Abstract

Metonymic language is a pervasive phenomenon. Metonymic type shifting, or argument *type coercion*, results in a selectional restriction violation where the argument's semantic class differs from the class the predicate expects. In this paper we present an unsupervised method that learns the selectional restriction of arguments and enables the detection of argument coercion. This method also generates an enhanced probabilistic resolution of logical metonymies. The experimental results indicate substantial improvements the detection of coercions and the ranking of metonymic interpretations.

1 Introduction

Metonymic language is pervasive in today's social interactions. For example, it is typical to find questions that require metonymic resolution:

(Q1) Did you enjoy War and Peace?
(Q2) Does anyone have any advice on how to start a bowling team?[1]

In order to process such questions and capture the intention of the person that posed them, coercions are needed. Question (Q1) is interpreted as whether you enjoyed *reading* "War and Peace", while (Q2) is interpreted as asking for advice on *organizing*, *forming*, or *registering* a bowling team. The quality of the answers therefore depends on the ability to (1) recognize when metonymic language is used, and (2) to produce coercions that capture the user's intention. One important step in this direction was taken by SemEval-2010 Task 7, which focused on the ability to recognize (a) an argument's selectional restriction for predicates such as *arrive at*, *cancel*, or *hear*, and (b) the type of coercion that licensed a correct interpretation of the metonymy. Details of the task are reported in (Pustejovsky et al., 2010). Approaches to metonymy based on this task are limited, however, because (a) the task is focused only on semantically non-ambiguous predicates and (b) the selectional restrictions of the arguments were chosen from a pre-defined set of six semantic classes (artifact, document, event, location, proposition, and sound). However, metonymy coercion systems capable of providing the interpretations of questions (Q1) and (Q2) clearly cannot operate with the simplifications designed for this task.

Inspired by recent advances in modeling selectional preferences with latent-variable models (Ritter et al., 2010; Ó Séaghdha, 2010), we propose an unsupervised model for learning selectional restrictions. The model assumes that (1) arguments have a single selected class exemplified by the selectional restriction, and (2) the selected class can be inferred from the data, in part by modeling how coercive each predicate is. The model is capable of operating with both ambiguous and disambiguated predicates, producing superior results for predicates that have been disambiguated. The selectional restrictions and coercions detected by the model reported in this paper can be used to enhance the logical metonymy approach reported in Lapata and Lascarides (2003). The experimental results show a significant improvement in the ranking of interpretations.

The rest of this paper is organized as follows. Section 2 discusses related work. Section 3 details unsupervised models that inform detection of metonymies. Section 4 outlines a method for disambiguating ambiguous predicates. Section 5 describes the enhanced interpretation of logical metonymies when conventional constraints are known. Section 6 outlines our implementation and experimental design. Section 7 presents our experimental results in three broad tasks: (i) semantic class induction, (ii) coercion detection, and (iii) logical metonymy interpretation. Section 8 summarizes the conclusions.

2 Previous Work

Lapata and Lascarides (2003) propose a probabilistic ranking model for logical metonymies. They estimate these probabilities using co-occurrence frequencies of predicate-argument pairs in a corpus. Shutova (2009) extends this approach to provide sense-disambiguated interpretations from WordNet (Fellbaum, 1998) by using the alternative interpretations to disambiguate polysemous words. Shutova and Teufel (2009) extend this approach further by clustering these sense-disambiguated interpretations into distinct groups of meaning (e.g., {*read*, *browse*, *look through*} and {*write*, *produce*, *work on*} for "*enjoy book*"). Not only do these approaches assume logical metonymies have already been identified, but they are susceptible to providing interpretations that are themselves logical metonymies (e.g., *finish book*). In this paper, we propose an enhancement to resolving logical metonymies by ruling out event-invoking predicates in order to provide more semantically valid interpretations.

Recently, the resolution of several linguistic problems has benefited from Latent Dirichlet Allocation (LDA) (Blei et al., 2003) models. Ó Séaghdha (2010) examines several selectional preference models based on LDA in predicting human judgements on predicate-argument plausibility. Both LDA and an extension, ROOTH-LDA (based on Rooth et al. (1999)), perform well at predicting plausibility on unseen predicate-argument pairs. Inspired by these results, we propose to extend selectional preference models in order to learn selectional restrictions.

Alternatively, unsupervised algorithms exist that both induce semantic classes (Rooth et al., 1999; Lin and Pantel, 2001) and cluster predicates by their selectional restrictions (Rumshisky et al., 2007) but none of these provide a sufficient framework for determining if a specific argument violates its predicate's selectional restriction.

3 Unsupervised Learning of Selectional Restrictions

In predicate-argument structures, predicates impose selectional restrictions in the form of semantic expectations on their arguments. Whenever the semantic class of the argument meets these constraints a *selection* occurs. For example, the predicate "*hear*" imposes the semantics related to sound on the argument "*voice*". Because the semantic class for "*voice*" conforms to these constraints, we call its semantic class the *selected class*. However, when the semantic class of the argument violates these constraints, we follow Pustejovsky et al. (2010) and refer to this as a *coercion*. In this case, we call the argument's semantic class the *coerced class*. For example, "*hear speaker*" is a coercion where the argument class, person, is implicitly coerced into the voice of the speaker, a sound.

3.1 A Baseline Model

We consider the LDA-based selectional preference model reported in Ó Séaghdha (2010) as a baseline for modeling selectional restrictions. Formally, we define our LDA baseline model as follows. Let V be the predicate vocabulary size, let A be the argument vocabulary size, and let K be the number of argument classes. Let a_i^v be the i^{th} (non-unique) argument realized by predicate v. Let c_i^v be the class for a_i^v. Let θ^v be the class distribution for predicate v and ϕ^k be the argument distribution for class k. The graphical model for this LDA is shown in Figure 1(a). The generative process for LDA is:

For each argument class $k = 1..K$:
1. Choose $\phi^k \sim$ Dirichlet(β)

For each unique predicate $v = 1..V$:
2. Choose $\theta^v \sim$ Dirichlet(α)

For every argument $i = 1..n^v$:
3. Choose $c_i^v \sim$ Multinomial(θ^v)
4. Choose $a_i^v \sim$ Multinomial($\phi^{c_i^v}$)

Following Griffiths and Steyvers (2004), we collapse θ and ϕ and estimate the model using Gibbs

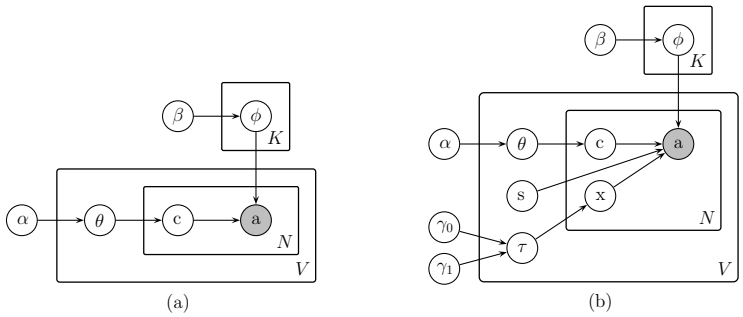

Figure 1: Graphical models for (a) LDA, and (b) coercion LDA (cLDA).

Sampling. This yields the update equation:

$$p(c_i^v = k|\mathbf{a}^v; \alpha, \beta) \propto \frac{f_{vk} + \alpha}{f_v + K\alpha} \frac{f_{ak} + \beta}{f_k + A\beta} \quad (1)$$

Where f_{ak} is the frequency of argument a being assigned class k; f_k is the frequency of class k being assigned to any argument; f_{vk} is the frequency of predicate v having an argument of class k; and f_v is the total number of non-unique arguments for predicate v.

3.2 A Coercion Model

We now incorporate our assumptions for selectional restriction modeling. Namely: (1) there is one selected class per predicate, and (2) the predicate's selected class can be chosen from the classes of its arguments. To accomplish this, we must also account for the coerciveness of each predicate. We assign a latent variable τ^v for each predicate v that controls how coercive v should be. The additional hyper-parameters γ_0 and γ_1 act as priors on τ^v. The generative process for this coercion LDA model, which we denote cLDA, is:

For each argument class $k = 1..K$:
1. Choose $\phi^k \sim$ Dirichlet(β)

For each unique predicate $v = 1..V$:
2. Choose $s^v \sim$ Uniform(1,K)
3. Choose $\theta^v \sim$ Dirichlet(α)[2]
4. Choose $\tau^v \sim$ Beta(γ_0, γ_1)

For every argument $i = 1..n^v$:
5. Choose $c_i^v \sim$ Multinomial(θ^v)
6. Choose $x_i^v \sim$ Bernoulli(τ^v)
7. If $x_i^v = 1$, Choose $a_i^v \sim$ Multinomial($\phi^{c_i^v}$)
   Else Choose $a_i^v \sim$ Multinomial(ϕ^{s^v})

The model variable s^v represents the selected class for predicate v. The coerced class is represented for each argument i by c_i^v, where x_i^v chooses between the selected and coerced class. The variable x_i^v is similar to switching variables in other graphical models such as Chemudugunta et al. (2007) and Reisinger and Mooney (2010), where switching variables are used to choose between a background distribution and a document-specific distribution. In this case, the switching variable chooses between a specific class and a predicate-specific distribution. The graphical model for cLDA is shown in Figure 1(b). Note that cLDA is virtually equivalent to LDA when τ^v is 1 and γ_1 is small because the selected class will be ignored. In this way, highly coercive predicates have less of an impact on the argument clustering because they are more reliant on the multinomial θ. We use Gibbs sampling to perform model inference and collapse θ, ϕ, and τ, integrating them out using multinomial-Dirichlet conjugacy (the Beta distribution used by τ is just a special case of the Dirichlet with only two parameters).

The update formula for the selected class s^v is:

$$\begin{aligned} p(s^v = k|\mathbf{a}^v, \mathbf{c}^v, \mathbf{x}^v; \alpha, \beta) \\ &\propto \prod_i^{n^v} P(a_i^v|s^v = k; \beta) \\ &\propto \prod_{i \in S^v} \frac{f_{a_i^v k} + \beta}{f_k + A\beta} \end{aligned} \quad (2)$$

Where n^v is the number of argument observations for predicate v; S^v is the set of arguments of v that are selections; and $f_{a_i^v k}$ is the frequency of word a_i^v being assigned to class k for any predicate. We then sample c_i^v and x_i^v jointly:

$$\begin{aligned} p(c_i^v = k, x_i^v = q|s^v, \mathbf{c}_{\bar{i}}^v, \mathbf{x}_{\bar{i}}^v, \mathbf{a}^v; \alpha, \beta, \gamma) \\ &\propto p(c_i^v{=}k; \alpha) p(x_i^v{=}q; \gamma) p(a_i^v|s^v, \mathbf{c}_{\bar{i}}^v, \mathbf{x}_{\bar{i}}^v, \mathbf{a}^v; \beta) \\ &\propto \frac{f_{vk} + \alpha}{f_v + K\alpha} \frac{f_{vq} + \gamma_q}{f_{v0} + \gamma_0 + f_{v1} + \gamma_1} \frac{f_{az} + \beta}{f_z + A\beta} \end{aligned} \quad (3)$$

[2]With the exception that the probability of drawing the selected class s^v is zero. This can be seen as drawing the multinomial θ^v from a Dirichlet distribution with K-1 components.

Where f_{vq}, f_{v0}, and f_{v1} is the frequency of x values that equal q, 0, and 1, respectively, for predicate v; f_{az} is the frequency of word a being in class z and f_z is the frequency all words being in class z, where z is defined as being equal to k when $x_i^v = 1$, or s^v when $x_i^v = 0$.

Note that Equation (2) results in a sampling of the selected class for v proportional to the number of arguments in each class for v, fulfilling our second assumption. Also note from Equation (3), the second term corresponds to the coerciveness of the predicate. When the predicate is very coercive, the marginal probability associated with $x_i^v = 0$ will be very low. If all predicates become entirely coercive, most x values will become 1 and the cLDA will become almost equivalent to an LDA model.

3.3 Coercion Detection

After the latent parameters have been estimated, we still require a method to determine if a given predicate-argument pair is a coercion or not. We assign a score in $[0, 1]$ instead of a binary value. Higher scores (near 1) indicate high likelihood of selection, while lower scores (near 0) indicate coercion. The LDA model must rely on a scoring method using the predicate-class and argument-class mixtures:

$$C_1(v, a) = \sum_k^K P(k|v)P(a|k) = \sum_k^K \theta_k^v \phi_a^k \quad (4)$$

Where θ_k^v represents the probability of any argument of v being in the class k and ϕ_a^k represents the probability of the argument a being in class k for any predicate. C_1 is also available as a scoring method for cLDA by including the proportion of the selected class s^v in θ. Note that since θ and ϕ are integrated out for both LDA and cLDA, we instead use their frequencies smoothed with α and β, respectively, which is their maximum likelihood estimate.

The cLDA model contains two useful parameters that can identify selections and coercions: the selected class s and the coercion indicator x. This yields two more coercion scoring metrics:

$$C_2(v, a) = P(a|s^v) = \phi_a^{s^v} \quad (5)$$

$$C_3(v, a) = P(x_a^v = 0|v, a) = 1.0 - \frac{\sum_{i \in I_a^v} x_i^v}{|I_a^v|} \quad (6)$$

Where s^v is the selected class for predicate v; I_a^v is the set of predicate-argument instances for predicate v and argument a; and x_i^v is 0 for a selection and 1 for a coercion. Of the three metrics, C_3 is the most direct measure of a coercion as it represents the average decision the model learned on the same predicate-argument pair. However, C_3 requires a large sample of instances for a particular predicate and argument, and so may be quite sparse. In practice, these different metrics have their own strengths and weaknesses and the best performing method often depends on the final task.

4 Predicate Sense Induction

Our assumption of a single selected class per predicate ignores predicate polysemy. However, the same lexical item may have multiple meanings, each with a separate selected class. We therefore propose a method of partitioning a predicate's arguments by the induced senses of the predicate. This allows separate induced predicates to each select a separate argument class. Consider the verb *fire*, which has at least two distinct common senses: (1) to shoot or propel an object (e.g., to fire a gun), and (2) to lay someone off (e.g., to fire an employee). The first sense selects a weapon (e.g., gun, bullet, rocket), while the second sense selects a person (e.g., employee, coach, apprentice).

Specifically, we employ tiered clustering (Reisinger and Mooney, 2010) using the words in the predicate's context. Tiered clustering is a discrete clustering method, as opposed to methods such as (Brody and Lapata, 2009) that assign a distribution of word senses to each word instance. Tiered clustering has several advantages over other discrete clustering approaches. First, tiered clustering learns a background word distribution in addition to the clusters. This reduces the impact that words common to most senses have on the clustering process and allow clusters to form around only the most salient words. Second, tiered clustering

Cluster 1 (18,391)	Cluster 2 (16,651)	Cluster 3 (18,749)	Cluster 4 (11,833)
shots	ball	hire	gun
gun	puck	letter	imagination
Israeli	hired	Yeltsin	grill
missiles	owner	minister	laser
rockets	shots	workforce	cells
officers	coaches	executives	engine
soldiers	net	employee	brain
rounds	circle	managers	!
bullets	Johnson	hired	engines
weapons	Williams	union	fire

Table 1: Context word clusters resulting from tiered clustering for the verb *fire* (includes the number of unique words belonging to each cluster).

uses a Chinese Restaurant Process (CRP) prior to control both the formation of new clusters (senses) and the bias toward larger clusters (more common senses). This conforms with our intuition of how word senses are distributed: a few common senses with a gradual transition to a long tail of rare senses. When deciding which cluster to use for a given predicate-argument pair, we use the cluster most associated with the argument.

We use a 10-token window around the predicate as features. The result of predicate induction on the verb *fire* is shown in Table 4. The first three clusters can be interpreted to be about (1) firing weapons, (2) sport-related shots (e.g., "*fired the puck*"), and (3) lay-offs. One must be careful in choosing the parameters for induction, however, as it is possible to partition a unique word sense such that coercions and selections are placed in a separate clusters. Section 6 discusses our parameter selection experiments.

5 Logical Metonymy Interpretation

Logical metonymies are a unique class of coercions due to the fact that their eventive interpretation can be derived from verbal predicates. For instance, for the logical metonymy "*enjoy book*", we know that *read* is a good candidate interpretation because (1) books are objects whose purpose is to be read and (2) reading is an event that may be enjoyed. We therefore expect to see many instances of both "*read book*" and "*enjoy reading*" (Lapata and Lascarides, 2003). Conversely, for coercions with non-eventive interpretations, such as "*arrive at meeting*", the interpretation (*location of*) is more dependent on the predicate (*arrive*) than the function of its argument (*meeting*).

In this section, we limit our discussion of logical metonymy to the verb-object case, its corresponding baseline for ranking interpretations, and our proposed enhancements. However, similar baselines exist for other types of logical metonymy, such as adjective-noun and noun-noun. Since our enhancement does not depend on any syntactic information beyond the predicate-argument instances needed for Section 3.2, it could easily be applied to those as well.

Lapata and Lascarides (2003) propose a probabilistic ranking model where the probability of an interpretation e for a verb-object pair (v, o) is proportional to the probability of all three in a verb-interpretation-object pattern.[3] For example, the probability that *read* is the correct interpretation of "*enjoy book*" is proportional to the likelihood of seeing "*enjoy reading book*" expressed as a syntactic dependency in a sufficiently large corpus. Due to data sparsity, they approximate this likelihood of seeing the object given the verb and interpretation to simply the likelihood of seeing the object given the interpretation. We denote this logical metonymy ranking method as LM_{LL}, formally defined as:

$$\begin{aligned} LM_{LL}(e; v, o) &= P_c(v, e, o) \\ &= P_c(e)P_c(v|e)P_c(o|e, v) \\ &\approx P_c(e)P_c(v|e)P_c(o|e) \\ &\approx \frac{f_c(v, e)f_c(o, e)}{N f_c(e)} \end{aligned} \quad (7)$$

Where P_c and f_c indicate probability and frequency, respectively, derived from corpus counts. See Lapata and Lascarides (2003) for a detailed explanation of how these frequencies are obtained.

This model, which we consider our baseline, is only partially correct as the corpus will contain coercions that form invalid interpretations. Consider the phrases "*enjoy finishing a book*" and "*enjoy discussing a book*". Both "*finish book*" and "*discuss book*" are coercions (and logical metonymies) themselves, and do not form a valid interpretation.[4]

[3] They use two patterns: "*v e*-ing *o*" and "v to e *o*", where e is tagged as a verb.

[4] For evidence of the frequency of these phrases, at the time of this writing, "*enjoy finishing a book*" and "*enjoy finishing the book*" have a combined 728 Google hits, while "*enjoy discussing a book*" and "*enjoy discussing the book*" have a com-

Thus, when discovering interpretations for logical metonymies, we must be aware of the selectional restrictions of candidate interpretations.

We propose to incorporate the coercion probability learned by our cLDA model in order to rank only those interpretations that are considered selections:

$$LM'(e; v, o) = P(v, e, o, x_o^e = 0) \quad (8)$$

However, due to the approximations made to estimate $P_c(v, e, o)$, this probability cannot be directly calculated as not all the frequencies reflect verb-object counts. Instead, we can combine the corpus probability $P_c(v, e, o)$ with the probability that the verb-object pair (e, o) is a coercion in our model. We denote this probability $P_x(e, o)$, and it may be derived from the scoring metrics in Equations (4), (5), or (6) above. We further propose three methods for enhancing the LM_{LL} baseline using $P_x(e, o)$ to approximate Equation 8.

A naive method for including information from our cLDA model is to consider the corpus probability, $P_c(v, e, o)$ and the coercion probability, $P_x(e, o)$, to be independent:

$$LM_{IND}(e; v, o) = P_c(v, e, o)P_x(e, o) \quad (9)$$

In other words, the rank of an interpretation is dictated by the unweighted combination of its corpus probability P_c and its coercion probability P_x. However, these two quantities are not likely to be independent. Most instances where e is used with either v or o are in fact selective.[5] We therefore experiment with two shallow learning methods for combining these two quantities.

The first method is a filtering approach where a threshold is learned for P_x:

$$LM_{TH}(e; v, o) = \begin{cases} P_c(v, e, o) & \text{if } P_x(e, o) \geq \delta \\ 0 & \text{otherwise} \end{cases} \quad (10)$$

Where the threshold δ is learned from a development set. We expect this model could suffer from noisy P_x values or to simply choose a threshold of zero due to the prominence of P_c.

Finally, we include a weighted linear model to discover the relative value of P_c and P_x:

$$LM_{WT}(e; v, o) = w_1 P_c(v, e, o) + w_2 P_x(e, o) \quad (11)$$

Where w_1 and w_2 are learned weights. We discuss how the parameters for LM_{TH} and LM_{WT} are learned in the experimental setup below.

6 Experimental Setup

We use the NYT subsection of the English Gigaword Fourth Edition (Parker et al., 2009) for a total of 1.8M newswire articles. The Stanford Dependency Parser (de Marneffe et al., 2006) is used to extract verb-object relations (*dobj*) that form the input to our model. To reduce noise, we keep only verbs listed in VerbNet (Kipper et al., 1998) with at least 100 argument instances, discarding *have* and *say*, which are too semantically flexible to select from clear semantic classes and so common they distort the class distributions. This results in 4,145 unique verbs with 51M argument instances (388K unique arguments). Additionally we use the dependency parser to extract open clausal complements of verbs (e.g., "*like to swim*") for use in logical metonymy interpretation. We believe this to be a more reliable alternative to the phrase chunk extraction patterns used in Lapata and Lascarides (2003). We keep clausal complements (*xcomp*) where the dependent is either a gerund or infinitive in order to estimate $P_c(v|e)$ in Equation (7).

For tiered clustering we use the same implementation as Reisinger and Mooney (2010)[6] to partition the surface form of the verb into one or more induced forms. Instead of using a fixed number of iterations, the clustering was run for 100 iterations past the best recorded log-likelihood in order to find the best possible fit to the data. We tuned the hyperparameters by maximizing the log-likelihood on a small held-out set of 20 predicate-argument pairs (10 selections, 10 coercions). The resulting partitions were fairly conservative, yielding 12,332 induced verbs or about 3 induced verb forms for every surface form, with 305 verbs not being partitioned at all.

We implemented both LDA and cLDA as described in Sections 3.1 and 3.2. For the α and β

bined 7,040 Google hits.

[5] For comparison, "*enjoy reading a book*" and "*enjoy reading the book*" have a combined 6.5 million Google hits

[6] Available at http://github.com/joeraii/UTML-Latent-Variable-Modeling-Toolkit

hyper-parameters, we used the MALLET (McCallum, 2002) defaults of 1.0 and 0.1, respectively, for both LDA and cLDA. We used the 20 predicate-argument pairs mentioned above to tune the γ hyper-parameters as well as the number of iterations. Both γ_0 and γ_1 were set to 100. We observed that for both LDA and cLDA, longer runs (in iterations) resulted in improved model log-likelihood but inferior results in terms of detecting coercions. It is not uncommon in topic modeling for model likelihood to not be completely correlated with the score on the task for which the topic model was intended (see Chang et al. (2009)). Both LDA and cLDA were found to perform best at 50 iterations on this data, after which their class distributions were less "smooth" and became rigidly associated with just a few classes, thus having a negative impact on coercion detection. While further iterations hurt coercion detection, only minor gains in model likelihood are seen. We believe the small number of iterations necessary for the model to converge is therefore a function of the data. In traditional topic modeling, documents are generally of similar size (i.e., within an order of magnitude). But in our data, many predicates have 10,000 times more instances than others. We have not yet empirically explored the impact of using a more uniform number of arguments for each predicate. This issue also makes it difficult to take multiple samples, which we experimented with unsuccessfully.

Our a priori intuition was that as the number of classes was increased, LDA would improve and cLDA would degrade due to its assumption of a single selected class. However, this did not always bear out in the results for every task described below. As such, instead of choosing a specific number of classes for each model, we describe results for each model with $K = 10$, 25, and 50.

For logical metonymy, both LM_{TH} and LM_{WT} require learned parameters. LM_{TH} needs a learned threshold while LM_{WT} needs two learned weights. For both, we split the data set into two partitions, learn the optimal threshold/weights on one partition, and use it as the parameters for the other partition. Both methods are trained on the final scoring metric, described in Section 7.3. For threshold learning, this involves finding the optimal cut-off to maximize the score. For weight learning, we use an exhaustive search over the range {1.0, 0.9, ..., 0.2, 0.1, 10^{-2}, 10^{-3}, ..., 10^{-14}} for both w_1 and w_2.

7 Results and Discussion

7.1 Semantic Class Induction

For the evaluation of the argument classes induced by our method, we use a subset of the WordNet lexicographer files, which correspond to coarse-grained semantic classes. We chose this form of evaluation because, unlike a named entity corpus, no sentential context is required and is therefore more consistent with the information available to our model. We use six of the larger, more semantically coherent WordNet classes: artifact, person, plant, animal, location, and food. We consider each of these a cluster and compare them to clusters composed of the top ten non-polysemous words (according to WordNet) in each of the classes generated by both the baseline (LDA) and our model (cLDA). Words not in both sets of clusters are removed. The result of this evaluation, compared with six clustering metrics, is shown in Table 2. For descriptions of NMI, Rand, and cluster F-measure, see Manning et al. (2008); for the B^3 metrics (Cluster and Element), see Bagga and Baldwin (1998); for the MUC metric, see Vilain et al. (1995). Each metric has different strengths and biases in regards to the number and distribution of clusters, so all are provided to give a general picture of class induction performance.

The best performing model on all metrics is cLDA with induced predicates using 10 classes. However, as the number of classes is increased and the granularity of the induced classes becomes more fine-grained, LDA (predictably) outperforms cLDA on most metrics. This is consistent with our intuition

induced predicates?		N			Y		
# classes		10	25	50	10	25	50
LDA	C_1	74.4	78.7	80.5	69.7	70.1	73.4
cLDA	C_1	80.6	**81.2**	80.9	76.2	78.4	77.5
	C_2	75.4	75.9	78.9	73.5	68.3	**80.8**
	C_3	67.8	70.8	67.4	70.9	67.4	74.1

Table 3: Accuracy on SemEval-2010 Task 7 data.

that a single-class assumption degrades as the number of classes increases.

For this evaluation, predicate induction also improved LDA for smaller numbers of classes, but not to the degree that it improved cLDA. Without predicate induction, LDA outperforms cLDA on all six metrics for 25 and 50 classes. With predicate induction, LDA outperforms cLDA on only one metric for 25 classes and five metrics for 50 classes. Thus the induced predicates do reduce the negative impact caused by the single selected class assumption for semantic class induction.

7.2 Coercion Detection

For the evaluation of coercion detection, we use the SemEval-2010 Task 7 data (Pustejovsky et al., 2010). This data uses the most common sense for each of five predicates (*arrive*, *cancel*, *deny*, *finish*, and *hear*) with a total of 2,070 sentences annotated with the argument's source type (the argument's semantic class) and target type (the predicate's selected class for that argument). We ignore the actual argument classes and evaluate on the coercion type, which is a selection when the source and target type match, and a coercion otherwise.

In order to evaluate unsupervised systems on this data, we use the corresponding training set (1,031 examples) to learn a threshold for coercion detection. At test time, if the model output is below the threshold, a coercion is inferred. Otherwise it is considered a selection. Therefore, the better a model can rank selections over coercions, the more accurate threshold it will learn. The results for this evaluation are shown in Table 3. The baseline for this task (threshold = 0, or all selections) is 67.4.

The best overall model on this data is cLDA using the C_1 coercion scoring method (Equation (4)). This method consistently outperforms the baseline LDA, especially for smaller numbers of classes, performing best with $K = 25$. The second metric, C_2, was not as reliable. The third metric, C_3, performed poorly on the task. As discussed in Section 3.3, C_3 is a direct result of the sampling for the predicate-argument pair in question and can thus be expected to perform poorly on rare predicate-argument pairs. Given that many of the arguments in this data are rare or unseen in the Gigaword data (e.g., "*cancel Renault*"), C_3's poor performance is understandable.

The use of predicate sense induction based on tiered clustering to overcome the single-class assumption caused significant degradation in performance on this task. Using automatically induced predicates instead of the surface form caused an average degradation of 2.6 points across the twelve tests. A potential explanation for this is that the evaluated predicates have a single dominant sense, meaning the single class assumption may be valid for these predicates (the task-defined selected classes are: location for *arrive*, event for *cancel* and *finish*, proposition for *deny*, and sound for *hear*). Therefore it would be interesting to evaluate it on a set of highly polysemous predicates with multiple dominant senses. Furthermore, the introduction of predicate sense induction was designed to help cLDA, and the performance degradation for these nine tests was not as large as it was for LDA. For cLDA, C_1 had an average degradation of 3.5 points compared to LDA's C_1 average degradation of 6.5 points. cLDA's C_2 had an average degradation of only 2.5 points and C_3 was actually improved by 2.1 points. This suggests that there is value in assigning different selected classes via sense induction, but that the two-step approach is not beneficial for these common predicates. This could be overcome by a joint approach of inducing predicate classes while simultaneously detecting coercions, as the presence of many coercions would be an indicator that more induced predicates are necessary.

7.3 Logical Metonymy Interpretation

For the evaluation of logical metonymy, we use both an existing data set and a newly created data set. Shutova and Teufel (2009) annotated 10 verb-object logical metonymies from Lapata and Lascarides (2003) with sense-disambiguated interpretations and organized the interpretations into clusters representing different possible meanings. For evaluation purposes we ignore the sense annotations and clusters and consider all lexical matchings of one of the annotated interpretations to be correct. The

Table 5: Mean average precision (MAP) scores on 100 logical metonymies manually annotated with interpretations. The bold items indicate the best scores with/without induced predicates as well as using/not using a threshold-based interpretation method.

data contains an average of 11 interpretations per metonymy and has a reported 70% recall.

In order to create a larger data set, we identified 100 verb-object logical metonymies, including those used in Lapata and Lascarides (2003). Three annotators were asked to provide up to five interpretations for each metonymy (they were not provided with any verbs from which to choose, only the verb-object pair). The annotators provided an average of 4.6 interpretations per metonymy. Because our goal was recall, inter-annotator agreement was necessarily low, and each logical metonymy had an average of 11.7 unique interpretations. All annotators agreed on at least one interpretation for 40 metonymies, while for 14 they had no interpretations in common.[7]

Since logical metonymy interpretation is usually evaluated as a ranking task, we score our methods using mean average precision (MAP):

$$\text{MAP} = \frac{1}{Q}\sum_{q=1}^{Q}\frac{\sum_{n=1}^{N}\text{prec}(n)\times\text{rel}(n)}{\text{interps}(q)} \qquad (12)$$

Where Q is the number of metonymies evaluated; N is the number of interpretations ranked; prec(n) is the precision at rank n; rel(n) = 1 if interpretation n is valid, 0 otherwise; and interps(q) is the number of valid interpretations for the metonymy q. We rank all 4,145 verbs as interpretations except for those removed by the threshold technique, as they have a score of zero. This can give LM_{TH} artificially high MAP scores since it may remove some valid interpretations that are low-ranking. However, since a smaller, higher precision list may be useful for many applications we still consider MAP a valid metric and indicate both the highest scoring method and the highest scoring non-threshold method. The results on the Shutova and Teufel (2009) data are

[7] Data available at http://www.hlt.utdallas.edu/∼kirk/data/lmet.zip

shown in Table 4. The results on our own data are shown in Table 5.

The scores reported in the Shutova and Teufel (2009) data are noticeably higher than the data we annotated. Since the metonymies in our data are a super-set of those in their data, and since for those metonymies our annotators provided approximately the same number of interpretations (110 versus 120), this likely indicates the remaining metonymies in our data are more difficult.

In all cases the best reported scores use cLDA. Unlike coercion detection on the SemEval data, C_3 performs very well, achieving the highest scores when no predicate sense induction is used. Also unlike coercion detection, LDA scores do not increase as the number of classes increase. We suspect both these differences have to do with the fact that the arguments in this data are far more common. Since LDA is a selectional preference model and its coercion scores correspond roughly to the plausibility of seeing a predicate-argument pair, it is less able to distinguish coercions in common arguments.

Of the logical metonymy ranking methods, LM_{TH} consistently produces the highest MAP scores. However, as stated before, by using a cut-off and removing low-ranking valid interpretations, the MAP score is increased, which might not be applicable to some applications. The best non-thresholded ranking method is LM_{IND}, which naively combines the LM_{LL} score with the coercion probability. In almost every case this beats out LM_{WT}. Upon inspection, we observed that the range of scale for the LM_{LL} scores are very inconsistent. This can make it difficult to learn a linear model using these scores as features, and as a result the learned weights were forced to ignore the coercion score and rely entirely on LM_{LL}. We attempted other scaling methods, such as a rank-based method, but these had poor results as well, so we leave the problem of the supervised learning these weights to future work.

Using induced senses did not result in the drastic and consistent degradation in performance seen on the SemEval data, and the highest non-threshold result for the Shutova and Teufel (2009) data used predicate induction. Both metonymy data sets were limited to the verbs found in Lapata and Lascarides (2003), which are still quite common (*attempt*, *begin*, *enjoy*, *expect*, *finish*, *prefer*, *start*, *survive*, *try*, *want*). However, the verbs used in our data set had a greater number of WordNet senses attested in a corpus than the SemEval data (an average of 4.4 senses for our data versus 3.0 senses for the SemEval data). This suggests the potential value of sense induction for highly polysemous predicates and further motivates the integration of sense induction within a selectional restriction model.

8 Conclusion

We have presented a novel topic model that extends an unsupervised selectional preference model (LDA) to an unsupervised selectional restriction model (cLDA) using two assumptions. For the first assumption, that each predicate has a single selected class, we proposed a predicate induction method to overcome predicate polysemy. This improved results for semantic class induction but proved harmful for detecting coercions on common predicates with a single, dominant sense. For the second assumption, that the selected class can be inferred from the data, we proposed a sampling method based on the classes of the predicate's arguments. Superior performance on coercion detection shows the merit of this assumption.

Additionally, we proposed methods for improving an existing task, logical metonymy interpretation, using the learned parameters of our model, showing positive results.

It is clear that our model may be improved by more accurate predicate sense induction. To this end, we plan to develop a model that simultaneously induces predicates and learns coercions, using knowledge of a predicate's coerciveness to inform the induction mechanism.

Acknowledgements

We would like to thank Diarmuid Ó Séaghdha, Bryan Rink, and Anna Rumshisky for several helpful conversations during the course of this work. We thank Mirella Lapata and Ekaterina Shutova for making the data from their experiments available as well as the organizers of SemEval-2010 Task 7 for the associated data set. Additionally, we thank Srikanth Gullapalli, Aileen McDermott, and Bryan Rink for annotating the data set used in our experiment. Finally, we thank the anonymous reviewers for their suggestions on improving this work.

Abstract

Measuring semantic relatedness between words or concepts is a crucial process to many Natural Language Processing tasks. Exiting methods exploit semantic evidence from a single knowledge source, and are predominantly evaluated only in the general domain. This paper introduces a method of harnessing different knowledge sources under a uniform model for measuring semantic relatedness between words or concepts. Using Wikipedia and WordNet as examples, and evaluated in both the general and biomedical domains, it successfully combines strengths from both knowledge sources and outperforms state-of-the-art on many datasets.

1 Introduction

Semantic relatedness (SR) measures how much two (strings of) words or concepts are related by encompassing all kinds of relations between them (Strube and Ponzetto, 2006). It is more general than semantic similarity. SR is often an important pre-processing step to many complex Natural Language Processing (NLP) tasks, such as Word Sense Disambiguation (Leacock and Chodorow, 1998; Han and Zhao, 2010), and information retrieval (Finkelstein et al., 2002). In the biomedical domain, SR is an important technique for discovering gene functions and interactions (Wu et al., 2005; Ye et al., 2005).

There is an abundant literature on measuring SR between words or concepts. Typically, these methods extract semantic evidence of words and concepts from a background knowledge source, with which their relatedness is assessed. The knowledge sources can be unstructured documents or (semi-)structured resources such as Wikipedia, WordNet, and domain specific ontologies (e.g., the Gene Ontology[1]).

In this paper, we identify two issues that have not been addressed in the previous works. First, existing works typically employ a single knowledge source of semantic evidence. Research (Strube and Ponzetto, 2006; Zesch and Gurevych, 2010; Zhang et al., 2010) has shown that the accuracy of an SR method differs depending on the choice of the knowledge sources, and there is no conclusion which knowledge source is superior to others. Zhang et al. (2010) argue that this indicates different knowledge sources may complement each other. Second, the majority of SR methods have been evaluated in general domains only, except a few earlier WordNet-based methods that have been adapted to biomedical ontologies and evaluated in that domain (Lord et al., 2003; Pedersen et al., 2006; Pozo et al., 2008). Given the significant attention that SR has received in specific domains (Pesquita et al., 2007), evaluation of SR methods in specific domains is increasingly important.

This paper addresses these issues by proposing a generic and uniform model for computing SR between words or concepts using multiple knowledge sources, and evaluating the proposed method in both general and specific domains. The method combines and integrates semantic evidence of words or concepts extracted from any knowledge source in a generic graph representation, with which the SR between concepts or words is computed. Using two of the most popular general-domain knowledge sources,

[1] http://www.geneontology.org/, last retrieved in Mar. 2011

Wikipedia and WordNet as examples, the method is evaluated on 7 benchmarking datasets, including three datasets from the biomedical domain and four from the general domain. It has achieved excellent results: compared to the baselines that use each single knowledge sources, combining both knowledge sources has improved the accuracy on all datasets by 2~11%; compared to state-of-the-art on the general domain datasets, the method achieves the best results on three datasets; and on the other three biomedical datasets, it obtains the best result in one case; and second and third best results on the other two among eight participating methods, where all other competitors exploit some domain-specific knowledge sources.

The remainder of this paper is organized as follows. Section 2 discusses related work; Section 3 presents the proposed method; Section 4 describes the experiments and evaluation; Section 5 discusses results and findings; Section 6 concludes this paper.

2 Related work

2.1 SR methods

Methods for computing SR can be classified into *path based*, *Information Content (IC) based*, *statistical* and *hybrid methods*. *Path based* methods (Hirst and St-Onge, 1998; Leacock and Chodorow, 1998; Pekar and Staab, 2002; Rada et al., 1989; Wu and Palmer, 1994) measure SR between words or concepts as a function of their distance in a semantic network, usually calculated based on the path connecting the words or concepts by certain semantic (typically *is-a*) links. *IC based methods* (Jiang and Conrath, 1997; Lin, 1998; Pirro et al., 2009; Resnik, 1995; Seco et al., 2004) assess relatedness between words or concepts by the amount of information they share, usually determined by a higher level concept that subsumes both concepts in a taxonomic structure. *Statistical methods* measure relatedness between words or concepts based on their distribution of contextual evidence. This can be formalized as co-occurrence statistics collected from unstructured documents (Chen et al., 2006; Cilibrasi and Vitanyi, 2007; Matsuo et al., 2006), or distributional concept or word vectors with features extracted from either unstructured documents (Harrington, 2010; Wojtinnek and Pulman, 2011) or (semi-)structured knowledge resources (Agirre et al., 2009; Gabrilovich and Markovitch, 2007; Gouws et al., 2010; Zesch and Gurevych, 2007; Zhang et al., 2010). *Hybrid methods* combine different purebred methods in certain ways. For example Riensche et al. (2007) employ both an *IC based* method (Resnik, 1995) and a *statistical* method (cosine vector similarity) in their study. Pozo et al. (2008) derive a taxonomy of terms from unstructured documents by applying hierarchical clustering based on corpus statistics, then apply *path based* method on this taxonomy to compute SR. Han and Zhao (2010) use one *IC based* method and two *statistical* methods to compute SR, then derive an aggregated score.

2.2 SR knowledge sources and domains

Computing SR requires background knowledge about concepts or words, which can be extracted from unstructured corpora, semi-structured and structured knowledge resources. Unstructured corpora are easier to create and cheaper to maintain, however, semantic relations between words or concepts are implicit. Methods (Chen et al., 2006; Cilibrasi and Vitanyi 2007; Matsuo et al., 2006) that exploit unstructured corpora typically depend on distributional statistics, and thus may ignore important semantic evidences present in (semi-)structured knowledge sources (Pan and Farrell, 2007). Recent studies (Harrington, 2010; Pozo et al., 2008; Wojtinnek and Pulman, 2011) propose to pre-process a corpus to learn a semantic network, with which SR is computed. This creates high pre-processing cost; also, the choice of corpus and its size often have a direct correlation with the accuracy of SR methods (Batet et al., 2010).

(Semi-)Structured knowledge sources on the other hand, organize semantic knowledge about concepts and words explicitly and interlink them with semantic relations. They have been popular choices in the studies of SR, and they include lexical resources such as WordNet, Wiktionary, and (semi-)structured encyclopedic resources such as Wikipedia. WordNet has been used in earlier studies (Hirst and St-Onge, 1998; Jiang and Conrath, 1997; Lin, 1998; Leacock and Chodorow 1998; Resnik, 1995; Seco et al., 2004; Wu and Palmer, 1994) and is still a preferred knowledge source in recent works (Agirre et al., 2009). However, its effectiveness may be hindered by its lack of coverage of specialized lexicons and domain specific concepts (Strube and Ponzetto,

2006; Zhang et al., 2010). Wikipedia and Wiktionary are collaboratively maintained knowledge sources and therefore may overcome this limitation. Wikipedia in particular, is found to have reasonable coverage of many domains (Holloway et al., 2007; Halavais, 2008). It has become increasingly popular in SR studies recently. However, research (Zesch and Gurevych, 2010) have shown that methods based on Wikipedia have no clear advantage over WordNet-based methods on some general domain datasets in terms of accuracy, while Zhang et al. (2010) argue that different knowledge sources may complement each other, and SR methods may benefit from harnessing different knowledge sources.

Several studies (Lord et al., 2003; Pedersen et al., 2006; Petrakis et al., 2006; Pozo et al., 2008) have adapted state-of-the-art to domain specific knowledge sources (e.g., the Gene Ontology, the MeSH[2]) and evaluated them therein. Despite these efforts, a large proportion of state-of-the-art is still only evaluated in the general domain.

2.3 SR methods similar to this work

Few works have attempted at combining different knowledge sources in SR studies, especially (semi-)structured knowledge sources. The closest studies are Han and Zhao (2010) and Tsang and Stevenson (2010). Han and Zhao firstly compute SR between words using three state-of-the-art SR methods separately. Next, one score is chosen subject to an arbitrary preference order, and used to create a connected graph of weighted edges between words. A recursive function is then applied to the graph to compute final SR scores between words. Essentially, each SR method is applied in isolation and features from different sources are used separately with each distinctive method. Although this retains advantages of each method, the limitations of them are also combined.

Tsang and Stevenson (2010) combine WordNet and unstructured documents by weighing each word found in WordNet using its frequency observed in a large corpus. The frequencies however, are sensitive to the choice of corpus, thus different corpora may result in different accuracies. Furthermore, their method is only applicable to computing SR between pairs of sets of words or concepts.

3 Methodology

We define a set of requirements for SR methods that harness different knowledge sources:

- It should improve over the same method based on a single knowledge source
- It should be generic and applicable to any knowledge source
- It should be robust in dealing with knowledge source specific features but also tolerate the quality and coverage issues of individual knowledge source

Our method of harnessing different knowledge sources contains four steps. Firstly (Section 3.1), each word or word segment is searched in each knowledge source to identify their *contexts* that is specific to that knowledge source. We define a *context* as the representation of meaning or a concept for a word. In the following, we say that each *context* is associated with a distinct concept. Secondly (Section 3.2), for each concept of an input word, features are extracted from its *context* and a graph representation of each concept and their features is created. Thirdly (Section 3.3), cross-source *contexts* are mapped where they refer to the same concept, thus their features from different sources can be combined to derive an enriched representation. This creates a final, uniform graph representation where input words are connected by shared features of their underlying candidate concepts. Then (Section 3.4) the graph is submitted to a generic algorithm to compute SR between words.

In the following, we discuss details with respect to different types of knowledge sources, while focusing on Wikipedia and WordNet in our experiments for two reasons. First, they are used by the majority of SR methods and are therefore most representative knowledge sources. Second, they have strongly distinctive and complementary characteristics, which make ideal testbeds for the requirements. On one hand, WordNet is a lexical resource containing rich and strict semantic relations between words, but lacks coverage of specialized vocabularies. On the other hand, Wikipedia is a semi-structured resource with good coverage of domains and named entities, but the semantic knowledge is organized in a looser way.

[2] http://www.nlm.nih.gov/mesh/ last retrieved in March 2011

3.1 Context retrieval

Given a pair of words or word segments, we firstly identify *contexts* representing the underlying meanings or concepts from each knowledge source. For lexical resources, this could be distinctive word senses. In **WordNet (WN)**, a context corresponds to a single synset, which corresponds to a concept. We search each word in WordNet and extract all possible synsets. Let *w* be a word or word segment (e.g., "cat"), and $C_w^{wn} = \{c_{1_w}^{wn}, c_{2_w}^{wn} \dots c_{k_w}^{wn}\}$ be the set of *k* concepts of *w* extracted from WordNet.

Using **Wikipedia (WK)** as an example semi-structured resource, the *context* can be an article that describes a unique concept. Thus we search for underlying articles that describe different concepts. Firstly, we search *w* in Wikipedia, where three situations may be anticipated. If a single non-disambiguation page describing a concept is returned, the concept is selected and the retrieval is complete. In the second case, a disambiguation page linking to all possible concept pages may be returned. This page lists all underlying concepts and entities referenced by *w* as links and a short description with each link. In this case, we always keep the first concept page, which is found often to be the most common sense of the word; additionally, we select other concept pages whose short descriptions contain the word *w*. We do not select all linked pages because many of these in fact link to a concept relevant to *w*, but not necessarily a candidate sense of *w*. Thirdly, if no pages are returned for *w*, we search for the most relevant page using *w* as keyword(s) in an inverted index of all Wikipedia pages (e.g., via search engines). We denote concepts retrieved from Wikipedia as $C_w^{wk} = \{c_{1_w}^{wk}, c_{2_w}^{wk} \dots c_{k_w}^{wk}\}$.

For unstructured sources such as documents, a simple approach could be defining a word *context* as a text passage around each occurrence of *w*, and grouping similar *contexts* of *w* as representation of its underlying meanings, or concepts. Alternatively, more complex approaches such as Pozo et al. (2008) and Harrington (2010) may be applied to extract a lexical network of words, whereby similar methods to WordNet can be applied.

3.2 Feature extraction and representation

Next, for each concept identified from a knowledge source, features are extracted from their corresponding *contexts*. In our case, for each $c \in C_w^{wk}$, we follow the work by Zhang et al. (2010) to extract four types of features from their corresponding Wikipedia pages. Figure 1 shows an example representation of a concept and its Wikipedia features:

- Words from page titles and redirection links (can be considered as synonyms)
- Words from categories, used as higher level hypernyms in some studies (Zesch et al., 2010; Strube and Ponzetto, 2006)
- Words from outgoing links
- Top *n* most frequent words from a page

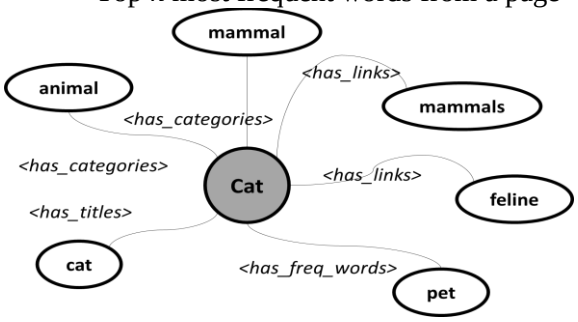

Figure 1. Representation of the concept "cat, the mammal" using different types of features extracted from Wikipedia. The shaded circle represents the concept; ovals represent feature values; edges connecting feature values to the concept and <labels> represent feature types

For each $c \in C_w^{wn}$, we extract ten features from WordNet: hypernyms, hyponyms, meronyms, holonyms, synonyms, antonyms, attributes, "see also" words, "related" words, and gloss. These are also represented in the same way as in Figure 1.

With unstructured sources, contextual words can be used as features. Alternatively, if a lexical network is extracted, features may be extracted in a similar way to those of WordNet.

Additionally, with WordNet and Wikipedia, we also propose several intra-resource feature merging strategies to study the effect of **feature diversification**. This is because, while some approaches (such as Agirre et al., 2009; Harrington, 2010; Yeh et al., 2009) do not distinguish different feature types in graph construction, or adopt a bag-of-words feature representation (such as Zesch and Gurevych, 2010), others (such as Yazdani and Popescu-Belis, 2010; Zhang et al., 2010) have used differentiated

feature types and weights in their model. We therefore carry out studies to investigate this issue. Specifically, for the original four Wikipedia features, we create a bag-of-words feature that simply merges all feature types (i.e., all edges in Figure 1 will have the same label). For the original ten WordNet features, we propose two merged representations corresponding to that of Wikipedia, so as to support the studies of feature enrichment in the following section. We introduce a bag-of-words feature that collapses all different feature types, and a four-feature representation as follow:

- *wn-synant* merges WordNet synonyms and antonyms.
- *wn-hypoer* merges WordNet hypernyms and hyponyms, collectively representing features by "*is-a*" semantic relation
- *wn-assc* merges WordNet meronyms, holonyms, related and "see also", which are features corresponding to associative relations
- *wn-dist* merges WordNet gloss and attributes that generally describe a concept.

3.3 Concept mapping and feature enrichment

Our method essentially harnesses different knowledge sources by combining features extracted from different sources in a uniform model. This requires two sub-processes: **cross-source concept mapping** and **cross-source feature enrichment**.

In **cross-source concept mapping,** concepts extracted from different knowledge sources are mapped according to similar meanings such that cross-source features can be combined. To do so, we select the concepts from one knowledge source as the reference concept set; then concepts from other knowledge sources are mapped to reference concepts of similar meanings. There can be different criteria of choosing reference knowledge source concepts. Empirically, we found it necessary to choose the knowledge source with broader coverage and richer features. This will be discussed later in Section 5. Following this strategy, in our example, C_w^{wk} is chosen as reference concepts, and for each $c_w^{wk} \in C_w^{wk}$ we select a $c_w^{wn} \in C_w^{wn}$ such that c_w^{wk} and c_w^{wn} refer to the same meaning. To do so, we apply a simple maximum set overlap metric to their feature values. Let *F(c)* be a function that returns all feature values of *c* as bag-of-words, then for each $c_w^{wk} \in C_w^{wk}$, it is mapped to a c_w^{wn} such that $|F(c_w^{wn})| \cap |F(c_w^{wk})|$ is maximized among all $c_w^{wn} \in C_w^{wn}$. The resulting concept candidates are denoted as C_w^{mapd}, where $c_w^{mapd} = \{c_w^{wk}, c_w^{wn}\}$ is a mapped set of concepts potentially referring to the same meaning. If $C_w^{wn} = \emptyset$ then $C_w^{mapd} = C_w^{ref}, i.e., C_w^{wk}$.

Next, **cross-source feature enrichment** creates a uniform feature representation for each mapped sets of concepts. The process can be considered as enriching the features from one knowledge source with others. The most straightforward approach is to simply collect features extracted from each knowledge source on to a single graph, retaining the diversity in feature types. For example, Figure 2 shows a graph representation based on the collection of the four Wikipedia features and the four derived WordNet features. We refer to this approach as "***feature combination***".

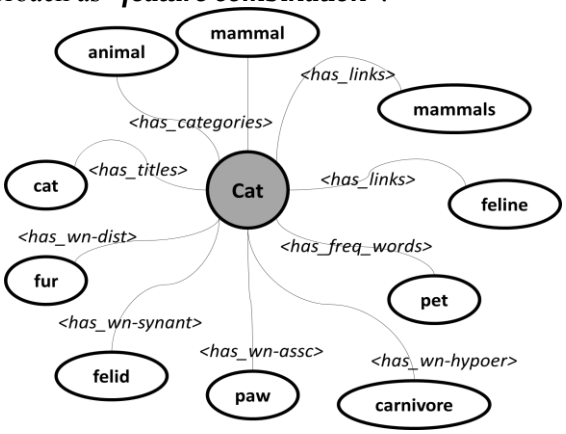

Figure 2. Representation of "cat, the mammal" after ***concept mapping*** and ***feature combination***

On the other hand, cross-source features may be merged according to their semantics. For example, WordNet and Wikipedia contain features based on synonyms of concepts; while Wikipedia and unstructured documents contain word distributional features. Thus we define "***feature integration***" as merging feature types from different knowledge sources into single types of features based on their similarity in semantics. With WordNet and Wikipedia, we integrate features as below (Figure 3):

- *merged-synant* merges Wikipedia page titles and redirection links with *wn-synant*
- *merged-hypoer* merges merges Wikipedia categories with *wn-hypoer*

- *merged-assc* merges Wikipedia links with *wn-assc*. We consider Wikipedia links bear other associative relations and are therefore merged with features extracted by other WordNet relations
- *merged-dist* merges Wikipedia frequent *n* words with *wn-dist*.

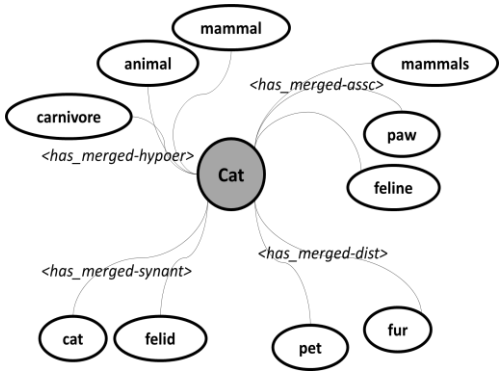

Figure 3. Representation of "cat, the mammal" after ***concept mapping*** and ***feature integration***

Note that the difference between cross-source ***feature combination*** and ***integration*** is that the former introduces more *types* of features, whereas the latter retains same number of feature types but increases *feature values* for each type. Both have the effect of establishing additional path (via features) between concepts, but in different ways.

With intra-resource **feature diversification,** cross-source ***feature combination*** and ***feature integration***, we create a total of nine intra- and cross-source feature representations to be tested with the uniform random walk model:

- four types of Wikipedia features (*wk-4F*)
- one type of Wikipedia features (*wk-1F*)
- ten types of WordNet features (*wn-10F*)
- four types of WordNet features (*wn-4F*)
- one type of WordNet features (*wn-1F*)
- *wk-4F combines wn-4F: wk-4F+wn4F,C*
- *wk-4F integrates wn-4F: wk-4F+wn4F,I*
- *wk-1F combines wn-1F: wk-1F+wn1F,C*
- *wk-1F integrates wn-1F: wk-1F+wn1F,I*

3.4 Computing SR using the graph

The algorithm for computing SR using the graph is based on the idea of random walk. It formalizes the idea that taking successive steps along the paths in a graph, the "easier" it is to arrive at a target node starting from a source node, the more related the two nodes are. Following the previous steps, the feature representations of all candidate concepts relevant to the input word pairs are joined, which creates a single undirected, weighted, bi-partite graph. Let *G = (V, E)* be the graph, where *V* is the set of nodes (concepts and feature values); *E* is the set of edges (feature types) that connect concepts and features. As shown in Figure 4, different concepts are connected if they share same values of same types of features, namely, there exists a path that connects one concept to another.

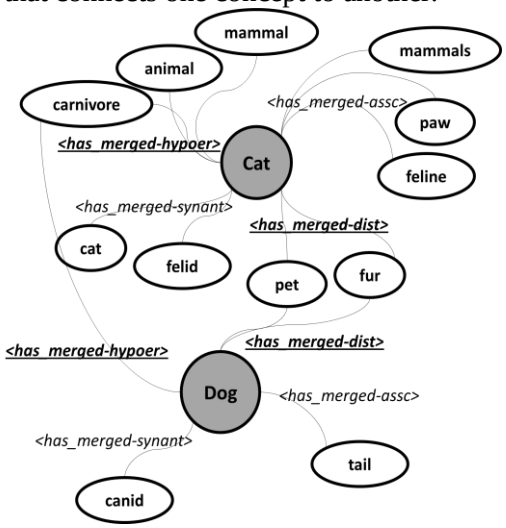

Figure 4. Paths are established between different concepts if they share values of same feature types <**bold underlined**>

Using Figure 4 it is easier to comprehend the difference between ***feature combination*** and ***integration***. Since concept nodes can only be connected by same types of edges (feature types), ***feature combination*** increases the chances of connectivity by adding in more types of edges, while ***integration*** merges similar types of edges across knowledge sources and increases the number of feature nodes connected by each type.

From the graph, we start by building an adjacency matrix *W* of initial probability distribution:

$$W_{ij} = \begin{cases} \sum_{l_k \in L} \frac{w(l_k)}{|(i,\cdot) \in E : l(i,\cdot) = l_k|}, (i,j) \in E \\ 0, otherwise \end{cases} \quad [1]$$

Where W_{ij} is the i^{th}-line and j^{th}-column entry of *W*, indexed by *V; l(i, j)* is a function that returns the type of edge (i.e., type of feature) connecting nodes *i* and *j*; *L* is the set of all possible types; *w(l)* returns the weight for that type. Essentially, *L* is the collection of all feature types, and *w(l)* assigns

a weight to a particular feature type. Next, we compute the transition probability matrix $P^{(t)}(j|i) = [(D^{-1}W)^t]_{ij}$ ($D_{ii} = \sum_k W_{ik}$), which returns the probability of reaching other nodes from a starting node on the graph after *t* steps. In this method, we follow the work by Rowe and Ciravegna (2010) to set *t=2* in order to preserve locally connected nodes. Next, we extract the probability vectors corresponding to concept nodes from *P*, and compute pair-wise relatedness using the cosine function. Effectively, this formalizes the notion that two concepts related to a third concept is also semantically related, which is similar to the hypothesis proposed by Patwardhan and Pedersen (2006) in their method based on second-order context vectors. The final SR between the input word pair is the maximum pair-wise concept SR.

4 Experiment and evaluation

We evaluate the method based on correlation against human judgment (gold standard) on seven benchmarking datasets covering both general and technical domains. These include four general domain datasets: the Rubenstein and Goodenough (1965) dataset containing 65 pairs of nouns (RG65); the Miller and Charles (1991) dataset that is a subset of the RG-65 dataset and contains 30 pairs (MC30); the Finkelstein et al. (2002) dataset with 353 pairs of words, including nouns, verbs, adjectives, as well as named entities. This contains two subsets, a set of 153 pairs (Fin153) and a set of 200 (Fin200) pairs each annotated by a different groups of annotators. Zesch and Gurevych (2010) show largely varying Inter-Annotator-Agreement (IAA) between the two sets (Table 1), and argue that they should be treated as separate datasets. Three biomedical datasets are selected to evaluate domain-specific performance of the proposed method. These include a set of 36 MeSH term pairs in Petrakis et al. (2006) (MeSH36), 30 pairs of medical terms annotated by a group of physicians as in Pedersen et al. (2006) (Ped30-p) and the same set annotated by a different group of medical coders (Ped30-c). Table 1 shows statistics of the seven datasets.

The correlation is computed using the Spearman rank order coefficient for two reasons. First, it is a better metric than other alternatives (Zesch and Gurevych, 2010). Second, it is consistent with the majority of studies such that results can be compared.

Dataset	Size	Domain	IAA
MC30	30	General	0.9
RG65	65	General	0.8
Fin153	153	General	0.73
Fin200	200	General	0.55
Ped30-p	30	Biomedical	0.68
Ped30-c	30	Biomedical	0.78
MeSH36	36	Biomedical	-

Table 1: Information of benchmarking datasets

We distribute feature weights *w(l)* across different feature types *L* evenly in each feature representation. Although Zhang et al. (2010) show that discriminated feature weights leads to improved accuracy; this is not the focus of this study. Since we aim to investigate the effects of harnessing different knowledge sources, we obtained baseline performances by applying the method to those feature representations based on single knowledge sources (i.e., *wk-4F, wk-1F, wn-10F, wn-4F, wn-1F*). Tables 2 and 3 show the best results obtained with baselines and corresponding knowledge sources and feature representation.

Dataset	Corr.	Feature	Coverage (% pairs)
MC30	0.77	*wn-1F*	77%
RG65	0.71	*wn-1F*	65%
Fin153	0.45	*wn-4F*	82%
Fin200	0.35	*wn-4F*	76%
Ped30-p	0.66	*wn-4F*	33%
Ped30-c	0.8	*wn-4F*	33%
MeSH36	0.49	*wn-1F*	50%

Table 2: Correlation obtained using *WordNet*. Many word pairs are not covered due to sparse feature space and lack of coverage. **Only covered pairs are accounted**.

Dataset	Corr.	Feature
MC30	0.74	*wk-1F*
RG65	0.67	*wk-1F*
Fin153	0.7	*wk-1F*
Fin200	0.51	*wk-4F*

Given the fact that some datasets (i.e., MC30, Ped30-p, Ped30-c, MeSH36) have a relatively low sample size, we cannot always be sure that correlation values are accurate or occurred by chance. Therefore, we measure the statistical significance of correlation by computing the *p-value* for the correlation values reported for our system in Tables 7 and 8. For all cases, a *p-value* of less than 0.001 is obtained, which indicates that correlation values are statistically significant.

5 Discussion

Single v.s. multiple knowledge sources As shown in Table 6, considering the best performances across all feature enrichment strategies and feature sets, the proposed method successfully harnessed different knowledge sources and improved over the baselines using single knowledge sources by 0.02 ~ 0.11. The biggest improvement (0.11) is on a domain-specific dataset, on which the method based on single knowledge source performed poorly in terms of coverage and accuracy. The best enrichment strategy that has consistently improved the baselines is *wk-4F+wn-4F, Integration* (Table 4 v.s. Table 3). With features enriched from *multiple* knowledge sources, the method also consistently improved over their *corresponding single*-source features on all datasets, except MeSH36, on which *wk-4F+wn-4F, Combination* (Table 4) slightly reduced the accuracy obtained with *wk-4F* (Table 3) only.

The large proportion of uncovered word pairs using WordNet is due to its lack of coverage of specialized lexicons, and sparser semantic content. For example, of all 115 distinctive terms in the Ped30 and MeSH36 datasets, 30% are not included in WordNet. And of all 447 distinctive words in all general domain datasets, only 69% have multiple synonyms. Features such as *attributes* and "*see also*" are present for less than 20 words. This is the reason that some approaches using WordNet (e.g., Agirre et al., 2009) require a graph of all WordNet lexicons to be built, thus intermediate words may "bridge" input words even if they do not connect directly by their features. Nevertheless, the improvement in accuracy and 100% coverage after harnessing both knowledge sources suggests that they complement each other well. On one hand, Wikipedia brings its strength in domain and content coverage; on the other hand, WordNet brings useful semantic evidences for words that are covered.

Concept mapping and feature enrichment methods While the set overlap based method for cross-source concept mapping using the reference knowledge source concepts is simple and proved successful, the accuracy of mapping and its correlation with the accuracy of the SR method was not studied. This will be explored in the future. Also, alternative mapping methods will be investigated. For example, Toral and Muñoz (2006) describe a different method of mapping Wikipedia articles to WordNet synsets; one could also adopt a simple disambiguation process to select the best candidate concept from each knowledge source suited for the input word pairs, whereby cross-source concept mapping becomes straightforward. In terms of feature enrichment strategies, there is no strong indication (Table 6) of which (*feature combination v.s. integration*) is more effective, although the system consistently outperforms the baselines (Table 4 v.s. Table 3) with the *wk-4F+wn-4F, Integration* strategy.

Feature diversification v.s. unification Table 5 suggests that in most cases, differentiating feature types leads to better results than merging them uniformly, despite the knowledge sources used. This is consistent with the findings by Zhang et al. (2010). This can be understandable since although unifying feature types effectively increases possibility of sharing features, equally, this may also increase the proportion of noisy features. For example, consider the Wikipedia article of "Horse" (animal), which has a category label "livestock"; and the article "Famine", which has an outgoing link "livestock" (in a sentence describing diseases that caused decline of livestock production). By differentiating the feature types "*has_category*" and "*has_outlink*", the two concepts will not be connected even if they both have the same word "livestock" in their feature representation. However, using a bag-of-words representation where feature types are undistinguished, the strength of their relatedness is boosted by sharing this word, which may be uninteresting in this occasion.

Compared against state-of-the-art, the proposed method has achieved promising results. Overall, by harnessing different knowledge sources, the method achieves, and in many cases, outperforms state-of-the-art. In the general domain, it outperforms state-of-the-art on three out of four datasets. It is worth noting that all methods based on WordNet generally have poor performance on the Fin153 and Fin200 datasets (Table 7). Despite the heterogeneity in these datasets, this may also relate to the quality of the feature space generated with WordNet. In fact methods using Wikipedia perform better on these datasets. With enriched features from both knowledge sources, the accuracies are further improved.

In the biomedical domain, the proposed method outperforms state-of-the-art on one dataset and produces competitive results on others. Note that all other methods exploit domain-specific ontologies and corpora. The *Ped06 best* and *Ped06 second* methods also depend on a corpus of one million documents. These results further confirmed the benefits of our method: harnessing knowledge from general-purpose knowledge sources of limited domain coverage, it is possible to achieve results that rival methods based on well-curated and specially tailored domain-specific knowledge sources. This is an encouraging finding. Although there are abundant resources in the biomedical domain for this type of tasks, such resources may be scarce in other domains and are expensive to build. However, the results suggest that the proposed method offers a more affordable approach that provides reasonable coverage and quality, even if individual general knowledge sources may be limited in themselves.

Generality of the method The proposed method represents features extracted from different knowledge sources in a generic manner, which facilitates cross-source feature enrichment and requires generic algorithm computation. As discussed in Section 3, semantic evidence of words and concepts may be extracted from different knowledge sources in different ways, while harnessed in the generic model. In contrast, other methods using multiple knowledge sources (e.g., Han and Zhao, 2010; Tsang and Stevenson, 2010) introduce algorithms that are bound to the knowledge sources, which may limit their adaptability and portability.

6 Conclusion

This paper introduced a generic method of harnessing different knowledge sources to compute semantic relatedness. We have shown empirically that different knowledge sources contain complementary semantic evidence, which, when combined together under a uniform model, can improve the accuracy of SR methods. Moreover, we have demonstrated its robustness in dealing with knowledge sources of different quality and coverage. Several remaining issues will be studied in the future. First, additional knowledge sources will be studied, particularly unstructured corpora and domain-specific resources. The experiments have shown that although harnessing different knowledge sources achieved encouraging results on biomedical datasets, they are still far from being perfect. While it should be appreciated that the results are obtained using only general purpose knowledge sources, it would be interesting to investigate whether harnessing domain specific knowledge sources (where available) further improves the performance. Second, different methods of concept mapping will be studied. We will also design methods for assessing the quality of mapping, and analyze their correlations with the SR methods. Third, analyses will be carried out to uncover the differences between feature combination and integration that have led to different accuracies.

Abstract

We re-investigate the rationale for and the effectiveness of adopting the notions of depth and density in WordNet-based semantic similarity measures. We show that the intuition for including these notions in WordNet-based similarity measures does not always stand up to empirical examination. In particular, the traditional definitions of depth and density as ordinal integer values in the hierarchical structure of WordNet does not always correlate with human judgment of lexical semantic similarity, which imposes strong limitations on their contribution to an accurate similarity measure. We thus propose several novel definitions of depth and density, which yield significant improvement in degree of correlation with similarity. When used in WordNet-based semantic similarity measures, the new definitions consistently improve performance on a task of correlating with human judgment.

1 Introduction

Semantic similarity measures are widely used in natural language processing for measuring distance between meanings of words. There are currently two mainstream approaches to deriving such measures, i.e., distributional and lexical resource-based approaches. The former usually explores the co-occurrence patterns of words in large collections of texts such as text corpora (Lin, 1998) or the Web (Turney, 2001). The latter takes advantage of mostly handcrafted information, such as dictionaries (Chodorow et al., 1985; Kozima and Ito, 1997) or thesauri (Jarmasz and Szpakowicz, 2003).

Another important resource in the latter stream is semantic taxonomies such as WordNet (Fellbaum, 1998). Despite their high cost of compilation and limited availability across languages, semantic taxonomies have been widely used in similarity measures, and one of the main reasons behind this is that the often complex notion of lexical semantic similarity can be approximated with ease by the distance between words (represented as nodes) in their hierarchical structures, and this approximation appeals much to our intuition. Even methods as simple as "hop counts" between nodes (e.g., that of Rada et al. 1989 on the English WordNet) can take us a long way. Meanwhile, taxonomy-based methods have been constantly refined by incorporating various structural features such as depth (Sussna, 1993; Wu and Palmer, 1994), density (Sussna, 1993), type of connection (Hirst and St-Onge, 1998; Sussna, 1993), word class (sense) frequency estimates (Resnik, 1999), or a combination these features (Jiang and Conrath, 1997). Most of these algorithms are fairly self-contained and easy to implement, with off-the-shelf toolkits such as that of Pedersen et al. (2004).

With the existing literature focusing on carefully weighting these features to construct a better semantic similarity measure, however, the rationale for adopting these features in calculating semantic similarity remains largely intuitive. To the best of our knowledge, there is no empirical study directly investigating the effectiveness of adopting structural features such as depth and density. This serves as the major motivation for this study.

The paper is organized as follows. In Section 2 we review the basic rationale for adopting depth

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1003–1011,
Edinburgh, Scotland, UK, July 27–31, 2011.

and density in WordNet-based similarity measures as well as existing literature on constructing such measures. In Section 3, we show the limitations of the current definitions of depth and density as well as possible explanations for these limitations.[1] We then propose new definitions to avoid such limitations in Section 4. The effectiveness of the new definitions is evaluated by applying them in semantic similarity measures in Section 5 and conclusions made in Section 6.

2 Related Work

The following are the current definitions of depth and density which we aim at improving. Given a node/concept c in WordNet, depth refers to the number of nodes between c and the root of WordNet, (i.e., the root has depth zero, its hyponyms depth one, and so on). There are more variations in the definition of density, but it is usually defined as the number of edges leaving c (i.e., its number of child nodes) or leaving its parent node(s) (i.e., its number of sibling nodes). We choose to use the latter since it is used by most of the existing literature.

2.1 The Rationale for Depth and Density

The rationale for using the notions of depth and density in WordNet-based semantic similarity measures is based on the following assumption:

Assumption 1 *Everything else being equal, two nodes are semantically closer if (a) they reside deeper in the* WordNet *hierarchy, or (b) they are more densely connected locally.*

This is the working assumption for virtually all WordNet-based semantic similarity studies using depth and/or density. For depth, the intuition is that adjacent nodes deep down the hierarchy are likely to be conceptually close, since the differentiation is based on finer details (Jiang and Conrath, 1997). Sussna (1993) termed the use of depth as *depth-relative scaling*, claiming that "only-siblings deep in a tree are more closely related than only-siblings higher in the tree". Richardson and Smeaton (1995) gave an hypothetical example illustrating this "only-siblings" situation, where *plant–animal* are the only two nodes under *living things*, and *wolfhound–foxhound* under *hound*. They claimed the reason that the former pair can be regarded as conceptually farther apart compared to the latter is related to the difference in depth.

As for the relation between density and similarity, the intuition is that if the overall semantic mass for a given node is constant (Jiang and Conrath, 1997), then the more neighboring nodes there are in a locally connected subnetwork, the closer its members are to each other. For example, *animal*, *person*, and *plant* are more strongly connected with *life form* than *aerobe* and *plankton* because the first three words all have high density in their local network structures (Richardson and Smeaton, 1995). Note that the notion of density here is not to be confused with the *conceptual density* used by Agirre and Rigau (1996), which is essentially a semantic similarity measure by itself.

In general, both observations on depth and density conform to intuition and are supported qualitatively by several existing studies. The main objective of this study is to empirically examine the validity of this assumption.

2.2 Semantic Similarity Measures Using Depth and/or Density

One of the first examples of using depth and density in WordNet-based similarity measures is that of Sussna (1993). The weight on an edge between two nodes c_1 and c_2 with relation r in WordNet is given as:

$$w(c_1, c_2) = \frac{w(c_1 \rightarrow_r c_2) + w(c_2 \rightarrow_r c_1)}{2d}$$

where d is the depth of the deeper of the two nodes. As depth increases, weight decreases and similarity in turn increases, conforming to Assumption 1. The edge weight was further defined as

$$w(c_1 \rightarrow_r c_2) = max_r - \frac{max_r - min_r}{n_r(c_1)}$$

where $n_r(X)$ is "the number of relations of type r leaving node X", which is essentially an implicit form of density, and max_r and min_r are the maximum and minimum of n_r, respectively. Note that this formulation of density contradicts Assumption

[1] Since the works we review in this section have different definitions of depth and density, we defer our formal definitions to Section 3.

1 since it is proportional to edge weight (left-hand-side) and thus negatively correlated to similarity.

Wu and Palmer (1994) proposed a concept similarity measure between two concepts c_1 and c_2 as:

$$sim(c_1,c_2) = \frac{2 \cdot dep(c)}{len(c_1,c) + len(c_2,c) + 2 \cdot dep(c)} \quad (1)$$

where c is the lowest common subsumer (LCS) of c_1 and c_2, and $len(\cdot,\cdot)$ is the number of edges between two nodes. The rationale is to adjust "hop count" (the first two terms in the denominator) with the depth of LCS: similarity between nodes with same-level LCS is in negative proportion to hop counts, while given the same hop count, a "deeper" LCS pulls the similarity score closer to 1.

Jiang and Conrath (1997) proposed a hybrid method incorporating depth and density information into an information-content-based model (Resnik, 1999):

$$\begin{aligned} w(c,p) =& (\frac{dep(p)+1}{dep(p)})^{\alpha} \\ & \times [\beta + (1-\beta)\frac{\bar{E}}{den(p)}] \\ & \times [IC(c) - IC(p)]T(c,p) \end{aligned} \quad (2)$$

Here, p and c are parent and child nodes in WordNet, $dep(\cdot)$ and $den(\cdot)$ denote the depth and density of a node, respectively, $\bar{E}$ is the average density over the entire network of WordNet, and α and β are two parameters controlling the contribution of depth and density values to the similarity score. $IC(\cdot)$ is the information content of a node based on probability estimates of word classes from a small sense-tagged corpus (Resnik, 1999), and $T(c,p)$ is a link-type factor differentiating different types of relations between c and p.

3 Limitations on the Current Definitions of Depth and Density

To what extent do the notions of depth and density help towards an accurate semantic similarity measure? Our empirical investigation below suggests that more often than not, they fail our intuition.

A direct assessment of the effectiveness of using depth and density is to examine their correlation with similarity. Empirical results in this section

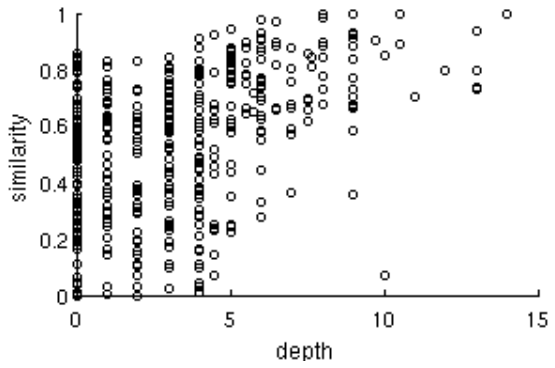

Figure 1: Correlation between depth and similarity.

are achieved by the following experimental setting. Depth is defined as the number of edges between the root of the hierarchy and the lowest common subsumer (LCS) of two nodes under comparison, and density as the number of siblings of the LCS.[2] Similarity is measured by human judgment on similarity between word pairs. Commonly used data sets for such judgments include that of Rubenstein and Goodenough (1965), Miller and Charles (1991), and Finkelstein et al. (2001) (denoted *RG*, *MC*, and *FG*, respectively). *RG* is a collection of similarity ratings of 65 word pairs averaged over judgments from 51 human subjects on a scale of 0 to 4 (from least to most similar). *MC* is a subset of 30 pairs out of the *RG* data set. These pairs were chosen to have evenly distributed similarity ratings in the original data set, and similarity judgment was elicited from 38 human judges with the same instruction as used for *RG*. *FG* is a much larger set consisting of 353 word pairs, and the rating scale is from 0 to 10. We combine the *RG* and *FG* data sets in order to maximize data size. Human ratings r on individual sets are normalized to r_n on 0 to 1 scale by the following formula:

$$r_n = \frac{r - r_{\min}}{r_{\max} - r_{\min}}$$

where $r_{\max}$ and $r_{\min}$ are the maximum and minimum of the original ratings, respectively. Correlation is evaluated using *Spearman's* ρ.

[2] We also tried several other variants of these definitions, e.g., using the maximum or minimum depth of the two nodes instead of the LCS. With respect to statistical significance tests, these variants all gave the same results as our primary definition.

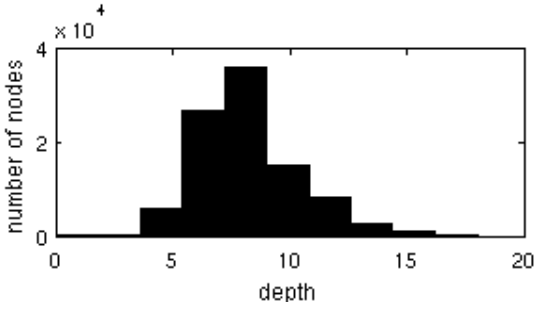

Figure 2: Histogram of depth of WordNet noun synsets.

3.1 Depth

The distribution of similarity of the combined data set over depth is plotted in Figure 1. For depth values under 5, similarity scores are fairly evenly distributed over depth, showing no statistical significance in correlation. For depth 5 and above, the shape of distribution resembles an upper-triangle, suggesting that (1) correlation with similarity becomes stronger in this range of depth value, and (2) data points with higher depth values tend to have higher similarity scores, but the reverse of the claim does not hold, i.e., word pairs with "shallower" LCS can also be judged quite similar by humans.

There are many more data points with lower depth values than with higher depth values in the combined data set. In order to have a fair comparison of statistical significance tests on the two value ranges for depth, we randomly sample an equal number (100) of data points from each value range, and the correlation coefficient between depth and similarity is averaged over 100 of such samplings. Correlation coefficients for depth value under 5 versus 5 and above are $\rho = 0.0881, p \approx 0.1$ and $\rho = 0.3779, p < 0.0001$, respectively, showing an apparent difference in degree of correlation.

Two interesting observations can be made from these results. Firstly, the notion of depth is relative to the distribution of number of nodes over depth value. For example, depth 20 by itself is virtually meaningless since it might be quite high if the majority of nodes in WordNet are of depth 10 or less, or quite low if the majority depth value are 50 or more. According to the histogram of depth values in WordNet (Figure 2), the distribution of number of nodes over depth value approximately conforms to a normal distribution $\mathcal{N}(8,2)$. It is visually quite noticeable that the actual quantity denoting how deep a node resides in WordNet is conflated at depth values below 5 or above 14. In other words, the distribution makes it rather inaccurate to say, for instance, that a node of depth 4 is twice as deep as a node of depth 2. This might explain the low degree of correlation between similarity and depth under 5 in Figure 1 (manifested by the long, vertical stripes across the entire range of similarity scores (0 to 1) for depth 4 and under), and also how the correlation increases with depth value. Unfortunately, we do not have enough data for depth above 14 to draw any conclusion on this higher end of the depth spectrum.

Secondly, even on the range of depth values with higher correlation with similarity, there is no definitive sufficient and necessary relation between depth and similarity (hence the upper triangle instead of a sloped line or band). Particularly, semantically more similar words are not necessarily deeper in the WordNet hierarchy. Data analysis reveals that the LCS of highly similar words can be quite close to the hierarchical root. Examples include *coast–shore*, which is judged to be very similar by humans (9 on a scale of 0–10 in both data sets). The latter is a hypernym of the former and thus the LCS of the pair, yet it is only four levels below the root node *entity* (via *geological formation*, *object*, and *physical entity*). Another situation is when the human judges confused relatedness with similarity, and WordNet fails to capture the relatedness with its hierarchical structure of lexical semantics: the pair *software–computer* can only be related by the root node *entity* as their LCS, although the pair is judged quite "similar" by humans (8.5 on 0 to 10 scale).

The only conclusive claim that can be made here is that word pairs with deeper LCS's tend to be more similar. However, since only word forms (rather than senses) are available in these psycho-linguistic experiments, the one similarity rating given by human judges sometimes fails to cover multiple senses for polysemous words. In the pair *stock–jaguar* of the *FG* set, for example, one sense of *stock* (*livestock, stock, farm animal: any animals kept for use or profit*) is closely connected to *jaguar* through a depth-10 LCS (*placental, placental mammal, eutherian, eutherian mammal*). However, the pair received a low similarity rating (0.92 on 0–10), prob-

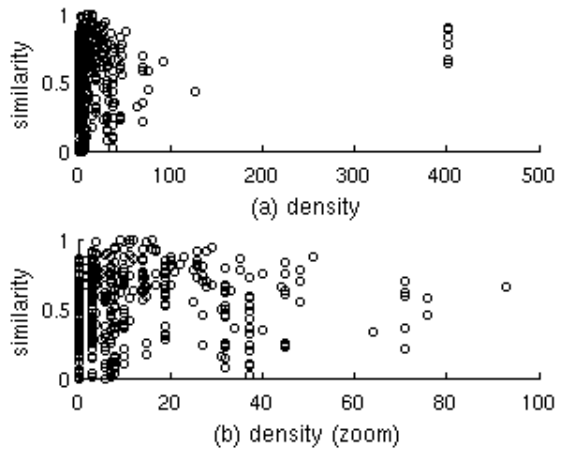

Figure 3: Correlation between density and similarity.

ably because judges associated the word form *stock* with its financial sense, especially when there was an abundant presence of pairs indicating this particular sense of the word (e.g., *stock–market*, *company–stock*).

3.2 Density

Comparing to depth, density exhibits much lower correlation with similarity (Figure 3-a and 3-b). We conducted correlation experiments between density and similarity with the same setting as for depth and similarity above. Data points with extremely high density values (up to over 400) are mostly idiosyncratic to the densely connected regions in WordNet and are numerically quite harmful. We thus excluded outliers with density values above 100 in the experiment.

Evaluation on the combined data set shows no correlation between density and similarity. To confirm the result, we break the experiments down to the three individual data sets, and the results are listed in Table 1. The correlation coefficient between density and similarity ranges from 0.10 to 0.27 There is no statistical significance of correlation on two of the three data sets (*MC* and *FG*), and the significance on *RG* is close to marginal with $p = 0.0366$.

Data analysis suggests that density values are often biased by particular fine-grainedness of local structures in WordNet. Qualitatively, Richardson and Smeaton (1995) previously observed that "the irregular densities of links between concepts results in unexpected conceptual distance measures". Empirically, on the one hand, more than 90% of WordNet nodes have density values less than or equal to 3. This means that for 90% of the LCS's, there are only three integer values for density to distinguish the varying degrees of similarity. In other words, such a range might be too narrow to have any real distinguishing power over similarity. On the other hand, there are outliers with extreme density values particular to the perhaps overly fine-grained subcategorization of some WordNet concepts, and these nodes can be LCS's of word pairs of drastically different similarity. The node *person*, *individual*, for example, can be the LCS of similar pairs such as *man–woman*, as well as quite dissimilar ones such as *boy–sage*, where the large density value does not necessarily indicate high degree of similarity.

Another crucial limitation of the definition of density is the information loss on specificity. In the existing literature, density is often adopted as a proxy for the degree of specificity of a concept, i.e., nodes in densely connected regions in WordNet are taken to be more specific and thus closer to each other. This information of a given node should be inherited by its hierarchical descendants, since specificity should monotonically increase as one descends the hierarchy. For example, the node *piano* has a density value of 15 under the node *percussion instrument*. However, the density value of its hyponyms *Grand piano*, *upright piano*, and *mechanical piano*, is only 3. Due to the particular structure of this subnetwork in WordNet, the *grand–upright* pair might be incorrectly regarded as less specific (and thus less similar) than, say, between *piano–gong*, both as percussion instruments.

4 New Definitions of Depth and Density

In this section, we formalize new definitions of depth and density to correct for their current limi-

	MC	*RG*	*FG*
dep_u	0.7201***	0.6798***	0.3751***
den_u	0.2268	0.2660*	0.1019
den_i	0.7338***	0.6751***	0.3445***

Table 2: Correlation between new definitions of depth/density and similarity.

tations discussed in Section 3.

4.1 Depth

The major problem with the current definition of depth is its failure to take into account the uneven distribution of number of nodes over the depth value. As seen in previous examples, the distribution is rather "flat" on both ends of depth value, which does not preserve the linearity of using the ordinal values of depth and thus introduces much inaccuracy.

To avoid this problem, we "re-curve" depth value to the cumulative distribution. Specifically, if we take the histogram distribution of depth value in Figure 2 as a probability density function, our approach is to project cardinal depth values onto its cumulative distribution function. The new depth is denoted dep_u and is defined as:

$$dep_u(c) = \frac{\sum_{c' \in WN} |\{c' : dep(c') \leq dep(c)\}|}{|WN|}$$

Here, $dep(\cdot)$ is the original depth value, and *WN* is the set of all nodes in WordNet. The resulting depth values not only reflect the flat ends, but also preserve linearity for the depth value range in the middle. In comparison with Table 1), correlation between dep_u and similarity increases over the original depth values on two of the three data sets (first row in Table 2 and decreases on the *RG* set. Later, in Section 5, we show how these marginal improvements translate into better similarity measures with statistical significance.

4.2 Density

In theory, a procedure analogous to the above cumulative definition can also be applied to density, i.e., by projecting the original values onto the cumulative distribution function. However, due to the Zipfian nature of density's histogram distribution (Figure 4, in contrast to Gaussian for depth in Figure 2), this is essentially to collapse most density values into a very small number of discrete values (which correspond to the original density of 1 to 3). Experiments show that it does not help in improving correlation with similarity scores (second row in Table 2 for den_u): correlation remains the same on *MC* and *RG*, and decreases slightly on *FG*.

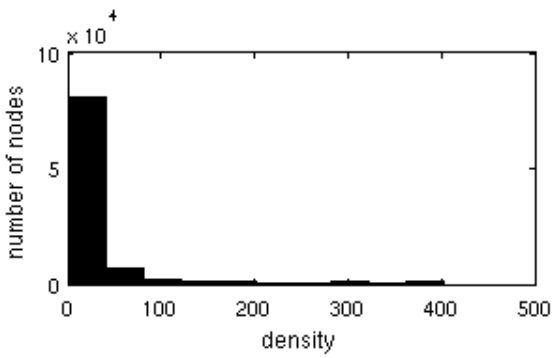

Figure 4: Histogram of density in WordNet.

We therefore resort to addressing the issue of information loss on specificity by inheritance. Intuitively, the idea is to ensure that a node be assigned no less density mass than its parent node(s). In the "piano" example (Section 3.2), the concept *piano* is highly specific due to its large number of siblings under the parent node *percussion instruments*. Consequently, the density of its child nodes *upright piano* and *grand piano* should inherit its specificity on top of their own.

Formally, we redefine density recursively as follows:

$$den_i(r) = 0$$
$$den_i(c) = \frac{\sum_{h \in hyper(c)} den_i(h)}{|hyper(c)|} + den(c)$$

where r is the root of WordNet hierarchy (with no hypernym), and $hyper(\cdot)$ is the set of hypernyms of a given concept. The first term is the inheritance part, normalized over all hypernyms of c in case of multiple inheritance, and the second term is the original value of density.

The resulting density values correlate significantly better with similarity. As shown in row 3 in Table 2, the correlation coefficients are about tripled on all three data sets with the new density definition den_i, and the significance of correlation is greatly improved as well (from non-correlating or

marginally correlating to strongly significantly correlating on all three data sets).

5 Using the New Definitions in Semantic Similarity Measures

In this section, we test the effectiveness of the new definitions of depth and density by using them in WordNet-based semantic similarity measures. The two similarity measures we experiment with are that of Wu and Palmer (1994) and Jiang and Conrath (1997). The first one used depth only, and the second one used both depth and density.

The task is to correlate the similarity measures with human judgment on similarity between word pairs. We use the same three data sets as in Section 3. despite the fact that *MC* is a subset of *RG* data set, we include both in order to compare with existing studies.

Correlation coefficient is calculated using *Spearman's* ρ, although results reported by some earlier studies used parametric tests such as the *Pearson Correlation Coefficient*. The reason for our choice is that the similarity scores of the word pairs in these data sets do not necessarily conform to normal distributions. Rather, we are interested in testing whether the artificial algorithms would give higher scores to pairs that are regarded closer in meaning by human judges. A non-parametric test suits better for this scenario. And this partly explains why our re-implementations of the models have lower correlation coefficients than in the original studies.

Note that there are other WordNet-based similarity measures using depth and/or density that we opt to omit for various reasons. Some of them were not designed for the particular task at hand (e.g., that of Sussna, 1993, which gives very poor correlation in this task). Others use depth of the entire WordNet hierarchy instead of individual nodes as a scaling factor (e.g., that of Leacock and Chodorow, 1998), which is unsuitable for illustrating the improvement brought about by the new depth and density definitions.

Parameterization of the weighting of depth and density is a common practice to control their individual contribution to the final similarity score (e.g., α and β in Equation (2)). Jiang and Conrath already had separate weights in their original study. In order to parameterize depth used by Wu and Palmer in their similarity measure, we also modify Equation (1) as follows:

$$sim(c_1,c_2) = \frac{2 \cdot dep^{\alpha}(c)}{len(c_1,c) + len(c_2,c) + 2 \cdot dep^{\alpha}(c)}$$

where depth is raised to the power of α to vary its contribution to the similarity score.

For a number of combinations of the weighting parameters, we report both the best performance and the averaged performance over all the parameter combinations. The latter number is meaningful in that it is a good indication of numerical stability of the parameterization. In addition, parameterization is able to generate multiple correlation coefficients, on which statistical tests can be run in order to show the significance of improvement. We use the range from 0 to 5 with step 1 for α and from 0 to 1 with step 0.1 for β.

Table 3 and 4 list the experiment results. In both models, the cumulative definition of depth dep_u consistently improve the performance of the similarity measures. In the Jiang and Conrath (1997) model, where density is applicable, the inheritance-based definition of density den_i also results in better correlation with human judgments. The optimal result is achieved when combining the new definitions of depth and density (row 4 in Table 4). For average performance, the improvement of all the new definitions over the original definitions is statistically

	Best			Average		
	MC	*RB*	*GR*	*MC*	*RB*	*GR*
dep	0.7671	0.7824	0.3773	0.7612	0.7686	0.3660

significant on all three data sets according to paired *t-test*.

6 Conclusions

This study explored effective uses of depth and/or density in WordNet-based similarity measures. We started by examining how well these two structural features correlate with human judgment on word pair similarities. This direct comparison showed that depth correlates with similarity only on certain value ranges, while density does not correlate with human judgment at all.

Further investigation revealed that the problem for depth lies in the simplistic representation as its ordinal integer values. The linearity in this representation fails to take into account the conflated quantity of depth in the two extreme ends of the depth spectrum. For density, a prominent issue is the information loss on specificity of WordNet concepts, which gives an inaccurate density value that is biased by the idiosyncratic constructions in densely connected regions in the hierarchy.

We then proposed new definitions of depth and density to address these issues. For depth, linearity in different value ranges is realistically reflected by projecting the depth value to its cumulative distribution function. The loss of specificity information in density, on the other hand, is corrected by allowing concepts to inherit specificity information from their parent nodes. The new definitions show significant improvement in correlation of semantic similarity given by human judges. In addition, when used in existing WordNet-based similarity measures, they consistently improve performance and numerical stability of the parameterization of the two features.

The notions of depth and density pertain to any hierarchical structure like WordNet, which suggests various extensions of this work. A natural next step of the current work is to apply the same idea to semantic taxonomies in languages other than English with available similarity judgments are also available. Extrinsic tasks using WordNet-based semantic similarity can potentially benefit from these refined notions of depth and density as well.

Abstract

This paper presents a novel method for the computation of word meaning in context. We make use of a factorization model in which words, together with their window-based context words and their dependency relations, are linked to latent dimensions. The factorization model allows us to determine which dimensions are important for a particular context, and adapt the dependency-based feature vector of the word accordingly. The evaluation on a lexical substitution task – carried out for both English and French – indicates that our approach is able to reach better results than state-of-the-art methods in lexical substitution, while at the same time providing more accurate meaning representations.

1 Introduction

According to the distributional hypothesis of meaning (Harris, 1954), words that occur in similar contexts tend to be semantically similar. In the spirit of this by now well-known adage, numerous algorithms have sprouted up that try to capture the semantics of words by looking at their distribution in texts, and comparing those distributions in a vector space model.

Up till now, the majority of computational approaches to semantic similarity represent the meaning of a word as the aggregate of the word's contexts, and hence do not differentiate between the different senses of a word. The meaning of a word, however, is largely dependent on the particular context in which it appears. Take for example the word *work* in sentences (1) and (2).

(1) The painter's recent work is a classic example of art brut.

(2) Equal pay for equal work!

The meaning of *work* is quite different in both sentences. In sentence (1), *work* refers to the product of a creative act, viz. a painting. In sentence (2), it refers to labour carried out as a source of income. The NLP community's standard answer to the ambiguity problem has always been some flavour of word sense disambiguation (WSD), which in its standard form boils down to choosing the best-possible fit from a pre-defined sense inventory. In recent years, it has become clear that this is in fact a very hard task to solve for computers and humans alike (Ide and Wilks, 2006; Erk et al., 2009; Erk, 2010).

With these findings in mind, researchers have started looking at different methods to tackle language's ambiguity, ranging from coarser-grained sense inventories (Hovy et al., 2006) and graded sense assignment (Erk and McCarthy, 2009), over word sense induction (Schütze, 1998; Pantel and Lin, 2002; Agirre et al., 2006), to the computation of individual word meaning in context (Erk and Padó, 2008; Thater et al., 2010; Dinu and Lapata, 2010). This research inscribes itself in the same line of thought, in which the meaning disambiguation of a word is not just the assignment of a pre-defined sense; instead, the original meaning representation of a word is adapted 'on the fly', according to – and specifically tailored for – the particular context in which it appears. To be able to do so, we build a factorization model in which words, together with their window-based context words and their dependency

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1012–1022,
Edinburgh, Scotland, UK, July 27–31, 2011.

relations, are linked to latent dimensions. The factorization model allows us to determine which dimensions are important for a particular context, and adapt the dependency-based feature vector of the word accordingly. The evaluation on a lexical substitution task – carried out for both English and French – indicates that our method is able to reach better results than state-of-the-art methods in lexical substitution, while at the same time providing more accurate meaning representations.

The remainder of this paper is organized as follows. In section 2, we present some earlier work that is related to the research presented here. Section 3 describes the methodology of our method, focusing on the factorization model, and the computation of meaning in context. Section 4 presents a thorough evaluation on a lexical substitution task, both for English and French. The last section then draws conclusions, and presents a number of topics that deserve further exploration.

2 Related work

One of the best known computational models of semantic similarity is latent semantic analysis — LSA (Landauer and Dumais, 1997; Landauer et al., 1998). In LSA, a term-document matrix is created, that contains the frequency of each word in a particular document. This matrix is then decomposed into three other matrices with a mathematical factorization technique called singular value decomposition (SVD). The most important dimensions that come out of the SVD are said to represent latent semantic dimensions, according to which nouns and documents can be represented more efficiently. Our model also applies a factorization technique (albeit a different one) in order to find a reduced semantic space.

The nature of a word's context is a determining factor in the kind of the semantic similarity that is induced. A broad context window (e.g. a paragraph or document) yields broad, topical similarity, whereas a small context window yields tight, synonym-like similarity. This has lead a number of researchers (e.g. Lin (1998)) to use the dependency relations that a particular word takes part in as context features. An overview of dependency-based semantic space models is given in Padó and Lapata (2007).

A number of researchers have exploited the notion of context to differentiate between the different senses of a word in an unsupervised way (a task labeled word sense induction or WSI). Schütze (1998) proposed a context-clustering approach, in which context vectors are created for the different instances of a particular word, and those contexts are grouped into a number of clusters, representing the different senses of the word. The context vectors are represented as second-order co-occurrences (i.e. the contexts of the target word are similar if the words they in turn co-occur with are similar). Van de Cruys (2008) proposed a model for sense induction based on latent semantic dimensions. Using a factorization technique based on non-negative matrix factorization, the model induces a latent semantic space according to which both dependency features and broad contextual features are classified. Using the latent space, the model is able to discriminate between different word senses. Our approach makes use of a similar factorization model, but we extend the approach with a probabilistic framework that is able to adapt the original vector according to the context of the instance.

Recently, a number of models emerged that aim to model the individual meaning of words in context. Erk and Padó (2008, 2009) make use of selectional preferences to express the meaning of a word in context; the meaning of a word in the presence of an argument is computed by multiplying the word's vector with a vector that captures the inverse selectional preferences of the argument. Thater et al. (2009) and Thater et al. (2010) extend the approach based on selectional preferences by incorporating second-order co-occurrences in their model; their model allows first-order co-occurrences to act as a filter upon the second-order vector space, which allows for the computation of meaning in context.

Erk and Padó (2010) propose an exemplar-based approach, in which the meaning of a word in context is represented by the activated exemplars that are most similar to it. And Mitchell and Lapata (2008) propose a model for vector composition, focusing on the different functions that might be used to combine the constituent vectors. Their results indicate that a model based on pointwise multiplication achieves better results than models based on vector addition.

Finally, Dinu and Lapata (2010) propose a probabilistic framework that models the meaning of words

as a probability distribution over latent dimensions ('senses'). Contextualized meaning is then modeled as a change in the original sense distribution. The model presented in this paper bears some resemblances to their approach; however, while their approach computes the contextualized meaning directly within the latent space, our model exploits the latent space to determine the features that are important for a particular context, and adapt the original (out-of-context) dependency-based feature vector of the target word accordingly. This allows for a more precise and more distinct computation of word meaning in context. Secondly, Dinu and Lapata use window-based context features to build their latent model, while our approach combines both window-based and dependency-based features.

3 Methodology

3.1 Non-negative Matrix Factorization

Our model uses non-negative matrix factorization (Lee and Seung, 2000) in order to find latent dimensions. There are a number of reasons to prefer NMF over the better known singular value decomposition used in LSA. First of all, NMF allows us to minimize the Kullback-Leibler divergence as an objective function, whereas SVD minimizes the Euclidean distance. The Kullback-Leibler divergence is better suited for language phenomena. Minimizing the Euclidean distance requires normally distributed data, and language phenomena are typically not normally distributed. Secondly, the non-negative nature of the factorization ensures that only additive and no subtractive relations are allowed. This proves particularly useful for the extraction of semantic dimensions, so that the NMF model is able to extract much more clear-cut dimensions than an SVD model. And thirdly, the non-negative property allows the resulting model to be interpreted probabilistically, which is not straightforward with an SVD factorization.

The key idea is that a non-negative matrix $\mathbf{A}$ is factorized into two other non-negative matrices, $\mathbf{W}$ and $\mathbf{H}$

$$\mathbf{A}_{i\times j} \approx \mathbf{W}_{i\times k}\mathbf{H}_{k\times j} \tag{1}$$

where k is much smaller than i, j so that both instances and features are expressed in terms of a few components. Non-negative matrix factorization enforces the constraint that all three matrices must be non-negative, so all elements must be greater than or equal to zero.

