, 2011.

of in-domain bilingual development data to discriminatively tune a *small* number of parameters in ϕ; and (3) a large amount of in-domain English monolingual data.

The novelty here is to exploit (3) to *discriminatively* tune the parameters θ of all *translation* model components,[2] $p_\theta(y|x)$ and $p_\theta(y)$, not merely train a generative *language* model $p_\theta(y)$, as is the norm.

Following the theoretical development below, the empirical effectiveness of our approach is demonstrated by replacing a key *supervised* discriminative training step in the development of large MT systems — learning the log-linear combination of several component model scores (viewed as features) to optimize a performance metric (e.g. BLEU) on a set of (x, y) pairs — with our *unsupervised* discriminative training using only y. One may hence contrast our approach with the traditional *supervised* methods applied to the MT task such as minimum error rate training (Och, 2003; Macherey et al., 2008), the averaged Perceptron (Liang et al., 2006), maximum conditional likelihood (Blunsom et al., 2008), minimum risk (Smith and Eisner, 2006; Li and Eisner, 2009), and MIRA (Watanabe et al., 2007; Chiang et al., 2009).

We perform experiments using the open-source MT toolkit **Joshua** (Li et al., 2009a), and show that adding unsupervised data to the traditional supervised training setup improves performance.

2 Supervised Discriminative Training via Minimization of Empirical Risk

Let us first review discriminative training in the *supervised* setting—as used in MERT (Och, 2003) and subsequent work.

One wishes to tune the parameters θ of some complex translation system $\delta_\theta(x)$. The function δ_θ, which translates Chinese x to English $y = \delta_\theta(x)$ need not be probabilistic. For example, θ may be the parameters of a scoring function used by δ, along with pruning and decoding heuristics, for extracting a high-scoring translation of x.

The goal of discriminative training is to minimize the expected loss of $\delta_\theta(\cdot)$, under a given task-specific **loss function** $\mathrm{L}(y', y)$ that measures how bad it would be to output y' when the correct output is y. For an MT system that is judged by the BLEU metric (Papineni et al., 2001), for instance, $\mathrm{L}(y', y)$ may be the negated BLEU score of y' w.r.t. y. To be precise, the goal[3] is to find θ with low **Bayes risk**,

$$\theta^* = \operatorname*{argmin}_\theta \sum_{x,y} p(x, y)\, \mathrm{L}(\delta_\theta(x), y) \qquad (1)$$

where $p(x, y)$ is the joint distribution of the input-output pairs.[4]

The true $p(x, y)$ is, of course, not known and, in practice, one typically minimizes **empirical risk** by replacing $p(x, y)$ above with the empirical distribution $\tilde{p}(x, y)$ given by a supervised training set $\{(x_i, y_i), i = 1, \ldots, N\}$. Therefore,

$$\begin{aligned} \theta^* &= \operatorname*{argmin}_\theta \sum_{x,y} \tilde{p}(x, y)\, \mathrm{L}(\delta_\theta(x), y) \\ &= \operatorname*{argmin}_\theta \frac{1}{N} \sum_{i=1}^{N} \mathrm{L}(\delta_\theta(x_i), y_i). \qquad (2) \end{aligned}$$

The search for θ^* typically requires the use of numerical methods and some regularization.[5]

3 Unsupervised Discriminative Training with Missing Inputs

3.1 Minimization of Imputed Risk

We now turn to the unsupervised case, where we have training examples $\{y_i\}$ but not their corresponding inputs $\{x_i\}$. We cannot compute the summand $\mathrm{L}(\delta_\theta(x_i), y_i)$ for such i in (2), since $\delta_\theta(x_i)$ requires to know x_i. So we propose to replace

[2] Note that the extra monolingual data is used only for tuning the model weights, but not for inducing new phrases or rules.

[3] This goal is different from the minimum risk training of Li and Eisner (2009) in a subtle but important way. In both cases, θ^* minimizes *risk* or *expected loss*, but the expectation is w.r.t. different distributions: the expectation in Li and Eisner (2009) is under the conditional distribution $p(y \mid x)$, while the expectation in (1) is under the joint distribution $p(x, y)$.

[4] In the terminology of statistical decision theory, $p(x, y)$ is a distribution over states of nature. We seek a *decision rule* $\delta_\theta(x)$ that will incur low expected loss on *observations* x that are generated from unseen states of nature.

[5] To compensate for the shortcut of using the unsmoothed empirical distribution rather than a posterior estimate of $p(x, y)$ (Minka, 2000), it is common to add a regularization term $||\theta||_2^2$ in the objective of (2). The regularization term can prevent overfitting to a training set that is not large enough to learn all parameters.

$\mathrm{L}(\delta_\theta(x_i), y_i)$ with the expectation

$$\sum_x p_\phi(x \mid y_i)\, \mathrm{L}(\delta_\theta(x), y_i), \quad (3)$$

where $p_\phi(\cdot \mid \cdot)$ is a "reverse prediction model" that attempts to impute the missing x_i data. We call the resulting variant of (2) the minimization of *imputed empirical risk*, and say that

$$\theta^* = \operatorname*{argmin}_\theta \frac{1}{N} \sum_{i=1}^{N} \sum_x p_\phi(x \mid y_i)\, \mathrm{L}(\delta_\theta(x), y_i) \quad (4)$$

is the estimate with the **minimum imputed risk**[6].

The minimum imputed risk objective of (4) could be evaluated by *brute force* as follows.

1. For each unsupervised example y_i, use the reverse prediction model $p_\phi(\cdot \mid y_i)$ to impute possible reverse translations $\mathcal{X}_i = \{x_{i1}, x_{i2}, \ldots\}$, and add each (x_{ij}, y_i) pair, weighted by $p_\phi(x_{ij} \mid y_i) \leq 1$, to an imputed training set .
2. Perform the supervised training of (2) on the *imputed* and *weighted* training data.

The second step means that we must use δ_θ to forward-translate each imputed x_{ij}, evaluate the loss of the translations y'_{ij} against the corresponding true translation y_i, and choose the θ that minimizes the weighted sum of these losses (i.e., the empirical risk when the empirical distribution $\tilde{p}(x, y)$ is derived from the imputed training set). Specific to our MT task, this tries to ensure that probabilistic "round-trip" translation, from the target-language sentence y_i to the source-language and back again, will have a low expected loss.[7]

The trouble with this method is that the reverse model p_ϕ generates a weighted lattice or hypergraph $\mathcal{X}_i$ encoding exponentially many translations of y_i, and it is computationally infeasible to forward-translate *each* $x_{ij} \in \mathcal{X}_i$. We therefore investigate several approximations to (4) in Section 3.4.

[6] One may exploit both supervised data $\{(x_i, y_i)\}$ and unsupervised data $\{y_j\}$ to perform semi-supervised training via an interpolation of (2) and (4). We will do so in our experiments.

[7] Our approach may be applied to other tasks as well. For example, in a speech recognition task, δ_θ is a speech recognizer that produces text, whereas p_ϕ is a speech *synthesizer* that must produce a distribution over audio (or at least over acoustic features or phone sequences) (Huang et al., 2010).

3.2 The Reverse Prediction Model p_ϕ

A *crucial* ingredient in (4) is the reverse prediction model $p_\phi(\cdot|\cdot)$ that attempts to impute the missing x_i. We will train this model in advance, doing the best job we can from available data, including any out-of-domain bilingual data as well as any in-domain monolingual data[8] x.

In the MT setting, δ_θ and p_ϕ may have similar parameterization. One translates Chinese to English; the other translates English to Chinese.

Yet the setup is not quite symmetric. Whereas δ_θ is a translation *system* that aims to produce a *single*, *low-loss* translation, the reverse version p_ϕ is rather a probabilistic *model*. It is supposed to give an accurate probability distribution over possible values x_{ij} of the missing input sentence x_i. All of these values are taken into account in (4), regardless of the loss that they would incur if they were evaluated for translation quality relative to the missing x_i.

Thus, ϕ does not need to be trained to minimize the risk itself (so there is no circularity). Ideally, it should be trained to match the underlying conditional distribution of x given y, by achieving a low conditional cross-entropy

$$\mathrm{H}(X \mid Y) = -\sum_{x,y} p(x, y) \log p_\phi(x \mid y). \quad (5)$$

In practice, ϕ is trained by (empirically) minimizing $-\frac{1}{M}\sum_{j=1}^{N} \log p_\phi(x_j \mid y_j) + \frac{1}{2\sigma^2}\|\phi\|_2^2$ on some bilingual data, with the regularization coefficient σ^2 tuned on held out data.

It may be tolerable for p_ϕ to impute mediocre translations x_{ij}. All that is necessary is that the (forward) translations generated from the imputed x_{ij} "simulate" the competing hypotheses that we would see when translating the correct Chinese input x_i.

3.3 The Forward Translation System δ_θ and The Loss Function $\mathbf{L}(\delta_\theta(x_i), y_i)$

The minimum empirical risk objective of (2) is quite general and various popular supervised training methods (Lafferty et al., 2001; Collins, 2002; Och, 2003; Crammer et al., 2006; Smith and Eisner,

[8] In a translation task from x to y, one usually does not make use of in-domain monolingual data x. But we *can* exploit x to train a language model $p_\phi(x)$ for the reverse translation system, which will make the imputed x_{ij} look like true Chinese inputs.

2006) can be formalized in this framework by choosing different functions for δ_θ and $\mathrm{L}(\delta_\theta(x_i), y_i)$. The generality of (2) extends to our minimum imputed risk objective of (4). Below, we specify the δ_θ and $\mathrm{L}(\delta_\theta(x_i), y_i)$ we considered in our investigation.

3.3.1 Deterministic Decoding

A simple translation rule would define

$$\delta_\theta(x) = \operatorname*{argmax}_y p_\theta(y \mid x) \tag{6}$$

If this $\delta_\theta(x)$ is used together with a loss function $\mathrm{L}(\delta_\theta(x_i), y_i)$ that is the negated BLEU score[9], our minimum imputed risk objective of (4) is equivalent to MERT (Och, 2003) *on the imputed training data*.

However, this would not yield a differentiable objective function. Infinitesimal changes to θ could result in discrete changes to the winning output string $\delta_\theta(x)$ in (6), and hence to the loss $\mathrm{L}(\delta_\theta(x), y_i)$. Och (2003) developed a specialized line search to perform the optimization, which is not scalable when the number of model parameters θ is large.

3.3.2 Randomized Decoding

Instead of using the argmax of (6), we assume *during training* that $\delta_\theta(x)$ is itself random, i.e. the MT system *randomly* outputs a translation y with probability $p_\theta(y \mid x)$. As a result, we will modify our objective function of (4) to take yet another expectation over the unknown y. Specifically, we will replace $\mathrm{L}(\delta_\theta(x), y_i)$ in (4) with

$$\sum_y p_\theta(y \mid x)\, \mathrm{L}(y, y_i). \tag{7}$$

Now, the minimum imputed empirical risk objective of (4) becomes

$$\theta^* = \operatorname*{argmin}_\theta \frac{1}{N} \sum_{i=1}^{N} \sum_{x,y} p_\phi(x \mid y_i)\, p_\theta(y \mid x)\, \mathrm{L}(y, y_i) \tag{8}$$

If the loss function $\mathrm{L}(y, y_i)$ is a negated BLEU, this is equivalent to performing minimum-risk training described by (Smith and Eisner, 2006; Li and Eisner, 2009) *on the imputed data*.[10]

[9] One can manipulate the loss function to support other methods that use deterministic decoding, such as Perceptron (Collins, 2002) and MIRA (Crammer et al., 2006).

[10] Again, one may manipulate the loss function to support other probabilistic methods that use randomized decoding, such as CRFs (Lafferty et al., 2001).

The objective function in (8) is now differentiable, since each coefficient $p_\theta(y \mid x)$ is a differentiable function of θ, and thus amenable to optimization by gradient-based methods; we use the L-BFGS algorithm (Liu et al., 1989) in our experiments. We perform experiments with the syntax-based MT system **Joshua** (Li et al., 2009a), which implements dynamic programming algorithms for second-order expectation semirings (Li and Eisner, 2009) to efficiently compute the gradients needed for optimizing (8).

3.4 Approximating $p_\phi(x \mid y_i)$

As mentioned at the end of Section 3.1, it is computationally infeasible to forward-translate *each* of the imputed reverse translations x_{ij}. We propose four approximations that are computationally feasible. Each may be regarded as a different approximation of $p_\phi(x \mid y_i)$ in equations (4) or (8).

k-best. For each y_i, add to the imputed training set only the k most probable translations $\{x_{i1}, \ldots x_{ik}\}$ according to $p_\phi(x \mid y_i)$. (These can be extracted from $\mathcal{X}_i$ using standard algorithms (Huang and Chiang, 2005).) Rescale their probabilities to sum to 1.

Sampling. For each y_i, add to the training set k independent samples $\{x_{i1}, \ldots x_{ik}\}$ from the distribution $p_\phi(x \mid y_i)$, each with weight $1/k$. (These can be sampled from $\mathcal{X}_i$ using standard algorithms (Johnson et al., 2007).) This method is known in the literature as *multiple imputation* (Rubin, 1987).

Lattice. [11] Under certain special cases it is be possible to compute the expected loss in (3) exactly via dynamic programming. Although $\mathcal{X}_i$ does contain exponentially many translations, it may use a "packed" representation in which these translations share structure. This representation may furthermore enable sharing work in forward-translation, so as to efficiently translate the entire set $\mathcal{X}_i$ and obtain a distribution over translations y. Finally, the expected loss under that distribution, as required by equation (3), may also be efficiently computable.

All this turns out to be possible if (a) the posterior distribution $p_\phi(x \mid y_i)$ is represented by an *un-*

[11] The lattice approximation is presented here as a theoretical contribution, and we do not empirically evaluate it since its implementation requires extensive engineering effort that is beyond the main scope of this paper.

ambiguous weighted finite-state automaton $\mathcal{X}_i$, (b) the forward translation system δ_θ is structured in a certain way as a weighted synchronous context-free grammar, and (c) the loss function decomposes in a certain way. We omit the details of the construction as beyond the scope of this paper.

In our experimental setting described below, (b) is true (using **Joshua**), and (c) is true (since we use a loss function presented by Tromble et al. (2008) that is an approximation to BLEU and is decomposable). While (a) is not true in our setting because $\mathcal{X}_i$ is a hypergraph (which is ambiguous), Li et al. (2009b) show how to *approximate* a hypergraph representation of $p_\phi(x \mid y_i)$ by an unambiguous WFSA. One could then apply the construction to this WFSA[12], obtaining an approximation to (3).

Rule-level Composition. Intuitively, the reason why the structure-sharing in the hypergraph $\mathcal{X}_i$ (generated by the reverse system) cannot be exploited during forward translating is that when the forward Hiero system translates a string $x_i \in \mathcal{X}_i$, it must parse it into recursive phrases.

But the structure-sharing within the hypergraph of $\mathcal{X}_i$ has already parsed x_i into recursive phrases, in a way determined by the reverse Hiero system; each translation phrase (or rule) corresponding to a hyperedge. To exploit structure-sharing, we can use a forward translation system that decomposes according to that existing parse of x_i. We can do that by considering *only* forward translations that respect the hypergraph structure of $\mathcal{X}_i$. The simplest way to do this is to require complete isomorphism of the SCFG trees used for the reverse and forward translations. In other words, this does round-trip imputation (i.e., from y to x, and then to y') at the rule level. This is essentially the approach taken by Li et al. (2010).

3.5 The Log-Linear Model p_θ

We have not yet specified the form of p_θ. Following much work in MT, we begin with a linear model

$$\text{score}(x, y) = \theta \cdot f(x, y) = \sum_k \theta_k f_k(x, y) \quad (9)$$

where $f(x, y)$ is a feature vector indexed by k. Our deterministic *test-time* translation system δ_θ simply outputs the highest-scoring y for fixed x. At *training time*, our randomized decoder (Section 3.3.2) uses the Boltzmann distribution (here a log-linear model)

$$p_\theta(y \mid x) = \frac{e^{\gamma \cdot \text{score}(x,y)}}{Z(x)} = \frac{e^{\gamma \cdot \text{score}(x,y)}}{\sum_{y'} e^{\gamma \cdot \text{score}(x,y')}} \quad (10)$$

The scaling factor γ controls the sharpness of the training-time distribution, i.e., the degree to which the randomized decoder favors the highest-scoring y. For large γ, our training objective approaches the imputed risk of the deterministic test-time system while remaining differentiable.

In a task like MT, in addition to the input x and output y, we often need to introduce a *latent* variable d to represent the hidden derivation that relates x to y. A derivation d represents a particular *phrase segmentation* in a phrase-based MT system (Koehn et al., 2003) and a *derivation tree* in a typical syntax-based system (Galley et al., 2006; Chiang, 2007). We change our model to assign scores not to an (x, y) pair but to the detailed derivation d; in particular, now the function f that extracts a feature vector can look at all of d. We replace y by d in (9)–(10), and finally define $p_\theta(y|x)$ by marginalizing out d,

$$p_\theta(y \mid x) = \sum_{d \in \mathrm{D}(x,y)} p_\theta(d \mid x) \quad (11)$$

where $\mathrm{D}(x, y)$ represents the set of derivations that yield x and y.

4 Minimum Imputed Risk vs. EM

The notion of imputing missing data is familiar from other settings (Little and Rubin, 1987), particularly the expectation maximization (EM) algorithm, a widely used generative approach. So it is instructive to compare EM with minimum imputed risk.

One can estimate θ by maximizing the log-likelihood of the data $\{(x_i, y_i), i = 1, \ldots, N\}$ as

$$\operatorname*{argmax}_\theta \frac{1}{N} \sum_{i=1}^{N} \log p_\theta(x_i, y_i). \quad (12)$$

If the x_i's are missing, EM tries to iteratively maximize the marginal probability:

$$\operatorname*{argmax}_\theta \frac{1}{N} \sum_{i=1}^{N} \log \sum_x p_\theta(x, y_i). \quad (13)$$

[12] Note that the forward translation of a WFSA is tractable by using a lattice-based decoder such as that by Dyer et al. (2008).

The E-step of each iteration comprises computing $\sum_x p_{\theta_t}(x \mid y_i) \log p_\theta(x, y_i)$, the *expected* log-likelihood of the complete data, where $p_{\theta_t}(x \mid y_i)$ is the conditional part of $p_{\theta_t}(x, y_i)$ under the current iterate θ_t, and the M-step comprises maximizing it:

$$\theta_{t+1} = \operatorname*{argmax}_\theta \frac{1}{N} \sum_{i=1}^{N} \sum_x p_{\theta_t}(x \mid y_i) \log p_\theta(x, y_i). \quad (14)$$

Notice that if we replace $p_{\theta_t}(x|y_i)$ with $p_\phi(x \mid y_i)$ in the equation above, and admit negated log-likelihood as a loss function, then the EM update (14) becomes identical to (4). In other words, the minimum imputed risk approach of Section 3.1 differs from EM in (i) using an externally-provided and static p_ϕ, instead of refining it at each iteration based on the current p_{θ_t}, and (ii) using a specific loss function, namely negated log-likelihood.

So why not simply use the maximum-likelihood (EM) training procedure for MT? One reason is that it is not discriminative: the loss function (e.g. negated BLEU) is ignored during training.

A second reason is that training good *joint* models $p_\theta(x, y)$ is computationally expensive. Contemporary MT makes heavy use of log-linear probability models, which allow the system designer to inject phrase tables, linguistic intuitions, or prior knowledge through a careful choice of features. Computing the objective function of (14) in closed form is difficult if p_θ is an arbitrary log-linear model, because the joint probability $p_\theta(x_i, y_i)$ is then defined as a ratio whose denominator Z_θ involves a sum over all possible sentence pairs (x, y) of any length.

By contrast, our discriminative framework will only require us to work with conditional models. While conditional probabilities such as $p_\phi(x \mid y)$ and $p_\theta(y \mid x)$ are also ratios, computing their denominators only requires us to sum over a packed forest of possible translations of a given y or x.[13]

In summary, EM would impute missing data using $p_\theta(x \mid y)$ and predict outputs using $p_\theta(y \mid x)$, both being conditional forms of the same joint model $p_\theta(x, y)$. Our minimum imputed risk training method is similar, but it instead uses a pair of separately parameterized, separately trained models $p_\phi(x \mid y)$ and $p_\theta(y \mid x)$. By sticking to conditional models, we can efficiently use more sophisticated model features, and we can incorporate the loss function when we train θ, which should improve both efficiency and accuracy at test time.

[13] Analogously, discriminative CRFs have become more popular than generative HMMs because they permit efficient training even with a wide variety of log-linear features (Lafferty et al., 2001).

5 Experimental Results

We report results on Chinese-to-English translation tasks using **Joshua** (Li et al., 2009a), an open-source implementation of Hiero (Chiang, 2007).

5.1 Baseline Systems

5.1.1 IWSLT Task

We train both reverse and forward baseline systems. The translation models are built using the corpus for the IWSLT 2005 Chinese to English translation task (Eck and Hori, 2005), which comprises 40,000 pairs of transcribed utterances in the travel domain. We use a *5-gram* language model with modified Kneser-Ney smoothing (Chen and Goodman, 1998), trained on the English (resp. Chinese) side of the bitext. We use a standard training pipeline and pruning settings recommended by (Chiang, 2007).

5.1.2 NIST Task

For the NIST task, the TM is trained on about 1M parallel sentence pairs (about 28M words in each language), which are sub-sampled from corpora distributed by LDC for the NIST MT evaluation using a sampling method implemented in **Joshua**. We also used a 5-gram language model, trained on a data set consisting of a 130M words in English Gigaword (LDC2007T07) and the bitext's English side.

5.2 Feature Functions

We use two classes of features f_k for discriminative training of p_θ as defined in (9).

5.2.1 Regular Hiero Features

We include ten features that are standard in Hiero (Chiang, 2007). In particular, these include one baseline language model feature, three baseline translation models, one word penalty feature, three features to count how many rules with an arity of

zero/one/two are used in a derivation, and two features to count how many times the unary and binary glue rules in Hiero are used in a derivation.

5.2.2 Target-rule Bigram Features

In this paper, we do not attempt to discriminatively tune a separate parameter for each bilingual rule in the Hiero grammar. Instead, we train several hundred features that generalize across these rules.

For each bilingual rule, we extract bigram features over the target-side symbols (including non-terminals and terminals). For example, if a bilingual rule's target-side is "*on the* X_1 *issue of* X_2" where X_1 and X_2 are non-terminals (with a position index), we extract the bigram features *on the*, *the* X, X *issue*, *issue of*, and *of* X. (Note that the position index of a non-terminal is ignored in the feature.) Moreover, for the terminal symbols, we will use their dominant POS tags (instead of the symbol itself). For example, the feature *the* X becomes *DT* X. We use 541 such bigram features for IWSLT task (and 1023 such features for NIST task) that fire frequently.

5.3 Data Sets for Discriminative Training

5.3.1 IWSLT Task

In addition to the 40,000 sentence pairs used to train the baseline generative models (which are used to compute the features f_k), we use three bilingual data sets listed in Table 1, also from IWSLT, for discriminative training: one to train the reverse model p_ϕ (which uses only the 10 standard Hiero features as described in Section 5.2.1),[14] one to train the forward model δ_θ (which uses both classes of features described in Section 5.2, i.e., 551 features in total), and one for test.

Note that the reverse model ϕ is always trained using the supervised data of Dev_ϕ, while the forward model θ may be trained in a supervised or semi-supervised manner, as we will show below.

In all three data sets, each Chinese sentence x_i has 16 English reference translations, so each y_i is actually a *set* of 16 translations. When we impute data from y_i (in the semi-supervised scenario), we actually impute 16 different values of x_i, by using p_ϕ to separately reverse translate each sentence in y_i. This effectively adds 16 pairs of the form (x_i, y_i) to the training set (see section 3.4), where each x_i is a different input sentence (imputed) in each case, but y_i is always the original set of 16 references.