Using the minimization of the Kullback-Leibler divergence as an objective function, we want to find the matrices $\mathbf{W}$ and $\mathbf{H}$ for which the Kullback-Leibler divergence between $\mathbf{A}$ and $\mathbf{WH}$ (the multiplication of $\mathbf{W}$ and $\mathbf{H}$) is the smallest. This factorization is carried out through the iterative application of update rules. Matrices $\mathbf{W}$ and $\mathbf{H}$ are randomly initialized, and the rules in 2 and 3 are iteratively applied – alternating between them. In each iteration, each vector is adequately normalized, so that all dimension values sum to 1.

$$\mathbf{H}_{a\mu} \leftarrow \mathbf{H}_{a\mu}\frac{\sum_i \mathbf{W}_{ia}\frac{\mathbf{A}_{i\mu}}{(\mathbf{WH})_{i\mu}}}{\sum_k \mathbf{W}_{ka}} \tag{2}$$

$$\mathbf{W}_{ia} \leftarrow \mathbf{W}_{ia}\frac{\sum_\mu \mathbf{H}_{a\mu}\frac{\mathbf{A}_{i\mu}}{(\mathbf{WH})_{i\mu}}}{\sum_v \mathbf{H}_{av}} \tag{3}$$

3.2 Combining syntax and context words

Using an extension of non-negative matrix factorization (Van de Cruys, 2008), it is possible to jointly induce latent factors for three different modes: words, their window-based context words, and their dependency-based context features. As input to the algorithm, three matrices are constructed that capture the pairwise co-occurrence frequencies for the different modes. The first matrix contains co-occurrence frequencies of words cross-classified by dependency-based features, the second matrix contains co-occurrence frequencies of words cross-classified by words that appear in the word's context window, and the third matrix contains co-occurrence frequencies of dependency-based features cross-classified by co-occurring context words. NMF is then applied to the three matrices, and the separate factorizations are interleaved (i.e. the results of the former factorization are used to initialize the factorization of the next matrix). A graphical representation of the interleaved factorization algorithm is given in figure 1.

When the factorization is finished, the three different modes (words, window-based context words and dependency-based features) are all represented according to a limited number of latent factors.

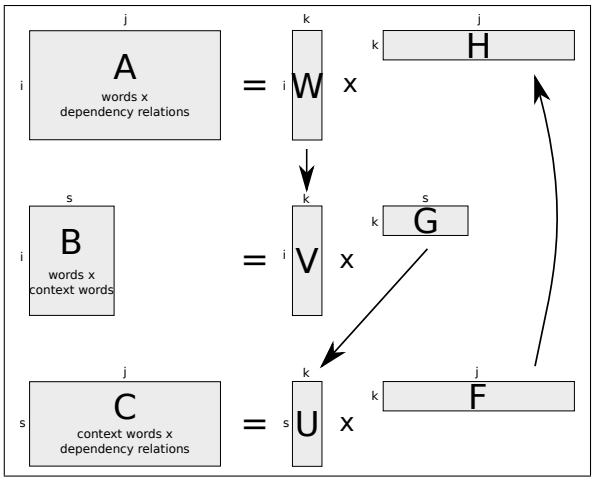

Figure 1: A graphical representation of the interleaved NMF

The factorization that comes out of the NMF model can be interpreted probabilistically (Gaussier and Goutte, 2005; Ding et al., 2008). More specifically, we can transform the factorization into a standard latent variable model of the form

$$p(w_i, d_j) = \sum_{z=1}^{K} p(z)p(w_i|z)p(d_j|z) \tag{4}$$

by introducing two $K \times K$ diagonal scaling matrices $\mathbf{X}$ and $\mathbf{Y}$, such that $\mathbf{X}_{kk} = \sum_i \mathbf{W}_{ik}$ and $\mathbf{Y}_{kk} = \sum_j \mathbf{H}_{kj}$. The factorization $\mathbf{WH}$ can then be rewritten as

$$\begin{aligned} \mathbf{WH} &= (\mathbf{WX}^{-1}\mathbf{X})(\mathbf{YY}^{-1}\mathbf{H}) \\ &= (\mathbf{WX}^{-1})(\mathbf{XY})(\mathbf{Y}^{-1}\mathbf{H}) \end{aligned} \tag{5}$$

such that $\mathbf{WX}^{-1}$ represents $p(w_i|\mathbf{z})$, $(\mathbf{Y}^{-1}\mathbf{H})^T$ represents $p(d_j|\mathbf{z})$, and $\mathbf{XY}$ represents $p(\mathbf{z})$. Using Bayes' theorem, it is now straightforward to determine $p(\mathbf{z}|w_i)$ and $p(\mathbf{z}|d_j)$.

$$p(\mathbf{z}|w_i) = \frac{p(w_i|\mathbf{z})p(\mathbf{z})}{p(w_i)} \tag{6}$$

$$p(\mathbf{z}|d_j) = \frac{p(d_j|\mathbf{z})p(\mathbf{z})}{p(d_j)} \tag{7}$$

3.3 Meaning in Context

3.3.1 Overview

Using the results of the factorization model described above, we can now adapt a word's feature vector according to the context in which it appears. Intuitively, the contextual features of the word (i.e. the window-based context words or dependency-based context features) pinpoint the important semantic dimensions of the particular instance, creating a probability distribution over latent factors. For a number of context words of a particular instance, we determine the probability distribution over latent factors given the context, $p(\mathbf{z}|C)$, as the average of the context words' probability distributions over latent factors (equation 8).

$$p(\mathbf{z}|C) = \frac{\sum_{w_i \in C} p(\mathbf{z}|w_i)}{|C|} \tag{8}$$

The probability distribution over latent factors given a number of dependency-based context features can be computed in a similar fashion, replacing w_i with d_j. Additionally, this step allows us to combine both windows-based context words and dependency-based context features in order to determine the latent probability distribution (e.g. by taking a linear combination).

The resulting probability distribution over latent factors can be interpreted as a semantic fingerprint of the passage in which the target word appears. Using this fingerprint, we can now determine a new probability distribution over dependency features given the context.

$$p(\mathbf{d}|C) = p(\mathbf{z}|C)p(\mathbf{d}|\mathbf{z}) \tag{9}$$

The last step is to weight the original probability vector of the word according to the probability vector of the dependency features given the word's context, by taking the pointwise multiplication of probability vectors $p(\mathbf{d}|w_i)$ and $p(\mathbf{d}|C)$.

$$p(\mathbf{d}|w_i, C) = p(\mathbf{d}|w_i) \cdot p(\mathbf{d}|C) \tag{10}$$

Note that this final step is a crucial one in our approach. We do not just build a model based on latent factors, but we use the latent factors to determine which of the features in the original word vector are the salient ones given a particular context. This allows us to compute an accurate adaptation of the original word vector in context.

Also note the resemblance to Mitchell and Lapata's best scoring vector composition model which, likewise, uses pointwise multiplication. However,

the model presented here has two advantages. First of all, it allows to take multiple context features into account, each of which contributes to the probability distribution over latent factors. Secondly, the target word and its features do not need to live in the same vector space (i.e. they do not need to be defined according to the same features), as the connections and the appropriate weightings are determined through the latent model.

3.3.2 Example

Let us exemplify the procedure with an example. Say we want to compute the distributionally similar words to the noun *record* in the context of example sentences (3) and (4).

(3) Jack is listening to a record.

(4) Jill updated the record.

First, we extract the context features for both instances, in this case $C_1 = \{listen^{-1}_{prep(to)}\}$ for sentence (3), and $C_2 = \{update^{-1}_{obj}\}$ for sentence (4).[1] Next, we compute $p(\mathbf{z}|C_1)$ and $p(\mathbf{z}|C_2)$ – the probability distributions over latent factors given the context – by averaging over the latent probability distributions of the individual context features.[2] Using these probability distributions over latent factors, we can now determine the probability of each dependency feature given the different contexts – $p(\mathbf{d}|C_1)$ and $p(\mathbf{d}|C_2)$.

The former step yields a general probability distribution over dependency features that tells us how likely a particular dependency feature is given the context that our target word appears in. Our last step is now to weight the original probability vector of the target word (the aggregate of dependency-based context features over all contexts of the target word) according to the new distribution given the context in which the target word appears. For the first sentence, features associated with the music sense of *record* (or more specifically, the dependency features associated with latent factors that are related to the feature $\{listen^{-1}_{prep(to)}\}$) will be emphasized, while features associated with unrelated latent factors are leveled out. For the second sentence, features that are associated with the administrative sense of *record* (dependency features associated with latent factors that are related to the feature $\{update^{-1}_{obj}\}$) are emphasized, while unrelated features are played down.

We can now return to our original matrix **A** and compute the top similar words for the two adapted vectors of *record* given the different contexts, which yields the results presented below.

1. **record**$_N$, C_1: *album*, *song*, *recording*, *track*, *cd*

2. **record**$_N$, C_2: *file*, *datum*, *document*, *database*, *list*

4 Evaluation

In this section, we present a thorough evaluation of the method described above, and compare it with related methods for meaning computation in context. In order to test the applicability of the method to multiple languages, we present evaluation results for both English and French.

4.1 Datasets

For English, we make use of the SEMEVAL 2007 English Lexical Substitution task (McCarthy and Navigli, 2007; McCarthy and Navigli, 2009). The task's goal is to find suitable substitutes for a target word in a particular context. The complete data set contains 200 target words (about 50 for each part of speech, viz. nouns, verbs, adjectives, and adverbs). Each target word occurs in 10 different sentences, which yields a total of 2000 sentences. Five annotators provided suitable substitutes for each target word in the different contexts.

For French, we developed a small-scale lexical substitution task ourselves, closely following the guidelines of the original English task. We manually selected 10 ambiguous French nouns, and for each noun we selected 10 different sentences from the FRWAC corpus (Baroni et al., 2009). Four different native French speakers were then asked to provide suitable substitutes for the nouns in context.[3]

[1] In this example we use dependency features, but the computations are similar for window-based context words.

[2] In this case, the sets of context features contain only one item, so the average probability distribution of the sets is just the latent probability distribution of their respective item.

[3] The task is provided as supplementary material to this paper; it is also available from the first author's website.

4.2 Implementational details

The model for English has been trained on part of the UKWaC corpus (Baroni et al., 2009), covering about 500M words. The corpus has been part of speech tagged and lemmatized with Stanford Part-Of-Speech Tagger (Toutanova and Manning, 2000; Toutanova et al., 2003), and parsed with MaltParser (Nivre et al., 2006) trained on sections 2-21 of the Wall Street Journal section of the Penn Treebank extended with about 4000 questions from the QuestionBank[4], so that dependency triples could be extracted. The sentences of the English lexical substitution task have been tagged, lemmatized and parsed in the same way. The model for French has been trained on the French version of Wikipedia ($\pm$ 100M words), parsed with the FRMG parser (Villemonte de La Clergerie, 2010) for French.

For English, we built different models for each part of speech (nouns, verbs, adjectives and adverbs), which yields four models in total. For each model, the matrices needed for our interleaved NMF factorization are extracted from the corpus. The noun model, for example, was built using 5K nouns, 80K dependency relations, and 2K context words[5] (excluding stop words) with highest frequency in the training set, which yields matrices of 5K nouns $\times$ 80K dependency relations, 5K nouns $\times$ 2K context words, and 80K dependency relations $\times$ 2K context words. The models for the three other parts of speech were constructed in a similar vein. For French, we only constructed a model for nouns, as our lexical substitution task for French is limited to this part of speech.

The interleaved NMF model was carried out using $K = 600$ (the number of factorized dimensions in the model), and applying 100 iterations.[6] The interleaved NMF algorithm was implemented in Matlab; the preprocessing scripts and scripts for vector computation in context were written in Python. Cosine was used as a similarity measure.

[4] http://maltparser.org/mco/english_parser/engmalt.html

[5] We used a fairly large, paragraph-like window of four sentences.

[6] We experimented with different values (in the range 300–1500) for K, but the models did not seem to improve much beyond $K = 600$; hence, we stuck with 600 factors, due to speed and memory advantages of a lower number of factors.

4.3 Measures

Up till now, most researchers have interpreted the lexical substitution task as a ranking problem, in which the possible substitutes are given beforehand and the goal is to rank the substitutes according to their suitability in a particular context, so that sound substitutes are given a higher rank than their non-suitable counterparts. This means that all possible substitutes for a given target word (extracted from the gold standard) are lumped together, and the system then has to produce a ranking for the complete set of substitutes.

We also adopt this approach in our evaluation framework, but we complement it with the original evaluation measures of the lexical substitution task, in which the system is not given a list of possible substitutes beforehand, but has to come up with the suitable candidates itself. This is a much harder task, but we believe that such an approach is more compelling in assessing the system's ability to induce a proper meaning representation for word usage in context. We coin the former approach *paraphrase ranking*, and the latter one *paraphrase induction*. In the next paragraphs, we will describe the actual evaluation measures that have been used for both approaches.

Paraphrase ranking Following Dinu and Lapata (2010), we compare the ranking produced by our model with the gold standard ranking using Kendall's τ_b (which is adjusted for ties). For reasons of comparison, we also compute general average precision (GAP, Kishida (2005)), which was used by Erk and Padó (2010) and Thater et al. (2010) to evaluate their rankings. Differences between models are tested for significance using stratified shuffling (Yeh, 2000), using a standard number of 10000 iterations.

We compare the results for paraphrase ranking to two different baselines. The first baseline is a random one, in which the gold standard is compared to an arbitrary ranking. The second baseline is a dependency-based vector space model that does not take the context of the particular instance into account (and thus returns the same ranking for each instance of the target word). This is a fairly competitive baseline, as noted by other researchers (Erk and Padó, 2008; Thater et al., 2009; Dinu and Lapata, 2010).

Paraphrase induction To evaluate the system's ability to come up with suitable substitutes from scratch, we use the measures designed to evaluate systems that took part in the original English lexical substitution task (McCarthy and Navigli, 2007). Two different measures were used, which were coined *best* and *out-of-ten (oot)*. The strict *best* measure allows the system to give as many candidate substitutes as it considers appropriate, but the credit for each correct substitute is divided by the total number of guesses. Recall is then calculated as the average annotator response frequency of substitutes found by the system over all items T.

$$R_{best} = \frac{\sum_{s \in M \cap G} f(s)}{|M| \cdot \sum_{s \in G} f(s)} \quad (11)$$

where M is the system's candidate list[7], G is the gold-standard data, and $f(s)$ is the annotator response frequency of the candidate.

The out-of-ten measure is more liberal; it allows the system to give up to ten substitutes, and the credit for each correct substitute is not divided by the total number of guesses. The more liberal measure was introduced to account for the fact that the lexical substitution task's gold standard is susceptible to a considerate amount of variation, and there is only a limited number of annotators.

$$P_{10} = \frac{\sum_{s \in M \cap G} f(s)}{\sum_{s \in G} f(s)} \quad (12)$$

where M is the system's list of 10 candidates, and G and $f(s)$ are the same as above. Because we only use the best guess with R_{best}, the two measures are exactly the same except for the number of candidates M.

4.4 Results

4.4.1 English

Table 1 presents the paraphrase ranking results of our approach, comparing them to the two baselines and to a number of previous approaches to meaning computation in context.

The first two models represent our baselines. The first baseline is the random baseline, where the candidate substitutes are ranked randomly (τ_b close to zero indicates that there is no correlation). The second baseline is a standard dependency-based vector space model, which yields the same ranking for all instances of a target word. Note that the second baseline is a rather competitive one.

model	τ_b	GAP
random	-0.61	29.98
vector$_{dep}$	16.57	45.08
EP09	–	32.2 ▼
EP10	–	39.9 ▼
TFP	–	45.94▼
DL	16.56	41.68
NMF$_{context}$	20.64**	47.60**
NMF$_{dep}$	22.49**	48.97**
NMF$_{c+d}$	**22.59****	**49.02****

Table 1: Kendall's τ_b and GAP paraphrase ranking scores for the English lexical substitution task. Scores marked with '▼' are copied from the authors' respective papers. Scores marked with '**' are statistically significant with $p < 0.01$ compared to the second baseline.

The next four models represent previous approaches to meaning computation in context. EP09 is Erk and Pado's (2009) selectional preference approach; EP10 is Erk and Pado's (2010) exemplar-based approach; TFP stands for Thater et al.'s (2010) approach; and DL is Dinu and Lapata's (2010) latent modeling approach. The results are reproduced from their respective papers, except for Dinu and Lapata's approach, which we reimplemented ourselves.[8] Note that the reproduced results (EP09, EP10 and TFP) are not entirely comparable, because the authors only use a subset of the lexical substitution task.

The last three models are instantiations of our approach: NMF$_{context}$ is a model that uses window-based context features, NMF$_{dep}$ is a model that uses dependency-based context features, and NMF$_{c+d}$ is a model that uses a linear combination of window-based and dependency-based context features, giving equal weight to both.

The three instantiations of our approach reach better results than all previous approaches. Moreover, our approach is the only one able to significantly

[7] In our evaluations, we calculate *best* using the system's best guess only, so the candidate list contains only one item.

[8] The original paper reports a slightly lower τ_b of 16.01 for their best scoring model.

beat our second (competitive) baseline of a standard dependency-based vector model. Comparing our three instantiations, the model that combines window-based context and dependency-based context scores best, closely followed by the dependency-based model. The model that only uses window-based context gets the lowest score of the three, but is still fairly competitive compared to the previous approaches. The differences between the models are statistically significant ($p < 0.01$), except for the difference between NMF$_{dep}$ and NMF$_{c+d}$.

model	n	v	a	r
vector$_{dep}$	15.85	11.68	16.71	25.29
NMF$_{context}$	20.58	16.24	21.00	27.22
NMF$_{dep}$	21.96	17.33	**24.57**	28.16
NMF$_{c+d}$	**22.68**	**17.47**	23.84	**28.66**

Table 2: Kendall's τ_b paraphrase ranking scores for the English lexical substitution task across different parts of speech

Table 2 shows the performance of the three model instantiations on paraphrase ranking across different parts of speech. The results largely confirm tendencies reported by other researchers (cfr. Dinu and Lapata (2010)), viz. that verbs are the most difficult, followed by nouns and adjectives. These parts of speech also benefit the most from the use of a contextualized model. Adverbs are easier, but there is less to be gained from using contextualized models.

model	R_{best}	P_{10}
vector$_{dep}$	8.78	30.21
DL	1.06	7.59
KU	20.65	46.15
IRST2	20.33	68.90
NMF$_{context}$	8.81	**30.49**
NMF$_{dep}$	7.73	26.92
NMF$_{c+d}$	**8.96**	29.26

Table 3: R_{best} and P_{10} paraphrase induction scores for the English lexical substitution task

Table 3 shows the performance of the different models on the paraphrase induction task. Note once again that our baseline vector$_{dep}$ – a simple dependency-based vector space model – is a highly competitive one. NMF$_{context}$ and NMF$_{c+d}$ are able to reach marginally better results, but the differences are not statistically significant. However, all of our models are able to reach much better results than Dinu and Lapata's approach. The results indicate that our approach, after vector adaptation in context, is still able to provide accurate similarity calculations across the complete word space. While other algorithms are able to rank candidate substitutes at the expense of accurate similarity calculations, our approach is able to do both. This is one of the important advantages of our approach.

For reasons of comparison, we also included the scores of the best performing models that participated in the SEMEVAL 2007 lexical substitution task (KU (Yuret, 2007) and IRST2 (Giuliano et al., 2007), which got the best scores for R_{best} and P_{10}, respectively). These models reach better scores compared to our models. Note, however, that all participants of the SEMEVAL 2007 lexical substitution task relied on a predefined sense inventory (i.e. WordNet, or a machine readable thesaurus). Our system, on the other hand, induces paraphrases in a fully unsupervised way. To our knowledge, this is the first time a fully unsupervised system is tested on the paraphrase induction task.

model	n	v	a	r
vector$_{dep}$	31.66	23.53	29.91	38.43
NMF$_{context}$	**33.73****	25.21*	28.58	36.45
NMF$_{dep}$	31.40	25.97**	20.56	31.48
NMF$_{c+d}$	33.37*	**25.99****	24.20	35.81

Table 4: P_{10} paraphrase induction scores for the English lexical substitution task across different parts of speech. Scores marked with '**' and '*' are statistically significant with respectively $p < 0.01$ and $p < 0.05$ compared to the baseline.

Table 4 presents the results for paraphrase induction (*oot*) across the different parts of speech. The results indicate that paraphrase induction works best for nouns and verbs, with statistically significant improvements over the baseline. The differences among the models themselves are not significant. Adjectives and adverbs yield lower scores, indicating that their

contextualization yields less precise vectors for meaning computation. Note, however, that the NMF$_{context}$ model is still quite apt for meaning computation, yielding results that are only slightly lower than the dependency-based vector space model.

4.4.2 French

This section presents the results on the French lexical substitution task. Table 5 presents the results for paraphrase ranking, while table 6 shows the models' performance on the paraphrase induction task.

model	Kendall's τ_b	GAP
vector$_{dep}$	7.79	36.46
DL	17.99	41.73
NMF$_{context}$	**18.63**	**44.96**
NMF$_{dep}$	17.15	44.66
NMF$_{c+d}$	18.40	43.14

Table 5: Kendall's τ_b and GAP paraphrase ranking scores for the French lexical substitution task

The results for paraphrase ranking in French (table 5) show similar tendencies as the results for English: all of our models are able to improve significantly over the dependency-based vector space baseline. Note, however, thar our models generally score a bit lower compared to the English results. This drop in performance is not present for Dinu and Lapata's model. The difference might be due to the difference in corpora size: for the method to operate at full power, we need to make a good estimate of the co-occurrences of three modes (words, window-based context words and dependency-based features), and thus our methods requires a significant amount of data. Nevertheless, our approach still yields the best results, with NMF$_{context}$ as the best scoring model.

Finally, the results for paraphrase induction in French (table 6) interestingly show a significant and large improvement over the baseline. The improvements indicate once again that the models are able to carry out precise similarity computations over the whole word space, while at the same time providing an adequately adapted contextualized meaning vector. Dinu and Lapata's model, which performs similarity calculations in the latent space, is not able to provide accurate word vectors, and thus perform worse at the paraphrase induction task.

model	R_{best}	P_{10}
vector$_{dep}$	6.38	24.43
DL	0.50	5.34
NMF$_{context}$	**10.71**	31.42
NMF$_{dep}$	9.65	28.52
NMF$_{c+d}$	10.64	**35.32**

Table 6: R_{best} and P_{10} paraphrase induction scores for the French lexical substitution task

5 Conclusion

In this paper, we presented a novel method for the modeling of word meaning in context. We make use of a factorization model based on non-negative matrix factorization, in which words, together with their window-based context words and their dependency relations, are linked to latent dimensions. The factorization model allows us to determine which particular dimensions are important for a target word in a particular context. A key feature of the algorithm is that we adapt the original dependency-based feature vector of the target word through the latent semantic space. By doing so, our model is able to make accurate similarity calculations for word meaning in context across the whole word space. Our evaluation shows that the approach presented here is able to improve upon the state-of-the art performance on paraphrase ranking. Moreover, our approach scores well for both paraphrase ranking and paraphrase induction, whereas previous approaches only seem capable of improving performance on the former task at the expense of the latter.

During our research, a number of topics surfaced that we consider worth exploring in the future. First of all, we would like to further investigate the optimal configuration for combining window-based and dependency-based contexts. At the moment, the performance of the combined model does not yield a uniform picture. The results might improve further if window-based context and dependency-based context are combined in an optimal way. Secondly, we would like to subject our approach to further evaluation, in particular on a number of different evaluation tasks, such as semantic compositionality. And thirdly, we would like to transfer the general idea of the approach presented in this paper to a tensor-

based framework (which is able to capture the multi-way co-occurrences of words, together with their window-based and dependency-based context features, in a natural way) and investigate whether such a framework proves beneficial for the modeling of word meaning in context.

Hierarchical Verb Clustering Using Graph Factorization

Lin Sun and Anna Korhonen
University of Cambridge, Computer Laboratory

ls418,alk23@cl.cam.ac.uk

Abstract

Most previous research on verb clustering has focussed on acquiring flat classifications from corpus data, although many manually built classifications are taxonomic in nature. Also Natural Language Processing (NLP) applications benefit from taxonomic classifications because they vary in terms of the granularity they require from a classification. We introduce a new clustering method called Hierarchical Graph Factorization Clustering (HGFC) and extend it so that it is optimal for the task. Our results show that HGFC outperforms the frequently used agglomerative clustering on a hierarchical test set extracted from VerbNet, and that it yields state-of-the-art performance also on a flat test set. We demonstrate how the method can be used to acquire novel classifications as well as to extend existing ones on the basis of some prior knowledge about the classification.

1 Introduction

A variety of verb classifications have been built to support NLP tasks. These include syntactic and semantic classifications, as well as ones which integrate aspects of both (Grishman et al., 1994; Miller, 1995; Baker et al., 1998; Palmer et al., 2005; Kipper, 2005; Hovy et al., 2006). Classifications which integrate a wide range of linguistic properties can be particularly useful for tasks suffering from data sparseness. One such classification is the taxonomy of English verbs proposed by Levin (1993) which is based on shared (morpho-)syntactic and semantic properties of verbs. Levin's taxonomy or its extended version in VerbNet (Kipper, 2005) has proved helpful for various NLP application tasks, including e.g. parsing, word sense disambiguation, semantic role labeling, information extraction, question-answering, and machine translation (Swier and Stevenson, 2004; Dang, 2004; Shi and Mihalcea, 2005; Zapirain et al., 2008).

Because verbs change their meaning and behaviour across domains, it is important to be able to tune existing classifications as well to build novel ones in a cost-effective manner, when required. In recent years, a variety of approaches have been proposed for automatic induction of Levin style classes from corpus data which could be used for this purpose (Schulte im Walde, 2006; Joanis et al., 2008; Sun et al., 2008; Li and Brew, 2008; Korhonen et al., 2008; Ó Séaghdha and Copestake, 2008; Vlachos et al., 2009). The best of such approaches have yielded promising results. However, they have mostly focussed on acquiring and evaluating flat classifications. Levin's classification is not flat, but taxonomic in nature, which is practical for NLP purposes since applications differ in terms of the granularity they require from a classification.

In this paper, we experiment with hierarchical Levin-style clustering. We adopt as our baseline method a well-known hierarchical method – agglomerative clustering (AGG) – which has been previously used to acquire flat Levin-style classifications (Stevenson and Joanis, 2003) as well as hierarchical verb classifications not based on Levin (Ferrer, 2004; Schulte im Walde, 2008). The method has also been popular in the related task of noun clus-

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1023–1033,
Edinburgh, Scotland, UK, July 27–31, 2011.

tering (Ushioda, 1996; Matsuo et al., 2006; Bassiou and Kotropoulos, 2011).

We introduce then a new method called Hierarchical Graph Factorization Clustering (HGFC) (Yu et al., 2006). This graph-based, probabilistic clustering algorithm has some clear advantages over AGG (e.g. it delays the decision on a verb's cluster membership at any level until a full graph is available, minimising the problem of error propagation) and it has been shown to perform better than several other hierarchical clustering methods in recent comparisons (Yu et al., 2006). The method has been applied to the identification of social network communities (Lin et al., 2008), but has not been used (to the best of our knowledge) in NLP before.

We modify HGFC with a new tree extraction algorithm which ensures a more consistent result, and we propose two novel extensions to it. The first is a method for automatically determining the tree structure (i.e. number of clusters to be produced for each level of the hierarchy). This avoids the need to predetermine the number of clusters manually. The second is addition of soft constraints to guide the clustering performance (Vlachos et al., 2009). This is useful for situations where a partial (e.g. a flat) verb classification is available and the goal is to extend it.

Adopting a set of lexical and syntactic features which have performed well in previous works, we compare the performance of the two methods on test sets extracted from Levin and VerbNet. When evaluated on a flat clustering task, HGFC outperforms AGG and performs very similarly with the best flat clustering method reported on the same test set (Sun and Korhonen, 2009). When evaluated on a hierarchical task, HGFC performs considerably better than AGG at all levels of gold standard classification. The constrained version of HGFC performs the best, as expected, demonstrating the usefulness of soft constraints for extending partial classifications.

Our qualitative analysis shows that HGFC is capable of detecting novel information not included in our gold standards. The unconstrained version can be used to acquire novel classifications from scratch while the constrained version can be used to extend existing ones with additional class members, classes and levels of hierarchy.

2 Target classification and test sets

The taxonomy of Levin (1993) groups English verbs (e.g. *break, fracture, rip*) into classes (e.g. 45.1 *Break* verbs) on the basis of their shared meaning components and (morpho-)syntactic behaviour, defined in terms of diathesis alternations (e.g. the causative/inchoative alternation, where an NP frame alternates with an intransitive frame: *Tony broke the window* $\leftrightarrow$ *The window broke*). It classifies over 3000 verbs in 57 top level classes, some of which divide further into subclasses. The extended version of the taxonomy in VerbNet (Kipper, 2005) classifies 5757 verbs. Its 5 level taxonomy includes 101 top level and 369 subclasses. We used three gold standards (and corresponding test sets) extracted from these resources in our experiments:

T1: The first gold standard is a flat gold standard which includes 13 classes appearing in Levin's original taxonomy (Stevenson and Joanis, 2003). We included this small gold standard in our experiments so that we could compare the flat version of our method against previously published methods. Following Stevenson and Joanis (2003), we selected 20 verbs from each class which occur at least 100 times in our corpus. This gave us 260 verbs in total.

T2: The second gold standard is a large, hierarchical gold standard which we extracted from VerbNet as follows: 1) We removed all the verbs that have less than 1000 occurrences in our corpus. 2) In order to minimise the problem of polysemy, we assigned each verb to the class which, according to VerbNet, corresponds to its predominant sense in WordNet (Miller, 1995). 3) In order to minimise the sparse data problem with very fine-grained classes, we converted the resulting classification into a 3-level representation so that the classes at the 4th and 5th level were combined. For example, the sub-classes of *Declare* verbs (numbered as 29.4.1.1.$\{$1,2,3$\}$) were combined into 29.4.1. 4) The classes that have fewer than 5 members were discarded. The total number of verb senses in the resulting gold standard is 1750, which is 33.2% of the verbs in VerbNet. T2 has 51 top level, 117 second level, and 133 third level classes.

T3: The third gold standard is a subset of T2 where singular classes (top level classes which do not divide into subclasses) are removed. This gold

standard was constructed to enable proper evaluation of the constrained version of HGFC (introduced in the following section) where we want to compare the impact of constraints across several levels of classification. T3 provides classification of 357 verbs into 11 top level, 14 second level, and 32 third level classes.

For each verb appearing in T1-T3, we extracted all the occurrences (up to 10,000) from the British National Corpus (Leech, 1992) and North American News Text Corpus (Graff, 1995).

3 Method

3.1 Features and feature extraction

Previous works on Levin style verb classification have investigated optimal features for this task (Stevenson and Joanis, 2003; Li and Brew, 2008; Sun and Korhonen, 2009)). We adopt for our experiments a set of features which have performed well in recent verb clustering works:

A: Subcategorization frames (SCFs) and their relative frequencies with individual verbs.

B: A with SCFs parameterized for prepositions.

C: B with SCFs parameterized for subjects appearing in grammatical relations associated with the verb in parsed data.

D: B with SCFs parameterized for objects appearing in grammatical relations associated with the verb in parsed data.

These features are purely syntactic. Although semantic features – verb selectional preferences – proved the best (when used in combination with syntactic features) in the recent work of Sun and Korhonen (2009), we left such features for future work because we noticed that different levels of classification are likely to require semantic features at different granularities.

We extracted the syntactic features using the system of Preiss et al. (2007). The system tags, lemmatizes and parses corpus data using the RASP (Robust Accurate Statistical Parsing toolkit (Briscoe et al., 2006)), and on the basis of the resulting grammatical relations, assigns each occurrence of a verb as a member of one of the 168 verbal SCFs. We parameterized the SCFs as described above using the information provided by the system.

3.2 Clustering

We introduce the agglomerative clustering (AGG) and Hierarchical Graph Factorization Clustering (HGFC) methods in the following two subsections, respectively. The subsequent two subsections present our extensions to HGFC: (i) automatically determining the cluster structure and (ii) adding soft constraints to guide clustering performance.

3.2.1 Agglomerative clustering

AGG is a method which treats each verb as a singleton cluster and then successively merges two closest clusters until all the clusters have been merged into one. We used the SciPy's implementation (Oliphant, 2007) of the algorithm. The cluster distance is measured using linkage criteria. We experimented with four commonly used linkage criteria: Single, Average, Complete and Ward's (Ward Jr., 1963). Ward's criterion performed the best and was used in all the experiments in this paper. It measures the increase in variance after two clusters are merged. The output of AGG tends to have excessive number of levels. Cut-based methods (Wu and Leahy, 1993; Shi and Malik, 2000) are frequently applied to extract a simplified view. We followed previous verb clustering works and cut the AGG hierarchy manually.

AGG suffers from two problems. The first is error propagation. When a verb is misclassified at a lower level, the error propagates to all the upper levels. The second is local pairwise merging, i.e. the fact that only two clusters can be combined at any level. For example, in order to group clusters representing Levin classes 9.1, 9.2 and 9.3 into a single cluster representing class 9, the method has to produce intermediate clusters, e.g. 9.{1,2} and 9.3. Such clusters do not always have a semantic interpretation. Although they can be removed using a cut-based method, this requires a pre-defined cut-off value which is difficult to set (Stevenson and Joanis, 2003). In addition, a significant amount of information is lost in pair-wise clustering. In the above example, only the clusters 9.{1,2} and 9.3 are considered, while alternative clusters 9.{1,3} and 9.2 are ignored. Ideally, information about all the possible intermediate clusters should be aggregated, but this is intractable in practice.

3.2.2 Hierarchical Graph Factorization Clustering

Our new method HGFC derives a probabilistic bipartite graph from the similarity matrix (Yu et al., 2006). The local and global clustering structures are learned via the random walk properties of the graph.

The method does not suffer from the above problems with AGG. Firstly, there is no error propagation because the decision on a verb's membership at any level is delayed until the full bipartite graph is available and until a tree structure can be extracted from it by aggregating probabilistic information from all the levels. Secondly, the bipartite graph enables the construction of a hierarchical structure without any intermediate classes. For example, we can group classes 9.{1,2,3} directly into class 9.

We use HGFC with the distributional similarity measure Jensen-Shannon Divergence ($d_{js}(v, v')$). Given a set of verbs, $V = \{v_n\}_{n=1}^{N}$, we compute a similarity matrix W where $W_{ij} = \exp(-d_{js}(v_1, v_2))$. W can be encoded by a undirected graph G (Figure 1(a)), where the verbs are mapped to vertices and the W_{ij} is the edge weight between vertices i and j.

The graph G and the cluster structure can be represented by a bipartite graph $K(V, U)$. V are the vertices on G. $U = \{u_p\}_{p=1}^{m}$ represent the hidden m clusters. For example, looking at Figure 1(b), V on G can be grouped into three clusters u_1, u_2 and u_3. The matrix B denotes the $n \times m$ adjacency matrix, with b_{ip} being the connection weight between the vertex v_i and the cluster u_p. Thus, B represents the connections between clusters at an upper and lower level of clustering. A flat clustering algorithm can be induced by computing B.

The bipartite graph K also induces a similarity (W') between v_i and v_j: $w'_{ij} = \sum_{p=1}^{m} \frac{b_{ip} b_{jp}}{\lambda_p} = (B\Lambda^{-1}B^T)_{ij}$ where $\Lambda = \text{diag}(\lambda_1, ..., \lambda_m)$. Therefore, B can be found by approximating the similarity matrix W of G using W' derived from K. Given a distance function ζ between two similarity matrices, B approximates W by minimizing the cost function $\zeta(W, B\Lambda^{-1}B^T)$. The coupling between B and Λ is removed by setting $H = B\Lambda^{-1}$:

$$\min_{H,\Lambda} \zeta(W, H\Lambda H^T), s.t. \sum_{i=1}^{n} h_{ip} = 1 \quad (1)$$

We use the divergence distance: $\zeta(X, Y) = \sum_{ij}(x_{ij} \log \frac{x_{ij}}{y_{ij}} - x_{ij} + y_{ij})$. Yu et al. (2006) showed that this cost function is non-increasing under the update rule:

$$\tilde{h}_{ip} \propto h_{ip} \sum_j \frac{w_{ij}}{(H\Lambda H^T)_{ij}} \lambda_p h_{jp} \text{ s.t.} \sum_i \tilde{h}_{ip} = 1 \quad (2)$$

$$\tilde{\lambda}_p \propto \lambda_p \sum_j \frac{w_{ij}}{(H\Lambda H^T)_{ij}} h_{ip} h_{jp} \text{ s.t.} \sum_p \tilde{\lambda}_p = \sum_{ij} w_{ij} \quad (3)$$

w_{ij} can be interpreted as the probability of the direct transition between v_i and v_j: $w_{ij} = p(v_i, v_j)$, when $\sum_{ij} w_{ij} = 1$. b_{ip} can be interpreted as:

$$\begin{aligned} p(u_p, u_q) &= p(u_p)p(u_p|u_q) = \sum_{i=1}^{n} \frac{b_{ip} b_{iq}}{d_i} \\ &= (B^T D^{-1} B)_{pq} \quad (4) \\ D &= \text{diag}(d_1, ..., d_n) \text{ where } d_i = \sum_{p=0}^{m} b_{ip} \end{aligned}$$

$p(u_p, u_q)$ is the similarity between the clusters. It takes into account of a weighted average of contributions from all the data. This is different from the linkage method where only the data from two clusters are considered.

Given the cluster similarity $p(u_p, u_q)$, we can construct a new graph G_1 (Figure 1(d)) with the clusters U as vertices. The cluster algorithm can be applied again (Figure 1(e)). This process can go on iteratively, leading to a hierarchical graph.

Algorithm 1 HGFC algorithm (Yu et al., 2006)

Require: N verbs V, number of clusters m_l for L levels
  Compute the similarity matrix W_0 from V
  Build the graph G_0 from W_0 , and $m_0 \leftarrow n$
  for $l = 1, 2$ to L **do**
    Factorize G_{l-1} to obtain bipartite graph K_l with the adjacency matrix B_l (eq. 1, 2 and 3)
    Build a graph G_l with similarity matrix $W_l = B_l^T D_l^{-1} B_l$ according to equation 4
  end for
  return $B_L, B_{L-1}...B_1$

Additional steps need to be performed in order to extract a tree from the hierarchical graph. Yu et al. (2006) performs the extraction via a propagation of probabilities from the bottom level clusters. For a verb v_i, the probability of assigning it to cluster $v_p^{(l)}$ at level l is given by:

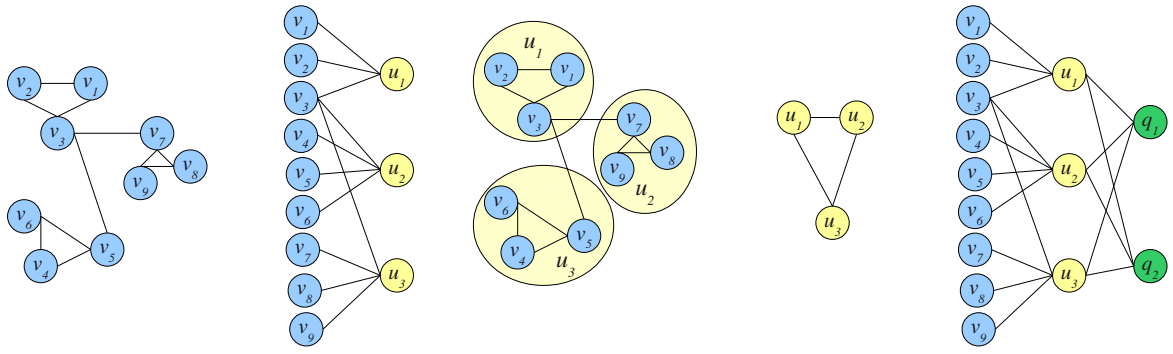

Figure 1: (a) An undirected graph G representing the similarity matrix; (b) The bipartite graph showing three clusters on G; (c) The induced clusters U; (d) The new graph G_1 over clusters U; (e) The new bipartite graph over G_1

$$p(v_p^{(l)}|v_i) = \sum_{V_{l-1}} ... \sum_{V_1} p(v_p^{(l)}|v^{(l-1)})...p(v^{(1)}|v_i)$$
$$= (D_1^{(-1)} B_1 D_2^{-1} B_2 D_3^{-1} B_3 ... D_l^{-1} B_l)_{ip} \quad (5)$$

This method might not extract a consistent tree structure, because the cluster membership at the lower level does not constrain the upper level membership. This prevented us from extracting a Levin style hierarchical classification in our initial experiments. For example, where two verbs were grouped together at a lower level, they could belong to separate clusters at an upper level. We therefore propose a new tree extraction algorithm (Algorithm 2).

The new algorithm starts from the top level bipartite graph, and generates consistent labels for each level by taking into account of the tree constraints set at upper levels.

Algorithm 2 Tree extraction algorithm for HGFC

Require: Given N, (B^l, m_l) on each level for L levels
On the top level L, collect the labels T^L (eq. 5)
Define C to be a $(m_{L-1} \times m_L)$ zero matrix, $C_{ij} \leftarrow 1$, where $i, j = \arg\max_{i,j}\{B_{ij}^L\}$
for $l = L-1$ to 1 **do**
  for $i = 1$ to N **do**
    Compute $p(v_p^l|v_i)$ for each cluster p (eq. 5)
    $t_i^l = \text{argmax}_p\{p(v_p^l|v_i)|p = 1...m_l, C_{pt_i^{l+1}} \neq 0\}$
  end for
  Redefine C to be a $(m_{l-1} \times m_l)$ zero matrix, $C_{ij} \leftarrow 1$, where $i, j = \arg\max_{i,j}\{B_{ij}^l\}$
end for
return Tree consistent labels $T^L, T^{L-1}...T^1$

3.2.3 Automatically determining the number of clusters for HGFC

HGFC needs the number of levels and clusters at each level as input. However, this information is not always available (e.g. when the goal is to actually learn this information automatically). We therefore propose a method for inferring the cluster structure from data. As shown in figure 1, a similarity matrix W models one-hop transitions that follow the links from vertices to neighbors. A walker can also go to other vertices via multi-hop transitions. According to the chain rule of the Markov process, the multi-hop transitions indicate a decaying similarity function on the graph (Yu et al., 2006). After t transitions, the similarity matrix (W_t) becomes:

$$W_t = W_{t-1} D_0^{-1} W_0$$

Yu et al. (2006) proved the correspondence between the HGFC levels (l) and the random walk time: $t = 2^{l-1}$. So the vertices at level l induce a similarity matrix of verbs after t-hop transitions. The decaying similarity function captures the different scales of clustering structure in the data (Azran and Ghahramani, 2006b). The upper levels would have a smaller number of clusters which represent a more global structure. After several levels, all the verbs are expected to be grouped into one cluster. The number of levels and clusters at each level can thus be learned automatically.

We therefore propose a method that uses the decaying similarity function to learn the hierarchical clustering structure. One simple modification to algorithm 1 is to set the number of clusters at level l

(m_l) to be $m_{l-1} - 1$. m is denoted as the number of clusters that have at least one member according to eq. 5. We start by treating each verb as a cluster at the bottom level. The algorithm stops when all the data points are merged into one cluster. The increasingly decaying similarity causes many clusters to have 0 members especially at lower levels, which are pruned in the tree extraction.

3.2.4 Adding constraints to HGFC

The basic version of HGFC makes no prior assumptions about the classification. It is useful for learning novel verb classifications from scratch. However, when wishing to extend an existing classification (e.g. VerbNet) it may be desirable to guide the clustering performance on the basis of information that is already known. We propose a constrained version of HGFC which makes uses of labels at the bottom level to learn upper level classifications. We do this by adding soft constraints to clustering, following Vlachos et al. (2009).

We modify the similarity matrix W as follows: If two verbs have different labels ($l_i \neq l_j$), the similarity between them is decreased by a factor a, and $a < 1$. We set a to 0.5 in the experiments. The resulting tree is generally consistent with the original classification. The influence of the underlying data (domain or features) is reduced according to a.

4 Experimental evaluation

We applied the clustering methods introduced in section 3 to the test sets described in section 2 and evaluated them both quantitatively and qualitatively, as described in the subsequent sections.

4.1 Evaluation methods

We used class based accuracy (ACC) and adjusted rand index (R_{adj}) to evaluate the results on the flat test set T1 (see section 2 for details of T1-T3).

ACC is the proportion of members of dominant clusters DOM-CLUST$_i$ within all classes c_i.

$$\mathrm{ACC} = \frac{\sum_{i=1}^{C} \text{verbs in DOM-CLUST}_i}{\text{number of verbs}}$$

The formula of R_{adj} is (Hubert and Arabie, 1985):

$$\mathrm{R}_{adj} = \frac{\sum_{i,j}\binom{n_{ij}}{2} - \sum_i \binom{n_{i\cdot}}{2}\sum_j \binom{n_{\cdot j}}{2}/\binom{n}{2}}{\frac{1}{2}[\sum_i \binom{n_{i\cdot}}{2} + \sum_j \binom{n_{\cdot j}}{2}] - \sum_i \binom{n_{i\cdot}}{2}\sum_j \binom{n_{\cdot j}}{2}/\binom{n}{2}}$$

where n_{ij} is the size of the intersection between class i and cluster j.

We used normalized mutual information (NMI) and F-Score (F) to evaluate hierarchical clustering results on T2 and T3. NMI measures the amount of statistical information shared by two random variables representing the clustering result and the gold-standard labels. Given random variables A and B:

$$\mathrm{NMI}(A,B) = \frac{I(A;B)}{[H(A)+H(B)]/2}$$

$$\mathrm{I}(A,B) = \sum_k \sum_j \frac{|(v_k \cap c_j|}{N} \log \frac{N|v_k \cap c_j|}{|v_k||c_j|}$$

where $|v_k \cap c_j|$ is the number of shared membership between cluster v_k and gold-standard class c_j. The normalized variant of mutual information (MI) enables the comparison of clustering with different cluster numbers (Manning et al., 2008).

F is the harmonic mean of precision (P) and recall (R). P is calculated using modified purity – a global measure which evaluates the mean precision of clusters. Each cluster is associated with its prevalent class. The number of verbs in a cluster K that take this class is denoted by $n_{prevalent}$(K).

$$\mathrm{mPUR} = \frac{\sum_{n_{prevalent(k_i)>2}} n_{prevalent(k_i)}}{\text{number of verbs}}$$

R is calculated using ACC.

$$\mathrm{F} = \frac{2 \cdot \mathrm{mPUR} \cdot \mathrm{ACC}}{\mathrm{mPUR} + \mathrm{ACC}}$$

F is not suitable for comparing results with different cluster numbers (Rosenberg and Hirschberg, 2007). Therefore, we only report NMI when the number of classes in clustering and gold-standard is substantially different.

Finally, we supplemented quantitative evaluation with qualitative evaluation of clusters produced by different methods.

4.2 Quantitative evaluation

We first evaluated AGG and the basic (unconstrained) HGFC on the small flat test set T1. The main purpose of this evaluation was to compare the results of our methods against previously published results on the same test set. The number of clusters (K) and levels (L) were inferred automatically for HGFC as described in section 3.2.3. However, to

make the results comparable with previously published ones, we cut the resulting hierarchy at the level of closest match (12 clusters) to the K (13) in the gold-standard. For AGG, we cut the hierarchy at 13 clusters.

Method	ACC	R_{adj}
HGFC	41.2	17.4
AGG (reproduced)	32.7	9.9
AGG (Stevenson and Joanis (2003)	31.0	9.0

Table 1: Comparison against Stevenson and Joanis (2003)'s result on T1 (using similar features).

Table 1 shows our results and the results of Stevenson and Joanis (2003) on T1 when employing AGG using Ward as the linkage criterion. In this experiment, we used the same feature set as Stevenson and Joanis (2003) (set B, see section 3.1) and were therefore able to reproduce their AGG result with a difference smaller than 2%. When using this simple feature set, HGFC outperforms the best performing AGG clearly: 8.5% in ACC and 7.3% in R_{adj}.

We also compared HGFC against the best reported clustering method on T1 to date – that of spectral clustering by Sun and Korhonen (2009). We used the feature sets C and D which are similar to the features (SCF parameterized by lexical prefences) in their experiments. HGFC obtains F of 49.93% on T1 which is 5% lower than the result of Sun and Korhonen (2009). The difference comes from the tree consistency requirement. When the HGFC is forced to produce a flat clustering (a one level tree only), it achieves the F of 52.55% which is very close to the performance of spectral clustering.

We then evaluated our methods on the hierarchical test sets T2 and T3. In the first set of experiments, we pre-defined the tree structure for HGFC by setting L to 3 and K at each level to be the K in the hierarchical gold standard. The hierarchy produced by AGG was cut into 3 levels according to Ks in the gold standard. This enabled direct evaluation of the results against the 3 level gold standards using both NMI and F.

The results are reported in tables 2 and 3. In these tables, N_c is the number of clusters in HGFC clustering while N_l is the number of classes in the gold standard (the two do not always correspond perfectly because a few clusters have zero members).

N_c	N_l	HGFC unconstrained		AGG	
		NMI	F	NMI	F
130	133	57.31	36.65	54.22	32.62
114	117	54.67	37.96	51.35	32.44
50	51	37.75	40.00	32.61	32.78

Table 2: Performance on T2 using a pre-defined tree structure.

N_c	N_l	HGFC unconstrained		HGFC constrained		AGG	
		NMI	F	NMI	F	NMI	F
31	32	51.65	42.01	91.47	92.07	49.70	40.30
15	14	42.75	47.70	82.16	82.80	39.19	43.69
11	11	38.91	51.17	71.69	75.00	34.88	44.80

Table 3: Performance on T3 using a pre-defined tree structure.

Table 2 compares the results of the unconstrained version of HGFC against those of AGG on our largest test set T2. As with T1, HGFC outperforms AGG clearly. The benefit can now be seen at 3 different levels of hierarchy. On average, the HGFC outperforms AGG 3.5% in NMI and 4.8% in F. The difference between the methods becomes clearer when moving towards the upper levels of the hierarchy.

Table 3 shows the results of both unconstrained and constrained versions of HGFC and those of AGG on the test set T3 (where singular classes are removed to enable proper evaluation of the constrained method). The results are generally generally better on this test set than on T2 – which is to be expected since T3 is a refined subset of T2[1].

Recall that the constrained version of HGFC learns the upper levels of classification on the basis of soft constraints set at the bottom level, as described earlier in section 3.2.4. As a consequence, NMI and F are both greater than 90% at the bottom level and the results at the top level are notably lower because the impact of the constraints degrades the further away one moves from the bottom level. Yet, the relatively high result across all levels shows that the constrained version of HGFC can be employed a useful method to extend the hierarchical structure of known classifications.

[1] NMI is higher on T2, however, because NMI has a higher baseline for larger number of clusters (Vinh et al., 2009). NMI is not ideal for comparing the results of T2 and T3.

T2			T3		
N_c	N_l	HGFC	N_c	N_l	HGFC
148	133	53.26	64	32	54.91
97	117	49.85	35	32	50.83
46	51	33.55	20	14	44.02
19	51	25.80	10	14	34.41
9	51	19.17	6	11	32.27
3	51	13.06			

Table 4: NMI of unconstrained HGFC when trees for T2 and T3 are inferred automatically.

Finally, Table 4 shows the results for the unconstrained HGFC on T2 and and T3 when the tree structure is not pre-defined but inferred automatically as described in section 3.2.3. 6 levels are learned for T2 and 5 for T3. The number of clusters produced ranges from 3 to 148 for T2 and from 6 to 64 for T3. We can see that the automatically detected cluster numbers distribute evenly across different levels. The scale of the clustering structure is more complete here than in the gold standards.

In the table, N_c indicates the number of clusters in the inferred tree, while N_l indicates the closest match to the number of classes in the gold standard. This evaluation is not fully reliable because the match between the gold standard and the clustering is poor at some levels of hierarchy. However, it is encouraging to see that the results do not drop dramatically until the match between the two is really poor.

4.3 Qualitative evaluation

To gain a better insight into the performance of HGFC, we conducted further qualitative analysis of the clusters the two versions of this method produced for T3. We focussed on the top level of 11 clusters (in the evaluation against the hierarchical gold standard, see table 3) as the impact of soft constraints is the weakest for the constrained method at this level.

As expected, the constrained HGFC kept many individual verbs belonging to same Verbnet subclass together (e.g. verbs *enjoy, hate, disdain, regret, love, despise, detest, dislike, fear* for the class 31.2.1) so that most clusters simply group lower level classes and their members together. Three nearly clean clusters were produced which only include sub-classes of the same class (e.g. 31.2.0 and 31.2.1 which both belong to 31.2 *Admire* verbs). However, the remaining 8 clusters group together sub-classes (and their members) belonging to unrelated parent classes. Interestingly, 6 of these make both syntactic and semantic sense. For example, several such 37.7 *Say* verbs and 29.5 *Conjencture* verbs are found together which share the meaning of communication and which take similar sentential complements.

In contrast, none of the clusters produced by the unconstrained HGFC represent a single VerbNet class. The majority represent a high number of classes and fewer members per class. Yet many of the clusters make syntactic and semantic sense. A good example is a cluster which includes member verbs from 9.7 *Spray/Load* verbs, 21.2 *Carve* verbs, 51.3.1 *Roll* verbs, and 10.4 *Wipe* verbs. The verbs included in this cluster share the meaning of specific type of motion and show similar syntactic behaviour.

Thorough Levin style investigation of especially the unconstrained method would require looking at shared diathesis alternations between cluster members. We left this for future work. However, the analysis we conducted confirmed that the constrained method could indeed be used for extending known classifications, while the unconstrained method is more suitable for acquiring novel classifications from scratch. The errors in clusters produced by both methods were mostly due to syntactic idiosyncracy and the lack of semantic information in clustering. We plan to address the latter problem in our future work.

5 Discussion and conclusion

We have introduced a new graph-based method – HGFC – to hierarchical verb clustering which avoids some of the problems (e.g. error propagation, pairwise cluster merging) reported with the frequently used AGG method. We modified HGFC so that it can be used to automatically determine the tree structure for clustering, and proposed two extensions to it which make it even more suitable for our task. The first involves automatically determining the number of clusters to be produced, which is useful when this is not known in advance. The second involves adding soft constraints to guide the clustering performance, which is useful when aiming to extend existing classification.

The results reported in the previous section are promising. On a flat test set (T1), the unconstrained version of HGFC outperforms AGG and performs very similarly with the best current flat clustering method (spectral clustering) evaluated on the same dataset. On the hierarchical test sets (T2 and T3), the unconstrained and constrained versions of HGFC outperform AGG clearly at all levels of classification. The constrained version of HGFC detects the missing hierarchy from the existing gold standards with high accuracy. When the number of clusters and levels is learned automatically, the unconstrained method produces a multi-level hierarchy. Our evaluation against a 3-level gold standard shows that such a hierarchy is fairly accurate. Finally, the results from our qualitative evaluation show that both constrained and unconstrained versions of HGFC are capable of learning valuable novel information not included in the gold standards.

The previous work on Levin style verb classification has mostly focussed on flat classifications using methods suitable for flat clustering (Schulte im Walde, 2006; Joanis et al., 2008; Sun et al., 2008; Li and Brew, 2008; Korhonen et al., 2008; Ó Séaghdha and Copestake, 2008; Vlachos et al., 2009). However, some works have employed hierarchical clustering as a method to infer flat clustering.

For example, Schulte im Walde and Brew (2002) employed AGG to initialize the KMeans clustering for German verbs. This gave better results than random initialization. Stevenson and Joanis (2003) used AGG for flat clustering on T1. They cut the hierarchy at the number of classes in the gold standard and found that it is difficult to automatically determine a good cut-off. Our evaluation in the previous section shows that HGFC outperforms their implementation of AGG.

AGG was also used by Ferrer (2004) who performed hierarchical clustering of 514 Spanish verbs. The results were evaluated against a hierarchical gold standard resembling that of Levin's classification in English (Vázquez et al., 2000). R_{adj} of 0.07 was reported for a 15-way classification which is comparable to the result of Stevenson and Joanis (2003).

Hierarchical clustering has also been performed for the related task of semantic verb classification. For example, Basili et al. (1993) identified the problems of AGG, and applied a conceptual clustering algorithm (Fisher, 1987) to Italian verbs. They used semi-automatically acquired semantic roles and the concept types as features. No quantitative results were reported. The qualitative evaluation shows that the resulting clusters are very fine-grained.

Schulte im Walde (2008) performed hierarchical clustering of German verbs using human verb association as features and AGG as a method. They focussed on two small collections of 56 and 104 verbs and evaluated the result against flat gold standard extracted from GermaNet (Kunze and Lemnitzer, 2002) and German FrameNet (Erk et al., 2003), respectively. They reported F of 62.69% for the 56 verbs, and F of 34.68% for the 104 verbs.

In the future, we plan to extend this research line in several directions. First, we will try to determine optimal features for different levels of clustering. For example, the general syntactic features (e.g. SCF) may perform the best at top levels of a hierarchy while more specific or refined features (e.g. SCF+pp) may be optimal at lower levels. We also plan to investigate incorporating semantic features, like verb selectional preferences, in our feature set. It is likely that different levels of clustering require more or less specific selectional preferences. One way to obtain the latter is hierarchical clustering of relevant noun data.

In addition, we plan to apply the unconstrained HGFC to specific domains to investigate its capability to learn novel, previously unknown classifications. As for the constrained version of HGFC, we will conduct a larger scale experiment on the VerbNet data to investigate what kind of upper level hierarchy it can propose for this resource (which currently has over 100 top level classes).

Finally, we plan to compare HGFC to other hierarchical clustering methods that are relatively new to NLP but have proved promising in other fields, including Bayesian Hierarchical Clustering (Heller and Ghahramani, 2005; Teh et al., 2008) and the method of Azran and Ghahramani (2006a) based on spectral clustering.

Abstract

A central topic in natural language processing is the design of lexical and syntactic features suitable for the target application. In this paper, we study convolution dependency tree kernels for automatic engineering of syntactic and semantic patterns exploiting lexical similarities. We define efficient and powerful kernels for measuring the similarity between dependency structures, whose surface forms of the lexical nodes are in part or completely different. The experiments with such kernels for question classification show an unprecedented results, e.g. 41% of error reduction of the former state-of-the-art. Additionally, semantic role classification confirms the benefit of semantic smoothing for dependency kernels.

1 Introduction

A central topic in Natural Language Processing is the design of lexical and syntactic features suitable for the target application. The selection of effective patterns composed of syntactic dependencies and lexical constraints is typically a complex task.

Additionally, the availability of training data is usually scarce. This requires the development of generalized features or the definition of semantic similarities between them, e.g. as proposed in (Resnik, 1995; Jiang and Conrath, 1997; Schtze, 1998; Pedersen et al., 2004a; Bloehdorn and Moschitti, 2007b; Davis et al., 2007) or in semi-supervised settings, e.g. (Chapelle et al., 2006). A semantic similarity can be defined at structural level over a graph, e.g. (Freeman, 1977; Bunke and Shearer, 1998; Brandes, 2001; Zhao et al., 2009), as well as combining structural and lexical similarity over semantic networks, e.g. (Cowie et al., 1992; Wu and Palmer, 1994; Resnik, 1995; Jiang and Conrath, 1997; Schtze, 1998; Leacock and Chodorow, 1998; Pedersen et al., 2004a; Budanitsky and Hirst, 2006). More recent research also focuses on mechanisms to define if two structures, e.g. graphs, are enough similar, as explored in (Mihalcea, 2005; Zhao et al., 2009; Fürstenau and Lapata, 2009; Navigli and Lapata, 2010).

On one hand, previous work shows that there is a substantial lack of automatic methods for engineering lexical/syntactic features (or more in general syntactic/semantic similarity). On the other hand, automatic feature engineering of syntactic or shallow semantic structures has been carried out by means of structural kernels, e.g. (Collins and Duffy, 2002; Kudo and Matsumoto, 2003; Cumby and Roth, 2003; Cancedda et al., 2003; Daumé III and Marcu, 2004; Toutanova et al., 2004; Shen et al., 2003; Gliozzo et al., 2005; Kudo et al., 2005; Titov and Henderson, 2006; Zelenko et al., 2002; Bunescu and Mooney, 2005; Zhang et al., 2006). The main idea of structural kernels is to generate structures that in turn represent syntactic or shallow semantic features. Most notably, the work in (Bloehdorn and Moschitti, 2007b) encodes lexical similarity in such kernels. This is essentially the syntactic tree kernel (STK) proposed in (Collins and Duffy, 2002) in which syntactic fragments from constituency trees can be matched even if they only differ in the leaf nodes (i.e. they have different surface forms). This implies matching scores lower than 1, depending on the semantic similarity of the corresponding leaves in the syntactic fragments.

Although this kernel achieves state-of-the-art performance in NLP tasks, such as Question Classifica-

Edinburgh, Scotland, UK, July 27–31, 2011.

tion (Bloehdorn and Moschitti, 2007b) and Textual Entailment (Mehdad et al., 2010), it offers clearly possibility of improvement: (i) better possibility to exploit semantic smoothing since, e.g., trivially STK only matches the syntactic structure *apple/orange* when comparing *the big beautiful apple* to *a nice large orange*; and (ii) STK cannot be effectively applied to dependency structures, e.g. see experiments and motivation in (Moschitti, 2006a). Additionally, to our knowledge, there is no previous study that clearly describes how dependency structures should be converted in trees to be fully and effectively exploitable by convolution kernels. Indeed, although the work in (Culotta and Sorensen, 2004) defines a dependency tree also using node similarity, it is not a convolution kernel: this results in a much poorer feature space.

In this paper, we propose a study of convolution kernels for dependency structures aiming at jointly modeling syntactic and lexical semantic similarity. More precisely, we define several dependency trees exploitable by the Partial Tree Kernel (PTK) (Moschitti, 2006a) and compared them with STK over constituency trees. Most importantly, we define an innovative and efficient class of kernels, i.e. the Smoothed Partial Tree Kernels (SPTKs), which can measure the similarity of structural similar trees whose nodes are associated with different but related lexicals. Given the convolution nature of such kernels any possible node path of lexicals provide a contribution smoothed by the similarity accounted by its nodes.

The extensive experimentation on two datasets of question classification (QC) and semantic role labeling (SRL), shows that: (i) PTK applied to our dependency trees outperforms STK, demonstrating that dependency parsers are fully exploitable for feature engineering based on structural kernels; (ii) SPTK outperforms any previous kernels achieving an unprecedented result of 41% of error reduction with respect to the former state-of-the-art on QC; and (iii) the experiments on SRL confirm that the approach can be applied to different tasks without any tuning and again achieving state-of-the-art accuracy.

In the reminder of this paper, Section 2 provides the background for structural and lexical similarity kernels. Section 3 introduces SPTK. Section 4 provides our representation models for dependency trees. Section 5 presents the experimental evaluation for QC and SRL. Section 6 derives the conclusions.

2 Kernel Background

In kernel-based machines, both learning and classification algorithms only depend on the inner product between instances. This in several cases can be efficiently and implicitly computed by kernel functions by exploiting the following dual formulation: $\sum_{i=1..l} y_i \alpha_i \phi(o_i)\phi(o) + b = 0$, where o_i and o are two objects, ϕ is a mapping from the objects to feature vectors $\vec{x_i}$ and $\phi(o_i)\phi(o) = K(o_i, o)$ is a kernel function implicitly defining such mapping. In case of structural kernels, K determines the shape of the substructures describing the objects above. The most general kind of kernels used in NLP are string kernels, e.g. (Shawe-Taylor and Cristianini, 2004), the Syntactic Tree Kernels (Collins and Duffy, 2002) and the Partial Tree Kernels (Moschitti, 2006a).

2.1 String Kernels

The String Kernels (SK) that we consider count the number of subsequences shared by two strings of symbols, s_1 and s_2. Some symbols during the matching process can be skipped. This modifies the weight associated with the target substrings as shown by the following SK equation:

$$SK(s_1, s_2) = \sum_{u \in \Sigma^*} \phi_u(s_1) \cdot \phi_u(s_2) = \sum_{u \in \Sigma^*} \sum_{\vec{I}_1 : u = s_1[\vec{I}_1]} \sum_{\vec{I}_2 : u = s_2[\vec{I}_2]} \lambda^{d(\vec{I}_1)+d(\vec{I}_2)}$$

where, $\Sigma^* = \bigcup_{n=0}^{\infty} \Sigma^n$ is the set of all strings, $\vec{I}_1$ and $\vec{I}_2$ are two sequences of indexes $\vec{I} = (i_1, ..., i_{|u|})$, with $1 \leq i_1 < ... < i_{|u|} \leq |s|$, such that $u = s_{i_1}..s_{i_{|u|}}$, $d(\vec{I}) = i_{|u|} - i_1 + 1$ (distance between the first and last character) and $\lambda \in [0, 1]$ is a decay factor.

It is worth noting that: (a) longer subsequences receive lower weights; (b) some characters can be omitted, i.e. gaps; (c) gaps determine a weight since the exponent of λ is the number of characters and gaps between the first and last character; and (c) the complexity of the SK computation is $O(mnp)$ (Shawe-Taylor and Cristianini, 2004), where m and n are the lengths of the two strings, respectively and p is the length of the largest subsequence we want to consider.

2.2 Tree Kernels

Convolution Tree Kernels compute the number of common substructures between two trees T_1 and T_2 without explicitly considering the whole fragment space. For this purpose, let the set $\mathcal{F} = \{f_1, f_2, \ldots, f_{|\mathcal{F}|}\}$ be a tree fragment space and $\chi_i(n)$ be an indicator function, equal to 1 if the target f_i is rooted at node n and equal to 0 otherwise. A tree-kernel function over T_1 and T_2 is $TK(T_1, T_2) = \sum_{n_1 \in N_{T_1}} \sum_{n_2 \in N_{T_2}} \Delta(n_1, n_2)$, N_{T_1} and N_{T_2} are the sets of the T_1's and T_2's nodes, respectively and $\Delta(n_1, n_2) = \sum_{i=1}^{|\mathcal{F}|} \chi_i(n_1)\chi_i(n_2)$. The latter is equal to the number of common fragments rooted in the n_1 and n_2 nodes. The Δ function determines the richness of the kernel space and thus different tree kernels. Hereafter, we consider the equation to evaluate STK and PTK [1].

2.2.1 Syntactic Tree Kernels (STK)

To compute STK is enough to compute $\Delta_{STK}(n_1, n_2)$ as follows (recalling that since it is a syntactic tree kernels, each node can be associated with a production rule): (i) if the productions at n_1 and n_2 are different then $\Delta_{STK}(n_1, n_2) = 0$; (ii) if the productions at n_1 and n_2 are the same, and n_1 and n_2 have only leaf children then $\Delta_{STK}(n_1, n_2) = \lambda$; and (iii) if the productions at n_1 and n_2 are the same, and n_1 and n_2 are not pre-terminals then $\Delta_{STK}(n_1, n_2) = \lambda \prod_{j=1}^{l(n_1)} (1 + \Delta_{STK}(c_{n_1}^j, c_{n_2}^j))$, where $l(n_1)$ is the number of children of n_1 and c_n^j is the j-th child of the node n. Note that, since the productions are the same, $l(n_1) = l(n_2)$ and the computational complexity of STK is $O(|N_{T_1}||N_{T_2}|)$ but the average running time tends to be linear, i.e. $O(|N_{T_1}| + |N_{T_2}|)$, for natural language syntactic trees (Moschitti, 2006a).

2.2.2 The Partial Tree Kernel (PTK)

The computation of PTK is carried out by the following Δ_{PTK} function: if the labels of n_1 and n_2 are different then $\Delta_{PTK}(n_1, n_2) = 0$; else $\Delta_{PTK}(n_1, n_2) =$

$$\mu\Big(\lambda^2 + \sum_{\vec{I}_1, \vec{I}_2, l(\vec{I}_1) = l(\vec{I}_2)} \lambda^{d(\vec{I}_1) + d(\vec{I}_2)} \prod_{j=1}^{l(\vec{I}_1)} \Delta_{PTK}(c_{n_1}(\vec{I}_{1j}), c_{n_2}(\vec{I}_{2j}))\Big)$$

where $d(\vec{I}_1) = \vec{I}_{1l(\vec{I}_1)} - \vec{I}_{11} + 1$ and $d(\vec{I}_2) = \vec{I}_{2l(\vec{I}_2)} - \vec{I}_{21} + 1$. This way, we penalize both larger trees and child subsequences with gaps. PTK is more general than the STK as if we only consider the contribution of shared subsequences containing all children of nodes, we implement the STK kernel. The computational complexity of PTK is $O(p\rho^2|N_{T_1}||N_{T_2}|)$ (Moschitti, 2006a), where p is the largest subsequence of children that we want consider and ρ is the maximal outdegree observed in the two trees. However the average running time again tends to be linear for natural language syntactic trees (Moschitti, 2006a).

2.3 Lexical Semantic Kernel

Given two text fragments d_1 and $d_2 \in D$ (the text fragment set), a general lexical kernel (Basili et al., 2005) defines their similarity as:

$$K(d_1, d_2) = \sum_{w_1 \in d_1, w_2 \in d_2} (\omega_1 \omega_2) \times \sigma(w_1, w_2) \quad (1)$$

where ω_1 and ω_2 are the weights of the words (features) w_1 and w_2 in the documents d_1 and d_2, respectively, and σ is a term similarity function, e.g. (Pedersen et al., 2004b; Sahlgren, 2006; Corley and Mihalcea, 2005; Mihalcea et al., 2005). Technically, any σ can be used, provided that the resulting Gram matrix, $\boldsymbol{G} = K(d_1, d_2)\ \forall d_1, d_2 \in D$ is positive semi-definite (Shawe-Taylor and Cristianini, 2004) (D is typically the training text set).

We determine the term similarity function through distributional analysis (Pado and Lapata, 2007), according to the idea that the meaning of a word can be described by the set of textual contexts in which it appears (*Distributional Hypothesis*, (Harris, 1964)). The contexts are words appearing in a n-window with target words: such a space models a generic notion of semantic relatedness, i.e. two words close in the space are likely to be either in paradigmatic or syntagmatic relation as in (Sahlgren, 2006). The original word-by-word context matrix M is decomposed through Singular Value Decomposition (SVD) (Golub and Kahan, 1965) into the product of three new matrices: U, S, and V so that S is diagonal and $M = USV^T$. M is approximated by $M_l = U_l S_l V_l^T$ in which only the first l columns of U and V are used, and only the first l greatest singular values are considered. This approximation supplies a way to project a generic term w_i into the l-

[1] To have a similarity score between 0 and 1, a normalization in the kernel space, i.e. $\frac{TK(T_1,T_2)}{\sqrt{TK(T_1,T_1) \times TK(T_2,T_2)}}$ is applied.

dimensional space using $W = U_l S_l^{1/2}$, where each row corresponds to the representation vectors $\vec{w_i}$. Therefore, given two words w_1 and w_2, the term similarity function σ is estimated as the cosine similarity between the corresponding projections $\vec{w_1}, \vec{w_2}$, i.e $\sigma(w_1, w_2) = \frac{\vec{w_1} \cdot \vec{w_2}}{\|\vec{w_1}\| \|\vec{w_2}\|}$. The latent semantic kernels (Siolas and d'Alch Buc, 2000; Cristianini et al., 2001) derive G by applying LSA, resulting in a valid kernel.

Another methods to design a valid kernel is to represent words as word vectors and compute σ as their scalar product between such vectors. For example, in (Bloehdorn et al., 2006), bag of hyponyms and hypernyms (up to a certain level of WordNet hierarchy) were used to build such vectors. We will refer to such similarity as WL (word list).

3 Smoothing Partial Tree Kernel (SPTK)

Combining lexical and structural kernels provides clear advantages on all-vs-all words similarity, which tends to semantically diverge. Indeed syntax provides the necessary restrictions to compute an effective semantic similarity. Following this idea, Bloedhorn & Moschitti (2007a) modified step (i) of Δ_{STK} computation as follows: (i) if n_1 and n_2 are pre-terminal nodes with the same number of children, $\Delta_{STK}(n_1, n_2) = \lambda \prod_{j=1}^{nc(n_1)} \sigma(lex(n_1), lex(n_2))$, where lex returns the node label. This allows to match fragments having same structure but different leaves by assigning a score proportional to the product of the lexical similarities of each leaf pair. Although it is an interesting kernel, the fact that lexicals must belong to the leaf nodes of exactly the same structures limits its applications. Trivially, it cannot work on dependency trees. Hereafter, we define a much more general smoothed tree kernel that can be applied to any tree and exploit any combination of lexical similarities, respecting the syntax enforced by the tree.

3.1 SPTK Definition

If n_1 and n_2 are leaves then $\Delta_\sigma(n_1, n_2) = \mu\lambda\sigma(n_1, n_2)$; else

$$\Delta_\sigma(n_1, n_2) = \mu\sigma(n_1, n_2) \times \Big(\lambda^2 + \sum_{\vec{I_1}, \vec{I_2}, l(\vec{I_1}) = l(\vec{I_2})} \lambda^{d(\vec{I_1}) + d(\vec{I_2})} \prod_{j=1}^{l(\vec{I_1})} \Delta_\sigma(c_{n_1}(\vec{I}_{1j}), c_{n_2}(\vec{I}_{2j}))\Big), \quad (2)$$

where σ is any similarity between nodes, e.g. between their lexical labels, and the other variables are the same of PTK.

3.2 Soundness

A completely formal proof of the validity of the Eq. 2 is beyond the purpose of this paper (mainly due to space reason). Here we give a first sketch: let us consider σ as a string matching between node labels and $\lambda = \mu = 1$. Each recursive step of Eq. 2 can be seen as a summation of $(1 + \prod_{j=1}^{l(\vec{I_1})} \Delta_{STK}(c_{n_1}(\vec{I}_{1j}), c_{n_2}(\vec{I}_{2j})))$, i.e. the Δ_{STK} recursive equation (see Sec. 2.2.1), for all subsequences of children $c_{n_1}(\vec{I}_{1j})$. In other words, PTK is a summation of an exponential number of STKs, which are valid kernels. It follows that PTK is a kernel. Note that the multiplication by λ and μ elevated to any power only depends on the target fragment. Thus, it just gives an additional weight to the fragment and does not violate the Mercer's conditions. In contrast, the multiplication by $\sigma(n_1, n_2)$ does depend on both comparing examples, i.e. on n_1 and n_2. However, if the matrix $\big[\sigma(n_1, n_2)\big] \forall n_1, n_2 \in f \in \mathcal{F}$ is positive semi-definite, a decomposition exists such that $\sigma(n_1, n_2) = \phi(n_1)\phi(n_2) \Rightarrow \Delta_\sigma(n_1, n_2)$ can be written as $\sum_{i=1}^{|\mathcal{F}|} \phi(n_1)\chi_i(n_1)\phi(n_2)\chi_i(n_2) = \sum_{i=1}^{|\mathcal{F}|} \phi_\sigma(n_1)\phi_\sigma(n_2)$ (see Section 2.2), which proves SPTK to be a valid kernel.

3.3 Efficient Evaluation

We followed the idea in (Moschitti, 2006a) for efficiently computing SPTK. We consider Eq. 2 evaluated with respect to sequences of different length p; it follows that

$$\Delta(n_1, n_2) = \mu\sigma(n_1, n_2)\big(\lambda^2 + \sum_{p=1}^{m} \Delta_p(c_{n_1}, c_{n_2})\big),$$

where Δ_p evaluates the number of common subtrees rooted in subsequences of exactly p children (of n_1 and n_2) and $m = min\{l(c_{n1}), l(c_{n2})\}$. Given the two child sequences $s_1 a = c_{n_1}$ and $s_2 b = c_{n_2}$ (a and b are the last children)

$$\Delta_p(s_1 a, s_2 b) = \Delta(a, b) \times \sum_{i=1}^{|s_1|} \sum_{r=1}^{|s_2|} \lambda^{|s_1| - i + |s_2| - r} \times \Delta_{p-1}(s_1[1:i], s_2[1:r])$$

where $s_1[1:i]$ and $s_2[1:r]$ are the child subsequences from 1 to i and from 1 to r of s_1 and s_2. If we name the double summation term as D_p, we can

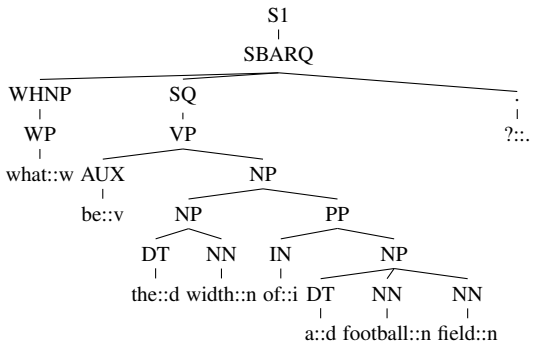

Figure 1: Constituent Tree (CT)

rewrite the relation as:

$$\Delta_p(s_1 a, s_2 b) = \begin{cases} \Delta(a,b) D_p(|s_1|,|s_2|) \text{ if } \sigma(a,b) > 0; \\ 0 \qquad\qquad\qquad otherwise. \end{cases}$$

Note that D_p satisfies the recursive relation:

$$D_p(k,l) = \Delta_{p-1}(s_1[1:k], s_2[1:l]) + \lambda D_p(k,l-1) + \lambda D_p(k-1,l) - \lambda^2 D_p(k-1,l-1)$$

By means of the above relation, we can compute the child subsequences of two sequences s_1 and s_2 in $O(p|s_1||s_2|)$. Thus the worst case complexity of the SPTK is identical to PTK, i.e. $O(p\rho^2|N_{T_1}||N_{T_2}|)$, where ρ is the maximum branching factor of the two trees. The latter is very small in natural language parse trees and we also avoid the computation of node pairs with non similar labels.

We note that PTK generalizes both (i) SK, allowing the similarity between sequences (node children) structured in a tree and (ii) STK, allowing the computation of STK over any possible pair of subtrees extracted from the original tree. For this reason, we do not dedicate additional space on the definition of the smoothed SK or smoothed STK, which are in any case important corollary findings of our research.

3.4 Innovative Features of SPTK

The most similar kernel to SPTK is the Syntactic Semantic Tree Kernel (SSTK) proposed in (Bloehdorn and Moschitti, 2007a; Bloehdorn and Moschitti, 2007b). However, the following aspects show the remarkable innovativeness of SPTK:

- SSTK can only work on constituency trees and not on dependency trees (see (Moschitti, 2006a)).
- The lexical similarity in SSTK is only applied to leaf nodes in exactly the same syntactic constituents. Only complete matching of the structure of subtrees is allowed: there is absolutely no flexibility, e.g. the NP structure "cable television system" has no match with the NP "video streaming system". SPTK provides matches between all possible relevant subparts, e.g. "television system" and "video system" (so also exploiting the meaningful similarity between "video" and "television").
- The similarity in the PTK equation is added such that SPTK still corresponds to a scalar product in the semantic/structure space[2].
- We have provided a fast evaluation of SPTK with dynamic programming (otherwise the computation would have required exponential time).

4 Dependency Tree Structures

The feature space generated by the structural kernels, presented in the previous section, obviously depends on the input structures. In case of PTK and SPTK different tree representations may lead to engineer more or less effective syntactic/semantic feature spaces. The next two sections provide our representation models for dependency trees and their discussion.

4.1 Proposed Computational Structures

Given the following sentence:

(s1) *What is the width of a football field?*

The representation tree for a phrase structure paradigm leaves little room for variations as shown by the constituency tree (CT) in Figure 1. We apply lemmatization to the lexicals to improve generalization and, at the same time, we add a generalized PoS-tag, i.e. noun (n::), verb (v::), adjective (::a), determiner (::d) and so on, to them. This is useful to measure similarity between lexicals belonging to the same grammatical category.

In contrast, the conversion of dependency structures in computationally effective trees (for the above kernels) is not straightforward. We need to decide the role of lexicals, their grammatical functions (GR), PoS-tags and dependencies. It is natural

[2]This is not trivial: for example if sigma is added in Eq. 2 by only multiplying the λ^{d1+d2} term, no valid space is generated.

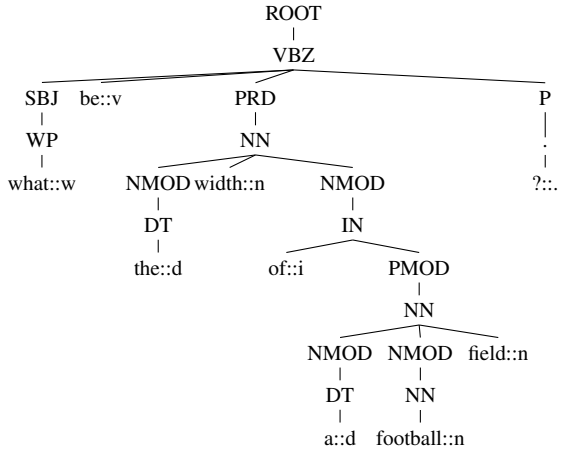

Figure 2: PoS-Tag Centered Tree (PCT)

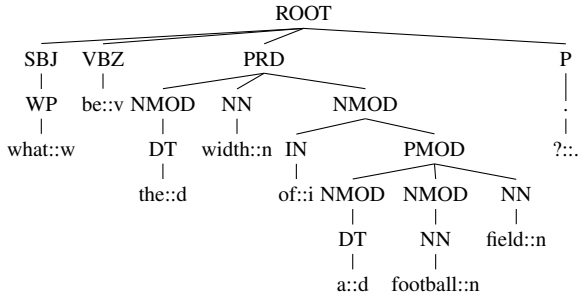

Figure 3: Grammatical Relation Centered Tree (GRCT)

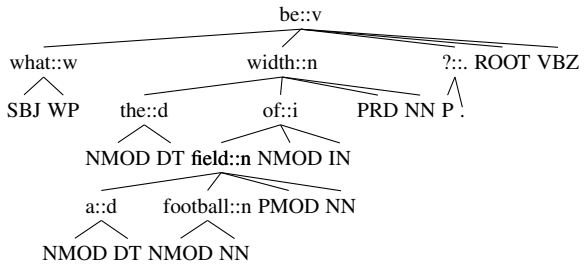

Figure 4: Lexical Centered Tree (LCT)

to associate edges with dependencies but, since our kernels cannot process labels on the arcs, they must be associated with tree nodes. The basic idea of our structures is to use (i) one of the three kinds of information above as central node, from which dependencies are drawn and (ii) all the other information as features (in terms of additional nodes) attached to the central nodes.

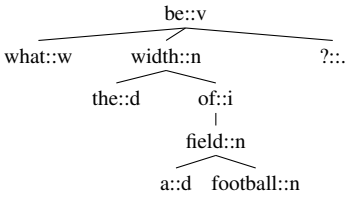

Figure 5: Lexical Only Centered Tree (LOCT)

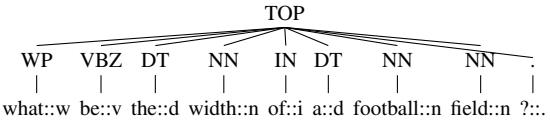

Figure 6: Lexical and PoS-Tag Sequences Tree (LPST)

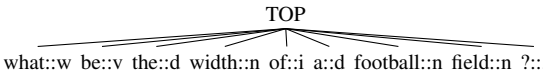

Figure 7: Lexical Sequences Tree (LST)

We define three main trees: the PoS-Tag Centered Tree (PCT), e.g. see Figure 2, where the GR is added as father and the lexical as a child; the GR Centered Tree (GRCT), e.g. see Figure 3, where the PoS-Tags are children of GR nodes and fathers of their associated lexicals; and the Lexical Centered Tree (LCT), e.g. see Figure 4, in which both GR and PoS-Tag are added as the rightmost children.

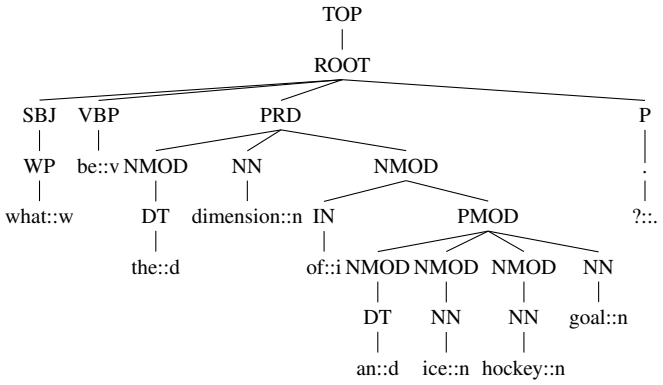

Figure 8: Grammatical Relation Centered Tree of (s2)

4.2 Comparative Structures

To better study the role of the above dependency structures, especially from a performance perspective, we define additional structures: the Lexical Only Centered Tree (LOCT), e.g. see Figure 5, which is an LCT only containing lexical nodes; the Lexical and PoS-Tag Sequences Tree (LPST), e.g. see Figure 6, which ignores the syntactic structure of the sentence being a simple sequence of PoS-Tag nodes, where lexicals are simply added as children; and the Lexical Sequence Tree (LST), where only lexical items are leaves of a single root node. PTK

and PSTK applied to it simulates a standard SK and an SK with smoothing, respectively.

4.3 Structural Features

Section 2 has already described the kind of features generated by SK, STK and PTK. However, it is interesting to analyze what happens when SPTK is applied. For example, given the following sentence syntactically and semantically similar to s1:

(s2) *What is the dimension of an ice hockey goal?*

Figure 8 shows the corresponding GRCT, whose largest PTK fragment shared with the GRTC of s1 (Fig. 3) is: *(ROOT (SBJ (WP (what::w))) (PRD (NMOD (DT (the::d))) (NN) (NMOD (IN (of::i)) (PMOD (NMOD (DT)) (NMOD (NN)) (NN)))) (P (. (?::.))))*. If smoothing is applied the matching is almost total, i.e. also the children: *width::n/dimension::n*, *football::n/hockey::n* and *field::n/goal::n* will be matched (with a smoothing equal to the product of their similarities).

The matching using LCT is very interesting: without smoothing, the largest subtree is: *(be::v (what::w (SBJ) (WP)) (ROOT))*; when smoothing is used only the fragment *(NMOD (NN (ice::n))* will not be part of the match. This suggests that LCT will probably receive the major benefit from smoothing. Additionally, with respect to all the above structures, LCT is the only one that can produce only lexical fragments, i.e. paths only composed by similar lexical nodes constrained by syntactic dependencies. All the other trees produce fragments in which lexicals play the role of features of GR or PoS-Tag nodes.

5 Experiments

The aim of the experiments is to analyze different levels of representation, i.e. structure, for syntactic dependency parses. At the same time, we compare with the constituency trees and different kernels to derive the best syntactic paradigm for convolution kernels. Most importantly, the role of lexical similarity embedded in syntactic structures will be investigated. For this purpose, we first carry out extensive experiments on coarse and fine grained QC and then we verify our findings on a completely different task, i.e. Argument Classification in SRL.

5.1 General experimental setup

Tools: for SVM learning, we extended the SVM-LightTK software[3] (Moschitti, 2006a) (which includes structural kernels in SVMLight (Joachims, 2000)) with the smooth match between tree nodes. For generating constituency trees, we used the Charniak parser (Charniak, 2000) whereas we applied LTH syntactic parser (described in (Johansson and Nugues, 2008a)) to generate dependency trees.

Lexical Similarity: we used the Eq. 1 with $\omega_1 = \omega_2 = 1$ and σ is derived with both approaches described in Sec. 2.3. The first approach is LSA-based: LSA was applied to ukWak (Baroni et al., 2009), which is a large scale document collection made by 2 billion tokens. More specifically, to build the matrix M, POS tagging is first applied to build rows with pairs $\langle$lemma, ::POS$\rangle$, or lemma::POS in brief. The contexts of such items are the columns of M and are short windows of size $[-3, +3]$, centered on the items. This allows for better capturing syntactic properties of words. The most frequent 20,000 items are selected along with their 20k contexts. The entries of M are the point-wise mutual information between them. The SVD reduction is then applied to M, with a dimensionality cut of $l = 250$. The second approach uses the similarity based on word list (WL) as provided in (Li and Roth, 2002).

Models: SVM-LightTK is applied to the different tree representations discussed in Section 4. Since PTK and SPTK are typically used in our experiments, to have a more compact acronym for each model, we associate the latter with the name of the structure, i.e. this indicates that PTK is applied to it. Then the presence of the subscript $_{WL}$ and $_{LSA}$ indicates that SPTK is applied along with the corresponding similarity, e.g. LCT$_{WL}$ is the SPTK kernel applied to LCT structure, using WL similarity. We experiment with multi-classification, which we model through *one-vs-all* scheme by selecting the category associated with the maximum SVM margin. The quality of such classification is measured with accuracy. We determine the statistical significance by using the model described in (Yeh, 2000) and implemented in (Padó, 2006).

The parameterization of each classifier is carried on a held-out set (30% of the training) and concerns with the setting of the trade-off parameter (option -c) and the Leaf Weight (LeW) (see Sec. 5.2), which is used to linearly scale the contribution of the leaf nodes. In contrast, the cost-factor parameter of the SVM-LightTK is set as the ratio between the num-

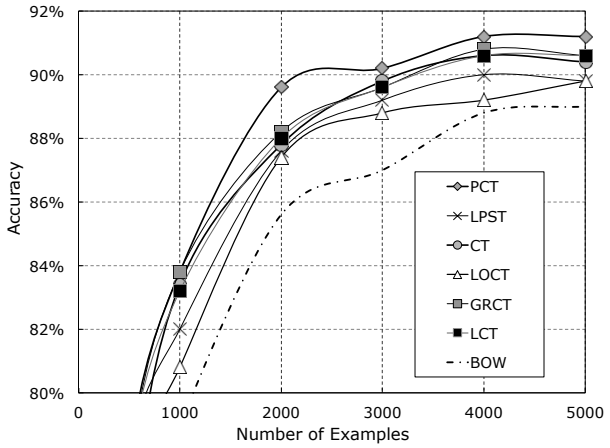

Figure 9: Learning curves: comparison with no similarity

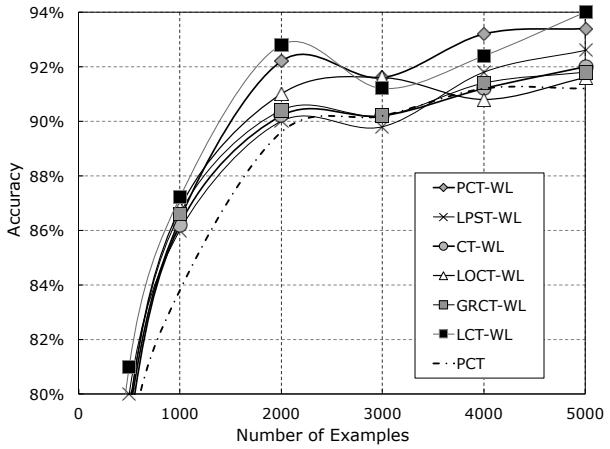

Figure 10: Learning curves: comparison with similarity

ber of negative and positive examples for attempting to have a balanced Precision/Recall.

5.2 QC experiments

For these experiments, we used the UIUC dataset (Li and Roth, 2002). It is composed by a training set of 5,452 questions and a test set of 500 questions[4]. Question classes are organized in two levels: 6 coarse-grained classes (like `ENTITY` or `HUMAN`) and 50 fine-grained sub-classes (e.g. `Plant`, `Food` as subclasses of `ENTITY`).

The outcome of the several kernels applied to several structures for the coarse and fine grained QC is reported in Table 1. The first column shows the experimented models, obtained by applying PTK/SPTK to the structures described in Sec. 4. The last two rows are: CT-STK, i.e. STK applied to a constituency tree and BOW, which is a linear kernel applied to lexical vectors. Column 2, 3 and 4 report the accuracy using no, LSA and WL similarity, where LeW is the amplifying parameter, i.e. a weight associated with the leaves in the tree. The last three columns refer to the fine grained task.

It is worth nothing that when no similarity is applied: (i) BOW produces high accuracy, i.e. 88.8% but it is improved by STK (the current state-of-the-art[5] in QC (Zhang and Lee, 2003; Moschitti et al., 2007)); (ii) PTK applied to the same tree of STK produces a slightly lower value (non-statistically significant difference); (iii) interestingly, when PTK is instead applied to dependency structures, it improves STK, i.e. 91.60% vs 91.40% (although not significantly); and (iv) LCT, strongly based on lexical nodes, is the least accurate, i.e 90.80% since it is obviously subject to data sparseness (fragments only composed by lexicals are very sparse).

The very important results can be noted when lexical similarity is used, i.e. SPTK is applied: (a) all the syntactic-base structures using both LSA or WL improve the classification accuracy. (b) CT gets the lowest improvement whereas LCT achieves an impressive result of 94.80%, i.e more than 41% of relative error reduction. It seems that the lexical similar paths when driven by syntax produces accurate features. Indeed, when syntax is missing such as for the unstructured lexical path of LST_{LSA}, the accuracy does not highly improve or may also decrease. Additionally, the result of our best model is so high that its errors only refer to questions like *What did Jesse Jackson organize ?*, where the classifier selected *Entity* instead of $Human$ category. These refer to clear cases where a huge amount of background knowledge is needed for deriving the exact solution.

Finally, on the fine grained experiments LCT still produces the most accurate outcome again exceeding the state-of-the-art (Zhang and Lee, 2003), where WL significantly improves on all models (CT included).

5.3 Learning curves

It is interesting to study the impact of syntactic/semantic kernels on the learning generalization. For this purpose, Fig. 9 reports the learning curve

[4] http://cogcomp.cs.illinois.edu/Data/QA/QC/

[5] Note that in (Bloehdorn and Moschitti, 2007b), higher accuracy values for smoothed STK are shown for different parameters but the best according to a validation set is not highlighted.

	COARSE						FINE					
	NO		LSA		WL		NO		LSA		WL

CT-STK	-	91.20%	-	-	-	-	-	82.20%	-	-	-	-
BOW	-	88.80%	-	-	-	-	-	83.20%	-	-	-	-

Table 1: Accuracy of structural several kernels on different structures for coarse and fine grained QC

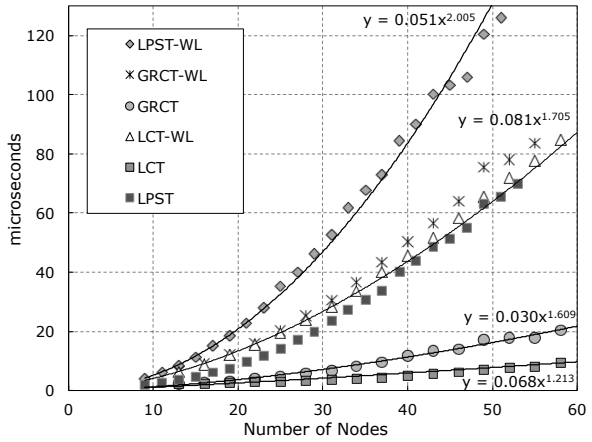

Figure 11: Micro-seconds for each kernel computation

of the previous models without lexical similarity whereas Fig. 10 shows the complete SPTK behavior through the different structures. We note that when no similarity is used the dependency trees better generalize than constituency trees or non-syntactic structures like LPST or BOW. When WL is activated, all models outperform the best kernel of the previous pool, i.e. PCT (see dashed line of Fig. 10 or the top curve in Fig. 9).

5.4 Kernel Efficiency

We plotted the average running time of each computation of PTK/SPTK applied to the different structures. We divided the examples from QC based on the number of nodes in each example. Figure 11 shows the elapsed time in function of the number of nodes for different tree representations. We note that: (i) when the WL is not active, LCT and GRCT are very fast as they impose hierarchical matching of subtrees; (ii) when the similarity is activated, LCT$_{WL}$ and GRCT$_{WL}$ tend to match many more tree fragments thus their complexity increases. However, the equations of the curve fit, shown in the figure, suggests that the trend is sub-quadratic ($x^{1.7}$). Only LPST$_{WL}$, which has no structure, matches a very large number of sequences of nodes, when the similarity is active. This increases the complexity, which results in an order higher than 2.

5.5 FrameNet Role Classification Experiments

To verify that our findings are general and that our syntactic/semantic dependency kernels can be effectively exploited for diverse NLP tasks, we experimented with a completely different application, i.e. FrameNet SRL classification (gold standard boundaries). We used the FrameNet version 1.3 with the 90/10% split between training and test set (i.e 271,560 and 30,173 examples respectively), as defined in (Johansson and Nugues, 2008b), one of the best system for FrameNet parsing. We used the LTH dependency parser. LSA was applied to the BNC corpus, the source of the FrameNet annotations.

For each of 648 frames, we applied SVM along with the best models for QC, i.e. GRCT and LCT, to learn its associated binary role classifiers (RC) for a total of 4,254 classifiers. For example, Figure 12 shows the LCT representation of the first two roles of the following sentence:

$[Bootleggers]_{\text{CREATOR}}, then$ **copy** $[the\ film]_{\text{ORIGINAL}}$ $[onto\ hundreds\ of\ VHS\ tapes]_{\text{GOAL}}$

Table 2 shows the results of the different multi-classifiers. GRCT and LCT show a large accuracy, i.e. 87.60. This improves up to 88.74 by activating the LSA similarity. The combination GRCT$_{LSA}$+LCT$_{LSA}$ significantly improves the above model, achieving 88.91%. This is very close to the state-of-the-art of SRL for classification (using a single classifier, i.e. no joint model), i.e. 89.6%, achieved in (Johansson and Nugues, 2008b).

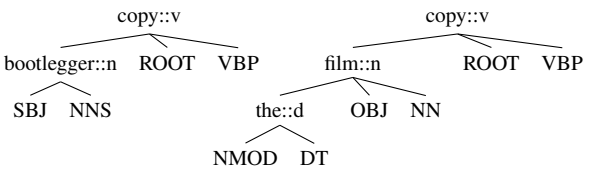

Figure 12: LCT Examples for argument roles

Kernel	Accuracy
GRCT	87.60%
$GRCT_{LSA}$	88,61%
LCT	87.61%
LCT_{LSA}	88.74%
GRCT + LCT	87.99%
$GRCT_{LSA}$ + LCT_{LSA}	**88.91%**

Table 2: Argument Classification Accuracy

Finally, it should be noted that, to learn and test the SELF_MOTION multi-classifier, containing 14,584 examples, distributed on 22 roles, SVM-SPTK employed 1.5 h and 10 minutes, respectively[6].

6 Final Remarks and Conclusion

In this paper, we have proposed a study on representation of dependency structures for the design of effective structural kernels. Most importantly, we have defined a new class of kernel functions, i.e. SPTKs, that carry out syntactic and lexical similarities on the above structures. SPTK exploits the latter by providing generalization trough lexical similarities constrained in them. This allows for automatically generating feature spaces of generalized syntactic/semantic dependency substructures.

To test our models, we carried out experiments on QC and SRL. These show that by exploiting the similarity between two sets of words carried out according to their dependency structure leads to an unprecedented result for QC, i.e. 94.8% of accuracy. In contrast, when no structure is used the accuracy does not significantly improves. We have also provided a fast algorithm for the computation of SPTK and empirically shown that it can easily scale.

It should be noted that our models are not absolutely restricted to QC and SRL. Indeed, since most of the NLP applications are based on syntactic and lexical representations, SPTK will have a major impact in most of them, e.g.:

- Question Answering, the high results for QC will positively impact on the overall task.
- SRL, SPTK alone reaches the state-of-the-art (SOA) (only 0.7% less) in FrameNet role classification. This is very valuable as previous work showed that tree kernels (TK) alone perform lower than models based on manually engineered features for SRL tasks, e.g., (Moschitti, 2004; Giuglea and Moschitti, 2004; Giuglea and Moschitti, 2006; Moschitti, 2006b; Che et al., 2006; Moschitti et al., 2008). Thus for the first time in an SRL task, a general tree kernel reaches the same accuracy of heavy manual feature design. This also suggests an improvement when used in combinations with manual feature vectors.
- Relation Extraction and Pronominal Coreference, whose state-of-the-art for some tasks is achieved with the simple STK-CT (see (Zhang et al., 2006) and (Yang et al., 2006; Versley et al., 2008), respectively).
- In word sense disambiguation tasks, SPTK can generalize context according to syntactic and semantic constraints (selectional restrictions) making very effective distributional semantic approaches.
- In Opinion Mining SPTK will allow to match sentiment words within their corresponding syntactic counterparts and improve the state-of-the-art (Johansson and Moschitti, 2010b; Johansson and Moschitti, 2010a).
- Experiments on Recognizing Textual Entailment (RTE) tasks, the use of SSTK (instead of STK-CT) improved the state-of-the-art (Mehdad et al., 2010). SPTK may provide further enhancement and innovative and effective dependency models.

The above points also suggest many promising future research directions, which we would like to explore.

Abstract

This paper investigates novel methods for incorporating syntactic information in probabilistic latent variable models of lexical choice and contextual similarity. The resulting models capture the effects of context on the interpretation of a word and in particular its effect on the appropriateness of replacing that word with a potentially related one. Evaluating our techniques on two datasets, we report performance above the prior state of the art for estimating sentence similarity and ranking lexical substitutes.

1 Introduction

Distributional models of lexical semantics, which assume that aspects of a word's meaning can be related to the contexts in which that word is typically used, have a long history in Natural Language Processing (Spärck Jones, 1964; Harper, 1965). Such models still constitute one of the most popular approaches to lexical semantics, with many proven applications. Much work in distributional semantics treats words as non-contextualised units; the models that are constructed can answer questions such as "how similar are the words *body* and *corpse*?" but do not capture the way the syntactic context in which a word appears can affect its interpretation. Recent developments (Mitchell and Lapata, 2008; Erk and Padó, 2008; Thater et al., 2010; Grefenstette et al., 2011) have aimed to address compositionality of meaning in terms of distributional semantics, leading to new kinds of questions such as "how similar are the usages of the words *body* and *corpse* in the phrase *the body/corpse deliberated the motion*...?" and "how similar are the phrases *the body deliberated the motion* and *the corpse rotted*?". In this paper we focus on answering questions of the former type and investigate models that describe the effect of syntactic context on the meaning of a single word.

The work described in this paper uses probabilistic latent variable models to describe patterns of syntactic interaction, building on the selectional preference models of Ó Séaghdha (2010) and Ritter et al. (2010) and the lexical substitution models of Dinu and Lapata (2010). We propose novel methods for incorporating information about syntactic context in models of lexical choice, yielding a probabilistic analogue to dependency-based models of contextual similarity. Our models attain state-of-the-art performance on two evaluation datasets: a set of sentence similarity judgements collected by Mitchell and Lapata (2008) and the dataset of the English Lexical Substitution Task (McCarthy and Navigli, 2009). In view of the well-established effectiveness of dependency-based distributional semantics and of probabilistic frameworks for semantic inference, we expect that our approach will prove to be of value in a wide range of application settings.

2 Related work

The literature on distributional semantics is vast; in this section we focus on outlining the research that is most directly related to capturing effects of context and compositionality.[1] Mitchell and Lapata (2008)

[1] The interested reader is referred to Padó and Lapata (2007) and Turney and Pantel (2010) for a general overview.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1047–1057,
Edinburgh, Scotland, UK, July 27–31, 2011.

follow Kintsch (2001) in observing that most distributional approaches to meaning at the phrase or sentence level assume that the contribution of syntactic structure can be ignored and the meaning of a phrase is simply the commutative sum of the meanings of its constituent words. As Mitchell and Lapata argue, this assumption clearly leads to an impoverished model of semantics. Mitchell and Lapata investigate a number of simple methods for combining distributional word vectors, concluding that pointwise multiplication best corresponds to the effects of syntactic interaction.

Erk and Padó (2008) introduce the concept of a *structured vector space* in which each word is associated with a set of selectional preference vectors corresponding to different syntactic dependencies. Thater et al. (2010) develop this geometric approach further using a space of *second-order* distributional vectors that represent the words typically co-occurring with the contexts in which a word typically appears. The primary concern of these authors is to model the effect of context on word meaning; the work we present in this paper uses similar intuitions in a probabilistic modelling framework.

A parallel strand of research seeks to represent the meaning of larger compositional structures using matrix and tensor algebra (Smolensky, 1990; Rudolph and Giesbrecht, 2010; Baroni and Zamparelli, 2010; Grefenstette et al., 2011). This nascent approach holds the promise of providing a much richer notion of context than is currently exploited in semantic applications.

Probabilistic latent variable frameworks for generalising about contextual behaviour (in the form of verb-noun selectional preferences) were proposed by Pereira et al. (1993) and Rooth et al. (1999). Latent variable models are also conceptually similar to non-probabilistic dimensionality reduction techniques such as Latent Semantic Analysis (Landauer and Dumais, 1997). More recently, Ó Séaghdha (2010) and Ritter et al. (2010) reformulated Rooth et al.'s approach in a Bayesian framework using models related to Latent Dirichlet Allocation (Blei et al., 2003), demonstrating that this "topic modelling" architecture is a very good fit for capturing selectional preferences. Reisinger and Mooney (2010) investigate nonparametric Bayesian models for teasing apart the context distributions of polysemous words. As described in Section 3 below, Dinu and Lapata (2010) propose an LDA-based model for lexical substitution; the techniques presented in this paper can be viewed as a generalisation of theirs. Topic models have also been applied to other classes of semantic task, for example word sense disambiguation (Li et al., 2010), word sense induction (Brody and Lapata, 2009) and modelling human judgements of semantic association (Griffiths et al., 2007).

3 Models

3.1 Latent variable context models

In this paper we consider generative models of lexical choice that assign a probability to a particular word appearing in a given linguistic context. In particular, we follow recent work (Dinu and Lapata, 2010; Ó Séaghdha, 2010; Ritter et al., 2010) in assuming a latent variable model that associates contexts with distributions over a shared set of variables and associates each variable with a distribution over the vocabulary of word types:

$$P(w|c) = \sum_{z \in Z} P(w|z)P(z|c) \tag{1}$$

The set of latent variables Z is typically much smaller than the vocabulary size; this induces a (soft) clustering of the vocabulary. Latent Dirichlet Allocation (Blei et al., 2003) is a powerful method for learning such models from a text corpus in an unsupervised way; LDA was originally applied to document modelling, but it has recently been shown to be very effective at inducing models for a variety of semantic tasks (see Section 2).

Given the latent variable framework in (1) we can develop a generative model of paraphrasing a word o with another word n in a particular context c:

$$P_{C \to T}(n|o,c) = \sum_{z} P(n|z)P(z|o,c) \tag{2}$$

$$P(z|o,c) = \frac{P(o|z)P(z|c)}{\sum_{z'} P(o|z')P(z'|c)} \tag{3}$$

In words, the probability $P(n|o,c)$ is the probability that n would be generated given the latent variable distribution associated with seeing o in context c; this latter distribution $P(z|o,c)$ can be derived using Bayes' rule and the assumption $P(o|z,c) = P(o|z)$.

Given a set of contexts C in which an instance o appears (e.g., it may be both the subject of a verb and modified by an adjective), (2) and (3) become:

$$P_{C\to T}(n|o,C) = \sum_z P(n|z)P(z|o,C) \quad (4)$$

$$P(z|o,C) = \frac{P(o|z)P(z|C)}{\sum_{z'} P(o|z')P(z'|C)} \quad (5)$$

$$P(z|C) = \frac{\prod_{c\in C} P(z|c)}{\sum_{z'} \prod_{c\in C} P(z'|c)} \quad (6)$$

Equation (6) can be viewed as defining a "product of experts" model (Hinton, 2002). Dinu and Lapata (2010) also use a similar formulation to (5), except that $P(z|o,C)$ is factorised over $P(z|o,C)$ rather than just $P(z|C)$:

$$P_{DL10}(z|o,C) = \prod_{c\in C} \frac{P(o|z)P(z|c)}{\sum_{z'} P(o|z')P(z'|c)} \quad (7)$$

In Section 5 below, we find that using (5) rather than (7) gives better results.

The model described above (henceforth $C \to T$) models the dependence of a target word on its context. An alternative perspective is to model the dependence of a set of contexts on a target word, i.e., we induce a model

$$P(c|w) = \sum_z P(c|z)P(z|w) \quad (8)$$

Making certain assumptions, a formula for $P(n|o,c)$ can be derived from (8):

$$P_{T\to C}(n|o,c) = \frac{P(c|o,n)P(n|o)}{P(c|o)} \quad (9)$$

$$P(c|o,n) = \sum_z P(c|z)P(z|o,n)$$

$$P(z|o,n) = \frac{P(z|o)P(z|n)}{\sum_{z'} P(z'|o)P(z'|n)} \quad (10)$$

$$P(c|o) = \sum_z P(c|z)P(z|o) \quad (11)$$

$$P(n|o) = 1/V \quad (12)$$

The assumption of a uniform prior $P(n|o)$ on the choice of a paraphrase n for o is clearly not appropriate from a language modelling perspective (one could imagine an alternative $P(n)$ based on corpus frequency), but in the context of measuring semantic similarity it serves well. The $T \to C$ model for a set of contexts C is:

$$P_{T\to C}(n|o,C) = \frac{P(C|o,n)P(n|o)}{P(C|o)} \quad (13)$$

$$P(C|o,n) = \sum_z P(z|o,n) \prod_{c\in C} P(c|z) \quad (14)$$

$$P(C|o) = \sum_z P(z|o) \prod_{c\in C} P(c|z) \quad (15)$$

$$P(z|o,C) = \frac{P(z|o)P(C|o)}{\sum_{z'} P(z'|o)P(C|o)} \quad (16)$$

With appropriate priors chosen for the distributions over words and latent variables, $P(n|o,C)$ is a fully generative model of lexical substitution. A non-generative alternative is one that estimates the similarity of the latent variable distributions associated with seeing n and o in context C. The principle that similarity between topic distributions corresponds to semantic similarity is well-known in document modelling and was proposed in the context of lexical substitution by Dinu and Lapata (2010). In terms of the equations presented above, we could compare the distributions $P(\mathbf{z}|o,C)$ with $P(\mathbf{z}|n,C)$ using equations (5) or (16). However, Thater et al. (2010) and Dinu and Lapata (2010) both observe that contextualising both o and n can degrade performance; in view of this we actually compare $P(\mathbf{z}|o,C)$ with $P(\mathbf{z}|n)$ and make the further simplifying assumption that $P(z|n) \propto P(n|z)$. The similarity measure we adopt is the Bhattacharyya coefficient, which is a natural measure of similarity between probability distributions and is closely related to the Hellinger distance used in previous work on topic modelling (Blei and Lafferty, 2007):

$$sim_{bhatt}(P_x(\mathbf{z}), P_y(\mathbf{z})) = \sum_z \sqrt{P_x(z)P_y(z)} \quad (17)$$

This measure takes values between 0 and 1.

In this paper we train LDA models of $P(w|c)$ and $P(c|w)$. In the former case, the analogy to document modelling is that each context type plays the role of a "document" consisting of all the words observed in that context in a corpus; for $P(c|w)$ the roles are reversed. The models are trained by Gibbs sampling using the efficient procedure of Yao et al. (2009). The empirical estimates for distributions over words and latent variables are derived from the assignment

of topics over the training corpus in a single sampling state. For example, to model $P(w|c)$ we calculate:

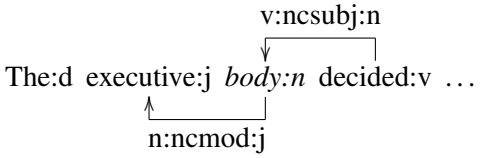
$$P(w|z) = \frac{f_{zw} + \beta}{f_{z\cdot} + N\beta} \quad (18)$$

$$P(z|c) = \frac{f_{zc} + \alpha_z}{f_{\cdot c} + \sum_{z'} \alpha_{z'}} \quad (19)$$

where f_{zw} is the number of words of type w assigned topic z, f_{zc} is the number of times z is associated with context c, $f_{z\cdot}$ and $f_{\cdot c}$ are the marginal topic and context counts respectively, N is the number of word types and α and β parameterise the Dirichlet prior distributions over $P(z|c)$ and $P(w|z)$. Following the recommendations of Wallach et al. (2009) we use asymmetric α and symmetric β; rather than using fixed values for these hyperparameters we estimate them from data in the course of LDA training using an EM-like method.[2] We use standard settings for the number of training iterations (1000), the length of the burnin period before hyperparameter estimation begins (200 iterations) and the frequency of hyperparameter estimation (50 iterations).

3.2 Context types

We have not yet defined what the contexts c look like. In vector space models of semantics it is common to distinguish between window-based and dependency-based models (Padó and Lapata, 2007); one can make the same distinction for probabilistic context models. A broad generalisation is that window-based models capture semantic association (e.g. *referee* is associated with *football*), while dependency models capture a finer-grained notion of similarity (*referee* is similar to *umpire* but not to *football*). Dinu and Lapata (2010) propose a window-based model of lexical substitution; the set of contexts in which a word appears is the set of surrounding words within a prespecified "window size". In this paper we also investigate dependency-based context sets derived from syntactic structure. Given a sentence such as



the set C of dependency contexts for the noun *body* is $\{$*executive:j:ncmod*$^{-1}$*:n*, *decide:v:ncsubj:n*$\}$, where $ncmod^{-1}$ denotes that *body* stands in an inverse non-clausal modifier relation to *executive* (we assume that nouns are the heads of their adjectival modifiers).

4 Experiment 1: Similarity in context

4.1 Data

Mitchell and Lapata (2008) collected human judgements of semantic similarity for pairs of short sentences, where the sentences in a pair share the same subject but different verbs. For example, *the sales slumped* and *the sales declined* should be judged as very similar while *the shoulders slumped* and *the shoulders declined* should be judged as less similar. The resulting dataset (henceforth ML08) consists of 120 such pairs using 15 verbs, balanced across high and low expected similarity. 60 subjects rated the data using a scale of 1–7; Mitchell and Lapata calculate average interannotator correlation to be 0.40 (using Spearman's ρ). Both Mitchell and Lapata and Erk and Padó (2008) split the data into a development portion and a test portion, the development portion consisting of the judgements of six annotators; in order to compare our results with previous research we use the same data split. To evaluate performance, the predictions made by a model are compared to the judgements of each annotator in turn (using ρ) and the resulting per-annotator ρ values are averaged.

4.2 Models

All models were trained on the written section of the British National Corpus (around 90 million words), parsed with RASP (Briscoe et al., 2006). The BNC was also used by Mitchell and Lapata (2008) and Erk and Padó (2008); as the ML08 dataset was compiled using words appearing more than 50 times in the BNC, there are no coverage problems caused by data sparsity. We trained LDA models for the grammatical relations *v:ncsubj:n* and *n:ncsubj*$^{-1}$*:v*

[2] We use the estimation methods provided by the MALLET toolkit, available from `http://mallet.cs.umass.edu/`.

	Model	PARA	SIM

	T → C	**0.41**	**0.41**
	T ↔ C	0.37	**0.41**
Erk and Padó (2008)	Mult	0.24	
	SVS	0.27	

Table 1: Performance (average ρ) on the ML08 test set

and used these to create predictors of type $C \rightarrow T$ and $T \rightarrow C$, respectively. For each predictor, we trained five runs with 100 topics for 1000 iterations and averaged the predictions produced from their final states. We investigate both the generative paraphrasing model (PARA) and the method of comparing topic distributions (SIM). For both PARA and SIM we present results using each predictor type on its own as well as a combination of both types ($T \leftrightarrow C$); for PARA the contributions of the types are multiplied and for SIM they are averaged.[3] One potential complication is that the PARA model is trained to predict $P(n|c, o)$, which might not be comparable across different combinations of subject c and verb o. Using $P(n|c, o)$ as a proxy for the desired joint distribution $P(n, c, o)$ is tantamount to assuming a uniform distribution $P(c, o)$, which can be defended on the basis that the choice of subject noun and reference verb is not directly relevant to the task. As shown by the results below, this assumption seems to work reasonably well in practice.

As well as reporting correlations for straightforward averages of each set of five runs, we also investigate whether the development data can be used to select an optimal subset of runs. This is done by simply evaluating every possible subset of 1–5 runs on the development data and picking the best-scoring subset.

4.3 Results

Table 1 presents the results of the PARA and SIM predictors on the ML08 dataset. The best results previously reported for this dataset were given by Erk and Padó (2008), who measured average ρ values of 0.24 for a vector multiplication method and 0.27 for their *structured vector space* (SVS) syntactic disambiguation method. Even without using the development set to select models, performance is well above the previous state of the art for all predictors except $\text{PARA}_{C \rightarrow T}$. Model selection on the development data brings average ρ up to 0.41, which is comparable to the human "ceiling" of 0.40 measured by Mitchell and Lapata. In all cases the $T \rightarrow C$ predictors outperform $C \rightarrow T$: models that associate target words with distributions over context clusters are superior to those that associate contexts with distributions over target words.

Figure 1 plots the beneficial effect of averaging over multiple runs; as the number of runs n is increased, the average performance over all combinations of n predictors chosen from the set of five $T \rightarrow C$ and five $C \rightarrow T$ runs is observed to increase monotonically. Figure 1 also shows that the model selection procedure is very effective at selecting the optimal combination of models; development set performance is a reliable indicator of test set performance.

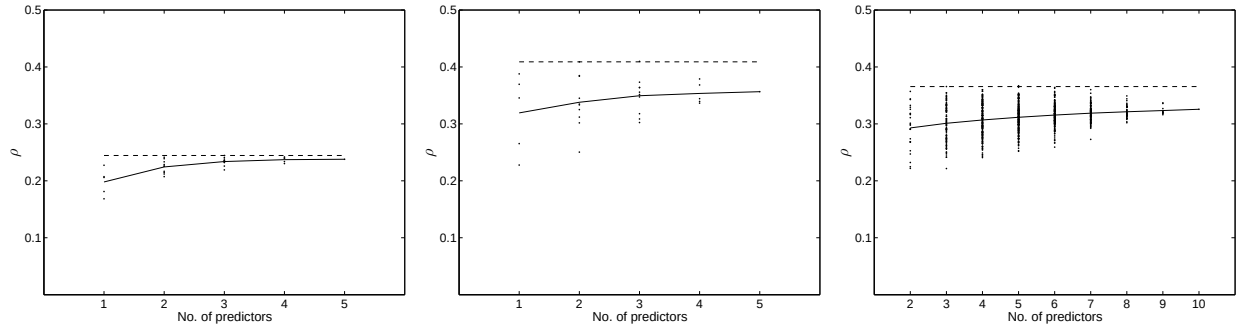
5 Experiment 2: Lexical substitution

5.1 Data

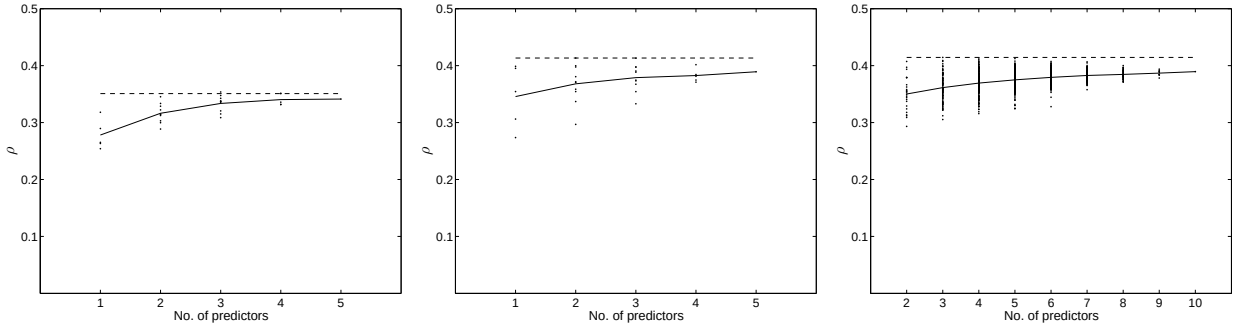
The English Lexical Substitution task, run as part of the SemEval-1 competition, required participants to propose good substitutes for a set of target words in various sentential contexts (McCarthy and Navigli, 2009). Table 2 shows two example sentences and the substitutes appearing in the gold standard, ranked by the number of human annotators who proposed each substitute. The dataset contains a total of 2,010 annotated sentences with 205 distinct target words across four parts of speech (noun, verb, adjective, adverb). In line with previous work on contextual disambiguation, we focus here on the subtask of ranking attested substitutes rather than proposing them from an unrestricted vocabulary. To this end, a candidate set is constructed for each target word from all the substitutes proposed for that word in all sentences in the dataset.

The data contains a number of multiword paraphrases such as *rush at*; as our models (like most

[3] This configuration seems the most intuitive; averaging PARA predictors and multiplying SIM also give good results.



(a) PARA: Target → Context (b) PARA: Context → Target (c) PARA: Target ↔ Context



(d) SIM: Target → Context (e) SIM: Context → Target (f) SIM: Target ↔ Context

Figure 1: Performance on the ML08 test set with different predictor types and different numbers of LDA runs per predictor type; the solid line tracks the average performance, the dashed line shows the performance of the predictor combination that scores best on the development set.

Realizing immediately that strangers have come, the animals *charge* them and the horses began to fight.	attack (5), rush at (1)
Commission is the amount *charged* to execute a trade.	levy (2), impose (1), take (1), demand (1)

Table 2: Examples for the verb *charge* from the English Lexical Substitution Task

current models of distributional semantics) do not represent multiword expressions, we remove such paraphrases and discard the 17 sentences which have only multiword substitutes in the gold standard.[4] There are also 7 sentences for which the gold standard contains no substitutes. This leaves a total of 1986 sentences. These sentences were lemmatised and parsed with RASP.

Previous authors have partitioned the dataset in various ways. Erk and Padó (2008) use only a subset of the data where the target is a noun headed by a verb or a verb heading a noun. Thater et al. (2010) discard sentences which their parser cannot parse and paraphrases absent from their training corpus and then optimise the parameters of their model through four-fold cross-validation. Here we aim for complete coverage on the dataset and do not perform any parameter tuning. We use two measures to evaluate performance: Generalised Averaged Precision (Kishida, 2005) and Kendall's τ_b rank correlation coefficient, which were used for this task by Thater et al. (2010) and Dinu and Lapata (2010), respectively. Generalised Averaged Precision (GAP) is a precision-like measure for evaluating ranked predictions against a gold standard. τ_b is a variant of Kendall's τ that is appropriate for data containing tied ranks. We do not use the "precision out of ten"

[4]Thater et al. (2010) and Dinu and Lapata (2010) similarly remove multiword paraphrases (Georgiana Dinu, p.c.).

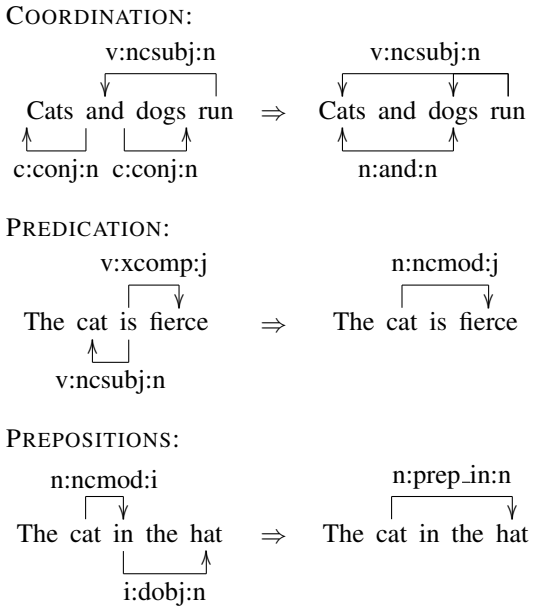


Table 3: Dependency graph preprocessing

measure that was used in the original Lexical Substitution Task; this measure assigns credit for the proportion of the first 10 proposed paraphrases that are present in the gold standard and in the context of ranking attested substitutes it is unclear how to obtain non-trivial results for target words with 10 or fewer possible substitutes. We calculate statistical significance of performance differences using stratified shuffling (Yeh, 2000).[5]

5.2 Models

We apply the models developed in Section 3.1 to the Lexical Substitution Task dataset using dependency- and window-based context information. Here we only use the SIM predictor type. PARA did not give satisfactory results; in particular, it tended to rank common words highly in most contexts.[6]

As before we compiled training data by extracting target-context cooccurrences from a text corpus. In addition to the parsed BNC described above we used a corpus of Wikipedia text consisting of over 45 million sentences (almost 1 billion words) parsed using the fast Combinatory Categorial Grammar (CCG) parser described by Clark et al. (2009). The dependency representation produced by this parser is interoperable with the RASP dependency format. In order to focus our models on semantically discriminative information and make inference more tractable we ignored all parts of speech other than nouns, verbs, adjectives, prepositions and adverbs. Stopwords and words of fewer than three characters were removed. We also removed the very frequent but semantically weak lemmas *be* and *have*.

We compare two classes of context models: models learned from window-based contexts and models learned from syntactic dependency contexts. For the syntactic models we extracted all dependencies and inverse dependencies between lemmas of the aforementioned POS types; in order to maximise the extraction yield, the dependency graph for each sentence was preprocessed using the transformations shown in Table 3. For the window-based context model we follow Dinu and Lapata (2010) in treating each word within five words of a target as a member of its context set.

It proved necessary to subsample the corpora in order to make LDA training tractable, especially for the window-based model where the training set of context-target counts is extremely dense (each instance of a word in the corpus contributes up to 10 context instances). For the window-based data, we divided each context-target count by a factor of 5 and a factor of 70 for the BNC and Wikipedia corpora respectively, rounding fractional counts to the closest integer. The choice of 70 for scaling Wikipedia counts is adopted from Dinu and Lapata (2010), who used the same factor for the comparably sized English Gigaword corpus. As the dependency data is an order of magnitude smaller we downsampled the Wikipedia counts by 5 and left the BNC counts untouched. Finally, we created a larger corpus by combining the counts from the BNC and Wikipedia datasets. Type and token counts for the BNC and combined corpora are given in Table 4.

We trained three LDA predictors for each corpus: a window-based predictor (W5), a Context $\rightarrow$ Target predictor ($C \rightarrow T$) and a Target $\rightarrow$ Context predictor ($T \rightarrow C$). For W5 the sets of types and contexts should be symmetrical (in practice there is some discrepancy due to preprocessing artefacts). For $C \rightarrow T$, individual models were trained for each of the four target parts of speech; in each case the set

[5] We use the software package available at `http://www.nlpado.de/~sebastian/sigf.html`.

[6] Favouring more general words may indeed make sense in some paraphrasing tasks (Nulty and Costello, 2010).

Table 5: Results on the English Lexical Substitution Task dataset; boldface denotes best performance at full coverage for each corpus

of types is the vocabulary for that part of speech and the set of contexts is the set of dependencies taking those types as dependents. For $T \rightarrow C$ we again train four models; the sets of types and contexts are reversed. For the both corpora we trained models with $Z = \{600, 800, 1000, 1200\}$ topics; for each setting of Z we ran five estimation runs. Each individual prediction of similarity between $P(z|C, o)$ and $P(z|n)$ is made by averaging over the predictions of all runs and over all settings of Z. Choosing a single setting of Z does not degrade performance significantly; however, averaging over settings is a convenient way to avoid having to pick a specific value.

We also investigate combinations of predictor types, once again produced by averaging: we combine $C \rightarrow T$ with $C \leftrightarrow T$ ($T \leftrightarrow C$) and combine each of these three models with W5.

5.3 Results

Table 5 presents the results attained by our models on the Lexical Substitution Task data. The dependency-based models have imperfect coverage (86% of the data); they can make no prediction when no syntactic context is provided for a target, perhaps as a result of parsing error. The window-based models have perfect coverage, but score noticeably lower. By combining dependency- and window-based models we can reach high performance with perfect coverage. All combinations outperform the corresponding W5 results to a statistically significant degree ($p < 0.01$). Performance at full coverage is already very good (GAP= 48.6, $\tau_b = 0.21$) on the BNC corpus, but the best results are attained by W5 + $T \leftrightarrow C$ trained on the combined corpus (GAP= 49.5, $\tau_b = 0.23$). The results for the W5 model trained on BNC data is comparable to that trained on the combined corpus; however the syntactic models show a clear benefit from the less sparse dependency data in the combined training corpus.

As remarked in Section 3.1, Dinu and Lapata (2010) use a slightly different formulation of $P(z|C, o)$. Using the window-based context model our formulation (5) outperforms (7) for both training corpora; the Dinu and Lapata (2010) version scores GAP $= 41.5, \tau_b = 0.15$ for the BNC corpus and GAP $= 42.0, \tau_b = 0.15$ for the combined corpus. The advantage of our formulation is statistically significant for all evaluation measures.

	Nouns		Verbs		Adjectives		Adverbs		Overall

Dinu and Lapata (2010) (NMF)	–	0.15	–	0.14	–	0.16	–	**0.26**	–	0.16

Table 6: Performance by part of speech

Table 6 gives a breakdown of performance by target part of speech for the BNC+Wikipedia-trained W5 and W5 + $T \leftrightarrow C$ models, as well as figures provided by previous researchers.[7] W5 + $T \leftrightarrow C$ outperforms W5 on all parts of speech using both evaluation metrics. As remarked above, previous researchers have used the corpus in slightly different ways; we believe that the results of Dinu and Lapata (2010) are fully comparable, while those of Thater et al. (2010) were attained on a slightly smaller dataset with parameters set through cross-validation. The results for W5 + $T \leftrightarrow C$ outperform all of Dinu and Lapata's per-POS and overall results except for a slightly superior score on adverbs attained by their NMF model ($\tau_b = 0.26$ compared to 0.24). Turning to Thater et al., we report higher scores for every POS with the exception of the verbs where their Model 1 achieves 45.9 GAP compared to 45.1; the overall average for W5 + $T \leftrightarrow C$ is substantially higher at 49.5 compared to 44.6. On balance, we suggest that our models do have an advantage over the current state of the art for lexical substitution.

6 Conclusion

In this paper we have proposed novel methods for modelling the effect of context on lexical meaning, demonstrating that information about syntactic context and textual proximity can fruitfully be integrated to produce state-of-the-art models of lexical choice. We have demonstrated the effectiveness of our techniques on two datasets but they are potentially applicable to a range of applications where semantic disambiguation is required. In future work, we intend to adapt our approach for word sense disambiguation as well as related domain-specific tasks such as gene name normalisation (Morgan et al., 2008). A further, more speculative direction for future research is to investigate more richly structured models of context, for example capturing correlations between words in a text within a framework similar to the Correlated Topic Model of Blei and Lafferty (2007) or more explicitly modelling polysemy effects as in Reisinger and Mooney (2010).

[7] The overall average GAP for Thater et al. (2010) does not appear in their paper but can be calculated from the score and number of instances listed for each POS.

Abstract

Lexical co-occurrence is an important cue for detecting word associations. We propose a new measure of word association based on a new notion of statistical significance for lexical co-occurrences. Existing measures typically rely on global unigram frequencies to determine expected co-occurrence counts. Instead, we focus only on documents that contain both terms (of a candidate word-pair) and ask if the distribution of the observed spans of the word-pair resembles that under a random null model. This would imply that the words in the pair are not related strongly enough for one word to influence placement of the other. However, if the words are found to occur closer together than explainable by the null model, then we hypothesize a more direct association between the words. Through extensive empirical evaluation on most of the publicly available benchmark data sets, we show the advantages of our measure over existing co-occurrence measures.

1 Introduction

Lexical co-occurrence is an important indicator of word association and this has motivated several co-occurrence[1] measures for word association like PMI (Church and Hanks, 1989), LLR (Dunning, 1993), Dice (Dice, 1945), and CWCD (Washtell and Markert, 2009). In this paper, we present a new measure of word association based on a new notion of statistical significance for lexical co-occurrences. In general, a lexical co-occurrence could refer to a pair of words that co-occur in a large number of documents; or it could refer to a pair of words that, although co-occur only in a small number of documents, occur close to each other within those documents. We formalize these ideas and construct a significance test that allows us to detect different kinds of co-occurrences within a single unified framework (a feature which is absent in current measures for co-occurrence). Another distinguishing feature of our measure is that it is based solely on the co-occurrence counts in the documents containing both words of the pair, unlike all existing measures which also take global unigram frequencies in account.

We need a null hypothesis that can account for an observed co-occurrence as a pure chance event and this in-turn requires a corpus generation model. Documents in a corpus can be assumed to be generated independent of each other. Existing co-occurrence measures further assume that each document is drawn from a multinomial distribution based on global unigram frequencies. The main concern with such a null model is the overbearing influence of the unigram frequencies on the detection of word associations. For example, the association between *anomochilidae* (dwarf pipe snakes) and *snake* could go undetected in our wikipedia corpus, since less than 0.1% of the pages containing *snake* also contained *anomochilidae*. Also, under current models, the expected *span*[2] of a word pair is very sensitive to the associated unigram frequencies: the expected span of a word pair composed of low frequency unigrams is much larger than that with high frequency unigrams. This is contrary to how word associa-

[1] We use the term co-occurrence to refer to a pair of words that co-occur in a document with an arbitrary number of intervening words.

[2] The *span* of an occurrence of a word-pair is the 'unsigned distance' between the positions of the corresponding word occurrences.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1058–1068,
Edinburgh, Scotland, UK, July 27–31, 2011.

tions appear in language, where semantic relationships manifest with small inter-word distances irrespective of the underlying unigram distributions.

Based on these considerations we employ a null model that represents each document as a bag of words [3]. A random permutation of the associated bag of words gives a linear representation for the document. Under this null model, the locations of an unrelated pair of words will likely be randomly distributed in the documents in which they co-occur. If the observed span distribution of a word-pair resembles that under the (random permutation) null model, then the relation between the words is not strong enough for one word to influence the placement of the other. However, if the words are found to occur closer together than explainable by our null model, then we hypothesize a more direct association between the words. Therefore, this null model detects biases in span distributions of word-pairs while being agnostic to variations in global unigram frequencies.

In this paper, we propose a new measure of word association based on the statistical significance of the observed span distribution of a word-pair. We perform extensive experiments on all the publicly available benchmark data sets[4] and compare our measure against other popular co-occurrence measures. Our experiments demonstrate the advantages of our measure over all the competing measures. The ranked list of word associations output by our measure has the best correlation with the corresponding gold-standard in three (out of seven) data sets in our experiments, while remaining in the top three in other four datasets. While different measures perform best on different data sets, our measure outperforms other measures by being consistently either the best measure or very close to the best measure on all the data sets. The average deviation of our measure's correlation with the gold-standard from the best measure's correlation with the gold-standard (average taken across all the datasets) is 0.02, which is the least average deviation among all the measures, the next best deviations being 0.04 and 0.06.

The paper is organized as follows. We present our notion of statistical significance of span distribution in Section 2. Algorithm for computing the proposed word association measure is described in Section 3. We discuss related work in Section 4. Performance evaluation is presented in Section 5 followed with conclusions in Section 6.

2 Lexically significant co-occurrences

Evidence for significant lexical co-occurrences can be gathered at two levels in the data – document-level and corpus-level. First, at the document level, we may find that for a given word-pair, a surprisingly high proportion of its occurrences *within* a document have smaller spans than they would have by random chance. Second, at the corpus-level, we may find a pair of words appearing closer-than-random in multiple documents in the corpus. We now describe how to combine both kinds of evidence to decide whether the nearby occurrences of a word-pair are statistically significant or not.

Let the *frequency* f of a word-pair α in a document D, be the maximum number of *non-overlapped occurrences* of α in D. A set of occurrences of a word-pair is said to be non-overlapped if the words corresponding to one occurrence from the set do not appear in-between the words corresponding to any other occurrence from the set.

Let $\widehat{f}^x$ denote the maximum number of non-overlapped occurrences of α in D with span less than a given threshold x. We refer to $\widehat{f}^x$ as the *span-constrained frequency* of α in D. Note that $\widehat{f}^x$ cannot exceed f.

2.1 Document-level significant co-occurrence

To assess the statistical significance of the word-pair α we ask if the span-constrained frequency $\widehat{f}^x$ (of α) is more than what we would expect in a document of size ℓ containing f 'random' occurrences of α. Our intuition is that if two words are associated in some way, they will often appear close to each other in the document and so the distribution of the spans will typically exhibit a bias toward values less than a suitably chosen threshold x.

[3] There can be many ways to associate a bag of words with a document. Details of this association are not important for us, except that the bag of words provides some kind of quantitative summary of the words within the document.

[4] We exclude very small data sets of 80 word pairs or less. Sizes of the seven datasets we used range from 351 word-pairs to 83,713 word-pairs.

Definition 1 *Consider the null hypothesis that the linear representation of a document is generated by choosing a random permutation of the bag of words associated with the document. Let ℓ be the length of the document and f denote the frequency of a word-pair in the document. For a given a span threshold x, we define $\pi_x(\widehat{f^x}, f, \ell)$ as the probability under the null that the word-pair will appear in the document with a span-constrained frequency of* at least $\widehat{f^x}$.

Observe that $\pi_x(0, f, \ell) = 1$ for any $x > 0$; also, for $x \geq \ell$ we have $\pi_x(f, f, \ell) = 1$ (i.e. all f occurrences will always have span less than x for $x \geq \ell$). However, for typical values of x (i.e. for $x \ll \ell$) the probability $\pi_x(\widehat{f^x}, f, \ell)$ decreases with increasing $\widehat{f^x}$. For example, consider a document of length 400 with 4 non-overlapped occurrences of α. The probabilities of observing at least 4, 3, 2, 1 and 0 occurrences of α within a span of 20 words are 0.007, 0.09, 0.41, 0.83, and 1.0 respectively. Since $\pi_{20}(3, 4, 400) = 0.09$, even if 3 of the 4 occurrences of α have span less than 20 words, there is 9% chance that the occurrences were a consequence of a random event. As a result, if we desired a confidence-level of at least 95%, we would have to declare observed co-occurrences of α as *insignificant*.

Given an ϵ ($0 < \epsilon < 1$) and a span threshold x (≥ 0) the document D is said to *support* the hypothesis "α is an ϵ-significant word-pair within the document" if we have $[\pi_x(\widehat{f^x}, f, \ell) < \epsilon]$. We refer to ϵ as the *document-level* evidence of the lexical co-occurrence of α.

2.2 Corpus-level significant co-occurrence

We now describe how to aggregate evidence for lexical significance by considering the occurrence of α across multiple documents in the corpus. Let $\{D_1, \ldots, D_K\}$ denote the set of K documents (from out of the entire corpus) that contain at least one occurrence of α. Let ℓ_i be the length of D_i, f_i be the frequency of α in D_i, and, $\widehat{f_i^x}$ be the *span-constrained frequency* of α in D_i. Define indicator variables z_i, $i = 1, \ldots, K$ as:

$$z_i = \begin{cases} 1 & \text{if } \pi_x(\widehat{f_i^x}, f_i, \ell_i) < \epsilon \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

As discussed previously, z_i indicates whether "α is an ϵ-significant word-pair within the document D_i." Note that we view $\widehat{f_i^x}$ as the only random quantity here, with x fixed by the user, and ℓ_i and f_i fixed given the document D_i and word-pair α. Let $Z = \sum_{i=1}^{K} z_i$; Z models the number of documents (out of K) that support the hypothesis "α is an ϵ-significant word-pair." The expected value of Z is given by

$$\begin{aligned} E(Z) &= \sum_{i=1}^{K} E(z_i) \\ &= \sum_{i=1}^{K} \pi_x(g_{\epsilon,x}(f_i, \ell_i), f_i, \ell_i) \quad (2) \end{aligned}$$

where $g_{\epsilon,x}(f_i, \ell_i)$ is given by *Definition 2* below.

Definition 2 *Given a document of length ℓ in which a word-pair has a frequency of f, and given a span threshold x, we define $g_{\epsilon,x}(f, \ell)$ as the smallest r for which the inequality $[\pi_x(r, f, \ell) < \epsilon]$ holds.*

Note that $g_{\epsilon,x}(f, \ell)$ is well-defined since $\pi_x(r, f, \ell)$ is non-increasing with respect to r. For the example given earlier, $g_{0.2,20}(4, 400) = 3$ and $g_{0.05,20}(4, 400) = 4$. Since each document in the corpus is assumed to be generated independently, z_i's are independent random variables and we can bound the deviation of the observed value of Z from its expectation using Hoeffding's Inequality – for any $t > 0$, we have

$$\begin{aligned} P[Z \geq E(Z) + Kt] &\leq \exp(-2Kt^2) \\ &= \delta \quad (3) \end{aligned}$$

Recall that Z models the number of documents supporting the hypothesis "α is an ϵ-significant word-pair."). Thus, the upper-bound δ ($= \exp(-2Kt^2)$), $0 < \delta < 1$ denotes the upper-bound on the probability that just due to random chance, more than $(E(Z) + Kt)$ documents out of K will support the hypothesis "α is an ϵ-significant word-pair." We call δ the *corpus-level* evidence of the lexical co-occurrence α. For example, in our corpus, the word-pair (*canyon, landscape*) occurs in $K = 416$ documents. For $\epsilon = 0.1$, we have ϵ-significant occurrences in $Z = 33$ documents (out of 416) , while $E(Z) = 14.34$. Suppose we want to be 99% sure that the occurrences of (*canyon, landscape*) in the 33 documents were a consequence of non-random phenomena. Let $\delta = 1 - 0.99 = 0.01$. By setting

word-1	*word-2*		
	$(0.1, 0.1)$	$(0.1, 0.4)$	$(0.4, 0.1)$
algae	green	mold	pool
amuse	entertain	clown	amaze
damn	hell	mad	bad
rat	dirty	ugly	disease
sedative	drug	narcotic	calm
topping	chocolate	flavour	caramel
umbrella	rain	dry	shade
unknown	known	dark	secret
worm	insect	dirt	fishing
wrap	cover	seal	bandage

Table 1: Examples of word-pairs from *Florida* dataset having statistically significant co-occurrences in the wikipedia corpus for different (ϵ, δ) combinations under a span constraint of 20 words.

$t = \sqrt{\ln \delta/(-2K)} = 0.07$, we get $E(Z) + Kt = 43.46$. Only if Z was 44 or more, there would be less than 1% chance of that being a random phenomena. Thus, we cannot be 99% sure that the observed co-occurrences in the 33 documents are non-random. Hence, our test declares (*canyon, landscape*) as *insignificant* at $\epsilon = 0.1, \delta = 0.01$. We now summarize our significance test in the definition below.

Definition 3 (Significant lexical co-occurrence) *Consider a word-pair α and a set of K documents containing at least one occurrence each of α. Fix a span threshold of x (> 0), a document-level evidence of ϵ ($0 < \epsilon < 1$) and a corpus-level evidence of δ ($0 < \delta < 1$). Let Z denote the number of documents (out of K) that support the hypothesis "α is ϵ-significant within the document." The word-pair α is said to be (ϵ, δ)-significant if we have $[Z \geq E(Z) + Kt]$, where $t = \sqrt{\log \delta/(-2K)}$ and $E(Z)$ is given by Eq. (2). The ratio $[Z/(E(Z) + Kt)]$ is called the* Co-occurrence Significance Ratio (CSR) *for α.*

2.3 Discussion

The significance test of *Definition 3* gathers both document-level and corpus-level evidence from data in calibrated amounts. Prescribing ϵ fixes the strength of the document-level hypothesis in our test, while, δ, controls the extent of corpus-level evidence we need to declare a word-pair as significant. A small δ demands that there must be multiple documents in the corpus, each of which, individually have some evidence of relatedness for the pair of words.

By running the significance test with different values of ϵ and δ, the CSR test can be used to detect different types of lexically significant co-occurrences. For example, the strongest lexical co-occurrences would have both strong document-level evidence (low ϵ) as well as high corpus-level evidence (low δ). Informally, these would represent pairs of words that appear multiple times with small spans within a document, in many documents, and in-practice, we find that multi-word expressions or pairs of words separated by stop words tend to dominate this type. On the other hand, a higher ϵ would represent word-pairs that appear relatively farther apart within a document, or a higher δ would represent word-pairs that appear together in relatively fewer documents. Note that to detect co-occurrences that exclusively correspond to (say) low ϵ and high δ, we would have to run the test with low ϵ and high δ, and then remove word-pairs that were also found significant at low ϵ and low δ.

In Table 1, we present some examples of different types of co-occurrences. The table lists word-pairs that were found to be statistically significant for different choices of (ϵ, δ). Note that a word-pair is reported under $(\epsilon = 0.1, \delta = 0.4)$ or $(\epsilon = 0.4, \delta = 0.1)$ only if it was not also found significant under other two parameter settings. The strongest correlations are the word-pairs corresponding to $(\epsilon = 0.1, \delta = 0.1)$ e.g., *algae-green*, *rat-dirty* and *worm-insect*. Different sets of weaker co-occurrences are detected depending on whether we relaxed δ or ϵ. For example, *algae-mold* is significant at a higher δ, while *algae-pool* is significant for higher ϵ.

The semantic notion of word association is an abstract concept and different kinds of associations (with potentially different statistical characterizations) may be preferred by human judges in different situations. While in Section 5, we discuss in detail various datasets used, the evaluation methodology, and the performance of CSR across datasets, we wish to point out here that in 3 out of 5 cross-validation runs for *wordsim* dataset, the best performing CSR parameters were $x = 50w$, $\epsilon = 0.1$ and $\delta = 0.9$, while in 3 out of 5 runs for *Minnesota* dataset, the best performing CSR parameters were $x = 20w$, $\epsilon = 0.3$ and $\delta = 0.5$. This gives us some indication that different kinds of word associations were preferred in different data sets.

3 Computing Co-occurrence Significance Ratio(CSR)

There are three main steps for computing CSR and the pseudocodes for these are listed in Procedures 1, 2 & 3. Of these, the first two can be run offline since they do not depend on the text corpus. They need to be run only once, after which CSR can be computed for any word-pair on any given corpus of documents. We describe these steps in the subsections below.

3.1 Computing histogram $hist_{f,\ell,x}(\cdot)$

The first step is to compute a histogram for the span-constrained frequency, $\widehat{f^x}$, of a word-pair whose frequency is f in a document of length ℓ, given a chosen span threshold of x (under our null model).

Definition 4 *Given a document of length ℓ and a span threshold of x, we define $hist_{f,\ell,x}(\widehat{f^x})$ as the number of ways to embed f non-overlapped occurrences of a word-pair in the document such that exactly $\widehat{f^x}$ occurrences have span less than x.*

Procedure 1 $ComputeHist(f, \ell, x)$ – Offline

Input f - number of non-overlapped occurrences; ℓ - document length; x - span threshold
Computes $hist_{f,\ell,x}[\cdot]$ as per *Definition 4*

```
1:  Initialize hist_{f,ℓ,x}[f̂^x] ← 0 for f̂^x = 0, ..., f
2:  if f > ℓ then
3:      return
4:  if f = 0 then
5:      hist_{f,ℓ,x}[0] ← 1
6:      return
7:  for i ← 1 to (ℓ − 1) do
8:      for j ← (i + 1) to ℓ do
9:          hist_{f−1,ℓ−j,x} ← ComputeHist(f − 1, ℓ − j, x)
10:         for k ← 0 to f − 1 do
11:             if (j − i) < x then
12:                 hist_{f,ℓ,x}[k + 1] ← hist_{f,ℓ,x}[k + 1]
                                          + hist_{f−1,ℓ−j,x}[k]
13:             else
14:                 hist_{f,ℓ,x}[k] ← hist_{f,ℓ,x}[k] + hist_{f−1,ℓ−j,x}[k]
```

Procedure 1 lists the pseudocode for computing the histogram $hist_{f,\ell,x}$. The main steps involve selecting a start and end position for embedding the very first occurrence (lines 7-8) and then recursively calling $ComputeHist(\cdot,\cdot,\cdot)$ (line 9). The i-loop selects a start position for the first occurrence of the word-pair, and the j-loop selects the end position. The recursion step now computes the number of ways to embed the remaining $(f-1)$ non-overlapped occurrences in the remaining $(\ell - j)$ positions. Once we have $hist_{f-1,\ell-j}$, we check whether the occurrence introduced at positions (i, j) will contribute to the $\widehat{f^x}$ count. If $(j - i) < x$, whenever there are k span-constrained occurrences in positions $(j + 1)$ to ℓ, there will be $(k + 1)$ span-constrained occurrences in positions 1 to ℓ. Thus, we increment $hist_{f,\ell}[k + 1]$ by the quantity $hist_{f-1,\ell-j}[k]$ (lines 10-12). However, if $(j - i) > x$, there is no contribution to the span-constrained frequency from the (i, j) occurrence, and so we increment $hist_{f,\ell}[k]$ by the quantity $hist_{f-1,\ell-j}[k]$ (lines 10-11, 13-14). Finally, we note that in our implementation we use memorization to avoid redundant recursive calls.

3.2 Computing $\pi_x(\cdot, f, \ell)$ distribution

Procedure 2 $ComputePiDist(f, \ell, x)$ – Offline

Input f - number of non-overlapped occurrences; ℓ - document length; x - span threshold
Computes Distribution $\pi_x[f, \ell, \cdot]$ as per *Definition 1* and $g_{\epsilon,x}[f, \ell]$ as per *Definition 2*

```
1: N[f, ℓ, x] = Σ_{k=0}^{f} hist_{f,ℓ,x}[k]
2: for f̂^x ← 0 to f do
3:     N_x[f̂^x, f, ℓ] ← Σ_{k=f̂^x}^{f} hist_{f,ℓ,x}[k]
4:     π_x[f̂^x, f, ℓ] ← N_x[f̂^x, f, ℓ] / N[f, ℓ, x]
5: g_{ϵ,x}[f, ℓ] ← min{r | π_x[r, f, ℓ] < ϵ}
```

The second offline step is computation of the $\pi_x(\cdot, f, \ell)$ distribution. We store the number of ways of embedding f non-overlapped occurrences of a word-pair in a document of length ℓ in the array $N[f, \ell]$. Similarly, the array $N_x[\widehat{f^x}, f, \ell]$ stores the number of ways of embedding f non-overlapped occurrences of the word-pair in a document of length ℓ, such that at least $\widehat{f^x}$ of the f occurrences have span less than x. To compute $N[f, \ell, x]$ and $N_x[\widehat{f^x}, f, \ell]$, we need the histogram $hist_{f,\ell,x}[\cdot]$ which is the output of *Procedure 1*. *Procedure 2* lists the pseudocode for computing $\pi_x(\widehat{f^x}, f, \ell)$ from $N(f, \ell)$ and $N_x(\widehat{f^x}, f, \ell)$ given $hist_{f,\ell}$ from *Procedure 1* (For the sake of readability the pseudocode does not describe some optimizations that we used in our implementation).

The *Procedure 1* is exponential in f and ℓ but it does not depend on the data corpus. Hence, we can run the Procedures 1 and 2 off-line, and publish the $\pi_x[]$ and $g_{\epsilon,x}[]$ tables for various x, $\widehat{f^x}$, f and

ℓ. Using these tables[5], anyone wishing to compute CSR needs to only run Procedure 3.

3.3 Computing CSR for a given word-pair

Procedure 3 $ComputeCSR(\alpha, \epsilon, \delta, x)$

Input α - word-pair; ϵ - document-level evidence; δ - corpus-level evidence; x - span threshold; Corpus of documents
Computes $CSR(\alpha)$ - Co-occurrence Significance Ratio (CSR) for α as per *Definition 3*

1: $\mathcal{D} \leftarrow \{D_1, \ldots, D_K\}$ // Set of documents from the corpus that each contain at least one occurrence of α.
2: $t \leftarrow \sqrt{\log \delta/(-2K)}$
3: $Z \leftarrow 0$ and $Z_E \leftarrow 0$
4: **for** $i \leftarrow 1$ to K **do**
5: $\quad \ell_i$ = Length of D_i
6: $\quad f_i$ = Frequency of α in D_i
7: $\quad \widehat{f}_i^x$ = Span-constrained frequency of α in D_i
8: $\quad$ **if** $\pi_x[\widehat{f}_i^x, f_i, \ell_i] < \epsilon$ **then**
9: $\quad\quad z_i \leftarrow 1$
10: $\quad$ **else**
11: $\quad\quad z_i \leftarrow 0$
12: $\quad Z \leftarrow Z + z_i$
13: $\quad Z_E \leftarrow Z_E + \pi_x[g_\epsilon[f_i, \ell_i, x], f_i, \ell_i]$
14: $CSR(\alpha) = Z/(Z_E + Kt)$

Procedure 3 implements the significance test given in *Definition 3* and requires that the $\pi_x[]$ and $g_{\epsilon,x}[]$ tables have already been computed offline.

The first step is to determine the subset $\mathcal{D}$ of documents containing the given word-pair (line 1). Then we compute t based on δ and K (the size of $\mathcal{D}$) (line 2). Next we determine how many of the K documents support the hypothesis "α is ϵ-significant within the document" (lines 3-12). The expected number of documents supporting the hypothesis is accumulated in Z_E (line 13). CSR is then computed as the ratio of Z to $(Z_E + Kt)$ (line 14).

3.4 Run-time overhead

The computation of Co-occurrence Significance Ratio (CSR) as given in Definition 3 might appear more complex than the simple formulae for other co-occurrence measures given in Table 2. However, bulk of the complexity in calculating CSR lies in the one-time (data independent) off-line computation of the $\pi_x[]$ and $g_{\epsilon,x}[]$ tables. Once these tables are published, the cost of comparing CSR for a given word pair is comparable to the cost of computing any other (spanned) measure in Table 2. The main data-dependent computations for a spanned measure are in determining span-constrained frequencies; all other steps are simple arithmetic operations or memory lookups. To illustrate this, Procedure 4 gives details of computing PMI. The comparison of Procedures 3 and 4 shows their almost parallel structures. The main overhead in these procedures is incurred in line 7, where span-constrained frequencies in a given document are computed.

Procedure 4 $ComputePMI(a, b)$

Input (x, y) - word pair;
Computes PMI (Table 2) for (x, y).

1: let $\mathcal{D} = \{D_1, \ldots, D_K\}$ // set of documents containing at least one occurrence of α.
2: N = total number of words in corpus
3: (f_x,f_y) = unigram frequencies of x, y in corpus
4: (p_x,p_y) = (f_x/N,f_y/N)
5: $\widehat{f} = 0$
6: **for** $i \leftarrow 1$ to K **do**
7: $\quad \widehat{f}_i$ = span-constrained frequency of α in D_i
8: $\quad \widehat{f} = \widehat{f} + \widehat{f}_i$
9: $\hat{p}_{x,y} = \widehat{f}/N$
10: $PMI = log(\frac{\hat{p}_{x,y}}{p_x p_y})$

4 Related Work

Existing word association measures can be divided into three broad categories: (i) *Co-occurrence measures* that rely on co-occurrence frequencies of both words in a corpus in addition to the individual unigram frequencies (Table 2), (ii) *Distributional similarity-based measures* that characterize a word by the distribution of other words around it (Agirre et al., 2009; Bollegala et al., 2007; Chen et al., 2006; Wandmacher et al., 2008), and (iii) *Knowledge-based measures* that use knowledge-sources like thesauri, semantic networks, or taxonomies (Milne and Witten, 2008; Hughes and Ramage, 2007; Gabrilovich and Markovitch, 2007; Yeh et al., 2009; Strube and Ponzetto, 2006; Finkelstein et al., 2002; Liberman and Markovitch, 2009).

In this paper, we focus on comparison with other co-occurrence measures. These measures are used in several domains like ecology, psychology, medicine, and language processing. Table 2 lists several measures chosen from all these domains. Except Ochiai (Ochiai, 1957; Janson and Vegelius, 1981) and the recently introduced

$\hat{p}(x,y)$	$\hat{f}(x,y)/N$
M	Harmonic mean of the spans of $\hat{f}(x,y)$ occurrences
$E\hat{f}(x,y)$	Expected value of $\hat{f}(x,y)$

Table 2: Co-occurrence measures.

CWCD[6] (Washtell and Markert, 2009) all other measures are well-known in the NLP community (Pecina and Schlesinger, 2006). Our results show that Ochiai and Chi-Square have almost identical performance, differing only in 3rd decimal digits. Rankings produced by Chi-square is almost monotonic with respect to the rankings produced by Ochiai. This is because, for most word pairs (x,y), $[f(x) \ll N]$, $[f(y) \ll N]$, $[f(x,y) \ll f(x)]$, and $[f(x,y) \ll f(y)]$. Therefore three of the four terms in the Chi-square summation become zero[7] and the fourth term approximates to the square of Ochiai. Similarly Jaccard and Dice coincide. While presenting our experimental results, we report these pairs of measures together.

[6]CWCD was reported in (Washtell and Markert, 2009) as the best performing variant among the so-called windowless (or spanless) measures. In our experiments, we implemented windowed (spanned) version of the CWCD measure.

[7]For example, $\hat{f}(x,\neg y) - Ef(x,\neg y) = f(x) - N \times pf(x) \times pf(\neg y) = f(x) - \frac{1}{N} \times f(x) \times f(\neg y) = f(x) - \frac{1}{N} \times f(x) \times N = 0$.

Table 3: Characteristics of data sets used.

5 Performance Evaluation

Two main aspects of word association studied in literature are: a) *semantic relatedness*, and b) *free association*. *Semantic relatedness* encompasses many different relationships between words, like synonymy, meronymy, antonymy, and functional association (Budanitsky and Hirst, 2006). *Free association* refers to the first response-words that come to mind when presented with a stimulus. (ESSLLI, 2008). We experiment with all the publicly available datasets that come with gold standard judgement of these aspects, except the very small ones with less than 80 word-pairs[8].

5.1 Datasets

Details[9] of the datasets used in our experiments are listed in Table 3. Each data set comes with a gold-standard of human judgments - a ranked list of association scores for the word-pairs in the data set. The *wordsim* dataset was prepared by asking the subjects to estimate the relatedness of the word pairs on a

[8](MillerCharles (Miller and Charles, 1991), Rubenstein-Goodenough (Rubenstein and Goodenough, 1965) and TOEFL (Landauer and Dumais, 1997))

[9]We removed word-pairs containing multiword expressions. For data sets with more than 10,000 word-pairs, we filtered out pairs that contain stop words listed in (StopWordList, 2010). For Edinburg (size 275393 after previous filtering), we further filtered word-pairs where the response was supported by only one respondant. Original and filtered data sets are available at http://www.cse.iitb.ac.in/~damani/papers/EMNLP11/resources.html

Table 5: Comparison of deviations from the best performing measure on each data set. Number of word-pairs in each dataset is shown in brackets against its name. Figures in brackets against the deviation values denote the ranks of the measures in the corresponding data sets.

scale from 0 to 10 (Finkelstein et al., 2002). The methodology for collecting *free association* data is explained at (ESSLLI, 2008): The degree of free association between a stimulus (S) and response (R) is the percentage of respondents who respond R as the first response when presented with stimulus S.

These datasets are of varying size, and they were constructed at different point in time, in different geographies. This allows us to compare different measures comprehensively under varying range of circumstances. To the best of our knowledge, no previous work has reported such a detailed comparison of co-occurrence measures.

5.2 Resources Used

We use the Wikipedia (Wikipedia, April 2008) corpus with 2.7 million articles (total of 1.24 Gigawords). We did no pre-processing - no lemmatization or function-word removal. When counting document size (in words), punctuations were ignored. Documents larger than 1500 words were partitioned such that each part was at most 1500 words[10]. We indexed the corpus using Lucene search engine library and used Lucene APIs to obtain various statistics and documents containing given word-pairs.

5.3 Methodology

Each measure listed in Table 2 produces a ranked list of association scores for the word-pairs in a data set. We evaluate each measure by the Spearman's rank correlation between the ranking produced by the measure and the gold-standard ranking.

The span threshold (or window-width) x is a user-defined parameter in all measures. In addition, CSR has the parameters ϵ and δ. For any measure, the ranking of word-pairs will likely change with chang-

[10]While this limit can be raised using heavier computing resources, we believe that partitioning documents of sizes greater than 1500 words was reasonable (especially since typical span values we used were less than 50, much less than 1500).

Table 6: Comparison of co-occurrence based measures with knowledge-based and distributional similarity based measures. These other measures have not been applied to the free association datasets shown in Table 3. Data for missing entries is not available. Note that *sim* and *rel* are subsets of *wordsim* dataset. Number of word-pairs in each dataset is shown in brackets against its name.

ing parameter values. Hence we follow the standard methodology of fixing parameters through cross validation. Specifically, we partition the data into five folds, four of which are used for training and one hold-out fold is used for testing. For each measure, the parameter values that achieve best correlation with human judgments on 4 training folds are used to predict on the 1 hold-out testing fold. This experiment is repeated 5 times for different training and test folds. The average rank correlation obtained by each measure over 5 cross-validation runs is reported for each dataset. We varied ϵ and δ between 0.01 and 0.90 and x between 5 and 50 words.

5.4 Results

For each measure and for each data set, the average correlation over the 5 cross-validation runs is reported in Table 4. The corresponding standard deviations are mentioned in the table's caption. The best performing measure in each case is highlighted in bold. While different measures performed best on different data sets, the results in Table 4 shows that CSR performs consistently well across all data sets. In all data sets the correlation for CSR was always either the best or close to the best.

As expected, our results are statistically more significant for the larger data sets, compared to the smaller ones. The standard deviations of the results are small for two largest data sets (less than 0.01 for Edinburg and Florida), gradually increasing (less than 0.02 for Kent and Minnesota), and becoming high (upto .15) for the three smallest datasets.

Although, among all measures, CSR has the best average correlation over all datasets, taking average of correlations across widely different dataset is not a meaningful way to decide on which measure to use. Ideally one would like to access an oracle to learn which measure will perform best on a particular unseen application dataset. Short of such an oracle, if one were to pick a fixed measure a-priori, then one would like to know how much worse off one is compared to the best measure for that dataset.

To compare different measures from this perspective, we compute the deviation of the correlation for each measure from the correlation of the best measure for each data set. These deviations are reported in Table 5, along with the corresponding ranks. The average deviation of CSR over all the data sets is 0.02, which is the least among all the measures, the next two being 0.04 and 0.06. CSR also has the least worst-deviation among all measures. Also, CSR is never ranked worse than 3 in any of the data sets. This is also the smallest worst-rank among all measures. Based on these results, we infer that CSR is overall the best performing co-occurrence based word association measure.

While the focus of our work is on the co-occurrence measures, for completeness, we present all the known results for knowledge and distributional similarity-based measures on the datasets un-

der consideration in Table 6. Note that in (Agirre et al., 2009), the *wordsim* data set was partitioned into two sets, namely *sim* and *rel*, and in *Esslli* shared task (ESSLLI, 2008), a 272 word pair subset of the *Edinburgh* dataset was chosen. To facilitate comparison, in addition to CSR, we also present results for PMI and Ochiai (Chi-Square) which are the best performing co-occurrence measures on *wordsim*, and *Esslli* datasets. For co-occurrence-based measures, we used 5-fold cross validation, which is inapplicable for parameterless measures. Results show that co-occurrence-based measures compare well with other resource-heavy measures.

6 Conclusions

In this paper, we introduced a new measure called CSR for word-association based on statistical significance of lexical co-occurrences. Our measure, while being agnostic to global unigram frequencies, detects skews in span distributions of word-pairs in documents containing both words. We carried out extensive evaluation on several benchmark datasets. Our experiments demonstrate the advantages of our measure over all the competing measures.

Learning the Information Status of Noun Phrases in Spoken Dialogues

Abstract

An entity in a dialogue may be old, new, or mediated/inferrable with respect to the hearer's beliefs. Knowing the information status of the entities participating in a dialogue can therefore facilitate its interpretation. We address the under-investigated problem of automatically determining the information status of discourse entities. Specifically, we extend Nissim's (2006) machine learning approach to information-status determination with lexical and structured features, and exploit learned knowledge of the information status of each discourse entity for coreference resolution. Experimental results on a set of Switchboard dialogues reveal that (1) incorporating our proposed features into Nissim's feature set enables our system to achieve state-of-the-art performance on information-status classification, and (2) the resulting information can be used to improve the performance of learning-based coreference resolvers.

1 Introduction

Information status is not a term unfamiliar to researchers working on discourse processing problems. It describes the extent to which a discourse entity, which is typically a noun phrase (NP), is *available* to the hearer given the speaker's assumptions about the hearer's beliefs. According to Nissim et al. (2004), a discourse entity can be *new*, *old*, or *mediated*. Informally, a discourse entity is (1) *old* to the hearer if it is known to the hearer and has previously been referred to in the dialogue, (2) *new* if it is unknown to her and has not been previously referred to; and (3) *mediated* if it is newly mentioned in the dialogue but she can infer its identity from a previously-mentioned entity. Information status is a subject that has received a lot of attention in theoretical linguistics (Halliday, 1976; Prince, 1981; Hajičová, 1984; Vallduví, 1992; Steedman, 2000).

Knowing the information status of discourse entities can potentially benefit many NLP applications. One such task is anaphora resolution. While there is general belief that definite descriptions are mostly anaphoric, Vieira and Poesio (2000) empirically show that only 30% of these NPs are anaphoric. Without being able to determine whether an NP is anaphoric, an anaphora resolver will attempt to resolve every NP, potentially damaging its precision. Since *new* entities are by definition new to the hearer and therefore cannot refer to a previously-introduced NP, knowledge of information status could be used to improve anaphora resolution.

Despite the potential usefulness of information status in NLP tasks, there has been little work on *learning* the information status of discourse entities. To investigate the plausibility of learning information status, Nissim et al. (2004) annotate a set of Switchboard dialogues with such information[1], and subsequently present a rule-based approach and a learning-based approach to acquiring such knowledge from the manual annotations (Nissim, 2006).

Our goals in this paper are two-fold. First, we describe a learning approach to the under-studied problem of determining the information status of discourse entities that extends Nissim's (2006) feature set with two novel types of features: lexical features and structured features based on syntactic parse trees. Second, we employ the automatically

[1]These and other linguistic annotations on the Switchboard dialogues were later released by the LDC as part of the NXT corpus, which is described in detail in Calhoun et al. (2010).

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1069–1080,
Edinburgh, Scotland, UK, July 27–31, 2011.

acquired knowledge of information status for coreference resolution. Experimental results on Nissim et al.'s (2004) corpus of Switchboard dialogues show that (1) adding our linguistic features to Nissim's feature set enables our system to outperform her system by 8.1% in F-measure, and (2) learned knowledge of information status can be used to improve coreference resolvers by 1.1–2.6% in F-measure.

The rest of this paper is organized as follows. We first illustrate with examples the concepts of *new*, *old*, and *mediated* entities. Then, we describe the dataset and the feature set that Nissim (2006) used in her approach. After that, we introduce our lexical and structured features. Finally, we evaluate the determination of information status as a standalone task and in the context of coreference resolution.

2 Old, New, and Mediated Entities

Since the concepts of *old*, *new*, and *mediated* entities are not widely known to researchers working outside the area of discourse processing, in this section we will explain them in more detail.

The terms *old* and *new* information have meant a variety of things over the years (Allerton, 1978; Prince, 1981; Horn, 1986). Since we use Nissim et al.'s (2004) corpus for training and evaluation, the definitions of these concepts we present here are those that Nissim et al. used to annotate their corpus. According to Nissim et al., their definitions are built upon Prince's (1981), and the categorization into *old*, *new*, and *mediated* entities resemble those of Strube (1998) and Eckert and Strube (2001).

Old. As mentioned before, an entity is *old* if it is both known to the hearer and has been mentioned in the conversation. More precisely, an entity is *old* if (1) it is coreferential with an entity introduced earlier, (2) it is a generic pronoun, or (3) it is a personal pronoun referring to the dialogue participants. To exemplify, consider the following sentences.

(1) I was angry that he destroyed **my** tent.
(2) **You** cannot leave until the test is over.

In Example 1, *my* is an *old* entity because it is coreferent with *I*. In Example 2, *You* is an *old* entity because it is a generic pronoun.

Mediated. An entity is *mediated* if it has not been previously introduced in the conversation, but can be inferred from already-mentioned entities or is generally known to the hearer. More specifically, an entity is *mediated* if (1) it is a generally known entity (e.g., *the Earth*, *China*, and most proper names), (2) it is a bound pronoun, or (3) it is an instance of *bridging* (i.e., an entity that is inferrable from a related entity mentioned earlier in the dialogue). As an example, consider the following sentences.

(3a) He passed by the door of Mary's house and saw that **the door** was painted purple.
(3b) He passed by Mary's house and saw that **the door** was painted purple.

In Example 3a, by the time the hearer processes the second occurrence of *the door*, she has already had a mental entity corresponding to *the door* (after processing the first occurrence). As a result, the second occurrence of *the door* is an *old* entity. In Example 3b, on the other hand, the hearer is not assumed to have any mental representation of the door in question, but she can infer that the door she saw was part of Mary's house. Hence, this occurrence of *the door* is a *mediated* entity. In general, an entity that is related to an earlier entity via a part-whole relation or a set-subset relation is *mediated*.

New. An entity is *new* if it has not been introduced in the dialogue and the hearer cannot infer it from previously mentioned entities.

In case more than one class is appropriate for a given entity, Nissim et al. employ additional tie-breaking rules. Suppose, for instance, that we have two occurrences of *China* in a dialogue. The second occurrence can be labeled as *old* (because it is coreferential with an earlier entity) or *mediated* (because it is a generally known entity). According to Nissim et al.'s rules, the entity will be labeled as *old*.

3 Dataset

We employ Nissim et al.'s (2004) dataset, which comprises 147 Switchboard dialogues. A total of 68,992 NPs are annotated with information status: 51.2% of them are labeled as *old*, 34.5% as *mediated* (henceforth *med*), and 14.3% as *new*. Nissim (2006) randomly split the instances created from these NPs into a training set (for classifier training), a development set (for feature development), and an evaluation set (for testing). Hence, the NPs from the same

	Training	Test
old	31358 (51.7%)	3931 (47.4%)
med	20778 (34.2%)	3036 (36.6%)
new	8567 (14.1%)	1322 (16.0%)
total	60703 (100%)	8289 (100%)

Table 1: Information status distribution of NPs.

document may be split across different sets.

Unlike Nissim (2006), we partition the 147 dialogues (rather than the instances) into a training set (117 dialogues) and a test set (30 dialogues). In other words, we do *not* randomize the instances, as we believe that it represents an unrealistic evaluation setting, for the following reasons. First, in practice, the test dialogues may not be available until test time. Second, we may want to examine how a system performs on a given dialogue. Finally, randomizing the instances does not allow us to apply learned knowledge of information status to coreference resolution, which needs to be performed for each dialogue. The information status distribution of the NPs in the training and test sets are shown in Table 1.

4 Baseline System

In this section, we describe our baseline system, which adopts a machine learning approach to determining the information status of a discourse entity.

Building SVM classifiers for information-status determination. We employ the support vector machine (SVM) learner as implemented in the SVM^{light} package (Joachims, 1999) to train three binary classifiers, one for predicting each of the three possible classes (i.e., *new*, *old*, and *med*), using a linear kernel in combination with the *one-versus-all* training scheme.[2] Each training instance represents a single NP and consists of the seven morpho-syntactic features that Nissim (2006) used in her learning-based approach (see Table 2 for an overview). Following Nissim, we extract the NPs directly from the gold-standard annotations, but the features are computed entirely automatically.

[2]SVM was chosen because it provides the option to employ kernels. The reason why we train three binary classifiers rather than just one multi-class classifier (using SVM^{multiclass}) is that SVM^{multiclass} does not permit the use of a non-linear kernel, which we will need to incorporate structured features later on.

Feature	Values
full prev mention	numeric
mention time	{first,second,more}
partial prev mention	{yes,no,NA}
determiner	{bare,def,dem,indef,poss,NA}
NP type	{pronoun,common,proper,other}
NP length	numeric
grammatical role	{subject,subjpass,pp,other}

Table 2: Nissim's feature set.

The seven features are all intuitively useful for determining information status. For instance, if an NP, NP$_k$, and a discourse entity that appears before it have the same string (full prev mention), then NP$_k$ is likely to be an *old* entity. Mention time is the categorical version of full prev mention and therefore serves to detect *old* entities. Partial prev mention is useful for detecting mediated entities, especially those that have a set-subset relation with a preceding entity. For instance, *your dogs* would be considered a partial previous mention of *my dogs* or *my three dogs*. The value "NA" stands for "not applicable", and is used for pronouns. Determiners and NP type are likely to be helpful for all three categories. For instance, indefinite NPs and pronouns are likely to be *new* and *old*, respectively. The "NP length" feature is motivated by the observation that *old* entities tend to contain less lexical materials than *new* entities. For instance, subsequent references to *Barack Obama* may simply be *Obama*.

Applying the classifiers. To determine the information status of an NP in a test dialogue, we create an instance for it as during training and present it independently to the three binary SVM classifiers, each of which returns a real value representing the signed distance of the instance from the hyperplane. We assign the instance to the class that is associated with the most positive classification value.

5 Our Features

We propose to extend Nissim's (2006) feature set with two types of features.

5.1 Lexical Features

As discussed, an entity should be labeled as *med* if it has not been introduced in the dialogue but is gener-

ally known to a human. Whether an entity is "generally known" may be easily determined by a human but not by a machine, since world knowledge is involved in the decision process. In particular, Nissim's feature set does not contain any features that encode the notion of a "generally known" entity.

Hence, it would be desirable to augment Nissim's feature set with features that indicate whether an entity is generally known or not. One way to do this is to (1) create a list of generally known entities, and then (2) create a binary feature that has the value *True* if and only if the entity under consideration appears in this list. The question, then, is: how can we obtain the list of generally known entities? We may manually assemble this list, but this could be a labor-intensive task. As a result, we propose to *acquire* this kind of world knowledge automatically from annotated data.

Specifically, we augment Nissim's feature set with the set of *unigrams* that appear in the training data. Given a training/test instance (i.e., discourse entity), we compute the values of its unigram features (henceforth *lexical features*) as follows. For each unigram, we check if it appears in the string representing the discourse entity. If so, its feature value is 1; otherwise, its value is 0. For instance, if the entity is *the red hat*, then all of its lexical features except *the*, *red*, and *hat* will have a value of 0.

It should perhaps not be too difficult to see why these lexical features are useful for the information-status classifier: these features enable the SVM learner to determine the extent to which a unigram correlates with each class. For instance, from the annotated data, the learner will learn that any instance of *China* cannot be labeled as *new*, and the decision of whether it should be an *old* entity or a *med* entity depends on whether it is coreferential with a previously-mentioned entity. Hence, the use of lexical features allows the learner to implicitly acquire some world knowledge.

We believe that lexicalization is an important step towards building high-performance text-processing systems. In fact, lexicalized models have demonstrated their effectiveness in other areas of language processing, such as syntactic and semantic parsing. While lexicalized models may be less portable to new genres and domains than their unlexicalized counterparts, we believe that this issue can be handled via domain adaptation techniques and should not be a reason against lexicalization.

5.2 Structured Features

In Nissim's (2006) feature set, there are a couple of features that capture NP-internal information, such as determiner, NP length, and NP type. However, there is only one feature that captures the syntactic context of an NP, grammatical role, which is computed based on the parse tree in which the NP resides. This is arguably a very shallow representation of its syntactic context. We hypothesize that we can train more accurate information-status classifiers if we have access to a richer representation of syntactic context. This motivates us to employ syntactic parse trees *directly* as features.

Before describing how this can be done, recall that in a traditional learning setting, the feature set employed by an off-the-shelf learning algorithm typically consists of *flat* features (i.e., features whose values are discrete- or real-valued, as the ones described in the previous section). Advanced machine learning algorithms such as SVMs, on the other hand, have enabled the use of *structured* features (i.e., features whose values are structures such as parse trees), owing to their ability to employ *kernels* to efficiently compute the similarity between two potentially complex structures.

Perhaps the main advantage of employing structured features is *simplicity*. To understand this advantage, consider learning in a setting where we can only employ flat features. If we want to use information from a parse tree as features in this setting, we will need to design heuristics to extract the desired parse-based features from parse trees. For certain tasks, designing a good set of heuristics can be time-consuming and sometimes difficult. On the other hand, SVMs enable a parse tree to be employed directly as a structured feature, obviating the need to design such heuristics.

Given two parse trees (as features), we compute their similarity using a convolution tree kernel (Collins and Duffy, 2001), which efficiently enumerates the number of common substructures in the two trees via dynamic programming. Note, however, that while we want to use a parse tree directly as a feature, we do *not* want to use the *entire* parse tree as a feature. Specifically, while using the entire parse

tree enables a richer representation of the syntactic context than using a *partial* parse tree, the increased complexity of the tree also makes it more difficult for the SVM learner to make generalizations.

To strike a better balance between having a rich representation of the context and improving the learner's ability to generalize, we extract a substructure from a parse tree and use it as the value of the structured feature of an instance. Specifically, given an instance corresponding to discourse entity e, we extract the substructure from the parse tree containing e as follows. Let $n(e)$ be the root of the subtree that spans all and only the words in e, and let $Parent(n(e))$ be its immediate parent node. We (1) take the subtree rooted at $Parent(n(e))$, (2) replace each leaf node in this subtree with a node labeled X, (3) replace the subtree rooted at $n(e)$ with a leaf node labeled Y, and (4) use the subtree rooted at $Parent(n(e))$ as the structured feature for the instance corresponding to e. Intuitively, the first three steps aim to provide generalizations by simplifying the tree. For instance, step (1) allows us to focus on using a small window as the context. Steps (2) and (3) help generalization by ignoring the words within e and its context. Note that using two labels, X and Y, enables the kernel to distinguish the discourse entity under consideration from its context within this substructure. In addition, we simply use a single node (Y) to represent the discourse entity, since any NP-internal information has presumably been captured by the flat features. We compute these structured features using hand-annotated parse trees.

While structured features have been employed for a multitude of tasks in syntax, semantics, and information extraction such as syntactic parsing (e.g., Collins (2002)), semantic parsing (e.g., Moschitti (2004)), named entity recognition (e.g., Cumby and Roth (2003), and relation extraction (e.g., Zelenko et al. (2003)), the same is not true for discourse processing tasks. We hope that our use of structured features for information-status classification can promote their use in discourse processing.

5.3 Combining Kernels

Recall that the flat features are computed using a linear kernel, while the structured features are computed using a tree kernel. If we want our learner to make use of more than one of these types of features, we need to employ a *composite* kernel to combine them. Specifically, we define and employ the following composite kernel:

$$K_c(F_1, F_2) = K_1(F_1, F_2) + K_2(F_1, F_2),$$

where F_1 and F_2 are the full set of features that represent the two entities under consideration, and K_1 and K_2 are the kernels we are combining. To ensure that both kernels contribute equally to the composite kernel, we normalize the values they return to the range [0,1].

6 Evaluation

Next, we evaluate the effectiveness of our features in improving information-status classification.

6.1 Results and Discussion

Results of four information-status classification systems are shown in Table 3. Under Original Nissim, we have the results copied verbatim from Nissim's (2006) paper. Baseline is the aforementioned baseline system, which is trained using Nissim's feature set. Baseline+Lexical is the system trained using Nissim's feature set augmented with lexical features. Finally, Baseline+Both is the system trained using Nissim's feature set augmented with both lexical and structured features. For each system, we show the recall (R), precision (P), and F-measure (F) of each of the three classes: *old*, *new*, and *med*. Before we describe the results, two points deserve mention. First, as noted earlier, Nissim partitioned the dialogues into training and test folds in a different way than us. In particular, Original Nissim and the remaining three systems were not evaluated on the same set of test instances. Hence, the Original Nissim results are not directly comparable with those of the other systems. We show them here just to provide another point of reference. Second, the results of the remaining three systems were obtained by aggregating the results of three binary SVM classifiers, as described earlier.

Comparing Baseline and Baseline+Lexical, we see that augmenting Nissim's feature set with lexical features improves the F-measure scores on all three classes. In particular, the F-measure and recall for *med* rise considerably by 3.0 and 7.8, respectively. This provides indirect empirical support for our earlier hypothesis that the *med* class can benefit from

	Original Nissim			Baseline			Baseline+Lexical			Baseline+Both		
	R	P	F	R	P	F	R	P	F	R	P	F
old	91.5	94.1	92.8	91.2	85.8	88.5	88.7	91.7	90.2	93.0	95.2	**94.1**
med	87.6	68.1	76.6	84.7	62.7	72.1	92.5	63.2	75.1	89.1	70.9	**79.0**
new	22.3	56.3	32.0	30.2	66.4	41.5	32.1	68.3	43.7	34.4	71.5	**46.5**
Accuracy	79.5			74.1			76.3			**82.2**		

Table 3: Per-class performance of four information-status classifiers.

the shallow world knowledge that these lexical features help to "extract" from annotated data.

Comparing Baseline+Lexical and Baseline+Both, we see that the addition of structured features enables a further boost to performance: F-measure increases by 2.8–3.9 for the three classes. These results substantiate our hypothesis that employing a richer representation of syntactic context is beneficial to information-status classification.

Comparing Baseline and Baseline+Both, we see that F-measure improves considerably by 5–6.9 for the three classes. Overall, these results provide suggestive evidence that both types of features are effective at improving an information-status classifier that employs Nissim's features.

For further comparison, we show the classification accuracies of the four systems in the last row of Table 3. As we can see, adding lexical features to the baseline features improves accuracy by 2.2%, and adding structured features further improves accuracy by 5.9%. Our two types of features, when used in combination with Nissim's features, improve the baseline substantially by an accuracy of 8.1%.

Note that while our results and Original Nissim's are not directly comparable, the two systems are consistent in terms of the relative performance for the three classes: best for *old* and worst for *new*. The poor performance for *new* is largely a consequence of its low recall, which can in turn be attributed to its lower representation in the dataset. Since many *new* instances are misclassified, a natural question is: are these instances misclassified as *old* or *med*? Similar questions can be raised for *old* and *med*, despite their substantially higher recall values than *new*.

To answer these questions, we need to better understand the kind of errors made by our approach. Consequently, we show in Table 4 the confusion matrix generated from the test set for our best-performing information-status classifier, Baseline+Both. The rows and the columns correspond to the gold tags and the classifier tags, respectively. As we can see, these numbers seem to suggest the "in-between" nature of mediated entities: when an *old* or *new* entity is misclassified, it is typically misclassified as *med* (rows 1 and 3); however, when a *med* entity is misclassified, it is equally likely to be misclassified as *old* and *new* (row 2).

C→ G↓	old	med	new
old	3656	257	18
med	167	2706	163
new	17	850	455

Table 4: Confusion matrix for the Baseline+Both classifier. C=Classifier tag; G=Gold tag

These results are perhaps not surprisingly, since intuitively *med* entities bear some resemblance to both *old* and *new* entities. For instance, the similarity between *med* and *old* stems from the fact that different instances of the same entity (e.g., *China*) can receive one of these two labels, with the decision dependent on whether the entity was previously mentioned in the dialogue. On the other hand, *med* and *new* are similar in that it may sometimes be difficult even for a human to determine whether certain entities should be labeled as *med* or *new*, since the decision depends on whether she believes these entities are *generally known* or not.

6.2 Relation to Anaphoricity Determination

Anaphoricity determination refers to the task of determining whether an NP is anaphoric or not, where an NP is considered anaphoric if it is part of a (non-singleton) coreference chain but is not the head of the chain (Ng and Cardie, 2002). In other words, an

	Anaphoricity			Baseline+Ana			Baseline+Lexical+Ana			Baseline+Both+Ana		
	R	P	F	R	P	F	R	P	F	R	P	F
old	91.4	86.6	88.9	91.3	87.3	89.3	90.8	91.7	91.3	92.8	94.9	93.9
med	84.3	63.1	72.2	84.9	64.1	73.1	92.3	64.7	76.1	88.7	71.1	78.9
new	30.8	66.4	42.1	31.1	66.9	42.5	32.9	68.7	44.5	34.1	71.7	46.2
Accuracy	74.7			75.1			77.6			82.0		

Table 5: Impact of knowledge of anaphoricity on the information-status classifiers.

NP is anaphoric if and only if it has an antecedent.

Given this definition, anaphoricity determination bears resemblance to information-status classification. For instance, an *old* entity is anaphoric, since it has been introduced earlier in the conversation and therefore have an antecedent. Similarly, a *new* or *med* entity is non-anaphoric, since the entity has not been previously introduced in the conversation and therefore cannot have an antecedent.

There has been a lot of recent work on anaphoricity determination (e.g., Bean and Riloff (1999), Uryupina (2003), Ng (2004), Denis and Baldridge (2007), Versley et al. (2008), Ng (2009), Zhou and Kong (2009)). Given the similarity between this task and information-status classification, a natural question is: will the anaphoricity features previously developed by coreference researchers be helpful for information-status classification? To answer this question, we (1) assemble a feature set composed of the 26 anaphoricity features previously used by Rahman and Ng (2009),[3] and then (2) repeat the experiments in Table 3, except that we augment the feature set used in each of these experiments with the anaphoricity features we assembled in step (1).

Results with the anaphoricity features are shown in Table 5. Under Anaphoricity, we have the results obtained using only the 29 anaphoricity features. As we can see, these results are comparable to those obtained using the Baseline features. Comparing each of Baseline+Ana and Baseline+Lexical+Ana with the corresponding experiments in Table 3, we see that the addition of anaphoricity features yields a mild performance improvement, which is consistent over all three classes. However, comparing the last column of the two tables, we can see that in the presence of the structured features, the anaphoricity features do not contribute positively to overall performance. Hence, in the coreference experiments in the next section, we will not employ anaphoricity features for information-status classification.

[3]These 26 features are derived from those employed by Ng and Cardie's (2002) anaphoricity determination system. See Footnote 2 of Rahman and Ng (2009) for details.

7 Application to Coreference Resolution

Since the significance of information-status classification stems in part from the potential benefits it brings to higher-level NLP applications, we determine whether our information-status classification systems can offer benefits to learning-based coreference resolution. Since the 147 information-status annotated dialogues are also coreference annotated, we use them in our coreference evaluation. To our knowledge, our work represents the first attempt to report coreference results on this dataset.

7.1 Coreference Models

While the so-called mention-pair coreference model has dominated coreference research for more than a decade since its appearance in the mid-1990s, a number of new coreference models have been proposed in recent years. To investigate whether these newer, presumably more sophisticated, coreference models can better exploit the automatically acquired information-status information, we will evaluate the usefulness of information-status information when used in combination with two different coreference models, the aforementioned mention-pair model and the recently-developed cluster-ranking model.

7.1.1 Mention-Pair Model

The mention-pair (MP) model, proposed by Aone and Bennett (1995) and McCarthy and Lehnert (1995), is a classifier that determines whether two NPs are co-referring or not. Each instance $\boldsymbol{i}(\mathrm{NP}_j, \mathrm{NP}_k)$ corresponds to two NPs, NP_j and NP_k, and is represented by 39 features. Table 1 of Rahman and

Ng (2009) contains a detailed description of these features. Linguistically, they can be divided into four categories: string-matching, grammatical, semantic, and positional. They can also be categorized based on whether they are relational or not. Specifically, relational features capture the relationship between NP_j and NP_k, whereas non-relational features capture the linguistic property of one of these NPs.

We follow Soon et al.'s (2001) method for creating training instances. Specifically, we create (1) a positive instance for each anaphoric NP NP_k and its closest antecedent NP_j; and (2) a negative instance for NP_k paired with each of the intervening NPs, NP_{j+1}, NP_{j+2}, ..., NP_{k-1}. The classification associated with a training instance is either positive or negative, depending on whether the two NPs are coreferent. To train the MP model, we use the SVM learner from SVM^{light} (Joachims, 1999).[4]

After training, the classifier is used to identify an antecedent for an NP in a test text. Specifically, each NP, NP_k, is compared in turn to each preceding NP, NP_j, from right to left, and selects NP_j as its antecedent if the pair is classified as coreferent. The process terminates as soon as an antecedent is found for NP_k or the beginning of the text is reached.

Despite its popularity, the MP model has two major weaknesses. First, since each candidate antecedent for an NP to be resolved (henceforth an *active NP*) is considered independently of the others, this model only determines how good a candidate antecedent is relative to the active NP, but not how good a candidate antecedent is relative to other candidates. So, it fails to answer the critical question of which candidate antecedent is most probable. Second, it has limitations in its expressiveness: the information extracted from the two NPs alone may not be sufficient for making a coreference decision.

7.1.2 Cluster-Ranking Model

The cluster-ranking (CR) model, proposed by Rahman and Ng (2009), addresses the two weaknesses of the MP model by combining the strengths of the *entity-mention* model (e.g., Luo et al. (2004), Yang et al. (2008)) and the *mention-ranking* model (e.g., Denis and Baldridge (2008)). Specifically, the CR model ranks the preceding clusters for an active NP so that the highest-ranked cluster is the one to which the active NP should be linked. Employing a ranker addresses the first weakness, as a ranker allows all candidates to be compared *simultaneously*. Considering preceding clusters rather than antecedents as candidates addresses the second weakness, as *cluster-level* features (i.e., features that are defined over any subset of NPs in a preceding cluster) can be employed.

Since the CR model ranks preceding clusters, a training instance $\boldsymbol{i}(c_j, \text{NP}_k)$ represents a preceding cluster c_j and an anaphoric NP NP_k. Each instance consists of features that are computed based solely on NP_k as well as cluster-level features, which describe the relationship between c_j and NP_k. Motivated in part by Culotta et al. (2007), we create cluster-level features from the *relational* features in our feature set using four predicates: NONE, MOST-FALSE, MOST-TRUE, and ALL. Specifically, for each relational feature X, we first convert X into an equivalent set of binary-valued features if it is multi-valued. Then, for each resulting binary-valued feature X_b, we create four binary-valued cluster-level features: (1) NONE-X_b is true when X_b is false between NP_k and each NP in c_j; (2) MOST-FALSE-X_b is true when X_b is true between NP_k and less than half (but at least one) of the NPs in c_j; (3) MOST-TRUE-X_b is true when X_b is true between NP_k and at least half (but not all) of the NPs in c_j; and (4) ALL-X_b is true when X_b is true between NP_k and each NP in c_j.

We train a cluster ranker to jointly learn anaphoricity determination and coreference resolution using SVM^{light}'s ranker-learning algorithm. Specifically, for each NP, NP_k, we create a training instance between NP_k and *each* preceding cluster c_j using the features described above. Since we are learning a joint model, we need to provide the ranker with the option to start a new cluster by creating an additional training instance that contains features that solely describes NP_k. The rank value of a training instance $\boldsymbol{i}(c_j, \text{NP}_k)$ created for NP_k is the rank of c_j among the competing clusters. If NP_k is anaphoric, its rank is HIGH if NP_k belongs to c_j, and LOW otherwise. If NP_k is non-anaphoric, its rank is LOW unless it is the additional training instance described above, which has rank HIGH.

After training, the cluster ranker processes the NPs in a test text in a left-to-right manner. For each

[4] For this and subsequent uses of the SVM learner in our experiments, we set all parameters to their default values.

active NP, NP_k, we create test instances for it by pairing it with each of its preceding clusters. To allow for the possibility that NP_k is non-anaphoric, we create an additional test instance that contains features that solely describe the active NP (similar to what we did in the training step above). All these test instances are then presented to the ranker. If the additional test instance is assigned the highest rank value by the ranker, then NP_k is classified as non-anaphoric and will not be resolved. Otherwise, NP_k is linked to the cluster that has the highest rank.

7.2 Coreference Experiments

7.2.1 Experimental Setup

The training/test split we use in the coreference experiments is the same as that in the information-status experiments. Specifically, we use the training set to train both the information-status classifier and our coreference models, apply the information-status classifier to each discourse entity in the test set, and have the coreference models resolve all and only those NPs that are labeled as *old* by the information-status classifier. Our decision to allow the coreference models to resolve only the *old* entities is motivated by the fact that *med* and *new* entities have *not* been previously introduced in the conversation and therefore do not have antecedents. The NPs used by the coreference models are the same as those accessible to the information-status classifier.

We employ two scoring programs, B^3 (Bagga and Baldwin, 1998) and ϕ_3-CEAF (Luo, 2005), to score the output of a coreference model. Given a gold-standard (i.e., key) partition, KP, and a system-generated (i.e., response) partition, RP, B^3 computes the recall and precision of each NP and averages these values at the end. Specifically, for each NP, NP_j, B^3 first computes the number of NPs that appear in both KP_j and RP_j, the clusters containing NP_j in KP and RP, respectively, and then divides this number by $|KP_j|$ and $|RP_j|$ to obtain the recall and precision of NP_j, respectively. On the other hand, CEAF finds the best one-to-one alignment between the key clusters and the response clusters using the Kuhn-Munkres algorithm (Kuhn, 1955), where the weight of an edge connecting two clusters is equal to the number of NPs that appear in both clusters. Precision and recall are equal to the sum of the weights of the edges in the alignment divided by the total number of NPs in the response and the key, respectively.

7.2.2 Results and Discussion

As our baseline, we employ our coreference models to generate NP partitions on the test documents *without* using any knowledge of information status. Results, reported in terms of recall (R), precision (P), and F-measure (F) using B^3 and ϕ_3-CEAF, are shown in row 1 of Table 6.[5] As we can see, the baseline achieves B^3 F-measures of 69.2 (MP) and 74.5 (CR) and CEAF F-measures of 61.6 (MP) and 68.5 (CR). These results suggest that the CR model is stronger than the MP model, corroborating previous empirical findings (Rahman and Ng, 2009).

Next, we examine the impact of learned knowledge of information status on the performance of a coreference model. Since knowledge of information status enables a coreference model to focus on resolving only the *old* entities, we hypothesize that the resulting model will have a higher precision than one that does not employ such knowledge. An equally important question is: will the F-measure of the resulting model improve? Since we are employing knowledge of information status in a *pipeline* coreference architecture where information-status classification is performed prior to coreference resolution, errors made by the (upstream) information-status classifier may propagate to the (downstream) coreference system. Given this observation, we hypothesize that the answer to the aforementioned question depends in part on the accuracy of information-status classification. In particular, the higher the accuracy of information-status classification is, the more likely the F-measure of the downstream coreference model will improve. To test this hypothesis, we conduct experiments where we employ the knowledge provided by the three information-status classifiers which, as discussed earlier, perform at varying levels of accuracy — the first one using only Nissim's features, the second one using both lexical and Nissim's features, and the last one using Nissim's features in combination with lexical and parse-based features — for our coreference models.

[5] Since gold-standard NPs are used in our experiments, CEAF precision is always equal to CEAF recall. For brevity, we only report F-measure scores for CEAF in the table.

System	Mention-Pair Model				Cluster-Ranking Model			
	B^3			CEAF	B^3			CEAF
	R	P	F	F	R	P	F	F
No knowledge of information status	78.6	61.8	69.2	61.6	78.2	71.1	74.5	68.5
Nissim features only	73.4	67.3	70.2	62.1	73.6	77.4	75.4	69.7
Nissim+Lexical features	71.0	69.5	70.2	61.9	73.7	77.3	75.4	69.9
Nissim+Lexical+Parse features	74.1	66.8	70.3	62.3	77.3	74.0	75.6	71.1
Perfect information status	76.7	68.1	72.1	66.4	77.1	79.5	78.3	74.2

Table 6: B^3 and CEAF coreference results.

Results of the coreference models employing knowledge provided by the three information-status classifiers are shown in rows 2–4 of Table 6. As expected, B^3 precision increases in comparison to the baseline, regardless of the coreference model and the scoring program. In addition, employing knowledge of information status always improves coreference performance: F-measure scores increase by 1.0–1.1% (B^3) and 0.3–0.7% (CEAF) for the MP model, and by 0.9–1.1% (B^3) and 1.2–2.6% (CEAF) for the CR model. These results suggest that the three information-status classifiers have achieved the level of accuracy needed for the coreference models to improve. On the other hand, it is somewhat surprising that the three information-status classifiers have yielded coreference systems that perform at essentially the same level of performance.

To understand why better information-status classification results do not necessarily yield better coreference performance, we take a closer look at the results of the coreference resolver employing Nissim's features (henceforth NISSIM) and the resolver employing our Nissim+Lexical+Parse features (henceforth FULL-FEATURE). Among the *old* entities that were correctly classified using our features and incorrectly classified by Nissim's features, we found that the precision of the FULL-FEATURE system suffered (since in many cases the coreference models identified wrong antecedents for these *old* entities) whereas the NISSIM system remained unaffected (since the entities were misclassified and would not be resolved by the models). In addition, although many *med* and *new* entities were correctly classified using our features and incorrectly classified (as *old*) using Nissim's features, we found that in many cases no antecedents were identified for these misclassified entities and hence the precision of the NISSIM system was not adversely affected.

Finally, we investigate whether our coreference system could be improved if it had access to perfect knowledge of information status (taken directly from the gold-standard annotations). This experiment will allow us to determine whether the usefulness of knowledge of information status for coreference resolution is limited by the accuracy in computing such knowledge. Results are shown in the last row of Table 6. As we can see, using perfect information-status knowledge yields a coreference system that improves those that employs automatically acquired information-status knowledge by 1.8–4.1% (MP) and 2.7–3.1% (CR) in F-measure. This indicates that the accuracy in computing such knowledge does play a role in determining its usefulness for coreference resolution.

8 Conclusions

We examined the problem of automatically determining the information status of discourse entities in spoken dialogues. In particular, we augmented Nissim's feature set with two types of features: lexical features, which capture in a shallow manner world knowledge implicitly encoded in the annotated data; and syntactic parse trees, which provide a richer representation of the syntactic context in which a discourse entity appears than grammatical roles. Results on 147 Switchboard dialogues demonstrated the effectiveness of these features: we obtained a significant improvement of 8.1% in accuracy over a information-status classifier trained on Nissim's feature set. In addition, we evaluated information-status classification in the context of coreference resolution, and showed that automatically acquired knowledge of information status can be profitably used to improve coreference systems.