Data set	Purpose	# of sentences	
		Chinese	English
Dev_ϕ	training ϕ	503	503×16
Dev_θ	training θ	503*	503×16
Eval_θ	testing	506	506×16

Table 1: **IWSLT Data sets used for discriminative training/test**. Dev_ϕ is used for discriminatively training of the reverse model ϕ, Dev_θ is for the forward model, and Eval_θ is for testing. The star * for Dev_θ emphasizes that some of its Chinese side will not be used in the training (see Table 2 for details).

5.3.2 NIST Task

For the NIST task, we use MT03 set (having 919 sentences) to tune the component parameters in both the forward and reverse baseline systems. Additionally, we use the English side of MT04 (having 1788 sentences) to perform semi-supervised tuning of the forward model. The test sets are MT05 and MT06 (having 1082 and 1099 sentences, respectively). In all the data sets, each source sentence has four reference translations.

5.4 Main Results

We compare two training scenarios: supervised and semi-supervised. The supervised system ("Sup") carries out discriminative training on a bilingual data set. The semi-supervised system ("+Unsup") additionally uses some monolingual English text for discriminative training (where we impute one Chinese translation per English sentence).

Tables 2 and 3 report the results for the two tasks under two training scenarios. Clearly, adding unsupervised data improves over the supervised case, by at least 1.3 BLEU points in IWSLT and 0.5 BLEU in NIST.

5.5 Results for Analysis Purposes

Below, we will present more results on the IWSLT data set to help us understand the behavior of the

[14] Ideally, we should train ϕ to minimize the conditional cross-entropy (5) as suggested in section 3.2. In the present results, we trained ϕ discriminatively to minimize risk, purely for ease of implementation using well versed steps.

Training scenario	Test BLEU
Sup, (200, 200×16)	47.6
+Unsup, 101×16 Eng sentences	49.0
+Unsup, 202×16 Eng sentences	48.9
+Unsup, 303×16 Eng sentences	49.7*

Table 2: **BLEU scores for semi-supervised training for IWSLT task.** The supervised system ("Sup") is trained on a subset of Dev_θ containing 200 Chinese sentences and 200×16 English translations. "+Unsup" means that we include additional (monolingual) English sentences from Dev_θ for semi-supervised training; for each English sentence, we impute the 1-best Chinese translation. A star * indicates a result that is signicantly better than the "Sup" baseline (paired permutation test, $p < 0.05$).

Training scenario	Test BLEU	
	MT05	MT06
Sup, (919, 919×4)	32.4	30.6
+Unsup, 1788 Eng sentences	33.0*	31.1*

Table 3: **BLEU scores for semi-supervised training for NIST task.** The "Sup" system is trained on MT03, while the "+Unsup" system is trained with additional 1788 English sentences from MT04. (Note that while MT04 has 1788×4 English sentences as it has four sets of references, we only use one such set, for computational efficiency of discriminative training.) A star * indicates a result that is signicantly better than the "Sup" baseline (paired permutation test, $p < 0.05$).

methods proposed in this paper.

5.5.1 Imputation with Different Reverse Models

A critical component of our unsupervised method is the reverse translation model $p_\phi(x \mid y)$. We wonder how the performance of our unsupervised method changes when the quality of the reverse system varies. To study this question, we used two different reverse translation systems, one with a language model trained on the Chinese side of the bitext ("WLM"), and the other one without using such a Chinese LM ("NLM"). Table 4 (in the fully unsupervised case) shows that the imputed Chinese translations have a far lower BLEU score without the language model,[15] and that this costs us about 1 English BLEU point in the forward translations. Still, even with the worse imputation (in the case of "NLM"), our forward translations improve as we add more monolingual data.

Data size	Imputed-CN BLEU		Test-EN BLEU	
	WLM	NLM	WLM	NLM
101	11.8	3.0	48.5	46.7
202	11.7	3.2	48.9	47.6
303	13.4	3.5	48.8	47.9

Table 4: **BLEU scores for unsupervised training with/without using a language model in the reverse system.** A data size of 101 means that we use only the English sentences from a subset of Dev_θ containing 101 Chinese sentences and 101×16 English translations; for each English sentence we impute the 1-best Chinese translation. "WLM" means a Chinese language model is used in the reverse system, while "NLM" means no Chinese language model is used. In addition to reporting the BLEU score on Eval_θ, we also report "Imputed-CN BLEU", the BLEU score of the imputed Chinese sentences against their corresponding Chinese reference sentences.

5.5.2 Imputation with Different k-best Sizes

In all the experiments so far, we used the reverse translation system to impute only a single Chinese translation for each English monolingual sentence. This is the 1-best approximation of section 3.4.

Table 5 shows (in the fully unsupervised case) that the performance does not change much as k increases.[16] This may be because that the 5-best sentences are likely to be quite similar to one another (May and Knight, 2006). Imputing a longer k-best list, a sample, or a lattice for x_i (see section 3.4) might achieve more diversity in the training inputs, which might make the system more robust.

6 Conclusions

In this paper, we present an unsupervised discriminative training method that works with missing inputs. The key idea in our method is to use a reverse model to impute the missing input from the observed output. The training will then forward translate the imputed input, and choose the parameters of the forward model such that the imputed risk (i.e.,

[15] The BLEU scores are low even *with* the language model because only one Chinese reference is available for scoring.

[16] In the present experiments, however, we simply weighted all k imputed translations equally, rather than in proportion to their posterior probabilities as suggested in Section 3.4.

Training scenario	Test BLEU
Unsup, k=1	48.5
Unsup, k=2	48.4
Unsup, k=3	48.9
Unsup, k=4	48.5
Unsup, k=5	48.4

Table 5: **BLEU scores for unsupervised training with different k-best sizes.** We use 101×16 monolingual English sentences, and for each English sentence we impute the k-best Chinese translations using the reverse system.

the expected loss of the forward translations with respect to the observed output) is minimized. This matches the intuition that the probabilistic "round-trip" translation from the target-language sentence to the source-language and back should have low expected loss.

We applied our method to two Chinese to English machine translation tasks (i.e. IWSLT and NIST). We showed that augmenting supervised data with unsupervised data improved performance over the supervised case (for both tasks).

Our discriminative model used only a small amount of training data and relatively few features. In future work, we plan to test our method in settings where there are large amounts of monolingual training data (enabling many discriminative features). Also, our experiments here were performed on a language pair (i.e., Chinese to English) that has quite rich bilingual resources in the domain of the test data. In future work, we plan to consider low-resource test domains and language pairs like Urdu-English, where bilingual data for novel domains is sparse.

Abstract

Mapping documents into an interlingual representation can help bridge the language barrier of cross-lingual corpora. Many existing approaches are based on word co-occurrences extracted from aligned training data, represented as a covariance matrix. In theory, such a covariance matrix should represent semantic equivalence, and *should* be highly sparse. Unfortunately, the presence of noise leads to dense covariance matrices which in turn leads to suboptimal document representations. In this paper, we explore techniques to recover the desired sparsity in covariance matrices in two ways. First, we explore word association measures and bilingual dictionaries to weigh the word pairs. Later, we explore different selection strategies to remove the noisy pairs based on the association scores. Our experimental results on the task of aligning comparable documents shows the efficacy of sparse covariance matrices on two data sets from two different language pairs.

1 Introduction

Aligning documents from different languages arises in a range of tasks such as parallel phrase extraction (Gale and Church, 1991; Rapp, 1999), mining translations for out-of-vocabulary words for statistical machine translation (Daume III and Jagarlamudi, 2011) and document retrieval (Ballesteros and Croft, 1996; Munteanu and Marcu, 2005). In this task, we are given a comparable corpora and some documents in one language are assumed to have a comparable document in the other language and the goal is to recover this hidden alignment. In this paper, we address this problem by mapping the documents into a common subspace (interlingual representation). This common subspace generalizes the notion of vector space model for cross-lingual applications (Turney and Pantel, 2010).

Most of the existing approaches use manually aligned document pairs to find a common subspace in which the aligned document pairs are maximally correlated. The sub-space can be found using either generative approaches based on topic modeling (Mimno et al., 2009; Jagarlamudi and Daumé III, 2010; Zhang et al., 2010; Vu et al., 2009) or discriminative approaches based on variants of Principal Component Analysis (PCA) and Canonical Correlation Analysis (CCA) (Susan T. Dumais, 1996; Vinokourov et al., 2003; Platt et al., 2010; Haghighi et al., 2008). Both styles rely on document level term co-occurrences to find the latent representation.

The discriminative approaches capture essential word co-occurrences in terms of two monolingual covariance matrices and a cross-covariance matrix. Subsequently, they use these covariance matrices to find projection directions in each language such that aligned documents lie close to each other (Sec. 2). The strong reliance of these approaches on the covariance matrices leads to problems, especially with the noisy data caused either by the noisy words in a document or the noisy document alignments. Noisy data is not uncommon and is usually the case with data collected from community based resources such as Wikipedia. This degrades performance of a

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 930–940,
Edinburgh, Scotland, UK, July 27–31, 2011.

variety of tasks, such as transliteration Mining (Klementiev and Roth, 2006; Hermjakob et al., 2008; Ravi and Knight, 2009) and multilingual web search (Gao et al., 2009).

In this paper, we address the problem of identifying and removing noisy entries in the covariance matrices. We address this problem in two stages. In the first stage, we explore the use of word association measures such as Mutual Information (MI) and Yule's ω (Reis and Judd, 2000) in computing the strength of a word pair (Sec. 3.1). We also explore the use of bilingual dictionaries developed from cleaner resources such as parallel data. In the second stage, we use the association strengths in filtering out the noisy word pairs from the covariance matrices. We pose this as a word pair selection problem and explore multiple strategies (Sec. 3.2).

We evaluate the utility of sparse covariance matrices in improving the bilingual projections incrementally (Sec. 4). We first report results on synthetic multi-view data where the true correspondences between features of different views are available. Moreover, this also lets us systematically explore the effect of noise level on the accuracy. Our experimental results show a significant improvement when the true correspondences are available. Later, we report our experimental results on the document alignment task on Europarl and Wikipedia data sets and on two language pairs. We found that sparsifying the covariance matrices helps in general, but using cleaner resource such bilingual dictionaries performed best.

2 Canonical Correlation Analysis (CCA)

In this section, we describe how Canonical Correlation Analysis is used to solve the problem of aligning bilingual documents. We mainly focus on representing the solution of CCA in terms of covariance matrices. Since most of the existing discriminative approaches are variants of CCA, showing the advantage of recovering sparseness in CCA makes it applicable to the other variants as well.

Given a training data of n aligned document pairs, CCA finds projection directions for each language, so that the documents when projected along these directions are maximally correlated (Hotelling, 1936). Let X ($d_1 \times n$) and Y ($d_2 \times n$) be the representation of data in both the languages and further assume that the data is centered (subtract the mean vector from each document *i.e.* $\mathbf{x}_i \leftarrow \mathbf{x}_i - \mu_x$ and $\mathbf{y}_i \leftarrow \mathbf{y}_i - \mu_y$). Then CCA finds projection directions $\mathbf{a}$ and $\mathbf{b}$ which maximize:

$$\frac{\mathbf{a}^T XY^T \mathbf{b}}{\sqrt{\mathbf{a}^T XX^T \mathbf{a}}\sqrt{\mathbf{b}^T YY^T \mathbf{b}}}$$
$$\text{s.t. } \mathbf{a}^T XX^T \mathbf{a} = 1 \ \& \ \mathbf{b}^T YY^T \mathbf{b} = 1$$

The projection directions are obtained by solving the generalized eigen system:

$$\begin{bmatrix} 0 & C^{xy} \\ C^{yx} & 0 \end{bmatrix} \begin{bmatrix} \mathbf{a} \\ \mathbf{b} \end{bmatrix} = \begin{bmatrix} (1\text{-}\lambda)C^{xx}+\lambda I & 0 \\ 0 & (1\text{-}\lambda)C^{yy}+\lambda I \end{bmatrix} \begin{bmatrix} \mathbf{a} \\ \mathbf{b} \end{bmatrix} \quad (1)$$

where $C^{xx} = XX^T$, $C^{yy} = YY^T$ are the monolingual covariance matrices, $C^{xy} = XY^T$ is the cross-covariance matrix and λ is the regularization parameter. Using these eigenvectors as columns, we form the projection matrices A and B. These projection matrices are used to map documents in both the languages into interlingual representation.

Given any new pair of documents, their similarity is computed by first mapping them into the lower dimensions space and computing the cosine similarity between their projections. In general, using all the eigenvectors is sub optimal and thus retaining top eigenvectors leads to better generalizability.

3 Covariance Selection

As shown above, the underlying objective function in most of the discriminative approaches is of the form $\mathbf{a}^T XY^T \mathbf{b}$. This can be rewritten as :

$$\begin{aligned} \mathbf{a}^T XY^T \mathbf{b} &= \sum_{k=1}^{n} \langle \mathbf{x}_k, \mathbf{a} \rangle \langle \mathbf{y}_k, \mathbf{b} \rangle \\ &= \sum_{k=1}^{n} \Big(\sum_{i=1}^{d_1} X_{i,k} a_i \cdot \sum_{j=1}^{d_2} Y_{j,k} b_j \Big) \\ &= \sum_{i=1}^{d_1} \sum_{j=1}^{d_2} a_i b_j \Big(\sum_{k=1}^{n} X_{i,k} Y_{j,k} \Big) \\ &= \sum_{i,j=1}^{d_1,d_2} a_i b_j C_{ij}^{xy} \quad (2) \end{aligned}$$

Similarly, the constraints can also be rewritten as $\sum_{i,j=1}^{d_1} a_i a_j C_{ij}^{xx} = 1$ and $\sum_{i,j=1}^{d_2} b_i b_j C_{ij}^{yy} = 1$.

Maximizing this objective function, under the constraints, involves a careful selection of the vectors $\mathbf{a}$ and $\mathbf{b}$ such that $a_i b_j$ is high whenever C_{ij}^{xy} is high. So, every non-zero entry of the cross-covariance matrix restricts the choice of the projection directions. While this may not be a severe problem when the training data is clean, but this is very uncommon especially in the case of high dimensional data like text documents. Moreover, the inherent ambiguity of natural languages increases the chances of seeing a noisy word in any document. Every occurrence of a noisy word will have a non-zero contribution towards the covariance matrix making it dense, which in turn prevents the selection of appropriate projection directions.

In this section, we describe some techniques to recover the sparsity by removing the noisy entries from the covariance matrices. We break this task into two sub problems: computing an association score for every word pair and then using an appropriate strategy to identify the noisy pairs based on their weights. We explore multiple ways to address both the steps in the following two sections. For the sake of convenience and clarity, we describe our techniques in the context of cross-covariance matrix between English and Spanish language pair. But these techniques extend directly to monolingual covariance matrices, and to different language pairs as well.

3.1 Computing Word Pair Association

The first step in filtering out the noisy word co-occurrences is to use an appropriate measure to compute the strength of word pairs (English and Spanish words). This is a well studied problem and several association measures have been proposed in the NLP literature (Dunning, 1993; Inkpen and Hirst, 2002; Moore, 2004). These association measures can be divided into groups based on the statistics they use (Hoang et al., 2009). Here we explore a few of them for sparsifying the cross-covariance matrix.

3.1.1 Covariance

The first option is to use the cross-covariance matrix itself. As noted above, when the data matrix is centered, the cross-covariance of an English word (e_i) with a Spanish word (f_j) is given by $\sum_{k=1}^{n} X_{ik} Y_{jk}$. It measures the strength with which two words co-occur together. This measure uses information about the occurrence of a word pair in aligned documents and doesn't use other statistics such as 'how often this pair *doesn't* co-occur together' and so on.

3.1.2 Mutual Information

Association measures like covariance and Pointwise Mutual Information, which only use the frequency with which a word pair co-occurs, often overestimate the strength of low frequent words (Moore, 2004). On the other hand, measures like Log-likelihood ratio (Dunning, 1993) and Mutual Information (MI) use other statistics like the marginal probabilities of each of the words.

For any two words, e_i and f_j, let n_{11}, n_{10}, n_{01} and n_{00} denote the number of documents in which both the words co-occur, only English word occurs, only Spanish word occurs and none of the words occur. Then the Mutual Information of this word pair is given by:

$$\text{MI}(e_i, f_j) = \frac{1}{n} \sum_{i,j \in \{0,1\}} n_{ij} \log \frac{n_{ij} \times n}{n_i n_j} \quad (3)$$

where n_i and n_j denote the number of documents in which the English and the Spanish word occurs and n is the total number of documents. We treat the occurrence of a word in a document slightly different from others, we treat a word as occurring in a document if it has occurred more than its average frequency in the corpus. Log-likelihood ratio and the MI differ only in terms of the constant they use, so we use only MI in our experiments.

3.1.3 Yule's ω

Yule's ω is another popular association measure used in psychology (Reis and Judd, 2000). It uses same statistics used by Mutual Information but differs in the way in which they are combined. MI converts the frequencies into probabilities before computing the association measure where as Yule's ω uses the observed frequencies directly, and doesn't make any assumptions about the underlying probability distributions. Given the same interpretation of the variables as introduced in the previous section, the Yule's ω is estimated as:

$$\omega = \frac{\sqrt{n_{00} n_{11}} - \sqrt{n_{01} n_{10}}}{\sqrt{n_{00} n_{11}} + \sqrt{n_{01} n_{10}}} \quad (4)$$

This way of combining the frequencies bears similarity with the log-odds ratio.

3.1.4 Bilingual Dictionary

The above three association measures use the same training data that is available to compute the covariance matrices in CCA. Thus, their utility in bringing additional information, which is not captured by the covariance matrices, is arguable (our experiments show that they are indeed helpful). Moreover, they use document level co-occurrence information which is coarse compared to the co-occurrence at sentence level or the translational information provided by a bilingual dictionary. So, we use bilingual dictionaries as our final resource to weigh the word co-occurrences. Notice that, using bilingual information brings in information gleaned from an external corpus.

We use translation tables learnt using Giza++ (Och and Ney, 2003) on Europarl data set. Since the translation tables are asymmetric, we combine translation tables from both the directions. We first use a threshold on the conditional probability to filter out the low probability ones and then convert them into joint probabilities before combining. For each word pair (e_i, f_j), we compute the score as:

$$\frac{1}{2}\Big(P(e_i|f_j)P(f_j) + P(f_j|e_i)P(e_i)\Big)$$

While the first three association measures can also be applied to monolingual data, bilingual dictionary can't be used for weighting monolingual word pairs. So in this case, we use either of the above mentioned techniques for weighting monolingual word pairs.

3.2 Selection Strategies

The next step after computing association measure for all word pairs is to use them in selecting the pairs that need to be retained. In this section, we describe some approaches such as thresholding and matching for the word pair selection.

3.2.1 Thresholding

A straight forward way to remove the noisy word co-occurrences is to zero out the entries of the cross-covariance matrix that are lower than a threshold. To understand the motivation, consider the rewritten objective function of CCA, $\mathbf{a}^T XY^T \mathbf{b} = \sum_{ij} C^{xy}_{ij} a_i b_j$. This is linear in terms of the individual components of the cross-covariance matrix. So, if we want to remove some of the entries of the covariance matrix with minimal change in the value of the objective function, then the optimal choice is to sort the entries of the covariance matrix and filter out the less confident word pairs.

3.2.2 Relative Thresholding

While the thresholding strategy described in the above section is very simple, it is often biased by the frequent words. Since a frequent word co-occurs with other words often, it naturally tends to have high association with most of the other words. As a result, absolute thresholding tends to remove all the less frequent word pairs while leaving the co-occurrences of the frequent words untouched. Eventually, this may lead to zeroing out some of the rows or the columns of the cross-covariance matrix.

To circumvent this, we try thresholding at word level. For every English word, we choose a few Spanish words that have high association and vice versa. Since the nearest neighbour property is asymmetric, we take the union of all the selected word pairs. That is, we retain a word pair, if either the Spanish word is in the top ranked list of the English word or vice versa.

3.2.3 Maximal Matching

Though relative thresholding overcomes the problem of zeroing out entire rows or columns posed by direct thresholding, it is still biased by the frequent words. The high association measure of a frequent English word with many Spanish words, makes it a nearest neighbour for lot of Spanish words. One way to prevent this is to discourage an already selected English word from associating with a new Spanish word. This requires a global knowledge of all the selected pairs and can not be done by looking at the individual words, as is the case with the greedy strategy employed by the relative thresholding.

We use matching to solve this problem. We formulate the selection of the word pairs as a network flow problem (Jagarlamudi et al., 2011). The objective is to select word pairs that have high association measure while constraining each word to be associated with only a few words from other language. Let I_{ij} denote an indicator variable taking a value of

0 or 1 depending on if the word pair (e_i, f_j) is selected or not. We want each word to be associated with k words from other language, *i.e.*$\sum_j I_{ij} = k$ and $\sum_i I_{ij} = k$. Moreover, we want word pairs with high association score to be selected. We can encode this objective and the constraints as the following optimization problem:

$$\arg\max_{I} \sum_{i,j=1}^{d_1,d_2} C_{ij}^{xy} I_{ij} \quad (5)$$
$$\forall i \sum_j I_{ij} = k;\ \forall j \sum_i I_{ij} = k;\ \forall i,j\ I_{ij} \in \{0,1\}$$

If $k = 1$, then this problem reduces to a linear assignment problem and can be solved optimally using the Hungarian algorithm (Jonker and Volgenant, 1987). For other values of k, this can be solved by relaxing the constraint $I_{ij} \in \{0,1\}$ to $0 \leq I_{ij} \leq 1$. The optimal solution of the relaxed problem can be found efficiently using linear programming (Ravindra et al., 1993). The uni-modular nature of the constraints guarantees an integral solution (Schrijver, 2003), so relaxing the original integer problem doesn't introduce any error in the optimal solution.

3.2.4 Monolingual Augmentation

The above three selection strategies operate on the covariance matrices independently. In this section we propose to combine them. Specifically, we propose to augment the set of selected bilingual word pairs using the monolingual word pairs. We first use any of the above mentioned strategies to select bilingual and monolingual word pairs. Let I^{xy}, I^{xx} and I^{yy} be the binary matrices that indicate the selected word pairs based on the bilingual and monolingual association scores. Then the monolingual augmentation strategy updates I^{xy} in the following way:

$$I^{xy} \leftarrow \text{Binarize}(I^{xx} I^{xy} I^{yy})$$

i.e., we multiply I^{xy} with the monolingual selection matrices and then binarize the resulting matrix. Our monolingual augmentation is motivated by the following probabilistic interpretation:

$$P(x,y) = \sum_{x',y'} P(x|x')P(y|y')P(x',y')$$

which can be rewritten as $P \leftarrow T^x P (T^y)^T$ where T^x and T^y are monolingual state transition matrices.

3.3 Our Approach

In this section we summarize our approach for the task of finding aligned documents from a cross-lingual comparable corpora. The training phase involves finding projection directions for documents of both the languages. We compute the covariance matrices using the training data. Then we use any of the word association measures (Sec. 3.1) along with a selection criteria (Sec. 3.2) to recover the sparseness in either only the cross-covariance or all of the covariance matrices. Let I^{xy}, I^{xx} and I^{yy} be the binary matrices which represent the word pairs that are selected based on the chosen sparsification technique. Now, we replace the covariance matrices in Eq. 1 as follows: $C^{xx} \leftarrow C^{xx} \otimes I^{xx}$, $C^{yy} \leftarrow C^{yy} \otimes I^{yy}$ and $C^{xy} \leftarrow C^{xy} \otimes I^{xy}$ where $\otimes$ denotes the element-wise matrix product. Subsequently, we solve the generalized eigenvalue problem shown in Eq. 1 to obtain the projection directions. Let A and B be the matrices formed with top eigenvectors of Eq. 1 as the columns. These projection matrices are used to map documents into the interlingual representation. Such an interlingual representation is useful in many tasks like cross-lingual text categorization (Bel et al., 2003) multilingual web search (Gao et al., 2009) and so on.