Harnessing WordNet Senses for Supervised Sentiment Classification

Abstract

Traditional approaches to sentiment classification rely on lexical features, syntax-based features or a combination of the two. We propose semantic features using word senses for a supervised document-level sentiment classifier. To highlight the benefit of sense-based features, we compare word-based representation of documents with a sense-based representation where WordNet senses of the words are used as features. In addition, we highlight the benefit of senses by presenting a part-of-speech-wise effect on sentiment classification. Finally, we show that even if a WSD engine disambiguates between a limited set of words in a document, a sentiment classifier still performs better than what it does in absence of sense annotation. Since word senses used as features show promise, we also examine the possibility of using similarity metrics defined on WordNet to address the problem of not finding a sense in the training corpus. We perform experiments using three popular similarity metrics to mitigate the effect of unknown synsets in a test corpus by replacing them with *similar* synsets from the training corpus. The results show promising improvement with respect to the baseline.

1 Introduction

Sentiment Analysis (SA) is the task of prediction of opinion in text. Sentiment classification deals with tagging text as positive, negative or neutral from the perspective of the speaker/writer with respect to a topic. In this work, we follow the definition of Pang et al. (2002) & Turney (2002) and consider a binary classification task for output labels as positive and negative.

Traditional supervised approaches for SA have explored lexeme and syntax-level units as features. Approaches using lexeme-based features use bag-of-words (Pang and Lee, 2008) or identify the roles of different *parts-of-speech (POS)* like adjectives (Pang et al., 2002; Whitelaw et al., 2005). Approaches using syntax-based features construct parse trees (Matsumoto et al., 2005) or use text parsers to model valence shifters (Kennedy and Inkpen, 2006).

Our work explores incorporation of semantics in a supervised sentiment classifier. We use the synsets in Wordnet as the feature space to represent word senses. Thus, a document consisting of words gets mapped to a document consisting of corresponding word senses. Harnessing WordNet senses as features helps us address two issues:

1. Impact of WordNet sense-based features on the performance of supervised SA
2. Use of WordNet similarity metrics to solve the problem of features unseen in the training corpus

The first points deals with evaluating sense-based features against word-based features. The second issue that we address is in fact an opportunity to improve the performance of SA that opens up because of the choice of sense space. Since sense-based features prove to generate superior sentiment classifiers, we get an opportunity to mitigate unknown

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1081–1091,
Edinburgh, Scotland, UK, July 27–31, 2011.

synsets in the test corpus by replacing them with known synsets in the training corpus. Note that such replacement is not possible if word-based representation were used as it is not feasible to make such a large number of similarity comparisons.

We use the corpus by Ye et al. (2009) that consists of travel domain reviews marked as positive or negative at the document level. Our experiments on studying the impact of Wordnet sense-based features deal with variants of this corpus manually or automatically annotated with senses. Besides showing the overall impact, we perform a POS-wise analysis of the benefit to SA. In addition, we compare the effect of varying training samples on a sentiment classifier developed using word based features and sense based features. Through empirical evidence, we also show that disambiguating some words in a document also provides a better accuracy as compared to not disambiguating any words. These four sets of experiments highlight our hypothesis that WordNet senses are better features as compared to words.

Wordnet sense-based space allows us to mitigate unknown features in the test corpus. Our synset replacement algorithm uses Wordnet similarity-based metrics which replace an unknown synset in the test corpus with the closest approximation in the training corpus. Our results show that such a replacement benefits the performance of SA.

The roadmap for the rest of the paper is as follows: Existing related work in SA and the differentiating aspects of our work are explained in section 2 Section 3 describes the sense-based features that we use for this work. We explain the similarity-based replacement technique using WordNet synsets in section 4. Our experiments have been described in section 5. In section 6, we present our results and related discussions. Section 7 analyzes some of the causes for erroneous classification. Finally, section 8 concludes the paper and points to future work.

2 Related Work

This work studies the benefit of a word sense-based feature space to supervised sentiment classification. However, a word sense-based feature space is feasible subject to verification of the hypothesis that sentiment and word senses are related. Towards this, Wiebe and Mihalcea (2006) conduct a study on human annotation of 354 words senses with polarity and report a high inter-annotator agreement. The work in sentiment analysis using sense-based features, including ours, assumes this hypothesis that *sense decides the sentiment*.

The novelty of our work lies in the following. Firstly our approach is distinctly. Akkaya et al. (2009) and Martn-Wanton et al. (2010) report performance of rule-based sentiment classification using word senses. Instead of a rule-based implementation, We used supervised learning. The supervised nature of our approach renders lexical resources unnecessary as used in Martn-Wanton et al. (2010). Rentoumi et al. (2009) suggest using word senses to detect sentence level polarity of news headlines. The authors use graph similarity to detect polarity of senses. To predict sentence level polarity, a HMM is trained on word sense and POS as the observation. The authors report that word senses particularly help understanding metaphors in these sentences. Our work differs in terms of the corpus and document sizes in addition to generating a general purpose classifier.

Another supervised approach of creating an emotional intensity classifier using concepts as features has been reported by Carrillo de Albornoz et al. (2010). This work is different based on the feature space used. The concepts used for the purpose are limited to affective classes. This restricts the size of the feature space to a limited set of labels. As opposed to this, we construct feature vectors that map to a larger sense-based space. In order to do so, we use synset offsets as representation of sense-based features.

Akkaya et al. (2009), Martn-Wanton et al. (2010) and Carrillo de Albornoz et al. (2010) perform sentiment classification of individual sentences. However, we consider a document as a unit of sentiment classification *i.e.* our goal is to predict a document on the whole as positive or negative. This is different from Pang and Lee (2004) which suggests that sentiment is associated only with subjective content. A document in its entirety is represented using sense-based features in our experiments. Carrillo de Albornoz et al. (2010) suggests expansion using WordNet relations which we also follow. This is a benefit that can be achieved only in a sense-based space.

3 Features based on WordNet Senses

In their original form, documents are said to be in lexical space since they consist of words. When the words are replaced by their corresponding senses, the resultant document is said to be in semantic space.

WordNet 2.1 (Fellbaum, 1998) has been used as the sense repository. Each word/lexeme is mapped to an appropriate synset in WordNet based on its sense and represented using the corresponding synset id of WordNet. Thus, the word *love* is disambiguated and replaced by the identifier *21758160* which consists of a POS category identifier *2* followed by synset offset identifier *1758160*. This paper refers to synset offset as synset identifiers or simply, senses.

This section first gives the motivation for using word senses and then, describes the approaches that we use for our experiments.

3.1 Motivation

Consider the following sentences as the first scenario.

1. *"Her face **fell** when she heard that she had been fired."*

2. *"The fruit **fell** from the tree."*

The word '*fell*' occurs in different senses in the two sentences. In the first sentence, '*fell*' has the meaning of '*assume a disappointed or sad expression*, whereas in the second sentence, it has the meaning of '*descend in free fall under the influence of gravity*'. A user will infer the negative polarity of the first sentence from the negative sense of '*fell*' in it while the user will state that the second sentence does not carry any sentiment. This implies that there is at least one sense of the word '*fell*' that carries sentiment and at least one that does not.

In the second scenario, consider the following examples.

1. *"The snake bite proved to be **deadly** for the young boy."*

2. *"Shane Warne is a **deadly** spinner."*

The word *deadly* has senses which carry opposite polarity in the two sentences and these senses assign the polarity to the corresponding sentence. The first sentence is negative while the second sentence is positive.

Finally in the third scenario, consider the following pair of sentences.

1. *"He speaks a **vulgar** language."*

2. *"Now that's real **crude** behavior!"*

The words *vulgar* and *crude* occur as synonyms in the synset that corresponds to the sense '*conspicuously and tastelessly indecent*'. The synonymous nature of words can be identified only if they are looked at as senses and not just words.

As one may observe, the first scenario shows that a word may have some sentiment-bearing and some non-sentiment-bearing senses. In the second scenario, we show that there may be different senses of a word that bear sentiments of opposite polarity. Finally, in the third scenario, we show how a sense can be manifested using different words, *i.e.*, words in a synset. The three scenarios motivate the use of semantic space for sentiment prediction.

3.2 Sense versus Lexeme-based Feature Representation

We annotate the words in the corpus with their senses using two sense disambiguation approaches.

As the first approach, **manual sense annotation** of documents is carried out by two annotators on two subsets of the corpus, the details of which are given in Section 5.1. This is done to determine the ideal case scenario- the skyline performance.

As the second approach, a state-of-art algorithm for domain-specific WSD proposed by Khapra et al. (2010) is used to obtain an automatically sense-tagged corpus. This algorithm called **iterative WSD or IWSD** iteratively disambiguates words by ranking the candidate senses based on a scoring function.

The two types of sense-annotated corpus lead us to four feature representations for a document:

1. Word senses that have been manually annotated (*M*)

2. Word senses that have been annotated by an automatic WSD (*I*)

3. *Manually* annotated word senses and words (both separately as features) (*Words + Sense(M)*)

4. *Automatically* annotated word senses and words (both separately as features) (*Words + Sense(I)*)

Our first set of experiments compares the four feature representations to find the feature representation with which sentiment classification gives the best performance. W+S(M) and W+S(I) are used to overcome non-coverage of WordNet for some noun synsets. In addition to this, we also present a part-of-speech-wise analysis of benefit to SA as well as effect of varying the training samples on sentiment classification accuracy.

3.3 Partial disambiguation as opposed to no disambiguation

The state-of-the-art automatic WSD engine that we use performs (approximately) with 70% accuracy on tourism domain (Khapra et al., 2010). This means that the performance of SA depends on the performance of WSD which is not very high in case of the engine we use.

A partially disambiguated document is a document which does not contain senses of all words. Our hypothesis is that disambiguation of even few words in a document can give better results than no disambiguation. To verify this, we create different variants of the corpus by disambiguating words which have candidate senses within a threshold. For example, a partially disambiguated variant of the corpus with threshold 3 for candidate senses is created by disambiguating words which have *a maximum of three candidate senses*. These synsets are then used as features for classification along with lexeme based features. We conduct multiple experiments using this approach by varying the number of candidate senses.

4 Advantage of senses: Similarity Metrics and Unknown Synsets

4.1 Synset Replacement Algorithm

Using WordNet senses provides an opportunity to use similarity-based metrics for WordNet to reduce the effect of unknown features. If a synset encountered in a test document is not found in the training corpus, it is replaced by one of the synsets present in the training corpus. The substitute synset is determined on the basis of its similarity with the synset in the test document. The synset that is replaced is referred to as an *unseen synset* as it is not known to the trained model.

For example, consider excerpts of two reviews, the first of which occurs in the training corpus while the second occurs in the test corpus.

1. " *In the night, it is a* ***lovely*** *city and...* "

2. " *The city has many* ***beautiful*** *hot spots for honeymooners.* "

The synset of '*beautiful*' is not present in the training corpus. We evaluate a similarity metric for all synsets in the training corpus with respect to the sense of *beautiful* and find that the sense of *lovely* is closest to it. Hence, the sense of *beautiful* in the test document is replaced by the sense of *lovely* which is present in the training corpus.

The replacement algorithm is described in Algorithm 1. The algorithm follows from the fact that the similarity value for a synset with itself is maximum.

4.2 Similarity metrics used

We conduct different runs of the replacement algorithm using three similarity metrics, namely LIN's similarity metric, Lesk similarity metric and Leacock and Chodorow (LCH) similarity metric. These runs generate three variants of the corpus. We compare the benefit of each of these metrics by studying their sentiment classification performance. The metrics can be described as follows:

LIN: The metric by Lin (1998) uses the information content individually possessed by two concepts in addition to that shared by them. The information content shared by two concepts A and B is given by their most specific subsumer (lowest superordinate(*lso*). Thus, this metric defines the similarity between two concepts as

$$sim_{LIN}(A,B) = \frac{2 \times \log Pr(lso(A,B))}{\log Pr(A) + \log Pr(B)} \quad (1)$$

```
Input: Training Corpus, Test Corpus,
Similarity Metric
Output: New Test Corpus
T:= Training Corpus;
X:= Test Corpus;
S:= Similarity metric;
train_concept_list = get_list_concept(T) ;
test_concept_list = get_list_concept(X);
for each concept C in test_concept_list do
    temp_max_similarity = 0 ;
    temp_concept = C ;
    for each concept D in train_concept_list do
        similarity_value = get_similarity_value(C,D,S);
        if (similarity_value > temp_max_similarity) then
            temp_max_similarity= similarity_value;
            temp_concept = D ;
        end
    end
    C = temp_concept ;
    replace_synset_corpus(C,X);
end
Return X ;
```

Algorithm 1: Synset replacement using similarity metric

Lesk: Each concept in WordNet is defined through gloss. To compute the Lesk similarity (Banerjee and Pedersen, 2002) between A and B, a scoring function based on the overlap of words in their individual glosses is used.

Leacock and Chodorow (LCH): To measure similarity between two concepts A and B, Leacock and Chodorow (1998) compute the shortest path through hypernymy relation between them under the constraint that there exists such a path. The final value is computed by scaling the path length by the overall taxonomy depth (D).

$$sim_{LCH}(A,B) = -\log\left(\frac{len(A,B)}{2D}\right) \quad (2)$$

5 Experimentation

We describe the variants of the corpus generated and the experiments in this section.

5.1 Data Preparation

We create different variants of the dataset by Ye et al. (2009). This dataset contains 600 positive and 591 negative reviews about seven travel destinations. Each review contains approximately 4-5 sentences with an average number of words per review being 80-85.

To create the manually annotated corpus, two human annotators annotate words in the corpus with senses for two disjoint subsets of the original corpus by Ye et al. (2009). The inter-annotation agreement for a subset of the corpus showed 91% sense overlap. The manually annotated corpus consists of 34508 words with 6004 synsets.

POS	#Words	P(%)	R(%)	F-Score(%)
Noun	12693	75.54	75.12	75.33
Adverb	4114	71.16	70.90	71.03
Adjective	6194	67.26	66.31	66.78
Verb	11507	68.28	67.97	68.12
Overall	34508	71.12	70.65	70.88

Table 1: Annotation Statistics for IWSD; P- Precision,R-Recall

The second variant of the corpus contains word senses obtained from automatic disambiguation using IWSD. The evaluation statistics of the IWSD is shown in Table 1. Table 1 shows that the F-score for noun synsets is high while that for adjective synsets is the lowest among all. The low recall for adjective POS based synsets can be detrimental to classification since adjectives are known to express direct sentiment (Pang et al., 2002). Hence, in the context of sentiment classification, disambiguation of adjective synsets is more critical as compared to disambiguation of noun synsets.

5.2 Experimental setup

The experiments are performed using C-SVM (linear kernel with default parameters[1]) available as a part of LibSVM[2] package. We choose to use SVM since it performs the best for sentiment classification (Pang et al., 2002). All results reported are average of five-fold cross-validation accuracies.

To conduct experiments on words as features, we first perform stop-word removal. The words are not stemmed since stemming is known to be detrimental to sentiment classification (Leopold and Kindermann, 2002). To conduct the experiments based on

[1] C=0.0,ϵ=0.0010

[2] http://www.csie.ntu.edu.tw/ cjlin/libsvm

Feature Representations	Accuracy(%)	PF	NF	PP	NP	PR	NR
Words (Baseline)	84.90	85.07	84.76	84.95	84.92	85.19	84.60
Sense (M)	89.10	88.22	89.11	91.50	87.07	85.18	91.24
Words + Sense (M)	90.20	89.81	90.43	92.02	88.55	87.71	92.39
Sense (I)	85.48	85.31	85.65	87.17	83.93	83.53	87.46
Words + Sense (I)	86.08	86.28	85.92	85.87	86.38	86.69	85.46

Table 2: Classification Results; PF-Positive F-score(%), NF-Negative F-score (%), PP-Positive Precision (%), NP-Negative Precision (%), PR-Positive Recall (%), NR-Negative Recall (%)

the synset representation, words in the corpus are annotated with synset identifiers along with POS category identifiers. For automatic sense disambiguation, we used the trained IWSD engine from Khapra et al. (2010). These synset identifiers along with POS category identifiers are then used as features. For replacement using semantic similarity measures, we used WordNet::Similarity 2.05 package by Pedersen et al. (2004).

To evaluate the result, we use accuracy, F-score, recall and precision as the metrics. Classification accuracy defines the ratio of the number of true instances to the total number of instances. Recall is calculated as a ratio of the true instances found to the total number of false positives and true positives. Precision is defined as the number of true instances divided by number of true positives and false negatives. Positive Precision (PP) and Positive Recall (PR) are precision and recall for positive documents while Negative Precision (NP) and Negative Recall (NR) are precision and recall for negative documents. F-score is the weighted precision-recall score.

6 Results and Discussions

6.1 *Comparison of various feature representations*

Table 2 shows results of classification for different feature representations. The baseline for our results is the unigram bag-of-words model (Baseline).

An improvement of 4.2% is observed in the accuracy of sentiment prediction when manually annotated sense-based features (M) are used in place of word-based features (Words). The precision of both the classes using features based on semantic space is also better than one based on lexeme space. While reported results suggest that it is more difficult to detect negative sentiment than positive sentiment (Gindl and Liegl, 2008), our results show that negative recall increases by around 8% in case of sense-based representation of documents.

The combined model of words and manually annotated senses (Words + Senses (M)) gives the best performance with an accuracy of 90.2%. This leads to an improvement of 5.3% over the baseline accuracy [3].

One of the reasons for improved performance is the feature abstraction achieved due to the synset-based features. The dimension of feature vector is reduced by a factor of 82% when the document is represented in synset space. The reduction in dimensionality may also lead to reduction in noise (Cunningham, 2008).

A comparison of accuracy of different sense representations in Table 2 shows that manual disambiguation performs better than using automatic algorithms like IWSD. Although overall classification accuracy improvement of IWSD over baseline is marginal, negative recall also improves. This benefit is despite the fact that evaluation of IWSD engine over manually annotated corpus gave an overall F-score of 71% (refer Table 1). For a WSD engine with a better accuracy, the performance of sense-based SA can be boosted further.

Thus, in terms of feature representation of documents, sense-based features provide a better overall performance as compared to word-based features.

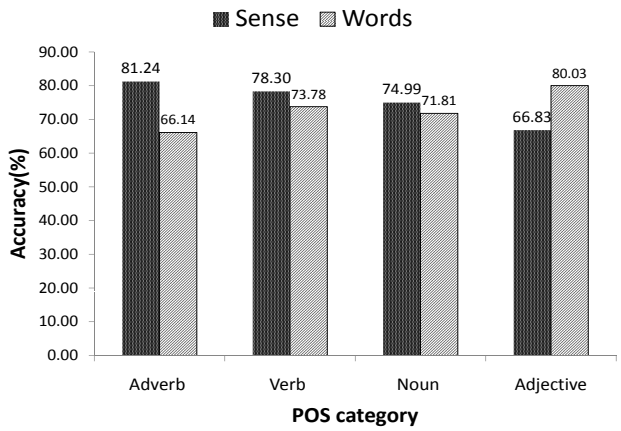

Figure 1: POS-wise statistics of manually annotated semantic space

6.2 *POS-wise analysis*

For each POS, we compare the performance of two models:

- Model trained on words of only that POS
- Model trained on word senses of only that POS

Figure 1 shows the parts-of-speech-wise classification accuracy of sentiment classification for senses (manual) and words. In the lexeme space, adjectives directly impact the classification performance. But it can be seen that disambiguation of adverb and verb synsets impact the performance of SA higher than disambiguation of nouns and adjectives.

While it is believed that adjectives carry direct sentiments, our results suggest that using adjectives alone as features may not improve the accuracy. The results prove that sentiment may be subtle at times and not expressed directly through adjectives.

As manual sense annotation is an effort and cost intensive process, the parts-of-speech-wise results suggest improvements expected from an automatic WSD engine so that it can aid sentiment classification. Table 1 suggests that the WSD engine works better for noun synsets compared to adjective and adverb synsets. While this is expected in a typical WSD setup, it is the adverbs and verbs that are more important for detecting sentiment in semantics space than nouns. The future WSD systems will have to show an improvement in their accuracy with respect to adverb and verb synsets.

	Sense		Words	
POS Category	**PF**	**NF**	**PF**	**NF**
Adverb	79.65	80.45	70.25	73.68
Verb	75.50	79.28	62.23	63.12
Noun	73.39	75.40	69.77	72.55
Adjective	63.11	65.03	78.29	79.20

Table 3: POS-wise F-score for sense (M) and Words;PF-Positive F-score(%), NF- Negative F-score (%)

Table 3 shows the positive and negative F-score statistics with respect to different POS. Detection of negative reviews using lexeme space is difficult. POS-wise statistics also suggest the same. It should be noted that adverb and verb synsets play an important role in negative class detection. Thus, an automatic WSD engine should give importance to the correct disambiguation of these POS categories.

6.3 *Effect of size of training corpus*

#Training Documents	**W**	**M**	**I**	**W+S(M)**	**W+S(I)**
100	76.5	87	79.5	82.5	79.5
200	81.5	88.5	82	90	84
300	79.5	92	81	89.5	82
400	82	90.5	81	94	85.5
500	83.5	91	85	96	82.5

Table 4: Accuracy (%) with respect to number of training documents; W: Words, M: Manual Annotation, I: IWSD-based sense annotation, W+S(M): Word+Senses (Manual annotation), W+S(I): Word+Senses(IWSD-based sense annotation)

From table 2, the benefit of sense disambiguation to sentiment prediction is evident. In addition, Table 4 shows variation of classification accuracy with respect to different number of training samples based on different approaches of annotation explained in previous sections. The results are based on a blind set of 90 test samples from both the polarity labels [4].

[3]The improvement in results of semantic space is found to be statistically significant over the baseline at 95% confidence level when tested using a paired t-test.

[4]No cross validation is performed for this experiment

Compared to lexeme-based features, manually annotated sense based features give better performance with lower number of training samples. IWSD is also better than lexeme-based features. A SA system trained on 100 training samples using manually annotated senses gives an accuracy of 87%. Word-based features never achieve this accuracy. An IWSD-based system requires lesser samples when compared to lexeme space for an equivalent accuracy. Note that model based on words + senses(M) features achieve an accuracy of 96% on this test set.

This implies that the synset space, in addition to benefit to sentiment prediction in general, requires *lesser number of training samples* in order to achieve the accuracy that lexeme space can achieve with a larger number of samples.

6.4 *Effect of Partial disambiguation*

Figure 2 shows the accuracy, positive F-score and negative F-score with respect to different thresholds of candidate senses for partially disambiguated documents as described in Section 3.3. We compare the performance of these documents with word-based features (B) and sense-based features based on manually (M) or automatically obtained senses (I). Note that Sense (I) and Sense (M) correspond to completely disambiguated documents.

In case of partial disambiguation using manual annotation, disambiguating words with less than three candidate senses performs better than others. For partial disambiguation that relies on an automatic WSD engine, a comparable performance to full disambiguation can be obtained by disambiguating words which have a maximum of four candidate senses.

As expected, completely disambiguated documents provide the best F-score and accuracy figures[5]. However, a performance comparable to complete disambiguation can be attained by disambiguating selective words.

Our results show that even if highly ambiguous (in terms of senses) words are not disambiguated by a WSD engine, the performance of sentiment classification improves.

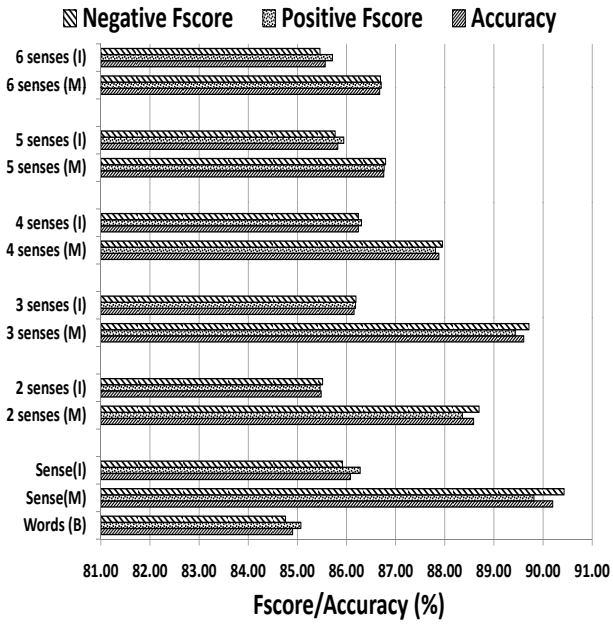

Figure 2: Partial disambiguation statistics: Accuracy,Positive F-score, Negative F-score variation with respect to sense disambiguation difficult level is shown. Words(B): baseline system

6.5 *Synset replacement using similarity metrics*

Table 5 shows the results of synset replacement experiments performed using similarity metrics defined in section 4. The similarity metric value NA shown in the table indicates that synset replacement is not performed for the specific run of experiment. For this set of experiments, we use the combination of sense and words as features (indicated by *Senses+Words (M)*).

Synset replacement using a similarity metric shows an improvement over using words alone. However, the improvement in classification accuracy is marginal compared to sense-based representation without synset replacement (Similarity Metric=NA).

Replacement using LIN and LCH metrics gives marginally better results compared to the vanilla setting in a manually annotated corpus. The same phenomenon is seen in the case of IWSD based approach[6]. The limited improvement can be due to the fact that since LCH and LIN consider only IS-A

[5] All results are statistically significant with respect to baseline

[6] Results based on LCH and LIN similarity metric for automatic sense disambiguation is not statistically significant with α=0.05

Feature Representation	Similarity Metric	Accuracy	PF	NF	PP	NP	PR	NR
Words (Baseline)	**NA**	84.90	85.07	84.76	84.95	84.92	85.19	84.60
Words + Sense(M)	**NA**	90.20	89.81	90.43	92.02	88.55	87.71	92.39
Words + Sense(I)	**NA**	86.08	86.28	85.92	85.87	86.38	86.69	85.46

Words + Sense (M)	**Lesk**	91.12	90.70	91.38	93.55	88.97	88.03	93.92
Words + Sense (I)	**LCH**	85.66	85.85	85.52	85.67	85.76	86.02	85.28
Words + Sense(I)	**LIN**	86.16	86.37	86.00	86.06	86.40	86.69	85.61
Words + Sense (I)	**Lesk**	86.25	86.41	86.10	86.31	86.26	86.52	85.95

Table 5: Similarity Metric Analysis using different similarity metrics with synsets and a combinations of synset and words;PF-Positive F-score(%), NF-Negative F-score (%), PP-Positive Precision (%), NP-Negative Precision (%), PR-Positive Recall (%), NR-Negative Recall (%)

Top information content features (in %)	IWSD synset #	Manual synsets #	Match synset #	Match Synsets (%)	Unmatched Synset(%)
10	601	722	288	39.89	60.11
20	1199	1443	650	45.05	54.95
30	1795	2165	1005	46.42	53.58
40	2396	2889	1375	47.59	52.41
50	2997	3613	1730	47.88	52.12

Table 6: Comparison of top information gain-based features of manually annotated corpora and automatically annotated corpora

relationship in WordNet, the replacement happens only for verbs and nouns. This excludes adverb synsets which we have shown to be the best features for a sense-based SA system.

Among all similarity metrics, the best classification accuracy is achieved using Lesk. The system performs with an overall classification accuracy of 91.12%, which is a substantial improvement of 6.2% over baseline. Again, it is only 1% over the vanilla setting that uses combination of synset and words. However, the similarity metric is not sophisticated as LIN or LCH.

Thus, we observe a marginal improvement by using similarity-based metrics for WordNet. A good metric which covers all POS categories can provide substantial improvement in the classification accuracy.

7 Error Analysis

For sentiment classification based on semantic space, we classify the errors into four categories. The examples quoted are from manual evaluation of the results.

1. *Effect of low disambiguation accuracy of IWSD engine:* SA using automatic sense annotation depends on the annotation system used. To assess the impact of IWSD system on sentiment classification, we compare the feature set based on manually annotated senses with the feature set based on automatically annotated senses. We compare the most informative features of the two classifiers. Table 6 shows the number of top informative features (synset) selected as the percentage of total synset features present when the semantic representation of documentation is used. The matched synset column represents the number of IWSD synsets that match

with manually annotated synsets.

The number of top performing features is more in case of manually annotated synsets. This can be attributed to the total number of synsets tagged in the two variant of the corpus. The reduction in the performance of SA for automatically annotated senses is because of the number of unmatched synsets.

Thus, although the accuracy of IWSD is currently 70%, the table indicates that IWSD can match the performance of manually annotated senses for SA if IWSD is able to tag correctly those top information content synsets. This aspect needs to be investigated further.

2. *Negation Handling:* For the purpose of this work, we concentrate on words as units for sentiment determination. Syntax and its contribution in understanding sentiment is neglected and hence, positive documents which contain negations are wrongly classified as negative. Negation may be direct as in the excerpt '*....what is there not to like about Vegas.*' or may be double as in the excerpt'*...that aren't insecure'*.

3. *Interjections and WordNet coverage:* Recent informal words are not covered in WordNet and hence, do not get disambiguated. The same is the case for interjections like *'wow'*,*'duh'* which sometimes carry direct sentiment. Lexical resources which include them can be used to incorporate information about these lexical units.

4. *Document Specificity:* The assumption underlying our analysis is that a document contains description of only one topic. However, reviews are generic in nature and tend to express contrasting sentiment about sub-topics . For example, a travel review about Paris can talk about restaurants in Paris, traffic in Paris, public behaviour, etc. with opposing sentiments. Assigning an overall sentiment to a document is subjective in such cases.

8 Conclusion & Future Work

This work presents an empirical benefit of WSD to sentiment analysis. The study shows that supervised sentiment classifier modeled on wordNet senses perform better than word-based features. We show how the performance impact differs for different automatic and manual techniques, parts-of-speech, different training sample size and different levels of disambiguation. In addition, we also show the benefit of using WordNet based similarity metrics for replacing unknown features in the test set. Our results support the fact that not only does sense space improve the performance of a sentiment classification system, but also opens opportunities for improvement using better similarity metrics.

Incorporation of syntactical information along with semantics can be an interesting area of work. More sophisticated features which include the two need to be explored. Another line of work is in the context of cross-lingual sentiment analysis. Current solutions are based on machine translation which is very resource-intensive. Using a bi-lingual dictionary which maps WordNet across languages, such a machine translation sub-system can be avoided.

Acknowledgment

We thank Jaya Saraswati and Rajita Shukla from CFILT Lab, IIT Bombay for annotating the dataset used for this work. We also thank Mitesh Khapra and Salil Joshi, IIT Bombay for providing us with the IWSD engine for the required experiments.

Abstract

In this paper, we introduce a *connotation lexicon*, a new type of lexicon that lists words with connotative polarity, i.e., words with positive connotation (e.g., award, promotion) and words with negative connotation (e.g., cancer, war). Connotation lexicons differ from much studied sentiment lexicons: the latter concerns words that *express* sentiment, while the former concerns words that *evoke* or *associate with* a specific polarity of sentiment. Understanding the connotation of words would seem to require common sense and world knowledge. However, we demonstrate that much of the connotative polarity of words can be inferred from natural language text in a nearly unsupervised manner. The key linguistic insight behind our approach is *selectional preference* of *connotative predicates*. We present graph-based algorithms using PageRank and HITS that collectively learn connotation lexicon together with connotative predicates. Our empirical study demonstrates that the resulting connotation lexicon is of great value for sentiment analysis complementing existing sentiment lexicons.

1 Introduction

In this paper, we introduce a ***connotation lexicon***, a new type of lexicon that lists words with connotative polarity, i.e., words with positive connotation (e.g., award, promotion) and words with negative connotation (e.g., cancer, war). Connotation lexicons differ from sentiment lexicons that are studied in much of previous research (e.g., Esuli and Sebastiani (2006), Wilson et al. (2005a)): the latter concerns words that *express* sentiment either explicitly or implicitly, while the former concerns words that *evoke* or even simply *associate with* a specific polarity of sentiment. To our knowledge, there has been no previous research that investigates polarized connotation lexicons.

Understanding the connotation of words would seem to require common sense and world knowledge at first glance, which in turn might seem to require human encoding of knowledge base. However, we demonstrate that much of the connotative polarity of words can be inferred from natural language text in a nearly unsupervised manner.

The key linguistic insight behind our approach is *selectional preference* of *connotative predicates*. We define a ***connotative predicate*** as a predicate that has selectional preference on the connotative polarity of some of its semantic arguments. For instance, in the case of the connotative predicate *"prevent"*, there is strong selectional preference on negative connotation with respect to the thematic role (semantic role) "THEME". That is, statistically speaking, people tend to associate negative connotation with the THEME of *"prevent"*, e.g., *"prevent cancer"* or *"prevent war"*, rather than positive connotation, e.g., *"prevent promotion"*. In other words, even though it is perfectly valid to use words with positive connotation in the THEME role of *"prevent"*, statistically more dominant connotative polarity is negative. Similarly, the THEME of *"congratulate"* or *"praise"* has strong selectional preference on positive connotation.

The theoretical concept supporting the selective

alleviate, accuse, avert, avoid, cause, complain, condemn, criticize, detect, eliminate, eradicate, mitigate, overcome, prevent, prohibit, protest, refrain, suffer, tolerate, withstand

Table 2: Negatively Connotative Predicates w.r.t. THEME

preference of connotative predicates is that of semantic prosody in corpus linguistics. Semantic prosody describes how some of the seemingly neutral words (e.g., "cause") can be perceived with positive or negative polarity because they tend to collocate with words with corresponding polarity (e.g., Sinclair (1991), Louw et al. (1993), Stubbs (1995), Stefanowitsch and Gries (2003)). In this work, we demonstrate that statistical approaches that exploit this very concept of semantic prosody can successfully infer connotative polarity of words.

Having described the key linguistic insight, we now illustrate our graph-based algorithms. Figure 1 depicts the mutually reinforcing relation between connotative predicates (nodes on the left-hand side) and words with connotative polarity (node on the right-hand side). The thickness of edges represents the strength of the association between predicates and arguments. For brevity, we only consider connotation of words that appear in the THEME thematic role.

We expect that words that appear often in the THEME role of various positively (or negatively) connotative predicates are likely to be words with positive (or negative) connotation. Likewise, predicates whose THEME contains words with mostly positive (or negative) connotation are likely to be positively (or negatively) connotative predicates. In short, we can induce the connotative polarity of words using connotative predicates, and inversely, we can learn new connotative predicates based on words with connotative polarity.

We hypothesize that this mutually reinforcing relation between connotative predicates and their arguments can be captured via graph centrality in graph-based algorithms. Given a small set of seed words for connotative predicates, our algorithms collectively learn connotation lexicon together with connotative predicates in a nearly unsupervised manner. A number of different graph representations are explored using both PageRank (Page et al., 1999) and HITS (Kleinberg, 1999) algorithms. Empirical study demonstrates that our graph based algorithms are highly effective in learning both connotation lexicon and connotative predicates.

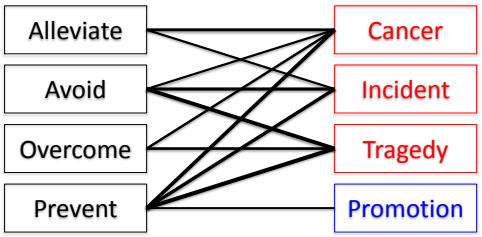

Figure 1: Bipartite graph of connotative predicates and arguments. Edge weights are proportionate to the association strength.

Finally, we quantify the practical value of our connotation lexicon in concrete sentiment analysis applications, and demonstrate that the connotation lexicon is of great value for sentiment classification tasks complementing conventional sentiment lexicons.

2 Connotation Lexicon & Connotative Predicate

In this section, we define *connotation lexicon* and *connotative predicates* more formally, and contrast them against words in conventional sentiment lexicons.

2.1 Connotation Lexicon

This lexicon lists words with positive and negative connotation, as defined below.

- **Words with positive connotation:** In this work, we define words with positive connotation as those that describe physical objects or abstract concepts that people generally value, cherish or care about. For instance, we regard words such as "freedom", "life", or "health" as

words with positive connotation. Some of these words may express subjectivity either explicitly or implicitly, e.g., "joy" or "satisfaction". However, a substantial number of words with positive connotation are purely objective, such as "life", "health", "tenure", or "scientific".

- **Words with negative connotation:** We define words with negative connotation as those that describe physical objects or abstract concepts that people generally disvalue or avoid. Similarly as before, some of these words may express subjectivity (e.g., "disappointment", "humiliation"), while many other are purely objective (e.g., "bedbug", "arthritis, "funeral").

Note that this explicit and intentional inclusion of objective terms makes connotation lexicons differ from sentiment lexicons: most conventional sentiment lexicons have focused on subjective words by definition (e.g., Wilson et al. (2005b)), as many researchers use the term *sentiment* and *subjectivity* interchangeably (e.g., Wiebe et al. (2005)).

2.2 Connotative Predicate

In this work, connotative predicates are those that exhibit selectional preference on the connotative polarity of some of their arguments. We emphasize that the polarity of connotative predicates does *not* coincide with the polarity of sentiment in conventional sentiment lexicons, as will be elaborated below.

- **Positively connotative predicate:** In this work, we define positively connotative predicates as those that expect positive connotation in some arguments. For example, "congratulate" or "save" are positively connotative predicates that expect words with positive connotation in the THEME argument: people typically congratulate something positive, and save something people care about. More examples are shown in Table 1.
- **Negatively connotative predicate:** In this work, we define negatively connotative predicates as those that expect negative connotation in some arguments. For instance, predicates such as "prevent" or "suffer" tend to project negative connotation in the THEME argument. More examples are shown in Table 2.

Note that positively connotative predicates are not necessarily positive sentiment words. For instance "save" is not a positive sentiment word in the lexicon published by Wilson et al. (2005b). Inversely, (strongly) positive sentiment words are not necessarily (strongly) positively connotative predicates, e.g., "illuminate", "agree". Likewise, negatively connotative predicates are not necessarily negative sentiment words. For instance, predicates such as "prevent", "detect", or "cause" are not negative sentiment words, but they tend to correlate with negative connotation in the THEME argument. Inversely, (strongly) negative sentiment words are not necessarily (strongly) negatively connotative predicates, e.g., "abandon" ("abandoned [something valuable]").

3 Graph Representation

In this section, we explore the graphical representation of our task. Figure 1 depicts the key intuition as a bipartite graph, where the nodes on the left-hand side correspond to connotative predicates, and the nodes on the right-hand side correspond to words in the THEME argument. There is an edge between a predicate p and an argument a, if the argument a appears in the THEME role of the predicate p. For brevity, we explore only verbs as the predicates, and words in the THEME role of the predicates as arguments. Our work can be readily extended to exploit other predicate-argument relations however.

Note that there are many sources of noise in the construction of graph. For instance, some of the predicates might be negated, changing the semantic dynamics between the predicate and the argument. In addition, there might be many unusual combinations of predicates and arguments, either due to data processing errors or due to idiosyncratic use of language. Some of such combinations can be valid ones (e.g., "prevent promotion"), challenging the learning algorithm with confusing evidence.

We hypothesize that by focusing on the important part of the graph via centrality analysis , it is possible to infer connotative polarity of words despite various noise introduced in the graph structure. This implies that it is important to construct the graph structure so as to capture important linguistic relations between predicates and arguments. With this goal in mind,

we next explore the directionality of the edges and different strategies to assign weights to them.

3.1 Undirected (Symmetric) Graph

First we explore undirected edges. In this case, we assign weight for each undirected edge between a predicate p and an argument a. Intuitively, the weight should correspond to the strength of relatedness or association between the predicate p and the argument a. We use Pointwise Mutual Information (PMI), as it has been used by many previous research to quantify the association between two words (e.g., Turney (2001), Church and Hanks (1990)). The PMI score between p and a is defined as follows:

$$w(p-a) := PMI(p,a) = log\frac{P(p,a)}{P(p)P(a)}$$

The log of the ratio is positive when the pair of words tends to co-occur and negative when the presence of one word correlates with the absence of the other word.

3.2 Directed (Asymmetric) Graph

Next we explore directed edges. That is, for each connected pair of a predicate p and an argument a, there are two edges in opposite directions: $e(p \rightarrow a)$ and $e(a \rightarrow p)$. In this case, we explore the use of asymmetric weights using conditional probability. In particular, we define weights as follows:

$$w(p \rightarrow a) := P(a|p) = \frac{P(p,a)}{P(p)}$$

$$w(a \rightarrow p) := P(p|a) = \frac{P(p,a)}{P(a)}$$

Having defined the graph structure, next we explore algorithms that analyze graph centrality via random walks. In particular, we investigate the use of HITS algorithm (Section 4), and PageRank (Section 5).

4 Lexicon Induction using HITS

The graph representation described thus far (Section 3) captures general semantic relations between predicates and arguments, rather than those specific to connotative predicates and arguments. Therefore in this section, we explore techniques to augment the graph representation so as to bias the centrality of the graph toward connotative predicates and arguments.

In order to establish a learning bias, we start with a small set of seed words for *just* connotative predicates. We use 20 words for each polarity, as listed in Table 1 and Table 2. These seed words act as prior knowledge in our learning. We explore two different techniques to incorporate prior knowledge into random walk, as will be elaborated in Section 4.2 & 4.3, followed by brief description of HITS in Section 4.1.

4.1 Hyperlink-Induced Topic Search (HITS)

HITS (Hyperlink-Induced Topic Search) algorithm (Kleinberg, 1999), also known as Hubs and authorities, is a link analysis algorithm that is particularly suitable to model mutual reinforcement between two different types of nodes: hubs and authorities. The definitions of hubs and authorities are given recursively. A (good) hub is a node that points to many (good) authorities, and a (good) authority is a node pointed by many (good) hubs.

Notice that the mutually reinforcing relationship is precisely what we intend to model between connotative predicates and arguments. Let $G = (P, A, E)$ be the bipartite graph, where P is the set of nodes corresponding to connotative predicates, A is the set of nodes corresponding to arguments, and E is the set of edges among nodes. $(P_i, A_j) \in E$ if and only if the predicate P_i and the argument A_i occur together as a predicate – argument pair in the corpus. The co-occurrence matrix derived from our corpus is denoted as L, where

$$L_{ij} = \begin{cases} w(i,j) & if(P_i, A_j) \in E \\ 0 & otherwise \end{cases}$$

The value of $w(i,j)$ is set to $w(i-j)$ as defined in Section 3.1 for undirected graphs, and $w(i \rightarrow j)$ defined in Section 3.2 for directed graphs.

Let $a(A_i)$ and $h(A_i)$ be the authority and hub score respectively, for a given node $A_i \in A$. Then we compute the authority and hub score recursively as follows:

$$a(A_i) = \sum_{P_i, A_j \in E} w(i,j)h(A_j) + \sum_{P_j, A_i \in E} h(P_j)w(j,i)$$

$$h(A_i) = \sum_{P_i, A_j \in E} w(i,j)a(A_j) + \sum_{P_j, A_i \in E} a(P_j)w(j,i)$$

The scores $a(P_i)$ and $h(P_i)$ for $P_i \in P$ are defined similarly as above.

In what follows, we describe two different techniques to incorporate prior knowledge. Note that it is possible to apply each of the following techniques to both directed and undirected graph representations introduced in Section 3. Also note that for each technique, we construct two separate graphs G^+ and G^- corresponding to positive and negative polarity respectively. That is, G^+ learns positively connotative predicates and arguments, while G^- learns negatively connotative predicates and arguments.

4.2 Prior Knowledge via Truncated Graph

First we introduce a method based on graph truncation. In this method, when constructing the bipartite graph, we limit the set of predicates P to only those words in the seed set, instead of including all words that can be predicates. In a way, the truncated graph representation can be viewed as the query induced graph on which the original HITS algorithm was invented (Kleinberg, 1999).

The truncated graph is very effective in reducing the level of noise that can be introduced by predicates of the opposite polarity. It may seem like we cannot discover new connotative predicates in the truncated graph however, as the graph structure is limited only to the seed predicates. We address this issue by alternating truncation to different side of the graph, i.e., left (predicates) or right (arguments), as illustrated in Figure 1, through multiple rounds of HITS.

For instance, we start with the graph $G = (P^o, A, E(P^o))$ that is truncated only on the left-hand side, with the seed predicates P^o. Here, $E(P^o)$ denotes the reduced set of edges discarding those edges that connect to predicates not in P^o. Then, we apply HITS algorithm until convergence to discover new words with connotation, and this completes the first round of HITS.

Next we begin the second round. Let A^o be the new words with connotation that are found in the first round. We now set A^o as seed words for the second phase of HITS, where we construct a new graph $G = (P, A^o, E(A^o))$ that is truncated only on the right-hand side, with full candidate words for predicates included on the left-hand side. This alternation can be repeated multiple times to discover many new connotative predicates and arguments.

4.3 Prior Knowledge via Focussed Graph

In the truncated graph described above, one potential concern is that the discovery of new words with connotation is limited to those that happen to correlate well with the seed predicates. To mitigate this problem, we explore an alternative technique based on the full graph, which we will name as *focussed graph*.

In this method, instead of truncating the graph, we simply emphasize the important portion of the graph via edge weights. That is, we assign high weights to those edges that connect a seed predicate with an argument, while assigning low weights for those edges that connect to a predicate outside the seed set. This way, we allow predicates not in the seed set to participate in hubs and authority scores, but in a much suppressed way. This method can be interpreted as a smoothed version of the truncated graph described in Section 4.2.

More formally, if the node A_i is connected to the seed predicate P_j, the value of co-occurrence matrix L_{ij} is defined by prior knowledge(e.g. $PMI(A_i, P_j)$ or $P(A_i|P_j)$), otherwise a small constant ϵ is assigned to the edge.

$$L_{ij} = \begin{cases} w(i,j) & if P_j \in E^o \\ \epsilon & otherwise \end{cases}$$

Similarly to the truncated graph, we proceed with multiple rounds of HITS, focusing different part of the bipartite graph alternately.

5 Lexicon Induction using PageRank

In this section, we explore the use of another popular approach for link analysis: PageRank (Page et al., 1999). We first describe PageRank algorithm briefly in Section 5.1, then introduce two different techniques to incorporate prior knowledge in Section 5.2 and 5.3.

5.1 PageRank

Let $G = (V, E)$ be the graph, where $v_i \in V = P \cup A$ are nodes (words) for the disjunctive set of predicates (P) and arguments (A), and $e_{(i,j)} \in E$ are edges. Let $In(i)$ be the set of nodes with an edge leading to n_i and similarly, $Out(i)$ be the set

of nodes that n_i has an edge leading to. At a given iteration of the algorithm, we update the score of n_i as follows:

$$S(i) = \alpha \sum_{j \in In(i)} S(j) \times \frac{w(i,j)}{|Out(i)|} + (1 - \alpha) \quad (1)$$

where the value α is constant *damping factor*. The value of α is typically set to 0.85. The value of $w(i,j)$ is set to $w(i-j)$ as defined in Section 3.1 for undirected graphs, and $w(i \rightarrow j)$ as defined in Section 3.2 for directed graphs. As before, we will consider two different techniques to incorporate prior knowledge into the graph analysis as follows.

5.2 Prior Knowledge via Truncated Graph

Unlike HITS, which was originally invented for a query-induced graph, PageRank is typically applied to the full graph. However, we can still apply the truncation technique introduced in Section 4.2 to PageRank as well. To do so, when constructing the bipartite graph, we limit the set of predicates P to only those words in the seed set, instead of including all words that can be predicates. Graph truncation eliminates the noise that can be introduced by predicates of the opposite polarity. However, in order to learn new predicates, we need to perform multiple rounds of PageRank, truncating different side of the bipartite graph alternately. Refer to Section 4.2 for futher details.

5.3 Prior Knowledge via Teleportation

We next explore what is known as teleportation technique for topic sensitive PageRank (Haveliwala, 2002). For this, we use the following equation that is slightly augmented from Equation 1.

$$S(i) = \alpha \sum_{j \in In(i)} S(j) \times \frac{w(i,j)}{|Out(i)|} + (1 - \alpha)\, \epsilon_i \quad (2)$$

Here, the new term ϵ_i is a *smoothing factor* that prevents cliques in the graph from garnering reputation through feedback (Bianchini et al. (2005)). In order to emphasize important portion of the graph, i.e., subgraphs connected to the seed set, we assign non-zero ϵ scores to only those important nodes, i.e., the seed set. Intuitively, this will cause the random walk to restart from the seed set with $(1-\alpha)$ = 0.15 probability for each step.

6 The Use of Google Web 1T Data

In order to implement the network of connotative predicates and arguments, we need a substantially large amount of documents. The quality of the co-occurrence statistics is expected to be proportionate to the size of corpus, but collecting and processing such a large amount of data is not trivial. We therefore resort to the Google Web 1T data (Brants and Franz., 2006), which consists of Google n-gram counts (frequency of occurrence of each n-gram) for $1 \leq n \leq 5$. The use of Web 1T data will lessen the challenge with respect to data acquisition, while still allowing us to enjoy the co-occurrence statistics of web-scale data. Because Web 1T data is just n-gram statistics, rather than a collection of normal documents, it does not provide co-occurrence statistics of any random word pairs. However, it provides a nice approximation to the particular co-occurrence statistics we are interested in, which are, predicate – argument pairs. This is because the THEME argument of a verb predicate is typically on the right hand side of the predicate, and the argument is within the close range of the predicate.

We now describe how to derive co-occurrence statistics of each predicate – argument pair using the Web 1T data. For a given predicate p and an argument a, we add up the count (frequency) of all n-grams ($2 \leq n \leq 5$) that match the following pattern:

$$[p]\ [\star]^{n-2}\ [a]$$

where p must be the first word (head), a must be the last word (tail), and $[\star]^{n-2}$ matches any $n-2$ number of words between p and a. Note that this rule enforces the argument a to be on the right hand side of the predicate p. To reduce the level of noise, we do not allow the wildcard $[\star]$ to match any punctuation mark, as such n-grams are likely to cross sentence boundaries representing invalid predicate – argument relations. We consider a word as a predicate if it is tagged as a verb by a Part-of-Speech tagger (Toutanova and Manning, 2000). For argument $[a]$, we only consider content-words.

The use of web n-gram statistics necessarily invites certain kinds of noise. For instance, some of the $[p]\ [\star]^{n-2}\ [a]$ patterns might not correspond to a valid predicate – argument relation. However, we expect that our graph-based algorithms — HITS and

PageRank — will be able to discern valid relations from noise, by focusing on the important part of the graph. In other words, we expect that good predicates will be supported by good arguments, and vice versa, thereby resulting in a reliable set of predicates and arguments that are mutually supported by each other.

7 Experiments

As a baseline, we use a simple method dubbed *FREQ*, which uses co-occurrence frequency with respect to the seed predicates. Using the pattern $[p]\ [\star]^{n-2}\ [a]$ (see Section 6), we collect two sets of n-gram records: one set using the positive connotative predicates, and the other using the negative connotative predicates. With respect to each set, we calculate the following for each word a,

- Given [a], the number of unique $[p]$ as $f1$
- Given [a], the number of unique phrases $[\star]^{n-2}$ as $f2$
- The number of occurrences of $[a]$ as $f3$

We then obtain the score σ_{a_+} for positive connotation and σ_{a_-} for negative connotation using the following equations that take a linear combination of $f1$, $f2$, and $f3$ that we computed above with respect to each polarity.

$$\sigma_{a_+} = \alpha \times \sigma_{f1_+} + \beta \times \sigma_{f2_+} + \gamma \times \sigma_{f3_+} \quad (3)$$

$$\sigma_{a_-} = \alpha \times \sigma_{f1_-} + \beta \times \sigma_{f2_-} + \gamma \times \sigma_{f3_-} \quad (4)$$

Note that the coefficients α, β and γ are determined experimentally. We assign positive polarity to the word a, if $\sigma_{a_+} >> \sigma_{a_-}$ and vice versa.

7.1 Comparison against Sentiment Lexicon

The polarity defined in the connotation lexicon differs from that of conventional sentiment lexicons in which we aim to recognize more subtle sentiment that correlates with words. Nevertheless, we provide agreement statistics between our connotation lexicon and conventional sentiment lexicons for comparison purposes. We collect statistics with respect to the following two resources: General Inquirer (Stone and Hunt, 1963) and Opinion Finder (Wilson et al., 2005b).

For polarity $\lambda \in \{+, -\}$, let $count_{\text{sentlex}(\lambda)}$ denote the total number of words labeled as λ in a given sentiment lexicon, and let $count_{\text{agreement}(\lambda)}$ denote the total number of words labeled as λ by both the given sentiment lexicon and our connotation lexicon. In addition, let $count_{\text{overlap}(\lambda)}$ denote the total number of words that are labeled as λ by our connotation lexicon that are also included in the reference lexicon with or without the same polarity. Then we compute $prec_\lambda$ as follows:

$$prec_\lambda\ \% = \frac{count_{\text{agreement}(\lambda)}}{count_{\text{overlap}(\lambda)}} \times 100$$

We compare $prec_\lambda\ \%$ for three different segments of our lexicon: the top 100, top 1000, and the entire lexicon. We compare the lexicons provided by the seven variations of our algorithm. Results are shown in Table 3 & 4.

The acronym of each different method is defined as follows: **HITS-sT** & **HITS-aT** correspond to the **S**ymmetric (undirected) and **A**symmetric (directed) version of the **T**runcated method respectively. **HITS-sF** & **HITS-aF** correspond to the

Positive: include, offer, obtain, allow, build, increase, ensure, contain, pursue, fulfill, maintain, recommend, represent, require, respect
Negative: abate, die, condemn, deduce, investigate, commit, correct, apologize, debilitate, dispel, endure, exacerbate, indicate, induce, minimize

Table 5: Examples of newly discovered connotative predicates

Positive: boogie, housewarming, persuasiveness, kickoff, playhouse, diploma, intuitively, monument, inaugurate, troubleshooter, accompanist
Negative: seasickness, overleap, gangrenous, suppressing, fetishist, unspeakably, doubter, bloodmobile, bureaucratized

Table 6: Examples of newly discovered words with connotations: these words are treated as neutral in some conventional sentiment lexicons.

symmetric and asymmetric version of the **F**ocused method. Finally, **Page-aT** & **Page-aF** correspond to the **T**runcation and teleportation (**F**ocused) respectively.

Asymmetric HITS on a directed truncated graph (**HITS-aT**) and topic-sensitive PageRank (**Page-aF**) achieve the best performance in most cases, especially for top ranked words which have a higher average frequency. The difference between these two top performers is not large, but statistically significant using wilcoxon test with $p < 0.03$. Standard PageRank (**Page-aT**) achieves the third best performance overall. All these top performing ones (**HITS-aT**, **Page-aF**, **Page-aT**) outperform the baseline approach (**FREQ**) statistically significantly with $p < 0.001$. For brevity, we omit the PageRank results based on the undirected graphs, as the performance of those was not as good as that of directed ones.

7.2 Extrinsic Evaluation via Sentiment Analysis

Next we perform extrinsic evaluation to quantify the practical value of our connotation lexicon in concrete sentiment analysis applications. In particular, we make use of our connotation lexicon for binary sentiment classification tasks in two different ways:

- Unsupervised classification by voting. We define r as the ratio of positive polarity words to negative polarity words in the lexicon. In our experiment, penalty is 0 for positive and -0.5 for negative.

$$score(x_+) = 1 + penalty_+(r, \#positive)$$

$$score(x_-) = -1 + penalty_-(r, \#negative)$$

- Supervised classification using SVM. We use bag-of-words features for baseline. In order to quantify the effect of different lexicons, we add additional features based on the following scores as defined below:

$$score_{raw}(x) = \sum_{w \epsilon x} s(w)$$

$$score_{purity}(x) = \frac{score_{raw}(x)}{\sum_{w \epsilon x} abs(s(w))}$$

The two corpora we use are SemEval2007 (Strapparava and Mihalcea, 2007) and Sentiment Twitter.[1] The Twitter dataset consists of tweets containing either a *smiley* emoticon (representing positive sentiment) or a *frowny* emoticon (representing negative sentiment), we randomly select 50000 *smiley* tweets and 50000 *frowny* tweets.[2] We perform a 5-fold cross validation.

In Table 8, we find very promising results, particularly for Twitter dataset, which is known to be very noisy. Notice that the use of Top 6k words from our connotation lexicon along with OpinionFinder lexicon boost the performance up to 78.0%, which is significantly better than than 71.4% using only the conventional OpinionFinder lexicon. This result shows that our connotation lexicon nicely complements existing sentiment lexicon, improving practical sentiment analysis tasks.

[1] http://www.stanford.edu/~alecmgo/cs224n/twitterdata.2009.05.25.c.zip

[2] We filter out stop-words and words appearing less than 3 times. For Twitter, we also remove usernames of the format *@username* occurring within tweet bodies.

7.3 Intrinsic Evaluation via Human Judgment

In order to measure the quality of the connotation lexicon, we also perform human judgment study on a subset of the lexicon. Human judges are asked to quantify the degree of connotative polarity of each given word using an integer value between 1 and 5, where 1 and 5 correspond to the most negative and positive connotation respectively. When computing the annotator agreement score or evaluating our connotation lexicon against human judgment, we consolidate 1 and 2 into a single negative class and 4 and 5 into a single positive class. The Kappa score between two human annotators is 0.78.

As a control set, we also include 100 words taken from the General Inquirer lexicon: 50 words with positive sentiment, and 50 words with negative sentiment. These words are included so as to measure the quality of human judgment against a well-established sentiment lexicon. The words were presented in a random order so that the human judges will not know which words are from the General Inquirer lexicon and which are from our connotative lexicon. For the words in the control set, the annotators achieved 94% (97% lenient) accuracy on the positive set and 97% on the negative set.

Note that some words appear in both positive and negative connotation graphs, while others appear in only one of them. For instance, if a given word x appears as an argument for only positive connotative predicates, but never for negative ones, then x would appear only in the positive connotation graph. This means that for such word, we can assume the connotative polarity even without applying the algorithms for graph centrality. Therefore, we first evaluate the accuracy of the polarity of such words that appear only in one of the connotation graphs. We discard words with low frequency (300 in terms of Google n-gram frequency), and randomly select 50 words from each polarity. The accuracy of such words is 88% by strict evaluation and 94.5% by lenient evaluation, where lenient evaluation counts words in our polarized connotation lexicon to be correct if the human judges assign non-conflicting polarities, i.e., either neutral or identical polarity.

For words that appear in both positive and negative connotation graphs, we determine the final polarity of such words as one with higher scores given by HITS or PageRank. We randomly select words that rank at 5% of top 100, top 1000, top 2000, and top 5000 by each algorithm for human judgment. We only evaluate the top performing algorithms – HITS-aT and Page-aF – and FREQ baseline. The stratified performance for each of these methods is given in Table 9.

8 Related Work

Graph based approaches have been used in many previous research for lexicon induction. A technique named *label propagation* (Zhu and Ghahramani, 2002) has been used by Rao and Ravichandran (2009) and Velikovich et al. (2010), while random walk based approaches, PageRank in particular, have been used by Esuli and Sebastiani (2007). In our work, we explore the use of both HITS (Kleinberg, 1999) and PageRank (Page et al., 1999) and

present systematic comparison of various options for graph representation and encoding of prior knowledge. We are not aware of any previous research that made use of HITS algorithm for connotation or sentiment lexicon induction.

Much of previous research investigated the use of dictionary network (e.g., WordNet) for lexicon induction (e.g., Kamps et al. (2004), Takamura et al. (2005), Adreevskaia and Bergler (2006), Esuli and Sebastiani (2006), Su and Markert (2009), Mohammad et al. (2009)), while relatively less research investigated the use of web documents (e.g., Kaji and Kitsuregawa (2007), Velikovich et al. (2010))).

Wilson et al. (2005b) first introduced the sentiment lexicon, spawning a great deal of research thereafter. At the beginning, sentiment lexicons were designed to include only those words that *express* sentiment, that is, *subjective* words. However in recent years, sentiment lexicons started expanding to include some of those words that simply associate with sentiment, even if those words are purely objective (e.g., Velikovich et al. (2010), Baccianella et al. (2010)). This trend applies even to the most recent version of the lexicon of Wilson et al. (2005b). We conjecture that this trend of broader coverage suggests that such lexicons are practically more useful than sentiment lexicons that include only those words that are strictly subjective. In this work, we make this transition more explicit and intentional, by introducing a novel *connotation lexicon*.

Mohammad and Turney (2010) focussed on emotion *evoked* by common words and phrases. The spirit of their work shares some similarity with ours in that it aims to find the emotion *evoked* by words, as opposed to *expressed*. Two main differences are: (1) our work aims to discover even more subtle association of words with sentiment, and (2) we present a nearly unsupervised approach, while Mohammad and Turney (2010) explored the use of Mechanical Turk to build the lexicon based on human judgment.

In the work of Osgood et al. (1957), it has been discussed that connotative meaning of words can be measured in multiple scales of semantic differential, for example, the degree of "goodness" and "badness". Our work presents statistical approaches that measure one such semantic differential automatically. Our graph construction to capture word-to-word relation is analogous to that of Collins-Thompson and Callan (2007), where the graph representation was used to model more general definitions of words.

9 Conclusion

We introduced the *connotation lexicon*, a novel lexicon that list words with connotative polarity, which will be made publically available. We also presented graph-based algorithms for learning connotation lexicon together with connotative predicates in a nearly unsupervised manner. Our approaches are grounded on the linguistic insight with respect to the selectional preference of connotative predicates. Empirical study demonstrates the practical value of the connotation lexicon for sentiment analysis encouraging further research in this direction.

Hypotheses Selection Criteria in a Reranking Framework for Spoken Language Understanding

Abstract

Reranking models have been successfully applied to many tasks of Natural Language Processing. However, there are two aspects of this approach that need a deeper investigation: (i) Assessment of hypotheses generated for reranking at classification phase: baseline models generate a list of hypotheses and these are used for reranking without any assessment; (ii) Detection of cases where reranking models provide a worst result: the best hypothesis provided by the reranking model is assumed to be always the best result. In some cases the reranking model provides an incorrect hypothesis while the baseline best hypothesis is correct, especially when baseline models are accurate. In this paper we propose solutions for these two aspects: (i) a semantic inconsistency metric to select possibly more correct n-best hypotheses, from a large set generated by an SLU basiline model. The selected hypotheses are reranked applying a state-of-the-art model based on Partial Tree Kernels, which encode SLU hypotheses in Support Vector Machines with complex structured features; (ii) finally, we apply a decision strategy, based on confidence values, to select the final hypothesis between the first ranked hypothesis provided by the baseline SLU model and the first ranked hypothesis provided by the re-ranker. We show the effectiveness of these solutions presenting comparative results obtained reranking hypotheses generated by a very accurate Conditional Random Field model. We evaluate our approach on the French MEDIA corpus. The results show significant improvements with respect to current state-of-the-art and previous re-ranking models.

1 Introduction

Discriminative reranking is a widely used approach for several Natural Language Processing (NLP) tasks: Syntactic Parsing (Collins, 2000), Named Entity Recognition (Collins, 2000; Collins and Duffy, 2001), Semantic Role Labelling (Moschitti et al., 2008), Machine Translation (Shen et al., 2004), Question Answering (Moschitti et al., 2007). Recently reranking approaches have been successfully applied also to Spoken Language Understanding (SLU) (Dinarelli et al., 2009b).

Discriminative Reranking combines two models: a first SLU model is used to generate a ranked list of *n*-best hypotheses; a reranking model sorts the list based on a different score and the final result is the new top ranked hypothesis. The advantage of reranking approaches is in the possibility to learn directly complex dependencies in the output domain, as this is provided in the hypotheses generated by the baseline model.

In previous approaches complex features are extracted from the hypotheses for both training and classification phase, but there are very few studies on approaches that can be applied to search in the hypotheses space generated by the baseline SLU model. Moreover, to keep overall computational cost reasonable, the size of the n-best list is typically small (few tens). This is a limitation since the larger is the hypotheses space generated, the more likely is to find a better hypothesis. On the other hand, reranking a large set of hypotheses is computationally

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1104–1115,
Edinburgh, Scotland, UK, July 27–31, 2011.

expensive, thus a strategy to select the best hypotheses to be re-ranked would overcome this problem.

Another aspect of reranking that deserves to be deeper studied is its applicability. Although a reranking model improves the baseline model in the overall performance, in some cases the reranked best hypotheses can contain more mistakes than the baseline best hypothesis. A strategy to decide when the reranking model should be applied and when the first hypothesis of the baseline model is more accurate would improve reranking performances.

In this paper, we propose two new models for improving discriminative reranking: (a) a semantic inconsistency metric that can be applied to SLU hypotheses to select those that are more likely to be correct; (b) a model selection strategy based on the confidence scores provided by the baseline SLU model and the reranker. This provides a decision function that detects if the original top ranked hypothesis is more accurate than the reranked best hypothesis.

Our re-ranking strategies turn out to be effective on very accurate baseline models based on state-of-the-art Conditinal Random Fields (CRF) implementation (Lavergne et al., 2010). We evaluate our approach on the well-known French MEDIA corpus for SLU (Bonneau-Maynard et al., 2006). The results show that our approach significantly improves both "traditional" reranking approaches and state-of-the-art SLU models.

The remainder of the paper is organized as follows: in Section 2 we introduce the SLU task. Section 3 describes our discriminative reranking framework for SLU, in particular the baseline model adopted, in sub-section 3.1, and the reranking model, in sub-section 3.2. Section 4 describes the two strategies proposed in this paper for SLU reranking, whereas the experiments to evaluate our approaches are described in Section 5. Finally, after a discussion in Section 6, in Section 7 we draw some conclusions.

2 Spoken Language Understanding

Spoken Language Understanding is the task of representing and extracting the meaning of natural language sentences. Designing a general meaning representation which can capture the semantics of a spoken language is very complex. Therefore, in practice, the meaning representations depend on the specific application domain being modeled.

For the corpus used in this work, the semantic representation is defined in an ontology described in (Bonneau-Maynard et al., 2006). As an example, given the following natural language sentence translated from the MEDIA corpus:

"*Good morning I would like to book an hotel room in London*"

The semantic representation extraction for the SLU task is performed in two steps:

1. **Automatic Concept Labeling**

   Null{*Good morning*} **command-task**{*I would like to book*} **object-bd**{*an hotel room*} **localization-city**{*in London*}

2. **Attribute-Value Extraction**

   command-task[reservation] **object-bd**[hotel] **localization-city**[London]

command-task, **object-bd** and **localization-city** are three domain concepts, called also "attributes", defined in the ontology and **Null** is the concept for words not associated to any concept. As shown in the example, **Null** concepts are removed from the final output since they don't bring any semantic content with respect to the application domain. **reservation**, **hotel** and **London** are the normalized attribute values, defined also in the application ontology. This representation is usually called attribute-value representation.

In the last decade several probabilistic models have been proposed for the Automatic Concept Labeling step: in (Raymond et al., 2006) a conceptual language model encoded in Stochastic Finite State Transducers (SFST) is proposed. In (Raymond and Riccardi, 2007), the SFST-based model is compared with Support Vector Machines (SVM) (Vapnik, 1998) and Conditional Random Fields (CRF) (Lafferty et al., 2001). Moreover, in (Hahn et al., 2008a) two more models are applied to SLU: a Maximum Entropy (EM) model and a model coming from the Statistical Machine Translation (SMT) community (it is actually a log-linear combination of SMT models). Among these models, CRF has shown in general superior performances on sequence labeling tasks like Named Entity Recognition (NER) (Tjong Kim Sang and De Meulder, 2003), Grapheme-to-Phoneme transcription (Sejnowski and Rosenberg,

1987) and also Spoken Language Understanding (Hahn et al., 2008a).

In addition to individual systems, more recently also some system combination approaches have been tried on SLU. In (Hahn et al., 2010), two such approaches are compared, one based on weighted ROVER (Fiscus, 1997) while the other is the reranking approach proposed in (Dinarelli et al., 2009b). Both system combination approaches are applied on the MEDIA corpus, thus we will refer to (Hahn et al., 2010) for a comparison with our approach.

Like the other tasks mentioned above, SLU is usually a supervised learning task, this means that models are learned from annotated data. This is an important aspect to take into account when designing SLU systems. In this respect accurate SLU models can in part alleviate the problem of manually annotating data.

The second step of SLU, that is Attribute Value Extraction (from now on *AVE*) is performed with two approaches: a) Rule-based approaches apply Regular Expressions (RE) to map the words realizing a concept into a normalized value. Regular expressions are defined for each attribute-value pair. Given a concept and its realizing surface form, if a RE for that concept matches the surface, the corresponding value is returned.

An example of surfaces that can be mapped into the value **hotel** given the concept **object-bd** is:

1. *an hotel room*
2. *a hotel room*
3. *the hotel*

   ...

Note that these surfaces share the same keyword for the concept **object-bd**, which is "*hotel*". Thus, a possible rule extracted from data, for the concept **object-bd** can be:

$R_{object-bd}(S)$ =
if S = "an hotel room" **or**
S = "a hotel room" **or**
S = "the hotel" **then**
return "hotel"
end

This kind of rules can be easily refined using regular expressions, so that they can capture all possible linguistic patterns containing the triggering keyword ("hotel" in the example).

b) The other approach used for attribute value extraction is based on probabilistic models. In this case the model learns from data the conditional probability of values V, given the concept C and the corresponding sequence of words W realizing the concept: $P(V|W, C)$.

The most meaningful work about AVE approaches in SLU tasks is (Hahn et al., 2010).

The model used in this work for *Automatic Concept Labeling* is based on CRF. For the *Attribute-Value Extraction* phase we use a combination of rule based and probabilistic approaches. The first is made of regular expressions, as explained above. The probabilistic approach is based again on CRF.

3 Reranking Framework

This section describes the different models involved in the pipeline realising our reranking framework:

- Conditional Random Fields
- Semantic Inconsistency Metric for hypotheses selection, which is optional and is applied only at the classification phase
- Support Vector Machines with Partial Tree Kernel
- Decision Strategy to detect when the top ranked hypothesis of the baseline model is more accurate than the reranked best hypothesis

It is important to underline that the phases involved in the reranking framewrok are distinguished for a matter of clarity. In principle, the phases from the hypotheses selection to the last, the decision strategy, can be thought of as a whole reranking model.

In the next two subsection we describe the two models used for hypotheses generation and for reranking: CRF and SVM with kernel methods. The two improvements proposed in this paper and listed above are presented in a dedicated section (4).

3.1 Conditional Random Fields

CRFs have been proposed for the first time for sequence segmentation and labeling tasks in (Lafferty et al., 2001). This model belongs to the family of exponential or log-linear models. Its main characteristics are the possibility to include a huge number

of features, like the Maximum Entropy (ME) model, but computing global conditional probabilities normalized at sentence level, instead of position level like in ME. In particular this last point results very effective since it solves the label bias problem, as pointed out in (Lafferty et al., 2001).

Given a sequence of N words $W_1^N = w_1, ..., w_N$ and its corresponding sequence of concepts $C_1^N = c_1, ..., c_N$, CRF trains the conditional probabilities

$$P(C_1^N|W_1^N) = \frac{1}{Z}\prod_{n=1}^{N}\exp\left(\sum_{m=1}^{M}\lambda_m \cdot h_m(c_{n-1}, c_n, w_{n-2}^{n+2})\right) \quad (1)$$

where λ_m are the training parameters. $h_m(c_{n-1}, c_n, w_{n-2}^{n+2})$ are the feature functions capturing conditional dependencies of concepts and words. Z is a probability normalization factor in order to model well defined probability distribution:

$$Z = \sum_{\tilde{c}_1^N}\prod_{n=1}^{N} H(\tilde{c}_{n-1}, \tilde{c}_n, w_{n-2}^{n+2}) \quad (2)$$

here $\tilde{c}_{n-1}$ and $\tilde{c}_n$ are the concepts hypothesized for the previous and current words, $H(\tilde{c}_{n-1}, \tilde{c}_n, w_{n-2}^{n+2})$ is an abbreviation for $\sum_{m=1}^{M}\lambda_m \cdot h_m(c_{n-1}, c_n, w_{n-2}^{n+2})$.

The CRF model used for the *Attribute-Value Extraction* phase learns in the same way the conditional probability $P(V_1^N|C_1^N, W_1^N)$. In particular we use attributes-words concatenations on the source side and attribute values on the target side.

Two particular effective implementations of CRFs have been recently proposed. One is described in (Hahn et al., 2009) and uses a margin based criterion for probabilities estimation. The other is described in (Lavergne et al., 2010) and has been implemented in the software *wapiti*[1]. The latter solution in particular trains the model using two different regularization factors at the same time:

Gaussian prior, used as *l2* regularization and used in many softwares to avoid overfitting;

Laplacian prior, used as *l1* regularization (Riezler and Vasserman, 2010), which has the effect to filter out features with very low scores.

[1]available at `http://wapiti.limsi.fr`

The two regularization parameters are used together in the model implementing the so-called *elastic net* regularization (Zou and Hastie, 2005):

$$l(\lambda) + \rho_1\|\lambda\|_1 + \frac{\rho_2}{2}\|\lambda\|_2^2 \quad (3)$$

λ is the set of parameters of the model introduced in equation 1, $l(\lambda)$ is the minus-logarithm of equation 1, used as loss function for training CRF. $\|\lambda\|_1$ and $\|\lambda\|_2$ are the *l1* and *l2* regularization, respectively, while ρ_1 and ρ_2 are two parameters that can be optimized as usual on development data or with cross validation.

As explained in (Lavergne et al., 2010), using *l1* regularization is an effective way for feature selection in CRF at training time. Note that other approaches have been proposed for feature selection, e.g. in (McCallum, 2003). This type of features selection, performed directly at training time, yields very accurate models, since only the most meaningful features are kept in the final model, which guarantee a strong robustness on unseen data.

In this work we refer in particular to the CRF implementation described in (Lavergne et al., 2010).

3.2 SVM and Kernel Methods

Our reranking model is based on SVM (Vapnik, 1998) with the use of the Partial Tree Kernel defined in (Moschitti, 2006).

SVMs are well-known machine learning algorithms belonging to the class of maximal-margin linear classifiers (Vapnik, 1998). The model represents a hyperplane which separates the training examples with a maximum margin. The hyperplane is learned using optimization theory and is represented in the dual form as a linear combination of training examples:

$\sum_{i=1..l} y_i\alpha_i\vec{x_i}\vec{x} + b = 0$,

where $\vec{x_i}, i \in [1, .., l]$ are training examples representing objects o_i and o in any feature space, y_i is the label associated with $\vec{x_i}$ and α_i are the lagrange multipliers. The dual form of the hyperplane shows that SVM training depends on the inner product between instances. Kernel methods theory (Shawe-Taylor and Cristianini, 2004), allows us to substitute the inner product with a so-called kernel function, computing the same result: $K(o_i, o) = \vec{x_i} \cdot \vec{x}$.

The interesting aspect of using such formulation is the possibility to compare objects in arbitrarily complex feature spaces implicitly, i.e. without knowing the features to be used. Since in real world scenarios data cannot be classified using a simple linear classifier, kernel methods can be used to carry out learning in complex feature spaces. In this work we use the Partial Tree Kernel (PTK) (Moschitti, 2006).

3.3 Reranking Model

In order to give an effective representation to SLU hypotheses in SVM, since we are using PTK, we need to represent as trees SLU hypotheses like the one described in section 2.

This problem is easily solved by transforming the hypotheses into trees like the one depicted in figure 1. Although there may be more formal solutions to represent semantic information of SLU hypotheses as trees, we would like to remark that the tree structure shown in figure 1 contains all the key information needed for our purposes: the first level of the tree represents the concept sequence annotated on surface form. The second level of the tree allow to implicitly represent the segmentation of each concept, while the third level, i.e. the leaves, are the input words. Moreover, from figure 1 we removed word categories associated to words in order to keep the figure readable. Word categories are provided together with the corpus as an application knowledge base. They comprise domain categories like city names, hotel names, street names etc., and some domain independent categories like numbers, dates, months etc. The categories are used at the same level of words, they provide a generalization over words and alleviate the effect of Out-of-Vocabulary (OOV) words.

The CRF model used as baseline generates the *n* most likely conceptual annotations for each input sentence. These are ranked by the global conditional probability of the concept sequence, given the input word sequence of CRF. The *n*-best list produced by the baseline model is the list of candidate hypotheses $H_1, H_2, .., H_n$ used in the reranking step.

The candidate hypotheses are organized into pairs, e.g. (H_1, H_2) or (H_1, H_3). We build training pairs such that a reranker can learn to select the best one between the two hypotheses in a pair, i.e. the more correct hypothesis with respect to a reference annotation and a given metric. In particular, we compute the edit distance of each hypothesis in the list, with respect to the manual annotation taken from the corpus. The best hypothesis H_b is used to build positive instances for the reranker as pairs (H_b, H_i) for $i \in [1..n]$ and $i \neq b$, negative instances are built as (H_i, H_b), with same constraints on index i. This means that, if n hypotheses are generated for a sentence, $2 \cdot n$ instances are generated from them. Note that by construction of pairs the model is symmetric, this provides a property that will be exploited at classification phase, as described in (Shen et al., 2003b).

Hypotheses are then converted into trees like the one shown in figure 1. Pairs of trees $e_k = (t_{i,k}, t_{j,k})$, for k varying along all the training or classification instances, are given as input to the SVM model to train the reranker using the following reranking kernel:

$$\begin{aligned} K_R(e_1, e_2) &= PTK(t_{1,1}, t_{1,2}) + PTK(t_{2,1}, t_{2,2}) \\ &- PTK(t_{1,1}, t_{2,2}) - PTK(t_{2,1}, t_{1,2}), \end{aligned} \quad (4)$$

where e_1 and e_2 are two pairs of trees to be compared.

The reranking kernel in equation 4, consisting in summing four different kernels, has been proposed in (Shen et al., 2003b) for syntactic parsing reranking, where the basic kernel was a Tree Kernel, and the idea was taken in turn from (Heibrich et al., 2000), where pairs where used to learn preference ranking. The same idea appears also, in a slightly different form, in early work about reranking, e.g. (Collins and Duffy, 2002). The same reranking schema has been used also in (Shen et al., 2004) for reranking different candidate hypotheses for machine translation.

For classification, observing that the model is symmetric and exploiting kernel properties, we can use, as classification instances, simple hypotheses instead of pairs. More precisely we use pairs where the second hypothesis is empty, i.e. $(H_i, 0)$, for $i \in [1..n]$. This simplification allow a relatively fast classification phase, since only n instances are generated for each sentence, instead of n^2. This simplification has been proposed in (Shen et al., 2003b).

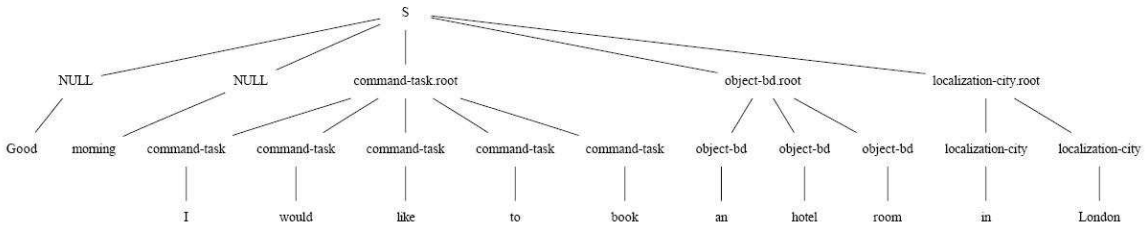

Figure 1: An example of semantic tree constructed from an SLU hypothesis from the MEDIA corpus and used in PTK

4 Hypotheses Selection Criteria

This section describes the main contribution of our work: first, a semantic inconsistency metric based on the AVE phase of SLU and allowing to select hypotheses generated by the baseline model; second, a strategy to decide, after the reranking phase, if it is more likely that the baseline best hypothesis is more accurate than the best reranked hypothesis and allowing to recover the mistake. Similar ideas have been proposed in (Dinarelli et al., 2010), here we propose a significant evolution and we give a much wider description and evaluation.

4.1 Hypotheses Selection via Attribute Value Extraction (AVE)

In previous reranking approaches (Collins, 2000; Collins and Duffy, 2002; Shen et al., 2003a; Shen et al., 2003b; Shen et al., 2004; Collins and Koo, 2005; Kudo et al., 2005; Dinarelli et al., 2009b), few hypotheses are generated with the baseline model, ranked by the model probability. These are then used for the reranking model. An interesting strategy to improve reranking performance is the selection of the best set of hypotheses to be reranked.

In this work we propose a semantic inconsistency metric (SIM) based on the attribute-value extraction phase that allows to select better n-best hypotheses. We combine the scores provided by the rule based approach and the CRF approach for AVE, computing a confidence measure.

The rule-based approach for AVE is defined by a set of rules that map concepts and their realizing words into the corresponding value. The rules are extracted from the training data, thus they are defined to extract correct values from well formed phrases annotated with correct concepts. This means that when the corresponding words are annotated with a wrong concept, the extracted value will probably be wrong. We use this property to compute a semantic inconsistency value for hypotheses, which in turn allows to select hypotheses with higher probabilities to be correct.

We show the application of SIM using the same example of Section 2. For space issues we abbreviate **command-task** with **com-task**, **object-bd** with **obj-bd** and **localization-city** with **loc-city**. We also suppose to have already removed **Null** concepts. From the same sentence, the three first hypotheses that may be generated by the baseline model are:

1. **obj-bd**{*I would like to book*} **obj-bd**{*an hotel room*} **loc-city**{*in London*}
2. **com-task**{*I would like to book*} **obj-bd**{*an hotel room*} **loc-city**{*in London*}
3. **com-task**{*I would like to book*} **obj-bd**{*an hotel*} **obj-bd**{*room*} **loc-city**{*in London*}

Two of these annotations show typical errors of an SLU model:
(i) wrong concepts annotation: in the first hypothesis the phrase "I would like to book" is erroneously annotated as **obj-bd**;
(ii) wrong concept segmentation: in the third hypothesis the phrase "an hotel room" is split in two concepts.

If we apply the AVE module to these hypotheses the result is:

1. **obj-bd**[] **obj-bd**[hotel] **loc-city**[london]
2. **cmd-task**[reservation] **obj-bd**[hotel] **loc-city**[london]
3. **cmd-task**[reservation] **obj-bd**[hotel] **obj-bd**[] **loc-city**[london]

As we can see the first concept **obj-bd** in the first hypothesis has an empty value since it was incorrectly annotated and, therefore, it is not supported

by words from which the AVE module can extract a correct value. In this case, the output of AVE is empty. In the same way, in the third hypothesis, the AVE module cannot extract a correct value from the phrase "room" since it doesn't contain any keyword for a **obj-bd** concept.

For each hypothesis, our SIM simply counts the number of wrong (or empty) values. In the example above, we have 1, 0 and 1 for the three hypothesis, respectively. Accordingly, the most accurate hypothesis under SIM is the second, which is also the correct one.

In order to combine the SIM score computed by the rule-based AVE module with the score provided by the CRF AVE model, we consider per-concept scores from both approaches. In particular, we formalize the definition of the SIM metric above on a concept c_i as $SIM(c_i, w_i^{1,...,m})$. The value of SIM is simply 0 if the rule-based AVE module can extract a value from the surface form $w_i^{1,...,m}$ realizing the concept c_i. 1 otherwise. For each concept in a hypothesis, we compute its semantic consistency $s(c_i)$ as

$$s(c_i) = \frac{P(v_i|c_i, w_i^{1,...,m})}{SIM(c_i, w_i^{1,...,m}) + 1} \quad (5)$$

where $P(v_i|c_i, w_i^{1,...,m})$ is the conditional probability output by the CRF model for the value v_i, given the concept c_i and its realizing surface $w_i^{1,...,m}$. Equation 5 means that the CRF score provided for a given value is halved if SIM returns 1, i.e. if the AVE module cannot extract any value. Otherwise the score output by the CRF AVE model is kept unchanged. The semantic inconsistency metric of an hypothesis H_k containing the concept sequence $C_1^N = c_1, ..., c_N$ is then defined as

$$S(H_k) = \sum_{i=1}^{N} s(c_i) \quad (6)$$

Using $S(H_k)$ as semantic inconsistency metric, we generate a huge number of hypotheses with the baseline model and we select only the top *n*-best. We use these hypotheses in the discriminative reranking model, instead of the original *n*-best generated by the CRF model. For simplicity, in general context we denote $S(H_k)$ as `SIM`.

4.2 Wrong Rerank Rejection

After the reranking model is applied, the first hypothesis is selected as final result. This choice assumes that the new hypothesis is more accurate than the one provided by the baseline model. In general this assumption is not true. Indeed, a reranking model must be carefully tuned in order to correctly rerank wrong first best hypotheses but keeping the original baseline best for correct hypotheses. When the baseline model is relatively accurate, the latter case occurs in most of the cases. In this situation it becomes hard to train an accurate reranking model.

Our idea to overcome this problem is to apply the reranking model and then post-process results to detect when the original best hypothesis is actually better than the reranked best.

For this purpose we propose a simple strategy based on the scores computed by the two models involved in reranking: CRF for the baseline and SVM with PTK for reranking.

Let H_{crf} and H_{RR} be the best hypothesis of the CRF and reranking (RR) models, respectively. Let $S_{crf}(H_{crf})$ and $S_{crf}(H_{RR})$ be the scores of the CRF model for H_{crf} and H_{RR}. In the same way, let $S_{RR}(H_{crf})$ and $S_{RR}(H_{RR})$ be the scores of the reranking model on the same hypotheses. We define the *confidence margin* of the CRF model the quantity: $M_{crf} = S_{crf}(H_{crf}) - S_{crf}(H_{RR})$.

In the same way we define the *confidence margin* of the RR model: $M_{RR} = S_{RR}(H_{crf}) - S_{RR}(H_{RR})$.

We compute two thresholds T_{crf} and T_{RR} for the

Average score	Feature type
0.0528186	Pref2
0.044189	CATEGORY-2

0.0314831	Suff2
0.030613	Suff4-2
...	...
0.0165602	Suff1
0.000579602	Pref1

Table 2: Ranks of average score given by the CRF model to feature types

two margins with respect to error rate minimization (with a *"line search"* algorithm).

We select the final best interpretation hypothesis for a given sentence with the decision function:

$$BestHypothesis = \begin{cases} H_{RR} & \text{if } M_{crf} \leq T_{crf} \text{ and } M_{RR} \geq T_{RR} \\ H_{crf} & \text{otherwise.} \end{cases}$$

Since this strategy allows to recover from reranking mistakes, we call it Wrong Rerank Rejection (WRR).

5 Experiments

The data used in our experiments are taken from the French MEDIA corpus (Bonneau-Maynard et al., 2006). The corpus is made of 1.250 Human-Machine dialogs acquired with a Wizard-of-Oz approach in the domain of informtation and reservation of French hotels. The data are split into training, development and test set. Statistics of the corpus are presented in table 1.

For our CRF models, both *Automatic Concept Annotation* and *Attribute Value Extraction* SLU phases, we used wapiti[2] (Lavergne et al., 2010). The CRF model for the first SLU phase integrates a traditional set of features like word prefixes and suffixes (of length up to 5), plus some *Yes/No* features like *"Does the word start with capital letter ?"*, *"Does the word contain non alphanumeric characters ?"*, *"Is the word preceded by non alphanumeric characteris ?"* etc. The CRF model for AVE integrates only words, prefixes and suffixes (length 3 and 4) concatenated with concepts. Since in this case labels are attribute values, which are a huge set with respect to concepts ($\tilde{7}$00 VS 99), using a lot of features would make model training problematic. Despite the reduced set of features, training error rate at both token and sentence level is under 1%. We didn't carry out optimization for parameters ρ_1 and ρ_2 of the elastic net (see section 3.1), default values lead in most cases to very accurate models.

MEDIA Text Input	DEV		TEST	
Model	Attr	Attr+Val	Attr	Attr+Val
CRF	12.1%	14.8%	11.5%	13.8%
CRF+RR	12.0%	14.6%	11.5%	13.7%
CRF+RR_{SIM}	11.7%	13.9%	11.3%	13.4%
CRF+RR_{WRR}	11.2%	13.4%	11.3%	13.0%

Table 3: Results of baseline CRF model and reranking models on MEDIA text input

Reranking models based on SVM and PTK have been trained with *"SVM-Light-TK"*[3]. Kernel parameters *M* and SVM parameter *C* have been optimized on the development set, as well as thresholds for the WRR (see section 4.2).

Concerning hypotheses generation, for training we generate 100 hypotheses, we select the best with respect to the edit distance and the reference annotation and we keep a total of 10 hypotheses to build pairs. For classification, with the "standard" reranking approach we generate and we keep the 10 best hypotheses. While using SIM for hypotheses selection, we generate 1.000 hypotheses and we keep the 10 best with respect to SIM. 1.000 is the best threshold between oracle accuracy and computational cost for evaluating the hypotheses.

Experiments have been performed on both manual and automatic transcriptions of dialog turns. For automatic transcriptions the WER of the ASR is 30.3% on development set and 31.4% on test set.

All results are reported in terms of Concept Error Rate (CER), which is the same as WER, but it is computed on concept sequences. In all cases we give results for both attributes only and attributes and values extraction

5.1 Results

In order to understand feature relevance, in table 2 we report feature types ranked by the average score given by the CRF model. Each type correspond to features at any position with respect to the target

word, with label unigrams. In contrast observation unigrams are distinguished from bigrams using suffixes *-1* and *-2* respectively. Feature types *wrd* are words converted to lower case, *Wrd* are words kept with original capitalization. Feature types *Pre*n are word prefixes of length n, *Suf*n are word suffixes of length n. *CATEGORY* features are word categories (see section 3.3). As we can see from the table, although feature relevance depends of course from the task, surprisingly word prefixes of length 2 are the most meaningful features. As expected, *CATEGORY* features are also very relevant features, since they provide a strong generalization over words. Another expected outcome is the fact that prefixes and suffixes of length 1 are the least relevant features.

In figure 2(a), 2(b) and 2(c) we show the curves resulting from optimization of parameters of reranking models. In particular we optimized the *M* kernel parameter (μ decay factor, see (Moschitti, 2006) for details), and the *C* SVM parameter, i.e. the scale factor for the soft margin (please refer to (Vapnik, 1998) for SVM details). Figure 2(b) shows the learning time as a function of the *C* SVM parameter. This gives an idea of how long takes training our reranking models.

In table 3 and 4 we report comparative results over the baseline CRF model, the baseline reranking model (*CRF+RR*) and the reranking models obtained applying the two improvements proposed in this work (*CRF+*RR_{SIM} and *CRF+*RR_{WRR}). As we can see, the baseline reranking model does not improve significantly the baseline CRF model. This outcome is expected since we don't use any other information in the reranking model than the semantic tree shown in figure 1. Previous approaches like for example (Collins and Duffy, 2002), use the baseline model score as feature, as that the reranking model cannot do worst than the baseline model. As we pointed out in section 4.2, this solution require a fine tuning of the reranking model, especially when the baseline model is relatively accurate. In our case, the CRF model has a Sentence Error Rate of 25.0% on the MEDIA test set. This means that 75% of the times the best hypothesis of CRF is correct. In turn this implies that the reranking model must not rerank 75% of times and rerank the other 25% of times, someway contrasting the evidence provided by the baseline model score. In contrast, using our *WRR* strategy, we can tune the reranking model to maximize reranking effect and recover from reranking errors applying *WRR*. As shown in tables 3 and 4, we consistently improve CRF baseline as well as reranking baseline *CRF+RR*, especially applying both SIM and WRR (*CRF+*RR_{WRR}). Comparing our results with those reported in (Hahn et al., 2010), we can see that our model reaches, and even im-

MEDIA Test set Model	OER[%]	correct found/present

Table 6: Significance tests on results of models described in this work. The significance test is based on computationally-intensive randomizations as described in (Yeh and Church, 2000).

proves in some cases, state-of-the-art performance. This is particularly meaningful since best results reported in (Hahn et al., 2010) are obtained combining 6 different SLU models.

In table 5 we report some statistics to show the effect of SIM on the 10-best hypotheses list. It is particularly interesting to see that when hypotheses selection is applied, oracle error rate (OER) drops of 2% points from an already accurate OER of 9.5%. This is reflected also by the number of oracles present in the 10-best list without applying and applying SIM. We pass from 2657 without SIM to 2758 applying our hypotheses selection metric.

Finally, in table 6 we report statistical significance tests over the models described in this work. We used the significance test described in (Yeh and Church, 2000), it is based on computationally-intensive randomizations of data and tests the null hypothesis, i.e. the lower the score, the higher the statistical significance of results difference. Scores in table 5 reflect results given in terms of CER. We can see that when the difference between results is small, this is not statistically significant, when the score is above 0.05, the difference between the two corresponding models is not significant. We can thus conclude that the reranking model we propose, using hypotheses selection and reranking errors recover, significantly improves baseline CRF model and "traditional" reranking models.

6 Discussion

Although the new ideas proposed in this paper are effective and interesting, an important issue is their applicability to other tasks and domains. In this respect, it is sufficient to note that our ideas comes from the multi-stage nature of the task and of the proposed reranking framework. SLU is performed in two intertwined steps, since attribute values are extracted from syntactic chunks annotated with concept in the first step. This allows to use the model for the second step to validate the output of the first step, and vice versa, which is the principle of our hypotheses selection metric. There are many other tasks, in NLP and in other domains, that can be modeled with multiple steps and thus the same idea of *"validation"* of the output of one step with the other's model output can be applied. An example is syntactic parsing, where in most cases parsing is performed upon POS tagging output.

7 Conclusions

In this paper we propose two improvements for reranking models to be integrated in a reranking framework for Spoken Language Understanding. The reranking model is based on a CRF baseline model and Support Vector Machines with the Partial Tree Kernel for the reraning model. The two improvements we propose are: i) hypotheses selection criteria, used before applying reranking to select better hypotheses amongst those generated by CRF. ii) a strategy to recover from reranking errors called Wrong Rerank Rejection.

We presented a full set of comparative results showing the viability of our approach. We can reach performances of state-of-the-art models, improving them in some cases, especially on automatic transcriptions coming from ASR (speech input).

In particular, the effectiveness of hypotheses selection is shown reporting the improvement of the Oracle Error Rate on the 10-best hypotheses list.

Abstract

A re-scoring strategy is proposed that makes it feasible to capture more long-distance dependencies in the natural language. Two pass strategies have become popular in a number of recognition tasks such as ASR (automatic speech recognition), MT (machine translation) and OCR (optical character recognition). The first pass typically applies a weak language model (n-grams) to a lattice and the second pass applies a stronger language model to N best lists. The stronger language model is intended to capture more long-distance dependencies. The proposed method uses RNN-LM (recurrent neural network language model), which is a long span LM, to re-score word lattices in the second pass. A hill climbing method (iterative decoding) is proposed to search over *islands of confusability* in the word lattice. An evaluation based on Broadcast News shows speedups of 20 over basic N best re-scoring, and word error rate reduction of 8% (relative) on a highly competitive setup.

1 Introduction

Statistical Language Models (LMs) have received considerable attention in the past few decades. They have proved to be an essential component in many statistical recognition systems such as ASR (automatic speech recognition), MT (machine translation) and OCR (optical character recognition). The task of a language model is to assign probability to any word sequence possible in the language. The probability of the word sequence $W \equiv w_1, \ldots, w_m \equiv w_1^m$ is typically factored using the chain rule:

$$P(w_1^m) = \prod_{i=1}^{m} P(w_i|w_1^{i-1}) \quad (1)$$

In modern statistical recognition systems, an LM tends to be restricted to simple n-gram models, where the distribution of the predicted word depends on the previous $(n-1)$ words i.e. $P(w_i|w_1^{i-1}) \approx P(w_i|w_{i-n+1}^{i-1})$.

Noam Chomsky argued that n-grams cannot learn long-distance dependencies that span over more than n words (Chomsky, 1957, pp.13). While that might seem obvious in retrospect, there was a lot of excitement at the time over the Shannon-McMillan-Breiman Theorem (Shannon, 1948) which was interpreted to say that, in the limit, under just a couple of minor caveats and a little bit of not-very-important fine print, n-gram statistics are sufficient to capture all the information in a string (such as an English sentence). Chomsky realized that while that may be true in the limit, n-grams are far from the most parsimonious representation of many linguistic facts. In a practical system, we will have to truncate n-grams at some (small) fixed n (such as trigrams or perhaps 5-grams). Truncated n-gram systems can capture many agreement facts, but not all.[1]

By long-distance dependencies, we mean facts like agreement and collocations that can span over many words. With increasing order of n-gram models we can, in theory, capture more regularities in the

[1]The discussion in this paragraph is taken as-is from an article (to appear) by Church (2012).

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1116–1127,
Edinburgh, Scotland, UK, July 27–31, 2011.

language. In addition, if we can move to more general models then we could hope to capture more, as well. However, due to data sparsity, it is hard to estimate a robust n-gram distribution for large values of n (say, $n > 10$) using the conventional Maximum Likelihood techniques, unless a more robust technique is employed for modeling which generalizes well on unseen events. Some of these well known long span / complex language models which have shown to perform very well on many speech tasks include: structured language model (Chelba and Jelinek, 2000; Roark, 2001; Wang and Harper, 2002; Filimonov and Harper, 2009), latent semantic analysis language model (Bellegarda, 2000), topic mixture language models (Iyer and Ostendorf, 1999), whole sentence exponential language models (Rosenfeld, 1997; Rosenfeld et al., 2001), feedforward neural networks (Bengio et al., 2001), recurrent neural network language models (Mikolov et al., 2010), among many others.

Although better modeling techniques can now capture longer dependencies in a language, their incorporation in decoders of speech recognition or machine translation systems becomes computationally challenging. Due to the prohibitive increase in the search space of sentence hypotheses (or longer length word sub sequences), it becomes challenging to use a long span language model in the first pass decoding. A word graph (word lattices for speech recognition systems and hypergraphs for machine translation systems), encoding exponential number of hypotheses is hence outputted at the first pass output on which a sophisticated and complex language model is deployed for re-scoring. However, sometimes even re-scoring of this refined search space can be computationally expensive due to explosion of state space.

Previously, we showed in (Deoras et al., 2011) how to tackle the problem of incorporating long span information during decoding in speech recognition systems by variationaly approximating (Bishop, 2006, pp. 462) the long span language model by a tractable substitute such that this substitute model comes closest to the long span model (closest in terms of Kullback Leibler Divergence (Cover and J.A.Thomas, 1991, pp. 20)). The tractable substitute was then used directly in the first pass speech recognition systems. In this paper we propose an approach that keeps the model intact but approximates the search space instead (which can become intractable to handle especially under a long span model), thus enabling the use of full blown model for re-scoring.With this approach, we can achieve full lattice re-scoring with a complex model, at a cost more than 20 times less than of a naive brute force approach that is commonly used today.

The rest of the paper is organized as follows: We discuss a particular form of long span language model in Sec. 2. In Sec. 3 we discuss two standard re-scoring techniques and then describe and demonstrate our proposed technique in Sec. 4. We present experimental results in Sec. 5 followed by conclusions and some remarks in Sec. 6.

2 Recurrent Neural Networks (RNN)

There is a long history of using neural networks to model sequences. Elman (1990) used recurrent neural network for modeling sentences of words generated by an artificial grammar. Work on statistical language modeling of real natural language data, together with an empirical comparison of performance to standard techniques was done by Bengio et al. (2001). His work has been followed by Schwenk (2007), who has shown that neural network language models actually work very well in the state-of-the-art speech recognition systems. Recurrent Neural Network based Language Models (RNN-LMs) (Mikolov et al., 2010) improved the ability of the original model to capture patterns in the language without using any additional features (such as part of speech, morphology etc) i.e. other than lexical ones. The RNN-LM was shown to have superior performance than the original feedforward neural network (Mikolov et al., 2011b). Recently, we also showed that this model outperforms many other advanced language modeling techniques (Mikolov et al., 2011a). We hence decided to work with this model. This model uses whole history to make predictions, thus it lies outside the family of n-gram models. Power of the model comes at a considerable computational cost. Due to the requirement of unlimited history, many optimization tricks for rescoring with feedforward-based NNLMs as presented by Schwenk (2007) cannot be applied during rescoring with RNN LM. Thus, this model is a good candidate

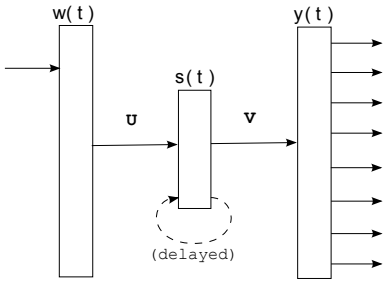

Figure 1: Schematic Representation of Recurrent Neural Network Language Model. The network has an input layer $\mathbf{w}$, a hidden layer $\mathbf{s}$ and an output layer $\mathbf{y}$. Matrices U and V represent synapses.

to show effectiveness and importance of our work.

The basic RNNLM is shown in Fig. 1. The model has an input layer $\mathbf{w}(t)$ that encodes previous word using 1 of N coding (thus, the size of the input layer is equal to the size of the vocabulary, and only the neuron that corresponds to the previous word in a sequence is set to 1). The hidden layer $\mathbf{s}(t)$ has additional recurrent connections that are delayed by one time step. After the network is trained, the output layer $\mathbf{y}(t)$ represents probability distribution for the current word, given the previous word and the state of the hidden layer from the previous time step.

The training is performed by 'backpropagation-through-time' algorithm that is commonly used for training recurrent neural networks (Rumelhart et al., 1986). More details about training, setting initial parameters, choosing size of the hidden layer etc. are presented in (Mikolov et al., 2010). Additional extensions that allow this model to be trained on large corpora are presented in (Mikolov et al., 2011b).

3 Standard Approaches for Rescoring

3.1 Word Lattice Rescoring

A word lattice, $\mathcal{L}$, obtained at the output of the first pass decoding, encodes exponential number (exponential in the number of states (nodes) present in the lattice) of hypotheses in a very compact data structure. It is a directed acyclic graph $G = (\mathcal{V}, \mathcal{E}, n_s, N_e)$, where $\mathcal{V}$ and $\mathcal{E}$ denote set of vertices (nodes / states) and edges (arcs / links), respectively. n_s and N_e denote the unique start state and set of end states.

A path, π, in a lattice is an element of $\mathcal{E}^*$ with consecutive transitions. We will denote the origin / previous state of this path by $p[\pi]$ and destination / next state of this path by $n[\pi]$. A path, π is called a *complete path* if $p[\pi] = n_s$ and $n[\pi] \in N_e$. A path, π, is called a *partial path* if $p[\pi] = n_s$ but $n[\pi]$ may or may not belong to N_e. A path, π, is called a *trailing path* if $p[\pi]$ may or may not be equal to n_s and $n[\pi] \in N_e$. We will also denote the time stamp at the start of the path by $T_s[\pi]$ and the time stamp at the end of the path by $T_e[\pi]$. Since there are nodes attached to the start and end of any path, we will denote the time stamp at any node $u \in \mathcal{V}$ by $T[u]$. Associated with every path, π, is also a word sequence $W[\pi] \in \mathcal{W}^*$, where $\mathcal{W}$ is the vocabulary used during speech recognition. For the sake of simplicity, we will distinguish word sequence of length 1 from the word sequences of length greater than 1 by using lower and upper casing i.e. $w[\cdot]$ and $W[\cdot]$ respectively.

The acoustic likelihood of the path $\pi \in \mathcal{E}^*$ is then given as:

$$A[\pi] = \prod_{j=1}^{|\pi|} P(\mathbf{a}_j | w[\pi_j])$$

where $\forall j \in \{1, 2, \ldots, |\pi|\} \quad \pi_j \in \mathcal{E}$, $\pi = \odot_{j=1}^{|\pi|} \pi_j$ and $P(\mathbf{a}_j | w[\pi_j])$ is the acoustic likelihood of the acoustic substring $\mathbf{a}_j$, spanning between $T_s[\pi_j]$ and $T_e[\pi_j]$, conditioned on the word $w[\pi_j]$ associated with the edge π_j.[2] Similarly, the language model score of the path π is given as:

$$L[\pi] = \prod_{j=1}^{|\pi|} P(w[\pi_j] | w[\pi_{j-1}], \ldots, w[\pi_{j-m+1}])$$

where $P(w[\pi_j] | w[\pi_{j-1}], \ldots, w[\pi_{j-m+1}])$ is the m-th order Markov approximation for estimating the probability of a word given the context upto that point. The speech recognizer, which uses m-th order Markov LM for first pass recognition, imposes a constraint on the word lattice such that at each state there exists an unambiguous context of consecutive $m-1$ words.

A first pass output is then a path π^* having Maximum a Posterior (MAP) probability.[3] Thus π^* is

[2] We will use $\odot$ symbol to denote concatenation of paths or word strings.

[3] Note that asterisk symbol here connotes that the path is *op-*

obtained as:

$$\pi^* = \underset{\substack{\pi: p[\pi]=n_s \\ n[\pi]\in N_e}}{\arg\max}\, A[\pi]^\gamma L[\pi],$$

where γ is the scaling parameter needed to balance the dynamic variability between the distributions of acoustic and language model (Ogawa et al., 1998). Efficient algorithms such as single source shortest path (Mohri et al., 2000) can be used for finding out the MAP path.

Under a new n-gram Language Model, rescoring involves replacing the existing language model scores of all paths π. If we denote the new language model by L_{new} and correspondingly the score of the path π by $L_{new}[\pi]$, then it is simply obtained as:

$$L_{new}[\pi] = \prod_{j=1}^{|\pi|} P(w[\pi_j]|w[\pi_{j-1}], \ldots, w[\pi_{j-n+1}])$$

where $P(w[\pi_j]|w[\pi_{j-1}], \ldots, w[\pi_{j-n+1}])$ is the n-th order Markov approximation for estimating the probability of a word given the unambiguous context of $n-1$ words under the new rescoring LM. If the Markov rescoring n-gram LM needs a bigger context for the task of prediction (i.e. $n > m$, where $m-1$ is the size of the unambiguous context maintained at every state of the word lattice), then each state of the lattice has to be split until an unambiguous context of length as large as that required by the new re-scoring language model is not maintained. The best path, π^* is then obtained as:

$$\pi^* = \underset{\substack{\pi: p[\pi]=n_s \\ n[\pi]\in N_e}}{\arg\max}\, A[\pi]^\eta L_{new}[\pi],$$

where η acts as the new scaling parameter which may or may not be equal to the old scaling parameter γ.

It should be noted that if the rescoring LM needs a context of the entire past in order to predict the next word, then the lattice has to be expanded by splitting the states many more times. This usually blows up the search space even for a reasonably small number of state splitting iterations. When the task is to do rescoring under a long span LM, such as RNN-LM, then *exact* lattice re-scoring option is not feasible. In order to tackle this problem, a suboptimal approach via N best list rescoring is utilized. The details of this method are presented next.

3.2 N best List Rescoring

N best list re-scoring is a popular way to capture some long-distance dependencies, though the method can be slow and it can be biased toward the weaker language model that was used in the first pass.

Given a word lattice, $\mathcal{L}$, top N paths $\{\pi_1, \ldots, \pi_N\}$ are extracted such that their joint likelihood under the baseline acoustic and language models are in descending order i.e. that:

$$A[\pi_1]^\gamma L[\pi_1] \geq A[\pi_2]^\gamma L[\pi_2] \geq \ldots \geq A[\pi_N]^\gamma L[\pi_N]$$

Efficient algorithms exist for extracting N best paths from word lattices (Chow and Schwartz, 1989; Mohri and Riley, 2002). If a new language model, L_{new}, is provided, which now need not be restricted to finite state machine family, then that can be deployed to get the score of the entire path π. If we denote the new LM scores by $L_{new}[\cdot]$, then under N best list paradigm, optimal path $\tilde{\pi}$ is found out such that:

$$\tilde{\pi} = \underset{\pi\in\{\pi_1,\ldots,\pi_N\}}{\arg\max}\, A[\pi]^\eta L_{new}[\pi], \qquad (2)$$

where η acts as the new scaling parameter which may or may not be equal to γ. If $N \ll |\mathcal{L}|$ (where $|\mathcal{L}|$ is the total number of complete paths in word lattice, which are exponentially many), then the path obtained using (2) is not guaranteed to be optimal (under the rescoring model). The short list of hypotheses so used for re-scoring would yield suboptimal output if the best path π^* (according to the new model) is not present among the top N candidates extracted from the lattice. This search space is thus said to be *biased* towards a weaker model mainly because the N best lists are representative of the model generating them. To illustrate the idea, we demonstrate below a simple analysis on a relatively easy task of speech transcription on WSJ data.[4] In this setup, the recognizer made use of a bi-

timal under some model. This should not be confused with the Kleene stars appearing as superscripts for $\mathcal{E}$ and $\mathcal{W}$, which serve the purpose of regular expressions implying 0 or many occurances of the element of $\mathcal{E}$ and $\mathcal{V}$ respectively.

[4] Full details about the setup can be found in (Deoras et al., 2010)

gram LM to produce lattices and hence N best lists. Each hypothesis in this set got a rank with the top most and highest scoring hypothesis getting a rank of 1, while the bottom most hypothesis getting a rank of N. We then re-scored these hypotheses with a better language model (either with a higher order Markov LM i.e. a trigram LM (*tg*) or the log linear combination of n-gram models and syntactic models (*n-gram+syntactic*) and re-ranked the hypotheses to obtain their new ranks. We then used Spearman's rank correlation factor, ρ, which takes values in $[-1, +1]$, with -1 meaning that the two ranked lists are negatively correlated (one list is in a reverse order with respect to the other list) and $+1$ meaning that the two ranked lists are positively correlated (the two lists are exactly the same). Spearman's rank correlation factor is given as:

$$\rho = 1 - \frac{6 \sum_{n=1}^{N} d_n^2}{N(N^2 - 1)}, \quad (3)$$

where d_n is the difference between the old and new rank of the n^{th} entry (in our case, difference between $n (\in \{1, 2, \ldots, N\})$ and the new rank which the n^{th} hypothesis got under the rescoring model).

Table 1 shows how the correlation factor drops dramatically when a better and a complementary LM is used for re-scoring, suggesting that the N best lists are heavily biased towards the starting models. Huge re-rankings suggests there is an opportunity to improve and also a need to explore more hypotheses, i.e. beyond N best lists.

Model	(ρ)	**WER (%)**
bg	1.00	18.2%
tg	0.41	17.4%
n-gram+syntactic	0.33	15.8%

Table 1: Spearman Rank Correlation on the N best list extracted from a bi-gram language model (*bg*) and re-scored with relatively better language models including, trigram LM (*tg*), and the log linear combination of n-gram models, and syntactic models (*n-gram+syntactic*). With a bigger and a better LM, the WER decreases at the expense of huge re-rankings of N best lists, only suggesting the fact that N best lists generated under a weaker model, are not reflective enough of a relatively better model.

In the next section, we propose an algorithm which keeps the representation of search space as simple as that of N best list, but does not restrict itself to top N best paths alone and hence does not get *biased* towards the starting weaker model.

4 Proposed Approach for Rescoring

A high level idea of our proposed approach is to identify *islands of confusability* in the word lattice and replace the problem of global search over word lattice by series of local search problems over these islands in an iterative manner. The motivation behind this strategy is the observation that the recognizer produces bursts of errors such that they have a temporal scope. The recognizer output (sentence hypotheses) when aligned together typically shows a pattern of confusions both at the word level and at the phrase level. Regions where there are singleton words competing with one another (reminiscent of a confusion bin of a Confusion Network (CN) (Mangu, 2000)), choice of 1 word edit distance works well for the formation of local neighborhood. Regions where there are phrases competing with other phrases, choice of variable length neighborhood works well. Previously, Richardson et al. (1995) demonstrated a hill climbing framework by exploring 1 word edit distance neighborhood, while in our own previous work (Deoras and Jelinek, 2009), we demonstrated working of iterative decoding algorithm, a hill climbing framework, for CNs, in which the neighborhood was formed by all words competing with each other in any given time slot, as defined by a confusion bin.

In this work, we propose a technique which generalizes very well on word lattices and overcomes the limitations posed by a CN or by the limited nature of local neighborhood. The size of the neighborhood in our approach is a *variable* factor which depends upon the confusability in any particular region of the word lattice. Thus the local neighborhood are in some sense a function of the confusability present in the lattice rather than some predetermined factor. Below we describe the process, virtue of which, we can cut the lattice to form many self contained smaller sized sub lattices. Once these sub lattices are formed, we follow a similar hill climbing procedure as proposed in our previous work (Deoras and Jelinek, 2009).

4.1 Islands of Confusability

We will continue to follow the notation introduced in section 3.1. Before we define the procedure for cutting the lattice into many small self contained lattices, we will define some more terms necessary for the ease of understandability of the algorithm.[5] For any node $v \in \mathcal{V}$, we define forward probability, $\alpha(v)$, as the probability of any partial path $\pi \in \mathcal{E}^*$, s.t. $p[\pi] = n_s, n[\pi] = v$ and it is given as:

$$\alpha(v) = \sum_{\substack{\pi \in \mathcal{E}^* \\ s.t. p[\pi]=n_s, n[\pi]=v}} A[\pi]^\gamma L[\pi] \qquad (4)$$

Similarly, for any node $v \in \mathcal{V}$, we define the backward probability, $\beta(v)$, as the probability of any trailing path $\pi \in \mathcal{E}^*$, s.t. $p[\pi] = v, n[\pi] \in N_e$ and it is given as:

$$\beta(v) = \sum_{\substack{\pi \in \mathcal{E}^* \\ s.t. p[\pi]=v, n[\pi] \in N_e}} A[\pi]^\gamma L[\pi] \qquad (5)$$

If we define the sum of joint likelihood under the baseline acoustic and language models of all paths in the lattice by Z, then it can simply be obtained as: $Z = \sum_{u \in N_e} \alpha(u) = \beta(n_s)$

In order to cut the lattice, we want to identify sets of nodes, $S_1, S_2, \ldots, S_{|\mathcal{S}|}$ such that for any set $S_i \in \mathcal{S}$ following conditions are satisfied:

1. For any two nodes $u, v \in S_i$ we have that: $T[u] = T[v]$. We will define this common time stamp of the nodes in the set by $T[S_i]$.
2. $\nexists\, \pi \in \mathcal{E}$ such that $T_s[\pi] < T[S_i] < T_e[\pi]$.

The first property can be easily checked by first pushing states into a linked list associated with each time marker (this can be done by iterating over all the states of the graph) then iterating over the unique time markers and retrieving back the nodes associated with it.The second property can be checked by first iterating over the unique time markers and for each of the marker, iterating over the arcs and terminating the loop as soon as some arc is found out violating property 2 for the specific time marker. Thus the time complexity for checking property 1 is $O(|\mathcal{V}|)$ and that for property 2 is $O(|\mathcal{T}| \times |\mathcal{E}|)$, where $|\mathcal{T}|$ is the total number of unique time markers. Usually $|\mathcal{T}| \ll |\mathcal{E}|$ and hence the time complexity for checking property 2 is almost linear in the number of edges. Thus effectively, the time complexity for cutting the lattice is $O(|\mathcal{V}| + |\mathcal{E}|)$.

Having formed such sets, we can now cut the lattice at time stamps associated with these sets i.e. that: $T[S_1], \ldots, T[S_{|\mathcal{S}|}]$. It can be easily seen that the number of sub lattices, C, will be equal to $|\mathcal{S}| - 1$.We will identify these sub lattices as $\mathcal{L}_1, \mathcal{L}_1, \ldots, \mathcal{L}_C$. At this point, we have not formed self contained lattices yet by simply cutting the parent lattice at the cut points.

Once we cut the lattice at these cut points, we implicitly introduce many new starting nodes and ending nodes for any sub lattice. We will refer to these nodes as exposed starting nodes and exposed ending nodes. Thus for some j^{th} sub lattice, $\mathcal{L}_j$, there will be as many new exposed starting nodes as there are nodes in the set S_j and as many exposed ending nodes as there are nodes in the set S_{j+1}. In order to make these sub lattices consistent with the definition of a word lattice (see Sec. 3.1), we unify all the exposed starting nodes and exposed ending nodes. To unify the exposed starting nodes, we introduce as many *new* edges as there are nodes in the set S_j such that they have a common starting node, $n_s[\mathcal{L}_j]$, (newly created) and distinct ending nodes present in S_j. To unify the exposed ending nodes of $\mathcal{L}_j$, we introduce as many *new* edges as there are nodes in the set S_{j+1} such that they have distinct starting nodes present in S_{j+1} and a common ending node $n_e[\mathcal{L}_j]$ (newly created). From the totality of these new edges and nodes along with the ones already present in $\mathcal{L}_j$ forms an induced directed acyclic subgraph $G[\mathcal{L}_j] = (\mathcal{V}[\mathcal{L}_j], \mathcal{E}[\mathcal{L}_j], n_s[\mathcal{L}_j], n_e[\mathcal{L}_j])$.

For any path $\pi \in \mathcal{E}[\mathcal{L}_j]$ such that $p[\pi] = n_s[\mathcal{L}_j]$ and $n[\pi] \in S_j$, we assign the value of $\alpha(n[\pi])$ to denote the joint likelihood $A[\pi]^\gamma L[\pi]$ and assign $epsilon$ for word associated with these edges i.e. $w[\pi]$. We assign $T[S_j] - \delta T$ to denote $T_s[\pi]$ and $T[S_j]$ to denote $T_e[\pi]$. Similarly, for any path $\pi \in \mathcal{E}[\mathcal{L}_j]$ such that $p[\pi] \in S_{j+1}$ and $n[\pi] = n_e[\mathcal{L}_j]$,

[5] Goel and Byrne (2000) previously demonstrated the lattice segmentation procedure to solve the intractable problem of MBR decoding. The cutting procedure in our work is different from theirs in the sense that we rely on time information for collating competing phrases, while they do not.

we assign the value of $\beta(p[\pi])$[6] to denote the joint likelihood $A[\pi]^{\gamma}L[\pi]$ and assign $epsilon$ for word associated with these edges i.e. $w[\pi]$. We assign $T[S_{j+1}]$ to denote $T_s[\pi]$ and $T[S_{j+1}] + \delta T$ to denote $T_e[\pi]$. This completes the process and we obtain self contained lattices, which if need be, can be independently decoded and/or analyzed.

4.2 Iterative Decoding on Word Lattices

Once we have formed the self contained lattices, $\mathcal{L}_1, \mathcal{L}_1, \ldots, \mathcal{L}_C$, where C is the total number of sub lattices formed, then the idea is to divide the re-scoring problem into many small re-scoring problems carried over the sub lattices one at a time by fixing single best paths from all the remaining sub lattices.

The inputs to the algorithm are the sub lattices (produced by cutting the parent lattice generated under some Markov n-gram LM) and a new rescoring LM, which now need not be restricted to finite state machine family. The output of the algorithm is a word string, $\mathbf{W}^*$, such that it is the concatenation of final decoded word strings from each sub lattice. Thus if we denote the final decoded path (under some decoding scheme, which will become apparent next) in the j^{th} sub lattice by π_j^* and the concatenation symbol by '$\cdot$', then $\mathbf{W}^* = W[\pi_1^*] \cdot W[\pi_2^*] \cdot \ldots \cdot W[\pi_C^*] = \odot_{j=1}^{C} W[\pi_j^*]$.

Algorithm 1 Iterative Decoding on word lattices.

Require: $\{\mathcal{L}_1, \mathcal{L}_1, \ldots, \mathcal{L}_C\}$, L_{new}
  PrevHyp $\leftarrow$ null
  CurrentHyp $\leftarrow \odot_{j=1}^{C} W[\hat{\pi}_j]$
  while PrevHyp $\neq$ CurrentHyp **do**
    for $i \leftarrow 1 \ldots C$ **do**

$$\hat{\pi}_i \leftarrow \underset{\substack{\pi_i \in \mathcal{E}_i^*: \\ p[\pi_i]=n_s[\mathcal{L}_i] \\ n[\pi_i]=n_e[\mathcal{L}_i]}}{\operatorname{argmax}} \Big(L_{new}[\hat{\pi_1} \cdot \ldots \cdot \pi_i \cdot \ldots \cdot \hat{\pi_k}] \times A[\pi_i]^{\eta} \prod_{\substack{j=1 \\ j \neq i}}^{k} A[\hat{\pi_j}]^{\eta} \Big)$$

    end for
    PrevHyp $\leftarrow$ CurrentHyp
    CurrentHyp $\leftarrow \odot_{j=1}^{C} W[\hat{\pi}_j]$
  end while
  $\forall j \in \{1, 2, \ldots, C\} \quad \pi_j^* \leftarrow \hat{\pi}_j$

[6]The values of $\alpha(\cdot)$ and $\beta(\cdot)$ are computed under parent lattice structure.

The algorithm is initialized by setting **PrevHypo** to null and **CurrHypo** to the concatenation of 1-best output from each sub lattice. During the initialization step, each sub lattice is analyzed independent of any other sub lattice and under the baseline acoustic scores and baseline n-gram LM scores, 1-*best* path is found out. Thus if we define the best path under baseline model in some j^{th} sub-lattice by $\hat{\pi}_j$, **CurrHypo** is then initialized to: $W[\hat{\pi}_1] \cdot W[\hat{\pi}_2] \cdot \ldots \cdot W[\hat{\pi}_C]$. The algorithm then runs as long as CurrHypo is not equal to PrevHypo. In each iteration, the algorithm sequentially re-scores each sub-lattice by keeping the surrounding context fixed. Once all the sub lattices are re-scored, that constitutes one iteration. At the end of each iteration, CurrHypo is set to the concatenation of 1 best paths from each sub lattice while PrevHypo is set to the old value of CurrHypo. Thus if we are analyzing some i^{th} sub-lattice in some iteration, then 1-best paths from all but this sub-lattice is kept fixed and a *new* 1-*best* path under the re-scoring LM is found out. It is not hard to see that the likelihood of the output under the new re-scoring model is guaranteed to increase monotonically after every decoding step.

Since the cutting of parent lattices produce many small lattices with considerably lesser number of nodes, in practice, an exhaustive search for the 1-best hypothesis can be carried out via N best list. Algorithm 1 outlines the steps for iterative decoding on word lattices.

4.3 Entropy Pruning

In this section, we will discuss a speed up technique based on entropy of the lattice. Entropy of a lattice reflects the confidence of the recognizer in recognizing the acoustics. Based on the observation that if the N best list / lattice generated under some model has a very low entropy, then the Spearman's rank correlation factor, ρ (Eqn. 3), tends to be higher even when the N best lists / lattice is re-ranked with a bigger and a better model. A low entropy under the baseline model only reflects the confidence of the recognizer in recognizing the acoustic. Table 2 shows the rank correlation values between two sets of N best lists. Both sets are produced by a bigram LM (bg). The entropy of N best lists in the first set is 0.05 nats or less. The N best lists in the second set have an entropy greater than 0.05 nats.

Both these sets are re-ranked with bigger and better models (see Table 1 for model definitions). We can see from Table 2 that the rank correlation values tend to be higher (indicating little re-rankings) when the entropy of the N best list, under the baseline model, is lower. Similarly, the rank-correlation values tend to be lower (indicating more re-rankings) whenever the entropy of the N best list is higher. Note that these entropy values are computed with respect to the starting model (in this case, bigram LM). Of course, if the starting LM is much weaker than the rescoring model, then the entropy values need not be reflective of the difficulty of the overall task. This observation then suggests that it is safe to rescore only those N best lists whose entropy under the starting model is higher than some threshold.

Rescoring Model	$\rho_{(H \leq 0.05)}$	$\rho_{(H > 0.05)}$
bg	1.00	1.00
tg	0.58	0.38
n-gram+syntactic	0.54	0.31

Table 2: Spearman Rank Correlation on the N best list extracted from a bi-gram language model (*bg*) and rescored with relatively better language models (see Table 1 for model definitions). Entropy under the baseline model correlates well with the rank correlation factor, suggesting that exhaustive search need not be necessary for utterances yielding lower entropy.

While computation of entropy for N best list is tractable, for a word lattice, the computation of entropy is intractable if one were to enumerate all the hypotheses. Even if we were able to enumerate all hypotheses, this method tends to be slower. Using efficient semiring techniques introduced by Li and Eisner (2009) or using posterior probabilities on the edges leading to end states, we can compute the entropy of a lattice in one single forward pass using dynamic programming. It should, however, be noted that, for dynamic programming technique to work, only n-gram LMs can be used. One has to resort to approximate entropy computation via N best list, if entropy under long span LM is desired.

4.3.1 Speed Up for Iterative Decoding

Our speed up technique is simple. Once we have formed self contained sub lattices, we want to prune all but the top few best complete paths (obtained under baseline / starting model) of those sub lattices whose entropy is below some threshold. Thus, believing in the original model's confidence, we want to focus only on those sub lattices which the recognizer found difficult to decode in the first pass. All other part of the parent lattice will be not be analyzed. The thresholds for pruning is very application and corpus specific and needs to be tuned on some held out data.

5 Experiments and Results

We performed recognition on the Broadcast News (BN) dev04f, rt03 and rt04 task using the state-of-the-art acoustic models trained on the English Broadcast News (BN) corpus (430 hours of audio) provided to us by IBM (Chen et al., 2009). IBM also provided us its state-of-the-art speech recognizer, Attila (Soltau et al., 2010) and two Kneser-Ney smoothed backoff n-gram LMs containing 4.7M n-grams ($n \leq 4$) and 54M n-grams ($n \leq 4$), both trained on 400M word tokens. We will refer to them as KN:BN-Small and KN:BN-Big respectively. We refer readers to (Chen et al., 2009) for more details about the recognizer and corpora used for training the models.

We trained two RNN based language models - the first one, denoted further as RNN-limited, was trained on a subset of the training data (58M tokens). It used 400 neurons in the hidden layer. The second model, denoted as RNN-all, was trained on all of the training data (400M tokens), but due to the computational complexity issues, we had to restrict its hidden layer size to 320 neurons.

We followed IBM's multi-pass decoding recipe using KN:BN-Small in the first pass followed by either N best list re-scoring or word lattice re-scoring using bigger and better models.[7] For the purpose of re-scoring, we combined all the relevant statistical models in one unified log linear framework reminiscent of work by Beyerlein (1998). We, however, trained the model weights by optimizing expected WER rather than 1-*best* loss as described in (Deoras et al., 2010). Training was done on N best lists of size 2K. We will refer to the log linear com-

[7]The choice of the order and size of LM to be used in the first pass decoding was determined by taking into consideration the capabilities of the decoder.

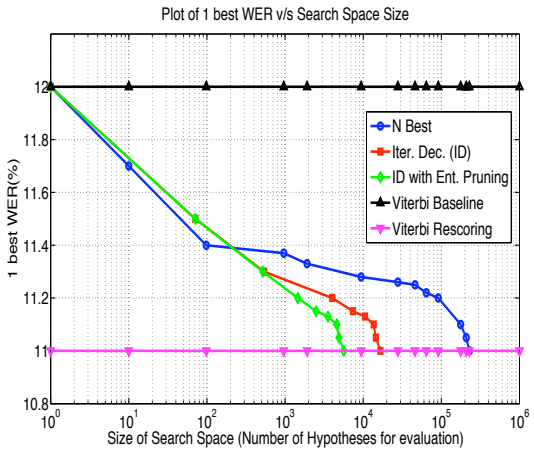

Figure 2: Plot of WER (y axis) on rt03+dev04f set versus the size of the search space (x axis). The baseline WER obtained using KN:BN-Small is 12% which then drops to 11% when KN:BN-Big is used for re-scoring. N best list search method obtains the same reduction in WER by evaluating as many as 228K sentence hypotheses on an average. The proposed method obtains the same reduction by evaluating 14 times smaller search space. The search effort reduces further to 40 times if entropy based pruning is employed during re-scoring.

bination of KN:BN-Big and RNN-limited by KN-RNN-lim; KN:BN-Big and RNN-all by KN-RNN-all and KN:BN-Big, RNN-limited and RNN-all by KN-RNN-lim-all.

We used two sets for decoding: rt03+dev04f set was used as a development set while rt04 was used as a blind set for the purpose of evaluating the performance of long span RNN models using the proposed approach. We made use of OpenFst C++ libraries (Allauzen et al., 2007) for manipulating lattice graphs and generating N best lists. Due to the presence of hesitation tokens in reference transcripts and the need to access the silence/pause tokens for penalizing short sentences, we treated these tokens as regular words before extracting sentence hypotheses. This, and poorly segmented nature of the test corpora, led to huge enumeration of sentence hypotheses.

5.1 n-gram LM for re-scoring

In this setup, we used KN:BN-Small as the baseline starting LM which yielded the WER of 12% on rt03+dev04f set. Using KN:BN-Big as the re-scoring LM, the WER dropped to 11%. Since the re-scoring LM belonged to the n-gram family, it was possible to compute the optimal word string by re-scoring the whole lattice (see Sec. 3.1). We now compare the performance of N best list approach (Sec. 3.2) with our proposed approach (Sec. 4). N best list achieved the best possible reduction by evaluating as many as 228K sentence hypotheses on an average. As against that, our proposed approach achieved the same performance by evaluating 16.6K sentence hypotheses, thus reducing the search efforts by **13.75** times. By carrying out entropy pruning (see Sec. 4.3) on sub lattices, our proposed approach required as little as 5.6K sentence hypotheses evaluations to obtain the same optimal performance, reducing the search effort by as much as **40.46** times. For the purpose of this experiment, entropy based pruning was carried out when the entropy of the sub lattice was below 5 nats. Table 3 compares the two search methods for this setup and Fig. 2 shows a plot of WER versus the size of the search space (in terms of number of sentence hypotheses evaluated by an n-gram language model).

On rt04, the KN:BN-Small LM gave a WER of 14.1% which then dropped to 13.1% after re-scoring with KN:BN-Big. Since the re-scoring model was an n-gram LM, it was possible to obtain the optimal performance via lattice update technique (see Sec. 3.1). We then carried out the re-scoring of the word lattices under KN:BN-Big using our proposed technique and found it to give the same performance yielding the WER of 13.1%.

5.2 Long Span LM for re-scoring

In this setup, we used the strongest n-gram LM as our baseline. We thus used KN:BN-Big as the baseline LM which yielded the WER of 11% on rt03+dev04f. We then used KN-RNN-lim-all for re-scoring. Due to long span nature of the re-scoring LM, it was not possible to obtain the optimal WER performance. Hence we have compared the performance of our proposed method with N best list approach. N best list achieved the lowest possible WER after evaluating as many as 33.8K sentence hypotheses on an average. As against that, our proposed approach in conjunction with entropy pruning obtained the same performance by evaluating just 1.6K sentence hypotheses, thus reducing the search by a factor of **21**. Fig 3 shows a plot of WER versus

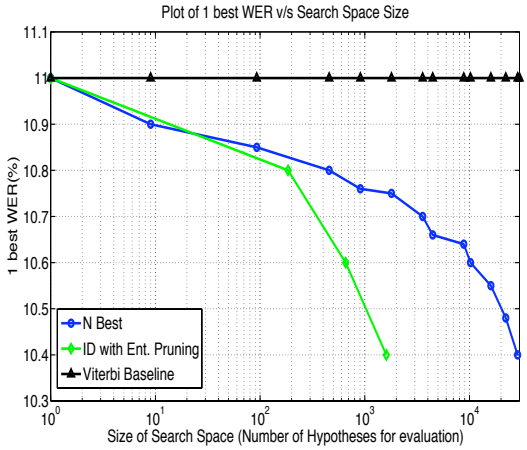

Figure 3: Plot of WER (y axis) on rt03+dev04f set versus the size of the search space (x axis). The baseline WER obtained using KN:BN-Big is 11% which then drops to 10.4% when KN-RNN-lim-all is used for re-scoring. N best list search method obtains this reduction in WER by evaluating as many as 33.8K sentence hypotheses on an average, while the proposed method (with entropy pruning) obtains the same reduction by evaluating 21 times smaller search space.

the size of the search space (in terms of number of sentence hypotheses evaluated by a long span language model).

In-spite of starting off with a very strong n-gram LM, the N best lists so extracted were still not representative enough of the long span rescoring models. Had we started off with KN:BN-Small, the N best list re-scoring method would have had no chance of finding the optimal hypothesis in reasonable size of hypotheses search space. Table 4 compares the two search methods for this setup when many other long span LMs were also used for re-scoring.

On rt04, the KN:BN-Big LM gave a WER of 13.1% which then dropped to **12.15**% after re-scoring with KN-RNN-lim-all using our proposed technique.[8] Since the re-scoring model was not an n-gram LM, it was not possible to obtain the optimal performance but we could enumerate huge N best list to approximate this value. Our proposed method is much faster than huge N best lists and no worse in terms of WER. As far as we know, the result obtained on these sets is the best performance ever reported on the Broadcast News corpus for speech recognition.

[8]The WER obtained using KN-RNN-lim and KN-RNN-all were 12.5% and 12.3% respectively.

Models	WER	NBest	ID	Saving
KN:BN-Small	12.0	-	-	-
KN:BN-Big	11.0	228K	5.6K	40

Table 3: The starting LM is a weak n-gram LM (KN:BN-Small) and the re-scoring LM is a much stronger but n-gram LM (KN:BN-Big). The baseline WER in this case is 12% and the optimal performance by the re-scoring LM is 11.0%. The proposed method outperforms N best list approach, in terms of search efforts, obtaining optimal WER.

Models	WER	NBest	ID	Saving
KN:BN-Big	11.0	-	-	-
KN-RNN-lim	10.5	42K	1.1K	38
KN-RNN-all	10.5	26K	1.3K	20
KN-RNN-lim-all	10.4	34K	1.6K	21

Table 4: The starting LM is a strong n-gram LM (KN:BN-Big) and the re-scoring model is a long span LM (KN-RNN-*). The baseline WER is 11.0%. Due to long span nature of the LM, optimal WER could not be estimated. The proposed method outperfoms N best list approach on every re-scoring task.

6 Conclusion

We proposed and demonstrated a new re-scoring technique for general word graph structures such as word lattices. We showed its efficacy by demonstrating huge reductions in the search effort to obtain a new state-of-the-art performance on a very competitive speech task of Broadcast news. As part of the future work, we plan to extend this technique for hypergraphs and lattices in re-scoring MT outputs with complex and long span language models.

Abstract

We propose an efficient way to train maximum entropy language models (MELM) and neural network language models (NNLM). The advantage of the proposed method comes from a more robust and efficient subsampling technique. The original multi-class language modeling problem is transformed into a set of binary problems where each binary classifier predicts whether or not a particular word will occur. We show that the binarized model is as powerful as the standard model and allows us to aggressively subsample negative training examples without sacrificing predictive performance. Empirical results show that we can train MELM and NNLM at $1\% \sim 5\%$ of the standard complexity with no loss in performance.

1 Introduction

Language models (LM) assign probabilities to sequences of words. They are widely used in many natural language processing applications. The probability of a sequence can be modeled as a product of local probabilities, as shown in (1), where w_i is the i^{th} word, and h_i is the word history preceding w_i.

$$P(w_1, w_2, ..., w_l) = \prod_{i=1}^{l} P(w_i|h_i) \qquad (1)$$

Therefore the task of language modeling reduces to estimating a set of conditional distributions $\{P(w|h)\}$. The n-gram LM is a dominant way to parametrize $P(w|h)$, where it is assumed that w only depends on the previous $n-1$ words. More complex models have also been proposed–MELM (Rosenfeld, 1996) and NNLM (Bengio et al., 2003) are two examples.

Modeling $P(w|h)$ can be seen as a multi-class classification problem. Given the history, we have to choose a word in the vocabulary, which can easily be a few hundred thousand words in size. For complex models such as MELM and NNLM, this poses a computational challenge for learning, because the resulting objective functions are expensive to normalize. In contrast, n-gram LMs do not suffer from this computational challenge. In the web era, language modelers have access to virtually unlimited amounts of data, while the computing power available to process this data is limited. Therefore, despite the demonstrated effectiveness of complex LMs, the n-gram is still the predominant approach for most real world applications.

Subsampling is a simple solution to get around the constraint of computing resources. For the purpose of language modeling, it amounts to taking only part of the text corpus to train the LM. For complex models such as NNLM, it has been shown that subsampling can speed up training greatly, at the cost of some degradation in predictive performance (Schwenk, 2007), allowing for trade-off between computational cost and LM quality.

Our contribution is a novel way to train complex LMs such as MELM and NNLM which allows much more aggressive subsampling without incurring as high a cost in predictive performance. The key to our approach is reducing the multi-class LM problem into a set of *binary* problems. Instead of training a V-class classifier, where V is the size of

the vocabulary, we train V binary classifiers, each one of which performs a *one-against-all* classification. The V trained binary probabilities are then renormalized to obtain a valid distribution over the V words. Subsampling here can be done in the *negative* examples. Since the majority of training examples are negative for each of the binary classifiers, we can achieve substantial computational saving by only keeping subsets of them. We will show that the binarized LM is as powerful as its multi-class counterpart, while being able to sustain much more aggressive subsampling. For certain types of LMs such as MELM, there are more benefits–the binarization leads to a set of completely independent classifiers to train, which allows easy parallelization and significantly lowers the memory requirement.

Similar one-against-all approaches are often used in the machine learning community, especially by SVM (support vector machine) practitioners to solve multi-class problems (Rifkin and Klautau, 2004; Allwein et al., 2000). The goal of this paper is to show that a similar technique can also be used for language modeling and that it enables us to subsample data much more efficiently. We show that the proposed approach is useful when the dominant modeling constraint is computing power as opposed to training data.

The rest of the paper is organized as follows. In section 2, we describe our binarization and subsampling techniques for language models with MELM and NNLM as two specific examples. Experimental results are presented in Section 3, followed by discussion in Section 4.

2 Approximating Language Models with Binary Classifiers

Suppose we have an LM that can be written in the form

$$P(w|h) = \frac{\exp a_w(h;\theta)}{\sum_{w'} \exp a_{w'}(h;\theta)}, \quad (2)$$

where $a_w(h;\theta)$ is a parametrized history representation for word w.

Given a training corpus of word history pairs with empirical distribution $\tilde{P}(h,w)$, the regularized log likelihood of the training set can be written as

$$\mathcal{L} = \sum_h \tilde{P}(h) \sum_w \tilde{P}(w|h) \log P(w|h) - r(\theta), \quad (3)$$

where $r(\theta)$ is the regularizing function over the parameters.

Assuming that $r(\theta)$ can be written as a sum over per-word regularizers, namely $r(\theta) = \sum_w r_w(\theta)$, we can take the gradient of the log likelihood w.r.t θ to show that the regularized MLE for the LM satisfies

$$\sum_h \tilde{P}(h) \sum_w P(w|h) \nabla_\theta a_w(h;\theta)$$
$$= \sum_{h,w} \tilde{P}(w,h) \nabla_\theta a_w(h;\theta) - \sum_w \nabla_\theta r_w(\theta). \quad (4)$$

For each word w, we can define a binary classifier that predicts whether the next word is w by

$$P_b(w|h) = \frac{\exp a_w(h;\theta)}{1 + \exp a_w(h;\theta)}. \quad (5)$$

The regularized training set log likelihood for all the binary classifiers is given by

$$\mathcal{L}_b = \sum_w \sum_h \tilde{P}(h) \Big[\tilde{P}(w|h) \log P_b(w|h)$$
$$+ \tilde{P}(\bar{w}|h) \log P_b(\bar{w}|h) \Big] - \sum_w r_w(\theta), \quad (6)$$

where $P_b(\bar{w}|h) = 1 - P_b(w|h)$ is the probability of w not occurring. Here we assume the same structure of the regularizer $r(\theta)$.

The regularized MLE for the binary classifiers satisfies

$$\sum_h \tilde{P}(h) \sum_w P_b(w|h) \nabla_\theta a_w(h;\theta)$$
$$= \sum_{h,w} \tilde{P}(w,h) \nabla_\theta a_w(h;\theta) - \sum_w \nabla_\theta r_w(\theta). \quad (7)$$

Notice the right hand sides of (4) and (7) are the same. Thus, taking $P'(w|h) = P_b(w|h)$ from ML trained binary classifiers gives an LM that meets the MLE constraints for language models. Therefore, if $\sum_w P_b(w|h) = 1$, ML training for the language model is equivalent to ML training of the binary classifiers and using the probabilities given by the classifiers as our LM probabilities.

Note that in practice, the probabilities given by the binary classifiers are not guaranteed to sum up to one. For tasks such as measuring perplexity,

these probabilities have to be normalized explicitly. Our hope is that for large enough data sets and rich enough history representation $a_w(h;\theta)$, we will get $\sum_w P_b(w|h) \approx 1$ so that renormalizing the classifiers to get

$$P'(w|h) = \frac{P_b(w|h)}{\sum_{w' \in V} P_b(w'|h)} \tag{8}$$

will not change the MLE constraint too much.

2.1 Stratified Sampling

We note that iterative estimation of the LM shown in (2) in general requires enumerating over the T training cases in the training set and computing the denominator of (2) for each case at a cost of $O(V)$. Thus, each iteration of training takes $O(VT)$ in general. The complexity of estimating each of the V binary classifiers is $O(T)$ per iteration, also giving $O(VT)$ per iteration in total.

However, as mentioned earlier, we are able to maximally subsample negative examples for each classifier. Thus the classifier for w is trained using the $C(w)$ positive examples and a proportion α of the $T - C(w)$ negative examples. The total number of training examples for all V classifiers is then $(1-\alpha)T + \alpha VT$. For large V, we choose $\alpha >> \frac{1}{1+V}$ so that this is approximately αVT. Thus, our complexity for estimating all V classifiers is $O(\alpha VT)$.

The resulting training set for each binary classifier is a stratified sample (Neyman, 1934), and our estimate needs to be calibrated to account for this. Since the training set subsamples negative examples by α, the resulting classifier will have a likelihood ratio

$$\frac{P_b(w|h)}{1 - P_b(w|h)} = \exp a_w(h;\theta) \tag{9}$$

that is overestimated by a factor of $\frac{1}{\alpha}$. This can be corrected by simply adding $\log \alpha$ to the bias (unigram) weight of the classifier.

2.2 Maximum Entropy LM

MELM is an effective alternative to the standard n-gram LM. It provides a flexible framework to incorporate different knowledge sources in the form of feature constraints. Specifically, MELM takes the form of (2), for word w following history h, we have the following probability definition,

$$P(w|h) = \frac{\exp \sum_i \theta_i f_i(h,w)}{\sum_{w' \in V} \exp \sum_i \theta_i f_i(h,w')}. \tag{10}$$

f_i is the i^{th} feature function defined over the word-history pair, θ_i is the feature weight associated with f_i. By defining general features, we have a natural framework to go beyond n-grams and capture more complex dependencies that exist in language. Previous research has shown the benefit of including various kinds of syntactic and semantic information into the LM (Khudanpur and Wu, 2000). However, despite providing a promising avenue for language modeling, MELM are computationally expensive to estimate. The bottleneck lies in the denominator of (10).

To estimate θ_is, gradient based methods can be used. The derivative of the likelihood function $\mathcal{L}$ w.r.t θ_i has a simple form, namely

$$\frac{\partial \mathcal{L}}{\partial \theta_i} = \sum_k f_i(w_k, h_k) - \sum_k \sum_{w' \in V} P(w'|h) f_i(w', h_k), \tag{11}$$

where k is the index of word-history pair in the training corpus. The first term in the derivative is the observed feature count in the training corpus, the second term is the expected feature count according to the model. In order to obtain $P(w'|h)$ in the second term, we need to compute the normalizer, which involves a very expensive summation over the entire vocabulary. As described earlier, the complexity for each iteration of training is at $O(VT)$, where T is the size of training corpus.

For feature sets that can be expressed hierarchically, for example n-gram feature set, where higher order n-grams imply lower order n-grams, Wu and Khudanpur (2000) exploit the structure of the normalizer, and precompute components that can be shared by different histories. For arbitrary feature sets, however, it may not be possible to establish the required hierarchical relations and the normalizer still needs to be computed explicitly. Goodman (2001) changes the original LM into a class-based LM, where each one of the two-step predictions only involves a much smaller summation in the normalizer. In addition, MELM estimation can be parallelized, with expected count computation done

separately for different parts of the training data and merged together at the end of each iteration. For models with massive parametrizations, this merge step can be expensive due to communication costs.

Obviously, a different way to expedite MELM training is to simply train on less data. We propose a way to do this without incurring a significant loss of modeling power, by reframing the problem in terms of binary classification. As mentioned above, we build V binary classifiers of the form in (5) to model the distribution over the V words. The binary classifiers use the same features as the MELM of (10), and are given by:

$$P_b(w|h) = \frac{\exp \sum_i \theta_i f_i(h, w)}{1 + \exp \sum_i \theta_i f_i(h, w)}. \quad (12)$$

We assume the features are partitioned over the vocabulary, so that each feature f_i has an associated w such that $f_i(h, w') = 0$ for all $w' \neq w$. Therefore, the corresponding θ_i affects only the binary classifier for w. This gives an important advantage in terms of parallelization–we have a set of binary classifiers with no feature sharing, and can be trained separately on different machines. The parallelized computations are completely independent and do not require the tedious communication between machines. Memory-wise, since the computations are independent, each word trainer only have to store features that are associated with the word, so the memory requirement for each individual worker is significantly reduced.

2.3 Neural Network LM

Neural Network Language Models (NNLM) have gained a lot of interest since their introduction (Bengio et al., 2003). While in standard language modeling, words are treated as discrete symbols, NNLM map them into a continuous space and learn their representations automatically. It is often believed that NNLM can generalize better to sequences that are not seen in the training data. However, despite having been shown to outperform standard n-gram LM (Schwenk, 2007), NNLM are computationally expensive to train.

Figure 1 shows the standard feed-forward NNLM architecture. Starting from the left part of the figure, each word of the $n-1$ words history is mapped to a

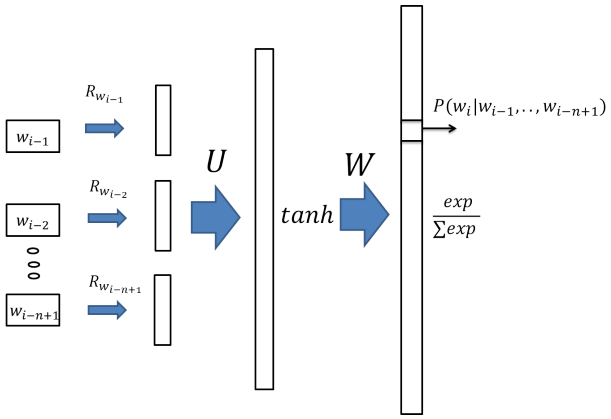

Figure 1: Feed-forward NNLM

continuous vector and concatenated. Through a nonlinear hidden layer, the neural network constructs a multinomial distribution at the output layer. Denoting the concatenated d-dimensional word representations $\mathbf{r}$, we have the following probability definition:

$$P(w_i = k|w_{i-1}, ..., w_{i-n+1}) = \frac{e^{a_k}}{\sum_m e^{a_m}}, \quad (13)$$

$$a_k = b_k + \sum_{l=1}^{h} W_{kl} \tanh(c_l + \sum_{j=1}^{(n-1)d} U_{lj} r_j), \quad (14)$$

where h denotes the hidden layer size, $\mathbf{b}$ and $\mathbf{c}$ are the bias vectors for the output nodes and hidden nodes respectively. Note that NNLM also has the form of (2).

Stochastic gradient descent is often used to maximize the training data likelihood under such a model. The gradient can be computed using the back-propagation method. To analyze the complexity, computing an n-gram conditional probability requires approximately

$$O((n-1)dh + h + Vh + V) \quad (15)$$

operations, where V is the size of the vocabulary. The four terms in the complexity correspond to computing the hidden layer, applying the nonlinearity, computing the output layer and normalization, respectively. The error propagation stage can be analyzed similarly and takes about the same number of operations. For typical values as used in our experiments, namely $n = 3$, $d = 50$, $h = 200$,

$V = 10000$, the majority of the complexity per iteration comes from the term hV. For large scale tasks, it may be impractical to train an NNLM.

A lot of previous research has focused on speeding up NNLM training. It usually aims at removing the computational dependency on V. Schwenk (2007) used a short list of frequent words such that a large number of out-of-list words are taken care of by a back-off LM. To reduce the gradient computation introduced by the normalizer, Bengio and Senecal (2008) proposed a different kind of importance sampling technique. A recent work (Mikolov et al., 2011) applied Goodman's class MELM trick (2001) to NNLM, in order to avoid the gigantic normalization. A similar technique has been introduced even earlier which took the idea of factorizing output layer to the extreme (Morin, 2005) by replacing the V-way prediction by a tree-style hierarchical prediction. The authors show a theoretical complexity reduction from $O(V)$ to $(\log V)$, but the technique requires a careful clustering which may not be easily attainable in practice.

Subsampling has also been proposed to accelerate NNLM training (Schwenk, 2007). The idea is to select random subsets of the training data in each epoch of stochastic gradient descent. After some epochs, it is very likely that all of the training examples have been seen by the model. We will show that our binary classifier representation leads to a more robust and promising subsampling strategy.

As with MELM, we notice that the parameters of (14) can be interpreted as also defining a set of V per-word binary classifiers

$$P_b(w_i = k|w_{i-1}, ..., w_{i-n+1}) = \frac{e^{a_k}}{1 + e^{a_k}}, \quad (16)$$

but with a common hidden layer representation. As in MELM, we will train the classifiers, and renormalize them to obtain an NNLM over the V words.

In order to train the classifiers, we need to compute all V output nodes and propagate the errors back. Since the hidden layer is shared, the classifiers are not independent, and the computations can not be easily parallelized to multiple machines. However, subsampling can be done differently for each classifier. Each training instance serves as a positive example for one classifier and as a negative example for only a fraction α of the others. The rest of the nodes are not computed and do not produce error signal for the hidden representation. We calibrate the classifiers after subsampled training as described above for MELM.

It is straightforward to show that the dominating term Vh in the complexity is reduced to αVh. We want to point out that compared with MELM, subsampling the negatives here does not always reduce the complexity proportionally. In cases where the vocabulary is very small, as shown in (15), computing the hidden layer can no longer be ignored. Nonetheless, real world applications such as speech recognition, usually involves a vocabulary of considerable size, therefore, subsampling in the binary setting can still achieve substantial speedup for NNLM.

3 Experimental Results

3.1 MELM

We evaluate the proposed technique on two datasets of different sizes. Our first dataset is obtained from Penn Treebank. Section 00-20 are used for training(972K tokens), section 21-22 are the validation set(77K), section 23-24(86K) are the test set. The vocabulary size of the experiment is $10,000$. This is one of the standard setups on which many researchers have reported perplexity results on (Mikolov et al., 2011).

The binary MELM is trained using stochastic gradient descent, no explicit regularization is performed (Zhang, 2004). The learning rate starts at 0.1 and is halved every time the perplexity on the validation set stops decreasing. It usually takes around 20 iterations before no significant improvement can be obtained on the validation set. The training stops at that time.

We compare perplexity with both the standard interpolated Kneser-Ney trigram model and the standard MELM. The MELM is L^2 regularized and estimated using a variant of generalized iterative scaling, the regularizer is tuned on the validation data. To demonstrate the effectiveness of our subsampling approach, we compare the subsampled versions of the binary MELM and the standard MELM. In order to obtain valid perplexities, the binary LMs are first renormalized explicitly according to equation (8) for each test history.

Model	PPL
KN Trigram	153.0
Standard MELM, Feat-I	154.2
Binary MELM, Feat-I	153.7
Standard MELM, Feat-II	140.2
Binary MELM, Feat-II	141.1

Table 1: Binary MELM vs. Standard MELM

We consider two kinds of feature sets: Feat-I contains only n-gram features, namely unigram, bigram and trigram features, with no count cutoff, the total number of features is $0.9M$. Feat-II is augmented with skip-1 bigrams and skip-1 trigrams (Goodman, 2001), as well as word trigger features as described in (Rosenfeld, 1996). The total number of features in this set is $1.9M$. Note that the speedup trick described in (Wu and Khudanpur, 2000) can be used for feat-I, but not feat-II.

Table 1 shows the perplexity results when no subsampling is performed. With only n-gram features, the binary MELM is able to match both standard MELM and the Kneser-Ney model. We can also see that by adding features that are known to be able to improve the standard MELM, we can get the same improvement in the binary setting.

Figure 2 shows the comparisons of the two types of MELM when the training data are subsampled. The standard MELM with n-gram features suffers drastically as we sample more aggressively. In contrast, the binary n-gram MELM(Feat-I) does not appear to be hurt by aggressive subsampling, even when 99% of the negative examples are discarded. The robustness also holds for Feat-II where more complicated features are added into the model. This suggests a very efficient way of training MELM– with only 1% of the computational cost, we are able to train an LM as powerful as the standard MELM.

We further test our approach on a second dataset which comes from Wall Street Journal corpus. It contains 26M training tokens and a test set of 22K tokens. We also have a held-out validation set to tune parameters. This set of experiments is intended to demonstrate that the binary subsampling technique is useful on a large text corpus where training a standard MELM is not practical, and gives a better LM than the commonly used Kneser-Ney baseline.

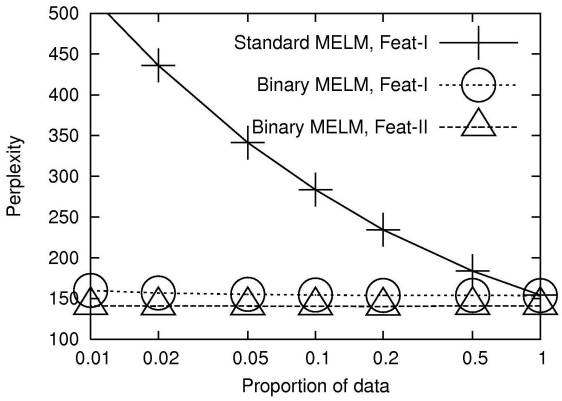

Figure 2: Subsampled Binary MELM vs. Subsampled Standard MELM

Model	PPL
KN Trigram	117.7
Standard MELM, Trigram	116.5
Binary MELM, Feat-III, 10%	110.2
Binary MELM, Feat-III, 5%	110.8
Binary MELM, Feat-III, 2%	112.1
Binary MELM, Feat-III, 1%	112.4

Table 2: Binary Subsampled MELM on WSJ

The binary MELM is trained in the same way as described in the previous experiment. Besides unigram, bigram and trigram features, we also added skip-1 bigrams and skip-1 trigrams, this gives us 7.5M features in total. We call this set of features feat-III. We were unable to train a standard MELM with feat-III or a binary MELM without subsampling because of the computational cost. However, with our binary subsampling technique, as shown in Table 2, we are able to benefit from skip n-gram features with only 5% of the standard MELM complexity. Also the performance does not degrade much as we discard more negative examples.

To show that such improvement in perplexity translates into gains in practical applications, we conducted a set of speech recognition experiments. The task is on Wall Street Journal, the LMs are trained on 37M tokens and are used to rescore the n-best list generated by the first pass recognizer with a trigram LM. The details of the experimental setup can be found in (Xu et al., 2009). Our baseline LM is an interpolated Kneser-Ney 4-gram model.

Note that the size of the vocabulary for the task

Model	Dev WER	Eval WER
KN 4-gram	11.8	17.2

Table 4: Binary NNLM vs. Standard NNLM. Fixed random subset.

Model	Interpolated PPL			
	100%	20%	10%	5%
Standard NNLM	132.7	145.6	148.6	150.7
Binary NNLM	-	132.1	134.2	138.0
KN trigram	153.0	-	-	-

Table 5: Binary NNLM vs. Standard NNLM. Fixed random subset. Interpolated with KN trigram.

is 20K, for the purpose of rescoring, we are only interested in the words that exist in the n-best list, therefore, for the binary MELM, we only have to train about 5300 binary classifiers. For comparison, the KN 4-gram also uses the same restricted vocabulary. The features for the binary MELM are n-gram features up to 4-grams plus skip-1 bigrams and skip-1 trigrams. The total number of features is 10M. We call this set of features Feat-IV.

Table 3 demonstrates the word error rate(WER) improvement enabled by our binary subsampling technique. Note that we can achieve 0.5% absolute WER improvement on the test set at only 1% of the standard MELM complexity. More specifically, with only 50 machines, such a reduction in complexity allows us to train a binary MELM with skip n-gram features in less than two hours, which is not possible for the standard MELM on 37M words.

Obviously, with more machines, the estimation can be even faster, it's also reasonable to expect that with more kinds of features, the improvement can be even larger. We think that the proposed technique opens the door for the utilization of the modeling framework provided by MELM at a scale that has not been possible before.

3.2 NNLM

We evaluate our binary subsampling technique on the same Penn Treebank corpus as described for the MELM experiments. Taking random subsets of the training data with the standard model is our primary baseline to compare with. The NNLM we train is a trigram LM with $tanh$ hidden units. The size of word representation and the size of hidden layer are tuned minimally on the validation set(Hidden layer size 200; Representation size 50). We adopt the same learning rate strategy as for training MELM, and the validation set is used to track perplexity performance and adjust learning rate correspondingly. All parameters are initialized randomly with mean 0 and variance 0.01. As with binary MELM, binary NNLM are explicitly renormalized to obtain valid perplexities.

In our first experiment, we keep the subsampled data fixed as we did for MELM. For the standard NNLM, it means only a subset of the data is seen by the model and it does not change through epochs; For binary NNLM, it means the subset of negative examples for each binary classifier does not change. Table 4 shows the perplexity results by NNLM itself and the interpolated results are shown in Table 5.

We can see that both models exhibit a tendency to deteriorate as we subsample more aggressively. However, the standard NNLM is clearly impacted more severely. With binary NNLM, we are able to retain all the gain after interpolation with only 20% of the negative examples.

Notice that with a fixed random subset, we are not replicating the experiments of Schwenk (Schwenk, 2007) exactly, although it is reasonable to expect both models are able to benefit from seeing different random subsets of the training data. This is verified by results in Table 6 and Table 7.

The standard NNLM benefits quite a lot going from using a fixed random subset to a variable random subset, but still demonstrates a clear tendency to deteriorate as we discard more and more data. On the constrast, the binary NNLM maintains all the performance gain with only 5% of the negative examples and still clearly outperforms its counterpart.

Model	PPL

4 Discussion

For the standard models, the amount of existent patterns fed into training heavily depends on the subsampling rate α. For a small α, the models will inevitably lose some training patterns given any reasonable number of epochs of training. Taking variable random subsets in each epoch can alleviate this problem to some extent, but still can not solve the fundamental problem. In the binary setting, we are able to do subsampling differently. While the complexity remains the same without subsampling, the majority of the complexity comes from processing negatives examples for each binary classifier. Therefore, we can achieve the same level of speedup as standard subsampling by only subsampling negative examples, and most importantly, it allows us to keep all the existent patterns(positive examples) in the training data. Of course, negative examples are important and even in the binary case, we benefit from including more of them, but since we have so many of them, they might not be as critical as positive examples in determining the distribution.

A similar conclusion can be drawn from Google's work on large LMs (Brants et al., 2007). Not having to properly smooth the LM, they are still able to benefit from large volumes of web text as training data. It is probably more important to have a high n-gram coverage than having a precise distribution.

The explanation here might lead us to wonder whether for the multi-class problem, subsampling the terms in the normalizer would achieve the same results. More specifically, instead of summing over all words in the vocabulary, we may choose to only consider α of them. In fact, the short-list approach in (Schwenk, 2007) and the adaptive importance sampling in (Bengio and Senecal, 2008) have exactly this intuition. However, in the multi-class setup, subsampling like this has to be very careful. We have to either have a good estimate of how much probability mass we've thrown away, as in the short-list approach, or have a good estimate of the entire normalizer, as in the importance sampling approach. It is very unlikely that an arbitrary random subsampling will not harm the model. Fortunately, in the binary case, the effect of random subsampling is much easier to analyze. We know exactly how much negative examples we've discarded, and they can be compensated easily in the end.

It is worth pointing out that the proposed technique is not restricted to MELM and NNLM. We have done experiments to binarize the class trick sometimes used for language modeling (Goodman, 2001; Mikolov et al., 2011), and it also proves to be useful. We plan to report these results in the future. More generally, for many large-scale multi-class problems, binarization and subsampling can be an effective combination to consider.

5 Conclusion

We propose efficient subsampling techniques for training large multi-class classifiers such as maximum entropy language models and neural network language models. The main idea is to replace a multi-way decision by a set of binary decisions. Since most of the training instances in the binary setting are negatives examples, we can achieve substantial speedup by subsampling only the negatives. We show by extensive experiments that this is more robust than subsampling subsets of training data for the original multi-class classifier. The proposed method can be very useful for building large language models and solving more general multi-class problems.

Abstract

In this paper, we propose a novel approach to automatic generation of aspect-oriented summaries from multiple documents. We first develop an event-aspect LDA model to cluster sentences into aspects. We then use extended LexRank algorithm to rank the sentences in each cluster. We use Integer Linear Programming for sentence selection. Key features of our method include automatic grouping of semantically related sentences and sentence ranking based on extension of random walk model. Also, we implement a new sentence compression algorithm which use dependency tree instead of parser tree. We compare our method with four baseline methods. Quantitative evaluation based on Rouge metric demonstrates the effectiveness and advantages of our method.

1 Introduction

In recent years, there has been much interest in the task of multi-document summarization. In this paper, we study the task of automatically generating aspect-oriented summaries from multiple documents. The goal of aspect-oriented summarization is to present the most important content to the user in a condensed form and a well-organized structure to satisfy the user's needs. A summary should follow a readable structure and cover all the aspects users are interested in. For example, a summary about natural disasters should include aspects about what happened, when/where it happened, reasons, damages, rescue efforts, etc. and these aspects may be scattered in multiple articles written by different news agencies. Our goal is to automatically collect aspects and construct summaries from multiple documents.

Aspect-oriented summarization can be used in many scenarios. First of all, it can be used to generate Wikipedia-like summary articles, especially used to generate introduction sections that summarizes the subject of articles before the table of contents and other elaborate sections. Second, opinionated text often contains multiple viewpoints about an issue generated by different people. Summarizing these multiple opinions can help people easily digest them. Furthermore, combined with search engines and question&answering systems, we can better organize the summary content based on aspects to improve user experience.

Despite its usefulness, the problem of modeling domain specific aspects for multi-document summarization has not been well studied. The most relevant work is by (Haghighi and Vanderwende, 2009) on exploring content models for multi-document summarization. They proposed a HIERSUM model for finding the subtopics or aspects which are combined by using KL-divergence criterion for selecting relevant sentences. They introduced a general content distribution and several specific content distributions to discover the topic and aspects for a single document collection. However, the aspects may be shared not only across documents in a single collection, but also across documents in different topic-related collections. Their model is conceptually inadequate for simultaneously summarizing multiple topic-related document collections. Furthermore, their sentence selection method based on KL-divergence cannot prevent redundancy across different aspects.

In this paper, we study how to overcome these

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1137–1146,
Edinburgh, Scotland, UK, July 27–31, 2011.

limitations. We hypothesize that comparatively summarizing topics across similar collections can improve the effectiveness of aspect-oriented multi-document summarization. We propose a novel extraction-based approach which consists of four main steps listed below:

Sentence Clustering: Our goal in this step is to automatically identify the different aspects and cluster sentences into aspects (See Section 2). We substantially extend the entity-aspect model in (Li et al., 2010) for generating general sentence clusters.

Sentence Ranking: In this step, we use an extension of LexRank algorithm proposed by (Paul et al., 2010) to score representative sentences in each cluster (See Section 3).

Sentence Compression: In this step, we aim to improve the linguistic quality of the summaries by simplifying the sentence expressions. We prune sentences using grammatical relations defined on dependency trees for recognizing important clauses and removing redundant subtrees (See Section 4).

Sentence Selection: Finally, we select one compressed version of the sentences from each aspect cluster. We use Integer Linear Programming (ILP) algorithm, which optimizes a *global* objective function, for sentence selection (McDonald, 2007; Gillick and Favre, 2009; Sauper and Barzilay, 2009) (See Section 5).

We evaluate our method using TAC2010 Guided Summarization task data sets[1] (Section 6). Our evaluation shows that our method obtains better ROUGE recall score compared with four baseline methods, and it also achieve reasonably high-quality aspect clusters in terms of purity.

2 Sentence Clustering

In this step, our goal is to discover event aspects contained in a document set and cluster sentences into aspects. Here we substantially extend the entity-aspect model in Li et al. (2010) and refer to it as event-aspect model. The main difference between our event-aspect model and entity-aspect model is that we introduce an additional layer of event topics and the separation of general and specific aspects.

Our extension is based upon the following observations. For example, specific events like "Columbine Massacre" and "Malaysia Resort Abduction" can be related to the "Attack" topic. Each event consists of multiple articles written by different news agencies. Interesting aspects may include "what happened, when, where, perpetrators, reasons, who affected, damages and countermeasures," etc[2]. We compared the "Columbine Massacre" and "Malaysia Resort Abduction" data sets and found 5 different kinds of words in the text: (1) stop words that occur frequently in any document collection; (2) general content words describing "damages" or "countermeasures" aspect of attacks; (3) specific content words describing "what happened", "who affected" or "where" aspect of the concrete event; (4) background words describing the general topic of "Attack"; (5) words that are local to a single document and do not appear across different documents. Table 1 shows four sentences related to two major aspects. We found that the entity-aspect model does not have enough capacity to cluster sentences into aspects (See Section 6). So we introduce additional layer to improve the effectiveness of sentence clustering. We also found that their one aspect per sentence assumption is not very strong in this scenario. Although a sentence may belong to a single general aspect, it still contains multiple specific aspect words like second sentence in Table 1. Therefore, We assume that each sentence belongs to both a general aspect and a specific aspect.

2.1 Event-Aspect Model

Stop words can be ignored by LDA model because they can be easily identified using a standard stop word list. Suppose that for a given event topic, there are in total C specific events for which we need to simultaneously generate summaries. We can assume four kinds of unigram language models (i.e. multinomial word distributions). For each event topic, there is a background model $\phi^{\mathcal{B}}$ that generates words commonly used in all documents, and there are A^G general aspect models ϕ^{ga} ($1 \leq ga \leq A^G$), where A^G is the number of general aspects. For each specific event in a topic, there are A^S specific aspect

Table 1: Four sentences on "COUNTERMEASURES" and "What, When, Where" aspects from the "Attack" topic. S: stop word. B: background word. GA: general aspect word. SA: specific aspect word. D: document word.

models ϕ^{sa} ($1 \leq sa \leq A^S$), where A^S is the number of specific aspects, and also there are D document models ϕ^d ($1 \leq d \leq D$), where D is the number of documents in this collection. We assume that these word distributions have a uniform Dirichlet prior with parameter β.

We introduce a level distribution σ that controls whether we choose a word from ϕ^{ga} or ϕ^{sa}. σ is sampled from $Beta(\delta_0, \delta_1)$ distribution. We also introduce an aspect distribution θ that controls how often a general or a specific aspect occurs in the collection, where θ is sampled from another Dirichlet prior with parameter α. There is also a multinomial distribution π that controls in each sentence how often we encounter a background word, a document word, or an aspect word. π has a Dirichlet prior with parameter γ.

Let S_d denote the number of sentences in document d, $N_{d,s}$ denote the number of words (after stop word removal) in sentence s of document d, and $w_{d,s,n}$ denote the n'th word in this sentence. We introduce hidden variables $z^{ga}_{d,s}$ and $z^{sa}_{d,s}$ to indicate that a sentence s of document d belongs to which general or specific aspects . We introduce hidden variables $y_{d,s,n}$ for each word to indicate whether a word is generated from the background model, the document model, or the aspect model. We also introduce hidden variables $l_{d,s,n}$ to indicate whether the n'th word in sentence s of document d is generated from the general aspect model. Figure 1 describes the process of generating the whole document collection. The plate notation of the model is shown in Figure 2. Note that the values of δ_0, δ_1, α_1, α_2, β and γ are fixed. The number of general and specific aspects A^G and A^S are also empirically set.

Given a document collection, i.e. the set of all $w_{d,s,n}$, our goal is to find the most likely assignment of $z^{ga}_{d,s}$, $z^{sa}_{d,s}$, $y_{d,s,n}$ and $l_{d,s,n}$ that maximizes distribution $p(\boldsymbol{z}, \boldsymbol{y}, \boldsymbol{l}|\boldsymbol{w}; \alpha, \beta, \gamma, \delta)$, where $\boldsymbol{z}$, $\boldsymbol{y}$, $\boldsymbol{l}$ and $\boldsymbol{w}$ represent the set of all z, y, l and w variables, respectively. With the assignment, sentences are naturally clustered into aspects, and words are labeled as either a background word, a document word, a general aspect word or a specific aspect word.

Inference can be done with Gibbs sampling, which is commonly used in LDA models (Griffiths and Steyvers, 2004).

In our experiments, we set $\alpha_1 = 5$, $\alpha_2 = 3$, $\beta = 0.01$, $\gamma = 20$, $\delta_1 = 10$ and $\delta_2 = 10$. We run 100 burn-in iterations through all documents in a collection to stabilize the distribution of $\boldsymbol{z}$ and $\boldsymbol{y}$ before collecting samples. We take 10 samples with a gap of 10 iterations between two samples, and average over these 10 samples to get the estimation for the parameters.

After estimating all the distributions, we can find the values of each $z^{ga}_{d,s}$ and $z^{sa}_{d,s}$ that gives us sentences clustered into general and specific aspects.

3 Sentence Ranking

In this step, we want to order the clustered sentences so that the representative sentences can be ranked higher in each aspect. Inspired by Paul et al. (2010), we use an extended LexRank algorithm to obtain top ranked sentences. LexRank (Erkan and Radev, 2004) algorithm defines a random walk mod-

1. Draw $\theta_1 \sim \text{Dir}(\alpha_1), \theta_2 \sim \text{Dir}(\alpha_2), \pi \sim \text{Dir}(\gamma)$ Draw $\sigma \sim \text{Beta}(\delta_0, \delta_1)$
2. For each event topic, there is a background model $\phi^{\mathcal{B}}$, and there are general aspect ga, where $1 \leq ga \leq A^G$
   (a) draw $\phi^{\mathcal{B}} \sim \text{Dir}(\beta)$
   (b) draw $\phi^{ga} \sim \text{Dir}(\beta)$
3. For each document collection, there are specific aspect sa, where $1 \leq sa \leq A^S$
   (a) draw $\phi^{sa} \sim \text{Dir}(\beta)$
4. For each document $d = 1, \ldots, D$,
   (a) draw $\phi^d \sim \text{Dir}(\beta)$
   (b) for each sentence $s = 1, \ldots, S_d$
      i. draw $z^{ga} \sim \text{Multi}(\theta_1)$
      ii. draw $z^{sa} \sim \text{Multi}(\theta_2)$
      iii. for each word $n = 1, \ldots, N_{d,s}$
         A. draw $l_{d,s,n} \sim \text{Binomial}(\sigma)$
         B. draw $y_{d,s,n} \sim \text{Multi}(\pi)$
         C. draw $w_{d,s,n} \sim \text{Multi}(\phi^{\mathcal{B}})$ if $y_{d,s,n} = 1$, $w_{d,s,n} \sim \text{Multi}(\phi^d)$ if $y_{d,s,n} = 2$, $w_{d,s,n} \sim \text{Multi}(\phi^{z^{sa}_{d,s}})$ if $y_{d,s,n} = 3$ and $l_{d,s,n} = 1$ or $w_{d,s,n} \sim \text{Multi}(\phi^{z^{ga}_{d,s}})$ if $y_{d,s,n} = 3$ and $l_{d,s,n} = 0$

Figure 1: The document generation process.

el on top of a graph that represents sentences to be summarized as nodes and their similarities as edges. The LexRank score of a sentence gives the expected probability that a random walk will visit that sentence in the long run. A variant is called continuous LexRank improved LexRank by making use of the strength of the similarity links. The continuous LexRank score can be computed using the following formula:

$$L(u) = \frac{d}{N} + (1-d) \sum_{v \in adj[u]} p(u|v) L(v)$$

where $L(u)$ is the LexRank value of sentence u, N is the total number of nodes in the graph, d is a damping factor for the convergence of the method, and $p(u|v)$ is the jumping probability between sentence u and its neighboring sentence v. $p(u|v)$ is defined using content similarity function $sim(u, v)$ between two sentences:

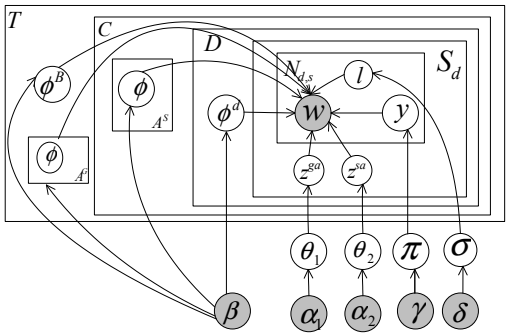

Figure 2: The event-aspect model.

$$p(u|v) = \frac{sim(u, v)}{\sum_{z \in adj[v]} sim(z, v)}$$

The major extension is to modify this jumping probability so as to favor visiting representative sentences. More specifically, we scale $sim(u, v)$ by the likelihood that the two sentences represent the same general aspect ga or specific aspect sa:

$$sim'(u, v) = sim(u, v)[\sum_{ga=1}^{A^G} P(ga|u)P(ga|v) + \sum_{sa=1}^{A^S} P(sa|u)P(sa|v)]$$

where the value $P(ga|u)$ and $P(sa|u)$ can be computed by our event-aspect model. We define $sim(u, v)$ as the $tf * idf$ weighted cosine similarity between two sentences.

We found that sentence ranking is better conducted before the compression because the pre-compressed sentences are more informative and the similarity function in LexRank can be better off with the complete information.

4 Sentence Compression

It has been shown that sentence compression can improve linguistic quality of summaries (Zajic et al., 2007; Gillick et al., 2010). Commonly used "Syntactic parse and trim" approach may produce poor compression results. For example, given the sentence "We have friends whose children go to Columbine, the freshman said", the procedure tries to remove the clause "the freshman said" from the parse tree by using the "SBAR" label to locate the

clause, and will result in "whose children go to Columbine", which is not adequate. Furthermore, some important temporal modifier, numeric modifier and clausal complement need to be retained because they reflect content aspects of the summary. Therefore, we propose the "dependency parse and trim" approach, which prunes sentences based on dependency tree representations, using English grammatical relations to recognize clauses and remove redundant structures. Table 2 shows two examples by removing redundant auxiliary clauses. Below is the sentence compression procedure:

1. Select possible subtree root nodes using grammatical relations, such as clausal complement, complementizer, or parataxis [3].

2. Decide which subtree root node can be the root of clause. If this root contains maximum number of child nodes and the collection of all child edges include object or auxiliary relations, it is selected as the root node.

3. Remove redundant modifiers such as adverbials, relative clause modifiers and abbreviations, participials and infinitive modifiers.

4. Traverse the subtrees and generate all possible compression alternatives using the subtree root node, then keep the top two longest sub sentences.

5. Drop the sub sentences shorter than 5 words.

5 Sentence Selection

After sentence pruning, we prepare for the final event summary generation process. In this step, we select one compressed version of the sentence from each aspect cluster. To avoid redundancy between aspects, we use Integer Linear Programming to optimize a global objective function for sentence selection. Inspired by (Sauper and Barzilay, 2009), we formulate the optimization problem based on sentence ranking information. More specifically, we would like to select exactly one compressed sentence which receives the highest possible ranking score from each aspect cluster subject to a series of constraints, such as redundancy and length. We employed lp_solver [4], an efficient mixed integer programming solver using the Branch-and-Bound algorithm to select sentences.

Original	**Compressed**
When rescue workers arrived, they said, only one of his limbs was visible.	When rescue workers arrived, only one of his limbs was visible.
Two days earlier, a massacre by two students at Columbine High, whose teams are called the Rebels, left 15 people dead and dozens wounded.	Two days earlier, a massacre by two students at Columbine High, left 15 people dead and dozens wounded.

Table 2: Example compressed sentences.

Assume that there are in total K aspects in an event topic. For each aspect j, there are in total R ranked sentences. The variables S_{jl} is a binary indicator of the sentence. That is, S_{jl}= 1 if the sentence is included in the final summary, and S_{jl} = 0 otherwise. l is the ranked position of the sentence in this aspect cluster.

Objective Function

Top ranked sentences are the most relevant corresponding to the related aspects which we want to include in the final summary. Thus we try to minimize the ranks of the sentences to improve the overall responsiveness.

$$\min(\sum_{j=1}^{K}\sum_{l=1}^{R_j} l \cdot S_{jl})$$

Exclusivity Constraints

To prevent redundancy in each aspect, we just choose one sentence from each general or specific aspect cluster. The constraint is formulated as follows:

$$\sum_{l=1}^{R_j} S_{jl} = 1 \qquad \forall j \in \{1 \dots K\}$$

[3] The parataxis relation is a relation between the main verb of a clause and other sentential elements, such as a sentential parenthetical, colon, or semicolon

[4] http://lpsolve.sourceforge.net/5.5/

Redundancy Constraints

We also want to prevent redundancy across different aspects. If sentence-similarity $sim(s_{jl}, s_{j'l'})$ between sentence s_{jl} and $s_{j'l'}$ is above 0.5, then we drop the pair and choose one sentence ranked higher from the pair otherwise. This constraint is formulated as follows:

$$(S_{jl} + S_{j'l'}) \cdot sim(s_{jl}, s_{j'l'}) \leq 0.5$$
$$\forall j, j' \in \{1 \dots K\} \forall l \in \{1 \dots R_j\} \forall l' \in \{1 \dots R_{j'}\}$$

Length Constraints

We add this constraint to ensure that the length of the final summary is limited to L words.

$$\sum_{j=1}^{K} \sum_{l=1}^{R_j} len_{jl} \cdot S_{jl} \leq L$$

where len_{jl} is the length of S_{jl}.

6 Evaluation

In order to systematically evaluate our method, we want to check (1) whether the whole system is effective, which means to quantitatively evaluate summary quality, and (2) whether individual components like clustering and compression algorithms are useful.

6.1 Data

We use TAC2010 Summarization task data set for the summary content evaluation. This data set provides 46 events. Each event falls into a predefined event topic. Each specific event includes an event statement and 20 relevant newswire articles which have been divided into 2 sets: Document Set A and Document Set B. Each document set has 10 documents, and all the documents in Set A chronologically precede the documents in Set B. We just use document Set A for our task. Assessors wrote model summaries for each event, so we can compare our automatic generated summaries with the model summaries. We combine topic related data sets together, then these data sets simultaneously annotated by our Event-aspect model. After labeling process, we run sentence ranking, compression and selection module to get final aspect-oriented summarizations.

6.2 Quality of summary

We use the ROUGE (Lin and Hovy, 2003) metric for measuring the summarization system performance. Ideally, a summarization criterion should be more recall oriented. So the average recall of ROUGE-1, ROUGE-2, ROUGE-SU4, ROUGE-W-1.2 and ROUGE-L were computed by running ROUGE-1.5.5 with stemming but no removal of stop words. We compare our method with the following four baseline methods.

Baseline 1

In this baseline, we try to compare different sentence clustering algorithms in the multi-document summarization scenario. First, we use CLUTO [5] to do K-means clustering. Then we try entity-aspect model proposed by Li et al. (2010) to do sentence clustering. Entity-aspect model is similar with "HIERSUM" content model proposed by Haghighi and Vanderwende (2009). We use the same ranking, compression, and selection components to generate aspect-oriented summaries for comparison.

Baseline 2

In this baseline, we compare our method with traditional ranking and selection summary generation framework (Erkan and Radev, 2004; Nenkova and Vanderwende, 2005) to show that our sentence clustering component is necessary in aspect-oriented summarization system. Also we want check whether sentence ranking combined with greedy based sentence selection can prevent redundancy effectively. We follow LexRank based sentence ranking combined with greedy sentence selection methods. We implement two greedy algorithms (Zhang et al., 2008; Paul et al., 2010). One is to select the top ranked sentence simultaneously by removing 10 redundant neighbor sentences from the sentence similarity graph if the summary length is less then 100 words. This is repeated until the graph cannot be partitioned. The similarity graph building threshold is 0.3, damping factor is 0.2 and error tolerance for Power Method in LexRank is 0.1. The other is to select top ranked sentences as long as the redundancy score (similarity) between a candidate sentence and

[5] http://glaros.dtc.umn.edu/gkhome/cluto/cluto/overview

current summary is under 0.5. This is repeated until the summary reaches a 100 word length limit.

Baseline 3

In this baseline, we compare our ILP based sentence selection with KL-divergence based sentence selection. The KL-divergence formula we use is below,

$$KL(P_S||Q_D) = \sum_w P(w) \log \frac{P(w)}{Q(w)}$$

where $P(S)$ is the empirical unigram distribution of the candidate summary S, and $Q(D)$ is the unigram distribution of document collection D. We only replaced our selection method with the KL-divergence selection method. Other parts are the same. After ranking sentences for each aspect, we add the sentence with the highest ranking score from each aspect sentence cluster as long as the KL-divergence between candidate and current summary does not decrease. This is repeated until the summary reaches a 100 word length limit. To our knowledge, this is the first work to directly compare Integer Linear Programming based sentence selection with KL-divergence based sentence selection in summarization generation framework.

Baseline 4

In this baseline, we directly compare our method with "HIERSUM" proposed by (Haghighi and Vanderwende, 2009). As in Baseline 1, we use entity-aspect model to approximate "HIERSUM" model. We replace unigram distribution of $P(w)$ in KL-divergence with learned distribution estimated by "HIERSUM" model. The KL-divergence based greedy sentence selection algorithm is similar to Baseline 3.

For fair comparison, Baselines 1, 2, 3 and 4 use the same sentence compression algorithm and have the summary length no more then 100 words. In Table 3, we show the average ROUGE recall of 46 summaries generated by our method and four baseline methods. We can see that our method gives better Rouge recall measures then the four baseline methods. For BL-1, we can see that LDA-based sentence clustering is better then k-means. For BL-2, we can see that traditional ranking plus greedy selection summary generation framework is not suitable for the aspect-oriented summarization task. More specifically, greedy-based sentence selection can not prevent redundancy effectively. BL-3 evaluation results showed that ILP-based sentence selection is better then KL-divergence selection in terms of preventing redundancy across different aspects. The measurement performance between BL-3 and BL-4 is close. They use the same KL-divergence based sentence selection, but topic model they use are different, and also BL-3 has a sentence ranking process. The Rouge recall of our method is better than BL-4. It is expected because our event-aspect model can better find the aspects and also prove that our LexRank based sentence ranking combined with ILP-based sentence selection can prevent redundancy.

Due to TAC2010 summarization community just compute ROUGE-2 and ROUGE-SU4 metrics for participants, our ROUGE-2 metric ranked 11 out of 23, ROUGE-SU4 metric ranked 12 out of 23. They use MEAD[6] as their baseline approach. The ROUGE-2 score of our approach achieve 0.06508 higher than MEAD's 0.05929. The ROUGE-SU4 score of our approach achieve 0.10146 higher than MEAD's 0.09112. Many systems that get higher performances leverage domain knowledge bases like Wikipedia or training data, but we didn't. The advantage of our method is that we generate summaries with totally unsupervised framework and this approach is domain adaptive.

6.3 Quality of aspect-oriented sentence clusters

To judge the quality of the aspect-oriented sentence clusters, we ask the human judges to group the ground truth sentences based on the aspect relatedness in each event topic. We then compute the purity of the automatically generated clusters against the human judged clusters. The results are shown in Table 4. In our experiments, we set the number of general aspect clusters A^G is 5 and specific aspect clusters A^S is 3. We can see from Table 4 that our generated aspect clusters can achieve reasonably good performance.

Attacks	2.3
Health and Safety	2.6
Endangered Resources	2.5
Investigations and Trials	2.4

Table 5: The average score of each event topic.

6.4 Quality of sentence compression

To judge the quality of the dependency tree based sentence compression algorithm, we ask the human judges to choose 20 sentences from each event topic then score them. The judges follow 3-point scale to score each compressed sentence: 1 means poor, 2 means barely acceptable, and 3 means good. We then compute the average scores. The results are shown in Table 5. To evaluate the effectiveness of sentence compression component, we conduct the system without sentence compression component, then compare it with our system. In Table 3, we can see that sentence compression can improve the system performance.

7 Related Work

Our event-aspect model is related to a number of previous extensions of LDA models. Chemudugunta et al. (2007) proposed to introduce a background topic and document-specific topics. Our background and document language models are similar to theirs. However, they still treat documents as bags of words rather then sets of sentences as in our models. Titov and McDonald (2008) exploited the idea that a short paragraph within a document is likely to be about the same aspect. The way we separate words into stop words, background words, document words and aspect words bears similarity to that used in (Daumé III and Marcu, 2006; Haghighi and Vanderwende, 2009). Paul and Girju (2010) proposed a topic-aspect model for simultaneously finding topics and aspects. The most related extension is entity-aspect model proposed by Li et al. (2010). The main difference between event-aspect model and entity-aspect model is our model further consider aspect granularity and add a layer to model topic-related events.

Filippova and Strube (2008) proposed a dependency tree based sentence compression algorithm. Their approach need a large corpus to build language model for compression, whereas we prune dependency tree using grammatical rules.

Paul et al. (2010) proposed to modify LexRank algorithm using their topic-aspect model. But their task is to summarize contrastive viewpoints in opinionated text. Furthermore, they use a simple greedy approach for constructing summary.

McDonald (2007) proposed to use Integer Linear Programming framework in multi-document sum-

marization. And Sauper and Barzilay (2009) use integer linear programming framework to automatically generate Wikipedia articles. There is a fundamental difference between their method and ours. They used trained perceptron algorithm for ranking excerpts, whereas we give an extended LexRank with integer linear programming to optimize sentence selection for our aspect-oriented multi-document summarization.

8 Conclusions and Future Work

In this paper, we study the task of automatically generating aspect-oriented summary from multiple documents. We proposed an event-aspect model that can automatically cluster sentences into aspects. We then use an extension of the LexRank algorithm to rank sentences. We took advantage of the output generated by the event-aspect model to modify jumping probabilities so as to favor visiting representative sentence. We also proposed dependency tree compression algorithm to prune sentence for improving linguistic quality of the summaries. Finally we use Integer Linear Programming Framework to select aspect relevant sentences. We conducted quantitative evaluation using standard test data sets. We found that our method gave overall better ROUGE scores than four baseline methods, and the new sentence clustering and compression algorithm are robust.

There are a number of directions we plan to pursue in the future in order to improve our method. First, we can possibly apply more linguistic knowledge to improve the quality of sentence compression. Currently the sentence compression algorithm may generate meaningless subtrees. It is relatively hard to decide which clause is redundant in terms of summarization. Second, we may explore more domain knowledge to improve the quality of aspect-oriented summaries. For example, we know that the "who-affected" aspect is related to person, and "when, where" are related to Time and Location. we can import Name Entity Recognition to annotate these phrases and then help locate relevant sentences. Third, we want to extend our event-aspect model to simultaneously find topics and aspects.

Abstract

Machine-produced text often lacks grammaticality and fluency. This paper studies grammaticality improvement using a syntax-based algorithm based on CCG. The goal of the search problem is to find an optimal parse tree among all that can be constructed through selection and ordering of the input words. The search problem, which is significantly harder than parsing, is solved by guided learning for best-first search. In a standard word ordering task, our system gives a BLEU score of 40.1, higher than the previous result of 33.7 achieved by a dependency-based system.

1 Introduction

Machine-produced text, such as SMT output, often lacks grammaticality and fluency, especially when using n-gram language modelling (Knight, 2007). Recent efforts have been made to improve grammaticality using local language models (Blackwood et al., 2010) and global dependency structures (Wan et al., 2009). We study grammaticality improvement using a syntax-based system.

The task is effectively a text-to-text generation problem where the goal is to produce a grammatical sentence from an ungrammatical and fragmentary input. The input can range from a bag-of-words (Wan et al., 2009) to a fully-ordered sentence (Blackwood et al., 2010). A general form of the problem is to construct a grammatical sentence from a set of un-ordered input words. However, in cases where the base system produces fluent subsequences within the sentence, constraints on the choice and order of certain words can be fed to the grammaticality improvement system. The input may also include words beyond the output of the base system, e.g. extra words from the SMT lattice, so that content word insertion and deletion can be performed implicity via word selection.

We study the above task using CCG (Steedman, 2000). The main challenge is the search problem, which is to find an optimal parse tree among all that can be constructed with any word choice and order from the set of input words. We use an approximate best-first algorithm, guided by learning, to tackle the more-than-factorial complexity. Beam-search is used to control the volume of accepted hypotheses, so that only a very small portion of the whole search space is explored. The search algorithm is guided by perceptron training, which ensures that the explored path in the search space consists of highly probable hypotheses. This framework of best-first search guided by learning is a general contribution of the paper, which could be applied to problems outside grammaticality improvement.

We evaluate our system using the generation task of word-order recovery, which is to recover the original word order of a fully scrambled input sentence (Bangalore et al., 2000; Wan et al., 2009). This problem is an instance of our general task formulation, but without any input constraints, or content word selection (since all input words are used). It is straightforward to use this task to evaluate our system and compare with existing approaches. Our system gave 40.1 BLEU score, higher than the dependency-based system of Wan et al. (2009), for which a BLEU score of 33.7 was reported.

2 The Grammar

Combinatory Categorial Grammar (CCG; Steedman (2000)) is a lexicalized grammar formalism, which associates words with lexical categories. Lexical categories are detailed grammatical labels, typically expressing subcategorisation information. CCG, and parsing with CCG, has been described in detail elsewhere (Clark and Curran, 2007; Hockenmaier, 2003); here we provide only a short description.

During CCG parsing, adjacent categories are combined using CCG's combinatory rules. For example, a verb phrase in English ($S\backslash NP$) can combine with an NP to its left:

$$NP \;\; S\backslash NP \Rightarrow S$$

In addition to binary rule instances, such as the one above, there are also unary rules which operate on a single category in order to change its type. For example, forward type-raising can change a subject NP into a complex category looking to the right for a verb phrase:

$$NP \Rightarrow S/(S\backslash NP)$$

Following Hockenmaier (2003), we extract the grammar by reading rule instances directly from the derivations in CCGbank (Hockenmaier and Steedman, 2007), rather than defining the combinatory rule schema manually as in Clark and Curran (2007).

3 The Search Algorithm

The input to the search algorithm is a set of words, each word having a count that specifies the maximum number of times it can appear in the output. Typically, most input words can occur only once in the output. However, punctuation marks and function words can be given a higher count. Depending on the fluency of the base output (e.g. the output of the base SMT system), some constraints can be given to specific input words, limiting their order or identifying them as an atomic phrase, for example.

The goal of the search algorithm is to find an optimal parse tree (including the surface string) among all that can be constructed via selecting and ordering a subset of words from the input multiset. The complexity of this problem is much higher than a typical parsing problem, since there is an exponential number of word choices for the output sentence, each with a factorial number of orderings. Moreover, dynamic programming packing for parsers, such as a CKY chart, is not applicable, because of the lack of a fixed word order.

We perform approximate search using a best-first algorithm. Starting from single words, candidate parses are constructed bottom-up. Similar to a best-first parser (Caraballo and Charniak, 1998), the highest scored hypothesis is expanded first. A hypothesis is expanded by applying CCG unary rules to the hypothesis, or by combining the hypothesis with existing hypotheses using CCG binary rules.

We use beam search to control the number of accepted hypotheses, so that the computational complexity of expanding each hypothesis is linear in the size of the beam. Since there is no guarantee that a goal hypothesis will be found in polynomial time, we apply a robustness mechanism (Riezler et al., 2002; White, 2004), and construct a default output when no goal hypothesis is found within a time limit.

3.1 Data Structures

Edges are the basic structures that represent hypotheses. Each edge is a CCG constituent, spanning a sequence of words. Similar to partial parses in a typical chart parser, edges have recursive structures. Depending on the number of subedges, edges can be classified into *leaf edges*, *unary edges* and *binary edges*. Leaf edges, which represent input words, are constructed first in the search process. Existing edges are expanded to generate new edges via unary and binary CCG rules. An edge that meets the output criteria is called a *goal edge*. In the experiments of this paper, we define a goal edge as one that includes all input words the correct number of times.

The *signature* of an edge consists of the category label, surface string and head word of the constituent. Two edges are *equivalent* if they share the same signature. Given our feature definitions, a lower scoring edge with the same signature as a higher scoring edge cannot be part of the highest scoring derivation.

The number of words in the surface string of an edge is called the *size* of the edge. Other important substructures of an edge include a bitvector and an array, which stores the indices of the input words that the edge contains. Before two edges are combined using a binary CCG rule, an *input check* is per-

formed to make sure that the total count for a word from the two edges does not exceed the count for that word in the input. Intuitively, an edge can record the count of each unique input word it contains, and perform the input check in linear time. However, since most input words typically occur once, they can be indexed and represented by a bitvector, which allows a constant time input check. The few multiple-occurrence words are stored in a count array.

In the best-first process, edges to be expanded are ordered by their scores, and stored in an *agenda*. Edges that have been expanded are stored in a *chart*. There are many ways in which edges could be ordered and compared. Here the chart is organised as a set of beams, each containing a fixed number of edges with a particular size. This is similar to typical decoding algorithms for phrase-based SMT (Koehn, 2010). In each beam, edges are ordered by their scores, and low score edges are pruned. In addition to pruning by the beam, only the highest scored edge is kept among all that share the same signature.

3.2 The Search Process

Figure 1 shows pseudocode for the search algorithm. During initialization, the agenda (a) and chart (c) are cleared. All candidate lexical categories are assigned to each input word, and the resulting leaf edges are put onto the agenda.

In the main loop, the best edge (e) is popped from the agenda. If e is a goal hypothesis, it is appended to a list of goals (*goal*), and the loop is continued without e being expanded. If e or any equivalent edge $\tilde{e}$ of e is already in the chart, the loop continues without expanding e. It can be proved that any edge in the chart must have been combined with $\tilde{e}$, and therefore the expansion of e is unnecessary.

Edge e is first expanded by applying unary rules, and any new edges are put into a list (*new*). Next, e is matched against each existing edge $\tilde{e}$ in the chart. e and $\tilde{e}$ can be combined if they pass the input check, and there is a binary rule in which the constituents are combined. e and $\tilde{e}$ are combined in both possible orders, and any resulting edge is added to *new*.

At the end of each loop, edges from *new* are added to the agenda, and *new* is cleared. The loop continues until a stopping criterion is met. A typical stopping condition is that *goal* contains N goal edges.

```
a ← INITAGENDA(input)
c ← INITCHART()
new ← []
goal ← []
while not STOP(goal, time):
  e ← POPBEST(a)
  if GOALTEST(e)
    APPEND(goal, e)
    continue
  for ẽ in c:
    if EQUIV(ẽ, e):
      continue
  for e′ in UNARY(e, grammar):
    APPEND(new, e′)
  for ẽ in c:
    if CANCOMBINE(e, ẽ):
      e′ ← BINARY(e, ẽ, grammar)
      APPEND(new, e′)
    if CANCOMBINE(ẽ, e):
      e′ ← BINARY(ẽ, e, grammar)
      APPEND(new, e′)
  for e′ in new:
    ADD(a, e′)
  ADD(c, e)
  new ← []
```

Figure 1: The search algorithm.

We set N to 1 in our experiments. For practical reasons we also include a timeout stopping condition. If no goal edges are found before the timeout is reached, a default output is constructed by the following procedure. First, if any two edges in the chart pass the input check, and the words they contain constitute the full input set, they are concatenated to form an output string. Second, when no two edges in the chart meet the above condition, the largest edge $\tilde{e}$ in the chart is chosen. Then edges in the chart are iterated over in the larger first order, with any edge that passes the input check with $\tilde{e}$ concatenated with $\tilde{e}$ and $\tilde{e}$ updated. The final $\tilde{e}$, which can be shorter than the input, is taken as the default output.

4 Model and Features

We use a discriminative linear model to score edges, where the score of an edge e is calculated using the global feature vector $\Phi(e)$ and the parameter vector

$\vec{w}$ of the model.

$$\text{SCORE}(e) = \Phi(e) \cdot \vec{w}$$

$\Phi(e)$ represents the counts of individual features of e. It is computed incrementally as the edge is built. At each constituent level, the incremental feature vector is extracted according to the feature templates from Table 1, and we use the term *constituent level vector* ϕ to refer to it. So for any edge e, $\phi(e)$ consists of features from the top rule of the hierarchical structure of e. $\Phi(e)$ can be written as the sum of $\phi(e')$ of all recursive subedges e' of e, including e itself:

$$\Phi(e) = \sum_{e' \in e} \phi(e')$$

The parameter update in Section 5 is in terms of constituent level vectors.

The features in Table 1 represent patterns including the constituent label; the head word of the constituent; the size of the constituent; word, POS and lexical category N-grams resulting from a binary combination; and the unary and binary rules by which the constituent is constructed. They can be classified roughly into "parsing" features (those about the parse structure, such as the binary rule) and "generation features" (those about the surface string, such as word bigrams), although some features, such as "rule + head word + non-head word", contain both types of information.

condition	feature
all edges	constituent + size
	constituent + head word
	constituent + size + head word
	constituent + head POS
size > 1	constituent + leftmost word
	constituent + rightmost word
	consti. + leftmost POS bigram
	consti. + rightmost POS bigram
	consti. + lmost POS + rmost POS
binary edges	the binary rule
	the binary rule + head word
	rule + head word + non-head word
	bigrams resulting from combination
	POS bigrams resulting from combi.
	word trigrams resulting from combi.
	POS trigrams resulting from combi.
	resulting lexical categary trigrams
	resulting word + POS bigrams
	resulting POS + word bigrams
	resulting POS + word + POS trigrams
unary edges	unary rule
	unary rule + headw

Table 1: Feature template definitions.

5 The Learning Algorithm

The statistical model plays two important roles in our system. First, as in typical statistical systems, it is expected to give a higher score to a more correct hypothesis. Second, it is also crucial to the speed of the search algorithm, since the best-first mechanism relies on a model to find goal hypotheses efficiently. As an indication of the impact of the model on efficiency, if the model parameters are set to all zeros, the search algorithm cannot find a result for the first sentence in the development data within two hours.

We perform training on a corpus of CCG derivations, where constituents in a gold-standard derivation serve as gold edges. The training algorithm runs the decoder on each training example, updating the model when necessary, until the gold goal edge is recovered. We use the perceptron (Rosenblatt, 1958) to perform parameter updates. The traditional perceptron has been adapted to structural prediction (Collins, 2002) and search optimization problems (Daumé III and Marcu, 2005; Shen et al., 2007). Our training algorithm can be viewed as an adaptation of the perceptron to our best-first framework for search efficiency and accuracy.