During the testing, given an English document $\mathbf{x}$, finding an aligned Spanish document involves solving:

$$\arg\max_{\mathbf{y}} \frac{\mathbf{x}^T \Big((AB^T) \otimes I^{xy} \Big) \mathbf{y}}{\sqrt{\mathbf{x}^T \Big((AA^T) \otimes I^{xx} \Big) \mathbf{x}} \sqrt{\mathbf{y}^T \Big((BB^T) \otimes I^{yy} \Big) \mathbf{y}}}$$

If the documents are normalized before hand, then the above equation reduces to computing only the numerator.

4 Experiments

4.1 Experimental Setup

We experiment with the task of finding aligned documents from a cross-lingual comparable corpora. In this task, we are given comparable corpora consisting of two document collections, each in a different language. As the corpora are comparable, some documents in one collection have a comparable document in the other collection. The task is to recover

this hidden alignment. The recovered alignment is compared against the ground truth.

We evaluate our idea of sparsifying the covariance matrices incrementally. We first evaluate the effectiveness of our approach on synthetic data, as it enables us to systematically study the effect of noise. Subsequently, we evaluate each of the above discussed sparsification strategies on real world data sets. We have discussed four possible ways for computing word association measure and three approaches for word pair selection. That leaves us 12 different ways for sparsifying the covariance matrices, with each method having parameters to control the amount of sparseness. We use a small amount of development data for model selection and parameter tuning and choose a few promising models. Finally, we compare these selected models with state-of-the-art baselines on two language pairs and on two different data sets.

In each case, we use the training data to learn the projection directions. And then, for each of the test documents, we find the aligned document from other language. We report average accuracy of the top ranked document and also the Mean Reciprocal Rank (MRR) of the true aligned document.

4.2 Synthetic Data

We follow the generative story introduced in Bach and Jordan (2005) to generate synthetic multi-view data. Their method does not assume any correspondence between the feature dimensions of both the views. We modify their approach slightly so that we know the actual correspondence between the features. We use these true feature correspondences for sparsification of the cross-covariance matrix.

We first generate a d dimensional vector in the common latent space and then use the projection matrices to map it into the individual feature spaces as follows:

$$z \sim \mathcal{N}(0, I_d)$$
$$x|z \sim (W_1 z + \mu_1) + \eta\, \mathcal{N}(0, I_{d_1})$$
$$y|z \sim (W_1 z + \mu_2) + \eta\, \mathcal{N}(0, I_{d_2})$$

Notice that we use the same projection matrix W_1 for both the views, this ensures a one-to-one correspondence between the features of both the spaces. Moreover, we also introduce a parameter η which controls the amount of noise in the data.

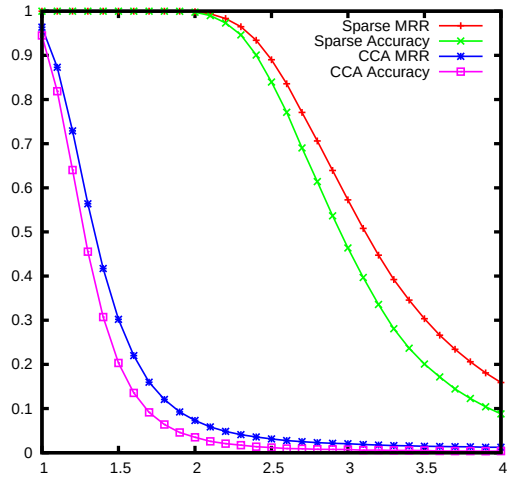

Figure 1: Accuracy of CCA and our sparsified version with the noise parameter.

We generate a total of 3000 pairs of points and use 2000 of them for training the models and the rest for evaluation. We use the true feature correspondences to form the cross-covariance selection matrix I^{xy} (Sec. 3.3). For this experiment, we use the full monolingual covariance matrices. We train both CCA and our sparse version on the training data and evaluate them on the test data. We repeat this multiple times and report the average accuracies. Fig. 1 shows the performance of CCA and our sparse CCA, as we vary the noise parameter η from 1 to 4. It is very clear that the sparse version performs significantly better than CCA. As the noise increases, the performance of CCA drops quickly. This experiment demonstrates a significant performance gain when the true correspondences are available. But this information is not available in the case of real world data sets, so we try to approximate it.

4.3 Model Selection

As we have discussed, there are several choices for computing the association measure and for selecting the word pairs to be retained. And each of them have sparsity parameters, giving raise to many possible models. For model selection, we use approximately 5000 document pairs collected from the Wikipedia between English and Spanish. We use the cross-language links provided as the ground truth. We tokenize the documents, retain only the most frequent 2000 words in each language and convert the docu-

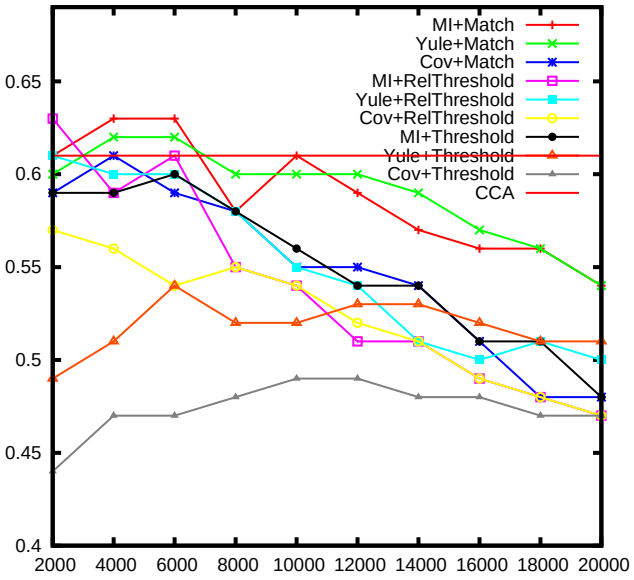

Figure 2: Comparison of the word association measures along with different selection criteria. The x-axis plots the number of non-zero entries in the covariance matrices and the y-axis plots the accuracy of top-ranked document.

ments into TFIDF vectors. We use 60% of the data for training different models and the rest for evaluating the models. We choose a few promising models based on this development set results and evaluate them on bigger data sets.

4.3.1 Selection Strategies

In the first experiment, we combine the three association measures, Covariance (Cov), MI and Yule's ω, with the three selection criteria, Threshold, Relative Threshold (RelThreshold) and Matching (Match). Fig. 2 shows the performance of these different combinations with varying levels of sparsity in the covariance matrices. The horizontal line represents the performance of CCA on this data set. We start with 2000 non-zero entries in the covariance matrices and experiment up to 20,000 non-zero entries. Since our data set has 2000 words in each language, 2000 non-zero entries in a covariance matrix implies that, on an average, every word is associated with only one word. This results in highly sparse covariance matrices.

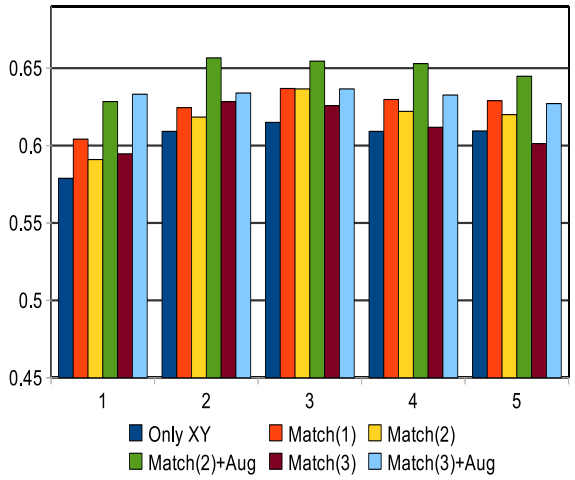
Overall, we observe that reducing the level of sparsity , *i.e.* selecting more number of elements in the covariance matrices, increases the performance slightly and then decreases again. From the figure, it seems that sparsifying the covariance matrices might help in improving the performance of the task. But it is interesting to note that not all the models perform better than CCA. In fact, both the models that achieve better scores use Matching as the selection criteria. This suggests that, apart from the weighting of the word pairs, appropriate selection of the word pairs is also equally important. In the rest of the experiments we mainly report results with Matching as the selection criterion. From this figure, we observe that Mutual Information and Yule's ω perform competitively but they consistently outperform models that use covariance as the association measure. So in the rest of the experiments we report results with MI or Yule's ω.

4.3.2 Amount of Sparsity

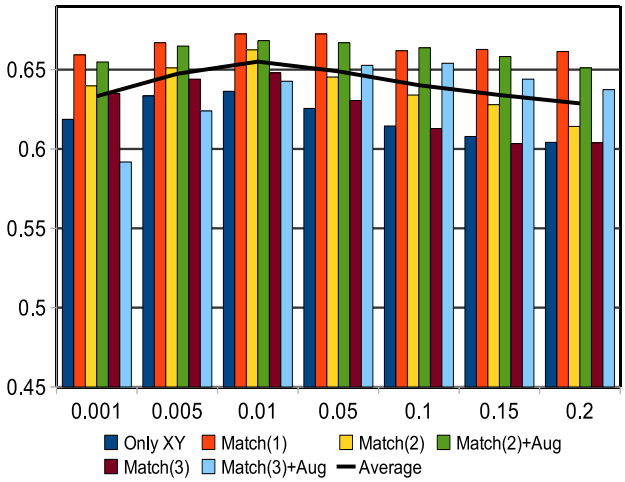
In the previous experiment, we used same level of sparsity for all the covariance matrices, *i.e.* same number of associations were selected for each word in all the three covariance matrices. In the following experiment, we use different levels of sparsity for the individual covariance matrices. Fig. 3 shows the performance of Yule+Match and Dictionary+Match combinations with different levels of sparsity. In the Yule+Match combination, we use Yule's ω association measure for weighting the word pairs and use matching for selection. In the Dictionary+Match combination, we use bilingual dictionary for sparsifying cross-covariance matrix, *i.e.* we keep all the word pairs whose conditional translation probability is above a threshold. And for monolingual word pairs, we use MI for weighting and matching for word pair selection.

For each level of sparsity of the cross-covariance matrix, we experiment with different levels of sparsity on the monolingual covariance matrices. 'Only XY' indicates we use the full monolingual covariance matrices. In 'Match(k)' runs, we allow each word to be associated with a total of k words (Eq. 5). 'Aug' indicates that we use monolingual augmentation to refine the sparsity of the cross-covariance matrix (Sec. 3.2.4).

From both the figures 3(a) and 3(b), we observe that 'Only XY' run (dark blue) performs poorly compared to the other runs, indicating that sparsifying all the covariance matrices is better than sparsifying only the cross-covariance matrix. In the



(a) Performance of Yule+Match combination. The x-axis plots the number of Spanish words selected per each English word and vice versa. This determines the sparsity of C^{xy}. Matching is used as selection criteria for all the covariance matrices.



(b) Performance of Dictionary+Match combination. The x-axis plots the threshold on bilingual translation probability and it determines the sparsity of C^{xy}. Matching is used to select *only* the monolingual sparsity.

Figure 3: Comparison of Yule+Match and Dictionary+Match combination with different levels of sparsity for the covariance matrices. In both the figures, the x-axis plots the sparsity of the cross-covariance matrix and for each value we try different levels of sparsity on the monolingual covariance matrices (which are grouped together). The description of these individual runs is provided in the relevant parts of the text. The y-axis plots the accuracy of the top-ranked document. CCA achieves 61% accuracy on this data set.

Yule+Match combination, Fig. 3(a), all the runs seem to be performing better when each English word is allowed to associate with 2 or 3 Spanish words and vice versa. Among different ways of selecting the monolingual word pairs, Match(2)+Aug performs better than the remaining runs. So we use Match(2)+Aug combination for the Yule's ω measure.

Unlike the Yule+Match combinations, there is no clear winner for Dictionary+Match combinations. First of all, the performance increase as we increase the translation probability threshold and then decreases again (indicated by the 'Average' performance in Fig. 3(b)). On an average, all the systems perform better with a threshold of 0.01, which we use in our final experiments. In this case, both Match(1) and Match(2)+Aug runs (orange and green bars respectively) perform competitively so we use both of these models in our final experiments.

In both the above experiments, the performance bars are very similar when we use MI instead of Yule and vice versa for weighting monolingual word pairs. Thus, to illustrate the main ideas we chose Yule's ω for the former combination and MI for the latter combination.

4.3.3 Promising Models

Based on the above experiments, we choose the following combinations for our final experiments. Yule(l)+Match(k), where $l \in \{2, 3\}$ is the number of Spanish words allowed for each English word and vice versa and k=2 is the number of monolingual word associations for each word. We also run both these combinations with monolingual augmentation, indicated by Yule(l)+Match(k)+Aug. For dictionary based weighting, Dictionary+Match(k), we choose a translation probability threshold of 0.01 and try $k \in \{1, 2\}$. Again, we run these combinations with monolingual augmentation identified by Dictionary+Match(k)+Aug.

4.4 Results

For our final results, we choose data in two language pairs (English-Spanish and English-German) from two different resources, Europarl (Koehn, 2005) and Wikipedia. For Europarl data sets, we artificially make them comparable by considering the first half

Table 1: Performance of our models in comparison with CCA and OPCA on English-Spanish and English-German language pairs. * and $^+$ indicate statistical significance measured by paired t-test at p=0.01 and 0.05 levels respectively. When an improvement is significant at p=0.01 it is automatically significant at p=0.05 and hence is not shown.

of English document and the second half of its aligned foreign language document (Mimno et al., 2009). For Wikipedia data set, we use the cross-language link as the ground truth. For each of these data sets, we choose approximately 5000 aligned document pairs. We remove the stop words and keep all the words that occur in at least five documents. After the preprocessing, on an average, we are left with 4700 words in each language. Subsequently we convert the documents into their TFIDF representation.

In Platt *et al.* (2010), the authors compare different systems on the comparable document retrieval task and show that discriminative approaches work better compared to their generative counter parts. So, here we compare only with the state-of-the-art discriminative systems such as CCA and OPCA (Platt et al., 2010). For each of the systems, we report the average results of five-fold cross validation. We divide the data into 3:1:1 ratio for training, validation and test sets. The validation data set is used to select the best number of dimensions of the common sub space. For both CCA and our models, we set the regularization parameter λ to 0.3 which we found works well in a relevant but different experiments. For OPCA, we manually tried different regularization parameters ranging from 0.0001 to 1 and found that a value of 0.001 worked best.

The results are shown in Table 1. On these data sets, both CCA and OPCA performed competitively. OPCA takes advantage of the common vocabulary in both the languages. But in our data sets, vocabulary of both the languages is treated differently, so it is not surprising that they give almost the same results. From the results, it is clear that sparsifying the covariance matrices helps improving the accuracies significantly. In all the four data sets, the best performing method always used dictionary for cross-lingual sparsity selection. This indicates that using fine granular information such as a bilingual dictionary gleaned from an external source is very helpful in improving the accuracies. Among the models that rely solely on the training data, models that use monolingual augmentation performed better on Wikipedia data set, while models that do not use augmentation performed better on Europarl data sets. This suggests that, when the aligned documents are clean (closer to being parallel) the statistics computed from cross-lingual corpora are trustworthy. As the documents become comparable, we need to use monolingual statistics to refine the bilingual statistics. Moreover, these models achieve higher gains in the case of Wikipedia data set compared to the gains in Europarl. This conforms with our initial hunch that, when the training data is clean the covariance matrices tend to be less noisy.

5 Discussion

In this paper, we have proposed the idea of sparsifyng covariance matrices to improve bilingual pro-

jection directions. We are not aware of any NLP research that attempts to recover the sparseness of the covariance matrices to improve the projection directions. Our work is different from the sparse CCA (Hardoon and Shawe-Taylor, 2011; Rai and Daumé III, 2009) proposed in the Machine Learning literature. Their objective is to find projection directions such that the original documents are represented as a sparse vectors in the common sub-space. Another seemingly relevant but different direction is the sparse covariance matrix selection research (Banerjee et al., 2005). The objective in this work is to find matrices such that the *inverse* of the covariance matrix is sparse which has applications in Gaussian processes.

In this paper, we tried sparsification in the context of CCA only but our technique is general and can be applied to its variants like OPCA. Our experimental results show that using external information such as bilingual dictionaries which is gleaned from cleaner resources brings significant improvements. Moreover, we also observe that computing word pair association measures from the same training data along with an appropriate selection criteria can *also* yield significant improvements. This is certainly encouraging and in future we would like to explore more sophisticated techniques to recover the sparsity based on the training data itself.

Entire Relaxation Path for Maximum Entropy Problems

Abstract

We discuss and analyze the problem of finding a distribution that minimizes the relative entropy to a prior distribution while satisfying max-norm constraints with respect to an observed distribution. This setting generalizes the classical maximum entropy problems as it relaxes the standard constraints on the observed values. We tackle the problem by introducing a re-parametrization in which the unknown distribution is distilled to a single scalar. We then describe a homotopy between the relaxation parameter and the distribution characterizing parameter. The homotopy also reveals an aesthetic symmetry between the prior distribution and the observed distribution. We then use the reformulated problem to describe a space and time efficient algorithm for tracking the *entire* relaxation path. Our derivations are based on a compact geometric view of the relaxation path as a piecewise linear function in a *two* dimensional space of the relaxation-characterization parameters. We demonstrate the usability of our approach by applying the problem to Zipfian distributions over a large alphabet.

1 Introduction

Maximum entropy (max-ent) models and its dual counterpart, logistic regression, is a popular and effective tool in numerous natural language processing tasks. The principle of maximum entropy was spelled out explicitly by E.T. Jaynes (1968). Applications of maximum entropy approach to natural language processing are numerous. A notable example and probably one of the earliest usages and generalizations of the maximum entropy principle to language processing is the work of Berger, Della Pietra$\times 2$, and Lafferty (Berger et al., 1996, Della Pietra et al., 1997). The original formulation of max-ent cast the problem as the task of finding the distribution attaining the highest entropy subject to *equality* constraints. While this formalism is aesthetic and paves the way to a simple dual in the form of a unique Gibbs distribution (Della Pietra et al., 1997), it does not provide sufficient tools to deal with input noise and sparse representation of the target Gibbs distribution. To mitigate these issues, numerous relaxation schemes of the equality constraints have been proposed. A notable recent work by Dudik, Phillips, and Schapire (2007) provided a general constraint-relaxation framework. See also the references therein for an in depth overview of other approaches and generalizations of max-ent. The constraint relaxation surfaces a natural parameter, namely, a relaxation value. The dual form of this free parameter is the regularization value of penalized logistic regression problems. Typically this parameter is set by experimentation using cross validation technique. The relaxed maximum-entropy problem setting is the starting point of this paper.

In this paper we describe and analyze a framework for *efficiently* tracking the entire relaxation path of constrained max-ent problems. We start in Sec. 2 with a generalization in which we discuss the problem of finding a distribution that minimizes the relative entropy to a given prior distribution while satisfying max-norm constraints with respect to an observed distribution. In Sec. 3 we tackle the problem by introducing a re-parametrization in which the

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 941–948,
Edinburgh, Scotland, UK, July 27–31, 2011.

unknown distribution is distilled to a single scalar. We next describe in Sec. 4 a homotopy between the relaxation parameter and the distribution characterizing parameter. This formulation also reveals an aesthetic symmetry between the prior distribution and the observed distribution. We use the reformulated problem to describe in Secs. 5-6 space and time efficient algorithms for tracking the *entire* relaxation path. Our derivations are based on a compact geometric view of the relaxation path as a piecewise linear function in a *two* dimensional space of the relaxation-characterization parameters. In contrast to common homotopy methods for the Lasso Osborne et al. (2000), our procedure for tracking the max-ent homotopy results in an uncharacteristically low complexity bounds thus renders the approach applicable for large alphabets. We provide preliminary experimental results with Zipf distributions in Sec. 8 that demonstrate the merits of our approach. Finally, we conclude in Sec. 9 with a brief discussion of future directions.

2 Notations and Problem Setting

We denote vectors with bold face letters, e.g. $\boldsymbol{v}$. Sums are denoted by calligraphic letters, e.g. $\mathcal{M} = \sum_j m_j$. We use the shorthand $[n]$ to denote the set of integers $\{1, \ldots, n\}$. The n'th dimensional simplex, denoted Δ, consists of all vectors $\boldsymbol{p}$ such that, $\sum_{j=1}^n p_j = 1$ and for all $j \in [n]$, $p_j \geq 0$. We generalize this notion to multiplicity weighted vectors. Formally, we say that a vector $\boldsymbol{p}$ with multiplicity $\boldsymbol{m}$ is in the simplex, $(\boldsymbol{p}, \boldsymbol{m}) \in \Delta$, if $\sum_{j=1}^n m_j p_j = 1$, and for all $j \in [n]$, $p_j \geq 0$, and $m_j \geq 0$.

The generalized relaxed maximum-entropy problem is concerned with obtaining an estimate $\boldsymbol{p}$, given a prior distribution $\boldsymbol{u}$ and an observed distribution $\boldsymbol{q}$ such that the relative entropy between $\boldsymbol{p}$ and $\boldsymbol{u}$ is as small as possible while $\boldsymbol{p}$ and $\boldsymbol{q}$ are within a given max-norm tolerance. Formally, we cast the following constrained optimization problem,

$$\min_{\boldsymbol{p}} \sum_{j=1}^n m_j p_j \log\left(\frac{p_j}{u_j}\right) \quad , \tag{1}$$

such that $(\boldsymbol{p}, \boldsymbol{m}) \in \Delta$; $\|\boldsymbol{p} - \boldsymbol{q}\|_\infty \leq 1/\nu$. The vectors $\boldsymbol{u}$ and $\boldsymbol{q}$ are dimensionally compatible with $\boldsymbol{p}$, namely, $(\boldsymbol{q}, \boldsymbol{m}) \in \Delta$ and $(\boldsymbol{u}, \boldsymbol{m}) \in \Delta$. The scalar ν is a relaxation parameter. We use $1/\nu$ rather than ν itself for reasons that become clear in the sequel.

We next describe the dual form of (1). We derive the dual by introducing Lagrange-Legendre multipliers for each of the constraints appearing in (1). Let $\alpha_j^+ \geq 0$ denote the multiplier for the constraint $q_j - p_j \leq 1/\nu$ and $\alpha_j^- \geq 0$ the multiplier for the constraint $q_j - p_j \geq -1/\nu$. In addition, we use γ as the multiplier for the constraint $\sum_j m_j p_j = 1$. fter some routine algebraic manipulations we get that the Lagrangian is,

$$\begin{aligned} &\textstyle\sum_{j=1}^n m_i \left(p_j \log\left(\frac{p_j}{u_j}\right) + \alpha_j (q_j - p_j) + \frac{|\alpha_j|}{\nu} \right) \\ &\qquad + \gamma \left(\textstyle\sum_{j=1}^n m_j p_j - 1 \right) \quad . \end{aligned} \tag{2}$$

To find the dual form we take the partial derivative of the Lagrangian with respect to each p_j, equate to zero, and get that $\log\left(\frac{p_j}{u_j}\right) + 1 - \alpha_j + \gamma = 0$, which implies that $p_j \sim u_j e^{\alpha_j}$. We now employ the fact that $(\boldsymbol{p}, \boldsymbol{m}) \in \Delta$ to get that the exact form for p_j is

$$p_j = \frac{u_j \mathrm{e}^{\alpha_j}}{\sum_{i=1}^n m_i u_i \mathrm{e}^{\alpha_i}} \quad . \tag{3}$$

Using (3) in the compact form of the Lagrangian we obtain the following dual problem

$$\max_{\boldsymbol{\alpha}} - \left\{ \log(Z) - \sum_{j=1}^n m_j q_j \alpha_j + \sum_{j=1}^n \frac{m_j}{\nu} |\alpha_j| \right\} \quad , \tag{4}$$

where $Z = \sum_{j=1}^n m_j u_j \mathrm{e}^{\alpha_j}$. We make rather little use of the dual form of the problem. However, the complementary slackness conditions that are necessary for optimality to hold play an important role in the next section in which we present a reformulation of the relaxed maximum entropy problem.