We choose to update parameters as soon as the best edge from the agenda is not a gold-standard edge. The intuition is that all gold edges are forced to be above all non-gold edges on the agenda. This is a strong precondition for parameter updates. An alternative is to update when a gold-standard edge falls off the chart, which corresponds to the precondition for parameter updates of Daumé III and Marcu (2005). However, due to the complexity of our search task, we found that reasonable training efficiency cannot be achieved by the weaker alternatives. Our updates lead both to correctness (edges in the chart are correct) and efficiency (correct edges are found at the first possible opportunity).

During a perceptron update, an incorrect prediction, corresponding to the current best edge in the agenda, is penalized, and the corresponding gold edge is rewarded. However, in our scenario it is not obvious what the corresponding gold edge should be, and there are many ways in which the gold edge could be defined. We investigated a number of alternatives, for example trying to find the "best match" for the incorrect prediction. In practice we found that the simple strategy of selecting the lowest scored gold-standard edge in the agenda was effective, and the results presented in this paper are based on this method.

After an update, there are at least two alternative methods to continue. The first is to reinitialize the agenda and chart using the new model, and continue until the current training example is correctly predicted. This method is called *aggressive training* (Shen et al., 2007). In order to achieve reasonable efficiency, we adopt a second approach, which is to continue training without reinitializing the agenda and chart. Instead, only edges from the top of the agenda down to the lowest-scoring gold-standard edge are given new scores according to the new parameters.

Figure 2 shows pseudocode for the learning algorithm applied to one training example. The initialization is identical to the test search, except that the list of goal edges is not maintained. In the main loop, the best edge e is popped off the agenda. If it is the gold goal edge, the training for this sentence finishes. If e is not a gold edge, parameter updates are performed and the loop is continued with e being discarded. Only gold edges are pushed onto the chart throughout the training process.

When updating parameters, the current non-gold edge (e) is used as the negative example, and the smallest gold edge in the agenda (*minGold*) is used as the corresponding positive example. The model parameters are updated by adding the constituent level feature vector (see Section 4) of *minGold*, and subtracting the constituent level feature vector of e. Note that we do not use the global feature vector in the update, since only the constituent level parameter vectors are compatible for edges with different sizes. After a parameter update, edges are rescored from the top of the agenda down to *minGold*.

The training algorithm iterates through all training examples N times, and the final parameter vector is used as the model. In our experiments, N is chosen according to results on development data.

```
a ← INITAGENDA(input)
c ← INITCHART()
new ← []
while true:
  e ← POPBEST(a)
  if GOLD(e) and GOALTEST(e):
    return
  if not GOLD(e):
    popped ← []
    n ← 0
    while n < GOLDCOUNT(a):
      ẽ ← POPBEST(a)
      APPEND(popped, ẽ)
      if GOLD(ẽ):
        minGold ← ẽ
        n ← n + 1
    w⃗ ← w⃗ − φ(e) + φ(minGold)
    for ẽ in popped:
      RECOMPUTESCORE(ẽ)
      ADD(a, ẽ)
    for ẽ in c:
      RECOMPUTESCORE(ẽ)
    continue
  for e′ in UNARY(e, grammar):
    APPEND(new, e′)
  for ẽ in c:
    if CANCOMBINE(e, ẽ):
      e′ ← BINARY(e, ẽ, grammar)
      APPEND(new, e′)
    if CANCOMBINE(ẽ, e):
      e′ ← BINARY(ẽ, e, grammar)
      APPEND(new, e′)
  for e′ in new:
    ADD(a, e′)
  ADD(c, e)
  new ← []
```

Figure 2: The learning algorithm.

6 Experiments

We use CCGBank (Hockenmaier and Steedman, 2007) for experimental data. CCGbank is the CCG version of the Penn Treebank. Sections 02–21 are

used for training, section 00 is used for development and section 23 for the final test.

Original sentences from CCGBank are transformed into bags of words, with sequence information removed, and passed to our system as input data. The system outputs are compared to the original sentences for evaluation. Following Wan et al. (2009), we use the BLEU metric (Papineni et al., 2002) for string comparison. Whilst BLEU is not an ideal measure of fluency or grammaticality, being based on n-gram precision, it is currently widely used for automatic evaluation and allows us to compare directly with existing work (Wan et al., 2009).

In addition to the surface string, our system also produces the CCG parse given an input bag of words. The quality of the parse tree can reflect both the grammaticality of the surface string and the quality of the trained grammar model. However, there is no direct way to automatically evaluate parse trees since output word choice and order can be different from the gold-standard. Instead, we indirectly measure parse quality by calculating the precision of CCG lexical categories. Since CCG lexical categories contain so much syntactic information, they provide a useful measure of parse quality. Again because the word order can be different, we turn both the output and the gold-standard into a bag of word/category pairs, and calculate the percentage of matched pairs as the lexical category precision.

For fair comparison with Wan et al. (2009), we keep base NPs as atomic units when preparing the input. Wan et al. (2009) used base NPs from Penn Treebank annotation, while we extract base NPs from the CCGBbank by taking as base NPs the NPs that do not recursively contain other NPs. These base NPs mostly correspond to the base NPs from the Penn Treebank. In the training data, there are 242,813 Penn Treebank base NPs with an average size of 1.09, and 216,670 CCGBank base NPs with an average size of 1.19.

6.1 Development Tests

Table 2 shows a set of development experiment results after one training iteration. Three different methods of assigning lexical categories are used. The first ("dictionary") is to assign all possible lexical categories to each input word from the dictionary. The lexical category dictionary is built using the training sections of CCGBank. For each word occurring more than 20 times in the corpus, the dictionary has an entry with all lexical categories the word has been seen with. For the rest of the words, the dictionary maintains an entry for each POS which contains all lexical categories it has been seen with. There are on average 26.8 different categories for each input word by this method.

Method	Timeout	BLEU	Length ratio	Timeout ratio
dictionary	0.5s	34.98	84.02	62.26
	1s	35.40	85.66	57.87
	5s	36.27	89.05	45.79
	10s	36.45	89.13	42,13
	50s	37.07	92.52	32.41
$\beta = 0.0001$	0.5s	36.54	84.26	66.07
	1s	37.50	86.69	58.22
	5s	38.75	90.15	43.23
	10s	39.14	91.35	38.36
	50s	39.58	93.09	30.53
$\beta = 0.075$	0.5s	40.87	85.66	61.27
	1s	42.04	87.99	53.11
	5s	43.99	91.20	40.30
	10s	44.23	92.14	35.70
	50s	45.08	93.70	29.43

Table 2: Development tests using various levels of lexical categories and timeouts, after one training iteration.

In practice, it is often unnecessary to leave lexical category disambiguation completely to the grammaticality improvement system. When it is reasonable to assume that the input sentence for the grammaticality improvement system is sufficiently fluent, a list of candidate lexical categories can be assigned automatically to each word via supertagging (Clark and Curran, 2007) on the input sequence. We use the C&C supertagger[1] to assign a set of probable lexical categories to each input word using the gold-standard order. When the input is noisy, the accuracy of a supertagger tends to be lower than when the input is grammatical. One way to address this problem is to allow the supertagger to produce a larger list of possible supertags for each input word, and leave the ambiguity to the grammatical improvement system. We simulate the noisy input situation by using

[1] http://svn.ask.it.usyd.edu.au/trac/candc/wiki/Download.

	Precision
dictionary	58.5%
$\beta = 0.0001$	59.7%
$\beta = 0.075\%$	77.0%

Table 3: Lexical category accuracies. Timeout = 5s. 1 training iteration.

a small probability cutoff (β) value in the supertagger, and supertag correctly ordered input sentences before breaking them into bags of words. With a β value of 0.0001, there are 5.4 lexical categories for each input word in the development test (which is smaller than the dictionary case).

The average number of lexical categories per word drops to 1.3 when β equals 0.075, which is the value used for parsing newspaper text in Clark and Curran (2007). We include this β in our experiments to compare the effect of different β levels.

The table shows that the BLEU score of the grammaticality improvement system is higher when a super tagger is used, and the higher the β value, the better the BLEU score. In practice, the β value should be set in accordance with the lack of grammaticality and fluency in the input. The dictionary method can be used when the output is extremely unreliable, while a small beta value can be used if the output is almost fluent.

Due to the default output mechanism on timeout, the system can sometimes fail to produce sentences that cover all input words. We choose five different timeout settings between 0.5s to 50s, and compare the speed/quality tradeoff. In addition to BLEU, we report the percentage of timeouts and the ratio of the sum of all output sentence lengths to the sum of all input sentence lengths.

When the timeout value increases, the BLEU score generally increases. The main effect of a larger timeout is the increased possibility of a complete sentence being found. As the time increases from 0.5s to 50s using the dictionary method, for example, the average output sentence length increases from 84% of the input length to 93%.

Table 3 shows the lexical category accuracies using the dictionary, and supertagger with different β levels. The timeout limit is set to 5 seconds. As the lexical category ambiguity decreases, the accuracy increases. The best lexical category accuracy of 77% is achieved when using a supertagger with a β level 0.075, the level for which the least lexical category disambiguation is required. However, compared to the 93% lexical category accuracy of a CCG parser (Clark and Curran, 2007), which also uses a β level of 0.075 for the majority of sentences, the accuracy of our grammaticality improvement system is much lower. The lower score reflects the lower quality of the parse trees produced by our system. Besides the difference in the algorithms themselves, one important reason is the much higher complexity of our search problem.

Length	dictionary	$\beta = 0.0001$	$\beta = 0.075$
≤ 5	75.65	89.42	92.64
≤ 10	57.74	66.00	78.54
≤ 20	42.44	48.89	58.23
≤ 40	37.48	40.32	46.00
≤ 80	36.50	39.01	44.26
all	36.27	38.75	43.99

Table 4: BLEU scores measured on different lengths on development data. Timeout = 5s. 1 training iteration.

Table 4 shows the BLEU scores measured by different sizes of input. We also give some example output sentences in Figure 3. It can be seen from the table that the BLEU scores are higher when the size of input is smaller. For sentences shorter than 20 words, our system generally produces reasonably fluent and grammatical outputs. For longer sentences, the grammaticality drops. There are three possible reasons. First, larger constituents require more steps to construct. The model and search algorithm face many more ambiguities, and error propagation is more severe. Second, the search algorithm often fails to find a goal hypothesis before timeout, and a default output that is less grammatical than a complete constituent is constructed. Long sentences have comparatively more input words uncovered in the output. Third, the upper bound is not 100, and presumably lower for longer sentences, because there are many ways to generate a grammatical sentence given a bag of words. For example, the bag { cats, chase, dogs } can produce two equally fluent and grammatical sentences.

The relatively low score for long sentences is un-

Figure 3: Example outputs on development data.

likely to be such a problem in practice, because the base system (e.g. an SMT system) is likely to produce sentences with locally fluent subsequences. When fluent local phrases in the input are treated as atomic units, the effective sentence length is shorter.

All the above development experiments were performed using only one training iteration. Figure 4 shows the effect of different numbers of training iterations. For the final test, based on the graphs in Figure 4, we chose the training iterations to be 8, 6 and 4 for the dictionary, $\beta = 0.0001$ and $\beta = 0.075$ methods, respectively.

6.2 Final Accuracies

Table 5 shows the final results of our system, together with the MST-based ("Wan 2009 CLE") and assignment-based ("Wan 2009 AB") systems of Wan et al. (2009). Our system outperforms the dependency grammar-based systems, and using a supertagger with small β value produces the best BLEU. Note that through the use of a supertagger, we are no longer assuming that the input is a bag of words without any order, and therefore only the dictionary results are directly comparable with Wan et al. (2009)[2].

7 Related Work

Both Wan et al. (2009) and our system use approximate search to solve the problem of input word ordering. There are three differences. First, Wan et al. use a dependency grammar to model grammaticality, while we use CCG. Compared to dependency trees, CCG has stronger category constraints on the parse structure. Moreover, CCG allows us to reduce the ambiguity level of the search algorithm through the assignment of possible lexical categories to input words, which is useful when the input has a basic degree of fluency, as is often the case in a grammaticality improvement task.

Second, we use learning to optimise search in order to explore a large search space. In contrast, Wan et al. break the search problem into a sequence of sub tasks and use greedy search to connect them. Finally, in addition to ordering, our algorithm further allows word selection. This gives our system the flexibility to support word insertion and deletion.

White (2004) describes a system that performs CCG realization using best-first search. The search process of our algorithm is similar to his work. The problem we solve is different from realization, which takes an input in logical form and produces a corresponding sentence. Without constraints, the word order ambiguities can be much larger with a bag of words, and we use learning to guide our search algorithm. Espinosa et al. (2008) apply hypertagging to logical forms to assign lexical categories for realization. White and Rajkumar (2009) further use perceptron reranking on N-best outputs to improve the quality.

The use of perceptron learning to improve search has been proposed in guided learning for easy-first search (Shen et al., 2007) and LaSO (Daumé III and Marcu, 2005). LaSO is a general framework for various search strategies. Our learning algorithm is similar to LaSO with best-first inference, but the parameter updates are different. In particular, LaSO updates parameters when all correct hypotheses are lost, but our algorithm makes an update as soon as the top item from the agenda is incorrect. Our algorithm updates the parameters using a stronger precondition, because of the large search space. Given an incorrect hypothesis, LaSO finds the corresponding gold hypothesis for perceptron update by constructing its correct sibling. In contrast, our algorithm takes the lowest scored gold hypothesis currently in the agenda to avoid updating parameters for hypotheses that may have not been constructed.

Our parameter update strategy is closer to the guided learning mechanism for the easy-first algorithm of Shen et al. (2007), which maintains a queue of hypotheses during search, and performs learning to ensure that the highest scored hypothesis in the queue is correct. However, in easy-first search, hypotheses from the queue are ranked by the score of their next action, rather than the hypothesis score. Moreover, Shen et al. use aggressive learning and regenerate the queue after each update, but we perform non-agressive learning, which is faster and is more feasible for our complex search space. Similar methods to Shen et al. (2007) have also been used in Shen and Joshi (2008) and Goldberg and Elhadad (2010).

8 Conclusion

We proposed a grammaticality improvement system using CCG, and evaluated it using a standard input word ordering task. Our system gave higher BLEU scores than the dependency-based system of Wan et al. (2009). We showed that the complex search problem can be solved effectively using guided learning for best-first search.

Potential improvements to our system can be made in several areas. First, a large scale language model can be incorporated into our model in the search algorithm, or through reranking. Second, a heuristic future cost (e.g. Varges and Mel-

lish (2010)) can be considered for each hypothesis so that it also considers the words that have not been used, leading to better search. Future work also includes integration with an SMT system, where content word selection will be applicable.

Abstract

Traditional computational approaches to referring expression generation operate in a deliberate manner, choosing the attributes to be included on the basis of their ability to distinguish the intended referent from its distractors. However, work in psycholinguistics suggests that speakers align their referring expressions with those used previously in the discourse, implying less deliberate choice and more subconscious reuse. This raises the question as to which is a more accurate characterisation of what people do. Using a corpus of dialogues containing 16,358 referring expressions, we explore this question via the generation of subsequent references in shared visual scenes. We use a machine learning approach to referring expression generation and demonstrate that incorporating features that correspond to the computational tradition does not match human referring behaviour as well as using features corresponding to the process of alignment. The results support the view that the traditional model of referring expression generation that is widely assumed in work on natural language generation may not in fact be correct; our analysis may also help explain the oft-observed redundancy found in human-produced referring expressions.

1 Introduction

Computational work on referring expression generation (REG) has an extensive history, and a wide variety of algorithms have been proposed, dealing with various facets of what is recognised to be a complex problem. Almost all of this work sees the task as being concerned with choosing those attributes of an intended referent that distinguish it from the other entities with which it might be confused (see, for example, Dale (1989), Dale and Reiter (1995), Krahmer et al. (2003), van Deemter and Krahmer (2007), Gardent and Striegnitz (2007)). Independently, an alternative way of thinking about reference has arisen within the psycholinguistics community: there is now a long tradition of work that explores how a dialogue participant's forms of reference are influenced by those previously used for a given entity. Most recently, this line of work has been discussed in terms of the notions of *alignment* (Pickering and Garrod, 2004) and *conceptual pacts* (Clark and Wilkes-Gibbs, 1986; Brennan and Clark, 1996).

We suspect that neither approach tells the full story, and so we are interested in exploring whether the two perspectives should be integrated. Using a large corpus of referring expressions in task-oriented dialogues, this paper presents a machine learning approach that allows us to combine features corresponding to the two perspectives. Our results show that models based on the alignment perspective outperform models based on traditional REG considerations, as well as a number of simpler baselines.

The paper is structured as follows. In Section 2, we outline the two perspectives on subsequent reference, and summarise related work. In Section 3, we describe the iMAP Corpus and the referring expressions it contains. In Section 4, we describe the approach we take to learning models of referential behaviour using this data, and in Section 5 we discuss the results of a number of experiments based

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1158–1167,
Edinburgh, Scotland, UK, July 27–31, 2011.

on this approach, followed by an error analysis in Section 6. Section 7 draws some conclusions and discusses future work.

2 Related Work

2.1 The Algorithmic Approach

We use the term *algorithmic approach* here to refer to the perspective that is common to the considerable body of work within computational linguistics on the problem of referring expression generation developed over the last 20 years. Much of this work takes as its starting point the characterisation of the problem expressed in (Dale, 1989). This work has focused on the design of algorithms which take into account the context of reference in order to decide what properties of an entity should be mentioned in order to distinguish that entity from others with which it might be confused. Early work was concerned with *subsequent* reference in *discourse*, inspired by Grosz and Sidner's (1986) observations on how the attentional structure of a discourse made particular referents accessible at any given point. More recently, attention has shifted to *initial* reference in *visual* domains, driven in large part by the availability of the TUNA dataset and the shared tasks that make use of it (Gatt et al., 2008). The construction of *distinguishing descriptions* has consistently been a key consideration in this body of work.

Scenarios that require the generation of references in multi-turn dialogues that concern visual scenes are likely to be among the first where we can expect computational approaches to referring expression generation to be practically useful. Surprisingly, however, the more recent work on initial reference in visual domains and the earlier work on subsequent reference in discourse remain somewhat distinct and separate from each other, despite much the same algorithms having been used in both. There is very little work that brings these two strands together by looking at both initial and subsequent references in dialogues that concern visual scenes. An exception here is the machine learning approach developed by Stoia et al. (2006), who aimed at building a dialogue system for a situated agent giving instructions in a virtual 3D world. However, their approach was concerned with choosing the *type* of reference to use (definite or indefinite, pronominal, bare or modified head noun), and not with the *content* of the reference; and their data set consisted of only 1242 referring expressions.

2.2 The Alignment Approach

Meanwhile, starting with the early work of Carroll (1980), a quite distinct strand of research in psycholinguistics has explored how a speaker's form of reference to an entity is impacted by the way that entity has been previously referred to in the discourse or dialogue. The general idea behind what we will call the *alignment approach* is that a conversational participant will often adopt the same semantic, syntactic and lexical alternatives as the other party in a dialogue. This perspective is most strongly associated with the work of Pickering and Garrod (2004). With respect to reference in particular, speakers are said to form *conceptual pacts* in their use of language (Clark and Wilkes-Gibbs, 1986; Brennan and Clark, 1996). Although there is disagreement about the exact mechanisms that enable alignment and conceptual pacts, the implication of much of this work is that one speaker introduces an entity by means of some description, and then (perhaps after some negotiation) both conversational participants share this form of reference, or a form of reference derived from it, when they subsequently refer to that entity.

Recent work by Goudbeek and Krahmer (2010) supports the view that subconscious alignment does indeed take place at the level of content selection for referring expressions. The participants in their study were more likely to use a dispreferred attribute to describe a target referent if this attribute had recently been used in a description by a confederate.

There is some work within natural language generation that attempts to model the process of alignment (Buschmeier et al., 2009; Janarthanam and Lemon, 2009), but this is predominantly concerned with what we might think of as the 'lexical perspective', focussing on lexical choice rather than the selection of appropriate semantic content for distinguishing descriptions.

2.3 Combined Models

This paper is not the first to look at how the algorithmic approach and the alignment approach might be integrated in REG. An early machine learning ap-

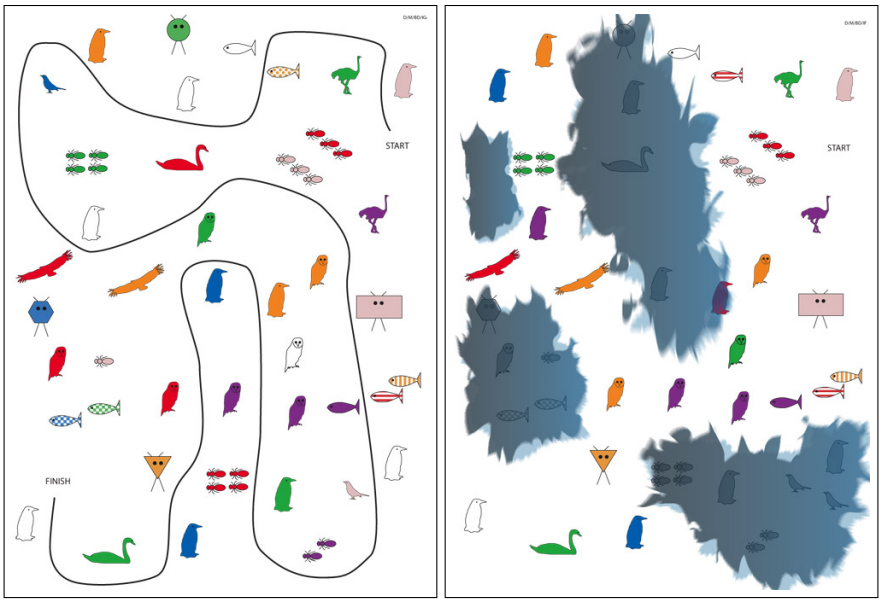

Figure 1: An example pair of maps.

proach to content selection was presented by Jordan and Walker (2000; 2005); they were also interested in an exploration of the validity of different psycholinguistic models of reference production, including Grosz and Sidner's (1986) model of discourse structure, the conceptual pacts model of Clark and colleagues, and the intentional influences model developed by Jordan (2000). However, their data set consists of only 393 referring expressions, compared to our 16,358, and these expressions had functions other than identification; most importantly, the entities referred to were not part of a shared visual scene as is the case in our data.

Gupta and Stent (2005) instantiated Dale and Reiter's (1995) Incremental Algorithm with a preference ordering that favours the attributes that were used in the previous mention of the same referent. In a second variant, they even require these attributes to be included in a subsequent reference. Differently from most other work on REG, they extended the task to include ordering of the attributes in the surface form. They therefore create a special evaluation metric that takes ordering into account, which makes it hard to compare the performance they report to that of any system that is not concerned with attribute ordering, such as ours. Their evaluation set was also considerably smaller than ours: they used 1294 and 471 referring expressions from two different corpora, compared to our test set of 4947 referring expressions.

More recently in (Viethen et al., 2010), we presented a rule-based system that addressed a specific instance of the problem we consider here, using the same corpus as we do: we singled out 2579 first references to landmarks by the second speaker ('second speaker initial references') and attempted to reproduce these using a system based on Dale and Reiter's (1995) Incremental Algorithm. Although the data set was a subset of the one used here, the system did not reach the same performance (see Section 5).

3 Referring Expressions in the iMAP Corpus

The iMAP Corpus (Louwerse et al., 2007) is a collection of 256 dialogues between 32 participant-pairs who contributed 8 dialogues each. Both participants had a map of the same environment, but one participant's map showed a route winding its way between the landmarks on the map; see Figure 1. The task was for this participant (the instruction giver, IG) to describe this route in such a way that their partner (the instruction follower, IF) could draw it onto their map; this was complicated by some discrepancies between the two maps, such

as missing landmarks, the unavailability of colour in some regions due to ink stains, and small differences between some landmarks.

The landmarks differ from each other in type, colour, and one other attribute, which is different for each type of landmark. For example, there are different *kinds* of birds (eagle, ostrich, penguin ...); fish differ by their *patterns* (dotted, checkered, plain ...), aliens have different *shapes* (circular, hexagonal ...), and bugs appear in small clusters of differing *numbers*. In addition to these inherent attributes of the landmarks, participants used spatial relations to other items on the map. Each referring expression in the corpus is annotated with a unique identifier corresponding to the landmark that it describes and the semantic values of the attributes that it contains. This collection of annotations forms the basic data we use in our experiments.

For each landmark R referred to in a dialogue, we view the sequence of references to this landmark as a *coreference chain*, notated $\langle R_1, R_2, \ldots, R_n \rangle$. By convention, R_1 is termed the *initial reference*, and all other references in the chain are *subsequent references*. From the corpus as a whole we extracted 34,127 referring expressions in 9558 chains. The average length of a chain is 4.74; and the longest coreference chain contains 43 references. References may be contributed to a chain by either speaker, and can be arbitrarily far apart: in the data, 4201 references are in the utterance immediately following the preceding reference in the chain, but the distance between references in a chain can be as high as 423 utterances.

We removed from the data any annotation that was not concerned with the four landmark attributes, type, colour, relation, or the landmark's other distinguishing attribute. For example, 'semantically empty' head nouns such as *thing* or *set*. Ordinal numbers that were annotated as the use of the number attribute were re-tagged as spatial relations, as these usually described the position of the target within a line of landmarks.

As a result of the removal of annotations not pertaining to the use of the four landmark attributes, 2785 referring expressions had no annotation left; we removed these instances from the final data set. We also do not attempt to replicate the remaining 5552 plural referring expressions or the 3062 pronouns found in the corpus.[1] However, we do include all of these instances in the feature extraction step, on the assumption that they might impact on the content of subsequent references. Similarly, we filter out 6369 initial references after we have extracted features from them, since we focus here on the generation of subsequent reference only. The remaining 16,358 referring expressions form the data which we use in our experiments.

Content Pattern	Count	Proportion
⟨other⟩	5893	36.0%
⟨other, type⟩	3684	22.5%
⟨other, colour⟩	1630	10.0%
⟨other, colour, type⟩	1021	6.2%
⟨colour⟩	969	5.9%
⟨relation⟩	777	4.7%
⟨other, relation⟩	587	3.6%
⟨type⟩	574	3.5%
⟨colour, type⟩	434	2.7%
⟨other, relation, type⟩	312	1.9%
⟨relation, type⟩	236	1.4%
⟨colour, relation⟩	99	0.6%
⟨other, colour, relation⟩	81	0.5%
⟨other, colour, relation, type⟩	44	0.3%
⟨colour, relation, type⟩	17	0.1%
Total	16,358	

Table 1: The 15 content patterns by frequency.

Contrary to findings from other corpora, in which colour was used much more frequently (Gatt, 2007; Viethen and Dale, 2008), the colour attribute was used in only 26.3% of the referring expressions in our data set. This is probably due to the often low reliability of colour in this task caused by the ink stains. The proportion of referring expressions mentioning the target's type might, at 38.7%, also seem low. This can be explained by the fact that one quarter of the landmarks, namely birds and buildings, are more likely to be described in terms of their specific kind than in terms of their generic type. This also helps explain why the overall use of the other attribute, which for some landmarks was their kind, was used in 81.0% of all instances. Spatial relations were used in 13.16% of the referring expressions, comparable to other corpora in the literature.

[1] The additional issues that arise in generating plural references and deciding when to use pronouns considerably complicate the problem; see (Gatt, 2007).

We can think of each referring expression as being a linguistic realisation of a *content pattern*: this is the collection of attributes that are used in that instance. The attributes can be derived from the property-level annotation given in the corpus. So, for example, if a particular reference appears as the noun phrase *the blue penguin*, annotated semantically as $\langle \mathsf{blue}, \mathsf{penguin} \rangle$, then the corresponding content pattern is $\langle \mathsf{colour}, \mathsf{kind} \rangle$. Our aim is to replicate the content pattern of each referring expression in the corpus. Table 1 lists the 15 content patterns that occur in our data set in order of frequency.

4 Modelling Referential Behaviour

4.1 The Two Perspectives

Our task is defined simply as follows: for each subsequent reference R in the corpus, can we predict the content pattern that will be used in that reference? As we noted at the outset of the paper, the literature would appear to suggest two distinct approaches to this problem. What we have characterised as the algorithmic approach can be summarised thus:

> At the point where a reference is required, a speaker determines the relevant features of other entities in the context, then computes the content of a referring expression which distinguishes the intended referent from the other entities.

The alignment approach, on the other hand, can be summarised thus:

> Speakers align the forms of reference they use to be similar or identical to references that have been used before. In particular, once a form of reference to the intended referent has been established, they tend to re-use that form of reference, or perhaps an abbreviated version of it.

The alignment approach would appear to be preferable on the grounds of computational cost: we would expect that retrieving a previously-used referring expression, or parts thereof, generally requires less computation than building a new referring expression from scratch.

On the other hand, if the context has changed in any way, then a previously-used form of reference may no longer be effective in identifying the intended referent, and recomputation may be required.[2] This is precisely the consideration on which the initial work on referring expression generation was based, inspired by Grosz and Sidner's (1986) observations about how the changing attentional structure of a discourse moves different entities in and out of focus. However, a straightforward recomputation of reference based on the current context carries the risk that the most effective set of properties to use may change quite radically; if no account is taken of the history of previous references to the entity, it's conceivable that one could produce a description that is so different from the previous description that they are virtually unrecogisable as descriptions of the same entity. Ideally, what we want to do is *modify* a previous description to do the job.

These observations suggest that, in order to choose the most appropriate form of reference for an entity, we need to simultaneously take account of:

- the other entities from which it must be distinguished, both in the visual context and in the preceding discourse (in other words, exactly the information that traditional algorithmic approaches consider);
- how this entity, and perhaps other entities, have been referred to in the past (precisely the information that the alignment approach considers).

Map Features	
Main_Map_type	most frequent type of LM on this map
Main_Map_other	other attribute if the most frequent type of LM
Mixedness	are other LM types present on this map?
Ink_Orderliness	shape of the ink blot(s) on the IF's map
Lmprop Features	
other_Att	type of the other attribute of the target
*[att]*_Value	value for each *att* of target
*[att]*_Difference	was *att* of target different between the two maps?
Missing	was target missing one of the maps?
Inked_Out	was target inked]_out on the IG's map?
Speaker Features	
Dyad_ID	ID of the pair of participant-pair
Speaker_ID	ID of the person who uttered this RE
Speaker_Role	was the speaker the IG or the IF?

Table 2: The Ind feature set.

[2] Unfortunately, determining what counts as a change of context, especially in visual scenes, is fraught with difficulty.

TradREG Features (Visual)	
Count_Vis_Distractors	number of visual distractors
Prop_Vis_Same_*[att]*	proportion of visual distractors with same *att*
Dist_Closest	distance to the closest visual distractor
Closest_Same_*[att]*	has the closest distractor the same *att*?
Dist_Closest_Same_*[att]*	distance to the closest distractor of same *att* as target
Cl_Same_type_Same_*[att]*	has the closest distractor of the same type also the same *att*?
TradREG Features (Discourse)	
Count_Intervening_LMs	number of other LMs mentioned since the last mention of the target
Prop_Intervening_*[att]*	proportion of intervening LMs for which *att* was used AND which have the same *att* as target

Table 3: The TradREG feature set.

Alignment Features (Recency)	
Last_Men_Speaker_Same	who made the last mention of target?
Last_Mention_*[att]*	was *att* used in the last mention of target?
Dist_Last_Mention_Utts	distance to the last mention of target in utterances
Dist_Last_Mention_REs	distance to the last mention of target in REs
Dist_Last_*[att]*_LM_Utts	distance in utterances to last use of *att* for target
Dist_Last_*[att]*_LM_REs	distance in REs to last use of *att* for target
Dist_Last_*[att]*_Dial_Utts	distance in utterances to last use of *att*
Dist_Last_*[att]*_Dial_REs	distance in REs to last use of *att*
Dist_Last_RE_Utts	distance to last RE in utterances
Last_RE_*[att]*	was *att* mentioned in the last RE?
Alignment Features (Frequency)	
Count_*[att]*_Dial	how often has *att* been used in the dialogue?
Count_*[att]*_LM	how often has *att* been used for target?
Quartile	quartile of the dialogue the RE was uttered in
Dial_No	number of dialogues already completed +1
Mention_No	number of previous mentions of target +1

Table 4: The Alignment feature set.

The set of features we describe next attempts to capture these two aspects of the problem.

4.2 Features

The number of factors that can be hypothesised as having an impact on the form of a referring expression in a dialogic setting associated with a visual domain is very large. Attempting to incorporate all of these factors into parameters for rule-based systems, and then experimenting with different settings for these parameters, is prohibitively complex. Instead, we here capture a wide range of factors as features that can be used by a machine learning algorithm to automatically induce from the data a classifier that predicts for a given set of features the attributes that should be used in a referring expression.

The features we extracted from the data set are listed in Tables 2–4.[3] They fall into five subsets. **Map** Features capture design characteristics of the maps the current dialogue is about; **Speaker** Features capture the identity and role of the participants; and **LMprop** Features capture the inherent visual properties of the target referent. For our experiments, we group the Map, LMprop and Speaker feature sets into one theory-independent set (**Ind**). Most importantly for our present considerations, **TradREG** Features capture factors that the traditional computational approaches to referring expression generation take account of, in particular properties of the discourse and visual distractors; and **Alignment** Features capture factors that we would expect to play a role in the psycholinguistic models of alignment and conceptual pacts.

[3] In these tables, *att* is an abbreviatory variable that is instantiated once for each of the four attributes type, colour, relation, and the other distinguishing attribute of the landmark. The abbreviation LM stands for landmark

4.3 The Models

For the experiments described here, we used a 70–30 split to divide the data into a training set (11,411 instances) and a test set (4,947 instances). In addition to the main prediction class *content pattern*, the split was stratified for Speaker_ID and Quartile to ensure that training and test set contained the same proportion of descriptions from each speaker and each quartile of the dialogues. We used the J48 algorithm implemented in the Weka toolkit (Witten and Frank, 2005) to train decision trees with the task of judging, based on the given features, which content pattern should be used.

First, we have three separate baseline models:

HeadNounOnly generates only the property that is the most likely head noun for the target, which is kind for birds and buildings and type for all

other landmarks. This is a form of 'reduced reference' strategy.

RepeatLast represents a very simplistic alignment approach. It generates the same content pattern that was used in the previous mention of the target referent.

MajorityClass generates the content pattern most commonly used in the training set.

We then have a number of models that use subsets of the features described above:

AllFeatures is a decision tree trained on all features;

TradREG is a decision tree trained on the TradREG features only;

Alignment is a decision tree trained on the Alignment features only;

Ind is a decision tree trained on the Ind features only;

Alignment+Ind is a decision tree trained on all but the TradREG features;

TradREG+Ind is a decision tree trained on all but the Alignment features; and

TradREG+Alignment is a decision tree trained on all but the Ind features.

5 Results

In this section we report how the models described in the previous section performed on the held-out test set in comparison to each other and to the three baselines.

We use Accuracy and average DICE score for our comparisons; these are the most commonly used measures in the REG literature (see, for example, Gatt et al., 2008). Given two sets of attributes, A and B, DICE is computed as

$$\text{DICE} = \frac{2 \times |A \cap B|}{|A| + |B|}. \quad (1)$$

This gives some measure of the overlap between two referring expressions, assigning a partial score if the two sets share attributes but are not identical. The Accuracy of a system is the proportion of test instances for which it achieves a DICE score of 1, signifying a perfect match.

	col	other	type	rel	Comb. Pattern	
	Acc	Acc	Acc	Acc	Acc	DICE
HeadOnly	n/a	n/a	n/a	n/a	23.1	0.49
RepLast	n/a	n/a	n/a	n/a	38.4	0.55
Majority	73.8	81.0	61.7	86.8	36.0	0.65
predicts	no	yes	no	no	⟨other⟩	
Trad	74.6	84.8	77.1	87.0	47.3	0.73
Align	83.6	84.1	80.7	87.5	54.6	0.78
Ind	81.9	82.8	81.4	88.0	52.7	0.78
Align+Ind	86.1	85.3	82.4	**88.7**	58.2	**0.81**
Trad+Ind	82.2	84.1	81.1	87.1	52.5	0.78
Trad+Align	84.1	84.0	80.1	86.8	53.9	0.78
AllFeatures	**86.2**	**85.8**	**83.2**	88.5	**58.8**	**0.81**

Table 5: Performance of our models compared to the baselines. Model names are abbreviated for space reasons. The Accuracy (given in %) of all models is significantly better than that of the highest performing baseline at p<.01 according to the χ^2 statistic.

We tested two different ways of generating content patterns based on the different feature sets described above: **PatternAtOnce** builds a decision tree that chooses one of the 15 content patterns that occur in our data set; whereas **CombinedPattern** builds attribute-specific decision trees (one for each of the four attributes that occur in the data: colour, other, type, and relation), and then combines their predictions into a complete content pattern. We found that CombinedPattern slightly outperformed PatternAtOnce, although the difference is not statistically significant for all feature sets. For space reasons, we report in what follows only on the slightly better-performing CombinedPattern model.

Table 5 compares the performances of the three baselines and the decision trees based on the five feature subsets for each of the individual attributes and for the combined content pattern; note that the HeadNounOnly and RepeatLast baselines do not make attribute-specific predictions. The table shows that the learned systems outperform all three baselines for the individual attributes as well as for the combined content pattern.

A comparison of the Alignment feature set and the TradREG feature set shows that the former outperforms the latter for the attribute-specific trees which predict the use of the colour attribute and the

use of relation, and that the combined patterns resulting from the Alignment trees are a better match of the human-produced patterns both in terms of Accuracy ($p<.01$ for all three categories, using χ^2) and DICE. Interestingly, even the theory-independent Ind features outperform the TradREG features.

The comparison between TradREG+Ind and Alignment+Ind again shows a clear advantage for the Alignment features: dropping them from the complete feature set significantly hurts performance compared to AllFeatures (χ^2=80.5, $p<.01$), while dropping the TradREG features has no significant impact. Also consistent with the results of the three individual feature sets, dropping the Ind features hurts performance more than dropping the TradREG features, but less than dropping the Alignment features. Training on the complete feature set (AllFeatures) achieves the highest performance, which is significantly better than that of all other features sets ($p<.01$ using χ^2) except Alignment+Ind.

These results suggest that considerations at the heart of traditional REG approaches do not play as important a role as those postulated by alignment-based models for the selection of semantic content for subsequent referring expressions.

We also note that the Accuracy scores achieved by our learned systems are similar to the best numbers previously reported in the REG literature. While Jordan and Walker's (2005) data set is not directly comparable, they achieved a maximum of 59.9% Accuracy, against our 58.8%. Stoia et al.'s (2006) best Accuracy was 31.2%, albeit on a slightly different task. Even in the arguably much simpler non-dialogic domains of the REG competitions concerned with pure content selection, the best performing system achieved only 53% Accuracy (see Gatt et al., 2008). The most comparable approach, the rule-based system we presented in (Viethen et al., 2010) for a subset of the data used here, was not able to outperform a RepeatLast baseline at 40.2% Accuracy and an average DICE score of 0.67.

6 Error Analysis

An important question to ask is how wrong the models really are when they do not succeed in perfectly matching a human-produced reference in our test set. It might be that they choose a completely different set of attributes from those included by the human speaker; however, the Accuracy score also counts as incorrect any set that only partly overlaps with the reference found in the test set.

	Acc	Dice	Super	Sub	Inter	Noover
Trad	47.3	0.75	14.4	22.2	5.5	10.5
Align	54.6	0.78	16.0	16.1	3.9	9.4
Ind	52.7	0.78	17.1	17.2	3.9	9.0
Align+Ind	58.2	0.81	16.0	14.8	3.1	7.9
Trad+Ind	52.5	0.78	17.4	17.5	3.8	8.8
Trad+Align	53.9	0.78	17.1	15.6	4.3	9.0
AllFeature	58.8	0.81	16.5	14.5	3.1	7.2

Table 6: The proportions of test instances for which each model produced a subset, a superset, some other form of intersection or no-overlap to the human reference.

The DICE score gives us a partial answer to this question, as it assigns a score that is based on the size of the overlap between the attribute set chosen by the model and that included by the human speaker. A DICE score that is equal to the Accuracy score would mean that each referring expression was either reproduced perfectly, or that a set of attributes was chosen that did not overlap with the original one at all. The fact that all our models achieved DICE scores much higher than their Accuracy scores shows that they only rarely got it completely wrong.

Table 6 gives a more fine-grained picture by listing, for each model, what percentage of the referring expressions it produced contained a subset of the attributes included in the human reference, what percentage were a superset, what percentage had another form of partial intersection, and what percentage had no commonality with the human reference. Interestingly, a large number of the referring expressions produced by the model trained only on TradREG features are subsets of the human reference. This indicates that human speakers tend to include more attributes than are strictly speaking necessary to distinguish the landmark.[4] The Alignment model does not as often produce a subset of the gold standard content pattern, suggesting that it might be alignment considerations that account for some of

[4]That humans often produce 'redundant' descriptions, in opposition to the target behaviour of some of the early REG algorithms, is of course an oft-observed fact.

	both corr.	both wrong	1st corr.	2nd corr.	either corr.	pot. Acc
Trad vs Ind	1797	1794	545	811	3153	63.7
Trad vs Align	1742	1647	600	958	3300	66.7
Trad vs Align+Ind	1849	1574	493	1031	3373	68.2
Align vs Trad+Ind	1908	1557	792	690	3390	68.5
Align vs Ind	1872	1511	828	736	3436	69.5
Ind vs Trad+Align	1840	1511	768	828	3436	69.5

Table 7: Comparison of the predictions for the combined content pattern between the models trained on mutually exclusive feature sets.

the apparent redundancy that human-produced referring expressions contain.

A second important question is whether the different feature sets are doing the same work, or whether they complement each other. Table 7 lists for those pairings of our learned models which were based on mutually exclusive feature sets how many referring expressions both models predicted correctly, how many both failed to predict, and how many were predicted correctly by either of the two models.

Note the high numbers in the columns listing the counts of instances which both models got either correct or wrong: these show that there is considerable overlap between all pairings. The smallest agreement lies at 3424 instances (68.2%) between TradREG (the least successful model) and Alignment+Ind (the most successful model). However, they also each predict correct solutions that the other misses: 493 (10.0%) for TradREG and 1031 (20.8%) for Alignment+Ind.

The last two columns of Table 7 show the number of instances that at least one of the two models in each pairing got correct and the proportion out of all test instances that this number represents. This proportion is the maximum Accuracy that could be achieved by a model that combines the two models in a pairing and then correctly chooses which one to use in each instance. The maximum Accuracies that could be achieved in this way on our data set lie just below 70%, significantly higher than any numbers reported in the literature on the task of generating subsequent reference.

7 Conclusions

Using the largest corpus of referring expressions to date, we have shown how both the traditional computational view of REG and the alternative psycholinguistic alignment approach can be captured via a large set of features for machine learning. Additionally, we defined a number of theory independent features. Using this approach we have presented three main findings.

First, we have demonstrated that a model using all these features to predict content patterns in subsequent references in shared visual scenes delivers an Accuracy of 58.8% and a DICE score of 0.81, outperforming models based only on features inspired by one of the two approaches. However, we found that the features based on traditional REG considerations do not contribute as much to this score as those based on the alignment approach, and that dropping the traditional REG features does not significantly hurt the performance of a model based on alignment and theory-independent features.

Second, our error analysis showed that the main reason for the low performance of a model based on traditional algorithmic features is that it often chooses too few attributes. The fact that the model based on the alignment features does not make this mistake so frequently suggests that it may be the psycholinguistic considerations incorporated in our alignment features that lead people to add those additional attributes.

Finally, while the different models make the same correct predictions about the content of referring expressions in many cases, there are also a considerable number of cases where the models based on either the traditional algorithmic features (10.0%) or the alignment and independent features (20.8%) alone make correct predictions that the other gets wrong; this suggests that a system with the ability to choose the correct model in each of those cases (perhaps based on a hypothesis as to whether or not the relevant context has changed) could reach an accuracy of almost 70% on our data set. In future work we plan to identify further features that will allow us to inform this choice so that we can move towards this level of performance.

Learning Sentential Paraphrases from Bilingual Parallel Corpora for Text-to-Text Generation

Juri Ganitkevitch, Chris Callison-Burch, Courtney Napoles, and **Benjamin Van Durme**
Center for Language and Speech Processing, and HLTCOE
Johns Hopkins University

Abstract

Previous work has shown that high quality *phrasal* paraphrases can be extracted from bilingual parallel corpora. However, it is not clear whether bitexts are an appropriate resource for extracting more sophisticated *sentential* paraphrases, which are more obviously learnable from monolingual parallel corpora. We extend bilingual paraphrase extraction to syntactic paraphrases and demonstrate its ability to learn a variety of general paraphrastic transformations, including passivization, dative shift, and topicalization. We discuss how our model can be adapted to many text generation tasks by augmenting its feature set, development data, and parameter estimation routine. We illustrate this adaptation by using our paraphrase model for the task of sentence compression and achieve results competitive with state-of-the-art compression systems.

1 Introduction

Paraphrases are alternative ways of expressing the same information (Culicover, 1968). Automatically generating and detecting paraphrases is a crucial aspect of many NLP tasks. In multi-document summarization, paraphrase detection is used to collapse redundancies (Barzilay et al., 1999; Barzilay, 2003). Paraphrase generation can be used for query expansion in information retrieval and question answering systems (McKeown, 1979; Anick and Tipirneni, 1999; Ravichandran and Hovy, 2002; Riezler et al., 2007). Paraphrases allow for more flexible matching of system output against human references for tasks like machine translation and automatic summarization (Zhou et al., 2006; Kauchak and Barzilay, 2006; Madnani et al., 2007; Snover et al., 2010).

Broadly, we can distinguish two forms of paraphrases: *phrasal paraphrases* denote a set of surface text forms with the same meaning:

the committee's second proposal
the second proposal of the committee

while *syntactic paraphrases* augment the surface forms by introducing nonterminals (or *slots*) that are annotated with syntactic constraints:

the NP_1's NP_2
the NP_2 of the NP_1

It is evident that the latter have a much higher potential for generalization and for capturing interesting paraphrastic transformations.

A variety of different types of corpora (and semantic equivalence cues) have been used to automatically induce paraphrase collections for English (Madnani and Dorr, 2010). Perhaps the most natural type of corpus for this task is a monolingual parallel text, which allows sentential paraphrases to be extracted since the sentence pairs in such corpora are perfect paraphrases of each other (Barzilay and McKeown, 2001; Pang et al., 2003). While rich syntactic paraphrases have been learned from monolingual parallel corpora, they suffer from very limited data availability and thus have poor coverage.

Other methods obtain paraphrases from raw monolingual text by relying on distributional similarity (Lin and Pantel, 2001; Bhagat and Ravichandran, 2008). While vast amounts of data are readily available for these approaches, the distributional similarity signal they use is noisier than the sentence-level correspondency in parallel corpora and additionally suffers from problems such as mistaking cousin expressions or antonyms (such as $\{boy, girl\}$ or $\{rise, fall\}$) for paraphrases.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1168–1179,
Edinburgh, Scotland, UK, July 27–31, 2011.

Abundantly available bilingual parallel corpora have been shown to address both these issues, obtaining paraphrases via a pivoting step over foreign language phrases (Bannard and Callison-Burch, 2005). The coverage of paraphrase lexica extracted from bitexts has been shown to outperform that obtained from other sources (Zhao et al., 2008a). While there have been efforts pursuing the extraction of more powerful paraphrases (Madnani et al., 2007; Callison-Burch, 2008; Cohn and Lapata, 2008; Zhao et al., 2008b), it is not yet clear to what extent sentential paraphrases can be induced from bitexts. In this paper we:

- Extend the bilingual pivoting approach to paraphrase induction to produce rich syntactic paraphrases.
- Perform a thorough analysis of the types of paraphrases we obtain and discuss the paraphrastic transformations we are capable of capturing.
- Describe how training paradigms for syntactic/sentential paraphrase models should be tailored to different text-to-text generation tasks.
- Demonstrate our framework's suitability for a variety of text-to-text generation tasks by obtaining state-of-the-art results on the example task of sentence compression.

2 Related Work

Madnani and Dorr (2010) survey a variety of data-driven paraphrasing techniques, categorizing them based on the type of data that they use. These include large monolingual texts (Lin and Pantel, 2001; Szpektor et al., 2004; Bhagat and Ravichandran, 2008), comparable corpora (Barzilay and Lee, 2003; Dolan et al., 2004), monolingual parallel corpora (Barzilay and McKeown, 2001; Pang et al., 2003), and bilingual parallel corpora (Bannard and Callison-Burch, 2005; Madnani et al., 2007; Zhao et al., 2008b). We focus on the latter type of data.

Paraphrase extraction using bilingual parallel corpora was proposed by Bannard and Callison-Burch (2005) who induced paraphrases using techniques from *phrase-based* statistical machine translation (Koehn et al., 2003). After extracting a bilingual phrase table, English paraphrases are obtained by pivoting through foreign language phrases. Since many paraphrases can be extracted for a phrase, Bannard and Callison-Burch rank them using a paraphrase probability defined in terms of the translation model probabilities $p(f|e)$ and $p(e|f)$:

$$p(e_2|e_1) = \sum_f p(e_2, f|e_1) \quad (1)$$

$$= \sum_f p(e_2|f, e_1)p(f|e_1) \quad (2)$$

$$\approx \sum_f p(e_2|f)p(f|e_1). \quad (3)$$

Several subsequent efforts extended the bilingual pivoting technique, many of which introduced elements of more contemporary *syntax-based* approaches to statistical machine translation. Madnani et al. (2007) extended the technique to *hierarchical* phrase-based machine translation (Chiang, 2005), which is formally a synchronous context-free grammar (SCFG) and thus can be thought of as a *paraphrase grammar*. The paraphrase grammar can paraphrase (or "decode") input sentences using an SCFG decoder, like the Hiero, Joshua or cdec MT systems (Chiang, 2007; Li et al., 2009; Dyer et al., 2010). Like Hiero, Madnani's model uses just one nonterminal X instead of linguistic nonterminals.

Three additional efforts incorporated linguistic syntax. Callison-Burch (2008) introduced syntactic constraints by labeling all phrases and paraphrases (even non-constituent phrases) with CCG-inspired slash categories (Steedman and Baldridge, 2011), an approach similar to Zollmann and Venugopal (2006)'s syntax-augmented machine translation (SAMT). Callison-Burch did not formally define a synchronous grammar, nor discuss decoding, since his presentation did not include hierarchical rules. Cohn and Lapata (2008) used the GHKM extraction method (Galley et al., 2004), which is limited to constituent phrases and thus produces a reasonably small set of syntactic rules. Zhao et al. (2008b) added slots to bilingually extracted paraphrase patterns that were labeled with part-of-speech tags, but not larger syntactic constituents.

Before the shift to statistical natural language processing, paraphrasing was often treated as syntactic transformations or by parsing and then generating

from a semantic representation (McKeown, 1979; Muraki, 1982; Meteer and Shaked, 1988; Shemtov, 1996; Yamamoto, 2002). Indeed, some work generated paraphrases using (non-probabilistic) synchronous grammars (Shieber and Schabes, 1990; Dras, 1997; Dras, 1999; Kozlowski et al., 2003).

After the rise of statistical machine translation, a number of its techniques were repurposed for paraphrasing. These include sentence alignment (Gale and Church, 1993; Barzilay and Elhadad, 2003), word alignment and noisy channel decoding (Brown et al., 1990; Quirk et al., 2004), phrase-based models (Koehn et al., 2003; Bannard and Callison-Burch, 2005), hierarchical phrase-based models (Chiang, 2005; Madnani et al., 2007), log-linear models and minimum error rate training (Och, 2003a; Madnani et al., 2007; Zhao et al., 2008a), and here syntax-based machine translation (Wu, 1997; Yamada and Knight, 2001; Melamed, 2004; Quirk et al., 2005).

Beyond cementing the ties between paraphrasing and syntax-based statistical machine translation, the novel contributions of our paper are (1) an in-depth analysis of the types of structural and sentential paraphrases that can be extracted with bilingual pivoting, (2) a discussion of how our English–English paraphrase grammar should be adapted to specific text-to-text generation tasks (Zhao et al., 2009) with (3) a concrete example of the adaptation procedure for the task of paraphrase-based sentence compression (Knight and Marcu, 2002; Cohn and Lapata, 2008; Cohn and Lapata, 2009).

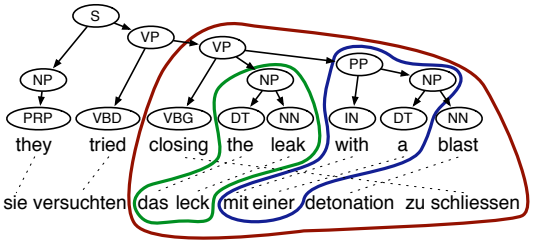
3 SCFGs in Translation

The model we use in our paraphrasing approach is a syntactically informed *synchronous context-free grammar* (SCFG). The SCFG formalism (Aho and Ullman, 1972) was repopularized for statistical machine translation by Chiang (2005). Formally, a *probabilistic* SCFG $\mathcal{G}$ is defined by specifying

$$\mathcal{G} = \langle \mathcal{N}, \mathcal{T}_S, \mathcal{T}_T, \mathcal{R}, S \rangle,$$

where $\mathcal{N}$ is a set of nonterminal symbols, $\mathcal{T}_S$ and $\mathcal{T}_T$ are the source and target language vocabularies, $\mathcal{R}$ is a set of rules and $S \in \mathcal{N}$ is the root symbol. The rules in $\mathcal{R}$ take the form:

$$C \rightarrow \langle \gamma, \alpha, \sim, w \rangle,$$



NP → das leck | the leak
PP/NN → mit einer | with a
VP → NP PP/NN detonation zu schliessen | closing NP PP/NN blast

Figure 1: Synchronous grammar rules for translation are extracted from sentence pairs in a bixtext which have been automatically parsed and word-aligned. Extraction methods vary on whether they extract only minimal rules for phrases dominated by nodes in the parse tree, or more complex rules that include non-constituent phrases.

where the rule's left-hand side $C \in \mathcal{N}$ is a nonterminal, $\gamma \in (\mathcal{N} \cup \mathcal{T}_S)^*$ and $\alpha \in (\mathcal{N} \cup \mathcal{T}_T)^*$ are strings of terminal and nonterminal symbols with an equal number of nonterminals $c_{NT}(\gamma) = c_{NT}(\alpha)$ and

$$\sim: \{1 \ldots c_{NT}(\gamma)\} \rightarrow \{1 \ldots c_{NT}(\alpha)\}$$

constitutes a one-to-one correspondency function between the nonterminals in γ and α. A non-negative weight $w \geq 0$ is assigned to each rule, reflecting the likelihood of the rule.

Rule Extraction Phrase-based approaches to statistical machine translation (and their successors) extract pairs of (e, f) phrases from automatically word-aligned parallel sentences. Och (2003b) described various heuristics for extracting phrase alignments from the Viterbi word-level alignments that are estimated using Brown et al. (1993) word-alignment models.

These phrase extraction heuristics have been extended so that they extract synchronous grammar rules (Galley et al., 2004; Chiang, 2005; Zollmann and Venugopal, 2006; Liu et al., 2006). Most of these extraction methods require that one side of the parallel corpus be parsed. This is typically done automatically with a statistical parser.

Figure 1 shows examples of rules obtained from a sentence pair. To extract a rule, we first choose a source side span f like *das leck*. Then we use phrase extraction techniques to find target spans e that are consistent with the word alignment (in this case *the*

leak is consistent with our f). The nonterminal symbol that is the left-hand side of the SCFG rule is then determined by the syntactic constituent that dominates e (in this case *NP*). To introduce nonterminals into the right-hand side of the rule, we can apply rules extracted over sub-phrases of f, synchronously substituting the corresponding nonterminal symbol for the sub-phrases on both sides. The synchronous substitution applied to f and e then yields the correspondency $\sim$.

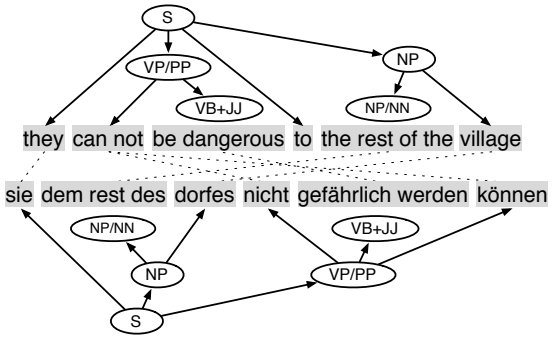
One significant differentiating factor between the competing ways of extracting SCFG rules is whether the extraction method generates rules only for constituent phrases that are dominated by a node in the parse tree (Galley et al., 2004; Cohn and Lapata, 2008) or whether they include arbitrary phrases, including non-constituent phrases (Zollmann and Venugopal, 2006; Callison-Burch, 2008). We adopt the extraction for all phrases, including non-constituents, since it allows us to cover a much greater set of phrases, both in translation and paraphrasing.

Feature Functions Rather than assigning a single weight w, we define a set of feature functions $\vec{\varphi} = \{\varphi_1 ... \varphi_N\}$ that are combined in a log-linear model:

$$w = -\sum_{i=1}^{N} \lambda_i \log \varphi_i. \quad (4)$$

The weights $\vec{\lambda}$ of these feature functions are set to maximize some objective function like BLEU (Papineni et al., 2002) using a procedure called minimum error rate training (MERT), owing to Och (2003a). MERT iteratively adjusts the weights until the decoder produces output that best matches reference translations in a development set, according to the objective function. We will examine appropriate objective functions for text-to-text generation tasks in Section 6.2.

Typical features used in statistical machine translation include phrase translation probabilities (calculated using maximum likelihood estimation over all phrase pairs enumerable in the parallel corpus), word-for-word lexical translation probabilities (which help to smooth sparser phrase translation estimates), a "rule application penalty" (which governs whether the system prefers fewer longer phrases or a greater number of shorter phrases), and a language model probability.



NP/NN → dem rest des | the rest of the
VB+JJ → gefährlich werden | be dangerous
NP → NP/NN dorfes | NP/NN village
VP/PP → nicht VB+JJ können | can not VB+JJ
S → sie NP VP/PP | they VP/PP to NP

Figure 2: An example derivation produced by a syntactic machine translation system. Although the synchronous trees are unlike the derivations found in the Penn Treebank, their yield is a good translation of the German.

Decoding Given an SCFG and an input source sentence, the decoder performs a search for the single most probable derivation via the CKY algorithm. In principle the best translation should be the English sentence e that is the most probable after summing over all $d \in D$ derivations, since many derivations yield the same e. In practice, we use a Viterbi approximation and return the translation that is the yield of the single best derivation:

$$\begin{aligned} \hat{e} &= \arg \max_{e \in Trans(f)} \sum_{d \in D(e,f)} p(d, e|f) \\ &\approx yield(\arg \max_{d \in D(e,f)} p(d, e|f)). \end{aligned} \quad (5)$$

Derivations are simply successive applications of the SCFG rules such as those given in Figure 2.

4 SCFGs in Paraphrasing

Rule Extraction To create a paraphrase grammar from a translation grammar, we extend the syntactically informed pivot approach of Callison-Burch (2008) to the SCFG model. For this purpose, we assume a grammar that translates from a given foreign language to English. For each pair of translation rules where the left-hand side C and foreign

string γ match:

$$C \rightarrow \langle \gamma, \alpha_1, \sim_1, \vec{\varphi}_1 \rangle$$
$$C \rightarrow \langle \gamma, \alpha_2, \sim_2, \vec{\varphi}_2 \rangle,$$

we create a paraphrase rule:

$$C \rightarrow \langle \alpha_1, \alpha_2, \sim, \vec{\varphi} \rangle,$$

where the nonterminal correspondency relation $\sim$ has been set to reflect the combined nonterminal alignment:

$$\sim \;\; = \;\; \sim_1^{-1} \circ \sim_2 \; .$$

Feature Functions In the computation of the features $\vec{\varphi}$ from $\vec{\varphi}_1$ and $\vec{\varphi}_2$ we follow the approximation in Equation 3, which yields lexical and phrasal paraphrase probability features. Additionally, we add a boolean indicator for whether the rule is an identity paraphrase, $\delta_{identity}$. Another indicator feature, $\delta_{reorder}$, fires if the rule swaps the order of two nonterminals, which enables us to promote more complex paraphrases that require structural reordering.

Decoding With this, paraphrasing becomes an English-to-English translation problem which can be formulated similarly to Equation 5 as:

$$\hat{e_2} \approx yield(\arg \max_{d \in D(e_2, e_1)} p(d, e_2 | e_1)).$$

Figure 3 shows an example derivation produced as a result of applying our paraphrase rules in the decoding process. Another advantage of using the decoder from statistical machine translation is that n-gram language models, which have been shown to be useful in natural language generation (Langkilde and Knight, 1998), are already well integrated (Huang and Chiang, 2007).

5 Analysis

A key motivation for the use of syntactic paraphrases over their phrasal counterparts is their potential to capture meaning-preserving linguistic transformations in a more general fashion. A phrasal system is limited to memorizing fully lexicalized transformations in its paraphrase table, resulting in poor generalization capabilities. By contrast, a syntactic paraphrasing system intuitively should be able to address this issue and learn well-formed and generic patterns that can be easily applied to unseen data.

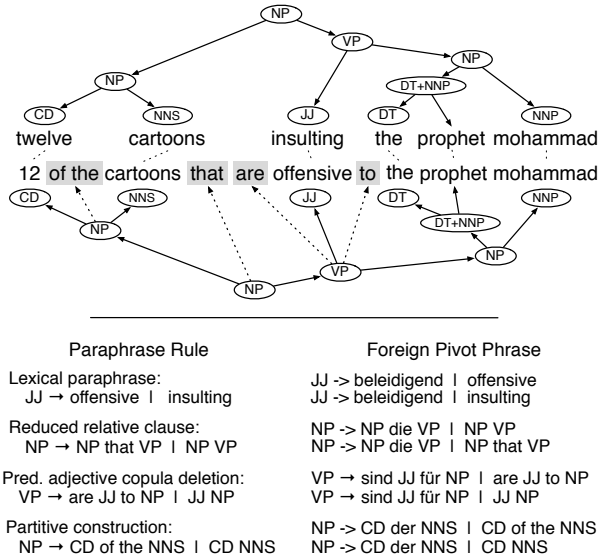


Figure 3: An example of a synchronous paraphrastic derivation. A few of the rules applied in the parse are show in the left column, with the pivot phrases that gave rise to them on the right.

To put this expectation to the test, we investigate how our grammar captures a number of well-known paraphrastic transformations.[1] Table 1 shows the transformations along with examples of the generic grammar rules our system learns to represent them. When given a transformation to extract a syntactic paraphrase for, we want to find rules that neither under- nor over-generalize. This means that, while replacing the maximum number of syntactic arguments with nonterminals, the rules ideally will both retain enough lexicalization to serve as sufficient evidence for the applicability of the transformation and impose constraints on the nonterminals to ensure the arguments' well-formedness.

The paraphrases implementing the *possessive rule* and the *dative shift* shown in Table 1 are a good examples of this: the two noun-phrase arguments to the expressions are abstracted to nonterminals while each rule's lexicalization provides an appropriate frame of evidence for the transform. This is important for a good representation of dative shift, which is a reordering transformation that fully applies to certain ditransitive verbs while other verbs are uncommon in one of the forms:

[1] The data and software used to extract the grammar we draw these examples from is described in Section 6.5.

Possessive rule	$NP \rightarrow$	the NN of the NNP	the NNP's NN
	$NP \rightarrow$	the NNS_1 made by NNS_2	the NNS_2's NNS_1
Dative shift	$VP \rightarrow$	give NN to NP	give NP the NN
	$VP \rightarrow$	provide NP_1 to NP_2	give NP_2 NP_1
Adv./adj. phrase move	$S/VP \rightarrow$	$ADVP$ they VBP	they VPB $ADVP$
	$S \rightarrow$	it is $ADJP$ VP	VP is $ADJP$
Verb particle shift	$VP \rightarrow$	VB NP up	VB up NP
Reduced relative clause	$SBAR/S \rightarrow$	although PRP VBP that	although PRP VBP
	$ADJP \rightarrow$	very JJ that S	JJ S
Partitive constructions	$NP \rightarrow$	CD of the NN	CD NN
	$NP \rightarrow$	all $DT\backslash NP$	all of the $DT\backslash NP$
Topicalization	$S \rightarrow$	NP, VP .	VP, NP .
Passivization	$SBAR \rightarrow$	that NP had VBN	which was VBN by NP
Light verbs	$VP \rightarrow$	take action $ADVP$	to act $ADVP$
	$VP \rightarrow$	TO take a decision PP	TO decide PP

Table 1: A selection of meaning-preserving transformations and hand-picked examples of syntactic paraphrases that our system extracts capturing these.

give *decontamination equipment* to *Japan*
give *Japan decontamination equipment*

provide *decontamination equipment* to *Japan*
? provide *Japan decontamination equipment*

Note how our system extracts a dative shift rule for *to give* and a rule that both shifts and substitutes a more appropriate verb for *to provide*.

The use of syntactic nonterminals in our paraphrase rules to capture complex transforms also makes it possible to impose constraints on their application. For comparison, as Madnani et al. (2007) do not impose any constraints on how the nonterminal X can be realized, their equivalent of the *topicalization* rule would massively overgeneralize:

$$S \rightarrow \quad X_1, X_2 \; . \quad | \quad X_2, X_1 \; .$$

Additional examples of transforms our use of syntax allows us to capture are the *adverbial phrase shift* and the *reduction of a relative clause*, as well as other phenomena listed in Table 1.

Unsurprisingly, syntactic information alone is not sufficient to capture all transformations. For instance it is hard to extract generic paraphrases for all instances of *passivization*, since our syntactic model currently has no means of representing the morphological changes that the verb undergoes:

the reactor *leaks* radiation
radiation *is leaking* from the reactor .

Still, for cases where the verb's morphology does not change, we manage to learn a rule:

the radiation that the reactor had *leaked*
the radiation which *leaked* from the reactor .

Another example of a deficiency in our synchronous grammar models are *light verb* constructs such as:

to take a *walk*
to *walk* .

Here, a noun is transformed into the corresponding verb – something our synchronous syntactic CFGs are not able to capture except through memorization.

Our survey shows that we are able to extract appropriately generic representations for a wide range of paraphrastic transformations. This is a surprising result which shows that bilingual parallel corpora can be used to learn sentential paraphrases, and that they are a viable alternative to other data sources like monolingual parallel corpora, which more obviously contain sentential paraphrases, but are scarce.

6 Text-to-Text Applications

The core of many text-to-text generation tasks is sentential paraphrasing, augmented with specific constraints or goals. Since our model borrows much of its machinery from statistical machine translation – a sentential rewriting problem itself – it is straightforward to use our paraphrase grammars to generate new sentences using SMT's decoding and parameter optimization techniques. Our framework can be adapted to many different text-to-text generation tasks. These could include text simplification, sen-

tence compression, poetry generation, query expansion, transforming declarative sentences into questions, and deriving hypotheses for textual entailment. Each individual text-to-text application requires that our framework be adapted in several ways, by specifying:

- A mechanism for extracting synchronous grammar rules (in this paper we argue that pivot-based paraphrasing is widely applicable).
- An appropriate set of rule-level features that capture information pertinent to the task (e.g. whether a rule simplifies a phrase).
- An appropriate "objective function" that scores the output of the model, i.e. a task-specific equivalent to the BLEU metric in SMT.
- A development set with examples of the sentential transformations that we are modeling.
- Optionally, a way of injecting task-specific rules that were not extracted automatically.

In the remainder of this section, we illustrate how our bilingually extracted paraphrases can be adapted to perform sentence compression, which is the task of reducing the length of sentence while preserving its core meaning. Most previous approaches to sentence compression focused only on the deletion of a subset of words from the sentence (Knight and Marcu, 2002). Our approach follows Cohn and Lapata (2008), who expand the task to include substitutions, insertions and reorderings that are automatically learned from parallel texts.

6.1 Feature Design

In Section 4 we discussed phrasal probabilities. While these help quantify how good a paraphrase is in general, they do not make any statement on task-specific things such as the change in language complexity or text length. To make this information available to the decoder, we enhance our paraphrases with four compression-targeted features. We add the count features c_{src} and c_{tgt}, indicating the number of words on either side of the rule as well as two difference features: $c_{dcount} = c_{tgt} - c_{src}$ and the analogously computed difference in the average word length in characters, c_{davg}.

6.2 Objective Function

Given our paraphrasing system's connection to SMT, the naive/obvious choice for parameter optimization would be to optimize for BLEU over a set of paraphrases, for instance parallel English reference translations for a machine translation task (Madnani et al., 2007). For a candidate C and a reference R, (with lengths c and r) BLEU is defined as:

$$\text{BLEU}_N(C,R) = \begin{cases} e^{(1-c/r)} \cdot e^{\sum_{n=1}^{N} \log w_n p_n} & \text{if } c/r \leq 1 \\ e^{\sum_{n=1}^{N} \log w_n p_n} & \text{otherwise} \end{cases},$$

where p_n is the modified n-gram precision of C against R, with typically $N = 4$ and $w_n = \frac{1}{N}$. The "brevity penalty" term $e^{(1-c/r)}$ is added to prevent short candidates from achieving perfect scores.

Naively optimizing for BLEU, however, will result in a trivial paraphrasing system heavily biased towards producing identity "paraphrases". This is obviously not what we are looking for. Moreover, BLEU does not provide a mechanism for directly specifying a per-sentence compression rate, which is desirable for the compression task.

Instead, we propose PRÉCIS, an objective function tailored to the text compression task:

$$\text{PRÉCIS}_{\lambda,\varphi}(I,C,R) = \begin{cases} e^{\lambda(\varphi - c/i)} \cdot \text{BLEU}(C,R) & \text{if } c/i \geq \varphi \\ \text{BLEU}(C,R) & \text{otherwise} \end{cases}$$

For an input sentence I, an output C and reference compression R (with lengths i, c and r), PRÉCIS combines the precision estimate of BLEU with an additional "verbosity penalty" that is applied to compressions that fail to meet a given target compression rate φ. We rely on the BLEU brevity penalty to prevent the system from producing overly aggressive compressions. The scaling term λ determines how severely we penalize deviations from φ. In our experiments we use $\lambda = 10$.

It is straightforward to find similar adaptations for other tasks. For text simplification, for instance, the penalty term can include a readability metric. For poetry generation we can analogously penalize outputs that break the meter (Greene et al., 2010).

6.3 Development Data

To tune the parameters of our paraphrase system for sentence compression, we need an appropriate cor-

pus of reference compressions. Since our model is designed to compress by paraphrasing rather than deletion, the commonly used deletion-based compression data sets like the Ziff-Davis corpus are not suitable. We have thus created a corpus of compression paraphrases. Beginning with 9570 tuples of parallel English–English sentences obtained from multiple reference translations for machine translation evaluation, we construct a parallel compression corpus by selecting the longest reference in each tuple as the source sentence and the shortest reference as the target sentence. We further retain only those sentence pairs where the compression rate cr falls in the range $0.5 < cr \leq 0.8$. From these, we randomly select 936 sentences for the development set, as well as 560 sentences for a test set that we use to gauge the performance of our system.

6.4 Grammar Augmentations

As we discussed in Section 5, the paraphrase grammar we induce is capable of representing a wide variety of transformations. However, the formalism and extraction method are not explicitly geared towards a compression application. For instance, the synchronous nature of our grammar does not allow us to perform deletions of constituents as done by Cohn and Lapata (2007)'s tree transducers. One way to extend the grammar's capabilities towards the requirements of a given task is by injecting additional rules designed to capture appropriate operations.

For the compression task, this could include adding rules to delete target-side nonterminals:

$$JJ \rightarrow JJ \mid \varepsilon$$

This would render the grammar asynchronous and require adjustments to the decoding process. Alternatively, we can generate rules that specifically delete particular adjectives from the corpus:

$$JJ \rightarrow \text{superfluous} \mid \varepsilon \ .$$

In our experiments we evaluate the latter approach by generating optional deletion rules for all adjectives, adverbs and determiners.

6.5 Experimental Setup

We extracted a paraphrase grammar from the French–English Europarl corpus (v5). The bitext was aligned using the Berkeley aligner and the English side was parsed with the Berkeley parser. We obtained the initial translation grammar using the SAMT toolkit (Venugopal and Zollmann, 2009).

Grammar	# Rules
total	42,353,318
w/o identity	23,641,016
w/o complex constituents	6,439,923
w/o complex const. & identity	5,097,250

Table 2: Number and distribution of rules in our paraphrase grammar. Note the significant number of identity paraphrases and rules with complex nonterminal labels.

The grammars we extract tend to be extremely large. To keep their size manageable, we only consider translation rules that have been seen more than 3 times and whose translation probability exceeds 10^{-4} for pivot recombination. Additionally, we only retain the top 25 most likely paraphrases of each phrase, ranked by a uniformly weighted combination of phrasal and lexical paraphrase probabilities.

We tuned the model parameters to our PRÉCIS objective function, implemented in the Z-MERT toolkit (Zaidan, 2009). For decoding we used the Joshua decoder (Li et al., 2010). The language model used in our paraphraser and the Clarke and Lapata (2008) baseline system is a Kneser-Ney discounted 5-gram model estimated on the Gigaword corpus using the SRILM toolkit (Stolcke, 2002).

6.6 Evaluation

To assess the output quality of the resulting sentence compression system, we compare it to two state-of-the-art sentence compression systems. Specifically, we compare against our implementation of Clarke and Lapata (2008)'s compression model which uses a series of constraints in an integer linear programming (ILP) solver, and Cohn and Lapata (2007)'s tree transducer toolkit (T3) which learns a synchronous tree substitution grammar (STSG) from paired monolingual sentences. Unlike SCFGs, the STSG formalism allows changes to the tree topology. Cohn and Lapata argue that this is a natural fit for sentence compression, since deletions introduce structural mismatches. We trained the T3 software[2] on the 936 $\langle \text{full}, \text{compressed} \rangle$ sentence pairs that comprise our development set. This is equivalent in size to the training corpora that Cohn and Lapata (2007) used (their training corpora ranged from

[2] www.dcs.shef.ac.uk/people/T.Cohn/t3/

882–1020 sentence pairs), and has the advantage of being in-domain with respect to our test set. Both these systems reported results outperforming previous systems such as McDonald (2006). To showcase the value of the adaptations discussed above, we also compare variants of our paraphrase-based compression systems: using Hiero instead of syntax, using syntax with or without compression features, using an augmented grammar with optional deletion rules.

We solicit human judgments of the compressions along two five-point scales: grammaticality and meaning. Judges are instructed to decide how much the meaning from a reference translation is retained in the compressed sentence, with a score of 5 indicating that all of the important information is present, and 1 being that the compression does not retain any of the original meaning. Similarly, a grammar score of 5 indicates perfect grammaticality, and a grammar score of 1 is assigned to sentences that are entirely ungrammatical. To ensure fairness, we perform pairwise system comparisons with compression rates strictly tied on the sentence-level. For any comparison, a sentence is only included in the computation of average scores if the difference between both systems' compression rates is < 0.05.[3]

Table 4 shows a set of pairwise comparisons for compression rates ≈ 0.5. We see that going from a Hiero-based to a syntactic paraphrase grammar yields a significant improvement in grammaticality. Adding compression-specific features improves grammaticality even further. Further augmenting the grammar with deletion rules significantly helps retain the core meaning at compression rates this high, however compared to the un-augmented syntactic system grammaticality scores drop. While our approach significantly outperforms the T3 system, we are not able to match ILP's results in grammaticality.

In Table 3 we compare our system to the ILP approach at a modest compression rate of ≈ 0.8. Here, we significantly outperform ILP in meaning retention while achieving comparable results in grammaticality. This improvement is significant at $p < 0.0001$, using the sign test, while the better grammaticality score of the ILP system is not statistically significant ($p < 0.088$). These results indicate that, over a variety of compression rates, our framework for text-to-text generation is performing as well as or better than specifically tailored state-of-the-art methods.

[3]Because evaluation quality correlates linearly with compression rate, the community-accepted practice of not comparing based on a closely tied compression rate is potentially subject to erroneous interpretation (Napoles et al., 2011).

	CR	Meaning	Grammar
Reference	0.73	4.26	4.35
Syntax+Feat.	0.80	**3.67**	3.38
ILP	0.80	3.50	3.49
Random Deletions	0.50	1.94	1.57

Table 3: Results of the human evaluation on longer compressions: pairwise compression rates (CR), meaning and grammaticality scores. Bold indicates a statistically significance difference at $p < 0.05$.

	CR	Meaning	Grammar
Hiero	0.56	2.57	2.35
Syntax	0.56	2.76	**2.67**
Syntax	0.53	2.70	2.49
Syntax+Feat.	0.53	2.71	**2.54**
Syntax+Feat.	0.54	2.79	**2.71**
Syntax+Aug.	0.54	**2.96**	2.52
Syntax+Aug.	0.52	2.87	2.40
ILP	0.52	2.83	**3.09**
Syntax+Aug.	0.50	2.41	**2.20**
T3	0.50	2.01	1.93

Table 4: Human evaluation for shorter compressions and for variations of our paraphrase system. +Feat. includes the compression features from Section 6.1, +Aug. includes optional deletion rules from Section 6.4.

Table 5 shows an example sentence drawn from our test set and the compressions produced by the different systems. We see that both the paraphrase and ILP systems produce good quality results, with the paraphrase system retaining the meaning of the source sentence more accurately.

7 Conclusion

In this work we introduced a method to learn syntactically informed paraphrases from bilingual parallel texts. We discussed the expressive power and limitations of our formalism and outlined straightforward adaptation strategies for applications in text-to-text generation. We demonstrated when our paraphrasing system was adapted to do sentence compression, it achieved results competitive with state-of-the-art compression systems with only minimal effort.

Abstract

Part-of-speech (POS) is an indispensable feature in dependency parsing. Current research usually models POS tagging and dependency parsing independently. This may suffer from error propagation problem. Our experiments show that parsing accuracy drops by about 6% when using automatic POS tags instead of gold ones. To solve this issue, this paper proposes a solution by jointly optimizing POS tagging and dependency parsing in a unique model. We design several joint models and their corresponding decoding algorithms to incorporate different feature sets. We further present an effective pruning strategy to reduce the search space of candidate POS tags, leading to significant improvement of parsing speed. Experimental results on Chinese Penn Treebank 5 show that our joint models significantly improve the state-of-the-art parsing accuracy by about 1.5%. Detailed analysis shows that the joint method is able to choose such POS tags that are more helpful and discriminative from parsing viewpoint. This is the fundamental reason of parsing accuracy improvement.

1 Introduction

In dependency parsing, features consisting of part-of-speech (POS) tags are very effective, since pure lexical features lead to severe data sparseness problem. Typically, POS tagging and dependency parsing are modeled in a pipelined way. However, the pipelined method is prone to error propagation, especially for Chinese. Due to the lack of morphological features, Chinese POS tagging is even harder than other languages such as English. The state-of-the-art accuracy of Chinese POS tagging is about 93.5%, which is much lower than that of English (about 97% (Collins, 2002)). Our experimental results show that parsing accuracy decreases by about 6% on Chinese when using automatic POS tagging results instead of gold ones (see Table 3 in Section 5). Recent research on dependency parsing usually overlooks this issue by simply adopting gold POS tags for Chinese data (Duan et al., 2007; Zhang and Clark, 2008b; Huang and Sagae, 2010). In this paper, we address this issue by jointly optimizing POS tagging and dependency parsing.

Joint modeling has been a popular and effective approach to simultaneously solve related tasks. Recently, many successful joint models have been proposed, such as joint tokenization and POS tagging (Zhang and Clark, 2008a; Jiang et al., 2008; Kruengkrai et al., 2009), joint lemmatization and POS tagging (Toutanova and Cherry, 2009), joint tokenization and parsing (Cohen and Smith, 2007; Goldberg and Tsarfaty, 2008), joint named entity recognition and parsing (Finkel and Manning, 2009), joint parsing and semantic role labeling (SRL) (Li et al., 2010), joint word sense disambiguation and SRL (Che and Liu, 2010), joint tokenization and machine translation (MT) (Dyer, 2009; Xiao et al., 2010) and joint parsing and MT (Liu and Liu, 2010). Note that the aforementioned "parsing" all refer to *constituent parsing*.

As far as we know, there are few successful models for jointly solving *dependency parsing* and other tasks. Being facilitated by Conference on Computational Natural Language Learning (CoNLL) 2008 and 2009 shared tasks, several joint models of dependency parsing and SRL have been proposed. Nevertheless, the top-ranked systems all adopt pipelined approaches (Surdeanu et al., 2008;

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1180–1191,
Edinburgh, Scotland, UK, July 27–31, 2011.

Hajič et al., 2009). Theoretically, joint modeling of POS tagging and dependency parsing should be helpful to the two individual tasks. On the one hand, syntactic information can help resolve some POS ambiguities which are difficult to handle for the sequential POS tagging models. On the other hand, more accurate POS tags should further improve dependency parsing.

For joint POS tagging and dependency parsing, the major issue is to design effective decoding algorithms to capture rich features and efficiently search out the optimal results from a huge hypothesis space.[1] In this paper, we propose several dynamic programming (DP) based decoding algorithms for our joint models by extending existing parsing algorithms. We also present effective pruning techniques to speed up our decoding algorithms. Experimental results on Chinese Penn Treebank show that our joint models can significantly improve the state-of-the-art parsing accuracy by about 1.5%.

The remainder of this paper is organized as follows. Section 2 describes the pipelined method, including the POS tagging and parsing models. Section 3 discusses the joint models and the decoding algorithms, while Section 4 presents the pruning techniques. Section 5 reports the experimental results and error analysis. We review previous work closely related to our method in Section 6, and conclude this paper in Section 7.

2 The Baseline Pipelined Method

Given an input sentence $\mathbf{x} = w_1...w_n$, we denote its *POS tag sequence* by $\mathbf{t} = t_1...t_n$, where $t_i \in \mathcal{T}$, $1 \leq i \leq n$, and $\mathcal{T}$ is the POS tag set. A *dependency tree* is denoted by $\mathbf{d} = \{(h, m) : 0 \leq h \leq n, 0 < m \leq n\}$, where (h, m) represents a dependency $w_h \rightarrow w_m$ whose *head* word (or *father*) is w_h and *modifier* (or *child*) is w_m. w_0 is an artificial root token which is used to simplify the formalization of the problem.

The pipelined method treats POS tagging and dependency parsing as two cascaded problems. First, an optimal POS tag sequence $\hat{\mathbf{t}}$ is determined.

$$\hat{\mathbf{t}} = \arg\max_{\mathbf{t}} Score_{\text{pos}}(\mathbf{x}, \mathbf{t})$$

Then, an optimal dependency tree $\hat{\mathbf{d}}$ is determined based on $\mathbf{x}$ and $\hat{\mathbf{t}}$.

$$\hat{\mathbf{d}} = \arg\max_{\mathbf{d}} Score_{\text{syn}}(\mathbf{x}, \hat{\mathbf{t}}, \mathbf{d})$$

2.1 POS Tagging

POS tagging is a typical sequence labeling problem. Many models have been successfully applied to sequence labeling problems, such as maximum-entropy (Ratnaparkhi, 1996), conditional random fields (CRF) (Lafferty et al., 2001) and perceptron (Collins, 2002). We use perceptron to build our POS tagging baseline for two reasons. Firstly, as a linear model, perceptron is simple, fast, and effective. It is competitive to CRF in tagging accuracy but requires much less training time (Shen et al., 2007). Secondly, perceptron has been successfully applied to dependency parsing as well (Koo and Collins, 2010). In this paper, perceptron is used in all models including the POS tagging model, the dependency parsing models and the joint models.

In a perceptron, the score of a tag sequence is

$$Score_{\text{pos}}(\mathbf{x}, \mathbf{t}) = \mathbf{w}_{\text{pos}} \cdot \mathbf{f}_{\text{pos}}(\mathbf{x}, \mathbf{t})$$

where $\mathbf{f}_{\text{pos}}(\mathbf{x}, \mathbf{t})$ refers to the feature vector and $\mathbf{w}_{\text{pos}}$ is the corresponding weight vector.

For POS tagging features, we follow the work of Zhang and Clark (2008a). Three feature sets are considered: *POS unigram*, *bigram* and *trigram* features. For brevity, we will refer to the three sets as $\underline{w_i\ t_i}$, $\underline{t_{i-1}\ t_i}$ and $\underline{t_{i-2}\ t_{i-1}\ t_i}$.

Given $\mathbf{w}_{\text{pos}}$, we adopt the Viterbi algorithm to get the optimal tagging sequence.

2.2 Dependency Parsing

Recently, graph-based dependency parsing has gained more and more interest due to its state-of-the-art accuracy. Graph-based dependency parsing views the problem as finding the highest scoring tree from a directed graph. Based on dynamic programming decoding, it can efficiently find an optimal tree in a huge search space. In a graph-based model, the

[1] It should be noted that it is straightforward to simultaneously do POS tagging and constituent parsing, as POS tags can be regarded as non-terminals in the constituent structure (Levy and Manning, 2003). In addition, Rush et al. (2010) describes an efficient and simple inference algorithm based on dual decomposition and linear programming relaxation to combine a lexicalized constituent parser and a trigram POS tagger.

score of a dependency tree is factored into scores of small parts (subtrees).

$$Score_{\text{syn}}(\mathbf{x}, \mathbf{t}, \mathbf{d}) = \mathbf{w}_{\text{syn}} \cdot \mathbf{f}_{\text{syn}}(\mathbf{x}, \mathbf{t}, \mathbf{d}) = \sum_{p \subseteq \mathbf{d}} Score_{\text{syn}}(\mathbf{x}, \mathbf{t}, p)$$

where p is a scoring part which contains one or more dependencies in the dependency tree $\mathbf{d}$. Figure 1 shows different types of scoring parts used in current graph-based models.

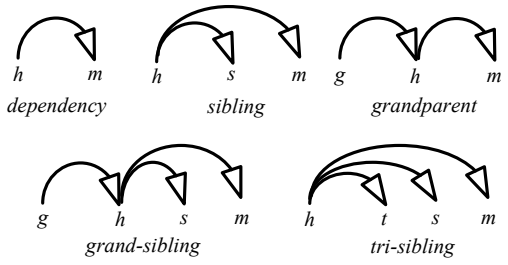

Figure 1: Different types of scoring parts used in current graph-based models (Koo and Collins, 2010).

Eisner (1996) proposes an $O(n^3)$ decoding algorithm for dependency parsing. Based on the algorithm, McDonald et al. (2005) propose the *first-order* model, in which the scoring parts only contains dependencies. The *second-order* model of McDonald and Pereira (2006) incorporates sibling parts and also needs $O(n^3)$ parsing time. The *second-order* model of Carreras (2007) incorporates both sibling and grandparent parts, and needs $O(n^4)$ parsing time. However, the grandparent parts are restricted to those composed of *outermost grandchildren*. Koo and Collins (2010) propose efficient decoding algorithms of $O(n^4)$ for *third-order* models. In their paper, they implement two versions of third-order models, Model 1 and Model 2 according to their naming. Model 1 incorporates only grand-sibling parts, while Model 2 incorporates both grand-sibling and tri-sibling parts. Their experiments on English and Czech show that Model 1 and Model 2 obtain nearly the same parsing accuracy. Therefore, we use Model 1 as our third-order model in this paper.

We use three versions of graph-based dependency parsing models.

- The first-order model (O1): the same with McDonald et al. (2005).
- The second-order model (O2): the same with Model 1 in Koo and Collins (2010), but without using grand-sibling features.[2]
- The third-order model (O3): the same with Model 1 in Koo and Collins (2010).

We adopt linear models to define the score of a dependency tree. For the third-order model, the score of a dependency tree is represented as:

$$\begin{aligned} Score_{\text{syn}}(\mathbf{x}, \mathbf{t}, \mathbf{d}) = & \sum_{\{(h,m)\} \subseteq \mathbf{d}} \mathbf{w}_{\text{dep}} \cdot \mathbf{f}_{\text{dep}}(\mathbf{x}, \mathbf{t}, h, m) \\ & + \sum_{\{(h,s)(h,m)\} \subseteq \mathbf{d}} \mathbf{w}_{\text{sib}} \cdot \mathbf{f}_{\text{sib}}(\mathbf{x}, \mathbf{t}, h, s, m) \\ & + \sum_{\{(g,h),(h,m)\} \subseteq \mathbf{d}} \mathbf{w}_{\text{grd}} \cdot \mathbf{f}_{\text{grd}}(\mathbf{x}, \mathbf{t}, g, h, m) \\ & + \sum_{\{(g,h),(h,s),(h,m)\} \subseteq \mathbf{d}} \mathbf{w}_{\text{gsib}} \cdot \mathbf{f}_{\text{gsib}}(\mathbf{x}, \mathbf{t}, g, h, s, m) \end{aligned}$$

For the first- and second-order models, the above formula is modified by deactivating extra parts.

For parsing features, we follow standard practice for graph-based dependency parsing (McDonald, 2006; Carreras, 2007; Koo and Collins, 2010). Since these features are highly related with our joint decoding algorithms, we summarize the features as follows.

- Dependency Features, $\mathbf{f}_{\text{dep}}(\mathbf{x}, \mathbf{t}, h, m)$
  - Unigram Features: $\underline{w_h t_h\ dir}$, $\underline{w_m t_m\ dir}$
  - Bigram Features: $\underline{w_h t_h\ w_m t_m\ dir\ dist}$
  - In Between Features: $\underline{t_h\ t_b\ t_m\ dir\ dist}$
  - Surrounding Features: $\underline{t_{h-1}\ t_h\ t_{h+1}\ t_{m-1}\ t_m\ t_{m+1}\ dir\ dist}$
- Sibling Features, $\mathbf{f}_{\text{sib}}(\mathbf{x}, \mathbf{t}, h, s, m)$ $\underline{w_h\ t_h\ w_s\ t_s\ w_m\ t_m\ dir}$
- Grandparent Features, $\mathbf{f}_{\text{grd}}(\mathbf{x}, \mathbf{t}, g, h, m)$ $\underline{w_g\ t_g\ w_h\ t_h\ w_m\ t_m\ dir\ gdir}$
- Grand-sibling Features, $\mathbf{f}_{\text{gsib}}(\mathbf{x}, \mathbf{t}, g, h, s, m)$ $\underline{w_g\ t_g\ w_h\ t_h\ w_s\ t_s\ w_m\ t_m\ dir\ gdir}$

[2]This second-order model incorporates grandparent features composed of all grandchildren rather than just outermost ones, and outperforms the one of Carreras (2007) according to the results in Koo and Collins (2010).

where b denotes an index between h and m; dir and $dist$ are the direction and distance of (h, m); $gdir$ is the direction of (g, h). We also use back-off features by generalizing from very specific features over word forms, POS tags, directions and distances to less sparse features over just POS tags or considering fewer nodes. To avoid producing too many sparse features, at most two word forms are used at the same time in sibling, grandparent and grand-sibling features, while POS tags are used instead for other nodes; meanwhile, at most four POS tags are considered at the same time for surrounding features.

3 Joint Models

In the joint method, we aim to simultaneously solve the two problems.

$$(\hat{\mathbf{t}}, \hat{\mathbf{d}}) = \arg\max_{\mathbf{t},\mathbf{d}} Score_{\text{joint}}(\mathbf{x}, \mathbf{t}, \mathbf{d})$$

Under the linear model, the score of a tagged dependency tree is:

$$\begin{aligned} Score_{\text{joint}}(\mathbf{x}, \mathbf{t}, \mathbf{d}) &= Score_{\text{pos}}(\mathbf{x}, \mathbf{t}) \\ &\quad + Score_{\text{syn}}(\mathbf{x}, \mathbf{t}, \mathbf{d}) \\ &= \mathbf{w}_{\text{pos}\oplus\text{syn}} \cdot \mathbf{f}_{\text{pos}\oplus\text{syn}}(\mathbf{x}, \mathbf{t}, \mathbf{d}) \end{aligned}$$

where $\mathbf{f}_{\text{pos}\oplus\text{syn}}(.)$ means the concatenation of $\mathbf{f}_{\text{pos}}(.)$ and $\mathbf{f}_{\text{syn}}(.)$. Under the joint model, the weights of POS and syntactic features, $\mathbf{w}_{\text{pos}\oplus\text{syn}}$, are simultaneously learned. We expect that POS and syntactic features can interact each other to determine an optimal joint result.

Similarly to the baseline dependency parsing models, we define the *first-*, *second-*, and *third-order* joint models according to the syntactic features contained in $\mathbf{f}_{\text{syn}}(.)$.

In the following, we propose two versions of joint models which can capture different feature sets and have different complexity.

3.1 Joint Models of Version 1

The crucial problem for the joint method is to design effective decoding algorithms to capture rich features and efficiently search out the optimal results from a huge hypothesis space. Eisner (2000) describes a preliminary idea to handle *polysemy* by extending parsing algorithms. Based on this idea, we extend decoding algorithms of McDonald et al. (2005) and Koo and Collins (2010), and propose two DP based decoding algorithms for our joint models of version 1.

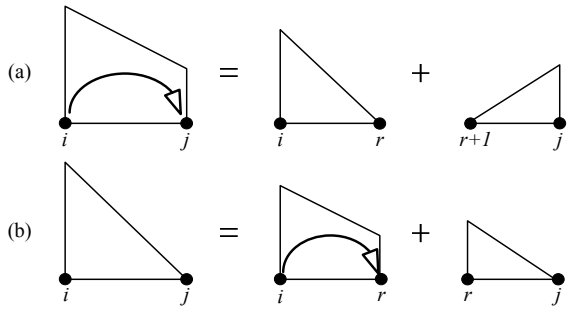

Figure 2: The DP structures and derivations of the first-order decoding algorithm of joint models of version 1. We omit symmetric right-headed versions for brevity. Trapezoids denote *incomplete spans*. Triangles denote *complete spans*. Solid circles denote POS tags of the corresponding indices.

The decoding algorithm of O1: As shown in Figure 2, the first-order joint decoding algorithm utilizes two types of dynamic programming structures. (1) ***I**ncomplete spans* consist of a dependency and the region between the head and modifier; (2) ***C**omplete spans* consist of a headword and its descendants on one side. Each span is recursively created by combining two smaller and adjacent spans in a bottom-up fashion.

The pseudo codes are given in Algorithm 1. $I_{(i,j)(t_i,t_j)}$ denotes an incomplete span from i to j whose boundary POS tags are t_i and t_j. $C_{(i,j)(t_i,t_j)}$ refers to a complete span from i to j whose boundary POS tags are t_i and t_j. Conversely, $I_{(j,i)(t_j,t_i)}$ and $C_{(j,i)(t_j,t_i)}$ represent spans of the other direction. Note that in these notations the first argument index always refers to the *head* of the span.

Line 6 corresponds to the derivation in Figure 2-(a). $Score_{\text{joint}}(\mathbf{x}, t_i, t_r, t_{r+1}, t_j, p = \{(i, j)\})$ captures the joint features invented by this combination, where $p = \{(i, j)\}$ means that the newly observed scoring part is the dependency (i, j). The syntactic features, denoted by $\mathbf{f}_{\text{syn}}(\mathbf{x}, t_i, t_j, i, j)$, can only incorporate *syntactic unigram and bigram* features. The surrounding and in between features are unavailable, because the context POS tags, such as t_b and t_{i-1}, are not contained in the DP struc-

Algorithm 1 The first-order joint decoding algorithm of version 1

1: $\forall 0 \le i \le n, t_i \in \mathcal{T}\ \ C_{(i,i)(t_i,t_i)} = 0$ ◁ initialization
2: **for** $w = 1..n$ **do** ◁ span width
3: **for** $i = 0..(n-w)$ **do** ◁ span start index
4: $j = i + w$ ◁ span end index
5: **for** $(t_i, t_j) \in \mathcal{T}^2$ **do**
6: $I_{(i,j)(t_i,t_j)} = \max_{i \le r < j} \max_{(t_r,t_{r+1}) \in \mathcal{T}^2} \{C_{(i,r)(t_i,t_r)} + C_{(j,r+1)(t_j,t_{r+1})} + Score_{\text{joint}}(\mathbf{x}, t_i, t_r, t_{r+1}, t_j, p = \{(i,j)\})\}$
7: $I_{(j,i)(t_j,t_i)} = \max_{i \le r < j} \max_{(t_r,t_{r+1}) \in \mathcal{T}^2} \{C_{(i,r)(t_i,t_r)} + C_{(j,r+1)(t_j,t_{r+1})} + Score_{\text{joint}}(\mathbf{x}, t_i, t_r, t_{r+1}, t_j, p = \{(j,i)\})\}$
8: $C_{(i,j)(t_i,t_j)} = \max_{i < r \le j} \max_{t_r \in \mathcal{T}} \{I_{(i,r)(t_i,t_r)} + C_{(r,j)(t_r,t_j)} + Score_{\text{joint}}(\mathbf{x}, t_i, t_r, t_j, p = \emptyset)\}$
9: $C_{(j,i)(t_j,t_i)} = \max_{i \le r < j} \max_{t_r \in \mathcal{T}} \{C_{(r,i)(t_r,t_i)} + I_{(j,r)(t_j,t_r)} + Score_{\text{joint}}(\mathbf{x}, t_i, t_r, t_j, p = \emptyset)\}$
10: **end for**
11: **end for**
12: **end for**

tures. Therefore, we adopt ***pseudo surrounding and in between features*** by simply fixing the context POS tags as the single most likely ones (McDonald, 2006). Taking the in between features as an example, we use $\underline{t_i\ \hat{t}_b\ t_j\ dir\ dist}$ instead, where $\hat{t}_b$ is the 1-best tag determined by the baseline POS tagger. The POS features, denoted by $\mathbf{f}_{\text{pos}}(\mathbf{x}, t_i, t_r, t_{r+1}, t_j)$, can only incorporate all *POS unigram and bigram* features.[3] Similarly, we use ***pseudo POS trigram features*** such as $\underline{\hat{t}_{r-1}\ t_r\ t_{r+1}}$.

Line 8 corresponds to the derivation in Figure 2-(b). Since this combination invents no scoring part ($p = \emptyset$), $Score_{\text{joint}}(\mathbf{x}, t_i, t_r, t_j, p = \emptyset)$ is only composed of POS features.[4]

Line 7 and Line 9 create spans in the opposite direction, which can be analogously illustrated. The space and time complexity of the algorithm are respectively $O(n^2q^2)$ and $O(n^3q^4)$, where $q = |\mathcal{T}|$.[5]

The decoding algorithm of O2 & O3: Figure 3 illustrates the second- and third-order decoding algorithm of joint models of version 1. A new kind of span, named the *sibling span*, is used to capture sibling structures. Furthermore, each span is augmented with a grandparent-index to capture both grandparent and grand-sibling structures. It is straightforward to derive the pseudo codes of the al-

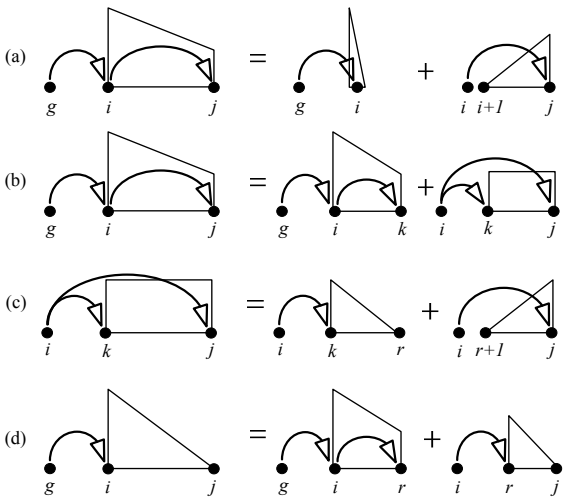

Figure 3: The DP structures and derivations of the second- and third-order joint decoding algorithm of version 1. For brevity, we elide the right-headed and right-grandparented versions. Rectangles represent sibling spans.

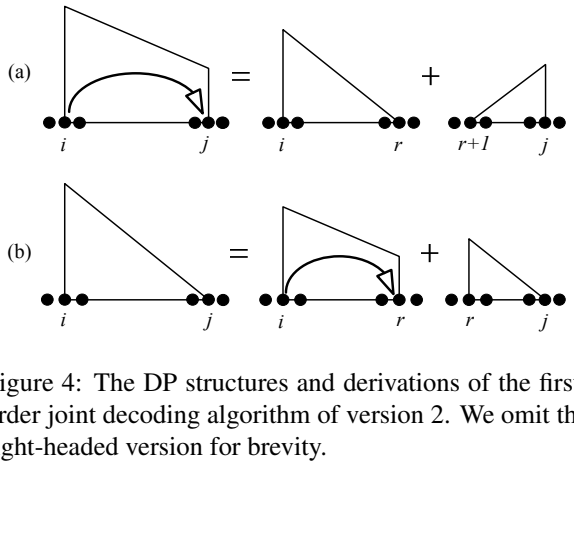

Figure 4: The DP structures and derivations of the first-order joint decoding algorithm of version 2. We omit the right-headed version for brevity.

[3] ① $\underline{w_r\ t_r}$ if $i \ne r$; ② $\underline{w_{r+1}\ t_{r+1}}$ if $r+1 \ne j$; ③ $\underline{t_r\ t_{r+1}}$ if $r \ne i$ or $r+1 \ne j$; ④ $\underline{t_i\ t_r}$ if $r-1 = i$; ⑤ $\underline{t_{r+1}\ t_j}$ if $r+2 = j$. Note that $\underline{w_i\ t_i}$, $\underline{w_j\ t_j}$ and $\underline{t_i\ t_j}$ (if $i = j-1$) are not incorporated here to avoid double counting.

[4] ① $\underline{w_r\ t_r}$ if $r \ne j$; ② $\underline{t_i\ t_r}$ if $i = r-1$; ③ $\underline{t_r\ t_j}$ if $r+1 = j$. Pseudo trigram features can be added accordingly.

[5] We can reduce the time complexity to $O(n^3q^3)$ by strictly adopting the DP structures in the parsing algorithm of Eisner (1996). However, that may make the algorithm harder to comprehend.

gorithm from Figure 3. We omit them due to space limitation. Pseudo surrounding, in between and POS trigram features are used due to the same reason as above. The space and time complexity of the algorithm are respectively $O(n^3q^3)$ and $O(n^4q^5)$.

3.2 Joint Models of Version 2

To further incorporate genuine syntactic surrounding and POS trigram features in the DP structures, we extend the algorithms of joint models of version 1, and propose our joint models of version 2.

The decoding algorithm of O1: Figure 4 illustrates the first-order joint decoding algorithm of version 2. Compared with the structures in Figure 2, each span is augmented with the POS tags surrounding the boundary indices. These context POS tags enable $Score_{\text{joint}}(.)$ in line 6-9 of Algorithm 1 to capture the ***syntactic surrounding and POS trigram features***, but also require enumeration of POS tags over more indices. For brevity, we skip the pseudo codes which can be easily derived from Algorithm 1. The space and time complexity of the algorithm are respectively $O(n^2q^6)$ and $O(n^3q^{10})$.

The decoding algorithm of O2 & O3: Using the same idea as above, the second- and third-order joint decoding algorithms of version 2 can be derived based on Figure 3. Again, we omit both its DP structures and pseudo codes for the sake of brevity. Its space and time complexity are respectively $O(n^3q^7)$ and $O(n^4q^{11})$.

In between features, which should be regarded as non-local features in the joint situation, still cannot be incorporated in our joint models of version 2. Again, we adopt the pseudo version.

3.3 Comparison

Based on the above illustration, we can see that joint models of version 1 are more efficient with regard to the number of POS tags for each word, but fail to incorporate syntactic surrounding features and POS trigram features in the DP structures. On the contrary, joint models of version 2 can incorporate both aforementioned feature sets, but have higher complexity. These two versions of models will be thoroughly compared in the experiments.

4 Pruning Techniques

In this section, we introduce two pruning strategies to constrain the search space of our models due to their high complexity.

4.1 POS Tag Pruning

The time complexity of the joint decoding algorithm is unbearably high with regard to the number of candidate POS tags for each word ($q = |\mathcal{T}|$). We find that it would be extremely time-consuming even when we only use two most likely POS tags for each word ($q = 2$) even for joint models of version 1. To deal with this problem, we propose a pruning method that can effectively reduce the POS tag space based on a probabilistic tagging model.

We adopt a conditional log-linear model (Lafferty et al., 2001), which defines a conditional distribution of a POS tag sequence $\mathbf{t}$ given $\mathbf{x}$:

$$P(\mathbf{t}|\mathbf{x}) = \frac{e^{\mathbf{w}_{\text{pos}} \cdot \mathbf{f}_{\text{pos}}(\mathbf{x},\mathbf{t})}}{\sum_{\mathbf{t}} e^{\mathbf{w}_{\text{pos}} \cdot \mathbf{f}_{\text{pos}}(\mathbf{x},\mathbf{t})}}$$

We use the same feature set $\mathbf{f}_{\text{pos}}$ defined in Section 2.1, and adopt the *exponentiated gradient* algorithm to learn the weight vector $\mathbf{w}_{\text{pos}}$ (Collins et al., 2008).

The marginal probability of tagging a word w_i as t is

$$P(t_i = t|\mathbf{x}) = \sum_{\mathbf{t}:\mathbf{t}[i]\equiv t} P(\mathbf{t}|\mathbf{x})$$

which can be efficiently computed using the *forward-backward* algorithm.

We define $\texttt{pmax}_i(\mathbf{x})$ to be the highest marginal probability of tagging the word w_i:

$$\texttt{pmax}_i(\mathbf{x}) = \max_{t \in \mathcal{T}} P(t_i = t|\mathbf{x})$$

We then define the allowable candidate POS tags of the word w_i to be

$$\mathcal{T}_i(\mathbf{x}) = \{t : t \in \mathcal{T}, P(t_i = t|\mathbf{x}) \geq \lambda_t \times \texttt{pmax}_i(\mathbf{x})\}$$

where λ_t is the pruning threshold. $\mathcal{T}_i(\mathbf{x})$ is used to constrain the POS search space by replacing $\mathcal{T}$ in Algorithm 1.

4.2 Dependency Pruning

The parsing time grows quickly for the second- and third-order models (both baseline and joint) when the input sentence gets longer ($O(n^4)$). Following Koo and Collins (2010), we eliminate unlikely dependencies using a form of coarse-to-fine pruning (Charniak and Johnson, 2005; Petrov and Klein, 2007). On the development set, 68.87% of the dependencies are pruned, while the oracle dependency accuracy is 99.77%. We use 10-fold cross validation to do pruning on the training set.

5 Experiments

We use the Penn Chinese Treebank 5.1 (CTB5) (Xue et al., 2005). Following the setup of Duan et al. (2007), Zhang and Clark (2008b) and Huang and Sagae (2010), we split CTB5 into training (secs 001-815 and 1001-1136), development (secs 886-931 and 1148-1151), and test (secs 816-885 and 1137-1147) sets. We use the head-finding rules of Zhang and Clark (2008b) to turn the bracketed sentences into dependency structures.

We use the standard *tagging **acc**uracy* to evaluate POS tagging. For dependency parsing, we use ***word** accuracy* (also known as *dependency accuracy*), ***root** accuracy* and ***compl**ete match rate* (all excluding punctuation) .

For the averaged training, we train each model for 15 iterations and select the parameters that perform best on the development set.

5.1 Results of POS Tag Pruning

Figure 5 shows the distribution of words with different number of candidate POS tags and the k-best oracle tagging accuracy under different λ_t. To avoid dealing with words that have many candidate POS tags, we further apply a hard criterion that the decoding algorithms only consider top k candidate POS tags.

To find the best λ_t, we train and evaluate the second-order joint model of version 1 on the training and development sets pruned with different λ_t (top k = 5). We adopt the second-order joint model of version 1 because of its efficiency compared with the third-order models and its capability of capturing rich features compared with the first-order models. The results are shown in Table 1. The model

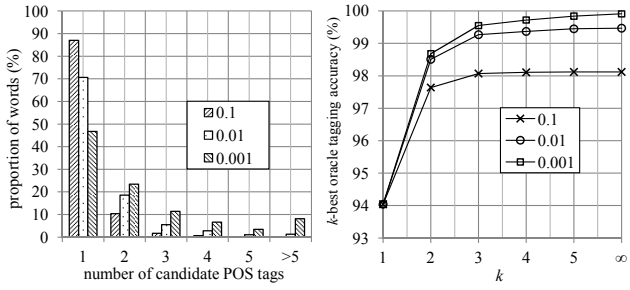

Figure 5: Results of POS tag pruning with different pruning threshold λ_t on the development set.

λ_t	word	root	compl.	acc.	speed
0.1	81.53	76.88	30.00	**94.17**	2.5
0.01	**81.83**	76.62	**30.62**	93.16	1.2
0.001	81.73	**77.38**	30.50	93.41	0.5

Table 1: Performance of the second-order joint model of version 1 with different pruning threshold λ_t (top k = 5) on the development set. "Acc." means the tagging accuracy. "Speed" refers to the parsing speed (the number of sentences processed per second).

with $\lambda_t = 0.1$ obtains the highest tagging accuracy, which is much higher than that of both $\lambda_t = 0.01$ and $\lambda_t = 0.001$. However, its parsing accuracy is inferior to the other two. $\lambda_t = 0.01$ produces slightly better parsing accuracy than $\lambda_t = 0.001$, and is twice faster. Finally, we choose $\lambda_t = 0.01$ due to the efficiency factor and our priority over the parsing accuracy.

Then we do experiments to find an optimal top k. Table 2 shows the results. We decide to choose $k = 3$ since it leads to best parsing accuracy.

From Table 1 and 2, we can have an interesting finding: it seems that the harder we filter the POS tag space, the higher tagging accuracy we get. In other words, **giving the joint model less flexibility of choosing POS tags leads to better tagging performance.**

Due to time limitation, we do not tune λ_t and k for other joint models. Instead, we simply adopt $\lambda_t = 0.01$ and top $k = 3$.

5.2 Final Results

Table 3 shows the final results on the test set. We list a few state-of-the-art results in the bottom. Duan07 refers to the results of Duan et al. (2007). They enhance the transition-based parsing model with

		Syntactic Metrics			Tagging Accuracy			Parsing Speed

5	81.83	76.62	**30.62**	93.16	1.2

Table 2: Performance of the second-order joint model of version 1 with different top k ($\lambda_t = 0.01$) on the development set.

the beam search. H&S10 refers to the results of Huang and Sagae (2010). They greatly expand the search space of the transition-based model by merging equivalent states with dynamic programming. Z&C08 refers to the results of Zhang and Clark (2008b). They use a hybrid model to combine the advantages of both graph-based and transition-based models. We also do experiments with two publicly available and widely-used parsers, MSTParser[6] and MaltParser[7]. MSTParser1 refers to the first-order graph-based model of McDonald et al. (2005), while MSTParser2 is the second-order model of McDonald and Pereira (2006). MaltParser is a transition-based parsing system. It integrates a number of classification algorithms and transition strategies. We adopt the support vector machine classifier and the arc-standard strategy (Nivre, 2008).

We can see that when using gold tags, our pipelined second- and third-order parsing models achieve best parsing accuracy, which is even higher than the hybrid model of Zhang and Clark (2008b). It is a little surprising that the second-order model slightly outperforms the third-order one. This may be possible, since Koo and Collins (2010) shows that the third-order model outperforms the second-order one by only 0.32% on English and 0.07% on Czech. In addition, we only use basic third-order features.

Both joint models of version 1 and 2 can consistently and significantly improve the parsing accuracy by about 1.5% for all first-, second- and third-order cases. Accidentally, the parsing accuracy of the second-order joint model of version 2 is lower

P → VV	52	24	JJ → NN	126	29
P → CC	39	13	VV → VA	67	10

Table 4: Error analysis of POS tagging. # means the error number of the corresponding pattern made by the baseline tagging model. ↓ and ↑ mean the error number reduced or increased by the joint model.

than that of its counterparts by about 0.3%. More experiments and further analysis may be needed to find out the reason. The two versions of joint models performs nearly the same, which indicates that using pseudo surrounding and POS trigram features may be sufficient for the joint method on this data set. In summary, we can conclude that **the joint framework is certainly helpful for dependency parsing.**

It is clearly shown in Table 3 that **the joint method surprisingly hurts the tagging accuracy**, which diverges from our discussion in Section 1. Some insights into this issue will be given in Section 5.3. Moreover, it seems that **the more syntactic features the joint method incorporates (from O1 to O3), the more the tagging accuracy drops**. We suspect that this is because the joint models are dominated by the syntactic features. Take the first-order joint model as an example. The dimension of the syntactic features $\mathbf{f}_{\text{syn}}$ is about 3.5 million, while that of $\mathbf{f}_{\text{pos}}$ is only about 0.5 million. The gap becomes much larger for the second- and third-order cases.

Comparing the parsing speed, we can find that the pruning of POS tags is very effective. The second-order joint model of version 1 can parse 1.7 sentences per second, while the pipelined second-order parsing model can parse 5.8 sentences per second, which is rather close considering that there is a factor of q^5.

5.3 Error Analysis

To find out the impact of our joint models on the individual tasks, we conduct detailed error analysis through comparing the results of the pipelined second-order parsing model and the second-order joint model of version 1.

Impact on POS tagging: Table 4 shows how the joint model changes the quantity of POS tagging error patterns compared with the pipelined model. An error pattern "X → Y" means that the focus word, whose true tag is 'X', is assigned a tag 'Y'. We choose these patterns with largest reduction or increase in the error number, and rank them in descending order of the variation.

From the left part of Table 4, we can see that the joint method is clearly better at resolving tagging ambiguities like {VV, NN} and {DEG, DEC}.[8] One common characteristic of these ambiguous pairs is that the local or even whole syntactic structure will be destructed if the wrong tag is chosen. In other words, resolving these ambiguities is critical and helpful from the parsing viewpoint. From another perspective, the joint model is capable of preferring the right tag with the help of syntactic structures, which is impossible for the baseline sequential labeling model.

In contrast, pairs like {NN, NR}, {VV, VA} and {NN, JJ} only slightly influence the syntactic structure when mis-tagged. The joint method performs worse on these ambiguous pairs, as shown in the right part of Table 4.

Impact on parsing: Table 5 studies the change of parsing error rates between the pipelined and joint model on different POS tag patterns. We present the most typical and prominent patterns in the table, and rank them in descending order of X's frequency of occurrence. We also show the change of proportion of different patterns, which is consistent with the results in Table 4.

From the table, we can see the joint model can achieve a large error reduction (0.8∼4.0%) for all the patterns "X → X". In other words, **the joint model can do better given the correct tags** than the pipelined method.

For all the patterns marked by ♢, except for the ambiguous pair {NN, JJ} (which we find is difficult to explain even after careful result analysis), the joint model also reduces the error rates (2.2∼15.4%). As

[8] DEG and DEC are the two POS tags for the frequently used auxiliary word "的" (dē, of) in Chinese. The associative "的" is tagged as DEG, such as "父亲/father 的 眼睛/eyes (eyes of the father)"; while the one in a relative clause is tagged as DEC, such as "他/he 取得/made 的 进步/progress (progress that he made)".

pattern	pipelined		joint	
	prop (%)	error (%)	prop (%)	error (%)
NN → NN	94.6	16.8	-1.1	-1.8
→ VV ♡	2.9	55.5	-0.5	+15.1
→ NR ♢	0.8	24.5	+0.7	-2.2
→ JJ ♢	0.7	17.9	+0.5	*+2.1*

→ NN ♢	9.8	18.3	+2.2	*+1.8*
DEG → DEG	86.5	11.1	+2.8	-3.6
→ DEC ♡	13.5	61.8	-3.1	+37.4
DEC → DEC	79.7	17.2	+12.1	-4.0
→ DEG ♡	20.2	56.5	-9.7	+40.2

Table 5: Comparison of parsing error rates on different POS tag patterns between the pipelined and joint models. Given a pattern "X → Y", "prop" means its *proportion* in all occurrence of 'X' ($\frac{Count(X \rightarrow Y)}{Count(X)}$), and "error" refers to its *parsing error rate* ($\frac{Count(\texttt{wrongly headed } X \rightarrow Y)}{Count(X \rightarrow Y)}$). The last two columns give the absolute reduction (-) or increase (+) in proportion and error rate made by the joint model. ♡ marks the patterns appearing in the left part of Table 4, while ♢ marks those in the right part of Table 4.

discussed earlier, these patterns concern ambiguous tag pairs which usually play similar roles in syntactic structures. This demonstrates that **the joint model can do better on certain tagging error patterns**.

For patterns marked by ♡, the error rate of the joint model usually increases by large margin. However, the proportion of these patterns is substantially decreased, since the joint model can better resolve these ambiguities with the help of syntactic knowledge.

In summary, we can conclude that the joint model is able to choose such POS tags that are more helpful and discriminative from parsing viewpoint. This is the fundamental reason of the parsing performance improvement.

6 Related Work

Theoretically, Eisner (2000) proposes a preliminary idea of extending the decoding algorithm for dependency parsing to handle polysemy. Here, word senses can be understood as POS-tagged words. Koo and Collins (2010) also briefly discuss that their third-order decoding algorithm can be modified to handle word senses using the idea of Eisner (2000).

In his PhD thesis, McDonald (2006) extends his second-order model with the idea of Eisner (2000) to study the impact of POS tagging errors on parsing accuracy. To make inference tractable, he uses top 2 candidate POS tags for each word based on a maximum entropy tagger, and adopts the single most likely POS tags for the surrounding and in between features. He conducts primitive experiments on English Penn Treebank, and shows that parsing accuracy can be improved from 91.5% to 91.9%. However, he finds that the model is unbearably time-consuming.

7 Conclusions

In this paper, we have systematically investigated the issue of joint POS tagging and dependency parsing. We propose and compare several joint models and their corresponding decoding algorithms which can incorporate different feature sets. We also propose an effective POS tag pruning method which can greatly improve the decoding efficiency. The experimental results show that our joint models can significantly improve the state-of-the-art parsing accuracy by more than 1.5%. Detailed error analysis shows that the fundamental reason for the parsing accuracy improvement is that the joint method is able to choose POS tags that are helpful and discriminative from parsing viewpoint.

Abstract

We propose a relaxed correspondence assumption for cross-lingual projection of constituent syntax, which allows a supposed constituent of the target sentence to correspond to an unrestricted treelet in the source parse. Such a relaxed assumption fundamentally tolerates the syntactic non-isomorphism between languages, and enables us to learn the target-language-specific syntactic idiosyncrasy rather than a strained grammar directly projected from the source language syntax. Based on this assumption, a novel constituency projection method is also proposed in order to induce a projected constituent treebank from the source-parsed bilingual corpus. Experiments show that, the parser trained on the projected treebank dramatically outperforms previous projected and unsupervised parsers.

1 Introduction

For languages with treebanks, supervised models give the state-of-the-art performance in dependency parsing (McDonald and Pereira, 2006; Nivre et al., 2006; Koo and Collins, 2010; Martins et al., 2010) and constituent parsing (Collins, 2003; Charniak and Johnson, 2005; Petrov et al., 2006). To break the restriction of the treebank scale, lots of works have been devoted to the unsupervised methods (Klein and Manning, 2004; Bod, 2006; Seginer, 2007; Cohen and Smith, 2009) and the semi-supervised methods (Sarkar, 2001; Steedman et al., 2003; McClosky et al., 2006; Koo et al., 2008) to utilize the unannotated text. In recent years, researchers have also conducted many investigations on syntax projection (Hwa et al., 2005; Ganchev et al., 2009; Smith and Eisner, 2009; Jiang et al., 2010), in order to borrow syntactic knowledge from another language.

Different from the bilingual parsing (Smith and Smith, 2004; Burkett and Klein, 2008; Zhao et al., 2009; Huang et al., 2009; Chen et al., 2010) that improves parsing performance with bilingual constraints, and the bilingual grammar induction (Wu, 1997; Kuhn, 2004; Blunsom et al., 2008; Snyder et al., 2009) that induces grammar from parallel text, the syntax projection aims to project the syntactic knowledge from one language to another. This seems especially promising for the languages that have bilingual corpora parallel to resource-rich languages with large treebanks. Previous works mainly focus on dependency projection. The dependency relationship between words in the parsed source sentences can be directly projected across the word alignment to words in the target sentences, following the direct correspondence assumption (DCA) (Hwa et al., 2005). Due to the syntactic non-isomorphism between languages, DCA assumption usually leads to conflicting or incomplete projection. Researchers have to adopt strategies to tackle this problem, such as designing rules to handle language non-isomorphism (Hwa et al., 2005), and resorting to the quasi-synchronous grammar (Smith and Eisner, 2009).

For constituency projection, however, the lack of isomorphism becomes much more serious, since a constituent grammar describes a language in a more detailed way. In this paper we propose a relaxed correspondence assumption (RCA) for constituency

Edinburgh, Scotland, UK, July 27–31, 2011.

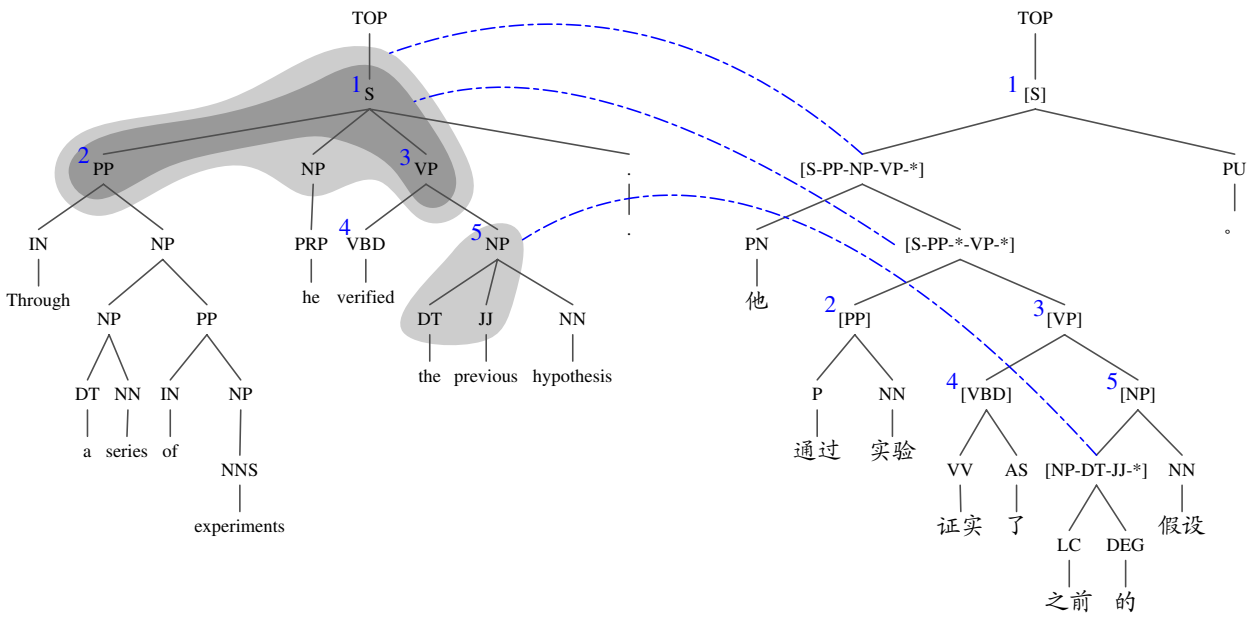

Figure 1: An example for constituency projection based on the RCA assumption. The projection is from English to Chinese. A dash dot line links a projected constituent to its corresponding treelet, which is marked with gray background; An Arabic numeral relates a directly-projected constituent to its counter-part in the source parse.

projection. It allows a supposed constituent of the target sentence to correspond to an unrestricted treelet in the source parse. Such a relaxed assumption fundamentally tolerates the syntactic non-isomorphism between languages, and enables us to learn the target-language-specific syntactic idiosyncrasy, rather than induce a strained grammar directly projected from the source language syntax. We also propose a novel cross-lingual projection method for constituent syntax based on the RCA assumption. Given a word-aligned source-parsed bilingual corpus, a PCFG grammar can be induced for the target language by maximum likelihood estimation on the exhaustive enumeration of candidate projected productions, where each nonterminal in a production is an unrestricted treelet extracted from the source parse. The projected PCFG grammar is then used to parse each target sentence under the guidance of the corresponding source tree, so as to produce an optimized projected constituent tree.

Experiments validate the effectiveness of the RCA assumption and the constituency projection method. We induce a projected Chinese constituent treebank from the FBIS Chinese-English parallel corpus with English sentences parsed by the Charniak parser. The Berkeley Parser trained on the projected treebank dramatically outperforms the previous projected and unsupervised parsers. This provides an promising substitute for unsupervised parsing methods, to the resource-scarce languages that have bilingual corpora parallel to resource-rich languages with human-annotated treebanks.

In the rest of this paper we first presents the RCA assumption, and the algorithm used to determine the corresponding treelet in the source parse for a candidate constituent in the target sentence. Then we describe the induction of the projected PCFG grammar and the projected constituent treebank from the word-aligned source-parsed parallel corpus. After giving experimental results and the comparison with previous unsupervised and projected parsers, we finally conclude our work and point out several aspects to be improved in the future work.

2 Relaxed Correspondence Assumption

The DCA assumption (Hwa et al., 2005) works well in dependency projection. A dependency grammar describes a sentence in a compact manner where the syntactic information is carried by the dependency relationships between pairs of words. It is reasonable to audaciously assume that the relationship of

a word pair in the source sentence also holds for the corresponding word pair in the target sentence. Compared with dependency grammar, constituent grammar depicts syntax in a more complex way that gives a sentence a hierarchically branched structure. Therefore the lack of syntactic isomorphism for constituency projection becomes much more serious, it will be hard and inappropriate to directly project the complex constituent structure from one language to another.

For constituency projection, we propose a relaxed corresponding assumption (RCA) to eliminate the influence of syntactic non-isomorphism between the source- and target languages. This assumption allows a supposed constituent of the target sentence to correspond to an unrestricted treelet in the source parse. A treelet is a connected subgraph in the source constituent tree, which covers a discontiguous sequence of words of the source sentence. This property enables a supposed constituent of the target sentence not necessarily to correspond to exactly a constituent of the source parse, so as to fundamentally tolerate the syntactic non-isomorphism between languages. Figure 1 gives an example of relaxed correspondence.

2.1 Corresponding Treelet Extraction

According to the word alignment between the source and target sentences, we can extract the treelet out of the source parse for any possible constituent span of the target sentence. Algorithm 1 shows the treelet extraction algorithm.

Given the target sentence $\mathbf{e}$, the parse tree $\mathbf{T_f}$ of the source sentence $\mathbf{f}$, and the word alignment $\mathbf{A}$ between $\mathbf{e}$ and $\mathbf{f}$, the algorithm extracts the corresponding treelet out of $\mathbf{T_f}$ for each candidate span of $\mathbf{e}$ (line 4-6). For a given span $\langle i, j \rangle$, its corresponding treelet in $\mathbf{T_f}$ can be extracted by a recursive top-down traversal in the tree. If all nodes in the current subtree $\mathbf{T}$ align outside of source subsequence $\mathbf{e}_{i:j}$, the recursion stops and returns an empty tree $\emptyset$, indicating that the subtree is eliminated from the final treelet (line 9-10). And, if all nodes in $\mathbf{T}$ align inside $\mathbf{e}_{i:j}$, the root of $\mathbf{T}$ is returned as the concise representation of the whole subtree (line 11-12). For the third situation, that is to say $\mathbf{T}$ aligns partly inside $\mathbf{e}_{i:j}$, the recursion has to continue to investigate the subtrees of $\mathbf{T}$ (line 14-15). The recursive traversal finally returns a treelet $\mathbf{t}$ that exactly corre-

sponds to the candidate constituent span $\langle i, j \rangle$ of the source sentence.

We can find that even for a smaller span, the recursive extraction procedure still starts from the root of the source tree. This leads to a expatiatory treelet with some redundant nodes on the top. Function PRUNETREE takes charge of the treelet pruning (line 6). It traverses the treelet to merge the successive empty sibling nodes (marked with asterisks) into one (line 18-19), then conducts a top-down pruning to delete the redundant branches until meeting a branch with more than one non-empty subtrees (line 20-22). Figure 2 shows the effect of the pruning operation with two examples. The pruning operation maps the two original treelets into the same simplified version, that is, the pruned treelet. The branches pruned out of the original treelet serve as the context of the pruned treelet. The bracketed representations of the pruned treelets, as shown above the treelet graphs, are used as the nonterminals of the projected target parses.

Since the overall complexity of the algorithm is $O(|\mathbf{e}|^3)$, it seems inefficient to collect the treelets for all spans in the target sentence. But in fact it runs fast on the realistic corpus in our experiments, we assume that the function EXTTREELET doesn't always consume $O(|\mathbf{e}|)$ because of the more or less isomorphism between two languages.

3 Projected Grammar and Treebank

This section describes how to build a projected constituent treebank based on the RCA assumption. According to the last section, each span of the target sentence could correspond to a treelet in the source parse. If a span $\langle i, j \rangle$ has a corresponding treelet $\mathbf{t}$, a candidate projected constituent can be defined as a triple $\langle i, j, \mathbf{t} \rangle$. For an n-way partition of this span,

$$\langle i, k_1 \rangle, \langle k_1 + 1, k_2 \rangle, .., \langle k_{n-1} + 1, j \rangle$$

if each sub-span $\langle k_{p-1}+1, k_p \rangle$ corresponds to a candidate constituent $\langle k_{p-1}+1, k_p, \mathbf{t}_p \rangle$, a candidate projected production can then be defined, denoted as

$$\langle i, j, \mathbf{t} \rangle \rightarrow \langle i, k_1, \mathbf{t}_1 \rangle \langle k_1+1, k_2, \mathbf{t}_2 \rangle .. \langle k_{n-1}+1, j, \mathbf{t}_n \rangle$$

There may be many candidate projected constituents because of arbitrary combination, the tree projection procedure aims to find the optimum tree from the parse forest determined by these candidate constituents. Each production in the optimum tree should satisfy this principle: the rule used in this production appears in the whole corpus as frequently as possible.

However, due to translation diversity and word alignment error, the real constituent tree of the target sentence may not be contained in the candidate projected constituents. We propose a relaxed and fault-tolerant tree projection strategy to tackle this problem. First, based on the distribution of candidate projected constituents over each single sentence, we estimate the distribution over the whole corpus for the rules used in these constituents, so as to obtain a projected PCFG grammar. Then, using a PCFG parser and this grammar, we parse each target sentence under the guidance of the candidate projected constituent set of the target sentence, so as to obtain the optimum projected tree as far as possible. In the following, we first describe the estimation of the projected PCFG grammar and then show the tree projection procedure.

3.1 Projected PCFG Grammar

From a human-annotated treebank, we can induce a PCFG grammar by estimating the frequency of the production rules, which are contained in the productions of the trees. But for each target sentence we don't know which candidate productions consist the correct constituent tree, so we can't estimate the frequency of the production rules directly.

A reasonable hypothesis is, if a candidate projected production for a target sentence happens to be in the correct parse of the sentence, the rule used in this production will appear frequently in the whole corpus. We assume that each candidate projected production may be a part of the correct parse, but with different probabilities. If we give each candidate projected production an appropriate probability and use this probability as the appearance frequency of this production in the correct parse, we can achieve an approximation of the PCFG grammar hidden in the target sentences. In this work, we restrict the productions to be binarized to reduce the computational complexity. It results in a binarized PCFG grammar, similar to previous unsupervised works.

To estimate the frequencies of the candidate pro-

ductions in the correct parse of the target sentence, we need first estimate the frequencies of the candidate spans, which are described as follows:

$$p(\langle i,j\rangle|\mathbf{e}) = \frac{\#\ of\ trees\ including\ \langle i,j\rangle}{\#\ of\ all\ trees} \quad (1)$$

The count of all binary trees of a target sentence $\mathbf{e}$ can be calculated similar to the β value calculation in the inside-outside algorithm. Without confusion, we adopt the symbol $\beta(i,j)$ to denote the count of binary tree for span $\langle i,j\rangle$:

$$\beta(i,j) = \begin{cases} 1 & i = j \\ \sum_{k=i}^{j-1} \beta(i,k) \cdot \beta(k+1,j) & i < j \end{cases} \quad (2)$$

$\beta(1,|\mathbf{e}|)$ is the count of binary trees of target sentence $\mathbf{e}$. We also need to calculate the count of binary tree fragments that cover the nodes outside span $\langle i,j\rangle$. This is similar to the calculation of the α value in the inside-outside algorithm. We also adopt the symbol $\alpha(i,j)$ here:

$$\alpha(i,j) = \begin{cases} 1 & i = 1, j = |\mathbf{e}| \\ \sum_{k=j+1}^{|\mathbf{e}|} \alpha(i,k) \cdot \beta(k+1,|\mathbf{e}|) & \\ + \sum_{k=1}^{i-1} \alpha(k,j) \cdot \beta(k,j-1) & \mathbf{else} \end{cases} \quad (3)$$

For simplicity we omit some conditions in above formulas. The count of trees containing span $\langle i,j\rangle$ is $\alpha(i,j) \cdot \beta(i,j)$. Equation 1 can be rewritten as

$$p(\langle i,j\rangle|\mathbf{e}) = \frac{\alpha(i,j) \cdot \beta(i,j)}{\beta(1,|\mathbf{e}|)} \quad (4)$$

On condition that $\langle i,j\rangle$ is a span in the parse of $\mathbf{e}$, the probability that $\langle i,j\rangle$ has two children $\langle i,k\rangle$ and $\langle k+1,j\rangle$ is

$$p(\langle i,k\rangle\langle k+1,j\rangle|\langle i,j\rangle) = \frac{\beta(i,k) \cdot \beta(k+1,j)}{\beta(i,j)} \quad (5)$$

Therefore, the probability that $\langle i,j\rangle$ is a span in the parse of $\mathbf{e}$ and has two children $\langle i,k\rangle$ and $\langle k+1,j\rangle$ can be calculated as follows:

$$\begin{aligned} &p(\langle i,j\rangle \rightarrow \langle i,k\rangle\langle k+1,j\rangle|\mathbf{e}) \\ &\quad = p(\langle i,j\rangle|\mathbf{e}) \cdot p(\langle i,k\rangle\langle k+1,j\rangle|\langle i,j\rangle) \\ &\quad = \frac{\alpha(i,j) \cdot \beta(i,k) \cdot \beta(k+1,j)}{\beta(1,|\mathbf{e}|)} \end{aligned} \quad (6)$$

Since each candidate projected span aligns to one treelet at most, this probability is also the frequency of the candidate projected production related to the three spans.

The counting approach above is based on the assumption that there is a uniform distribution over the projected trees for every target sentence. The inside and outside algorithms and the other counting formulae are used to calculate the expected counts under this assumption. This looks like a single iteration of EM.

A binarized projected PCFG grammar can then be easily induced by maximum likelihood estimation. Due to word alignment errors, free translation, and exhaustive enumeration of possible projected productions, such a PCFG grammar may contain too much noisy nonterminals and production rules. We introduce a threshold b_{RULE} to filter the grammar. A production rule can be reserved only if its frequency is larger than b_{RULE}.

3.2 Relaxed Tree Projection

The projected PCFG grammar is used in the procedure of constituency projection. Such a grammar, as a kind of global syntactic knowledge, can attenuate the negative effect of word alignment error, free translation and syntactic non-isomorphism for the constituency projection between each single sentence pair. To obtain as optimal a projected constituency tree as possible, we have to integrate two kinds of knowledge: the local knowledge in the candidate projected production set of the target sentence, and the global knowledge in the projected PCFG grammar.

The integrated projection strategy can be conducted as follows. We parse each target sentence with the projected PCFG grammar $\mathbf{G}$, and use the candidate projected production set $\mathbf{D}$ to guide the PCFG parsing. The parsing procedure aims to find an optimum projected tree, which maximizes both the PCFG tree probability and the count of productions that also appear in the candidate projected pro-

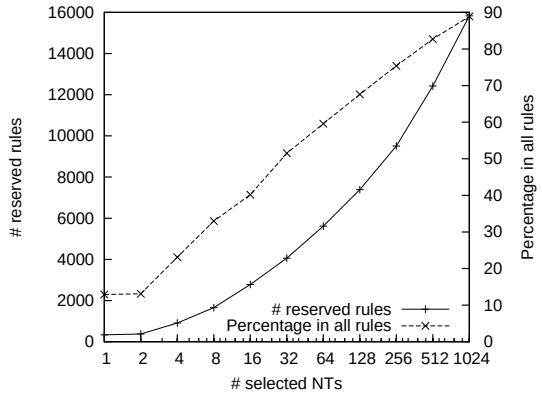

Figure 3: Rule counts corresponding to selected nonterminal sets, and their frequency summation proportions to the whole rule set.

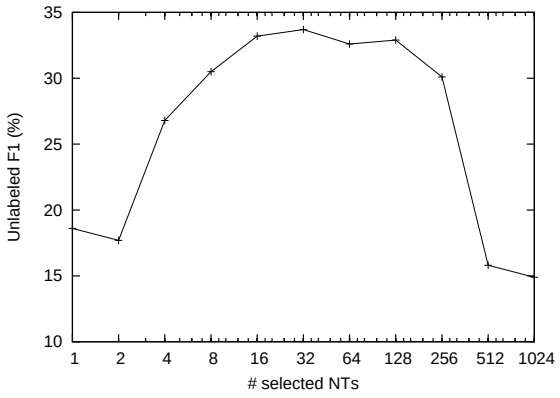

Figure 4: Performance curve of the projected PCFG grammars corresponding to different sizes of nonterminal sets.

duction set. The two optimization objectives can be coordinated as follows:

$$\tilde{y} = \underset{y}{\operatorname{argmax}} \prod_{d \in y} (p(d|\mathbf{G}) \cdot e^{\lambda \cdot \delta(d, \mathbf{D})}) \quad (7)$$

Here, d represents a production; δ is a boolean function that returns 1 if d appears in $\mathbf{D}$ and returns 0 otherwise; λ is a weight coefficient that needs to be tuned to maximize the quality of the projected treebank.

4 Experiments

Our work focuses on the constituency projection from English to Chinese. The FBIS Chinese-English parallel corpus is used to obtain a projected constituent treebank. It contains 239 thousand sentence pairs, with about 6.9/8.9 million Chinese/English words. We parse the English sentences with the Charniak Parser (Charniak and Johnson, 2005), and tag the Chinese sentences with a POS tagger implemented faithfully according to (Collins, 2002) and trained on the Penn Chinese Treebank 5.0 (Xue et al., 2005). We perform word alignment by runing GIZA++ (Och and Ney, 2000), and then use the alignment results for constituency projection.

Following the previous works of unsupervised constituent parsing, we evaluate the projected parser on the subsets of CTB 1.0 and CTB 5.0, which contain no more than 10 or 40 words after the removal of punctuation. The gold-standard POS tags are directly used for testing. The evaluation for unsupervised parsing differs slightly from the standard PARSEVAL metrics, it ignores the multiplicity of brackets, brackets of span one, and the bracket labels. In all experiments we report the unlabeled F1 value which is the harmonic mean of the unlabeled precision and recall.

4.1 Projected PCFG Grammar

An initial projected PCFG grammar can be induced from the word-aligned and source-parsed parallel corpus according to section 3.1. Such an initial grammar is huge and contains a large amount of projected nonterminals and production rules, where many of them come from free translation and word alignment errors. We conservatively set the filtration threshold b_{RULE} as 1.0 to discard the rules with frequency less than one, the rule count falls dramatically from 3.3 millions to 92 thousands.

Figure 3 shows the statistics of the remained production rules. We sort the projected nonterminals according to their frequencies and select the top 2^N ($1 \leq N \leq 10$) best ones, and then discard the rules that fall out of the selected nonterminal set. The frequency summation of the rule set corresponding to 32 best nonterminals accounts for nearly 90% of the frequency summation of the whole rule set.

We use the developing set of CTB 1.0 (chapter 301-325) to evaluate the performance of a series of filtered grammars. Figure 4 gives the unlabeled F1 value of each grammar on all trees in the developing set. The filtered grammar corresponding to the set of top 32 nonterminals achieves the highest performance. We denote this grammar as $\mathbf{G}_{32}$ and use it

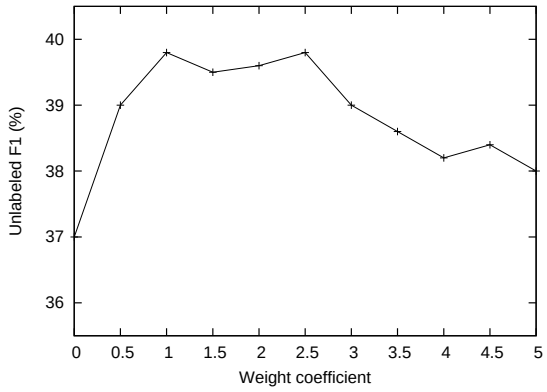

Figure 5: Performance curve of the Berkeley Parser trained on 5 thousand projected trees. The weight coefficient λ ranges from 0 to 5.

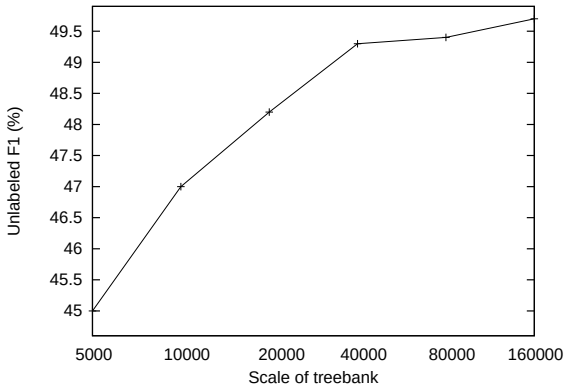

Figure 6: Performance curve of the Berkeley Parser trained on different amounts of best project trees. The scale of the selected treebank ranges from 5000 to 160000.

in the following tree projection procedure.

4.2 Projected Treebank and Parser

The projected grammar $\mathbf{G}_{32}$ provides global syntactic knowledge for constituency projection. Such global knowledge and the local knowledge carried by the candidate projected production set are integrated in a linear weighted manner as in Formula 7. The weight coefficient λ is tuned to maximize the quality of the projected treebank, which is indirectly measured by evaluating the performance of the parser trained on it.

We select the first 5 thousand sentence pairs from the Chinese-English FBIS corpus, and induce a series of projected treebanks using different λ, ranging from 0 to 5. Then we train the Berkeley Parser on each projected treebank, and test it on the developing set of CTB 1.0. Figure 5 gives the performance curve, which reports the unlabeled F1 values of the projected parsers on all sentences of the developing set. We find that the best performance is achieved with λ between 1 and 2.5, with slight fluctuation in this range. It can be concluded that, the projected PCFG grammar and the candidate projected production set do represent two different kinds of constraints, and we can effectively coordinate them by tuning the weight coefficient. Since different λ values in this range result in slight performance fluctuation of the projected parser, we simply set it to 1 for the constituency projection on the whole FBIS corpus.

There are more than 200 thousand projected trees induced from the Chinese-English FBIS corpus. It is a heavy burden for a parser to train on so large a treebank. And on the other hand, the free translation and word alignment errors result in many projected trees of poor-quality. We design a criteria to approximate the quality of the projected tree y for the target sentence x:

$$\tilde{Q}(y) = \sqrt[|x|-1]{\prod_{d \in y} (p(d|\mathbf{G}) \cdot e^{\lambda \cdot \delta(d, \mathbf{D})})} \qquad (8)$$

and use an amount of best projected trees instead of the whole projected treebank to train the parser. Figure 6 shows the performance of the Berkeley Parser trained on different amounts of selected trees. The performance of the Berkeley Parser constantly improves along with the increment of selected trees. However, treebanks containing more than 40 thousand projected trees can not brings significant improvement. The parser trained on 160 thousand trees only achieves an F1 increment of 0.4 points over the one trained on 40 thousand trees. This indicates that the newly added trees do not give the parser more information due to their projection quality, and a larger parallel corpus may lead to better parsing performance.

The Berkeley Parser trained on 160 thousand best projected trees is used in the final test. Table 1 gives the experimental results and the comparison with related works. This is a sparse table since the experiments of previous researchers focused on different data sets. Our projected parser significantly

outperforms the parser of Jiang et al. (2010), where they directly adapt the DCA assumption of (Hwa et al., 2005) from dependency projection to constituency projection and resort to a better word alignment and a more complicated tree projection algorithm. This indicates that the RCA assumption is more suitable for constituency projection than the DCA assumption, and can induce a better grammar that much more reflects the language-specific syntactic idiosyncrasy of the target language.

Our projected parser also obviously surpasses existing unsupervised parsers. The parser of Seginer (2007) performs slightly better on CTB 5.0 sentences no more than 10 words, but obviously falls behind on sentences no more than 40 words. Figure 7 shows the unlabeled F1 of our parser on a series of subsets of CTB 5.0 with different sentence length upper limits. We find that even on the whole treebank, our parser still gives a promising result. Compared with unsupervised parsing, constituency projection can make use of the syntactic information of another language, so that it probably induce a better grammar. Although comparing a syntax projection technique to supervised or semi-supervised techniques seems unfair, it still suggests that if a resource-poor language has a bilingual corpus parallel to a resource-rich language with a human-annotated treebank, the constituency projection based on RCA assumption is a promising substitute for unsupervised parsing.

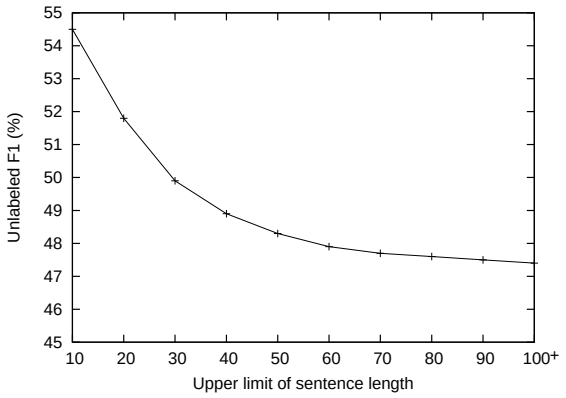

Figure 7: Performance of the Berkeley Parser on subsets of CTB 5.0 with different sentence length upper limits. 100+ indicates the whole treebank.

5 Conclusion and Future Works

This paper describes a relaxed correspondence assumption (RCA) for constituency projection. Under this assumption a supposed constituent in the target sentence can correspond to an unrestricted treelet in the parse of the source sentence. Different from the direct correspondence assumption (DCA) widely used in dependency projection, the RCA assumption is more suitable for constituency projection, since it fundamentally tolerates the syntactic non-isomorphism between the source and target languages. According to the RCA assumption we propose a novel constituency projection method. First, a projected PCFG grammar is induced from the word-aligned source-parsed parallel corpus. Then, the tree projection is conducted on each sentence pair by a PCFG parsing procedure, which integrates both the global knowledge in the projected PCFG grammar and the local knowledge in the set of candidate projected productions.

Experiments show that the parser trained on the projected treebank significantly outperforms the projected parsers based on the DCA assumption. This validates the effectiveness of the RCA assumption and the constituency projection method, and indicates that the RCA assumption is more suit-

able for constituency projection than the DCA assumption. The projected parser also obviously surpasses the unsupervised parsers. This suggests that if a resource-poor language has a bilingual corpus parallel to a resource-rich language with a human-annotated treebank, the constituency projection based on RCA assumption is an promising substitute for unsupervised methods.

Although achieving appealing results, our current work is quite coarse and has many aspects to be improved. First, the word alignment is the fundamental precondition for projected grammar induction and the following constituency projection, we can adopt the better word alignment strategies to improve the word alignment quality. Second, the PCFG grammar is too weak due to its context free assumption, we can adopt more complicated grammars such as TAG (Joshi et al., 1975), in order to provide a more powerful global syntactic constraints for the tree projection procedure. Third, the current tree projection algorithm is too simple, more bilingual constraints could lead to better projected trees. Last but not least, the constituency projection and the unsupervised parsing make use of different kinds of knowledge, therefore the unsupervised methods can be integrated into the constituency projection framework to achieve better projected grammars, treebanks, and parsers.

Abstract

The computation of logical form has been proposed as an intermediate step in the translation of sentences to logic. Logical form encodes the resolution of scope ambiguities. In this paper, we describe experiments on a modest-sized corpus of regulation annotated with a novel variant of logical form, called *abstract syntax trees* (ASTs). The main step in computing ASTs is to order scope-taking operators. A learning model for ranking is adapted for this ordering. We design features by studying the problem of comparing the scope of one operator to another. The scope comparisons are used to compute ASTs, with an F-score of 90.6% on the set of ordering decisons.

1 Introduction

May (1985) argued for a level of *logical form* as a prelude to translating sentences to logic. Just as a parse tree determines the constituent structure of a sentence, a logical form of a sentence represents one way of resolving scope ambiguities. The level of logical form is an appealing layer of modularity; it allows us to take a step beyond parsing in studying scope phenomenon, and yet, avoid the open problem of fully translating sentences to logic.

Data-driven analyses of scope have been of interest in psycholinguistics (Kurtzman and MacDonald, 1993) and more recently in NLP (Srinivasan and Yates, 2009). The focus has typically been on predicting the preferred scopal ordering of sentences with two quantifying determiners, for example, in the sentence "every kid climbed a tree". In the related problem of translating database queries to logic, Zettlemoyer and Collins (2009) and Wong and Mooney (2007) consider the scope of adjectives in addition to determiners, for example the scope of "cheapest" in the noun phrase "the cheapest flights from Boston to New York". To our knowledge, empirical studies of scope have been restricted to phenomenon between and within noun phrases.

In this paper, we describe experiments on a novel annotation of scope phenomenon in regulatory texts – Section 610 of the Food and Drug Administration's Code of Federal Regulations[1] (FDA CFR). Determiners, modals, negation, and verb phrase modifiers are the main scope-taking operators. We have annotated 195 sentences with a variant of logical form, called *abstract syntax trees* (ASTs). Our focus is on the problem of computing the AST, given a (variant of a) parse tree of a sentence.

The long term goal of this work is to assist in the translation of regulation to logic, for the application of conformance checking. The problem is to formally determine whether an organization conforms to regulation, by checking the organization's records using the logical translation of regulation. Conformance checking has been of interest in a variety of regulatory contexts, and examples include privacy policy (Barth et al., 2006; Jones and Sergot, 1992; Anderson, 1996) and business contracts (Governatori et al., 2006; Grosof et al., 1999).

We now discuss some problems that arise in defin-

ing logical form and the assumptions that we make to circumvent these problems.

1.1 Problems and Assumptions

A key assumption of logical form is that the translation from language to logic is syntax-based. As a result, the logic needs to be expressive enough to accomodate a syntactic translation. There is no consensus logic for constructs, such as, plurals, purpose clauses, and certain modals. This leads to the following problem in defining logical form.

How do we define the logical form of a sentence, without defining the logic? We adopt a specific formalism that accomodates a subset of the constructs found in regulation. We generalize from the formalized constructs to other constructs. Some of these generalizations may need revision in the future.

We assume that sentences in regulation are translated to statements in logic of the form:

$$(\mathrm{id})\ \varphi(x_1, ..., x_n) \mapsto \psi(x_1, ..., x_n)$$

where, "id" is an identifier, φ is *the precondition*, ψ is *the postcondition*, and $x_1, ..., x_n$ are free variables. The distinction between pre and postconditions has been adopted by most logics for regulation, to accomodate exceptions to laws (Sergot et al., 1986; Makinson and van der Torre, 2000; Governatori et al., 2006). The pre and postconditions are expressed in a modal logic that we designed in prior work (Dinesh et al., 2011). In describing the logical form, we will sketch how the logical form can be mapped to logic. But, we do not assume that the reader has a detailed understanding of the logic.

Given the assumptions about the logic, our goal is to transform a regulatory sentence into a structure that lets us determine: (I) the constituents of a sentence that contribute to the pre/postcondition, and (II) the scope of operators in the pre/postcondition. The structures that we use are called *abstract syntax trees* (ASTs), which can be understood as a restricted kind of logical form for regulatory texts.

1.2 Contributions and Outline

In this paper, we focus on the problem of computing the AST given a (kind of) parse tree for a sentence. The main step is is to *order or rank* scope-taking operators. A learning model for ranking is adapted for this ordering. We design features by studying the problem of comparing the scope of one operator to another. The pairwise scope comparisons are then used to compute ASTs, with an F-score of 90.6% on the set of ordering decisons.

The rest of this paper is organized as follows. We define ASTs using an example in Section 2, and setup the learning problem in Section 3. We then describe the corpus using statistics about operators in Section 4. In Section 5, we describe experiments on comparing the scope of an operator to another. We use the pairwise scope comparisons, in Section 6 to comput the AST. We discuss related work in Section 7 and conclude in Section 8.

2 Abstract Syntax Trees

We describe *abstract syntax trees* (ASTs) using an example from CFR Section 610.11:

(1) A general safety test for the detection of extraneous toxic contaminants shall be performed on biological products intended for administration to humans.

We discuss the translation in logic and the AST for the fragment of (1) that appears in black. In order to keep figures to a manageable size, we restrict attention to fragments of sentences, by graying out portions. The term AST is borrowed from compilers (Aho et al., 1986), where it is used as an intermediate step in the semantic interpretation of programs.

Translation in Logic: The sentence (1) is formally expressed as:

$$(1)\ \mathrm{bio\_prod}(x) \mapsto \mathcal{O}_{m(x)}(\exists y : \mathrm{test}(y) \wedge \psi(x, y))$$

where, $\psi(x, y) = \mathrm{gensaf}(y) \wedge \mathrm{ag}(y, m(x)) \wedge \mathrm{ob}(y, x)$

The predicates and function symbols are read as follows. $\mathrm{bio\_prod}(x)$ - "x is a biological product". $m(x)$ denotes the manufacturer of x. The modal operator $\mathcal{O}$ stands for "obligation". $\mathrm{test(y)}$ - "y is a test (event)". $\mathrm{gensaf}(y)$ - "y is a general safety procedure". $\mathrm{ag}(y, m(x))$ - "the agent of y is $m(x)$", and $\mathrm{ob}(y, x)$ - "the object of the event y is x". The formalized version of the law is read as follows: "If x is a biological product, then the manufacturer $m(x)$ is required/obligated to perform a general safety test y which has x as its object". We refer the reader to (Dinesh et al., 2011) for details on the logic.

The distinction between pre and postconditions is a non-trivial assumption. As with all logic-programming formalisms, only free variables are "shared" between pre and postconditons. This implies that all existential quantification, modals, and negation appear within the pre or postcondition. In the example above, the existential quantifier ($\exists y$) and the modal ($\mathcal{O}$) appear within the postcondition.

Abstract Syntax Tree: The AST for (1) is shown in Figure 1. The main nodes of interest are the internal nodes labeled $\boxed{\lambda}$. An internal node with $n+1$ children corresponds to an *n-ary operator*. The first child of the internal node is the operator. Operators are labeled with a part-of-speech tag, for example, "D" for determiner, "M" for modal, and "O" for other. The remaining n children are its arguments. We use the term *nuclear scope* to refer to the last (n^{th}) argument of the operator, and the term *restrictor* to refer to any other argument. We borrow these terms from the literature on quantifier scope for determiners (Heim and Kratzer, 1998, Chapter 7).

For example, the phrase "general safety test" is in the restrictor of the operator A, and the variable $\boxed{y}$ is in its nuclear scope. The modal shall is a unary operator, and doesn't have a restrictor. Non-unary operators bind the variable displayed on the internal node. The variable $\boxed{y}$ is bound by the operator A.

Implicit operators are inserted when there is no overt word or phrase. In Figure 1, the implicit operators are underlined. The generic noun phrase "biological products" is associated with the implicit determiner all. Similarly, we use the implicit operator Post to mark the position of the postcondition.

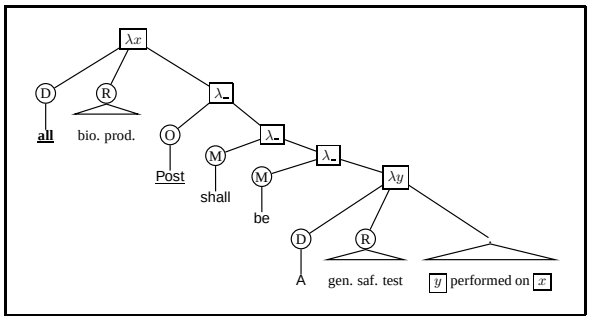

Figure 1: Example of an abstract syntax tree (AST).

We conclude this section with some notation for describing ASTs. Given an AST for a sentences, we say that an operator o_i *scopes over* o_j, denoted $o_i \gg o_j$, if o_j appears in the nuclear scope of o_i. For example, in Figure 1, we have all $\gg$ Post, all $\gg$ shall, all $\gg$ A, Post $\gg$ A, and shall $\gg$ A. In addition, we say that *the restrictor of* o_i *scopes over* o_j, denoted $R(o_i) \gg o_j$, if o_j appears in the restrictor of o_i. Such configurations occur with PP-modification of NPs, and we discuss examples in later sections.

3 Computing ASTs – Overview

In this section, we give an overview of our approach to computing ASTs. We will assume as given a Processed Parse Tree (PPT) of a sentence, with the operators and their restrictors identified. An example is discussed in Section 3.1. Given such a PPT, the AST is computed in two steps: (1) finding the preterminal at which an operator takes scope, and (2) ordering the operators associated with a preterminal. We describe the second step in Section 3.2, and then briefly outline the first step in Section 3.3. The steps are described in reverse order, because in most cases, the operators associated with a preterminal are determined directly by syntactic attachment.

3.1 Processed Parse Trees

We compute ASTs from processed parse trees (PPTs) of sentences. Figure 2 gives the PPT corresponding to the AST in Figure 1.

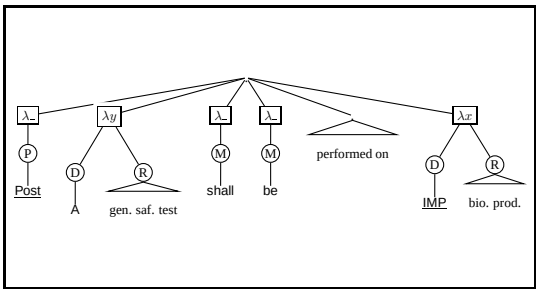

Figure 2: Processed parse tree (PPT) for (1).

A PPT provides the set of operators in a sentence, associated with their restrictors. For example, the determiner "a" has the restrictor *general safety test*. The phrase *biological products* has no explicit determiner associated with it, and the corresponding operator in the PPT is labeled "IMP" for *implicit*. In addition, the postcondition marker "Post" is also identified. Except for the postcon-

dition marker, annotator-specified implicit operators are not given in the PPT.

There are two main types of nodes in the PPT – *operators* and *preterminals*. The nodes labeled with the symbol λ, e.g., $\boxed{\lambda\_}$ and $\boxed{\lambda x}$, correspond to operators. The root of the PPT and the restrictors of the operators, are the preterminals. Based on this example, it may seem that a sentence just has a list of operators. While this is true of example (1), embedded operators arise, for example, in the context of PP-modification of NPs and relative clauses. We will discuss an example in Section 3.3.

In this work, the PPTs are obtained by removing all scope decisions from the AST. To a first approximation, we start by removing all operators from the AST, and then, replace the corresponding variables by the operators. Implicit unary operators (such as the postcondition marker) are placed at the start of the preterminal.

It is worthwhile to consider whether it is reasonable to assume PPTs as given. We believe that this assumption is (slightly) stronger than assuming perfect parse trees. Although the PPT leaves certain chunks of the sentence unprocessed, in most cases, the unprocessed chunks correspond to base NPs. The main additional piece of information is the existence of a postcondition marker for each main clause of a sentence. We believe that computation of PPTs is better seen as a problem of syntax rather than scope, and we set it aside to future work. Our focus here is on converting a PPT to an AST.

3.2 Ordering Operators

The problem of learning to order a set of items is not new. Cohen et al. (1998) give a learning theoretic perspective, and Liu (2009) surveys information retrieval applications. The approach that we use can be seen as a probabilistic version of the boosting approach developed by Cohen et al. (1998). We explain the step of ordering operators, by revisiting the example of the general safety test, from Section 2.

Given the PPT in Figure 2, we compute the AST in Figure 1 by *ordering* or *ranking* the operators. For example, we need to determine that the implicit determiner associated with *biological products* is universal, and hence, we have $\underline{\mathsf{IMP}} \gg \underline{\mathsf{Post}}$. However, the determiner "A" associated with *general safety test* is existential, and hence, we have $\underline{\mathsf{Post}} \gg \mathsf{A}$.

We now develop some notation to describe the scopal ordering of operators. A PPT τ is viewed as a set of preterminal nodes, and we will write – (a) $\mathfrak{p} \in \tau$ to denote that $\mathfrak{p}$ occurs in τ, and (b) $|\tau|$ to denote the number of preterminals in τ. A preterminal $\mathfrak{p}$ is viewed as an ordered set of operators $\mathfrak{p} = (\mathsf{o}^1, ..., \mathsf{o}^{|\mathfrak{p}|})$. For example, in Figure 2, the root preterminal $\mathfrak{p}$ has $|\mathfrak{p}| = 5$, and the operators $\mathsf{o}^1 = \underline{\mathsf{Post}}$, $\mathsf{o}^2 = \mathsf{A}$, $\mathsf{o}^3 = \mathsf{shall}$, and so on.

An AST α contains a ranking of operators associated with each preterminal, denoted $\mathfrak{r}_\alpha(\mathfrak{p})$. The ranks of operators are denoted by subscripts. Let $\mathfrak{p} = (\mathsf{o}^1, ..., \mathsf{o}^5)$ be the root preterminal of the PPT in Figure 2. The ranking associated with the AST in Figure 1 is given by $\mathfrak{r}_\alpha(\mathfrak{p}) = (\mathsf{o}^1_2, \mathsf{o}^2_5, \mathsf{o}^3_3, \mathsf{o}^4_4, \mathsf{o}^5_1)$. For example, $\mathsf{o}^2_5 = \mathsf{A}$ denotes that the determiner "A" appears second in the surface order (Figure 2) and fifth or lowest in the scope order (Figure 1). Similarly, $\mathsf{o}^5_1 = \underline{\mathsf{IMP}}$ denotes that the implicit determiner appears fifth or last in the surface order (Figure 2) and first or highest in the scope order (Figure 1). Note that the subscript suffices to identify the position of an operator in the AST.

Model: We now describe the learning model for ordering operators. Given a PPT τ, let $\mathcal{A}(\tau)$ be the set of all possible ASTs. Our goal is to find the AST which has the highest probability given the PPT:

$$\alpha^* = \arg \max_{\alpha \in \mathcal{A}(\tau)} P(\alpha|\tau)$$

The conditional probability of an AST is defined as:

$$P(\alpha|\tau) = \prod_{\mathfrak{p} \in \tau} P(\mathfrak{r}_\alpha(\mathfrak{p})|\tau)$$

$$P(\mathfrak{r}_\alpha(\mathfrak{p})|\tau) = \prod_{i=1}^{|\mathfrak{p}|-1} \prod_{j=i+1}^{|\mathfrak{p}|} P(\mathsf{o_i} \gg \mathsf{o_j}|\tau)$$

In other words, $P(\alpha|\tau)$ is modeled as the product of the probabilities of the ranking of each preterminal, which is in turn expressed as the product of the probabilities of the pairwise ordering decisions. The model falls under the class of pairwise ranking approaches (Liu, 2009). We will consider the problem of estimating the probabilities in Section 5, and the problem of searching for the best AST in Section 6.

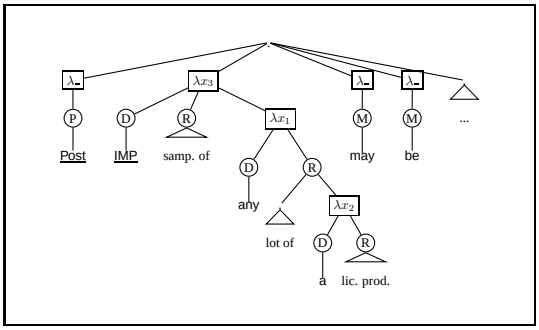

Figure 3: PPT for (2)

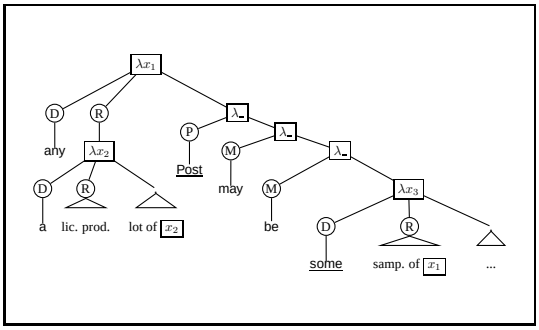

Figure 4: AST for (2)

3.3 Finding the Scope Preterminal

In the example that we discussed in the previous section, there were no embedded operators, i.e., an operator or its variable located in the restrictor of another. An embedded operator can either – (a) take scope within the restrictor of the embedding operator, or (b) outscope the embedding operator. To account for the second case, we need to determine whether it is appropriate to lift an embedded operator to a higher preterminal than the one to which it is associated syntactically.

We discuss an example of *inverse linking* (Larson, 1985) to illustrate the problem. Consider the following sentence:

(2) Samples of any lot of a licensed product, except for radioactive biological products, together with the protocols showing results of applicable tests, may at any time be required to be sent to the Director, Center for Biologics Evaluation and Research.

The PPT and AST for (2) are shown in Figures 3 and 4 respectively. Consider the noun phrase "IMP samples of any lot of a licensed product" in the PPT. The implicit determiner IMP in the PPT is interpreted as the existential determiner some in the AST. The three operators are related as follows in the AST: any $\gg$ some and R(any) $\gg$ a, i.e., any outscopes the implicit determiner, and a appears in the restrictor of any. Observe that the variables x_1 and x_2, which are associated with any and a, appear in the restrictors of some and any respectively. As a result, in the PPT, in Figure 3, any and a appear in the restrictor of IMP and any. The PPT provides a standard parse of PP-modification of NPs.

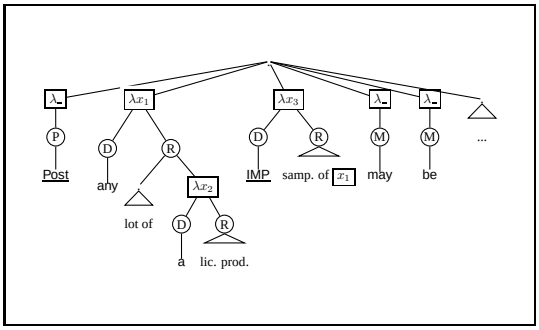

Figure 5: Second PPT for (2), obtained from the PPT in Figure 3, by raising any to the root preterminal.

The important feature of this example is that the determiner "any" is syntactically embedded in the restrictor of IMP in the PPT (Figure 4), but it outscopes the implicit determiner in the AST (Figure 3). As a result, the PPT in Figure 3 cannot be converted to the AST in Figure 4 simply by ranking sibling operators (as we did in the previous section).

To handle such cases, we convert the PPT in Figure 3 to a second PPT (shown in Figure 5). The only allowed operation during this conversion is to raise an embedded operator to a higher preterminal. The PPT in Figure 5 is obtained by raising any to the root preterminal, making it a sibling of the implicit determiner IMP in the PPT in Figure 5. This second PPT can be converted to the AST by reordering sibling operators. The learning model used for this step is similar to the one used to order operators, and in the interests of space, we omit the details.

4 Brief Overview of the Corpus

We have annotated 195 sentences from the FDA CFR Section 610 with ASTs. The operators are divided into the following types – determiners (e.g.,

every, a, at least), modal auxiliaries (e.g., must, be), VP modifiers (e.g., if, for, after), negation and coordinating conjunctions (e.g., and, but, or). The majority of the corpus was annotated by a single annotator. However, to estimate inter-annotator agreement, a set of 32 sentences was annotated by a second annotator. In this section, we restrict ourselves to presenting statistics that highlight part of the guidelines and motivate the features that we use to order operators. An example-based justification of guidelines, and a discussion of inter-annotator agreement can be found in (Dinesh, 2010).

De Re vs De Dicto: We narrow our focus to one part of the annotation, the *de re* vs *de dicto* distinction. Informally, operators with *de re* scope occur in the precondition of the logical translation of a sentence, while those with *de dicto* scope occur in the postcondition. This distinction is of key importance in the application of conformance checking, as it helps determine the facts that need to be provided by an organization (*de re*), and the actions that an organization is required to take (*de dicto*).

For simplicity, we further restrict attention to operators that are siblings of the postcondition in the AST, and ignore the operators embedded in prepositional phrases and clauses, for example. A (main clause) operator o is said to have *de re* scope iff it outscopes the postcondition marker ($o \gg \underline{Post}$). Otherwise, the operator is said to have *de dicto* scope ($\underline{Post} \gg o$). In the example of the general safety test from Section 2, the implicit determiner associated with "biological products" has *de re* scope, while all other operators in the sentence have *de dicto* scope.

Operator Type	Number of Instances	De Re Scope Percentage
Determiner	277	59.9%
Modal Aux	268	0%
VP Modifier	132	68.2%
CC	36	22.2%
Neg	33	0%
Other	74	17.6%

Table 1: De Re scope distribution. An operator has *de re* scope iff it outscopes the postcondition marker.

Table 1 shows the percentage of each type of operator that has *de re* scope. Modal auxiliaries and negation are umambigous to this distinction, and always have *de dicto* scope. Note that a type of operator with 50% occuring *de re* is ambiguous, while 0% or 100% are unambiguous. Thus, from Table 1, we can conclude that determiners, and VP modifiers are the most ambiguous types. And, more features are needed to disambiguate them.

Determiner Type	Number of Instances	De Re Scope Percentage
Universal	74	100%
Existential	12	0%
Ambiguous	50	28%
Deictic	127	53.5%
Other	14	35.7%

Table 2: De Re scope distribution for determiners.

Determiners: We divide the determiners into the following subtypes: universal/generic (e.g., every, all), existential (some), ambiguous (e.g., a, an), deictic (e.g., the, those), and other (e.g., at least, at most). The guidelines for annotation were as follows – (a) universal determiners have *de re* scope, (b) existential determiners have *de dicto* scope, and (c) for other determiners, the annotator needs to decide whether a particular use is interpreted existentially or universally. Table 2 shows *de re* scope distribution for each of these subtypes. As expected, universal and existential determiners are unambiguous, while ambiguous and deictic determiners show more variety. For example, the deictic determiner the can refer to a specific entity ("the FDA") or have a universal interpretation ("the products").

Thus, to disambiguate between *de re* and *de dicto* interpretations for determiners, we need two types of features – (1) Features to predict whether ambiguous and deictic determiners are universal or not, and (2) Features to determine the type of implicit determiners. In Table 2, we assume that the type of implicit determiners are given. This assumption is unrealistic. Rather, we need to predict the type of such determiners, during the computation of the AST.

VP Modifier Type	Number of Instances	De Re Scope Percentage
Temporal and Conditional	73	100%
Purpose	8	0%
References to Laws	33	0.9%
Other	29	65.5%

Table 3: De Re scope distribution for VP modifiers.

VP Modifiers: We divide the VP modifiers into the following subtypes: temporal and conditional (e.g., after, if), purpose (for), references to laws (which are a special type of modifier in the legal domain, e.g., "as specified in paragraph (c)"), and other (e.g., regardless, notwithstanding). Table 3 shows the percentage of each subtype of modifier that has *de re* scope. Following the guidelines for annotation, the temporal and conditional modifiers are always *de re*, the purpose modifiers and modifiers conveying references to laws are always *de dicto*.

5 Comparing the Scope of Operators

We now consider a subproblem in computing the AST – comparing the scope of pairs of operators. In Section 6, we will use the classifiers that perform comparisons, to compute the AST. All experiments in this section use the MAXENT implentation from the MALLET toolkit (McCallum, 2002). We begin by revisiting *de re-de dicto* distinction from Section 4. Then, we generalize to other comparisons.

De Re vs De Dicto: The (binary) classification problem is as follows. Our observations are triples $x = (\mathsf{o}, \mathsf{o}', \tau)$ are such that there is a preterminal $\mathfrak{p} \in \tau$, $\{\mathsf{o}, \mathsf{o}'\} \subseteq \mathfrak{p}$, and $\mathsf{o}' = \underline{\mathsf{Post}}$. In other words, we are considering operators (o) that are siblings of the postcondition marker (o'). An observation has the label 1 if $\mathsf{o} \gg \mathsf{o}'$ (*de re* scope), and a label of 0 otherwise (*de dicto* scope).

Features: We use the following (classes of) features for an observation $x = (\mathsf{o}, \mathsf{o}', \tau)$:

- TYPE - The type and subtype of the operator. We use the subtypes from Section 4 only for explicit operators.
- PRE-VERB - Tracks whether o and o' appear before or after the main verb of the sentence.
- PRE-VERB + PERF - Conjunction of the previous feature with whether the main verb is *perform*. The verb *perform* is frequent in the CFR, and its subject is typically given *de dicto* scope, as it is the main predicate of the sentence.
- POS - The part-of-speech of the head word. For example, for the noun phrase *biological products*, the head word is *products*, and the POS is NNS (plural common noun). And, this POS tag may indicate a generic/universal interpretation.

	Count	MAJORITY	TYPE	ALL
All	823	66.2%	84.1%	89.2%
No MD	522	53.2%	74.9%	83.7%
DT	277	59.9%	62.9%	81.2%
Imp. DT	100	69%	-	76%

Table 4: De Re vs De Dicto classification. Average accuracies over 10-fold cross-validation. The rows describe the subset of observations considered, and the columns describe the subset of features used.

Experiments: We evaluate the features by performing 10-fold cross-validation. The results are summarized in Table 4. The rows describe the subset of observations used. "All" includes all observations, "No MD" excludes the modal auxiliaries, "DT" includes only the determiners, and "Imp. DT" includes only implicit determiners. The columns describe the features used. MAJORITY is the majority baseline, i.e., the accuracy obtained by predicting the most frequent class or the majority class. The majority class is *de dicto* when all operators are considered (the first row), and *de re* in all other rows. The TYPE column gives the accuracy when only the type and subtypes are used as features. This column does not apply to implicit determiners, as the subtype information is unavailable. And, finally, the ALL column gives the accuracy when all features are used.

From Table 4, we can conclude that the TYPE feature is useful in making the *de re-de dicto* distinction, and further gains are obtained by using ALL features. The most dramatic improvement is for determiners, and indeed, our features were designed for this case. However, the performance gains are not very high for implicit determiners, and further investigation is needed.

Next, we apply the features to more general operator comparisons. The first row of Table 5 considers observations $x = (\mathsf{o}, \mathsf{o}', \tau)$, where o and o' are siblings, and predicts whether $\mathsf{o} \gg \mathsf{o}'$. The second row considers observations where o' is embedded syntactically within o, and predicts whether $\mathrm{R}(\mathsf{o}) \gg \mathsf{o}'$. In other words, the problem is to determine whether a syntactically embedded operator remains scopally embedded, or whether it has inverse scope (see Section 3.3).

	Count	MAJORITY	TYPE	ALL
Siblings	2793	76.1%	83.3%	87.5%
Embedded	5081	95%	95.3%	96.4%

Table 5: Ordering siblings and embedded operators. Average accuracies over 10-fold cross-validation. The columns describe the subset of features used.

6 From Operator Comparisons to ASTs

We now consider the problem of computing the AST given the classifiers for comparing operators. Section 6.1 describes the algorithms used. In Section 6.2, we develop metrics to evaluate the computation of ASTs. We conclude, in Section 6.3, by evaluating different algorithms using the metrics.

6.1 Algorithms

We begin by discussing the intractability of the problem of ranking or ordering operators. Then, we sketch the search heuristics used.

Intractability: The decision version of the ranking problem is NP-complete. A similar result is established by Cohen et al. (1998) in the context of a boosting approach to ranking.

Theorem 1. *The following problem is NP-complete:*
Input: *A PPT τ, a preterminal $\mathfrak{p} \in \tau$, probabilities $P(\mathfrak{o}^i \gg \mathfrak{o}^j|\tau)$, and $c \in [0,1]$*
Output: *Yes, if there is an ordering $\mathfrak{r}$ such that $P(\mathfrak{r}(\mathfrak{p})|\tau) \geq c$*

The proof is by reduction from ACYCLIC SUBGRAPH (Karp, 1972) – finding a subgraph which is acyclic and has at least k edges.

Heuristics: To order operators, we use a beam search procedure. Each search state consists preterminal, in which the first i ranks have been assigned to operators. We then search over next states by assigning the rank $i+1$ to one of the remaining operators. We used a beam size of 10^4 in our experiments. In most cases, the number of operators per preterminal is less than 7. As a result, the total number of possible orderings is typically less than 7!, and a beam size of 10^4 is sufficient to compute an exact ordering. In other words, due to the size restrictions, in most cases, beam search is equivalent to exact (exhaustive) search.

To handle embedded operators, we use a simple greedy heuristic. We enumerate the operators in the initial PPT, corresponding to an in-order traversal. For each operator, we attach it to the most likely ancestor, given the attachment decisions for the previous operators. This heuristic is optimal for the case where the depth of embedding is at most 1, which is the common case.

6.2 Metrics

In this section, we describe metrics used to evaluate the computation of ASTs. Let τ be the initial PPT, α the correct AST, and α^* the computed AST. We define accuracy at various levels.

The simplest metric is to define accuracy at *the level of ASTs*, i.e., by computing the fraction of cases for which $\alpha = \alpha^*$. However, this metric is harsh, in the sense that it does not give algorithms partial credit for getting a portion of the AST correct.

The next possible metric is to define accuracy at *the level of preterminals*. Let $\mathfrak{p}$ be a preterminal. Note that τ, α and α^* share the same set of preterminals, but may associate different operators with them. We say that $\mathfrak{p}$ is correct in α^*, if it is associated with the same set of operators as in α, and for all $\{\mathfrak{o}, \mathfrak{o}'\} \subseteq \mathfrak{p}$, we have $\mathfrak{o} \gg \mathfrak{o}'$ w.r.t. α^* iff $\mathfrak{o} \gg \mathfrak{o}'$ w.r.t. α. In other words, the preterminals are identical, both in terms of the set of operators and the ordering between pairs of operators. While preterminal-level accuracy gives partial credit, it is still a little harsh, in the sense that an algorithm which makes one ordering mistake at a preterminal is penalized the same as an algorithm which makes multiple mistakes.

Finally, we consider metrics to define accuracy at *the level of pairs of operators*. Let $\mathfrak{p}$ be a preterminal. The set $\mathrm{Pairs}(\mathfrak{p}, \alpha)$ consists of pairs of operators $(\mathfrak{o}, \mathfrak{o}')$ such that $\mathfrak{o}$ and $\mathfrak{o}'$ are both associated with $\mathfrak{p}$ in α, and $\mathfrak{o} = \mathfrak{o}'$ or $\mathfrak{o} \gg \mathfrak{o}'$. The set $\mathrm{Pairs}(\mathfrak{p}, \alpha^*)$ is defined similarly using α^* instead of α. Given the sets $\mathrm{Pairs}(\mathfrak{p}, \alpha)$ and $\mathrm{Pairs}(\mathfrak{p}, \alpha^*)$, precision, recall, and f-score are defined in the usual way. We leave the details to the reader.

6.3 Results

We evaluate the following algorithms:

1. No Embedding – The AST is computed purely by reordering operators within a preterminal in the PPT.

(a) SURFACE – No reordering is performed, i.e., the order of operators in the AST respects the surface order

(b) TYPE – Using only type and subtype information for the operators

(c) ALL – Using all the features described in Section 5

2. ALL+ – The initial PPT is transformed into a second PPT before reordering (as described in Section 3.3). All features are used.

	Prec.	Rec.	F	$\mathfrak{p}$	α
SURF.	86.9%	82.7%	84.6%	81%	4.2%
TYPE	90.4%	86%	88.1%	83.6%	24.7%
ALL	**92**%	87.6%	89.8%	85.1%	33.5%
ALL+	91.9%	**89.4**%	**90.6**%	**85.9**%	**36.2**%

Table 6: Performance of the algorithms in computing the ASTs. Averaged over 10-fold cross-validation. 195 ASTs in total, an average of 8.6 preterminals per AST, and 1.8 operators per preterminal.

Table 6 summarizes the performance of the algorithms, under the various metrics. The accuracies are averaged over 10-fold cross-validation. A total of 195 ASTs are used. The average number of preterminals per AST is 8.6, with an average of 1.8 operators per preterminal. The best number under each metric is shown in bold-face. By adding features, we improve the precision from 86.9% to 90.4% to 92% in moving from SURFACE to TYPE to ALL. By handling embedded operators, we improve the recall from 87.6% to 89.4% in moving from ALL to ALL+. As we saw in Section 5, in 95% of the cases, the embedded operators respects syntactic scope, and as a result, we obtain only modest gains from handling embedded operators.

The reader may feel that the F-score of 90.6% is quite high given the size of our training data. This score is inflated by inclusion of reflexive pairs, of the form (o, o). Such pairs are included for the following (technical) reasons. The algorithm that handles embedded operators (ALL+) usually raises them from a single operator node (as in Figure 3) to a multi-operator node (as in Figure 5). If it makes an incorrect decision to raise an operator it takes a precision hit, at the multi-operator node (because it has some false positives). By contrast, an algorithm loses precision for failing to correctly raise, only when we encounter the single operator node.

For these reasons, it is better to consider the relative improvement in F-score over the baseline. The relative improvement of ALL+ over SURFACE in terms of F-score is 36.6%. We believe that the preterminal-level accuracy is more indicative in an absolute sense. Furthermore, when we restrict attention to those preterminals with two or more operators in the PPT, the accuracy of ALL+ is 69.4%.

7 Related Work

ASTs can be seen as a middle ground between two lines of research in translating sentences to logic.

At one end of the spectrum, we have methods that achieve good accuracy on restricted texts. The two main corpora that have been considered are the GEOQUERY corpus (Thompson et al., 1997) and the ATIS-3 corpus (Dahl et al., 1994). The GEOQUERY corpus consists of queries to a geographical database. The queries were collected from students participating in a study and the average sentence length is 8 words. The ATIS corpus is collected from subjects' interaction with a database of flight information, using spoken natural language. The utterances have be transcribed, and the average sentence length is 10 words (Berant et al., 2007). Algorithms, which achieve good accuracy, have been developed to compute the logical translation for these queries (Zettlemoyer and Collins, 2005; Wong and Mooney, 2007; Zettlemoyer and Collins, 2009). The annotated sentences in the FDA CFR Section 610.40 are longer (about 30 words on average), and contain modalities which are not present in these corpora.

At the other end of the spectrum, Bos et al. (Bos et al., 2004) have developed a broad-coverage parser to translate sentences to a logic based on discourse representation theory. Here, there is no direct method to evaluate the correctness of the translation. However, indirect evaluations are possible, for example, by studying improvement in textual entailment tasks.

To summarize, there are techniques that either produce an accurate translation for sentences in a limited domain, or produce some translation for sentences in a broader range of texts. ASTs offer a middle ground in two ways. First, we focus on regula-

tory texts which are less restricted than the database queries in the GEOQUERY and ATIS corpora, but do not exhibit anaphoric phenomenon found in genres, such as, newspaper text. In (Dinesh et al., 2007), we discuss lexical statistics that show significant differences in the distribution of anaphoric items in the CFR and Wall Street Journal (WSJ) corpora. For example, the frequency of pronouns and anaphoric discourse connectives is significantly lower in the CFR than in the WSJ. Instead, the CFR has an idiosyncratic mechanism for referring to sentences, using phrases such as "except as specified in paragraph (c) and (d)". A question of interest is whether the GEOQUERY and ATIS corpora show similar peculiarities in terms of anaphora. The second difference between our approach and others is that we do not attempt to translate all the way to logic. The level of logical form lets us obtain a direct evaluation, while leaving open the design of parts of the logic.

8 Conclusions

We described experiments on a modest-sized corpus of regulatory sentences, annotated with a novel variant of logical form, called *abstract syntax trees* (ASTs). An example from the corpus was presented in Section 2 and some statistics, describing the corpus, were discussed in Section 4. In Sections 3, 5, and 6, we developed and tested algorithms to convert a processed parse tree (PPT) to an AST. The main step in this conversion was to rank or order the operators at a preterminal. We presented a probabilistic model for ranking, investigated the design of features, and developed search heuristics. The best algorithm, which uses all features and handles embedded operators, achieves an F-score of 90.6%.

An important direction for further inquiry is in the design of better features. Various types of features have been proposed for the scopal ordering of determiners. Examples include syntactic features (Ioup, 1975; Reinhart, 1983), such as position and voice, semantic features (Grimshaw, 1990; Jackendoff, 1972), such as thematic roles. More recently, Srinivasan and Yates (2009) showed how pragmatic information, for example "there are more people than cities", can be leveraged for scope disambiguation. We experimented with lexico-syntactic features in this work, and leave an investigation of semantic and pragmatic features to future work.

Abstract

The notion of infix probability has been introduced in the literature as a generalization of the notion of prefix (or initial substring) probability, motivated by applications in speech recognition and word error correction. For the case where a probabilistic context-free grammar is used as language model, methods for the computation of infix probabilities have been presented in the literature, based on various simplifying assumptions. Here we present a solution that applies to the problem in its full generality.

1 Introduction

Probabilistic context-free grammars (PCFGs for short) are a statistical model widely used in natural language processing. Several computational problems related to PCFGs have been investigated in the literature, motivated by applications in modeling of natural language syntax. One such problem is the computation of **prefix probabilities** for PCFGs, where we are given as input a PCFG $\mathcal{G}$ and a string w, and we are asked to compute the probability that a sentence generated by $\mathcal{G}$ starts with w, that is, has w as a prefix. This quantity is defined as the possibly infinite sum of the probabilities of all strings of the form wx, for any string x over the alphabet of $\mathcal{G}$.

The problem of computation of prefix probabilities for PCFGs was first formulated by Persoon and Fu (1975). Efficient algorithms for its solution have been proposed by Jelinek and Lafferty (1991) and Stolcke (1995). Prefix probabilities can be used to compute probability distributions for the next word or part-of-speech, when a prefix of the input has already been processed, as discussed by Jelinek and Lafferty (1991). Such distributions are useful for speech recognition, where the result of the acoustic processor is represented as a lattice, and local choices must be made for a next transition. In addition, distributions for the next word are also useful for applications of word error correction, when one is processing 'noisy' text and the parser recognizes an error that must be recovered by operations of insertion, replacement or deletion.

Motivated by the above applications, the problem of the computation of **infix probabilities** for PCFGs has been introduced in the literature as a generalization of the prefix probability problem. We are now given a PCFG $\mathcal{G}$ and a string w, and we are asked to compute the probability that a sentence generated by $\mathcal{G}$ has w as an infix. This probability is defined as the possibly infinite sum of the probabilities of all strings of the form xwy, for any pair of strings x and y over the alphabet of $\mathcal{G}$. Besides applications in computation of the probability distribution for the next word token and in word error correction, infix probabilities can also be exploited in speech understanding systems to score partial hypotheses in algorithms based on beam search, as discussed by Corazza et al. (1991).

Corazza et al. (1991) have pointed out that the computation of infix probabilities is more difficult than the computation of prefix probabilities, due to the added ambiguity that several occurrences of the given infix can be found in a single string generated by the PCFG. The authors developed solutions for the case where some distribution can be defined on

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1213–1221,
Edinburgh, Scotland, UK, July 27–31, 2011.

the distance of the infix from the sentence boundaries, which is a simplifying assumption. The problem is also considered by Fred (2000), which provides algorithms for the case where the language model is a probabilistic regular grammar. However, the algorithm in (Fred, 2000) does not apply to cases with multiple occurrences of the given infix within a string in the language, which is what was pointed out to be the problematic case.

In this paper we adopt a novel approach to the problem of computation of infix probabilities, by removing the ambiguity that would be caused by multiple occurrences of the given infix. Although our result is obtained by a combination of well-known techniques from the literature on PCFG parsing and pattern matching, as far as we know this is the first algorithm for the computation of infix probabilities that works for general PCFG models without any restrictive assumption.

The remainder of this paper is structured as follows. In Section 2 we explain how the sum of the probabilities of all trees generated by a PCFG can be computed as the least fixed-point solution of a non-linear system of equations. In Section 3 we recall the construction of a new PCFG out of a given PCFG and a given finite automaton, such that the language generated by the new grammar is the intersection of the languages generated by the given PCFG and the automaton, and the probabilities of the generated strings are preserved. In Section 4 we show how one can efficiently construct an unambiguous finite automaton that accepts all strings with a given infix. The material from these three sections is combined into a new algorithm in Section 5, which allows computation of the infix probability for PCFGs. This is the main result of this paper. Several extensions of the basic technique are discussed in Section 6. Section 7 discusses implementation and some experiments.

2 Sum of probabilities of all derivations

Assume a probabilistic context-free grammar $\mathcal{G}$, represented by a 5-tuple (Σ, N, S, R, p), where Σ and N are two finite disjoint sets of **terminals** and **nonterminals**, respectively, $S \in N$ is the **start symbol**, R is a finite set of **rules**, each of the form $A \to \alpha$, where $A \in N$ and $\alpha \in (\Sigma \cup N)^*$, and p is a function from rules in R to real numbers in the interval $[0, 1]$.

The concept of **left-most derivation** in one step is represented by the notation $\alpha \stackrel{\pi}{\Rightarrow}_{\mathcal{G}} \beta$, which means that the left-most occurrence of any nonterminal in $\alpha \in (\Sigma \cup N)^*$ is rewritten by means of some rule $\pi \in R$. If the rewritten nonterminal is A, then π must be of the form $(A \to \gamma)$ and β is the result of replacing the occurrence of A in α by γ. A left-most derivation with any number of steps, using a sequence d of rules, is denoted as $\alpha \stackrel{d}{\Rightarrow}_{\mathcal{G}} \beta$. We omit the subscript $\mathcal{G}$ when the PCFG is understood. We also write $\alpha \stackrel{*}{\Rightarrow} \beta$ when the involved sequence of rules is of no relevance. Henceforth, all derivations we discuss are implicitly left-most.

A **complete** derivation is either the empty sequence of rules, or a sequence $d = \pi_1 \cdots \pi_m$, $m \geq 1$, of rules such that $A \stackrel{d}{\Rightarrow} w$ for some $A \in N$ and $w \in \Sigma^*$. In the latter case, we say the complete derivation starts with A, and in the former case, with d an empty sequence of rules, we assume the complete derivation starts and ends with a single terminal, which is left unspecified. It is well-known that there exists a bijective correspondence between left-most complete derivations starting with nonterminal A and parse trees derived by the grammar with root A and a yield composed of terminal symbols only.

The **depth** of a complete derivation d is the length of the longest path from the root to a leaf in the parse tree associated with d. The length of a path is defined as the number of nodes it visits. Thus if $d = \pi$ for some rule $\pi = (A \to w)$ with $w \in \Sigma^*$, then the depth of d is 2.

The probability $p(d)$ of a complete derivation $d = \pi_1 \cdots \pi_m$, $m \geq 1$, is:

$$p(d) \quad = \quad \prod_{i=1}^{m} p(\pi_i).$$

We also assume that $p(d) = 1$ when d is an empty sequence of rules. The probability $p(w)$ of a string w is the sum of all complete derivations deriving that string from the start symbol:

$$p(w) \quad = \quad \sum_{d:\ S \stackrel{d}{\Rightarrow} w} p(d).$$

With this notation, **consistency** of a PCFG is de-

fined as the condition:

$$\sum_{d,w:\ S \stackrel{d}{\Rightarrow} w} p(d) \quad = \quad 1.$$

In other words, a PCFG is consistent if the sum of probabilities of all complete derivations starting with S is 1. An equivalent definition of consistency considers the sum of probabilities of all strings:

$$\sum_{w} p(w) \quad = \quad 1.$$

See (Booth and Thompson, 1973) for further discussion.

In practice, PCFGs are often required to satisfy the additional condition:

$$\sum_{\pi=(A\rightarrow\alpha)} p(\pi) \quad = \quad 1,$$

for each $A \in N$. This condition is called **properness**. PCFGs that naturally arise by parameter estimation from corpora are generally consistent; see (Sánchez and Benedí, 1997; Chi and Geman, 1998). However, in what follows, neither properness nor consistency is guaranteed.

We define the **partition function** of $\mathcal{G}$ as the function Z that assigns to each $A \in N$ the value

$$Z(A) \quad = \quad \sum_{d,w} p(A \stackrel{d}{\Rightarrow} w). \tag{1}$$

Note that $Z(S) = 1$ means that $\mathcal{G}$ is consistent. More generally, in later sections we will need to compute the partition function for non-consistent PCFGs.

We can characterize the partition function of a PCFG as a solution of a specific system of equations. Following the approach in (Harris, 1963; Chi, 1999), we introduce generating functions associated with the nonterminals of the grammar. For $A \in N$ and $\alpha \in (N \cup \Sigma)^*$, we write $f(A, \alpha)$ to denote the number of occurrences of symbol A within string α. Let $N = \{A_1, A_2, \ldots, A_{|N|}\}$. For each $A_k \in N$, let m_k be the number of rules in R with left-hand side A_k, and assume some fixed order for these rules. For each i with $1 \leq i \leq m_k$, let $A_k \rightarrow \alpha_{k,i}$ be the i-th rule with left-hand side A_k.

For each k with $1 \leq k \leq |N|$, the **generating function** associated with A_k is defined as

$$g_{A_k}(z_1, z_2, \ldots, z_{|N|}) = \sum_{i=1}^{m_k} \Big(p(A_k \rightarrow \alpha_{k,i}) \cdot \prod_{j=1}^{|N|} z_j^{f(A_j, \alpha_{k,i})} \Big). \tag{2}$$

Furthermore, for each $i \geq 1$ we recursively define functions $g^{(i)}_{A_k}(z_1, z_2, \ldots, z_{|N|})$ by

$$g^{(1)}_{A_k}(z_1, z_2, \ldots, z_{|N|}) = g_{A_k}(z_1, z_2, \ldots, z_{|N|}), \tag{3}$$

and, for $i \geq 2$, by

$$\begin{aligned} &g^{(i)}_{A_k}(z_1, z_2, \ldots, z_{|N|}) = \\ &\quad g_{A_k}(\ g^{(i-1)}_{A_1}(z_1, z_2, \ldots, z_{|N|}), \\ &\qquad g^{(i-1)}_{A_2}(z_1, z_2, \ldots, z_{|N|}), \ldots, \\ &\qquad g^{(i-1)}_{A_{|N|}}(z_1, z_2, \ldots, z_{|N|})\ ). \end{aligned} \tag{4}$$

Using induction it is not difficult to show that, for each k and i as above, $g^{(i)}_{A_k}(0, 0, \ldots, 0)$ is the sum of the probabilities of all complete derivations from A_k having depth not exceeding i. This implies that, for $i = 0, 1, 2, \ldots$, the sequence of the $g^{(i)}_{A_k}(0, 0, \ldots, 0)$ monotonically converges to $Z(A_k)$.

For each k with $1 \leq k \leq |N|$ we can now write

$$\begin{aligned} &Z(A_k) = \\ &= \lim_{i\rightarrow\infty}\ g^{(i)}_{A_k}(0, \ldots, 0) \\ &= \lim_{i\rightarrow\infty}\ g_{A_k}(\ g^{(i-1)}_{A_1}(0, 0, \ldots, 0), \ldots, \\ &\qquad\qquad g^{(i-1)}_{A_{|N|}}(0, 0, \ldots, 0)\ ) \\ &= g_{A_k}(\ \lim_{i\rightarrow\infty}\ g^{(i-1)}_{A_1}(0, 0, \ldots, 0), \ldots, \\ &\qquad \lim_{i\rightarrow\infty}\ g^{(i-1)}_{A_{|N|}}(0, 0, \ldots, 0)\ ) \\ &= g_{A_k}(Z(A_1), \ldots, Z(A_{|N|})). \end{aligned}$$

The above shows that the values of the partition function provide a solution to the system of the following equations, for $1 \leq k \leq |N|$:

$$z_k \quad = \quad g_{A_k}(z_1, z_2, \ldots, z_{|N|}). \tag{5}$$

In the case of a general PCFG, the above equations are non-linear polynomials with positive (real) coefficients. We can represent the resulting system in vector form and write $\mathbf{X} = \mathbf{g}(\mathbf{X})$. These systems

are called monotone systems of polynomial equations and have been investigated by Etessami and Yannakakis (2009) and Kiefer et al. (2007). The sought solution, that is, the partition function, is the least fixed point solution of $\mathbf{X} = \mathbf{g}(\mathbf{X})$.

For practical reasons, the set of nonterminals of a grammar is usually divided into maximal subsets of mutually recursive nonterminals, that is, for each A and B in such a subset, we have $A \stackrel{*}{\Rightarrow} uB\alpha$ and $B \stackrel{*}{\Rightarrow} vA\beta$, for some u, v, α, β. This corresponds to a **strongly connected component** if we see the connection between the left-hand side of a rule and a nonterminal member in its right-hand side as an edge in a directed graph. For each strongly connected component, there is a separate system of equations of the form $\mathbf{X} = \mathbf{g}(\mathbf{X})$. Such systems can be solved one by one, in a bottom-up order. That is, if one strongly connected component contains nonterminal A, and another contains nonterminal B, where $A \stackrel{*}{\Rightarrow} uB\alpha$ for some u, α, then the system for the latter component must be solved first.

The solution for a system of equations such as those described above can be irrational and non-expressible by radicals, even if we assume that all the probabilities of the rules in the input PCFG are rational numbers, as observed by Etessami and Yannakakis (2009). Nonetheless, the partition function can still be approximated to any degree of precision by iterative computation of the relation in (4), as done for instance by Stolcke (1995) and by Abney et al. (1999). This corresponds to the so-called fixed-point iteration method, which is well-known in the numerical calculus literature and is frequently applied to systems of non-linear equations because it can be easily implemented.

When a number of standard conditions are met, each iteration of (4) adds a fixed number of bits to the precision of the solution; see Kelley (1995, Chapter 4). Since each iteration can easily be implemented to run in polynomial time, this means that we can approximate the partition function of a PCFG in polynomial time in the size of the PCFG itself and in the number of bits of the desired precision.