3 Problem Reformulation

First note that the primal problem is a strictly convex function over a compact convex domain. Thus, its optimum exists and is unique. Let us now characterize the form of the solution. We partition the set of indices in $[n]$ into three disjoint sets depending on whether the constraint $|p_j - q_j| \leq 1/\nu$ is active and its form. Concretely, we define

$$\begin{aligned} I_- &= \{1 \leq j \leq n \mid p_j = q_j - 1/\nu\} \\ I_0 &= \{1 \leq j \leq n \mid |p_j - q_j| < 1/\nu\} \\ I_+ &= \{1 \leq j \leq n \mid p_j = q_j + 1/\nu\} \quad . \end{aligned} \tag{5}$$

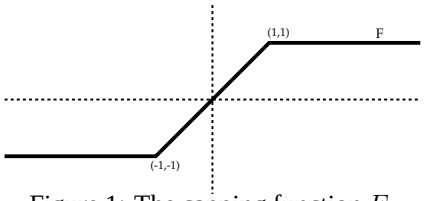

Figure 1: The capping function F.

Recall that $Z = \sum_{j=1}^{n} m_j u_j e^{\alpha_j}$. Thus, from (3) we can rewrite $p_j = u_j e^{\alpha_j}/Z$. We next use the complementary slackness conditions (see for instance (Boyd and Vandenberghe, 2004)) to further characterize the solution. For any $j \in I_-$ we must have $\alpha_j^- = 0$ and $\alpha_j^+ \geq 0$ therefore $\alpha_j \geq 0$, which immediately implies that $p_j \geq u_j/Z$. By definition we have that $p_j = q_j - 1/\nu$ for $j \in I_-$. Combining these two facts we get that $u_j/Z \leq q_j - 1/\nu$ for $j \in I_-$. Analogous derivation yields that $u_j/Z \geq q_j + 1/\nu$ for $j \in I_+$. Last, if the set I_0 is not empty then for each j in I_0 we must have $\alpha_j^+ = 0$ and $\alpha_j^- = 0$ thus $\alpha_j = 0$. Resorting again to the definition of $\boldsymbol{p}$ from (3) we get that $p_j = u_j/Z$ for $j \in I_0$. Since $|p_j - q_j| < 1/\nu$ for $j \in I_0$ we get that $|u_j/Z - q_j| < 1/\nu$. To recap, there exists $Z > 0$ such that the optimal solution takes the following form,

$$p_j = \begin{cases} q_j - 1/\nu & u_j/Z \leq q_j - 1/\nu \\ u_j/Z & |u_j/Z - q_j| < 1/\nu \\ q_j + 1/\nu & u_j/Z \geq q_j + 1/\nu \end{cases} \quad . \tag{6}$$

We next introduce an key re-parametrization, defining $\mu = \nu/Z$. We also denote by $F(\cdot)$ the capping function $F(x) = \max\{-1, \min\{1, x\}\}$. A simple illustration of the capping function is given in Fig. 1. Equipped with these definition we can rewrite (6) as follows,

$$p_j = q_j + \frac{1}{\nu} F(\mu u_j - \nu q_j) \ . \tag{7}$$

Given $\boldsymbol{u}$, $\boldsymbol{q}$, and ν, the value of μ can be found by using $\sum_j m_j p_j = \sum_j m_j q_j = 1$, which implies

$$G(\nu, \mu) \stackrel{\text{def}}{=} \sum_{j=1}^{n} m_j F(\mu u_j - \nu q_j) = 0 \ . \tag{8}$$

We defer the derivation of the actual algorithm for computing μ (and in turn $\boldsymbol{p}$) to the next section. In the meanwhile let us continue to explore the rich structure of the general solution. Note that $\mu, \boldsymbol{u}$ are interchangeable with $\nu, \boldsymbol{q}$. We can thus swap the roles of the prior distribution with the observed distribution and obtain an analogous characterization. In the next section we further explore the dependence of μ on ν. The structure we reveal shortly serves as our infrastructure for deriving efficient algorithms for following the regularization path.

4 The function $\mu(\nu)$

In order to explore the dependency of μ on ν let us introduce the following sums

$$\begin{aligned} \mathcal{M} &= \sum_{j \in I_+} m_j - \sum_{j \in I_-} m_j \\ \mathcal{U} &= \sum_{j \in I_0} m_j \, u_j \\ \mathcal{Q} &= \sum_{j \in I_0} m_j \, q_j \ . \end{aligned} \tag{9}$$

Fixing ν and using (9), we can rewrite (8) as follows

$$\mu \mathcal{U} - \nu \mathcal{Q} + \mathcal{M} = 0 \ . \tag{10}$$

Clearly, so long as the partition of $[n]$ into the sets I_+, I_-, I_0 is intact, there is a simple linear relation between μ and ν. The number of possible subsets I_-, I_0, I_+ is finite. Thus, the range $0 < \nu < \infty$ decomposes into a finite number of intervals each of which corresponds to a fixed partition of $[n]$ into I_+, I_-, I_0. In each interval μ is a linear function of ν, unless I_0 is empty. Let ν_∞ be the smallest ν value for which I_0 is empty. Let μ_∞ be its corresponding μ value. If I_0 is never empty for any finite value of ν we define $\nu_\infty = \mu_\infty = \infty$. Clearly, replacing (ν, μ) with $(\kappa\nu, \kappa\mu)$ for any $\kappa \geq 1$ and $\nu \geq \nu_\infty$ yields the same feasible solution as $I_+(\kappa\nu) = I_+(\nu)$, $I_-(\alpha\nu) = I_-(\nu)$. Hence, as far as the original problem is concerned there is no reason to go past ν_∞ during the process of characterizing the solution. We recap our derivation so far in the following lemma.

Lemma 4.1 *For $0 \leq \nu \leq \nu_\infty$, the value of μ as defined by (7) is a unique. Further, the function $\mu(\nu)$ is a piecewise linear continuous function in ν. When $\nu \geq \nu_\infty$ letting $\mu = \mu_\infty \nu/\nu_\infty$ keeps (7) valid.*

We established the fact that $\mu(\nu)$ is a piecewise linear function. The lingering question is how many

linear sub-intervals the function can attain. To study this property, we take a geometric view of the plane defined by (ν, μ). Our combinatorial characterization of the number of sub-intervals makes use of the following definitions of lines in $\mathbb{R}^2$,

$$\ell_{+j} = \{(\nu,\mu) \mid u_j\mu - q_j\nu = +1\} \quad (11)$$
$$\ell_{-j} = \{(\nu,\mu) \mid u_j\mu - q_j\nu = -1\} \quad (12)$$
$$\ell_0 = \{(\nu,\mu) \mid \mu\mathcal{U} - \nu\mathcal{Q} + \mathcal{M} = 0\} \ , \quad (13)$$

where $-\infty < \nu < \infty$ and $j \in [n]$. The next theorem gives an upper bound on the number of linear segments the function $\mu()$ may attain. While the bound is quadratic in the dimension, for both artificial data and real data the bound is way too pessimistic.

Theorem 4.2 *The piecewise linear function $\mu(\nu)$ consists of at most n^2 linear segments for $\nu \in \mathbb{R}_+$.*

Proof Since we showed that that $\mu(\nu)$ is a piecewise linear function, it remains to show that it has at most n^2 linear segments. Consider the two dimensional function $G(\nu, \mu)$ from (8). The (ν, μ) plane is divided by the $2n$ straight lines $\ell_1, \ell_2, \ldots, \ell_n, \ell_{-1}, \ell_{-2}, \ldots, \ell_{-n}$ into at most $2n^2+1$ polygons. The latter property is proved by induction. It clearly holds for $n = 0$. Assume that it holds for $n-1$. Line ℓ_n intersects the previous $2n-2$ lines at no more than $2n-2$ points, thus splitting at most $2n-1$ polygons into two separate polygonal parts. Line ℓ_{-n} is parallel to ℓ_n, again adding at most $2n-1$ polygons. Recapping, we obtain at most $2(n-1)^2 + 1 + 2(2n-1) = 2n^2 + 1$ polygons, as required per induction. Recall that $\mu(\nu)$ is linear inside each polygon. The two extreme polygons where $G(\nu, \mu) = \pm\sum_{j=1}^n m_j$ clearly disallow $G(\nu, \mu) = 0$, hence $\mu(\nu)$ can have at most $2n^2 - 1$ segments for $-\infty < \nu < \infty$. Lastly, we use the symmetry $G(-\nu, -\mu) = -G(\nu, \mu)$ which implies that for $\nu \in \mathbb{R}_+$ there are at most n^2 segments. ■

This result stands in contrast to the Lasso homotopy tracking procedure (Osborne et al., 2000), where the worst case number of segments seems to be exponential in n. Moreover, when the prior $\boldsymbol{u}$ is uniform, $u_j = 1/\sum_{j=1}^n m_j$ for all $j \in [n]$, the number of segments is at most $n+1$. We defer the analysis of the uniform case to a later section as the proof stems from the algorithm we describe in the sequel.

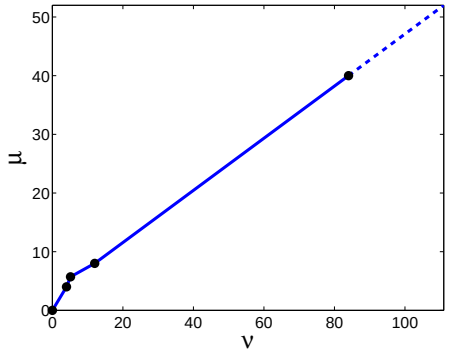

Figure 2: An illustration of the function $\mu(\nu)$ for a synthetic 3 dimensional example.

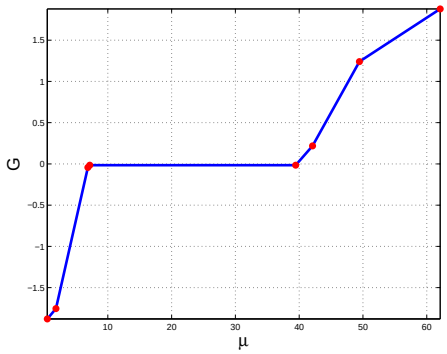

Figure 3: An illustration of the function $G(\mu)$ for a synthetic 4 dimensional example and a $\nu = 17$.

5 Algorithm for a Single Relaxation Value

Suppose we are given $\boldsymbol{u}, \boldsymbol{q}, \boldsymbol{m}$ and a specific relaxation value $\tilde{\nu}$. How can we find $\boldsymbol{p}$? The obvious approach is to solve the one dimensional monotonically nondecreasing equation $G(\mu) \stackrel{\text{def}}{=} G(\tilde{\nu}, \mu) = 0$ by bisection. In this section we present a more efficient and direct procedure that is guaranteed to find the optimal solution $\boldsymbol{p}$ in a finite number of steps. Clearly $G(\mu)$ is a piecewise linear function with at most $2n$ easily computable change points of the slope. See also Fig. (5) for an illustration of $G(\cdot)$. In order to find the slope change points we need to calculate the point (ν, μ_j) for all the lines $\ell_{\pm j}$ where $1 \le j \le n$. Concretely, these values are

$$\mu_j = \frac{\nu q_{|j|} + \text{sign}(j)}{u_{|j|}} \ . \quad (14)$$

We next sort the above values of μ_j and denote the resulting sorted list as $\mu_{\pi_1} \le \mu_{\pi_2} \le \cdots \le \mu_{\pi_{2n}}$. For any $0 \le j \le 2n$ let $\mathcal{M}_j, \mathcal{U}_j, \mathcal{Q}_j$ be the sums, defined

in (9), for the line segment $\mu_{\pi_{j-1}} < \mu < \mu_{\pi_j}$ (denoting $\mu_{\pi_0} = -\infty$, $\mu_{\pi_{2n+1}} = \infty$). We compute the sums $\mathcal{M}_j, \mathcal{U}_j, \mathcal{Q}_j$ incrementally, starting from $\mathcal{M}_0 = -\sum_{i=1}^n m_i$, $\mathcal{U}_0 = \mathcal{Q}_0 = 0$. Once the values of $j-1$'th sums are known, we can compute the next sums in the sequence as follows,

$$\begin{aligned} \mathcal{M}_j &= \mathcal{M}_{j-1} + m_{|\pi_j|} \\ \mathcal{U}_j &= \mathcal{U}_{j-1} - \mathrm{sign}(\pi_j)\, m_{|\pi_j|}\, u_{|\pi_j|} \\ \mathcal{Q}_j &= \mathcal{Q}_{j-1} - \mathrm{sign}(\pi_j)\, m_{|\pi_j|}\, q_{|\pi_j|} \ . \end{aligned}$$

From the above sums we can compute the value of the function $G(\nu, \mu)$ at the end point of the line segment $(\mu_{\pi_{j-1}}, \mu_{\pi_j})$, which is the same as the start point of the line segment $(\mu_{\pi_j}, \mu_{\pi_{j+1}})$,

$$\begin{aligned} G_j &= \mathcal{M}_{j-1} + \mathcal{U}_{j-1}\,\mu_j - \mathcal{Q}_{j-1}\,\nu \\ &= \mathcal{M}_j + \mathcal{U}_j\,\mu_j - \mathcal{Q}_j\,\nu \ . \end{aligned}$$

The optimal value of μ resides in the line segment for which $G(\cdot)$ attains 0. Such a segment must exist since $G_0 = \mathcal{M}_0 = -\sum_{i=1}^n m_i < 0$ and $G_{2n} = -\mathcal{M}_0 > 0$. Therefore, there exists an index $1 \le j < 2n$, where $G_j \le 0 \le G_{j+1}$. Once we bracketed the feasible segment for μ, the optimal value of μ is found by solving the linear equation (10),

$$\mu = \left(\mathcal{Q}_j\,\nu - \mathcal{M}_j\right)/\mathcal{U}_j \quad . \tag{15}$$

From the optimal value of μ it is straightforward to construct $\boldsymbol{p}$ using (7). Due to the sorting step, the algorithm's run time is $O(n\log(n))$ and it takes linear space. The number of operations can be reduced to $O(n)$ using a randomized search procedure.

6 Homotopy Tracking

We now shift gears and focus on the main thrust of this paper, namely, an efficient characterization of the *entire* regularization path for the maximum entropy problem. Since we have shown that the optimal solution $\boldsymbol{p}$ can be straightforwardly obtained from the variable μ, it suffices to efficiently track the function $\mu(\nu)$ as we traverse the plane (ν, μ) from $\nu = 0$ through the last change point which we denoted as (ν_∞, μ_∞). In this section we give an algorithm that traverses $\mu(\nu)$ by locating the intersections of ℓ_0 with the fixed lines $\ell_{-n}, \ell_{-n+1}, \ldots, \ell_{-1}, \ell_1, \ldots, \ell_n$ and updating ℓ_0 after each intersection.

More formally, the local homotopy tracking follows the piecewise linear function $\mu(\nu)$, segment by segment. Each segment corresponds to a subset of the line ℓ_0 for a *given* triplet $(\mathcal{M}, \mathcal{U}, \mathcal{Q})$. It is simple to show that $\mu(0) = 0$, hence we start with

$$\nu = 0,\ \mathcal{M} = 0,\ \mathcal{U} = \mathcal{Q} = 1 \ . \tag{16}$$

We now track the value of μ as ν increases, and the relaxation parameter $1/\nu$ decreases. The characterization of ℓ_0 remains intact until ℓ_0 hits one of the lines ℓ_j for $1 \le |j| \le n$. To find the line intersecting ℓ_0 we need to compute the potential intersection points $(\nu_j, \mu_j) = \ell_0 \cap \ell_j$ which amounts to calculating $\nu_{-n}, \nu_{-n+1}, \ldots, \nu_{-1}, \nu_1, \nu_2, \cdots, \nu_n$ where

$$\nu_j = \frac{\mathcal{M} u_{|j|} + \mathcal{U}\mathrm{sign}(j)}{\mathcal{Q} u_{|j|} - \mathcal{U} q_{|j|}} \ . \tag{17}$$

The lines for which the denominator is zero correspond to infeasible intersection and can be discarded. The smallest value ν_j which is larger than the current traced value of ν corresponds to the next line intersecting ℓ_0.

While the above description is mathematically sound, we devised an equivalent intersection inspection scheme which is more numerically stable and efficient. We keep track of partition I_-, I_0, I_1 through the vector,

$$s_j = \begin{cases} -1 & j \in I_- \\ 0 & j \in I_0 \\ +1 & j \in I_+ \end{cases} \ .$$

Initially $s_1 = s_2 = \cdots = s_n = 0$. What kind of intersection does ℓ_0 have with ℓ_j? Recall that $\frac{\mathcal{Q}}{\mathcal{U}}$ is the slope of ℓ_0 while $\frac{q_{|j|}}{u_{|j|}}$ is the slope of ℓ_j. Thus $\frac{\mathcal{Q}}{\mathcal{U}} > \frac{q_{|j|}}{u_{|j|}}$ means that the $|j|$'th constraint is moving "up" from I_- to I_0 or from I_0 to I_+. When $\frac{\mathcal{Q}}{\mathcal{U}} < \frac{q_{|j|}}{u_{|j|}}$ the $|j|$'th constraint is moving "down" from I_+ to I_0 or from I_0 to I_-. See also Fig. 4 for an illustration of the possible transitions between the sets. For instance, the slope of $\mu(\nu)$ on the bottom left part of the figure is larger than the slope the line it intersects. Since this line defines the boundary between I_- and I_0, we transition from I_- to I_0. We need only consider $1 \le |j| \le n$ of the following types. Moving "up" from I_- to I_0 requires

$$s_{|j|} = -1 \qquad j < 0 \qquad \mathcal{Q} u_{|j|} - \mathcal{U} q_{|j|} > 0 \ .$$

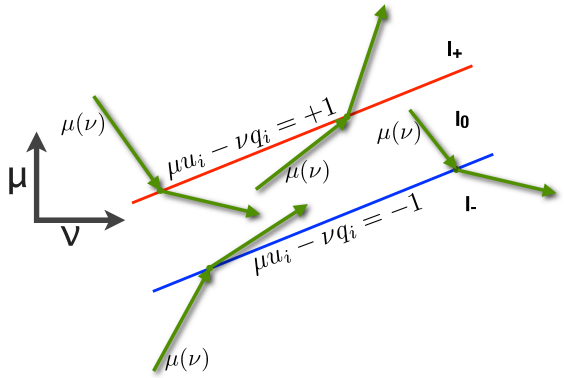

Figure 4: Illustration of the possible intersections between $\mu(\nu)$ and ℓ_j and the corresponding transition between the sets $I_\pm, I_0$.

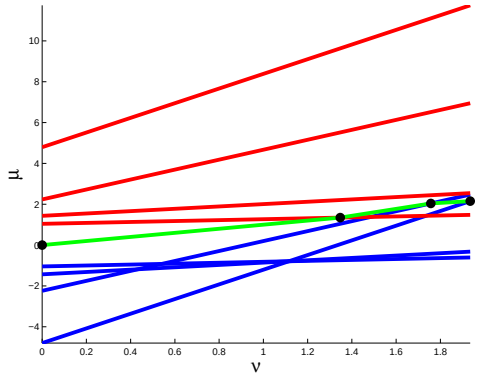

Figure 5: The result of the homotopy tracking for a 4 dimensional problem. The lines ℓ_j for $j < 0$ are drawn in blue and for $j > 0$ in red. The function $\mu(\nu)$ is drawn in green and its change points in black. Note that although the dimension is 4 the number of change points is rather small and does not exceed 4 either in this simple example.

Similarly, moving "down" from I_+ to I_0 requires

$$s_{|j|} = 1 \qquad j > 0 \qquad \mathcal{Q}u_{|j|} - \mathcal{U}q_{|j|} < 0 \ .$$

Finally, moving "up" or "down" from I_0 entails

$$s_{|j|} = 0 \qquad j(\mathcal{Q}u_{|j|} - \mathcal{U}q_{|j|}) > 0 \ .$$

If there are no eligible ν_j's, we have finished traversing $\mu()$. Otherwise let index j belong to the the smallest eligible ν_j. Infinite accuracy guarantees that $\nu_j \geq \nu$. In practice we perform the update

$$\begin{aligned}
\nu &\leftarrow \max(\nu, \nu_j) \\
\mathcal{M} &\leftarrow \mathcal{M} + \operatorname{sign}(\mathcal{Q}u_{|j|} - \mathcal{U}q_{|j|})\, m_{|j|} \\
\mathcal{U} &\leftarrow \mathcal{U} + \left(2\left|s_{|j|}\right| - 1\right)\, m_{|j|}\, u_{|j|} \\
\mathcal{Q} &\leftarrow \mathcal{Q} + \left(2\left|s_{|j|}\right| - 1\right)\, m_{|j|}\, q_{|j|} \\
s_j &\leftarrow s_j + \operatorname{sign}(\mathcal{Q}u_{|j|} - \mathcal{U}q_{|j|}) \ .
\end{aligned}$$

We are done with the tracking process when I_0 is empty, i.e. for all j $s_j \neq 0$.

The local homotopy algorithm takes $O(n)$ memory and $O(nk)$ operations where k is the number of change points in the function $\mu(\nu)$. This algorithm is simple to implement, and when k is relatively small it is efficient. An illustration of the tracking result, $\mu(\nu)$, along with the lines $\ell_{\pm j}$, that provide a geometrical description of the problem, is given in Fig. 5.

7 Uniform Prior

We chose to denote the prior distribution as $\boldsymbol{u}$ to underscore the fact that in the case of no prior knowledge $\boldsymbol{u}$ is the *uniform* distribution,

$$\mathrm{u} \stackrel{\text{def}}{=} u_j = \left(\sum_{i=1}^{n} m_i\right)^{-1} \ .$$

In this case the objective function amounts to the negative entropy and by flipping the sign of the objective we obtain the classical maximum entropy problem. The fact that the prior probability is the same for all possible observations infuses the problem with further structure which we show how to exploit in this section. Needless to say though that all the results we obtained thus far are still valid.

Let us consider a point (ν, μ) on the boundary between I_0 and I_+, namely, there exist a line ℓ_{+i} such that,

$$\mu u_i - \nu q_i = \mu \mathrm{u} - \nu q_i = 1 \ .$$

By definition, for any $j \in I_0$ we have

$$\mu u_j - \nu q_j = \mu \mathrm{u} - \nu q_j < 1 = \mu \mathrm{u} - \nu q_i \ .$$

Thus, $q_i < q_j$ for all $j \in I_0$ which implies that

$$m_j \,\mathrm{u}\, q_j \ > \ m_j \,\mathrm{u}\, q_i \ . \tag{18}$$

Summing over $j \in I_0$ we get that

$$\mathcal{Q}\,\mathrm{u} \ = \ \sum_{j \in I_0} m_j \, q_j \,\mathrm{u} \ > \ \sum_{j \in I_0} m_j \,\mathrm{u}\, q_i \ = \ \mathcal{U} q_i \ ,$$

hence,

$$\frac{q_i}{u_i} = \frac{q_i}{\mathrm{u}} < \frac{\mathcal{Q}}{\mathcal{U}}$$

and we must be moving "up" from I_0 to I_+ when the line ℓ_0 hits ℓ_i. Similarly we must be moving "down" from when ℓ_0 hits on the boundary between I_0 and I_-. We summarize these properties in the following theorem.

Theorem 7.1 *When the prior distribution $\boldsymbol{u}$ is uniform, $I_-(\nu)$ and $I_+(\nu)$ are monotonically nondecreasing and $I_0(\nu)$ is monotonically nonincreasing in $\nu > 0$. Further, the piecewise linear function $\mu(\nu)$ consists of at most $n+1$ line segments.*

The homotopy tracking procedure when the prior is uniform is particularly simple and efficient. Intuitively, there is a sole condition which controls the order in which indices would enter $I_\pm$ from I_0, which is simply how "far" each q_i is from u, the single prior value. Therefore, the algorithm starts by sorting $\boldsymbol{q}$. Let $q_{\pi_1} > q_{\pi_2} > \cdots > q_{\pi_n}$ denote the sorted vector. Instead of maintaining the vector of set indicators $\boldsymbol{s}$, we merely maintain two indices j_- and j_+ which designate the size of I_- and I_+ that were constructed thus far. Due to the monotonicity property of the sets $I_\pm$ as ν grows, the two sets can be written as, $I_- = \{\pi_j \,|\, 1 \le j < j_-\}$ and $I_+ = \{\pi_j \,|\, j_+ < j \le n\}$. The homotopy tracking procedure starts as before with $\nu = 0$, $\mathcal{M} = 0$, $\mathcal{U} = \mathcal{Q} = 1$. We also set $j_- = 1$ and $j_+ = n$ which by definition imply that $I_\pm$ are empty and $I_0 = [n]$. In each tracking iteration we need to compare only two values which we compactly denote as,

$$\nu_\pm = \frac{\mathcal{M}\mathrm{u} \pm \mathcal{U}}{\mathcal{Q}\mathrm{u} - \mathcal{U} q_{\pi_{j_\pm}}} \ .$$

When $\nu_- \le \nu_+$ we just encountered a transition from I_0 to I_- and as we encroach I_- we perform the updates, $\nu \leftarrow \nu_-$, $\mathcal{M} \leftarrow \mathcal{M} - m_{\pi_{j_-}}$, $\mathcal{U} \leftarrow \mathcal{U} - m_{\pi_{j_-}}\mathrm{u}$, $\mathcal{Q} \leftarrow \mathcal{Q} - m_{\pi_{j_-}} q_{\pi_{j_-}}$, $j_- \leftarrow j_- + 1$. Similarly when $\nu_- > \nu_+$ we perform the updates $\nu \leftarrow \nu_+$, $\mathcal{M} \leftarrow \mathcal{M} + m_{\pi_{j_+}}$, $\mathcal{U} \leftarrow \mathcal{U} - m_{\pi_{j_+}}\mathrm{u}$, $\mathcal{Q} \leftarrow \mathcal{Q} - m_{\pi_{j_+}} q_{\pi_{j_+}}$, $j_+ \leftarrow j_+ - 1$.

The tracking process stops when $j_- > j_+$ as we exhausted the transitions out of the set I_0 which becomes empty. Homotopy tracking for a uniform prior takes $O(n)$ memory and $O(n \log(n))$ operations and is very simple to implement.

We also devised a global homotopy tracking algorithms that requires a priority queue which facilitates insertions, deletions, and finding the largest element in the queue in $O(\log(n))$ time. The algorithm requires $O(n)$ memory and $O(n^2 \log(n))$ operations. Clearly, if the number of line segments constituting $\mu(\nu)$ is greater than $n \log(n)$ (recall that the upper bound is $O(n^2)$) then the global homotopy procedure is faster than the local one. However, as we show in Sec. 8, in practice the number of line segments is merely linear and it thus suffices to use the local homotopy tracking algorithm.

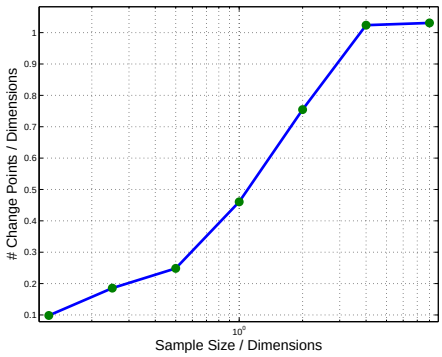

Figure 6: The number of line-segments in the homotopy as a function of the number of samples used to build the observed distribution $\boldsymbol{q}$.

8 Number of line segments in practice

The focus of the paper is the design and analysis of a novel homotopy method for maximum entropy problems. We thus left with relatively little space to discuss the empirical aspects of our approach. In this section we focus on one particular experimental facet that underscores the usability of our apparatus. We briefly discuss current natural language applications that we currently work on in the next section.

The practicality of our approach hinges on the number of line segments that occur in practice. Our bounds indicate that this number can scale quadratically with the dimension, which would render the homotopy algorithm impractical when the size of the alphabet is larger than a few thousands. We therefore extensively tested the *actual* number of line segments in the resulting homotopy when $\boldsymbol{u}$ and $\boldsymbol{q}$ are Zipf (1949) distributions. We used an alphabet of size $50,000$ in our experiments. The distribution $\boldsymbol{u}$ was set to be the Zipf distribution with an offset parameter of 2, that is, $u_i \sim 1/(i+2)$. We defined a "mother" distribution for $\boldsymbol{q}$, denoted $\bar{\boldsymbol{q}}$, which is

a plain Zipf distribution without an offset, namely $\bar{q}_i \sim 1/i$. We then sampled $n/2^l$ letters according to the distribution $\bar{\boldsymbol{q}}$ where $l \in -3, \ldots, 3$. Thus the smallest sample was $n/2^3 = 6,250$ and the largest sample was $n/3^{-3} = 40,000$. Based on the sample we defined the observed distribution $\boldsymbol{q}$ such that q_i is proportional to the number of times the i'th letter appeared in the sample. We repeated the process 100 times for each sample size and report average results. Note that when the sample is substantially smaller than the dimension the observed distribution $\boldsymbol{q}$ tends to be "simple" as it consists of many zero components. In Fig. 6 we depict the average number line segments for each sample size. When the sample size is one eighth of the dimension we average st most $0.1\,n$ line segments. More importantly, even when the size of the sample is fairly large, the number of lines segments is linear in the dimension with a constant close to one. We also performed experiments with large sample sizes for which the empirical distribution $\boldsymbol{q}$ is very close to the mother distribution $\bar{\boldsymbol{q}}$. We seldom found that the number of line segments exceeds $4n$ and the mode is around $2n$. These findings render our approach usable even in the very large natural language applications.

9 Conclusions

We presented a novel efficient apparatus for tracking the entire relaxation path of maximum entropy problems. We currently study natural language processing applications. In particular, we are in the process of devising homotopy methods for domain adaptation Blitzer (2008) and language modeling based on context tree weighting (Willems et al., 1995). We also examine generalization of our approach in which the relative entropy objective is replaced with a separable Bregman (Censor and Zenios, 1997) function. Such a generalization is likely to distill further connections to the other homotopy methods, in particular the least angle regression algorithm of Efron et al. (2004) and homotopy methods for the Lasso in general (Osborne et al., 2000). We also plan to study separable Bregman functions in order to derive entire path solutions for less explored objectives such as the Itakura-Saito spectral distance (Rabiner and Juang, 1993) and distances especially suited for natural language processing.

A Non-negative Matrix Factorization Based Approach for Active Dual Supervision from Document and Word Labels

Chao Shen and **Tao Li**

Florida International University
Miami, FL 33199 USA
{cshen001,taoli}@cs.fiu.edu

Abstract

In active dual supervision, not only informative examples but also features are selected for labeling to build a high quality classifier with low cost. However, how to measure the informativeness for both examples and feature on the same scale has not been well solved. In this paper, we propose a non-negative matrix factorization based approach to address this issue. We first extend the matrix factorization framework to explicitly model the corresponding relationships between feature classes and examples classes. Then by making use of the reconstruction error, we propose a unified scheme to determine which feature or example a classifier is most likely to benefit from having labeled. Empirical results demonstrate the effectiveness of our proposed methods.

1 Introduction

Active learning, as an effective paradigm to optimize the learning benefit from domain experts' feedback and to reduce the cost of acquiring labeled examples for supervised learning, has been intensively studied in recent years (McCallum and Nigam, 1998; Tong and Koller, 2002; Settles, 2009). Traditional approaches for active learning query the human experts to obtain the labels for intelligently chosen data samples. However, in text classification where the input data is generally represented as document-word matrices, human supervision can be obtained on both documents and words. For example, in sentiment analysis of product reviews, human labelers can label reviews as positive or negative, they can also label the words that elicit positive sentiment (such as "sensational" and "electrifying") as positive and words that evoke negative sentiment (such as "depressed" and "unfulfilling") as negative. Recent work has demonstrated that labeled words (or feature supervision) can greatly reduce the number of labeled samples for building high-quality classifiers (Druck et al., 2008; Zaidan and Eisner, 2008). In fact, different kinds of supervision generally have different acquisition costs, different degrees of utility and are not mutually redundant (Sindhwani et al., 2009). Ideally, effective active learning schemes should be able to utilize different forms of supervision.

To incorporate the supervision on words and documents at same time into the active learning scheme, recently an active dual supervision (or dual active learning) has been proposed (Melville and Sindhwani, 2009; Sindhwani et al., 2009). Comparing with traditional active learning which aims to select the most "informative" examples (e.g., documents) for domain experts to label, active dual supervision selects both the "informative" examples (e.g., documents) and features (e.g., words) for labeling. For active dual supervision to be effective, there are three important components: a) an underlying learning mechanism that is able to learn from both the labeled examples and features (i.e., incorporating supervision on both examples and features); b) methods for estimating the value of information for example and feature labels; and c) a scheme that should be able to trade-off the costs and benefits of the different forms of supervision since they have different labeling costs and different benefits.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 949–958,
Edinburgh, Scotland, UK, July 27–31, 2011.

In Sindhwani et al.'s initial work on active dual supervision (Sindhwani et al., 2009), a transductive bipartite graph regularization approach is used for learning from both labeled examples and features. In addition, uncertainty sampling and experimental design are used for selecting informative examples and features for labeling. To trade-off between different types of supervision, a simple probabilistic interleaving scheme where the active learner probabilistically queries the example oracle and the feature oracle is used. One problem in their method is that *the values of acquiring the feature labels and the example labels are not on the same scale*.

Recently, Li et al. (Li et al., 2009) proposed a dual supervision method based on constrained non-negative tri-factorization of the document-term matrix where the labeled features and examples are naturally incorporated as sets of constraints. Having a framework for incorporating dual-supervision based on matrix factorization, gives rise to the natural question of *how to perform active dual supervision in this setting*. Since rows and columns are treated equally in estimating the errors of matrix factorization, another question is can we address *the scaling issue in comparing the value of feature labels and example labels*.

In this paper, we study the problem of active dual supervision using non-negative matrix tri-factorization. Our work is based on the dual supervision framework using constrained non-negative tri-factorization proposed in (Li et al., 2009). We first extend the framework to explicitly model the corresponding relationships between feature classes and example classes. Then by making use of the reconstruction error criterion in matrix factorization, we propose a unified scheme to evaluate the value of feature and example labels. Instead of comparing the estimated performance increase of new feature labels or example labels, our proposed scheme assumes that a better supervision (a feature label or a example label) should lead to a more accurate reconstruction of the original data matrix. In our proposed scheme, *the value of feature labels and example labels is computed on the same scale*. The experiments show that our proposed unified scheme to query selection (i.e., feature/example selection for labeling) outperforms the interleaving schemes and the scheme based on expected log gain.

The rest of this paper is organized as follows: the related work is discussed in Section 2, and the dual supervision framework based on non-negative matrix tri-factorization is introduced in Section 3. We extend non-negative matrix tri-factorization to active learning settings in Section 4, and propose a unified scheme for query selection in Section 5. Experiments are presented in Section 6, and finally Section 7 concludes the paper.

2 Related Work

We point the reader to a recent report (Settles, 2009) for an in-depth survey on active learning. In this section, we briefly cover related work to position our contributions appropriately.

Active Learning/Active Dual Supervision Most prior work in active learning has focused on pooled-based techniques, where examples from an unlabeled pool are selected for labeling (Cohn et al., 1994). With the study of learning from labeled features, many research efforts on active learning with feature supervision are also reported (Melville et al., 2005; Raghavan et al., 2006). (Godbole et al., 2004) proposed the notion of feature uncertainty and incorporated the acquired feature labels into learning by creating one-term mini-documents. (Druck et al., 2009) performed active learning via feature labeling using several uncertainty reduction heuristics using the learning model developed in (Druck et al., 2008). (Sindhwani et al., 2009) studied the problem of active dual supervision from examples and features using a graph-based dual supervision method with a simple probabilistic method for interleaving feature labels and example labels. In our work, we develop our active dual supervision framework using constrained non-negative tri-factorization and also propose a unified scheme to evaluate the value of feature and example labels. We note the very recent work of (Attenberg et al., 2010), which proposes a unified approach for the dual active learning problem using expected utility where the utility is defined as the log gain of the classification model with a new labeled document or word. Conceptually, our proposed unified scheme is a special case of the expected utility framework where the utility is computed using the matrix reconstruction error. The utility based on the log gain of the classification

model may not be reliable as small model changes resulted from a single additional example label or feature label may not be reflected in the classification performance (Attenberg et al., 2010). The empirical comparisons show that our proposed unified scheme based on reconstruction error outperforms the expected log gain.

Dual Supervision Note that a learning method that is capable of performing dual supervision (i.e., learning from both labeled examples and features) is the basis for active dual supervision. Dual supervision is a relatively new area of research and few methods have been developed for dual supervision. In (Sindhwani and Melville, 2008; Sindhwani et al., 2008), a bipartite graph regularization model (GRADS) is used to diffuse label information along both sides of the document-term matrix and to perform dual supervision for semi-supervised sentiment analysis. Conceptually, their model implements a co-clustering assumption closely related to Singular Value Decomposition (see also (Dhillon, 2001; Zha et al., 2001) for more on this perspective). In (Sandler et al., 2008), standard regularization models are constrained using graphs of word co-occurrences. In (Melville et al., 2009), Naive Bayes classifier is extended, where the parameters, the conditional word distributions given the classes, are estimated by combining multiple sources, e.g. document labels and word labels. Our work is based on the dual supervision framework using constrained non-negative tri-factorization.

3 Learning with Dual Supervision via Tri-NMF

Our dual supervision model is based on non-negative matrix tri-factorization (Tri-NMF), where the non-negative input document-word matrix is approximated by 3 factor matrices as $X \approx GSF^T$, in which, X is an $n \times m$ document-term matrix, G is an $n \times k$ non-negative orthogonal matrix representing the probability of generating a document from a document cluster, F is an $m \times k$ non-negative orthogonal matrix representing the probability of generating a word from a word cluster, and S is a $k \times k$ non-negative matrix providing the relationship between document cluster space and word cluster space.

While Tri-NMF is first applied in co-clustering, Li et al. (Li et al., 2009) extended it to incorporate labeled words and documents as dual supervision via two loss terms in the objective function of Tri-NMF as following:

$$\begin{aligned} \min_{F,G,S} \quad & \|X - GSF^T\|^2 \\ & +\alpha \,\mathrm{trace}[(F - F_0)^T C_1 (F - F_0)] \\ & +\beta \,\mathrm{trace}[(G - G_0)^T C_2 (G - G_0)]. \end{aligned} \tag{1}$$

Here, $\alpha > 0$ is a parameter which determines the extent to which we enforce $F \approx F_0$ to its labeled rows. C_1 is a $m \times m$ diagonal matrix whose entry $(C_1)_{ii} = 1$ if the row of F_0 is labeled, that is, the class of the i-th word is known and $(C_1)_{ii} = 0$ otherwise. $\beta > 0$ is a parameter which determines the extent to which we enforce $G \approx G_0$ to its labeled rows. C_2 is a $n \times n$ diagonal matrix whose entry $(C_2)_{ii} = 1$ if the row of G_0 is labeled, that is, the category of the i-th document is known and $(C_2)_{ii} = 0$ otherwise. The squared loss terms ensure that the solution for G, F in the otherwise unsupervised learning problem be close to the prior knowledge G_0, F_0. So the partial labels on documents and words can be described using G_0 and F_0, respectively.

4 Dual Supervision with Explicit Class Alignment

4.1 Modeling the Relationships between Word Classes and Document Classes

In the solution to Equation 1, we have $S = G^T X F$, or

$$S_{lk} = g_l^T X f_k = \frac{1}{|R_l|^{1/2} |C_k|^{1/2}} \sum_{i \in R_l} \sum_{j \in C_k} X_{ij}, \tag{2}$$

where $|R_l|$ is the size of the l-th document class, and $|C_k|$ is the size of the k-th word class (Ding et al., 2006). Note that S_{lk} represents properly normalized within-class sum of weights ($l = k$) and between-class sum of weights ($l \neq k$). So, S represents the relationship between the classes over documents and the classes over words. Under the assumption that the i-th document class should correspond to the i-th word class, S should be an approximate diagonal matrix, since the documents of i-th class is more likely to contain the words of the i-th class. Note

that S is not an exact diagonal matrix, since a document of one class apparently can use words from other classes (especially G and F are required to be approximately orthogonal, which means the classification is rigorous). However, in Equation 1, there are no explicit constraints on the relationship between word classes and document classes. Instead, the relationship is established and enforced implicitly using existing labeled documents and words.

In active learning, the set of starting labeled documents or words is small, and this may generate an ill-formed S, leading to an incorrect alignment of word classes and document classes. To explicitly model the relationships between word classes and document classes, we constrain the shape of S via an extra loss term in the objective function as follows:

$$\begin{aligned}\min_{F,G,S} \quad & \|X - GSF^T\|^2 \\ & +\alpha \operatorname{trace}[(F - F_0)^T C_1 (F - F_0)] \\ & +\beta \operatorname{trace}[(G - G_0)^T C_2 (G - G_0)] \\ & +\gamma \operatorname{trace}[(S - S_0)^T (S - S_0)]\end{aligned} \tag{3}$$

where S_0 is a diagonal matrix.

How to Choose S_0 If there is no orthogonal constraint on F, G and I-divergence is used as the objective function, it can been shown that the factors of Tri-NMF have probabilistic interpretation (Ding et al., 2008; Shen et al., 2011):

$$\begin{aligned} F_{il} &= P(w = w_i | z_w = l), \\ G_{jk} &= P(d = d_j | z_d = k), \\ S_{kl} &= P(z_d = k, z_w = l), \end{aligned} \tag{4}$$

where w is word variable, d is document variable, and z_w, z_d are random variables indicating word class and document class respectively. F and G represent posterior distributions for words and documents, and S represents the joint distribution of document class and word class. With such an interpretation, S_0 can be easily decided in balanced classification problems with each diagonal entry equals to one over the number of classes.

However, in our setting of Tri-NMF, orthogonal constraints are enforced on F, G and Euclidean distance is used as the objective function. To precompute S_0, one way is to first solve the optimization problem Equation 1 with another constraint that S should be diagonal. Alternatively, to keep it simple, we ignore the known label information and just assume there exists a diagonal matrix S_0 and two orthogonal matrices G, F, that

$$GS_0F^T \approx X.$$

Then

$$\begin{aligned} \operatorname{trace}[XX^T] &\approx \operatorname{trace}[GS_0F^TFS_0^TG^T], \\ &= \operatorname{trace}[S_0S_0^TF^TFG^TG], \\ &= \operatorname{trace}[S_0S_0^T], \\ &= \textstyle\sum_k (S_0)_{kk}^2. \end{aligned} \tag{5}$$

So if a classification problem is balanced with K classes, S_0 can be estimated as following:

$$(S_0)_{kl} = \begin{cases} \sqrt{\frac{\operatorname{trace}[XX^T]}{K}} & l = k, \\ 0 & \text{otherwise.} \end{cases} \tag{6}$$

4.2 Computing Algorithm

This optimization problem can be solved using the following update rules

$$\begin{aligned} G_{jk} &\leftarrow G_{jk} \frac{XFS + \beta C_2 G_0}{(GG^TXFS + \beta GG^TC_2G)_{jk}}, \\ S_{jk} &\leftarrow S_{jk} \frac{F^TX^TG + \gamma S_0}{(F^TFSG^TG + \gamma S)_{jk}}, \\ F_{jk} &\leftarrow F_{jk} \frac{X^TGS^T + \alpha C_1 F_0}{(FF^TX^TGS^T + \alpha C_1 F)_{jk}}. \end{aligned} \tag{7}$$

The algorithm consists of an iterative procedure using the above three rules until convergence.

Theorem 4.1 *The above iterative algorithm converges.*

Theorem 4.2 *At convergence, the solution satisfies the Karuch-Kuhn-Tucker (KKT) optimality condition, i.e., the algorithm converges correctly to a local optima.*

Theorem 4.1 can be proved using the standard auxiliary function approach (Lee and Seung, 2001).

Proof of Theorem 4.2: Proof for the update rules of G, F is the same as in (Li et al., 2009). Here we focus on the update rule of S. We want to minimize

$$\begin{aligned} L(S) = \quad & \|X - GSF^T\|^2 \\ & +\alpha \operatorname{trace}[(F - F_0)^T C_1 (F - F_0)] \\ & +\beta \operatorname{trace}[(G - G_0)^T C_2 (G - G_0)] \\ & +\gamma \operatorname{trace}[(S - S_0)^T (S - S_0)]. \end{aligned} \tag{8}$$

The gradient of L is

$$\frac{\partial L}{\partial S} = 2F^T FSG^T G - 2F^T X^T G + 2\gamma(S - S_0)$$

The KKT complementarity condition for the non-negativity of S_{jk} gives

$$[2F^T FSG^T G - 2F^T X^T G + 2\gamma(S - S_0)]_{jk} S_{jk} = 0.$$

This is the fixed point relation that local minima for S must satisfy, which is equivalent with the update rule of S in Equation 7. ∎

5 A Unified Scheme for Query Selection Using the Reconstruction Error

5.1 Introduction

An ideal active dual supervision scheme should be able to evaluate the value of acquiring labels for documents and words on the same scale. In the initial study of dual active supervision, different scores are used for documents and words (e.g. uncertainty for documents and certainty for words), and thus they are not on the same scale (Sindhwani et al., 2009). Recently, the framework of Expected Utility (Estimated Risk Minimization) is proposed in (Attenberg et al., 2010). At each step of the framework, the next word or document selected for labeling is the one that will result in the highest estimated improvement in classifier performance as defined as:

$$EU(q_j) = \sum_{k=1}^{K} P(q_j = c_k) U(q_j = c_k), \quad (9)$$

where K is the class number, $P(q_j = c_k)$ indicates the probability that q_j, j-th query (a word or document), belongs to the k-th class, and the $U(q_j = c_k)$ indicates the utility that q_j belongs to the k-th class. However, the choice of the utility measure is still a challenge.

5.2 Reconstruction Error

In our matrix factorization framework, rows and columns are treated equally in estimating the errors of matrix factorization, and the reconstruction error is thus a natural measure of utility. Let the current supervision knowledge be G_0, F_0. To select a new unlabeled document/word for labeling, we assume that a good supervision should lead to a good constrained factorization for the document-term matrix, $X \approx GSF^T$. If the new query q_j is a word and its label is k, then the new factorization is

$$\begin{aligned} & G^*_{j=k}, S^*_{j=k}, F^*_{j=k} \\ = \; & \arg\min_{G,S,F} \|X - GSF^T\|^2 \\ & + \alpha \,\mathrm{trace}[(G - G_0)^T C_2 (G - G_0)] \\ & + \beta \,\mathrm{trace}[(F - F_{0,j=k})^T C_1 (F - F_{0,j=k})] \\ & + \gamma \,\mathrm{trace}[(S - S_0)^T (S - S_0)], \end{aligned} \quad (10)$$

where $F_{0,j=k}$ is same as F_0 except that $F_{0,j=k}(j,k) = 1$. In other words, we obtained a new factorization using the labeled words. Similarly, if the new query q_j is a document, then the new factorization is

$$\begin{aligned} & G^*_{j=k}, S^*_{j=k}, F^*_{j=k} \\ = \; & \arg\min_{G,S,F} \|X - GSF^T\|^2 \\ & + \alpha \,\mathrm{trace}[(G - G_{0,j=k})^T C_2 (G - G_{0,j=k})] \\ & + \beta \,\mathrm{trace}[(F - F_0)^T C_1 (F - F_0)] \\ & + \gamma \,\mathrm{trace}[(S - S_0)^T (S - S_0)], \end{aligned} \quad (11)$$

where $G_{0,j=k}$ is same as G_0 except that $G_{0,j=k}(j,k) = 1$. In other words, we obtained a new factorization using the labeled documents. Then the new reconstruction error is

$$RE(q_j = k) = \|X - G^*_{j=k} S^*_{j=k} F^*_{j=k}\|^2. \quad (12)$$

So the expected utility of a document or word label query, q_j, can be computed as

$$EU(q_j) = \sum_{k=1}^{K} P(q_j = k) * (-RE(q_j = k)). \quad (13)$$

To calculate the $P(q_j = k)$, which is the posterior distribution for words or documents, probabilistic interpretation of Tri-NMF is abused. When a query q_j is a word, $P(q_j = k)$ is

$$\begin{aligned} & P(z_w = k | w = w_i) \\ \propto \; & P(w = w_i | z_w = k) \textstyle\sum_{j=1}^{K} P(z_w = k, z_d = j) \\ = \; & F_{ik} * \textstyle\sum_{j=1}^{K} S_{kj}, \end{aligned} \quad (14)$$

otherwise,

$$\begin{aligned} & P(z_d = k | d = d_i) \\ \propto \; & P(d = d_i | z_d = k) \textstyle\sum_{j=1}^{K} P(z_w = j, z_d = k) \\ = \; & G_{ik} * \textstyle\sum_{j=1}^{K} S_{jk}. \end{aligned} \quad (15)$$

5.3 Algorithm Description

Computational Improvement: It can be computationally intensive if the reconstruction error is computed for all unknown documents and words. Inspired by (Attenberg et al., 2010), we first select the top 100 unknown words that the current model is most certain about, and the top 100 unknown documents that the current model is most uncertain about. Then we identify the words or documents in this pool with the highest expected utility (reconstruction error). Equations 14 and 15 are used to perform the initial selection of top 100 unknown words and top 100 unknown documents.

Algorithm 1 Active Dual Supervision Algorithm Based on Matrix Factorization

INPUT: X, document-word matrix; F_0, current labeled words; G_0, current labeled documents; O, the oracle

OUTPUT: G, classification result for all documents in X

1. Get base factorization of X: G, S, F.
2. Active dual supervision

repeat

D is the set of top 100 unlabeled documents with most uncertainty;

W is the set of top 100 unlabeled words with most certainty;

$Q = D \cup W$;

for all $q \in Q$ **do**

for $k = 1$ to K **do**

Get $G^*_{q=k}, F^*_{q=k}, S^*_{q=k}$ by Equation 10 or Equation 11 according to whether the query q is a document or a word;

Calculate $EU(q)$ by Equation 13;

$q* = \arg\max_q EU(q)$;

Acquire new label of q^*, l from O;

$G, F, S = G^*_{q^*=l}, F^*_{q^*=l}, S^*_{q^*=l}$;

until stop criterion is met.

The overall algorithm procedure is described in Algorithm 1. First we iteratively use the updating rules of Equation 7 to obtain the factorization G, F, S based on initial labeled documents and words. Then to select a new query, for each unlabeled document or word in the pool and for each possible class, we compute the reconstruction error with new supervision (using the current factorization results as initialization values). It is efficient to compute a new factorization due to the sparsity of the matrices. The document-term matrix is typically very sparse with $z \ll nm$ non-zero entries while k is typically also much smaller than document number n, and word number m. By using sparse matrix multiplications and avoiding dense intermediate matrices, updating F, S, G each takes $O(k^2(m+n)+kz)$ time per iteration which scales linearly with the dimensions and density of the data matrix (Li et al., 2009). Empirically, the number of iterations that is needed to compute the new factorization is usually very small (less than 10).

6 Experiments

6.1 Experiments Settings

Three popular binary text classification datasets are used in the experiments: ibm-mac (1937 examples), baseball-hockey (1988 examples) and med-space (1972 examples) datasets. All of them are drawn from the 20-newsgroups text collection[1] where the task is to assign messages into the newsgroup in which they appeared. Top 1500 frequent words in each dataset are used as features in the binary vector representation. These datasets have labels for all the documents. For a document query, the oracle returns its label. We construct the word oracle in the same manner as in (Sindhwani et al., 2009): first compute the information gain of words with respect to the known true class labels in the training splits of a dataset, and then the top 100 words as ranked by information gain are assigned the label which is the class in which the word appears more frequently. To those words with labels, the word oracle returns its label; otherwise, the oracle returns a "don't know" response (no word label is obtained for learning, but the word is excluded from the following query selection).

Results are averaged over 10 random training-test splits. For each split, 30% examples are used for testing. All methods are initialized by a random choice of 10 document labels and 10 word labels. For simplicity, we follow the widely used cost model (Raghavan and Allan, 2007; Druck et al.,

[1] http://www.ai.mit.edu/people/jrennie/20_newsgroups/

2008; Sindhwani et al., 2009) where features are roughly 5 times cheaper to label than examples, so we assume the cost is 1 for a word query and is 5 for a document query. We set $\alpha = \beta = 5, \gamma = 1$ for all the following experiments[2].

Figure 1: Comparing the performance of dual supervision via Tri-NMF w/ and w/o the constraint on S.

[2]We do not perform fine tuning on the parameters since the main objective of the paper is to demonstrate the effectiveness of matrix factorization based methods for dual active supervision. A vigorous investigation on the parameter choices is our further work.

6.2 Experimental Results

Effect of Constraints on S in Constrained Tri-NMF Figure 1 demonstrates the effectiveness of dual supervision with explicit class alignment via Tri-NMF as described in Section 4. When there are enough labeled documents and words, the constraints on S have a relative small impact on the performance of dual supervision. However, in the beginning phase of active learning, the labeled dataset can be small (such as 10 labeled documents and 10 labeled words). In this case, without the constraint of S, the matrix factorization may generate incorrect class alignment, thus lead to almost random classification results (around 50% accuracy), as shown in Figure 1, and further make unreasonable the following evaluation of queries.

Comparing Query Selection Approaches Figure 2 compares our proposed unified scheme (denoted as *Expected-reconstruction-error*) with the following baselines using Tri-NMF as the classifier for dual supervision: (1). *Interleaved-uncertainty* which first selects feature query by certainty and sample query by uncertainty and then combines the two types of queries using an interleaving scheme. The interleaving probability (probability to select the query as a document) is set as 0.2, 0.4, 0.6 and 0.8. (2). *Expected-log-gain* which selects feature and sample query by maximizing the expected log gain. *Expected-reconstruction-error* outperforms interleaving schemes with all the different interleaving probability values with which we experimented. It also has a better performance than *Expected-log-gain*. Although log gain is a finer-grained utility measure of classifier performance than accuracy and has a good performance in the setting with a large set of starting labeled documents (e.g., 100 documents), it is not reliable especially in the setting with a small set of labeled data. Different from the *Expected-log-gain*, *Expected-reconstruction-error* estimates the utility using the matrix reconstruction error, making use of information of all documents and words, including those unlabeled.

Comparing Interleaving Scheme vs. the Unified Scheme To further demonstrate the benefit of the proposed unified scheme , we compare it with its interleaved version: *Interleaved-expected-*

Figure 3: Comparing the unified and interleaving scheme based on reconstruction error.

construction-error which computes the utility of a query using the reconstruction error, but uses interleaving scheme to decide which type of query to select. We experiment with different interleaving probability values ranging from 0.2 to 0.8, which lead to quite different performance results. From Figure 3, the optimal interleaving probability value varies on different datasets. For example, the probability value of 0.8 is among the optimal interleaving probability values on baseball-hockey dataset but performs poorly on ibm-mac dataset. This observation also illustrates the need for a unified scheme, because of the difficulty in choosing the optimal interleaving probability value. Although the proposed unified scheme is not significantly better than its interleaving counterparts for all interleaving probability values on all datasets, it avoids the bad choices.

Figure 5 presents the sequence of different query types selected by our unified scheme and it clearly demonstrates the distribution patterns of different query types. At the beginning phase of active learning, word queries have much higher probabilities to be selected, which is consistent with the result of previous work: feature labels can be more effective than examples in text classification (Druck et al., 2008). And in the later learning phase, documents are more likely to be selected, since the number of words that can benefit the classification is much smaller than the effective documents.

Reconstruction Error vs. Interleaving uncertainty using GRADS It should be pointed out that *our unified scheme for query selection based on reconstruction error does not rely on the estimation of model performance on training data and can be easily integrated with other dual supervision mod-*

els such as GRADS (Sindhwani et al., 2008). Figure 4 shows the comparison of GRADS using the interleaved scheme with an interleaving probability of 0.5, and using our unified scheme based on reconstruction error. Among the 3 datasets we used, the reconstruction error based approach outperforms the interleaving scheme on baseball-hockey and ibm-mac, and has similar performance with the interleaving scheme on med-space.

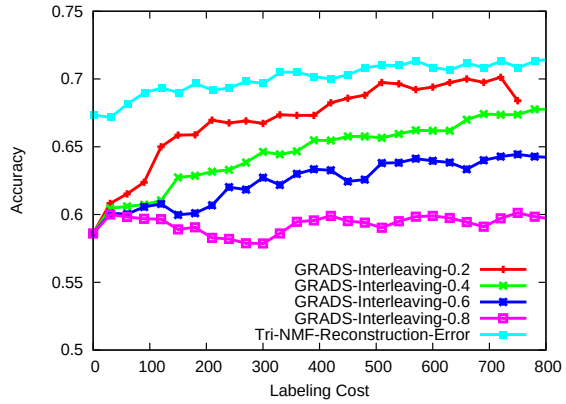

Figure 6: Comparing active dual supervision using matrix factorization with GRADS on sentiment analysis.

Comparing Active Dual Supervision Using Matrix Factorization with GRADS on Sentiment Analysis The sentiment analysis experiment is conducted on the movies review dataset (Pang et al., 2002), containing 1000 positive and 1000 negative movie reviews. The results are shown in Figure 6. The experimental results clearly demonstrate the effectiveness of our approach, denoted as *Tri-NMF-Reconstruction-Error*.

7 Conclusions

In this paper, we study the problem of active dual supervision, and propose a matrix tri-factorization based approach to address the issue, how to evaluate labeling benifit of different types of queries (examples or features) in the same scale. Following extending the nonnegative matrix tri-factorization to the active dual supervision setting, we use the reconstruction error to evaluate the value of feature and example labels. Experimental results show that our proposed approach outperforms existing methods.

Splitting Noun Compounds via Monolingual and Bilingual Paraphrasing: A Study on Japanese Katakana Words

University of Tokyo, Tokyo, Japan
kitsure@tkl.iis.u-tokyo.ac.jp

Abstract

Word boundaries within noun compounds are not marked by white spaces in a number of languages, unlike in English, and it is beneficial for various NLP applications to split such noun compounds. In the case of Japanese, noun compounds made up of katakana words (i.e., transliterated foreign words) are particularly difficult to split, because katakana words are highly productive and are often out-of-vocabulary. To overcome this difficulty, we propose using monolingual and bilingual paraphrases of katakana noun compounds for identifying word boundaries. Experiments demonstrated that splitting accuracy is substantially improved by extracting such paraphrases from unlabeled textual data, the Web in our case, and then using that information for constructing splitting models.

1 Introduction

1.1 Japanese katakana words and noun compound splitting

Borrowing is a major type of word formation in Japanese, and numerous foreign words (proper names or neologisms etc.) are continuously being imported from other languages (Tsujimura, 2006). Most borrowed words in modern Japanese are transliterations[1] from English and they are referred to as *katakana words* because transliterated foreign words are primarily spelled by using katakana characters in the Japanese writing system.[2] Compounding is another type of word formation that is common in Japanese (Tsujimura, 2006). In particular, noun compounds are frequently produced by merging two or more nouns together. These two types of word formation yield a significant amount of katakana noun compounds, making Japanese a highly productive language.

In Japanese as well as some European and Asian languages (e.g., German, Dutch and Korean), constituent words of compounds are not separated by white spaces, unlike in English. In those languages, it is beneficial for various NLP applications to split such compounds. For example, compound splitting enables SMT systems to translate a compound on a word-by-word basis, even if the compound itself is not found in the translation table (Koehn and Knight, 2003; Dyer, 2009). In the context of IR, decompounding has an analogous effect to stemming, and it significantly improves retrieval results (Braschler and Ripplinger, 2004). In abbreviation recognition, the definition of an abbreviation is often in the form of a noun compound, and most abbreviation recognition algorithms assume that the definition is properly segmented; see e.g., (Schwartz and Hearst, 2003; Okazaki et al., 2008).

This has led NLP researchers to explore methods for splitting compounds, especially noun compounds, in various languages (Koehn and Knight, 2003; Nakazawa et al., 2005; Alfonseca et al., 2008a). While many methods have been presented, they basically require expensive linguistic resources to achieve high enough accuracy. For example, Alfonseca et al. (2008b) employed a word dictionary, which is obviously useful for this task. Other studies have suggested using bilingual resources such as parallel corpora (Brown, 2002; Koehn and Knight,

[1] Some researchers use the term transcription rather than transliteration (Breen, 2009). Our terminology is based on studies on machine transliteration (Knight and Graehl, 1998).

[2] The Japanese writing system has four character types: hiragana, katakana, kanji, and Latin alphabet.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 959–969,
Edinburgh, Scotland, UK, July 27–31, 2011.

2003; Nakazawa et al., 2005). The idea behind those methods is that compounds are basically split into constituent words when they are translated into English, where the compounded words are separated by white spaces, and hence splitting rules can be learned by discovering word alignments in bilingual resources.

The largest obstacle that makes compound splitting difficult is the existence of out-of-vocabulary words, which are not found in the abovementioned linguistic resources. In the Japanese case, it is known that katakana words constitute a large source of out-of-vocabulary words (Brill et al., 2001; Nakazawa et al., 2005; Breen, 2009). As we have discussed, katakana words are very productive, and thus we can no longer expect existent linguistic resources to have sufficient coverage. According to (Breen, 2009), as many as 20% of katakana words in news articles, which we think include less out-of-vocabulary words than Web and other noisy textual data, are out-of-vocabulary. Those katakana words often form noun compounds, and pose a substantial difficulty for Japanese text processing (Nakazawa et al., 2005).

1.2 Paraphrases as implicit word boundaries

To alleviate the errors caused by out-of-vocabulary words, we explored the use of unlabeled textual data for splitting katakana noun compounds. Since the amount of unlabeled text available is generally much larger than word dictionaries and other expensive linguistic resources, it is crucial to establish a methodology for taking full advantage of such easily available textual data. While several approaches have already been proposed, their accuracies are still unsatisfactory (section 2.1).

From a broad perspective, our approach can be seen as using paraphrases of noun compounds. As we will see in section 4 and 5, katakana noun compounds can be paraphrased into various forms that strongly indicate word boundaries within the original noun compound. This paper empirically demonstrates that splitting accuracy can be significantly improved by extracting such paraphrases from unlabeled text, the Web in our case, and then using that information for constructing splitting models.

Specifically, two types of paraphrases are investigated in this paper. Section 4 explores monolingual paraphrases that can be generated by inserting certain linguistic markers between constituent words of katakana noun compounds. Section 5, in turn, explores bilingual paraphrases (specifically, back-transliteration). Since katakana words are basically transliterations from English, back-transliterating katakana noun compounds is also useful for splitting. To avoid terminological confusion, monolingual paraphrases are simply referred to as paraphrases and bilingual paraphrases are referred to as back-transliterations hereafter.

We did experiments to empirically evaluate our method. The results demonstrated that both paraphrase and back-transliteration substantially improved the performance in terms of F_1-score, and the best performance was achieved when they were combined. We also confirmed that our method outperforms the previously proposed splitting methods by a wide margin. All these results strongly suggest the effectiveness of paraphrasing and back-transliteration for identifying word boundaries within katakana noun compounds.

2 Related Work

2.1 Compound splitting

A common approach to splitting compounds without expensive linguistic resources is an unsupervised method based on word or string frequencies estimated from unlabeled text (Koehn and Knight, 2003; Ando and Lee, 2003; Schiller, 2005; Nakazawa et al., 2005; Holz and Biemann, 2008). Amongst others, Nakazawa et al. (2005) also investigated ways of splitting katakana noun compounds. Although the frequency-based method generally achieves high recall, its precision is not satisfactory (Koehn and Knight, 2003; Nakazawa et al., 2005). Our experiments empirically compared our method with the frequency-based methods, and the results demonstrate the advantage of our method.

Our approach can be seen as augmenting discriminative models of compound splitting with large external linguistic resources, i.e., textual data on the Web. In a similar spirit, Alfonseca et al. (2008b) proposed the use of query logs for compound splitting.[3] Their experimental results, however, did not clearly

[3] Although they also proposed using anchor text, this slightly degraded the performance.

demonstrate their method's effectiveness. Without the query logs, the accuracy is reported to drop only slightly from 90.55% to 90.45%. In contrast, our experimental results showed statistically significant improvements as a result of using additional resources. Moreover, we used only textual data, which is easily available, unlike query logs.

Holz and Biemann (2008) proposed a method for splitting and paraphrasing German compounds. While their work is related to ours, their algorithm is a pipeline model and paraphrasing result is not employed during splitting.

2.2 Other research topics

Our study is closely related to word segmentation, which is an important research topic in Asian languages including Japanese. Although we can use existing word segmentation systems for splitting katakana noun compounds, it is difficult to reach the desired accuracy, as we will empirically demonstrate in section 6. One reason for this is that katakana noun compounds often include out-of-vocabulary words, which are difficult for the existing segmentation systems to deal with. See (Nakazawa et al., 2005) for a discussion of this point. From a word segmentation perspective, our task can be seen as a case study focusing on a certain linguistic phenomenon of particular difficulty. More importantly, we are unaware of any attempts to use paraphrases or transliterations for word segmentation in the same way as we do.

Recent studies have explored using paraphrase statistics for parsing (Nakov and Hearst, 2005a; Nakov and Hearst, 2005b; Bansal and Klein, 2011). Although these studies successfully demonstrated the usefulness of paraphrases for improving parsers, the connection between paraphrases and word segmentation (or noun compound splitting) was not at all discussed.

Our method of using back-transliterations for splitting katakana noun compounds (section 5) is closely related to methods for mining transliteration from the Web text (Brill et al., 2001; Cao et al., 2007; Oh and Isahara, 2008; Wu et al., 2009). What most differentiates these studies from our work is that their primary goal is to build a machine transliteration system or to build a bilingual dictionary itself; none of them explored splitting compounds.

Table 1: Basic features.

ID	Feature	Description
1	y_i	constituent word 1-gram
2	$y_{i-1}y_i$	constituent word 2-gram
3	$\textsc{Len}(y_i)$	#characters of y_i (1, 2, 3, 4, or $\geq$5)
4	$\textsc{Dict}(y_i)$	true if y_i is in the dictionary

3 Supervised Approach

The task we examine in this paper is splitting a katakana noun compound x into its constituent words, $\boldsymbol{y} = (y_1, y_2 \ldots y_{|\boldsymbol{y}|})$. Note that the output can be a single word, i.e., $|\boldsymbol{y}| = 1$. Since it is possible that the input is an out-of-vocabulary word, it is not at all trivial to identify a single word as such. A naive method would erroneously split an out-of-vocabulary word into multiple constituent words.

We formalize our task as a structure prediction problem that, given a katakana noun compound x, predicts the most probable splitting $\boldsymbol{y}^*$.

$$\boldsymbol{y}^* = \operatorname*{argmax}_{\boldsymbol{y} \in \mathcal{Y}(x)} \boldsymbol{w} \cdot \boldsymbol{\phi}(\boldsymbol{y}),$$

where $\mathcal{Y}(x)$ represents the set of all splitting options of x, $\boldsymbol{\phi}(\boldsymbol{y})$ is a feature vector representation of $\boldsymbol{y}$, and $\boldsymbol{w}$ is a weight vector to be estimated from labeled data.

Table 1 summarizes our basic feature set. Features 1 and 2 are word 1-gram and 2-gram features, respectively. Feature 3 represents the length of the constituent word. $\textsc{Len}(y)$ returns the number of characters of y (1, 2, 3, 4, or $\geq$5). Feature 4 indicates whether the constituent word is registered in an external dictionary (see section 6.1). $\textsc{Dict}(y)$ returns true if the word y is in the dictionary.

In addition to those basic features, we also employ paraphrases and back-transliterations of katakana noun compounds as features. The features are detailed in sections 4 and 5, respectively.

We can optimize the weight vector $\boldsymbol{w}$ using an arbitrary training algorithm. Here we adopt the averaged perceptron algorithm for the sake of time efficiency (Freund and Schapire, 1999). The perceptron offers efficient online training, and it performs comparatively well with batch algorithms such as SVMs. Since we use only factored features (see table 1, section 4 and section 5), dynamic programming can be used to locate $\boldsymbol{y}^*$.

Table 2: Paraphrase rules and examples. The first column represents the type of linguistic marker to be inserted, the second column shows the paraphrase rules, and the last column gives examples.

Type	Rule	Example
Centered dot	$X_1X_2 \rightarrow X_1 \cdot X_2$	アンチョビパスタ → アンチョビ・パスタ (anchovy pasta) (anchovy · pasta)
Possessive marker	$X_1X_2 \rightarrow X_1$ の X_2	アンチョビパスタ → アンチョビの パスタ (anchovy pasta) (with anchovy) (pasta)
Verbal suffix	$X_1X_2 \rightarrow X_1$ する X_2 $X_1X_2 \rightarrow X_1$ した X_2	ダウンロードファイル→ダウンロードしたファイル (download file) (downloaded) (file)
Adjectival suffix	$X_1X_2 \rightarrow X_1$ な X_2 $X_1X_2 \rightarrow X_1$ 的 X_2 $X_1X_2 \rightarrow X_1$ 的な X_2	サプライズギフト → サプライズなギフト (surprise gift) (surprising) (gift)

4 Paraphrasing

In this section, we argue that paraphrases of katakana noun compounds provides useful information on word boundaries. Consequently, we propose using paraphrase frequencies as features for training the discriminative model.

4.1 Paraphrasing noun compounds

A katakana noun compound can be paraphrased into various forms, some of which provide information on the word boundaries within the original compound.

(1) a. アンチョビパスタ
(anchovy pasta)
b. アンチョビ・パスタ
(anchovy · pasta)
c. アンチョビの パスタ
(with anchovy) (pasta)

These examples are paraphrases of each other. (1a) is in the form of a noun compound, within which the word boundary is ambiguous. In (1b), on the other hand, a centered dot ・ is inserted between the constituent words. In the Japanese writing system, the centered dot is sometimes, but not always, used to separate long katakana compounds for the sake of readability. (1c) is the noun phrase generated from (1a) by inserting the possessive marker 'の', which can be translated as *with* in this context, between the constituent words. If we observe paraphrases of (1a) such as (1b) and (1c), we can guess that a word boundary exists between 'アンチョビ (anchovy)' and 'パスタ (pasta)'.

4.2 Paraphrase rules

The above discussion led us to use paraphrase frequencies estimated from Web text for splitting katakana noun compounds. For this purpose, we established the seven paraphrase rules illustrated in Table 2. The rules are in the form of $X_1X_2 \rightarrow X_1MX_2$, where X_1 and X_2 represent nouns, and M is a certain linguistic marker (e.g., the possessive marker 'の'). The left-hand term corresponds to a compound to be paraphrased and the right-hand term represents its paraphrase. For instance, X_1 = 'アンチョビ (anchovy)', X_2 = 'パスタ (pasta)', and M = 'の'. The paraphrase rules we use are based on the rules proposed by Kageura et al. (2004) for expanding complex terms, primarily noun compounds, into their variants.

4.3 Web-based frequency as features

We introduce a new feature using the paraphrase rules and Web text. As preprocessing, we use regular expressions to count the frequencies of all potential paraphrases of katakana noun compounds on the Web in advance.

(katakana)+ ・ (katakana)+
(katakana)+ の (katakana)+
(katakana)+ する (katakana)+
...

where (katakana) corresponds to one katakana character. Given a candidate segmentation $\boldsymbol{y}$ at test time, we generate paraphrases of the noun compound by setting $X_1 = y_{i-1}$ and $X_2 = y_i$, and applying the paraphrase rules. We then use $\log(F + 1)$, where F is the sum of the Web-based frequencies of the gen-

erated paraphrases, as the feature of the boundary between y_{i-1} and y_i.

As the feature value, we use the logarithmic frequency, rather than the raw frequency, for scaling. Since the other features have binary value, we found, in initial experiments, that the importance of this feature is overemphasized if we use the raw frequency. Note that we use $\log(F+1)$ rather than $\log F$ so as to avoid the feature value being zero when $F = 1$.

5 Back-transliteration

Most katakana words are transliterations from English, where words are separated by white spaces. It is, therefore, reasonable to think that back-transliterating katakana noun compounds into English would provide information on word boundaries, in a similar way to paraphrasing.

This section presents a method for extracting back-transliterations of katakana words from monolingual Web text, and establishing word alignments between those katakana and English words (Table 3). In what follows, the pair of katakana words and its English back-transliteration is referred to as a *transliteration pair*. If the transliteration pair is annotated with word alignment information as in Table 3, it is referred to as a *word-aligned transliteration pair*.

Using word-aligned transliteration pairs extracted from the Web text, we derive a binary feature indicating whether katakana word y_i corresponds to a single English word. Additionally, we derive another feature indicating whether a katakana word 2-gram $y_{i-1}y_i$ corresponds to an English word 2-gram.

5.1 Parenthetical expressions

In Japanese and other Asian languages, transliterated words are sometimes followed by their English back-transliterations inside parentheses:

(2) a. アメリカでは ‖ ジャンク (junk) フード (food) (junk food) と...

b. トラックバック ‖ スパム (spam) (spam) を撃退する...

where the underline indicates the Japanese text that is followed by English back-transliteration. We extract word-aligned transliteration pairs from such parenthetical expressions by establishing the correspondences between pre-parenthesis and in-parenthesis words.

Table 3: Word-aligned transliteration pairs. The number indicates the word alignment.

Japanese	**English**
ジャンク$_1$フード$_2$	junk$_1$ food$_2$
スパム$_3$	spam$_3$

To accomplish this, we have to resolve three problems: (a) English words inside parenthesis do not always provide a back-transliteration of the pre-parenthesis text, (b) the left boundary of the pre-parenthesis text, denoted as '‖' in the example, has to be identified, and (c) pre-parenthesis text, which is a katakana noun compound in our case, has to be segmented into words.

Although several studies have explored mining transliterations from such parenthetical expressions (Cao et al., 2007; Wu et al., 2009), the last problem has not been given much attention. In the past studies, the pre-parenthesis text is assumed to be correctly segmented by, typically, using existent word segmentation systems. This is, however, not appropriate for our purpose, because pre-parenthesis text is a katakana noun compound, which is hard for existing systems to handle, and hence the alignment quality is inevitably affected by segmentation errors.

To handle these three problems, we use the phonetic properties of the transliterations. For the purpose of explanation, we shall first focus on problem (c). Since transliterated katakana words preserve the pronunciation of the original English words to some extent (Knight and Graehl, 1998), we can discover the correspondences between substrings of the two languages based on phonetic similarity:

(3) a. [ジャン]$_1$[ク]$_2$[フー]$_3$[ド]$_4$

b. [jun]$_1$[k]$_2$ [foo]$_3$[d]$_4$

Note that these are the pre-parenthesis and in-parenthesis text in (2a). The substrings surrounded by square brackets with the same number correspond to each other. Given such a correspondence, we can segment the pre-parenthesis text (3a) according to its English counterpart (3b), in which words

Table 4: Example of the substring alignment $\mathcal{A}$ between f ='ジャンクフード' and e ='junkfood' ($|\mathcal{A}| = 4$).

(f_i, e_i)	$\log p(f_i, e_i)$
(ジャン, jun)	-10.767
(ク, k)	-5.319
(フー, foo)	-11.755
(ド, d)	-5.178

are separated by white space. We can recognize that the katakana string 'ジャンク', which is the concatenation of the first two substrings in (3a), forms a single word because it corresponds to the English word *junk*, and so on. Consequently, (3a) can be segmented into two words, 'ジャンク (junk)' and 'フード (food)'. The word alignment is trivially established.

For problems (a) and (b), we can also use the phonetic similarity between pre-parenthesis and in-parenthesis text. If the parenthetical expression does not provide the transliteration, or if the left boundary is erroneously identified, we can expect the phonetic similarity to become small. Such situations thus can be identified.

The remainder of this section details this approach. Section 5.2 presents a probabilistic model for discovering substring alignment such as (3). Section 5.3 shows how to extract word-aligned transliteration pairs by using the probabilistic model.

5.2 Phonetic similarity model

To establish the substring alignment between katakana and Latin alphabet strings, we use the probabilistic model proposed by (Jiampojamarn et al., 2007). Let f and e be katakana and alphabet strings, and $\mathcal{A}$ be the substring alignment between them. More precisely, $\mathcal{A}$ is a set of corresponding substring pairs (f_i, e_i) such that $f = f_1 f_2 \dots f_{|\mathcal{A}|}$ and $e = e_1 e_2 \dots e_{|\mathcal{A}|}$. The probability of such alignment is defined as

$$\log p(f, e, \mathcal{A}) = \sum_{(f_i, e_i) \in \mathcal{A}} \log p(f_i, e_i).$$

Since $\mathcal{A}$ is usually unobservable, it is treated as a hidden variable. Table 4 illustrates an example of the substring alignment between f ='ジャンクフード' and e ='junkfood', and the likelihood of each substring pair estimated in our experiment.

The model parameters are estimated from a set of transliteration pairs (f, e) using the EM algorithm. In the E-step, we estimate $p(\mathcal{A}|f, e)$ based on the current parameters. In the parameter estimation, we restrict both f_i and e_i to be at most three characters long. Doing this not only makes the E-step computationally efficient but avoids over-fitting by forbidding too-long substrings to be aligned. In the M-step, the parameter is re-estimated using the result of the E-step. We can accomplish this by using an extension of the forward-backward algorithm. See (Jiampojamarn et al., 2007) for details.

Given a new transliteration pair (f, e), we can determine the substring alignment as

$$\mathcal{A}^* = \operatorname*{argmax}_{\mathcal{A}} \log p(f, e, \mathcal{A}).$$

In finding the substring alignment, a white space on the English side is used as a constraint, so that the English substring e_i does not span a white space.

5.3 Extracting word-aligned transliteration pairs

The word-aligned transliteration pairs are extracted using the phonetic similarity model, as follows.

First, candidate transliteration pairs (f, e) are extracted from the parenthetical expressions. This is done by extracting English words inside parentheses and pre-parenthesis text written in katakana. English words are normalized by lower-casing capital letters.

Second, we determine the left boundary by using the confidence score: $\frac{1}{N} \log p(f, e, \mathcal{A}^*)$, where N is the number of English words. The term $\frac{1}{N}$ prevents the score from being unreasonably small when there are many words. We truncate f by removing the leftmost characters one by one, until the confidence score exceeds a predefined threshold θ. If f becomes empty, the pair is regarded as a non-transliteration and discarded.

Finally, for the remaining pairs, the Japanese side is segmented and the word alignment is established according to $\mathcal{A}^*$. This results in a list of word-aligned transliteration pairs (Table 3).

6 Experiments and Discussion

We conducted experiments to investigate how the use of the paraphrasing and the back-transliteration

improves the performance of the discriminative model.

6.1 Experimental setting

To train the phonetic similarity model, we used a set of transliteration pairs extracted from the Wikipedia.[4] Since person names are almost always transliterated when they are imported from English into Japanese, we made use of the Wikipedia articles that belong to the *Living people* category. From the titles of those articles, we automatically extracted person names written in katakana, together with their English counterparts obtainable via the multilingual links provided by the Wikipedia. This yielded 17,509 transliteration pairs for training. In performing the EM algorithm, we tried ten different initial parameters and selected the model that achieved the highest likelihood.

The data for training and testing the perceptron was built using a Japanese-English dictionary EDICT.[5] We randomly extracted 5286 entries written in katakana from EDICT and manually annotated word boundaries by establishing word correspondences to their English transliterations. Since English transliterations are already provided by EDICT, the annotation can be trivially done by native speakers of Japanese. Using this data set, we performed 2-fold cross-validation for testing the perceptron. The number of iterations was set to 20 in all the experiments.

To compute the dictionary-based feature DICT(y) in our basic feature set, we used NAIST-jdic.[6] It is the largest dictionary used for Japanese word segmentation, and it includes 19,885 katakana words.

As Web corpora, we used 1.7 G sentences of blog articles. From the corpora, we extracted 14,966,205 (potential) paraphrases of katakana noun compounds together with their frequencies. We also extracted 151,195 word-aligned transliteration pairs. In doing this, we ranged the threshold θ in $\{-10, -20, \cdots -150\}$ and chose the value that performed the best ($\theta = -80$).

The results were evaluated using precision, recall, F_1-score, and accuracy. Precision is the number of correctly identified words divided by the number of all identified words, recall is the number of correctly identified words divided by the number of all oracle words, the F_1-score is their harmonic mean, and accuracy is the number of correctly split katakana noun compounds divided by the number of all the katakana noun compounds.

6.2 Baseline systems

We compared our system with three frequency-based baseline system, two supervised baselines, and two state-of-the-art word segmentation baselines. The first frequency-based baseline, UNIGRAM, performs compound splitting based on a word 1-gram language model (Schiller, 2005; Alfonseca et al., 2008b):

$$\boldsymbol{y}^* = \operatorname*{argmax}_{\boldsymbol{y} \in \mathcal{Y}(x)} \prod_i p(y_i),$$

where $p(y_i)$ represents the probability of y_i. The second frequency-based baseline, GMF, outputs the splitting option with the highest geometric mean frequency of the constituent words (Koehn and Knight, 2003):

$$\boldsymbol{y}^* = \operatorname*{argmax}_{\boldsymbol{y} \in \mathcal{Y}(x)} \mathrm{GMF}(\boldsymbol{y}) = \operatorname*{argmax}_{\boldsymbol{y} \in \mathcal{Y}(x)} \Big\{ \prod_i f(y_i) \Big\}^{1/|\boldsymbol{y}|},$$

where $f(y_i)$ represents the frequency of y_i. The third frequency-based baseline, GMF2, is a modification of GMF proposed by Nakazawa et al. (2005). It is based on the following score instead of GMF($\boldsymbol{y}$):

$$\mathrm{GMF2}(\boldsymbol{y}) = \begin{cases} \mathrm{GMF}(\boldsymbol{y}) & (|\boldsymbol{y}| = 1) \\ \frac{\mathrm{GMF}(\boldsymbol{y})}{\frac{C}{N^l} + \alpha} & (|\boldsymbol{y}| \geq 2), \end{cases}$$

where C, N, and α are hyperparameters and l is the average length of the constituent words. Following (Nakazawa et al., 2005), the hyperparameters were set as C = 2500, N = 4, and α = 0.7. We estimated $p(y)$ and $f(y)$ from the Web corpora.

The first supervised baseline, AP, is the averaged perceptron model trained using only the basic feature set. The second supervised baseline, AP+GMF2 is a combination of AP and GMF2, which performed the best amongst the frequency-based baselines. Following (Alfonseca et al.,

Table 5: Comparison with baseline systems.

Type	System	P	R	F_1	Acc
Frequency	UNIGRAM	64.2	49.7	56.0	63.0
	GMF	42.9	62.0	50.7	47.5
	GMF2	67.4	76.0	71.5	72.5
Supervised	AP	81.9	82.5	82.2	83.4
	AP+GMF2	83.0	83.9	83.4	84.2
	PROPOSED	**86.4**	**87.4**	**87.1**	**87.6**
Word seg.	JUMAN	71.4	60.1	65.3	69.8
	MECAB	72.4	73.7	67.8	71.6

2008b), GMF2 is integrated into AP as two binary features indicating whether GMF2($\boldsymbol{y}$) is larger than any other candidates, and whether GMF2($\boldsymbol{y}$) is larger than the non-split candidate. Although Alfonseca et al. (2008b) also proposed using (the log of) the geometric mean frequency as a feature, doing so degraded performance in our experiment.

Regarding the two state-of-the-art word segmentation systems, one is JUMAN,[7] a rule-based word segmentation system (Kurohashi and Nagao, 1994), and the other is MECAB,[8] a supervised word segmentation system based on CRFs (Kudo et al., 2004). These two baselines were chosen in order to show how well existing word segmentation systems perform this task. Although the literature states that it is hard for existing systems to deal with katakana noun compounds (Nakazawa et al., 2005), no empirical data on this issue has been presented until now.

6.3 Splitting result

Table 5 compares the performance of our system (PROPOSED) with the baseline systems. First of all, we can see that PROPOSED clearly improved the performance of AP, demonstrating the effectiveness of using paraphrases and back-transliterations.

Our system also outperformed all the frequency-based baselines (UNIGRAM, GMF, and GMF2). This is not surprising, since the simple supervised baseline, AP, already outperformed the unsupervised frequency-based ones. Indeed similar experimental results were also reported by Alfonseca (2008a). An interesting observation here is the comparison between PROPOSED and AP+GMF2. It reveals that our approach improved the performance of AP more than the frequency-based method did. These results indicate that paraphrasing and back-transliteration are more informative clues than the simple frequency of constituent words. We would like to note that the higher accuracy of PROPOSED in comparison with the baselines is statistically significant ($p < 0.01$, McNemar's test).

The performance of the two word segmentation baselines (JUMAN and MECAB) is significantly worse in our task than in the standard word segmentation task, where nearly 99% precision and recall are reported (Kudo et al., 2004). This demonstrates that splitting a katakana noun compound is not at all a trivial task to resolve, even for the state-of-the-art word segmentation systems. On the other hand, PROPOSED outperformed both JUMAN and MECAB in this task, meaning that our technique can successfully complement the weaknesses of the existing word segmentation systems.

By analyzing the errors, we interestingly found that some of the erroneous splitting results are still acceptable to humans. For example, while 'アップロード (upload)' was annotated as a single word in the test data, our system split it into 'アップ (up)' and 'ロード (load)'. Although the latter splitting may be useful in some applications, it is judged as wrong in our evaluation framework. This implies the importance of evaluating the splitting results in some extrinsic tasks. We leave it to a future work.

6.4 Investigation on out-of-vocabulary words

In our test data, 2681 out of the 5286 katakana noun compounds contained at least one out-of-vocabulary word that are not registered in NAIST-jdic. Table 6 illustrates the results of the supervised systems for those 2681 and the remaining 2605 katakana noun compounds (referred to as w/ OOV and w/o OOV data, respectively). While the accuracy exceeds 90% for w/o OOV data, it is substantially degraded for w/ OOV data. This is consistent with our claim that out-of-vocabulary words are a major source of errors in splitting noun compounds.

The three supervised systems performed almost equally for w/o OOV data. This is because AP trivially performs very well on this subset, and it is difficult to get any further improvement. On the other hand, we can see that there are substantial performance gaps between the systems for w/ OOV data. This result reflects the effect of the additional fea-

tures more directly than is shown in table 5.

6.5 Effect of the two new features

To see the effect of the new features in more detail, we looked at the performances of our system using different feature sets (Table 7). The first column represents the feature set we used: BASIC, PARA, TRANS, and ALL represent the basic features, the paraphrase feature, the back-transliteration feature, and all the features. The results demonstrate that adding either of the new features improved the performance, and the best result was when they were used together. In all cases, the improvement over BASIC was statistically significant ($p < 0.01$, McNemar's test).

Next, we investigated the coverage of the features. Our test data comprised 7709 constituent words, 4937 (64.0%) of which were covered by NAIST-jdic. The coverage was significantly improved when using the back-transliteration feature. We observed that 6216 words (80.6%) are in NAIST-jdic or word-aligned transliteration pairs extracted from the Web text. This shows that the back-transliteration feature successfully reduced the number of out-of-vocabulary words. On the other hand, we observed that the paraphrase and back-transliteration features were activated for 79.5% (1926/2423) and 15.5% (376/2423) of the word boundaries in our test data.

Overall, we see that the coverage of these features is reasonably good, although there is still room for further improvement. It would be beneficial to use larger Web corpora or more paraphrase rules, for example, by having a system that automatically learns rules from the corpora (Barzilay and McKeown, 2001; Bannard and Callison-Burch, 2005).

6.6 Sensitivity on the threshold θ

Finally we investigated the influence of the threshold θ (Figure 1 and 2). Figure 1 illustrates the system performance in terms of F_1-score for different values of θ. While the F_1-score drops when the value of θ is too large (e.g., -20), the F_1-score is otherwise almost constant. This demonstrates it is generally easy to set θ near the optimal value. More importantly, the F_1-score is consistently higher than BASIC irrespective of the value of θ. Figure 2 represents the number of distinct word-aligned transliteration pairs that were extracted from the Web corpora. We see that most of the extracted transliteration pairs have high confidence score.

Table 7: Effectiveness of paraphrase (PARA) and back-transliteration feature (TRANS).

Feature set	P	R	F_1	Acc
BASIC	81.9	82.5	82.2	83.4
BASIC+PARA	85.1	85.3	85.2	85.9
BASIC+TRANS	85.1	86.3	85.7	86.5
ALL	**86.4**	**87.4**	**87.1**	**87.6**

7 Conclusion

In this paper, we explored the idea of using monolingual and bilingual paraphrases for splitting katakana noun compounds in Japanese. The experiments demonstrated that our method significantly improves the splitting accuracy by a large margin in comparison with the previously proposed methods. This means that paraphrasing provides a simple and effective way of using unlabeled textual data for identifying implicit word boundaries within katakana noun compounds.

Although our investigation was restricted to katakana noun compounds, one might expect that a similar approach would be useful for splitting other types of noun compounds (e.g., German noun compounds), or for identifying general word boundaries, not limited to those between nouns, in Asian languages. We think these are research directions worth exploring in the future.

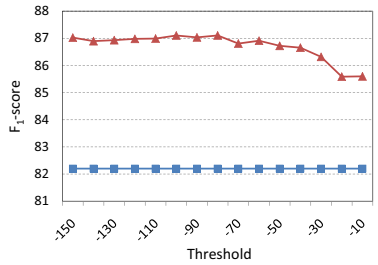

Figure 1: Influence of the threshold θ (x-axis) on the F_1-score (y-axis). The triangles and squares represent systems using the ALL and BASIC feature sets, respectively.

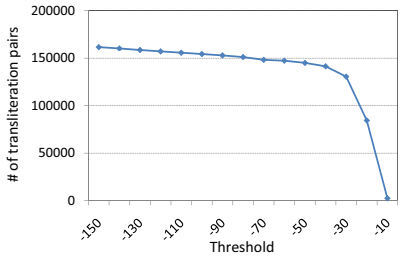

Figure 2: The number of distinct word-aligned transliterations pairs that were extracted from the Web corpora for different values of θ.

Enhancing Chinese Word Segmentation Using Unlabeled Data

Abstract

This paper investigates improving supervised word segmentation accuracy with unlabeled data. Both large-scale in-domain data and small-scale document text are considered. We present a unified solution to include features derived from unlabeled data to a discriminative learning model. For the large-scale data, we derive string statistics from Gigaword to assist a character-based segmenter. In addition, we introduce the idea about transductive, document-level segmentation, which is designed to improve the system recall for out-of-vocabulary (OOV) words which appear more than once inside a document. Novel features[1] result in relative error reductions of 13.8% and 15.4% in terms of F-score and the recall of OOV words respectively.

1 Introduction

Chinese sentences are written in continuous sequence of characters without explicit delimiters such as space characters. To find the basic language units, i.e. words, segmentation is a necessary initial step for Chinese language processing. Previous research shows that word segmentation models trained on labeled data are reasonably accurate. In this paper, we investigate improving supervised word segmentation with unlabeled data.

We distinguish three types of unlabeled data, namely large-scale in-domain data, out-of-domain data and small-scale document text. Both large-scale in-domain and out-of-domain data is popular for enhancing NLP tasks. Learning from these two types of unlabeled data normally involves semi-supervised learning. The difference between them is that out-of-domain data is usually used for domain adaptation. For a number of NLP tasks, there are relatively large amounts of labeled training data. In this situation, supervised learning can provide competitive results, and it is difficult to improve them any further by using extra unlabeled data. Chinese word segmentation is one of this kind of tasks, since several large-scale manually annotated corpora are publicly available. In this work, we first exploit unlabeled in-domain data to improve strong supervised models. We leave domain adaptation for our future work.

We introduce the third type of unlabeled data with a *transductive learning*, *document-level* view. Many applications of word segmentation involve processing a whole document, such as information retrieval. In this situation, the text of the current document can provide additional useful information to segment a sentence. Take the word "氨纶丝/elastane" for example[2]. As a translated terminology word, it lacks compositionality. Moreover, this word appears rarely in general texts. As a result, if it does not appear in the training data, it is very hard for statistical models to recognize this word. Nevertheless, when we deal with an article discussing an elastane company, this word may appear more than once in this article, and the document information can help recognize this word. This idea is closely related to transductive learning in the sense that the segmentation model knows something about the problem it

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 970–979,
Edinburgh, Scotland, UK, July 27–31, 2011.

is going to resolve. In this work, we are also concerned with enhancing word segmentation with the document information.

We present a unified "feature engineering" approach for learning segmentation models from both labeled and unlabeled data. Our method is a simple two-stage process. First, we use unannotated corpus to extract string and document information, and then we use these information to construct new statistics-based and document-based feature mapping for a discriminative word segmenter. We are relying on the ability of discriminative learning method to identify and explore informative features, which play central role to boost the segmentation performance. This simple solution has been shown effective for named entity recognition (Miller et al., 2004) and dependency parsing (Koo et al., 2008). In their implementations, word clusters derived from unlabeled data are imported as features to discriminative learning approaches.

To demonstrate the effectiveness of our approach, we conduct experiments on the Penn Chinese Treebank (CTB) data. CTB is a collection of documents which are separately annotated. This annotation style allows us to evaluate our transductive segmentation method. Our experiments show that both statistics-based and document-based features are effective in the word segmentation application. In general, the use of unlabeled data can be motivated by two concerns: First, given a fixed amount of labeled data, we might wish to leverage unlabeled data to improve the performance of a supervised model. Second, given a fixed target performance level, we might wish to use unlabeled data to reduce the amount of annotated data necessary to reach this target. We show that our approach yields improvements for fixed data sets, even when large-scale labeled data is available. The new features result in relative error reductions of 13.8% and 15.4% in terms of the balanced F-score and the recall of out-of-vocabulary (OOV) words respectively. By conducting experiments on data sets of varying sizes, we demonstrate that for fixed levels of performance, the new features derived from unlabeled data can significantly reduce the need of labeled data.

The remaining part of the paper is organized as follows. Section 2 describes the details of our system, especially the design of the derived features.

B	Current character is the start of a word consisting of more than one character.
E	Current character is the end of a word consisting of more than one character.
I	Current character is a middle of a word consisting of more than two characters.
S	Current character is a word consisting of only one character.

Table 1: The start/end representation.

Section 3 presents experimental results and empirical analysis. Section 4 reviews the related work. Section 5 concludes the paper.

2 Method

2.1 Discriminative Character-based Word Segmentation

The Character-based approach is a dominant word segmentation solution for Chinese text processing. This approach treats word segmentation as a sequence tagging problem, assigning labels to the characters indicating whether a character locates at the beginning of, inside or at the end of a word. This character-by-character method was first proposed by (Xue, 2003), and a number of discriminative sequential learning algorithms have been exploited, including structured perceptron (Jiang et al., 2009), the Passive-Aggressive algorithm (Sun, 2010), conditional random fields (CRFs) (Tseng et al., 2005), and latent variable CRFs (Sun et al., 2009). In this work, we use the *Start/End* representation to express the position information of every character. Table 2.1 shows the meaning of each character label. For example, the target label representation of the book title "赵紫阳总理的秘密日记/The Secret Journal of Premier Zhao Ziyang" is as follows.

赵	紫	阳	总	理	的	秘	密	日	记
B	I	E	B	E	S	B	E	B	E

Key to our approach is to allow informative features derived from unlabeled data to assist the segmenter. In our experiments, we employed three different feature sets: a baseline feature set which draws upon "normal" information from labeled training data, a statistics-based feature set that uses statistical information derived from a large-scale in-domain corpus, and a document-based feature set

that uses information encoded in the surrounding text.

2.2 Baseline Features

In this work, to train a good traditional supervised segmenter, our baseline feature templates includes the ones described in (Sun et al., 2009; Sun, 2010). These features are divided into two types: character features and word type features. Note that the word type features are indicator functions that fire when the local character sequence matches a word uni-gram or bi-gram. Dictionary containing word uni-grams and bi-grams is collected from the training data. To conveniently illustrate, we denote a candidate character token c_i with a context $...c_{i-1}c_ic_{i+1}...$. We use $c_{[s:e]}$ to express a string that starts at the position s and ends at the position e. For example, $c_{[i:i+1]}$ expresses a character bi-gram c_ic_{i+1}. The character features are listed below.

- *Character uni-grams*: c_s $(i-3<s<i+3)$
- *Character bi-grams*: c_sc_{s+1} $(i-3<s<i+3)$
- Whether c_s and c_{s+1} are *identical*, for $i-2<s<i+2$.
- Whether c_s and c_{s+2} are *identical*, for $i-4<s<i+2$.

The word type features are listed as follows.

- The *identity* of the string $c_{[s:i]}$ $(i-6<s<i)$, if it matches a word from the list of uni-gram words;
- The *identity* of the string $c_{[i:e]}$ $(i<e<i+6)$, if it matches a word; multiple features could be generated.
- The *identity* of the bi-gram $c_{[s:i-1]}c_{[i:e]}$ $(i-6<s,e<i+6)$, if it matches a word bi-gram from the list of uni-gram words.
- The *identity* of the bi-gram $c_{[s:i]}c_{[i+1:e]}$ $(i-6<s,e<i+6)$, if it matches a word bi-gram; multiple features could be generated.

Idiom In linguistics, idioms are usually presumed to be figures of speech contradicting the principle of compositionality. As a result, it is very hard to recognize out-of-vocabulary idioms for word segmentation. Nonetheless, the lexicon of idioms can be taken as a close set, which helps resolve the problem well. In our previous work (Sun, 2011), we collect 12992 idioms from several free online Chinese dictionaries. This linguistic resource is publicly available[3]. In this paper, we use this idiom dictionary to derive the following feature.

- Does c_i locate at the beginning of, inside or at the end of an idiom? If the string $c_{[s:i]}$ $(s<i)$ matches an item from the idiom lexicon, the feature template receives a string value "E-IDIOM". Similarly, we can define when this feature ought to be set to "B-IDIOM" or "I-IDIOM". Note that all idioms are larger than one character, so there is no "S-IDIOM" feature here.

2.3 Statistics-based Features

In order to distill information from unlabeled data, we borrow ideas from some previous research on unsupervised word segmentation. The statistical information acquired from a relatively large amount of unlabeled data are designed as features correlated with the position where a character locates in a word token. These features are based on three widely used criteria.

2.3.1 Mutual Information

Empirical mutual information is widely used in NLP. Informally, mutual information compares the probability of observing x and y together with the probabilities of observing x and y independently. If there is a genuine association between x and y, the $I(x,y)=\log\frac{p(x,y)}{p(x)p(y)}$ should be greater than 0.

Some previous work claimed that the larger the mutual information between two consecutive strings, the higher the possibility of the two strings being combined together. We adopt this idea in our character-based segmentation model. The empirical mutual information between two character bi-grams is computed by counting how often they appear in the large-scale unlabeled corpus. Given a

[3] http://www.coli.uni-saarland.de/~wsun/idiom.txt.

Chinese character string $c_{[i-2:i+1]}$, the mutual information between substrings $c_{[i-2:i-1]}$ and $c_{[i:i+1]}$ is computed as:

$$MI(c_{[i-2:i-1]}, c_{[i:i+1]}) = \log \frac{p(c_{[i-2:i+1]})}{p(c_{[i-2:i-1]})p(c_{[i:i+1]})}$$

For each character c_i, we incorporate the MI of the character bi-grams into our model. They include,

- $MI(c_{[i-2:i-1]}, c_{[i:i+1]})$,
- $MI(c_{[i-1:i]}, c_{[i+1:i+2]})$.

2.3.2 Accessor Variety

When a string appears under different linguistic environments, it may carry a meaning. This principle is introduced as the *accessor variety* criterion for identifying meaningful Chinese words in (Feng et al., 2004). This criterion evaluates how independently a string is used, and thus how likely it is that the string can be a word. Given a string s, which consists of l ($l \geq 2$) characters, we define the *left accessor variety* of $L^l_{av}(s)$ as the number of distinct characters that precede s in a corpus. Similarly, the *right accessor variety* $R^l_{av}(s)$ is defined as the number of distinct characters that succeed s.

We first extract all strings whose length are between 2 and 4 from the unlabeled data, and calculate their accessor variety values. For each character c_i, we then incorporate the following information into our model,

- Accessor variety of strings with length 4: $L^4_{av}(c_{[i:i+3]})$, $L^4_{av}(c_{[i+1:i+4]})$, $R^4_{av}(c_{[i-3:i]})$, $R^4_{av}(c_{[i-4:i-1]})$;
- Accessor variety of strings with length 3: $L^3_{av}(c_{[i:i+2]})$, $L^3_{av}(c_{[i+1:i+3]})$, $R^3_{av}(c_{[i-2:i]})$, $R^3_{av}(c_{[i-3:i-1]})$;
- Accessor variety of strings with length 2: $L^2_{av}(c_{[i:i+1]})$, $L^2_{av}(c_{[i+1:i+2]})$, $R^2_{av}(c_{[i-1:i]})$, $R^2_{av}(c_{[i-2:i-1]})$.

2.3.3 Punctuation as Anchor Words

Punctuation marks are symbols that indicate the structure and organization of written language, as well as intonation and pauses to be observed when reading aloud. Punctuation marks can be taken as perfect word delimiters, and can be used as anchor words to harvest lexical knowledge. The preceding and succeeding strings of punctuations carry additional wordbreak information, since punctuations should be segmented as a word. Note that such information is biased because not all words can appear before or after punctuations. For example, punctuations can not be followed by particles, such as "了", "着" and "过" which are indicators of aspects. Nevertheless, our experiments will show this kind of information is still useful for word segmentation.

When a string appears many times preceding or succeeding punctuations, there tends to be wordbreaks succeeding or preceding that string. To utilize the wordbreak information provided by punctuations, we extract all strings with length $l (2 \leq l \leq 4)$ which precede or succeed punctuations in the unlabeled data. We define the *left punctuation variety* of $L^l_{pv}(s)$ as the number of times a punctuation precedes s in a corpus. Similarly, the *right punctuation variety* $R^l_{pv}(s)$ is defined as the number of how many times a punctuation succeeds s. These two variables evaluate how likely a string can be separated at its start or end positions.

We first gather all strings surrounding punctuations in the unlabeled data, and calculate their punctuation variety values. The length of each string is also restricted between 2 and 4. For each character c_i, we import the following information into our model,

- Punctuation variety of strings with length 4: $L^4_{pv}(c_{[i:i+3]})$, $R^4_{pv}(c_{[i-3:i]})$;
- Punctuation variety of strings with length 3: $L^3_{pv}(c_{[i:i+2]})$, $R^3_{pv}(c_{[i-2:i]})$;
- Punctuation variety of strings with length 2: $L^2_{pv}(c_{[i:i+1]})$, $R^2_{pv}(c_{[i-1:i]})$.

Punctuations can be viewed as *mark-up's* of Chinese text. Our motivation to use the punctuation information to assist a word segmenter is similiar to (Spitkovsky et al., 2010) in a way to explore "artificial" word (or phrase) break symbols. In their work, four common HTML tags are successfully used as raw phrase bracketings to improve unsupervised dependency parsing.

2.3.4 Binary or Numeric Features

The derived information introduced above is all expressed as real values. The natural way to incorporate these statistics into a discriminative learning model is to directly use them as numeric features. However, our experiments show that this simple choice does not work well. The reason is that these statistics actually behave non-linearly to predict character labels. For each type of statistics, one weight alone cannot capture the relation between its value and the possibility that a string forms a word. Instead, we represent these statistics as discrete features.

For the mutual information, this is done by rounding down decimal number. The integer part of each MI value is used as a string feature. For the accessor variety and punctuation variety information, since their values are integer, we can directly use them as string features. The accessor variety and punctuation variety could be very large, so we set thresholds to cut off large values to deal with the data sparse problem. Specially, if an accessor variety value is greater than 50, it is incorporated as a feature "> 50"; if the value is greater than 30 but not greater than 50, it is incorporated as a feature "$30 - 50$"; else the value is individually incorporated as a string feature. For example, if the left accessory variety of a character bi-gram $c_{[i:i+1]}$ is 29, the binary feature "$L^2_{av}(c_{[i:i+1]})$=29" will be set to 1, while other related binary features such as "$L^2_{av}(c_{[i:i+1]}) = 15$" or "$L^2_{av}(c_{[i:i+1]}) > 50$" will be set to 0. Similarly, we can discretize the punctuation variety features. However, we only set one threshold, 30, for this value. These thresholds can be tuned by using held-out data.

2.4 Document-based Features

It is meaningless to derive statistics of a document and use it for word segmentation, since most documents are relatively short, and values are statistically unreliable. Our experiments confirm this idea. Instead, we propose the following binary features which are based on the *string count* in the given document that is simply the number of times a given string appears in that document. For each character c_i, our document-based features include,

- Whether the string count of $c_{[s:i]}$ is equal to that of $c_{[s:i+1]}$ $(i - 3 \leq s \leq i)$. Multiple features are generated for different string length.

- Whether the string count of $c_{[i:e]}$ is equal to that of $c_{[i-1:e]}$ $(i \leq e \leq i + 3)$. Multiple features are generated for different string length.

The intuition is as follows. The string counts of $c_{[s:i]}$ and $c_{[s:i+1]}$ being equal means that when $c_{[s:i]}$ appears, it appears inside $c_{[s:i+1]}$. In this case, $c_{[s:i]}$ is not independently used in this document, and this feature suggests the segmenter not assign a "S" or "E" label to the character c_i. Similarly, the string counts of $c_{[i:e]}$ and $c_{[i-1:e]}$ being equal means $c_{[i:e]}$ is not independently used in this document, and this feature suggests segmenter not assign a "S" or "B" label to c_i. We do not directly use the string counts to prevent a bias towards longer documents.

3 Experiments

3.1 Setting

The SIGHAN Bakeoffs provide several large-scale labeled data for the research on Chinese word segmentation. Although these data sets are labeled on continuous run texts, they do not contain the document boundary information. CTB is a segmented, part-of-speech tagged, and fully bracketed corpus in the constituency formalism. It is also an popular data set to evaluate word segmentation methods, such as (Jiang et al., 2009; Sun, 2011). CTB is a collection of documents which are separately annotated. This annotation style allows us to calculate the so-called document-based features and to further evaluate our approach. In this paper, we use CTB 6.0 as our main corpus and define the training, development and test sets according to the Chinese sub-task of the CoNLL 2009 shared task[4]. Table 2 shows the statistics of our experimental settings.

Data set	# of sent.	# of words	# of char.
Training	22277	609060	1004266
Devel.	1763	49646	83710
Test	2557	73152	121008

Table 2: Training, development and test data on CTB 6.0

[4]We would like to thank Prof. Nianwen Xue for the help with the division of the data

Chinese Gigaword is a comprehensive archive of newswire text data that has been acquired over several years by the Linguistic Data Consortium (LDC). The large-scale unlabeled data we use in our experiments comes from the Chinese Gigaword (LDC2005T14). We choose the Mandarin news text, i.e. Xinhua newswire. This data covers all news published by Xinhua News Agency (the largest news agency in China) from 1991 to 2004, which contains over 473 million characters.

F-score is used as the accuracy measure. Define precision p as the percentage of words in the decoder output that are segmented correctly, and recall r as the percentage of gold standard output words that are correctly segmented by the decoder. The (balanced) F-score is $2pr/(p+r)$. We also report the recall of OOV words. Note that, all idioms in our extra idiom lexicon are added into the in-vocabulary word list.

CRFsuite (Okazaki, 2007) is an implementation of Conditional Random Fields (CRFs) (Lafferty et al., 2001) for labeling sequential data. It is a speed-oriented implementation, which is written in pure C. In our experiments, we use this toolkit to learn global linear models for segmentation. We use the stochastic gradient descent algorithm to resolve the optimization problem, and set default values for other learning parameters.

3.2 Main Results

Table 3 summarizes the segmentation results on the development data with different configurations, representing a few choices between baseline, statistics-based and document-based feature sets. In this table, the symbol "+" means features of current configuration contains both the baseline features and new features for semi-supervised or transductive learning. From this table, we can clearly see the impact of features derived from the large-scale unlabeled data and the current document. Comparison between the performance of the baseline and "+MI" shows that the widely used mutual information is not helpful. Both good segmentation techniques and valuable labeled corpora have been developed, and pure supervised systems can provide strong performance. It is not a trial to design new features to enhance supervised models.

There are significant increases when accessor variety features and punctuation variety features are separately added. Extending the length of neighboring string helps a little from 2 to 3. Although the OOV recall increases when the length is extended from 3 to 4, there is no improvement of the overall balanced F-score. The line "+MI+AV(2,3,4)+PU(2,3,4)" shows the performance when all statistics-based features are added. The combination of the "AV" and "PU" features gives further helps. This system can be seen as a pure semi-supervised system. The line "+DOC" is the result when document-based features are added. In spite of its simplicity, the document-based features can help the task. However, when we combine statistics-based features with document-based features, we cannot get further improvement in terms of F-score.

Devel.	P	R	$F_{\beta=1}$	R_{oov}
Baseline	95.41	95.52	95.46	77.68
+MI	95.50	95.48	95.49	77.98
+AV(2)	95.85	96.04	95.94	79.31
+AV(2,3)	95.95	96.19	96.07	80.61
+AV(2,3,4)	96.14	95.99	96.07	81.83
+PU(2)	95.86	96.07	95.97	79.70
+PU(2,3)	95.98	96.25	96.11	80.42
+PU(2,3,4)	96.00	96.19	96.10	80.53
+MI+AV(2,3,4)+PU(2,3,4)				
	96.17	96.22	96.19	80.42
+DOC	95.69	95.64	95.66	79.89
+MI+AV(2,3,4)+PU(2,3,4)+DOC				
	96.21	96.23	96.22	81.75

Table 3: Segmentation performance with different feature sets on the development data. Abbreviations: MI=mutual information; AV=accessor variety; PU=punctuation variety; DOC=document features. The numbers in each bracket pair are the lengths of strings. For example, PU(2,3) means punctuation variety features of character bi-grams and tri-grams are added.

Table 4 shows the segmentation performance on the test data set. The final results of our system are achieved with the "+MI+AV(2,3,4)+PU(2,3,4)+DOC" feature configuration. The new features result in relative error reductions of 13.8% and 15.4% in terms of the balanced F-score and the recall of OOV words respectively.

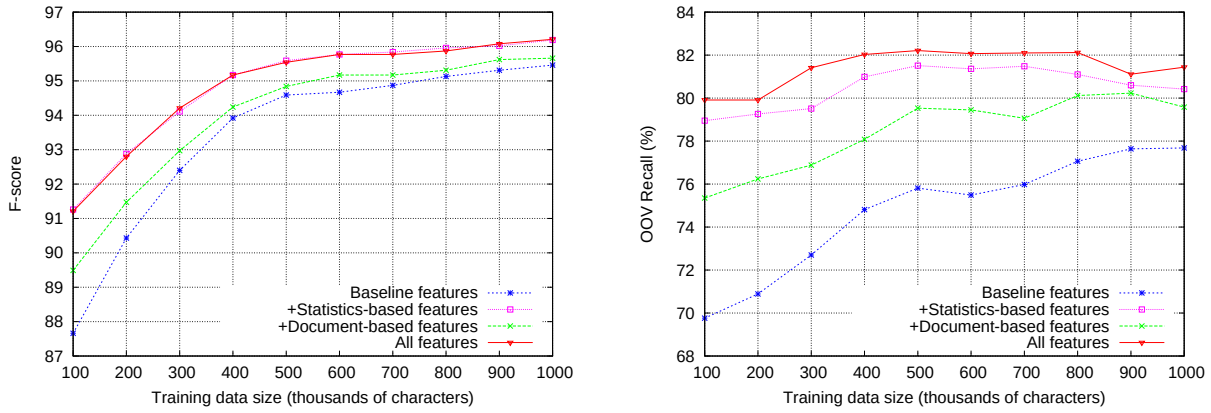

Figure 1: The learning curves of different models.

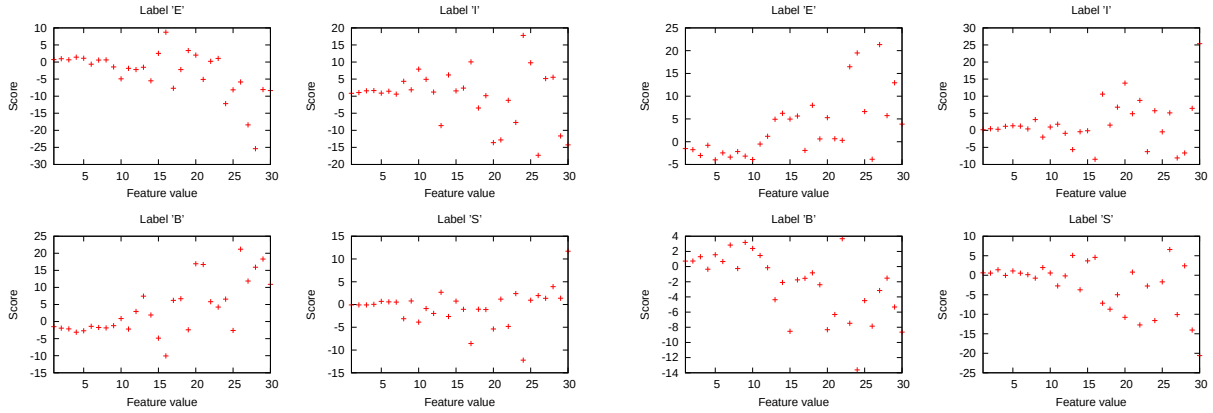

Figure 2: Scatter plot of feature score against feature value. The left side shows is $L^2_{pv}(c_{[i:i+1]}$ feature while the right side is the $R^2_{pv}(c_{[i:i+1]}$ feature.

Test	P	R	$F_{\beta=1}$	R_{oov}
Baseline	95.21	94.90	95.06	75.52
Final	95.86	95.62	95.74	79.28

Table 4: Segmentation performance on the test data.

3.3 Learning Curves

We performed additional experiments to evaluate the effect of the derived features as the amount of training data is varied. Figure 1 displays the F-score and the OOV recall of systems with different feature sets when trained on smaller portions of the labeled data. Note that there is no change in the configuration of the unlabeled data. We can clearly see that the derived features obtain consistent gains regardless of the size of the training set. The improvement is more significant when little labeled data is applied. Both statistics-based features and document-based features can help improve the overall performance. Especially, they can help to recognize more unknown words, which is important for many applications. The F-score of semi-supervised models, i.e. models trained with statistics-based features, does not achieve further improvement when document-based features are added. Nonetheless, the OOV recall obtains slightly improvements.

It is interesting to consider the amount by which derived features reduce the need for supervised data, given a desired level of accuracy. The change of the F-score in Figure 1 suggests that derived features reduce the need for supervised data by roughly a factor of 2. For example, the performance of the model with extra features trained on 500k characters

is slightly higher than the performance of the model with only baseline features trained on the whole labeled data.

3.4 Feature Analysis

We discussed the choice of using binary or numeric features in Section 2.3.4. In our experiment, when the accessor variety and punctuation variety information are integrated as numeric features, they do not contribute. To show the non-linear way that these features contribute to the prediction problem, we present the scatter plots of the score of each feature (i.e. the weight multiply the feature value) against the value of the feature. Figure 2 shows the relation between the score and the value of the punctuation variety features. For example, the weight of the binary feature "$L^2_{pu}(c_{[i:i+1]}) = 26$ combined with the label "B" learned by the final model is 0.815141, so the score of this combination is $0.815141 \times 26 = 21.193666$ and a point $(26, 21.193666)$ is drawn. These plots indicate the punctuation variety features contribute to the final model in a very complicated way. It is impossible to use one weight to capture it. The accessor variety features affect the model in the same way, so we do not give detailed discussions. We only show the same scatter plot of the $L^2_{av}(c_{[i:i+1]})$ feature template in Figure 3.

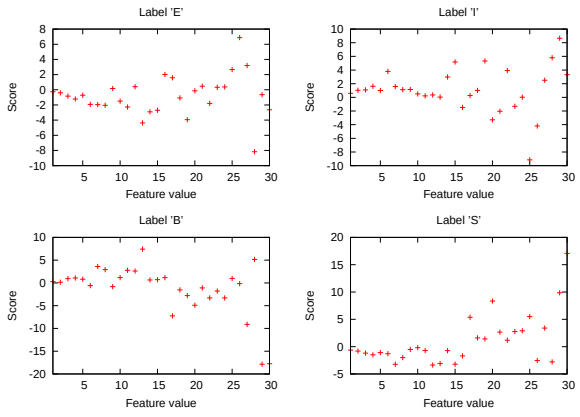

Figure 3: Scatter plot of feature score against feature value for $L^2_{av}(c_{[i:i+1]})$.

4 Related Work

Xu et al. (2008) presented a Bayesian semi-supervised approach to derive task-oriented word segmentation for machine translation (MT). This method learns new word types and word distributions on unlabeled data by considering segmentation as a hidden variable in MT. Different from their concern, our focus is general word segmentation.

The "feature-engineering" semi-supervised approach has been successfully applied to named entity recognition (Miller et al., 2004) and dependency parsing (Koo et al., 2008). These two papers demonstrated the effectiveness of using word clusters as features in discriminative learning. Moreover, Turian et al. (2010) compared different word clustering algorithms and evaluated their effect on both named entity recognition and text chunking.

As mentioned earlier, the feature design is inspired by some previous research on word segmentation. The accessor variety criterion is proposed to extract word types, i.e. the list of possible words, in (Feng et al., 2004). Different from their work, our method resolves the segmentation problem of running texts, in which this criterion is used to define features correlated with the character position labels. Li and Sun (2009) observed that punctuations are perfect delimiters which provide useful information for segmentation. Their method can be viewed as a self-training procedure, in which extra punctuation information is incorporated to filter out automatically predicted samples. We use the punctuation information in a different way. In our method, the counts of the preceding and succeeding strings of punctuations are incorporated directly as features into a supervised model.

In machine learning, transductive learning is a learning framework that typically makes use of unlabeled data. The goal of transductive learning is to only infer labels for the unlabeled data points in the test set rather than to learn a general classification function that can be applied to any future data sets. This means that the test data is known as a priori knowledge and can be used to construct better hypotheses. Although the idea to explore the document-level information in our work is similar to transductive learning, we do not use state-of-the-art transductive learning algorithms which involve learning when they meet the test data. For real-world applications, our approach is efficient by avoiding re-training.

5 Conclusion and Future Work

In this paper, we have presented a simple yet effective approach to explore unlabeled data for Chinese word segmentation. We are concerned with large-scale in-domain data and the document text. Experiments show that our approach achieves substantial improvement over a competitive baseline. Especially, the informative features derived from unlabeled data lead to significant improvement of the recall of unknown words. Our immediate concern for future work is to exploit the out-of-domain data to improve the robustness of current word segmentation systems. The idea would be to extract domain information from unlabeled data and define them as features in our unified approach. The word-based approach is an alternative for word segmentation. This kind of segmenters sequentially predicts whether the local sequence of characters make up a word. A natural avenue for future work is the extension of our method to the word-based approach. The word segmentation task is similar to constituency parsing, in the sense of finding boundaries of language units. Another interesting question is whether our method can be adapted to resolve constituency parsing.