In practical applications where large PCFGs are empirically estimated from data sets, the standard conditions mentioned above for the polynomial time approximation of the partition function are usually met. However, there are some degenerate cases for which these standard conditions do not hold, resulting in exponential time behaviour of the fixed-point iteration method. This has been firstly observed in (Etessami and Yannakakis, 2005).

An alternative iterative algorithm for the approximation of the partition function has been proposed by Etessami and Yannakakis (2009), based on Newton's method for the solution of non-linear systems of equations. From a theoretical perspective, Kiefer et al. (2007) have shown that, after a certain number of initial iterations, Newton's method adds a fixed number of bits to the precision of the approximated solution, even in the above mentioned cases in which the fixed-point iteration method shows exponential time behaviour. However, these authors also show that, in some degenerate cases, the number of iterations needed to compute the first bit of the solution can be at least exponential in the size of the system.

Experiments with Newton's method for the approximation of the partition functions of PCFGs have been carried out in several application-oriented settings, by Wojtczak and Etessami (2007) and by Nederhof and Satta (2008), showing considerable improvements over the fixed-point iteration method.

3 Intersection of PCFG and FA

It was shown by Bar-Hillel et al. (1964) that context-free languages are closed under intersection with regular languages. Their proof relied on the construction of a new CFG out of an input CFG and an input finite automaton. Here we extend that construction by letting the input grammar be a probabilistic CFG. We refer the reader to (Nederhof and Satta, 2003) for more details.

To avoid a number of technical complications, we assume the finite automaton has no epsilon transitions, and has only one final state. In the context of our use of this construction in the following sections, these restrictions are without loss of generality. Thus, a finite automaton (FA) $\mathcal{M}$ is represented by a 5-tuple $(\Sigma, Q, q_0, q_f, \Delta)$, where Σ and Q are two finite sets of **terminals** and **states**, respectively, q_0 is the **initial** state, q_f is the **final** state, and Δ is a finite set of **transitions**, each of the form $s \stackrel{a}{\mapsto} t$, where $s, t \in Q$ and $a \in \Sigma$.

A **complete computation** of $\mathcal{M}$ accepting string

$w = a_1 \cdots a_n$ is a sequence $c = \tau_1 \cdots \tau_n$ of transitions such that $\tau_i = (s_{i-1} \overset{a_i}{\mapsto} s_i)$ for each i ($1 \leq i \leq n$), for some $s_0, s_1, \ldots, s_n$ with $s_0 = q_0$ and $s_n = q_f$. The language of all strings accepted by $\mathcal{M}$ is denoted by $L(\mathcal{M})$. A FA is **unambiguous** if at most one complete computation exists for each accepted string. A FA is **deterministic** if there is at most one transition $s \overset{a}{\mapsto} t$ for each s and a.

For a FA $\mathcal{M}$ as above and a PCFG $\mathcal{G} = (\Sigma, N, S, R, p)$ with the same set of terminals, we construct a new PCFG $\mathcal{G}' = (\Sigma, N', S', R', p')$, where $N' = Q \times (\Sigma \cup N) \times Q$, $S' = (q_0, S, q_f)$, and R' is the set of rules that is obtained as follows.

- For each $A \rightarrow X_1 \cdots X_m$ in R and each sequence $s_0, \ldots, s_m$ with $s_i \in Q$, $0 \leq i \leq m$, and $m \geq 0$, let $(s_0, A, s_m) \rightarrow (s_0, X_1, s_1) \cdots (s_{m-1}, X_m, s_m)$ be in R'; if $m = 0$, the new rule is of the form $(s_0, A, s_0) \rightarrow \epsilon$. Function p' assigns the same probability to the new rule as p assigned to the original rule.

- For each $s \overset{a}{\mapsto} t$ in Δ, let $(s, a, t) \rightarrow a$ be in R'. Function p' assigns probability 1 to this rule.

Intuitively, a rule of $\mathcal{G}'$ is either constructed out of a rule of $\mathcal{G}$ or out of a transition of $\mathcal{M}$. On the basis of this correspondence between rules and transitions of $\mathcal{G}'$, $\mathcal{G}$ and $\mathcal{M}$, it is not difficult to see that each derivation d' in $\mathcal{G}'$ deriving string w corresponds to a unique derivation d in $\mathcal{G}$ deriving the same string and a unique computation c in $\mathcal{M}$ accepting the same string. Conversely, if there is a derivation d in $\mathcal{G}$ deriving string w, and some computation c in $\mathcal{M}$ accepting the same string, then the pair of d and c corresponds to a unique derivation d' in $\mathcal{G}'$ deriving the same string w. Furthermore, the probabilities of d and d' are equal, by definition of p'.

Let us now assume that each string w is accepted by at most one computation, i.e. $\mathcal{M}$ is unambiguous. If a string w is accepted by $\mathcal{M}$, then there are as many derivations deriving w in $\mathcal{G}'$ as there are in $\mathcal{G}$. If w is not accepted by $\mathcal{M}$, then there are zero derivations deriving w in $\mathcal{G}'$. Consequently:

$$\sum_{\substack{d', w: \\ S' \overset{d'}{\Rightarrow}_{\mathcal{G}'} w}} p'(d') \quad = \quad \sum_{\substack{d, w: \\ S \overset{d}{\Rightarrow}_{\mathcal{G}} w \wedge w \in L(\mathcal{M})}} p(d),$$

or more succinctly:

$$\sum_{w} p'(w) \quad = \quad \sum_{w \in L(\mathcal{M})} p(w).$$

Note that the above construction of $\mathcal{G}'$ is exponential in the largest value of m in any rule from $\mathcal{G}$. For this reason, $\mathcal{G}$ is usually brought in binary form before the intersection, i.e. the input grammar is transformed to let each right-hand side have at most two members. Such a transformation can be realized in linear time in the size of the grammar. We will return to this issue in Section 7.

4 Obtaining unambiguous FAs

In the previous section, we explained that unambiguous finite automata have special properties with respect to the grammar $\mathcal{G}'$ that we may construct out of a FA $\mathcal{M}$ and a PCFG $\mathcal{G}$. In this section we discuss how unambiguity can be obtained for the special case of finite automata accepting the language of all strings with given infix $w \in \Sigma^*$:

$$L_{infix}(w) \quad = \quad \{xwy \mid x, y \in \Sigma^*\}.$$

Any deterministic automaton is also unambiguous. Furthermore, there seem to be no practical algorithms that turn FAs into equivalent unambiguous FAs other than the algorithms that also determinize them. Therefore, we will henceforth concentrate on deterministic rather than unambiguous automata.

Given a string $w = a_1 \cdots a_n$, a finite automaton accepting $L_{infix}(w)$ can be straightforwardly constructed. This automaton has states $s_0, \ldots, s_n$, transitions $s_0 \overset{a}{\mapsto} s_0$ and $s_n \overset{a}{\mapsto} s_n$ for each $a \in \Sigma$, and transition $s_{i-1} \overset{a_i}{\mapsto} s_i$ for each i ($1 \leq i \leq n$). The initial state is s_0 and the final state is s_n. Clearly, there is nondeterminism in state s_0.

One way to make this automaton deterministic is to apply the general algorithm of determinization of finite automata; see e.g. (Aho and Ullman, 1972). This algorithm is exponential for general FAs. An alternative approach is to construct a deterministic finite automaton directly from w, in line with the Knuth-Morris-Pratt algorithm (Knuth et al., 1977; Gusfield, 1997). Both approaches result in the same deterministic FA, which we denote by $\mathcal{I}_w$. However, the latter approach is easier to implement in such a

way that the time complexity of constructing the automaton is linear in $|w|$.

The automaton $\mathcal{I}_w$ is described as follows. There are $n+1$ states $t_0, \ldots, t_n$, where as before n is the length of w. The initial state is t_0 and the final state is t_n. The intuition is that $\mathcal{I}_w$ reads a string $x = b_1 \cdots b_m$ from left to right, and when it has read the prefix $b_1 \cdots b_j$ ($0 \leq j \leq m$), it is in state t_i ($0 \leq i < n$) if and only if $a_1 \cdots a_i$ is the longest prefix of w that is also a suffix of $b_1 \cdots b_j$. If the automaton is in state t_n, then this means that w is an infix of $b_1 \cdots b_j$.

In more detail, for each i ($1 \leq i \leq n$) and each $a \in \Sigma$, there is a transition $t_{i-1} \overset{a}{\mapsto} t_j$, where j is the length of the longest string that is both a prefix of w and a suffix of $a_1 \cdots a_{i-1}a$. If $a = a_i$, then clearly $j = i$, and otherwise $j < i$. To ensure that we remain in the final state once an occurrence of infix w has been found, we also add transitions $t_n \overset{a}{\mapsto} t_n$ for each $a \in \Sigma$. This construction is illustrated in Figure 1.

5 Infix probability

With the material developed in the previous sections, the problem of computing the infix probabilities can be effectively solved. Our goal is to compute for given infix $w \in \Sigma^*$ and PCFG $\mathcal{G} = (\Sigma, N, S, R, p)$:

$$\sigma_{\mathit{infix}}(w, \mathcal{G}) = \sum_{z \in L_{\mathit{infix}}(w)} p(z).$$

In Section 4 we have shown the construction of finite automaton $\mathcal{I}_w$ accepting $L_{\mathit{infix}}(w)$, by which we obtain:

$$\sigma_{\mathit{infix}}(w, \mathcal{G}) = \sum_{z \in L(\mathcal{I}_w)} p(z).$$

As $\mathcal{I}_w$ is deterministic and therefore unambiguous, the results from Section 3 apply and if $\mathcal{G}' = (\Sigma, N', S', R', p')$ is the PCFG constructed out of $\mathcal{G}$ and $\mathcal{I}_w$ then:

$$\sigma_{\mathit{infix}}(w, \mathcal{G}) = \sum_{z} p'(z).$$

Finally, we can compute the above sum by applying the iterative method discussed in Section 2.

6 Extensions

The approach discussed above allows for a number of generalizations. First, we can replace the infix w by a **sequence** of infixes $w_1, \ldots, w_m$, which have to occur in the given order, one strictly after the other, with arbitrary infixes in between:

$$\sigma_{\mathit{island}}(w_1, \ldots, w_m, \mathcal{G}) = \sum_{x_0, \ldots, x_m \in \Sigma^*} p(x_0 w_1 x_1 \cdots w_m x_m).$$

This problem was discussed before by (Corazza et al., 1991), who mentioned applications in speech recognition. Further applications are found in computational biology, but their discussion is beyond the scope of this paper; see for instance (Apostolico et al., 2005) and references therein. In order to solve the problem, we only need a small addition to the procedures we discussed before. First we construct separate automata $\mathcal{I}_{w_j}$ ($1 \leq j \leq m$) as explained in Section 4. These automata are then composed into a single automaton $\mathcal{I}_{(w_1,\ldots,w_m)}$. In this composition, the outgoing transitions of the final state of $\mathcal{I}_{w_j}$, for each j ($1 \leq j < m$), are removed and that final state is merged with the initial state of the next automaton $\mathcal{I}_{w_{j+1}}$. The initial state of the composed automaton is the initial state of $\mathcal{I}_{w_1}$, and the final state is the final state of $\mathcal{I}_{w_m}$. The time costs of constructing $\mathcal{I}_{(w_1,\ldots,w_m)}$ are linear in the sum of the lengths of the strings w_j.

Another way to generalize the problem is to replace w by a finite set $L = \{w_1, \ldots, w_m\}$. The objective is to compute:

$$\sigma_{\mathit{infix}}(L, \mathcal{G}) = \sum_{w \in L, x, y \in \Sigma^*} p(xwy)$$

Again, this can be solved by first constructing a deterministic FA, which is then intersected with $\mathcal{G}$. This FA can be obtained by determinizing a straightforward nondeterministic FA accepting L, or by directly constructing a deterministic FA along the lines of the Aho-Corasick algorithm (Aho and Corasick, 1975). Construction of the automaton with the latter approach takes linear time.

Further straightforward generalizations involve formalisms such as probabilistic tree adjoining grammars (Schabes, 1992; Resnik, 1992). The technique from Section 3 is also applicable in this case,

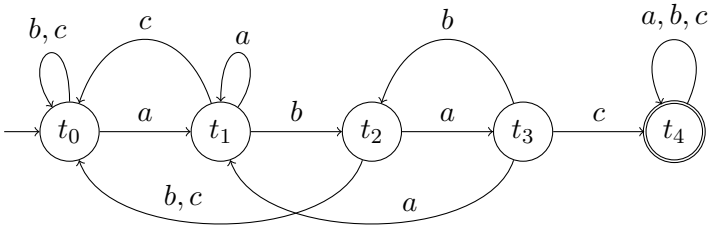

Figure 1: Deterministic automaton that accepts all strings over alphabet $\{a, b, c\}$ with infix *abac*.

as the construction from Bar-Hillel et al. (1964) carries over from context-free grammars to tree adjoining grammars, and more generally to the linear context-free rewriting systems of Vijay-Shanker et al. (1987).

7 Implementation

We have conducted experiments with the computation of infix probabilities. The objective was to identify parts of the computation that have a high time or space demand, and that might be improved. The experiments were run on a desktop with a 3.0 GHz Pentium 4 processor. The implementation language is C++.

The set-up of the experiments is similar to that in (Nederhof and Satta, 2008). A probabilistic context-free grammar was extracted from sections 2-21 of the Penn Treebank version II. Subtrees that generated the empty string were systematically removed. The result was a CFG with 10,035 rules, 28 nonterminals and 36 parts-of-speech. The rule probabilities were determined by maximum likelihood estimation. The grammar was subsequently binarized, to avoid exponential behaviour, as explained in Section 3.

We have considered 10 strings of length 7, randomly generated, assuming each of the parts-of-speech has the same probability. For all prefixes of those strings from length 2 to length 7, we then computed the infix probability. The duration of the full computation, averaged over the 10 strings of length 7, is given in the first row of Table 1.

In order to solve the non-linear systems of equations, we used Broyden's method. It can be seen as an approximation of Newton's method. It requires more iterations, but seems to be faster overall, and more scalable to large problem sizes, due to the avoidance of matrix inversion, which sometimes makes Newton's method prohibitively expensive. In our experiments, Broyden's method was generally faster than Newton's method and much faster than the simple iteration method by the relation in (4). For further details on Broyden's method, we refer the reader to (Kelley, 1995).

The main obstacle to computation for infixes substantially longer than 7 symbols is the memory consumption rather than the running time. This is due to the required square matrices, the dimension of which is the number of nonterminals. The number of nonterminals (of the intersection grammar) naturally grows as the infix becomes longer.

As explained in Section 2, the problem is divided into smaller problems by isolating disjoint sets of mutually recursive nonterminals, or strongly connected components. We found that for the application to the automata discussed in Section 4, there were exactly three strongly connected components that contained more than one element, throughout the experiments. For an infix of length n, these components are:

- C_1, which consists of nonterminals of the form (t_i, A, t_j), where $i < n$ and $j < n$,
- C_2, which consists of nonterminals of the form (t_i, A, t_j), where $i = j = n$, and
- C_3, which consists of nonterminals of the form (t_i, A, t_j), where $i < j = n$.

This can be easily explained by looking at the structure of our automata. See for example Figure 1, with cycles running through states $t_0, \ldots, t_{n-1}$, and cycles through state t_n. Furthermore, the grammar extracted from the Penn Treebank is heavily recursive,

infix length	2	3	4	5	6	7
total running time	1.07	1.95	5.84	11.38	23.93	45.91
Broyden's method for C_1	0.46	0.90	3.42	6.63	12.91	24.38
Broyden's method for C_2	0.08	0.04	0.07	0.04	0.03	0.09
Broyden's method for C_3	0.20	0.36	0.81	1.74	5.30	9.02

Table 1: Running time for infixes from length 2 to length 7. The infixes are prefixes of 10 random strings of length 7, and reported CPU times (in seconds) are averaged over the 10 strings.

so that almost every nonterminal can directly or indirectly call any other.

The strongly connected component C_2 is always the same, consisting of 2402 nonterminals, for each infix of any length. (Note that binarization of the grammar introduced artificial nonterminals.) The last three rows of Table 1 present the time costs of Broyden's method, for the three strongly connected components.

The strongly connected component C_3 happens to correspond to a *linear* system of equations. This is because a rule in the intersection grammar with a left-hand side (t_i, A, t_j), where $i < j = n$, must have a right-hand side of the form (t_i, A', t_j), or of the form $(t_i, A_1, t_k)\ (t_k, A_2, t_j)$, with $k \leq n$. If $k < n$, then only the second member can be in C_3. If $k = n$, only first member can be in C_3. Hence, such a rule corresponds to a linear equation within the system of equations for the entire grammar.

A linear system of equations can be solved analytically, for example by Gaussian elimination, rather than approximated through Newton's method or Broyden's method. This means that the running times in the last row of Table 1 can be reduced by treating C_3 differently from the other strongly connected components. However, the running time for C_1 dominates the total time consumption.

The above investigations were motivated by two questions, namely whether any part of the computation can be precomputed, and second, whether infix probabilities can be computed incrementally, for infixes that are extended to the left or to the right. The first question can be answered affirmatively for C_2, as it is always the same. However, as we can see in Table 1, the computation of C_2 amounts to a small portion of the total time consumption.

The second question can be rephrased more precisely as follows. Suppose we have computed the infix probability of a string w and have kept intermediate results in memory. Can the computation of the infix probability of a string of the form aw or wa, $a \in \Sigma$, be computed by relying on the existing results, so that the computation is substantially faster than if the computation were done from scratch?

Our investigations so far have not found a positive answer to this second question. In particular, the systems of equations for C_1 and C_3 change fundamentally if the infix is extended by one more symbol, which seems to at least make incremental computation very difficult, if not impossible. Note that the algorithms for the computation of prefix probabilities by Jelinek and Lafferty (1991) and Stolcke (1995) do allow incrementality, which contributes to their practical usefulness for speech recognition.

8 Conclusions

We have shown that the problem of infix probabilities for PCFGs can be solved by a construction that intersects a context-free language with a regular language. An important constraint is that the finite automaton that is input to this construction be unambiguous. We have shown that such an automaton can be efficiently constructed. Once the input probabilistic PCFG and the FA have been combined into a new probabilistic CFG, the infix probability can be straightforwardly solved by iterative algorithms. Such algorithms include Newton's method, and Broyden's method, which was used in our experiments. Our discussion ended with an open question about the possibility of incremental computation of infix probabilities.

Parse Correction with Specialized Models for Difficult Attachment Types

Abstract

This paper develops a framework for syntactic dependency parse correction. Dependencies in an input parse tree are revised by selecting, for a given dependent, the best governor from within a small set of candidates. We use a discriminative linear ranking model to select the best governor from a group of candidates for a dependent, and our model includes a rich feature set that encodes syntactic structure in the input parse tree. The parse correction framework is parser-agnostic, and can correct attachments using either a generic model or specialized models tailored to difficult attachment types like coordination and pp-attachment. Our experiments show that parse correction, combining a generic model with specialized models for difficult attachment types, can successfully improve the quality of predicted parse trees output by several representative state-of-the-art dependency parsers for French.

1 Introduction

In syntactic dependency parse correction, attachments in an input parse tree are revised by selecting, for a given dependent, the best governor from within a small set of candidates. The motivation behind parse correction is that attachment decisions, especially traditionally difficult ones like pp-attachment and coordination, may require substantial contextual information in order to be made accurately. Because syntactic dependency parsers predict the parse tree for an entire sentence, they may not be able to take into account sufficient context when making attachment decisions, due to computational complexity. Assuming nonetheless that a predicted parse tree is mostly accurate, parse correction can revise difficult attachments by using the predicted tree's syntactic structure to restrict the set of candidate governors and extract a rich set of features to help select among them. Parse correction is also appealing because it is *parser-agnostic*: it can be trained to correct the output of any dependency parser.

In Section 2 we discuss work related to parse correction, pp-attachment and coordination resolution. In Section 3 we discuss dependency structure and various statistical dependency parsing approaches. In Section 4 we introduce the parse correction framework, and Section 5 describes the features and learning model used in our implementation. In Section 6 we present experiments in which parse correction revises the predicted parse trees of four state-of-the-art dependency parsers for French. We provide concluding remarks in Section 7.

2 Related Work

Previous research directly concerning parse correction includes that of Attardi and Ciaramita (2007), working on English and Swedish, who use an approach that considers a fixed set of revision rules: each rule describes movements in the parse tree leading from a dependent's original governor to a new governor, and a classifier is trained to select the correct revision rule for a given dependent. One drawback of this approach is that the classes lack semantic coherence: a sequence of movements does not necessarily have the same meaning across differ-

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1222–1233,
Edinburgh, Scotland, UK, July 27–31, 2011.

ent syntactic trees. Hall and Novák (2005), working on Czech, define a neighborhood of candidate governors centered around the original governor of a dependent, and a Maximum Entropy model determines the probability of each candidate-dependent attachment. We follow primarily from their work in our use of neighborhoods to delimit the set of candidate governors. Our main contributions are: specialized corrective models for difficult attachment types (coordination and pp-attachment) in addition to a general corrective model; more sophisticated features, feature combinations, and feature selection; and a ranking model trained directly to select the true governor from among a set of candidates.

There has also been other work on techniques similar to parse correction. Attardi and Dell'Orletta (2009) investigate *reverse revision*: a left-to-right transition-based model is first used to parse a sentence, then a right-to-left transition-based model is run with additional features taken from the left-to-right model's predicted parse. This approach leads to improved parsing results on a number of languages. While their approach is similar to parse correction in that it uses a predicted parse to inform a subsequent processing step, this information is used to improve a second parser rather than a model for correcting errors. McDonald and Pereira (2006) consider a method for recovering non-projective attachments from a graph representation of a sentence, in which an optimal projective parse tree has been identified. The parse tree's edges are allowed to be rearranged in ways that introduce non-projectivity in order to increase its overall score. This rearrangement approach resembles parse correction because it is a second step that can revise attachments made in the first step, but it differs in a number of ways: it is dependent on a graph-based parsing approach, it does not model errors made by the parser, and it can only output non-projective variants of the predicted parse tree.

As a process that revises the output of a syntactic parser, parse reranking is also similar to parse correction. A well-studied subject (e.g. the work of Charniak and Johnson (2005) and of Collins and Koo (2005)), parse reranking is concerned with the reordering of n-best ranked parse trees output by a syntactic parser. Parse correction has a number of advantages compared to reranking: it can be used with parsers that do not output n-best ranked parses, it can be easily restricted to specific attachment types, and its output space of parse trees is not limited to those appearing in an n-best list. However, parse reranking has the advantage of selecting the globally optimal parse for a sentence from an n-best list, while parse correction makes only locally optimal revisions in the predicted parse for a sentence.

2.1 Difficult Attachment Types

Research on pp-attachment traditionally formulates the problem in isolation, as in the work of Pantel and Lin (2000) and of Olteanu and Moldovan (2005). Examples consist of tuples of the form (v, n_1, p, n_2), where either v or n_1 is the true governor of the pp comprising p and n_2, and the task is to choose between v and n_1. Recently, Atterer and Schütze (2007) have criticized this formulation as unrealistic because it uses an oracle to select candidate governors, and they find that successful approaches for the isolated problem perform no better than state-of-the-art parsers on pp-attachment when evaluated on full sentences. With parse correction, candidate governors are identified automatically with no (v, n_1, p, n_2) restriction, and for several representative parsers we find that parse correction improves pp-attachment performance.

Research on coordination resolution has also often formulated the problem in isolation. Resnik (1999) uses semantic similarity to resolve noun-phrase coordination of the form (n_1, cc, n_2, n_3), where the coordinating conjunction cc coordinates either the heads n_1 and n_2 or the heads n_1 and n_3. The same criticism as the one made by Atterer and Schütze (2007) for pp-attachment might be applied to this approach to coordination resolution. In another formulation, the input consists of a raw sentence, and coordination structure is then detected and disambiguated using discriminative learning models (Shimbo and Hara, 2007) or coordination-specific parsers (Hara et al., 2009). Finally, other work has focused on introducing specialized features for coordination into existing syntactic parsing models (Hogan, 2007). Our approach is novel with respect to previous work by directly modeling the correction of coordination errors made by general-purpose dependency parsers.

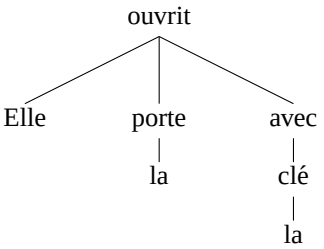

Figure 1: An unlabeled dependency tree for: *Elle ouvrit la porte avec la clé.* (*She opened the door with the key*).

3 Dependency Parsing

Dependency syntax involves the representation of syntactic information for a sentence in the form a directed graph, whose edges encode word-to-word relationships. An edge from a *governor* to a *dependent* indicates, roughly, that the presence of the dependent is syntactically legitimated by the governor. An important property of dependency syntax is that each word, except for the root of the sentence, has exactly one governor; dependency syntax is thus represented by trees. Figure 1 shows an example of an unlabeled dependency tree.[1] For languages like English or French, most sentences can be represented with a *projective* dependency tree: for any edge from word g to word d, g dominates any intervening word between g and d.

Dependency trees are appealing syntactic representations, closer than constituency trees to the semantic representations useful for NLP applications. This is true even with the projectivity requirement, which occasionally creates syntax-semantics mismatches. Dependency trees have recently seen a surge of interest, particularly with the introduction of supervised models for dependency parsing using linear classifiers. Such parsers fall into two main categories: transition-based parsing and graph-based parsing. Additionally, an alternative method for obtaining the dependency parse for a sentence is to parse the sentence with a constituency-based parser and then use an automatic process to convert the output into dependency structure.

[1]Edges are generally labeled with the surface grammatical function that the dependent bears with respect to its governor. In this paper we focus on unlabeled dependency parsing, setting aside labeling as a separate task.

3.1 Transition-Based Parsing

In transition-based dependency parsing, whose seminal works are that of Yamada and Matsumoto (2003) and Nivre (2003), the parsing process applies a sequence of incremental actions, which typically manipulate a buffer position in the sentence and a stack for built sub-structures. Actions are of the type "*read word from buffer*", "*build a dependency from node on top of the stack to node that begins the buffer*", etc. In a greedy version of this process, the action to apply at each step is deterministically chosen to be the best-scoring action according to a classifier, which is trained on a dependency treebank converted into sequences of actions. The strengths of this framework are $O(n)$ time complexity and a lack of restrictions on the locality of features. A major drawback is its greedy behavior: it can potentially make difficult attachment decisions early in the processing of a sentence, without being able to reconsider them when more information becomes available. Beamed versions of the algorithm (Johansson and Nugues, 2006) partially address this problem, but still do not provide a global optimization for selecting the output parse tree.

3.2 Graph-Based Parsing

In graph-based dependency parsing, whose seminal work is that of McDonald et al. (2005), the parsing process selects the globally optimal parse tree from a graph containing attachments (directed edges) between each pair of words (nodes) in a sentence. It finds the k-best scoring parse trees, both during training and at parse time, where the score of a tree is the sum of the scores of its *factors* (consisting of one or more linked edges). While large factors are desirable for capturing sophisticated linguistic constraints, they come at the cost of time complexity: for the projective case, adaptations of Eisner's algorithm (Eisner, 1996) are $O(n^3)$ for 1-edge factors (McDonald et al., 2005) or sibling 2-edge factors (McDonald and Pereira, 2006), and $O(n^4)$ for general 2-edge factors (Carreras, 2007) or 3-edge factors (Koo and Collins, 2010).

3.3 Constituency-Based Parsing

Beyond the two main approaches to dependency parsing, there is also the approach of constituency-

based parsing followed by a conversion step to dependency structure. We use the three-step parsing architecture previously tested for French by Candito et al. (2010a): (i) A constituency parse tree is output by the BerkeleyParser, which has been trained to learn a probabilistic context-free grammar with latent annotations (Petrov et al., 2006) that has parsing time complexity $O(n^3)$ (Matsuzaki et al., 2005); (ii) A functional role labeler using a Maximum Entropy model adds functional annotations to links between a verb and its dependents; (iii) Constituency trees are automatically converted into projective dependency trees, with remaining unlabeled dependencies assigned labels using a rule-based approach.

3.4 Baseline Parsers

In this paper, we use the following baseline parsers: MaltParser (Nivre et al., 2007) for transition-based parsing; MSTParser (McDonald et al., 2005) (with sibling 2-edge factors) and BohnetParser (Bohnet, 2010) (with general 2-edge factors) for graph-based parsing; and BerkeleyParser (Petrov et al., 2006) for constituency-based parsing.

For MaltParser and MSTParser, we use the best settings from a benchmarking of parsers for French (Candito et al., 2010b), except that we remove unsupervised word clusters as features. The parsing models are thus trained using features including predicted part-of-speech tags, lemmas and morphological features. For BohnetParser, we trained a new model using these same predicted features. For BerkelyParser, which was included in the benchmarking experiments, we trained a model using the so-called "desinflection" process that addresses data sparseness due to morphological variation: both at training and parsing time, terminal symbols are word forms in which redundant morphological suffixes are removed, provided the original part-of-speech ambiguities are kept (Candito et al., 2010b).

All models are trained on the French Treebank (FTB) (Abeillé and Barrier, 2004), consisting of 12,351 sentences from the *Le Monde* newspaper, either "desinflected" for the BerkeleyParser, or converted to projective dependency trees (Candito et al., 2010a) for the three dependency-native parsers.[2] For the dependency-native models, features include predicted part-of-speech (POS) tags from the MElt tagger (Denis and Sagot, 2009), as well as predicted lemmas and morphological features from the Le*fff* lexicon (Sagot, 2010). These models constitute the state-of-the-art for French dependency parsing: unlabeled attachment scores (UAS) on the FTB test set are 89.78% for MaltParser, 91.04% for MSTParser, 91.78% for BohnetParser, and 90.73% for BerkeleyParser.

INPUT: Predicted parse tree T

LOOP: For each chosen dependent $d \in D$

- Identify candidates C_d from T
- Predict $\hat{c} = \underset{c \in C_d}{\operatorname{argmax}}\ S(c, d, T)$
- Update $T\{gov(d) \leftarrow \hat{c}\}$

OUTPUT: Corrected version of parse tree T

Figure 2: The parse correction algorithm.

4 Parse Correction

The parse correction algorithm is a post-processing step to dependency parsing, where attachments from the predicted parse tree of a sentence are corrected by considering alternative candidate governors for each dependent. This process can be useful for attachments made too early in transition-based parsing, or with features that are too local in MST-based parsing.

The input is the predicted parse T of a sentence. From T a set D of dependent nodes are chosen for attachment correction. For each $d \in D$ in left-to-right sentence order, a set C_d of candidate governors from T is identified, and then the highest scoring $c \in C_d$, using a function $S(c, d, T)$, is assigned as the new governor of d in T. Pseudo-code for parse correction is shown in Figure 2.[3]

[2] The projectivity constraint is linguistically valid for most French parses: the authors report $< 2\%$ non-projective edges in a hand-corrected subset of the converted FTB.

[3] Contrary to Hall and Novák (2005), our iterative algorithm (along with the fact that C_d never includes nodes that are dominated by d) ensures that corrected structures are trees, so it does not require additional processing to eliminate cycles and preserve connectivity.

4.1 Choosing Dependents

Various criteria may be used to choose the set D of dependents to correct. In the work of Hall and Novák (2005) and of Attardi and Ciaramita (2007), D contains all nodes in the input parse tree. However, one advantage of parse correction is its ability to focus on specific attachment types, so an additional criterion for choosing dependents is to look separately at those dependents that correspond to difficult attachment types.

Analyzing errors made by the dependency parsers introduced in Section 3 on the development set of the FTB, we observe that two major sources of error across different parsers are coordination and pp-attachment. Coordination accounts for around 10% of incorrect attachments and has an error rate ranging from $30 - 40\%$, while pp-attachment accounts for around 30% of incorrect attachments and has an error rate of around 15%.

In this paper, we pay special attention to coordination and pp-attachment. Given the FTB annotation scheme, coordination can be corrected by changing the governor (first conjunct) of the coordinating conjunction that governs the second conjunct, and pp-attachment can be corrected by changing the governor of the preposition that heads the pp.[4] We thus train specialized corrective models for when the dependents are coordinating conjunctions and prepositions, in addition to a generic corrective model that can be applied to any dependent.[5]

4.2 Identifying Candidate Governors

The set of candidate governors C_d for a dependent d can be chosen in different ways. One method is to let every other node in T be a candidate governor for d. However, parser error analysis has shown that errors often occur in local contexts. Hall and Novák (2005) define a neighborhood as a set of nodes $N_m(d)$ around the original predicted governor c_o of d, where $N_m(d)$ includes all nodes in the parse tree T within graph distance m of d that pass through c_o. They find that around $2/3$ of the incorrect attachments in the output of Czech parses can be corrected by selecting the best governor from within $N_3(d)$. Similarly, in oracle experiments reported in section 6, we find that around $1/2$ of coordination and pp-attachments in the output of French parses can be corrected by selecting the best governor from within $N_3(d)$. We thus use neighborhoods to delimit the set of candidate governors.

While one can simply assign $C_d \leftarrow N_m(d)$, we add additional restrictions. First, in order to preserve projectivity within T, we keep in C_d only those c such that the update $T\{gov(d) \leftarrow c\}$ would result in a projective tree.[6] Additionally, we discard candidates with certain POS categories that are very unlikely to be governors: clitics and punctuation are always discarded, while determiners are discarded if the dependent is a preposition.

4.3 Scoring Candidate Governors

A new governor $\hat{c}$ for a dependent d is predicted by selecting the highest scoring candidate $c \in C_d$ according to a function $S(c, d, T)$, which takes into account features over c, d, and the parse tree T. We use a linear model for our scoring function, which allows for relatively fast training and prediction. Our scoring function uses a weight vector $\vec{w} \in \mathbb{F}$, where $\mathbb{F}$ is the feature space for dependents we wish to correct (either generic, or specialized for prepositions or for coordinating conjunction), as well as the mapping $\Phi : \mathbb{C}\times\mathbb{D}\times\mathbb{T} \rightarrow \mathbb{F}$ from combinations of candidate $c \in \mathbb{C}$, dependent $d \in \mathbb{D}$, and parse tree $T \in \mathbb{T}$, to vectors in the feature space $\mathbb{F}$. The scoring function returns the inner product of $\vec{w}$ and $\Phi(c, d, T)$:

$$S(c, d, T) = \vec{w} \cdot \Phi(c, d, T) \quad (1)$$

4.4 Algorithm Complexity

The time complexity of our algorithm is $O(n)$ in the length n of the input sentence, which is consistent with past work on parse correction by Hall and Novák (2005) and by Attardi and Ciaramita (2007).

[4] The FTB handles pp-attachment in a typical fashion, but coordination may be handled differently by other schemes (e.g. the coordinating conjunction governs both conjuncts).

[5] In our experiments, we never revise punctuation and clitic dependents. Since punctuation attachments mostly carry little meaning, they are often annotated inconsistently and ignored in parsing evaluations (including ours). Clitics are not revised because they have a very low attachment error rate (2%).

[6] We also keep candidates that would lead to a non-projective tree, as long as it would be projective if we ignored punctuation. This relaxation of the projectivity constraint leads to better oracle scores while retaining the key linguistic properties of projectivity.

Attachments for up to n dependents in a sentence are deterministically corrected in one pass. For each such dependent d, the algorithm uses a linear model to select a new governor after extracting features for a local set of candidate governors C_d, whose size does not dependent on n in the average case.[7] Locality in candidate governor identification and feature extraction preserves linear time complexity in the overall algorithm.

5 Model Learning

We now discuss our training setup, features, and learning approach for obtaining the weight vector $\vec{w}$.

5.1 Training Setup

The parse correction training set pairs gold parse trees with corresponding predicted parse trees output by a syntactic parser, and it is obtained using a jackknifing procedure to automatically parse the gold-annotated training section of a dependency treebank with a syntactic dependency parser.

We extract separate training sets for each type of dependent we wish to correct (generic, prepositions, coordinating conjunctions). Given p, then for each token d we wish to correct in a sentence in the training section, we note its true governor g_d in the gold parse tree of the sentence, identify a set of candidate governors C_d in the predicted parse T, and get feature vectors $\{\Phi(c, d, T) : c \in C_d\}$.

5.2 Feature Space

In order to learn an effective scoring function, we use a rich feature space $\mathbb{F}$ that encodes syntactic context surrounding a candidate-dependent pair (c, d) within a parse tree T. Our primary features are indicator functions for realizations of linguistic or tree-based feature classes.[8] From these primary features we generate more complex feature combinations of length up to P, which are then added to $\mathbb{F}$. Each combo represents a set of one or more primary features, and is an indicator function that fires if and only if all of its members do.

[7] Degenerate parse trees (e.g. flat trees) could lead to cases where $|C_d|$=n, but for linguistically coherent parse trees $|C_d|$ is rather $O(k^m)$, where k is the average -*arity* of syntactic parse trees and m is the neighborhood distance used.

[8] For instance, there is a binary feature that is 1 if feature class "POS of c" takes on the value "verb", and 0 otherwise.

5.2.1 Primary Feature Classes

The primary feature classes we use are listed below, grouped into categories corresponding to their use in different corrective models (d_{obj} is the object of the dependent, c_{gov} is the governor of the candidate, and c_{d-1} and c_{d+1} are the closest dependents of c linearly to the left and right, respectively, of d).

Generic features (always included)

- POS, lemma, and number of dependents of c
- POS and dependency label of c_{d-1}
- POS and dependency label of c_{d+1}
- POS of c_{gov}
- POS and lemma of d
- POS of d_{obj} and whether d_{obj} has a determiner
- Whether c is the predicted governor of d
- Binned linear distance between c and d
- Linear direction of c with respect to d
- POS sequence for nodes on path from c to d
- Graph distance between c and d
- Whether there is punctuation between c and d

Features exclusive to coordination

Whether d would coordinate two conjuncts that:

- Have the same POS
- Have the same word form
- Have number agreement
- Are both nouns with the same cardinality
- Are both proper nouns or both common nouns
- Are both prepositions with the same word form
- Are both prepositions with object of same POS

Features exclusive to pp-attachment

- Whether d immediately follows a punctuation
- Whether d heads a pp likely to be the agent of a passive verb
- If c is a coordinating conjunction, then whether c would coordinate two prepositions with the same word form, and whether there is at least one open-category word linearly between c and d (in which case c is an unlikely governor)

– If c is linearly after d, then whether there exists a plausible rival candidate to the left of d (implemented as whether there is a noun or adjective linearly before d, without any intervening finite verb)

5.2.2 Feature Selection

Feature combos allow our models to effectively sidestep linearity constraints, at the cost of an exponential increase in the size of the feature space $\mathbb{F}$. In order to accommodate combos, we use feature selection to help reduce the resulting space.

Our first feature selection technique is to apply a frequency threshold: if a feature or a combo appears less than K times among instances in our training set, we remove it from $\mathbb{F}$. In addition to making the feature space more tractable, frequency thresholding makes our scoring function less reliant on rare features and combos.

Following frequency thresholding, we employ an additional technique using conditional entropy (CE) that we term *CE-reduction*. Let Y be a random variable for whether or not an attachment is true, and let A be a random variable for different combos that can appear in an attachment. We calculate the CE of a combo a with respect to Y as follows,

$$H(Y|A{=}a) = -\sum_{y \in Y} p(y|a) \log p(y|a) \quad (2)$$

where the probability $p(y|a)$ is approximated from the training set as $freq(a, y)/freq(a)$, with example balancing used here to account for more false attachments ($Y = 0$) than true ones ($Y = 1$) in our training set. Having calculated the CE of each combo, we remove from $\mathbb{F}$ those combos for which a subset combo (or feature) exists with equal or lesser CE. This eliminates any overly specific combo a when the extra features encoded in a, compared to some subset b, do not help a explain Y any better than b.

5.3 Ranking Model

The ranking setting for learning is used when a model needs to discriminate between mutually exclusive candidates that vary from instance to instance. This is typically used in parse reranking (Charniak and Johnson, 2005), where for each sentence the model must select the correct parse from within an n-best list. Denis and Baldridge (2007) also show that ranking outperforms a binary classification approach to pronoun resolution (using a Maximum Entropy model), where for each pronominal anaphor the model must select the correct antecedent among candidates in a text.[9]

INPUT: Aggressiveness C, rounds R.
INITIALIZE: $\vec{w}_0 \leftarrow (0, ..., 0), \vec{w}_{avg} \leftarrow (0, ..., 0)$
REPEAT: R times
LOOP: For $t = 1, 2, \ldots, |X|$
· Get feature vectors $\{\vec{x}_{t,c} : c \in C_{d_t}\}$
· Get true governor $g_t \in C_{d_t}$
· Let $h_t = \underset{c \in C_{d_t} - \{g_t\}}{\text{argmax}} \ (\vec{w}_{t-1} \cdot \vec{x}_{t,c})$
· Let $m_t = (\vec{w}_{t-1} \cdot \vec{x}_{t,g_t}) - (\vec{w}_{t-1} \cdot \vec{x}_{t,h_t})$
IF: $m_t < 1$
· Let $\tau_t = \min\left\{C\ ,\ \frac{1-m_t}{\|\vec{x}_{t,g_t} - \vec{x}_{t,h_t}\|^2}\right\}$
· Set $\vec{w}_t \leftarrow \vec{w}_{t-1} + \tau_t(\vec{x}_{t,g_t} - \vec{x}_{t,h_t})$
ELSE:
· Set $\vec{w}_t \leftarrow \vec{w}_{t-1}$
· Set $\vec{w}_{avg} \leftarrow \vec{w}_{avg} + \vec{w}_t$
· Set $\vec{w}_0 \leftarrow \vec{w}_{|X|}$
OUTPUT: $\vec{w}_{avg}/(R \cdot |X|)$

Figure 3: Averaged PA-Ranking training algorithm.

In our ranking approach to parse correction (PA-Ranking), the weight vector is trained to select the true governor from a set of candidates C_d for a dependent d. The training set X is defined such that the t^{th} instance is a collection of feature vectors $\{\vec{x}_{t,c} = \Phi(c, d_t, T_t) : c \in C_{d_t}\}$, where C_{d_t} is the candidate set for the dependent d_t within the predicted parse T_t, and the class is the true governor g_t. Instances in which $g_t \notin C_{d_t}$ are discarded.

PA-Ranking training is carried out using a variation of the Passive-Aggressive algorithm (Crammer et al., 2006), which has been adapted to the ranking setting, implemented using the Polka library.[10] For each training iteration t, the margin is defined as

[9] We considered a binary training approach to parse correction in which the model is trained to independently classify candidates as true or false governors, as used by Hall and Novák (2005). However, we found that this approach performs no better (and often worse) than the ranking approach, and is less appropriate from a modeling standpoint.

[10] `http://polka.gforge.inria.fr/`

$m_t = (\vec{w}_{t-1} \cdot \vec{x}_{t,g_t}) - (\vec{w}_{t-1} \cdot \vec{x}_{t,h_t})$, where h_t is the highest scoring incorrect candidate. The algorithm is *passive* because an update to the weight vector is made if and only if $m_t < 1$, either for incorrect predictions ($m_t < 0$) or for correct predictions with insufficient margin ($0 \leq m_t < 1$). The new weight vector $\vec{w}_t$ is as close as possible to $\vec{w}_{t-1}$, subject to the *aggressive* constraint that the new margin be greater than 1. We use weight averaging, so the final output $\vec{w}_{avg}$ is the average over the weight vectors after each training step. Pseudo-code for the training algorithm is shown in Figure 3. The rounds parameter R determines the number of times to run through the training set, and the aggressiveness parameter C sets an upper limit on the update magnitude.

6 Experiments

We present experiments where we applied parse correction to the output of four state-of-the-art dependency parsers for French. We conducted our evaluation on the FTB using the standard training, development (dev), and test splits (containing 9,881, 1,235 and 1,235 sentences, respectively). To train our parse correction models, we generated specialized training sets corresponding to each parser by doing 10-fold jackknifing on the FTB training set (cf. Section 5.1). Each parser was run on the FTB dev and test sets, providing baseline unlabeled attachment score (UAS) results and output parse trees to be corrected.

6.1 Oracles and Neighborhood Size

To determine candidate neighborhood size, we considered an oracle scoring function that always selects the true governor of a dependent if it appears in the set of candidate governors, and otherwise selects the predicted governor. Results for this oracle on the dev set are shown in Table 1. The baseline corresponds to m=1, where the oracle just selects the predicted governor. Incrementing m to 2 and to 3 resulted in substantial gains in oracle UAS, but further incrementing m to 4 resulted in a relatively small additional gain. We found that average candidate set size increases about linearly in m, so we decided to use m=3 in order to have a high UAS upper bound without adding candidates that are very unlikely to be true governors.

		Neighborhood Size (m)			
		Base	2	3	4
Berkeley	Coords	67.2	76.5	82.8	84.8
	Preps	82.9	88.5	92.2	93.2
	Overall	90.1	94.0	96.0	96.5
Bohnet	Coords	70.1	80.6	85.6	87.7
	Preps	85.4	89.4	93.4	94.5
	Overall	91.2	94.4	96.1	96.6
Malt	Coords	60.9	72.2	78.2	80.5
	Preps	82.6	88.1	92.6	93.7
	Overall	89.3	93.2	95.1	95.8
MST	Coords	63.6	73.7	80.7	84.4
	Preps	84.7	89.4	93.4	94.4
	Overall	90.2	93.7	95.6	96.2
MST	Overall	Reranking top-100 parses: 95.4			

Table 1: Parse correction oracle UAS (%) for different neighborhood sizes, by dependent type (coordinating conjunctions, prepositions, or all dependents). Also, a reranking oracle for MSTParser using the top-100 parses.

We also compared the oracle for parse correction with an oracle for parse reranking, in which the parse with the highest UAS for a sentence is selected from the top-100 parses output by MSTParser. We found that for MSTParser, the oracle for parse correction using neighborhood size m=3 (95.6% UAS) is comparable to the oracle for parse reranking using the top-100 parses (95.4% UAS). This is an encouraging result, showing that parse correction is capable of the same improvement as parse reranking without needing to process an n-best list of parses.

6.2 Feature Space Parameters

For the feature space $\mathbb{F}$, we performed a grid search to find good values for the parameters K (frequency threshold), P (combo length), and CE-reduction. We found that P=3 with CE-reduction allowed for the most compactness without sacrificing correction performance, for all of our corrective models. Additionally, K=2 worked well for the coordinating conjunction models, while K=10 worked well for the preposition and generic models. CE-reduction proved useful in greatly reducing the feature space without lowering correction performance: it reduced the size of the coordinating conjunction models from 400k to 65k features each, the preposition models from 400k to 75k features each, and the generic models from 800k to 200k features each.

	Corrective Configuration	UAS (%)		
		Coords	Preps	Overall

	Generic	64.2*	86.2	91.25*
	Specialized	68.0*	86.2	91.36*

Table 2: Coordinating conjunction, preposition, and overall UAS (%) by corrective configuration on the test set. Significant improvements over the baseline starred.

6.3 Corrective Configurations

For our evaluation of parse correction, we compared two different configurations: *generic* (corrects all dependents using the generic model) and *specialized* (corrects coordinating conjunctions and prepositions using their respective specialized models, and corrects other dependents using the generic model). The PA-Ranking aggressiveness parameter C was set to 1 for our experiments, while the rounds parameter R was tuned separately for each corrective model using the dev set. For our final tests, we applied each combination of parser + corrective configuration by sequentially revising all dependents in the output parse that had a relevant POS tag given the corrective configuration. In the FTB test set, this amounted to an evaluation over 5,706 preposition tokens, 801 coordinating conjunction tokens, and 31,404 overall (non-punctuation) tokens.[11]

6.4 Results

Final results for the test set are shown in Table 2. The overall UAS of each parser (except BohnetParser) was significantly improved under both corrective configurations.[12] The *specialized* configuration performed as well as, and in most cases better than, the *generic* configuration, indicating the usefulness of specialized models and features for difficult attachment types. Interestingly, the lower the baseline parser's UAS, the larger the overall improvement from parse correction under the *specialized* configuration: MaltParser had the lowest baseline and the highest error reduction (6.8%), BerkeleyParser had the second-lowest baseline and the second-highest error reduction (5.4%), MSTParser had the third-lowest baseline and the third-highest error reduction (3.6%), and BohnetParser had the highest baseline and the lowest error reduction (1.2%). It may be that the additional errors made by a low-baseline parser, compared to a high-baseline parser, involve relatively simpler attachments that parse correction can better model.

Parse correction achieved significant improvements for coordination resolution under the *specialized* configuration for each parser. MaltParser and MSTParser had very low baseline coordinating conjunction UAS (around 60%), while BerkeleyParser and BohnetParser had higher baselines (around 70%). The highest error reduction was achieved by MSTParser (19.0%), followed by MaltParser (10.4%), BerkeleyParser (10.1%), and finally BohnetParser (7.5%). The result for MSTParser was surprising: although it had the second-highest baseline overall UAS, it shared the lowest baseline coordinating conjunction UAS and had the highest error reduction with parse correction. An explanation for this result is that the annotation scheme for coordination structure in the dependency FTB has the first conjunct governing the coordinating conjunction, which governs the second conjunct. Since MSTParser is limited to sibling 2-edge factors (cf. section 3), it is unable to jointly consider a full coordination structure. BohnetParser, which uses general 2-edge factors, can consider full coordination structures and consequently has a much higher baseline coordinating conjunction UAS than MSTParser.

Parse correction achieved significant but modest improvements in pp-attachment performance under the *specialized* configuration for MaltParser and BerkeleyParser. However, parse correction did not significantly improve pp-attachment performance for MSTParser or BohnetParser, the two parsers that had the highest baseline preposition UAS (around

[11] Since the MElt tagger and BerkeleyParser POS tagging accuracies were around 97%, the sets of tokens considered for revision differed slightly from the sets of tokens (with gold POS tags) used to calculate UAS scores.

[12] We used McNemar's Chi-squared test with $p = 0.05$ for all significance tests.

		Modification Type			
		$w \rightarrow c$	$c \rightarrow w$	$w \rightarrow w$	Mods

	Overall	183	88	117	1.1 %

Table 3: Breakdown of modifications made under the *specialized* configuration for each parser, by dependent type. $w \rightarrow c$ is wrong-to-correct, $c \rightarrow w$ is correct-to-wrong, $w \rightarrow w$ is wrong-to-wrong, and Mods is the percentage of tokens modified.

86%). These results are a bit disappointing, but they suggest that there may be a performance ceiling for pp-attachment beyond which rich lexical information (syntactic and semantic) or full sentence contexts are needed. For English, the average human performance on pp-attachment for the (v, n_1, p, n_2) problem formulation is just 88.2% when given only the four head-words, but increases to 93.2% when given the full sentence (Ratnaparkhi et al., 1994). If similar levels of human performance exist for French, additional sources of information may be needed to improve pp-attachment performance.

In addition to evaluating UAS improvements for parse correction, we took a closer look at the best corrective configuration (*specialized*) and analyzed the types of attachment modifications made (Table 3). In most cases there were around $2-3$ times as many error-correcting modifications ($w \rightarrow c$) as error-creating modifications ($c \rightarrow w$), and the overall % of tokens modified was very low overall (around 1-2%). Parse correction is thus conservative in the number of modifications made, and rather accurate when it does decide to modify an attachment.

Finally, we compared the running times of the four parsers, as well as that of parse correction, on the test set using a 2.66 GHz Intel Core 2 Duo machine. BerkeleyParser took 600s, BohnetParser took 450s using both cores (800s using a single core), MaltParser took 45s, and MSTParser took 1000s. A rough version of parse correction in the *specialized* configuration took around 200s (for each parser). An interesting result is that parse correction improves MaltParser the most while retaining an overall time complexity of $O(n)$, compared to $O(n^3)$ or higher for the other parsers. This suggests that linear-time transition-based parsing and parse correction could combine to form an attractive system that improves parsing performance while retaining high speed.

7 Conclusion

We have developed a parse correction framework for syntactic dependency parsing that uses specialized models for difficult attachment types. Candidate governors for a given dependent are identified in a neighborhood around the predicted governor, and a scoring function selects the best governor. We used discriminative linear ranking models with features encoding syntactic context, and we tested parse correction on coordination, pp-attachment, and generic dependencies in the outputs of four representative statistical dependency parsers for French. Parse correction achieved improvements in unlabeled attachment score for three out of the four parsers, with MaltParser seeing the greatest improvement. Since both MaltParser and parse correction run in $O(n)$ time, a combined system could prove useful in situations where high parsing speed is required.

Future work on parse correction might focus on developing specialized models for other difficult attachment types, such as verb-phrase attachment (verb dependents account for around 15% of incorrect attachments across all four parsers). Also, selectional preferences and subcategorization frames (from hand-built resources or extracted using distributional methods) could make for useful features in the pp-attachment corrective model; we suspect that richer lexical information is needed in order to increase the currently modest improvements achieved by parse correction on pp-attachment.

Abstract

We describe a generative model for non-projective dependency parsing based on a simplified version of a transition system that has recently appeared in the literature. We then develop a dynamic programming parsing algorithm for our model, and derive an inside-outside algorithm that can be used for unsupervised learning of non-projective dependency trees.

1 Introduction

Dependency grammars have received considerable attention in the statistical parsing community in recent years. These grammatical formalisms offer a good balance between structural expressivity and processing efficiency. Most notably, when non-projectivity is supported, these formalisms can model crossing syntactic relations that are typical in languages with relatively free word order.

Recent work has reduced non-projective parsing to the identification of a maximum spanning tree in a graph (McDonald et al., 2005; Koo et al., 2007; McDonald and Satta, 2007; Smith and Smith, 2007). An alternative to this approach is to use transition-based parsing (Yamada and Matsumoto, 2003; Nivre and Nilsson, 2005; Attardi, 2006; Nivre, 2009; Gómez-Rodríguez and Nivre, 2010), where there is an incremental processing of a string with a model that scores transitions between parser states, conditioned on the parse history. This paper focuses on the latter approach.

The above work on transition-based parsing has focused on greedy algorithms set in a statistical framework (Nivre, 2008). More recently, dynamic programming has been successfully used for projective parsing (Huang and Sagae, 2010; Kuhlmann et al., 2011). Dynamic programming algorithms for parsing (also known as chart-based algorithms) allow polynomial space representations of all parse trees for a given input string, even in cases where the size of this set is exponential in the length of the string itself. In combination with appropriate semirings, these packed representations can be exploited to compute many values of interest for machine learning, such as best parses and feature expectations (Goodman, 1999; Li and Eisner, 2009).

In this paper we move one step forward with respect to Huang and Sagae (2010) and Kuhlmann et al. (2011) and present a polynomial dynamic programming algorithm for non-projective transition-based parsing. Our algorithm is coupled with a simplified version of the transition system from Attardi (2006), which has high coverage for the type of non-projective structures that appear in various treebanks. Instead of an additional transition operation which permits swapping of two elements in the stack (Titov et al., 2009; Nivre, 2009), Attardi's system allows reduction of elements at non-adjacent positions in the stack. We also present a *generative* probabilistic model for transition-based parsing. The implication for this, for example, is that one can now approach the problem of unsupervised learning of non-projective dependency structures within the transition-based framework.

Dynamic programming algorithms for non-projective parsing have been proposed by Kahane et al. (1998), Gómez-Rodríguez et al. (2009) and Kuhlmann and Satta (2009), but they all run in exponential time in the 'gap degree' of the parsed structures. To the best of our knowledge, this paper is the first to

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1234–1245,
Edinburgh, Scotland, UK, July 27–31, 2011.

introduce a dynamic programming algorithm for inference with non-projective structures of unbounded gap degree.

The rest of this paper is organized as follows. In §2 and §3 we outline the transition-based model we use, together with a probabilistic generative interpretation. In §4 we give the tabular algorithm for parsing, and in §5 we discuss statistical inference using expectation maximization. We then discuss some other aspects of the work in §6 and conclude in §7.

2 Transition-based Dependency Parsing

In this section we briefly introduce the basic definitions for transition-based dependency parsing. For a more detailed presentation of this subject, we refer the reader to Nivre (2008). We then define a specific transition-based model for non-projective dependency parsing that we investigate in this paper.

2.1 General Transition Systems

Assume an input alphabet Σ with a special symbol $\$ \in \Sigma$, which we use as the root of our parse structures. Throughout this paper we denote the input string as $w = a_0 \cdots a_{n-1}$, $n \geq 1$, where $a_0 = \$$ and $a_i \in \Sigma \setminus \{\$\}$ for each i with $1 \leq i \leq n-1$.

A **dependency tree** for w is a directed tree $G_w = (V_w, A_w)$, where $V_w = \{0, \ldots, n-1\}$ is the set of nodes, and $A_w \subseteq V_w \times V_w$ is the set of arcs. The root of G_w is the node 0. The intended meaning is that each node in V_w encodes the position of a token in w. Furthermore, each arc in A_w encodes a dependency relation between two tokens. We write $i \rightarrow j$ to denote a directed arc $(i, j) \in A_w$, where node i is the head and node j is the dependent.

A **transition system** (for dependency parsing) is a tuple $S = (C, T, I, C_t)$, where C is a set of configurations, defined below, T is a finite set of **transitions**, which are partial functions $t\colon C \rightharpoonup C$, I is a total initialization function mapping each input string to a unique initial configuration, and $C_t \subseteq C$ is a set of terminal configurations.

A **configuration** is defined relative to some input string w, and is a triple (σ, β, A), where σ and β are disjoint lists called **stack** and **buffer**, respectively, and $A \subseteq V_w \times V_w$ is a set of arcs. Elements of σ and β are nodes from V_w and, in the case of the stack, a special symbol ¢ that we will use as initial stack symbol. If t is a transition and c_1, c_2 are configurations such that $t(c_1) = c_2$, we write $c_1 \vdash_t c_2$, or simply $c_1 \vdash c_2$ if t is understood from the context.

Given an input string w, a parser based on S incrementally processes w from left to right, starting in the initial configuration $I(w)$. At each step, the parser nondeterministically applies one transition, or else it stops if it has reached some terminal configuration. The dependency graph defined by the arc set associated with a terminal configuration is then returned as one possible analysis for w.

Formally, a **computation** of S is a sequence $\gamma = c_0, \ldots, c_m$, $m \geq 1$, of configurations such that, for every i with $1 \leq i \leq m$, $c_{i-1} \vdash_{t_i} c_i$ for some $t_i \in T$. In other words, each configuration in a computation is obtained as the value of the preceding configuration under some transition. A computation is called **complete** whenever $c_0 = I(w)$ for some input string w, and $c_m \in C_t$.

We can view a transition-based dependency parser as a device mapping strings into graphs (dependency trees). Without any restriction on transition functions in T, these functions might have an infinite domain, and could thus encode even non-recursively enumerable languages. However, in standard practice for natural language parsing, transitions are always specified by some finite mean. In particular, the definition of each transition depends on some finite window at the top of the stack and some finite window at the beginning of the buffer in each configuration. In this case, we can view a transition-based dependency parser as a notational variant of a push-down transducer (Hopcroft et al., 2000), whose computations output sequences that directly encode dependency trees. These transducers are nondeterministic, meaning that several transitions can be applied to some configurations. The transition systems we investigate in this paper follow these principles.

We close this subsection with some additional notation. We denote the stack with its topmost element to the right and the buffer with its first element to the left. We indicate concatenation in the stack and buffer by a vertical bar. For example, for $k \in V_w$, $\sigma|k$ denotes some stack with topmost element k and $k|\beta$ denotes some buffer with first element k. For $0 \leq i \leq n-1$, β_i denotes the buffer

$[i, i+1, \ldots, n-1]$; for $i \geq n$, β_i denotes [] (the empty buffer).

2.2 A Non-projective Transition System

We now turn to give a description of our transition system for non-projective parsing. While a projective dependency tree satisfies the requirement that, for every arc in the tree, there is a directed path between its headword and each of the words between the two endpoints of the arc, a non-projective dependency tree may violate this condition. Even though some natural languages exhibit syntactic phenomena which require non-projective expressive power, most often such a resource is used in a limited way.

This idea is demonstrated by Attardi (2006), who proposes a transition system whose individual transitions can deal with non-projective dependencies only to a limited extent, depending on the distance in the stack of the nodes involved in the newly constructed dependency. The author defines this distance as the **degree** of the transition, with transitions of degree one being able to handle only projective dependencies. This formulation permits parsing a subset of the non-projective trees, where this subset depends on the degree of the transitions. The reported coverage in Attardi (2006) is already very high when the system is restricted to transitions of degree two or three. For instance, on training data for Czech containing 28,934 non-projective relations, 27,181 can be handled by degree two transitions, and 1,668 additional dependencies can be handled by degree three transitions. Table 1 gives additional statistics for treebanks from the CoNLL-X shared task (Buchholz and Marsi, 2006).

We now turn to describe our variant of the transition system of Attardi (2006), which is equivalent to the original system restricted to transitions of degree two. Our results are based on such a restriction. It is not difficult to extend our algorithms (§4) to higher degree transitions, but this comes at the expense of higher complexity. See §6 for more discussion on this issue.

Let $w = a_0 \cdots a_{n-1}$ be an input string over Σ defined as in §2.1, with $a_0 = \$$. Our transition system for non-projective dependency parsing is

$$S^{(\mathrm{np})} = (C, T^{(\mathrm{np})}, I^{(\mathrm{np})}, C_t^{(\mathrm{np})}),$$

Language	Deg. 2	Deg. 3	Deg. 4

Japanese	1484	143	9
Portuguese	3104	424	37
Slovene	601	48	13
Spanish	66	7	0
Swedish	1566	226	79
Turkish	579	185	8

Table 1: The number of non-projective relations of various degrees for several treebanks (training sets), as reported by the parser of Attardi (2006). Deg. stands for 'degree.' The parser did not detect non-projective relations of degree higher than 4.

where C is the same set of configurations defined in §2.1. The initialization function $I^{(\mathrm{np})}$ maps each string w to the initial configuration $([\dot{\varsigma}], \beta_0, \emptyset)$. The set of terminal configurations $C_t^{(\mathrm{np})}$ contains all configurations of the form $([\dot{\varsigma}, 0], [], A)$, for any set of arcs A.

The set of transition functions is defined as

$$T^{(\mathrm{np})} = \{\mathsf{sh}_b \mid b \in \Sigma\} \cup \{\mathsf{la}_1, \mathsf{ra}_1, \mathsf{la}_2, \mathsf{ra}_2\},$$

where each transition is specified below. We let variables i, j, k, l range over V_w, and variable σ is a list of stack elements from $V_w \cup \{\dot{\varsigma}\}$:

$$\begin{aligned}
\mathsf{sh}_b: &\quad (\sigma, k|\beta, A) \vdash (\sigma|k, \beta, A) \text{ if } a_k = b;\\
\mathsf{la}_1: &\quad (\sigma|i|j, \beta, A) \vdash (\sigma|j, \beta, A \cup \{j \rightarrow i\});\\
\mathsf{ra}_1: &\quad (\sigma|i|j, \beta, A) \vdash (\sigma|i, \beta, A \cup \{i \rightarrow j\});\\
\mathsf{la}_2: &\quad (\sigma|i|j|k, \beta, A) \vdash (\sigma|j|k, \beta, A \cup \{k \rightarrow i\});\\
\mathsf{ra}_2: &\quad (\sigma|i|j|k, \beta, A) \vdash (\sigma|i|j, \beta, A \cup \{i \rightarrow k\}).
\end{aligned}$$

Each of the above transitions is undefined on configurations that do not match the forms specified above. As an example, transition la_2 is not defined for a configuration (σ, β, A) with $|\sigma| \leq 2$, and transition sh_b is not defined for a configuration $(\sigma, k|\beta, A)$ with $b \neq a_k$, or for a configuration $(\sigma, [], A)$.

Transition sh_b removes the first node from the buffer, in case this node represents symbol $b \in \Sigma$,

and pushes it into the stack. These transitions are called **shift** transitions. The remaining four transitions are called **reduce** transitions, i.e., transitions that consume nodes from the stack. Notice that in the transition system at hand all the reduce transitions decrease the size of the stack by one element. Transition la_1 creates a new arc with the topmost node on the stack as the head and the second-topmost node as the dependent, and removes the latter from the stack. Transition ra_1 is symmetric with respect to la_1. Transitions la_1 and ra_1 have degree one, as already explained. When restricted to these three transitions, the system is equivalent to the so-called stack-based arc-standard model of Nivre (2004). Transition la_2 and transition ra_2 are very similar to la_1 and ra_1, respectively, but with the difference that they create a new arc between the topmost node in the stack and a node which is two positions below the topmost node. Hence, these transitions have degree two, and are the key components in parsing of non-projective dependencies.

We turn next to describe the equivalence between our system and the system in Attardi (2006). The transition-based parser presented by Attardi pushes back into the buffer elements that are in the top position of the stack. However, a careful analysis shows that only the first position in the buffer can be affected by this operation, in the sense that elements that are pushed back from the stack are never found in buffer positions other than the first. This means that we can consider the first element of the buffer as an additional stack element, always sitting on the top of the top-most stack symbol.

More formally, we can define a function $m_c : C \rightarrow C$ that maps configurations in the original algorithm to those in our variant as follows:

$$m_c((\sigma, k|\beta, A)) = (\sigma|k, \beta, A)$$

By applying this mapping to the source and target configuration of each transition in the original system, it is easy to check that $c_1 \vdash c_2$ in that parser if and only if $m_c(c_1) \vdash m_c(c_2)$ in our variant. We extend this and define an isomorphism between computations in both systems, such that a computation $c_0, \ldots, c_m$ in the original parser is mapped to a computation $m_c(c_0), \ldots, m_c(c_m)$ in the variant, with both generating the same dependency graph A. This proves that our notational variant is in fact equivalent to Attardi's parser.

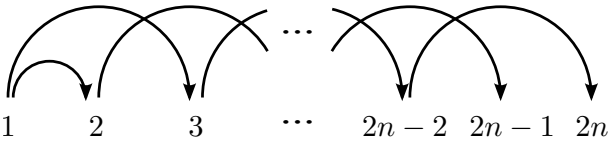

Figure 1: A dependency structure of arbitrary gap degree that can be parsed with Attardi's parser.

A relevant property of the set of dependency structures that can be processed by Attardi's parser, even when restricted to transitions of degree two, is that the number of discontinuities present in each of their subtrees, defined as the **gap degree** by Bodirsky et al. (2005), is not bounded. For example, the dependency graph in Figure 1 has gap degree $n - 1$, and it can be parsed by the algorithm for any arbitrary $n \geq 1$ by applying $2n$ sh_b transitions to push all the nodes into the stack, followed by $(2n - 2)$ ra_2 transitions to create the crossing arcs, and finally one ra_1 transition to create the dependency $1 \rightarrow 2$.

As mentioned in §1, the computational complexity of the dynamic programming algorithm that will be described in later sections does not depend on the gap degree, contrary to the non-projective dependency chart parsers presented by Gómez-Rodríguez et al. (2009) and by Kuhlmann and Satta (2009), whose running time is exponential in the maximum gap degree allowed by the grammar.

3 A Generative Probabilistic Model

In this section we introduce a generative probabilistic model based on the transition system of §2.2. In formal language theory, there is a standard way of giving a probabilistic interpretation to a non-deterministic parser whose computations are based on sequences of elementary operations such as transitions. The idea is to define conditional probability distributions over instances of the transition functions, and to 'combine' these probabilities to assign probabilities to computations and strings.

One difficulty we have to face with when dealing with transition systems is that the notion of computation, defined in §2.1, depends on the input string, because of the buffer component appearing in each configuration. This is a pitfall to generative model-

ing, where we are interested in a system whose computations lead to the *generation* of any string. To overcome this problem, we observe that each computation, defined as a sequence of stacks and buffers (the configurations) can equivalently be expressed as a sequence of stacks and transitions.

More precisely, consider a computation $\gamma = c_0, \ldots, c_m$, $m \geq 1$. Let σ_i, be the stack associated with c_i, for each i with $0 \leq i \leq m$. Let also C_σ be the set of all stacks associated with configurations in C. We can make explicit the transitions that have been used in the computation by rewriting γ in the form $\sigma_0 \vdash_{t_1} \sigma_1 \cdots \sigma_{m-1} \vdash_{t_m} \sigma_m$. In this way, γ generates a string that is composed by all symbols that are pushed into the stack by transitions sh_b, in the left to right order.

We can now associate a probability to (our representation of) sequence γ by setting

$$p(\gamma) = \prod_{i=1}^{m} p(t_i \mid \sigma_{i-1}). \tag{1}$$

To assign probabilities to complete computations we should further multiply $p(\gamma)$ by factors $p_s(\sigma_0)$ and $p_e(\sigma_m)$, where p_s and p_e are start and end probability distributions, respectively, both defined over C_σ. Note however that, as defined in §2.2, all initial configurations are associated with stack $[\dot{\varsigma}]$ and all final configurations are associated with stack $[\dot{\varsigma}, 0]$, thus p_s and p_e are deterministic. Note that the Markov chain represented in Eq. 1 is *homogeneous*, i.e., the probabilities of the transition operations do not depend on the time step.

As a second step we observe that, according to the definition of transition system, each $t \in T$ has an infinite domain. A commonly adopted solution is to introduce a special function, called **history** function and denoted by H, defined over the set C_σ and taking values over some finite set. For each $t \in T$ and $\sigma, \sigma' \in C_\sigma$, we then impose the condition

$$p(t \mid \sigma) = p(t \mid \sigma')$$

whenever $H(\sigma) = H(\sigma')$. Since H is finitely valued, and since T is a finite set, the above condition guarantees that there will only be a finite number of parameters $p(t \mid \sigma)$ in our model.

So far we have presented a general discussion of how to turn a transition-based parser into a generative probabilistic model, and have avoided further specification of the history function. We now turn our attention to the non-projective transition system of §2.2. To actually transform that system into a parametrized probabilistic model, and to develop an associated efficient inference procedure as well, we need to balance between the amount of information we put into the history function and the computational complexity which is required for inference.

We start the discussion with a naïve model using a history function defined by a fixed size window over the topmost portion of the stack. More precisely, each transition is conditioned on the lexical form of the three symbols at the top of the stack σ, indicated as $b_3, b_2, b_1 \in \Sigma$ below, with b_1 referring to the topmost symbol. The parameters of the model are defined as follows.

$$\begin{aligned}
p(\mathsf{sh}_b \mid b_3, b_2, b_1) &= \theta^{\mathsf{sh}_b}_{b_3,b_2,b_1} \ , \quad \forall b \in \Sigma \ , \\
p(\mathsf{la}_1 \mid b_3, b_2, b_1) &= \theta^{\mathsf{la}_1}_{b_3,b_2,b_1} \ , \\
p(\mathsf{ra}_1 \mid b_3, b_2, b_1) &= \theta^{\mathsf{ra}_1}_{b_3,b_2,b_1} \ , \\
p(\mathsf{la}_2 \mid b_3, b_2, b_1) &= \theta^{\mathsf{la}_2}_{b_3,b_2,b_1} \ , \\
p(\mathsf{ra}_2 \mid b_3, b_2, b_1) &= \theta^{\mathsf{ra}_2}_{b_3,b_2,b_1} \ .
\end{aligned}$$

The parameters above are subject to the following normalization conditions, for every choice of $b_3, b_2, b_1 \in \Sigma$:

$$\begin{aligned}
&\theta^{\mathsf{la}_1}_{b_3,b_2,b_1} + \theta^{\mathsf{ra}_1}_{b_3,b_2,b_1} + \theta^{\mathsf{la}_2}_{b_3,b_2,b_1} + \\
&\theta^{\mathsf{ra}_2}_{b_3,b_2,b_1} + \sum_{b \in \Sigma} \theta^{\mathsf{sh}_b}_{b_3,b_2,b_1} = 1 \ .
\end{aligned}$$

This naïve model presents two practical problems. The first problem relates to the efficiency of an inference algorithm, which has a quite high computational complexity, as it will be discussed in §5. A second problem arises in the probabilistic setting. Using this model would require estimating many parameters which are based on trigrams. This leads to higher sample complexity to avoid sparse counts: we would need more samples to accurately estimate the model.

We therefore consider a more elaborated model, which tackles both of the above problems. Again, let $b_3, b_2, b_1 \in \Sigma$ indicate the lexical form of the three symbols at the top of the stack. We define the

distributions $p(t \mid \sigma)$ as follows:

$$p(\mathsf{sh}_b \mid b_1) = \theta_{b_1}^{\mathsf{sh}_b}, \ \ \forall b \in \Sigma \ ,$$
$$p(\mathsf{la}_1 \mid b_2, b_1) = \theta_{b_1}^{\mathsf{rd}} \cdot \theta_{b_2,b_1}^{\mathsf{la}_1} \ ,$$
$$p(\mathsf{ra}_1 \mid b_2, b_1) = \theta_{b_1}^{\mathsf{rd}} \cdot \theta_{b_2,b_1}^{\mathsf{ra}_1} \ ,$$
$$p(\mathsf{la}_2 \mid b_3, b_2, b_1) = \theta_{b_1}^{\mathsf{rd}} \cdot \theta_{b_2,b_1}^{\mathsf{rd}_2} \cdot \theta_{b_3,b_2,b_1}^{\mathsf{la}_2} \ ,$$
$$p(\mathsf{ra}_2 \mid b_3, b_2, b_1) = \theta_{b_1}^{\mathsf{rd}} \cdot \theta_{b_2,b_1}^{\mathsf{rd}_2} \cdot \theta_{b_3,b_2,b_1}^{\mathsf{ra}_2} \ .$$

The parameters above are subject to the following normalization conditions, for every $b_3, b_2, b_1 \in \Sigma$:

$$\sum_{b \in \Sigma} \theta_{b_1}^{\mathsf{sh}_b} + \theta_{b_1}^{\mathsf{rd}} = 1 \ , \tag{2}$$
$$\theta_{b_2,b_1}^{\mathsf{la}_1} + \theta_{b_2,b_1}^{\mathsf{ra}_1} + \theta_{b_2,b_1}^{\mathsf{rd}_2} = 1 \ , \tag{3}$$
$$\theta_{b_3,b_2,b_1}^{\mathsf{la}_2} + \theta_{b_3,b_2,b_1}^{\mathsf{ra}_2} = 1 \ . \tag{4}$$

Intuitively, parameter θ_b^{rd} denotes the probability that we perform a reduce transition instead of a shift transition, given that we have seen lexical form b at the top of the stack. Similarly, parameter $\theta_{b_2,b_1}^{\mathsf{rd}_2}$ denotes the probability that we perform a reduce transition of degree 2 (see §2.2) instead of a reduce transition of degree 1, given that we have seen lexical forms b_1 and b_2 at the top of the stack.

We observe that the above model has a number of parameters $|\Sigma| + 4 \cdot |\Sigma|^2 + 2 \cdot |\Sigma|^3$ (not all independent). This should be contrasted with the naïve model, that has a number of parameters $4 \cdot |\Sigma|^3 + |\Sigma|^4$.

4 Tabular parsing

We present here a dynamic programming algorithm for simulating the computations of the system from §2–3. Given an input string w, our algorithm produces a compact representation of the set $\Gamma(w)$, defined as the set of all possible computations of the model when processing w. In combination with the appropriate semirings, this method can provide for instance the highest probability computation in $\Gamma(w)$, or else the probability of w, defined as the sum of all probabilities of computations in $\Gamma(w)$.

We follow a standard approach in the literature on dynamic programming simulation of stack-based automata (Lang, 1974; Tomita, 1986; Billot and Lang, 1989). More recently, this approach has also been applied by Huang and Sagae (2010) and by Kuhlmann et al. (2011) to the simulation of projective transition-based parsers. The basic idea in this approach is to decompose computations of the parser into smaller parts, group them into equivalence classes and recombine to obtain larger parts of computations.

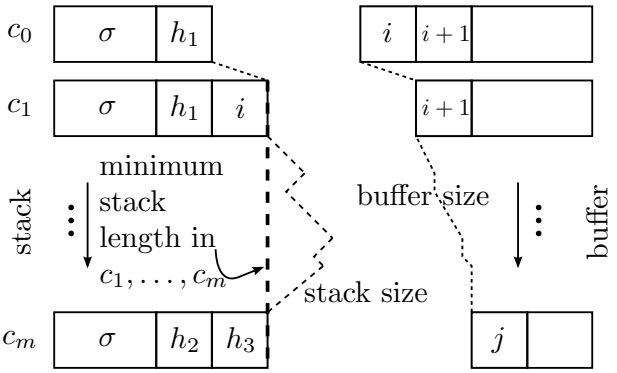

Figure 2: Schematic representation of the computations γ associated with item $[h_1, i, h_2 h_3, j]$.

Let $w = a_0 \cdots a_{n-1}$, V_w and $S^{(np)}$ be defined as in §2. We use a structure called **item**, defined as

$$[h_1, i, h_2 h_3, j],$$

where $0 \leq i < j \leq n$ and $h_1, h_2, h_3 \in V_w$ must satisfy $h_1 < i$ and $i \leq h_2 < h_3 < j$. The intended interpretation of an item can be stated as follows; see also Figure 2.

- There exists a computation γ of $S^{(\mathrm{np})}$ on w having the form $c_0, \ldots, c_m$, $m \geq 1$, with $c_0 = (\sigma | h_1, \beta_i, A)$ and $c_m = (\sigma | h_2 | h_3, \beta_j, A')$ for some stack σ and some arc sets A and A';
- For each i with $1 \leq i < m$, the stack σ_i associated with configuration c_i has the list σ at the bottom and satisfies $|\sigma_i| \geq |\sigma| + 2$.

Some comments on the above conditions are in order here. Let $t_1, \cdots, t_m$ be the sequence of transitions in $T^{(np)}$ associated with computation γ. Then we have $t_1 = \mathsf{sh}_{a_i}$, since $|\sigma_1| \geq |\sigma| + 2$. Thus we conclude that $|\sigma_1| = |\sigma| + 2$.

The most important consequence of the definition of item is that each transition t_i with $2 \leq i \leq m$ does not depend on the content of the σ portion of the stack σ_i. To see this, consider transition $c_{i-1} \vdash_{t_i} c_i$. If $t_i = \mathsf{sh}_{a_i}$, the content of σ is irrelevant at

this step, since in our model sh_{a_i} is conditioned only on the topmost stack symbol of σ_{i-1}, and we have $|\sigma_{i-1}| \geq |\sigma| + 2$.

Consider now the case of $t_i = \mathsf{la}_2$. From $|\sigma_i| \geq |\sigma| + 2$ we have that $|\sigma_{i-1}| \geq |\sigma| + 3$. Again, the content of σ is irrelevant at this step, since in our model la_2 is conditioned only on the three topmost stack symbols of σ_{i-1}. A similar argument applies to the cases of $t_i \in \{\mathsf{ra}_2, \mathsf{la}_1, \mathsf{ra}_1\}$.

From the above, we conclude that if we apply the transitions $t_1, \ldots, t_m$ to stacks of the form $\sigma|h_1$, the resulting computations have all identical probabilities, independently of the choice of σ.

Each computation satisfying the two conditions above will be called an **I-computation** associated with item $[h_1, i, h_2 h_3, j]$. Notice that an I-computation has the overall effect of replacing node h_1 sitting above a stack σ with nodes h_2 and h_3. This is the key property in the development of our algorithm below.

We specify our dynamic programming algorithm as a deduction system (Shieber et al., 1995). The deduction system starts with axiom $[\dot{\varsigma}, 0, \dot{\varsigma}0, 1]$, corresponding to an initial stack $[\dot{\varsigma}]$ and to the shift of $a_0 = \$$ from the buffer into the stack. The set $\Gamma(w)$ is non-empty if and only if item $[\dot{\varsigma}, 0, \dot{\varsigma}0, n]$ can be derived using the inference rules specified below. Each inference rule is annotated with the type of transition it simulates, along with the arc constructed by the transition itself, if any.

$$\frac{[h_1, i, h_2 h_3, j]}{[h_3, j, h_3 j, j+1]} \ (\mathsf{sh}_{a_j})$$

$$\frac{[h_1, i, h_2 h_3, k] \quad [h_3, k, h_4 h_5, j]}{[h_1, i, h_2 h_5, j]} \ (\mathsf{la}_1; h_5 \rightarrow h_4)$$

$$\frac{[h_1, i, h_2 h_3, k] \quad [h_3, k, h_4 h_5, j]}{[h_1, i, h_2 h_4, j]} \ (\mathsf{ra}_1; h_4 \rightarrow h_5)$$

$$\frac{[h_1, i, h_2 h_3, k] \quad [h_3, k, h_4 h_5, j]}{[h_1, i, h_4 h_5, j]} \ (\mathsf{la}_2; h_5 \rightarrow h_2)$$

$$\frac{[h_1, i, h_2 h_3, k] \quad [h_3, k, h_4 h_5, j]}{[h_1, i, h_2 h_4, j]} \ (\mathsf{ra}_2; h_2 \rightarrow h_5)$$

The above deduction system infers items in a bottom-up fashion. This means that longer computations over substrings of w are built by combining shorter ones. In particular, the inference rule sh_{a_j} asserts the existence of I-computations consisting of a single sh_{a_j} transition. Such computations are represented by the consequent item $[h_3, j, h_3 j, j+1]$, indicating that the index of the shifted word a_j is added to the stack by pushing it on top of h_3.

The remaining four rules implement the reduce transitions of the model. We have already observed in §2.2 that all available reduce transitions shorten the size of the stack by one unit. This allows us to combine pairs of I-computations with a reduce transition, resulting in a computation that is again an I-computation. More precisely, if we concatenate an I-computation asserted by an item $[h_1, i, h_2 h_3, k]$ with an I-computation asserted by an item $[h_3, k, h_4 h_5, j]$, we obtain a computation that has the overall effect of increasing the size of the stack by 2, replacing the topmost stack element h_1 with stack elements h_2, h_4 and h_5. If we now apply any of the reduce transitions from the inventory of the model, we will remove one of these three nodes from the stack, and the overall result will be again an I-computation, which can then be asserted by a certain item. For example, if we apply the reduce transition la_1, the consequent item is $[h_1, i, h_2 h_5, j]$, since an la_1 transition removes the second topmost element from the stack (h_4). The other reduce transitions remove a different element, and thus their rules produce different consequent items.

The above argument shows the soundness of the deduction system, i.e., an item $I = [h_1, i, h_2 h_3, j]$ is only generated if there exists an I-computation $\gamma = c_0, \ldots, c_m$ with $c_0 = (\sigma|h_1, \beta_i, A)$ and $c_m = (\sigma|h_2|h_3, \beta_j, A')$. To prove completeness, we must show the converse result, i.e., that the existence of an I-computation γ implies that item I is inferred. We first do this under the assumption that the inference rule for the shift transitions do not have an antecedent, i.e., items $[h_1, j, h_1 j, j+1]$ are considered as axioms. We proceed by using strong induction on the length m of the computation γ.

For $m = 1$, γ consists of a single transition sh_{a_j}, and the corresponding item $I = [h_1, j, h_1 j, j+1]$ is constructed as an axiom. For $m > 1$, let γ be as specified above. The transition that produced

c_m must have been a reduce transition, otherwise γ would not be an I-computation. Let c_k be the rightmost configuration in $c_0, \ldots, c_{m-1}$ whose stack size is $|\sigma| + 2$. Then it can be shown that the computations $\gamma_1 = c_0, \ldots, c_k$ and $\gamma_2 = c_k, \ldots, c_{m-1}$ are again I-computations. Since γ_1 and γ_2 have strictly fewer transitions than γ, by the induction hypothesis, the system constructs items $[h_1, i, h_2 h_3, k]$ and $[h_3, k, h_4 h_5, j]$, where h_2 and h_3 are the stack elements at the top of c_k. Applying to these items the inference rule corresponding to the reduce transition at hand, we can construct item I.

When the inference rule for the shift transition has an antecedent $[h_1, i, h_2 h_3, j]$, as indicated above, we have the overall effect that I-computations consisting of a single transition shifting a_j on the top of h_3 are simulated only in case there exists a computation starting with configuration $([\text{¢}], \beta_0)$ and reaching a configuration of the form $(\sigma | h_2 | h_3, \beta_j)$. This acts as a filter on the search space of the algorithm, but does not invalidate the completeness property. However, in this case the proof is considerably more involved, and we do not report it here.

An important property of the deduction system above, which will be used in the next section, is that the system is unambiguous, that is, each **I-computation** is constructed by the system in a unique way. This can be seen by observing that, in the sketch of the completeness proof reported above, there always is an unique choice of c_k that decomposes I-computation γ into I-computations γ_1 and γ_2. In fact, if we choose a configuration $c_{k'}$ other than c_k with stack size $|\sigma| + 2$, the computation $\gamma_2' = c_{k'}, \ldots, c_{m-1}$ will contain c_k as an intermediate configuration, which violates the definition of I-computation because of an intervening stack having size not larger than the size of the stack associated with the initial configuration.

As a final remark, we observe that we can keep track of all inference rules that have been applied in the computation of each item by the above algorithm, by encoding each application of a rule as a reference to the pair of items that were taken as antecedent in the inference. In this way, we obtain a parse forest structure that can be viewed as a hypergraph or as a non-recursive context-free grammar, similar to the case of parsing based on context-free grammars. See for instance Klein and Manning (2001) or Nederhof (2003). Such a parse forest encodes all valid computations in $\Gamma(w)$, as desired.

The algorithm runs in $\mathcal{O}(n^8)$ time. Using methods similar to those specified in Eisner and Satta (1999), we can reduce the running time to $\mathcal{O}(n^7)$. However, we do not further pursue this idea here, and proceed with the discussion of exact inference, found in the next section.

5 Inference

We turn next to specify exact inference with our model, for computing feature expectations. Such inference enables, for example, the derivation of an expectation-maximization algorithm for unsupervised parsing.

Here, a feature is a function over computations, providing the count of a pattern related to a parameter. We denote by $f^{\mathsf{la}_2}_{b_3,b_2,b_1}(\gamma)$, for instance, the number of occurrences of transition la_2 within γ with topmost stack symbols having word forms $b_3, b_2, b_1 \in \Sigma$, with b_1 associated with the topmost stack symbol.

Feature expectations are computed by using an inside-outside algorithm for the items in the tabular algorithm. More specifically, given a string w, we associate each item $[h_1, i, h_2 h_3, j]$ defined as in §4 with two quantities:

$$I([h_1, i, h_2 h_3, j]) = \sum_{\gamma = ([h_1], \beta_i), \ldots, ([h_2, h_3], \beta_j)} p(\gamma) \; ; \tag{5}$$

$$O([h_1, i, h_2 h_3, j]) = \sum_{\substack{\sigma, \gamma = ([\text{¢}], \beta_0), \ldots, (\sigma | h_1, \beta_i) \\ \gamma' = (\sigma | h_2 | h_3, \beta_j), \ldots, ([\text{¢}, 0], \beta_n)}} p(\gamma) \cdot p(\gamma') \; . \tag{6}$$

$I([h_1, i, h_2 h_3, j])$ and $O([h_1, i, h_2 h_3, j])$ are called the **inside** and the **outside** probabilities, respectively, of item $[h_1, i, h_2 h_3, j]$. The tabular algorithm of §4 can be used to compute the inside probabilities. Using the gradient transformation (Eisner et al., 2005), a technique for deriving outside probabilities from a set of inference rules, we can also compute $O([h_1, i, h_2 h_3, j])$. The use of the gradient transformation is valid in our case because the tabular algorithm is unambiguous (see §4).

Using the inside and outside probabilities, we can now efficiently compute feature expectations for our

$$E_{p(\gamma|w)}[f^{\mathsf{la}_2}_{b_3,b_2,b_1}(\gamma)] = \sum_{\gamma \in \Gamma(w)} p(\gamma \mid w) \cdot f^{\mathsf{la}_2}_{b_3,b_2,b_1}(\gamma) = \frac{1}{p(w)} \cdot \sum_{\gamma \in \Gamma(w)} p(\gamma) \cdot f^{\mathsf{la}_2}_{b_3,b_2,b_1}(\gamma)$$

$$= \frac{1}{p(w)} \cdot \sum_{\substack{\sigma,i,k,j,\\ h_1,h_2,h_3,h_4,h_5,\\ \text{s.t. } a_{h_2}=b_3,\\ a_{h_4}=b_2,\, a_{h_5}=b_1}} \sum_{\substack{\gamma_0=([\c{c}],\beta_0),\ldots,(\sigma|h_1,\beta_i),\\ \gamma_1=(\sigma|h_1,\beta_i),\ldots,(\sigma|h_2|h_3,\beta_k),\\ \gamma_2=(\sigma|h_2|h_3,\beta_k),\ldots,(\sigma|h_2|h_4|h_5,\beta_j),\\ \gamma_3=(\sigma|h_2|h_5,\beta_j),\ldots,([\c{c},0],\beta_n)}} p(\gamma_0) \cdot p(\gamma_1) \cdot p(\gamma_2) \cdot p(\mathsf{la}_2 \mid b_3, b_2, b_1) \cdot p(\gamma_3)$$

$$= \frac{\theta^{\mathsf{rd}}_{b_1} \cdot \theta^{\mathsf{rd}_2}_{b_2,b_1} \cdot \theta^{\mathsf{la}_2}_{b_3,b_2,b_1}}{p(w)} \cdot \sum_{\substack{\sigma,i,j,\\ h_1,h_2,h_5,\text{ s.t.}\\ a_{h_2}=b_3,\, a_{h_5}=b_1}} \sum_{\substack{\gamma_0=([\c{c}],\beta_0),\ldots,(\sigma|h_1,\beta_i),\\ \gamma_3=(\sigma|h_2|h_5,\beta_j),\ldots,([\c{c},0],\beta_n)}} p(\gamma_0) \cdot p(\gamma_3) \cdot$$

$$\cdot \sum_{\substack{k,h_3,h_4,\\ \text{s.t. } a_{h_4}=b_2}} \sum_{\gamma_1=(\sigma|h_1,\beta_i),\ldots,(\sigma|h_2|h_3,\beta_k)} p(\gamma_1) \cdot \sum_{\gamma_2=(\sigma|h_2|h_3,\beta_k),\ldots,(\sigma|h_2|h_4|h_5,\beta_j)} p(\gamma_2)$$

Figure 3: Decomposition of the feature expectation $E_{p(\gamma|w)}[f^{\mathsf{la}_2}_{b_3,b_2,b_1}(\gamma)]$ into a finite summation. Quantity $p(w)$ above is the sum over all probabilities of computations in $\Gamma(w)$.

model. Figure 3 shows how to express the expectation of feature $f^{\mathsf{la}_2}_{b_3,b_2,b_1}(\gamma)$ by means of a finite summation. Using Eq. 5 and 6 and the relation $p(w) = I([\c{c}, 0, \c{c}0, n])$ we can then write:

$$E_{p(\gamma|w)}[f^{\mathsf{la}_2}_{b_3,b_2,b_1}(\gamma)] = \frac{\theta^{\mathsf{rd}}_{b_1} \cdot \theta^{\mathsf{rd}_2}_{b_2,b_1} \cdot \theta^{\mathsf{la}_2}_{b_3,b_2,b_1}}{I([\c{c}, 0, \c{c}0, n])} \cdot$$

$$\cdot \sum_{\substack{i,j,h_1,h_4,h_5,\\ \text{s.t. } a_{h_4}=b_2,\, a_{h_5}=b_1}} O([h_1, i, h_4 h_5, j]) \cdot$$

$$\cdot \sum_{\substack{k,h_2,h_3,\\ \text{s.t. } a_{h_2}=b_3}} I([h_1, i, h_2 h_3, k]) \cdot I([h_3, k, h_4 h_5, j]) \; .$$

Very similar expressions can be derived for the expectations for features $f^{\mathsf{ra}_2}_{b_3,b_2,b_1}(\gamma)$, $f^{\mathsf{la}_1}_{b_2,b_1}(\gamma)$, and $f^{\mathsf{ra}_1}_{b_2,b_1}(\gamma)$. As for feature $f^{\mathsf{sh}_b}_{b_1}(\gamma)$, $b \in \Sigma$, the above approach leads to

$$E_{p(\gamma|w)}[f^{\mathsf{sh}_b}_{b_1}(\gamma)] =$$

$$= \frac{\theta^{\mathsf{sh}_b}_{b_1}}{I([\c{c}, 0, \c{c}0, n])} \cdot \sum_{\substack{\sigma,i,h,\text{ s.t.}\\ a_h=b_1,\, a_i=b}} O([h, i, hi, i+1]) \; .$$

As mentioned above, these expectations can be used, for example, to derive an EM algorithm for our model. The EM algorithm in our case is not completely straightforward because of the way we parametrize the model. We give now the re-estimation steps for such an EM algorithm. We assume that all expectations below are taken with respect to a set of parameters $\boldsymbol{\theta}$ from iteration $s-1$ of the algorithm, and we are required to update these $\boldsymbol{\theta}$. To simplify notation, let us assume that there is only one string w in the training corpus. For each $b_1 \in \Sigma$, we define:

$$Z_{b_1} = \sum_{b_2 \in \Sigma} E_{p(\gamma|w)} \left[f^{\mathsf{la}_1}_{b_2,b_1}(\gamma) + f^{\mathsf{ra}_1}_{b_2,b_1}(\gamma) \right]$$

$$+ \sum_{b_3,b_2 \in \Sigma} E_{p(\gamma|w)} \left[f^{\mathsf{la}_2}_{b_3,b_2,b_1}(\gamma) + f^{\mathsf{ra}_2}_{b_3,b_2,b_1}(\gamma) \right] \; ;$$

$$Z_{b_2,b_1} = \sum_{b_3 \in \Sigma} E_{p(\gamma|w)} \left[f^{\mathsf{la}_2}_{b_3,b_2,b_1}(\gamma) + f^{\mathsf{ra}_2}_{b_3,b_2,b_1}(\gamma) \right] \; .$$

We then have, for every $b \in \Sigma$:

$$\theta^{\mathsf{sh}_b}_{b_1}(s) \leftarrow \frac{E_{p(\gamma|w)}[f^{\mathsf{sh}_b}_{b_1}(\gamma)]}{Z_{b_1} + \sum_{b' \in \Sigma} E_{p(\gamma|w)}[f^{\mathsf{sh}_{b'}}_{b_1}(\gamma)]} \; .$$

Furthermore, we have:

$$\theta^{\mathsf{la}_1}_{b_2,b_1}(s) \leftarrow \frac{E_{p(\gamma|w)}[f^{\mathsf{la}_1}_{b_2,b_1}(\gamma)]}{Z_{b_2,b_1} + E_{p(\gamma|w)}\left[f^{\mathsf{la}_1}_{b_2,b_1}(\gamma) + f^{\mathsf{ra}_1}_{b_2,b_1}(\gamma)\right]},$$

and:

$$\theta^{\mathsf{la}_2}_{b_3,b_2,b_1}(s) \leftarrow \frac{E_{p(\gamma|w)}[f^{\mathsf{la}_2}_{b_3,b_2,b_1}(\gamma)]}{E_{p(\gamma|w)}\left[f^{\mathsf{la}_2}_{b_3,b_2,b_1}(\gamma) + f^{\mathsf{ra}_2}_{b_3,b_2,b_1}(\gamma)\right]}.$$

The rest of the parameter updates can easily be derived using the above updates because of the sum-to-1 constraints in Eq. 2–4.

6 Discussion

We note that our model inherits spurious ambiguity from Attardi's model. More specifically, we can have different derivations, corresponding to different system computations, that result in identical dependency graphs and strings. While running our tabular algorithm with the Viterbi semiring efficiently computes the highest probability computation in $\Gamma(w)$, spurious ambiguity means that finding the highest probability dependency tree is NP-hard. This latter result can be shown using proof techniques similar to those developed by Sima'an (1996). We leave it for future work how to eliminate spurious ambiguity from the model.

While in the previous sections we have described a tabular method for the transition system of Attardi (2006) restricted to transitions of degree up to two, it is possible to generalize the model to include higher-degree transitions. In the general formulation of Attardi parser, transitions of degree d create links involving nodes located d positions beneath the topmost position in the stack:

$$\mathsf{la}_d: \quad (\sigma|i_1|i_2|\ldots|i_{d+1},\beta,A) \vdash (\sigma|i_2|\ldots|i_{d+1},\beta,A\cup\{i_{d+1}\rightarrow i_1\});$$

$$\mathsf{ra}_d: \quad (\sigma|i_1|i_2|\ldots|i_{d+1},\beta,A) \vdash (\sigma|i_1|i_2|\ldots|i_d,\beta,A\cup\{i_1\rightarrow i_{d+1}\}).$$

To define a transition system that supports transitions up to degree D, we use a set of items of the form $[s_1\ldots s_{D-1}, i, e_1\ldots e_D, j]$, corresponding (in the sense of §4) to computations of the form $c_0,\ldots,c_m$, $m \geq 1$, with $c_0 = (\sigma|s_1|\ldots|s_{D-1},\beta_i,A)$ and $c_m = (\sigma|e_1|\ldots|e_D,\beta_j,A')$. The deduction steps corresponding to reduce transitions in this general system have the general form

$$\frac{[s_1\ldots s_{D-1}, i, e_1 m_1\ldots m_{D-1}, j] \quad [m_1\ldots m_{D-1}, j, e_2\ldots e_{D+1}, w]}{[s_1\ldots s_{D-1}, i, e_1\ldots e_{c-1}e_{c+1}\ldots e_{D+1}, w]}\ (e_p\rightarrow e_c)$$

where the values of p and c differ for each transition: to obtain the inference rule corresponding to a la_d transition, we make $p = D+1$ and $c = D+1-d$; and to obtain the rule for a ra_d transition, we make $p = D+1-d$ and $c = D+1$. Note that the parser runs in time $O(n^{3D+2})$, where D stands for the maximum transition degree, so each unit increase in the transition degree adds a cubic factor to the parser's polynomial time complexity. This is in contrast to a previous tabular formulation of the Attardi parser by Gómez-Rodríguez et al. (2011), which ran in exponential time.

The model for the transition system we give in this paper is generative. It is not hard to naturally extend this model to the discriminative setting. In this case, we would condition the model on the input string to get a conditional distribution over derivations. It is perhaps more natural in this setting to use arbitrary weights for the parameter values, since the computation of a normalization constant (the probability of a string) is required in any case. Arbitrary weights in the generative setting could be more problematic, because it would require computing a normalization constant corresponding to a sum over all *strings* and derivations.

7 Conclusion

We presented in this paper a generative probabilistic model for non-projective parsing, together with the description of an efficient tabular algorithm for parsing and doing statistical inference with the model.

Abstract

This paper introduces Chart Inference (CI), an algorithm for deriving a CCG category for an unknown word from a partial parse chart. It is shown to be faster and more precise than a baseline brute-force method, and to achieve wider coverage than a rule-based system. In addition, we show the application of CI to a domain adaptation task for question words, which are largely missing in the Penn Treebank. When used in combination with self-training, CI increases the precision of the baseline StatCCG parser over subject-extraction questions by 50%. An error analysis shows that CI contributes to the increase by expanding the number of category types available to the parser, while self-training adjusts the counts.

1 Introduction

Unseen lexical items are a major cause of error in strongly lexicalised parsers such as those based on CCG (Clark and Curran, 2003; Hockenmaier, 2003). The problem is especially acute for less privileged languages, but even in the case of English, we are aware of many category types entirely missing from the Penn Treebank (Clark et al., 2004).

In the case of totally unseen words, the standard method used by StatCCG (Hockenmaier, 2003) and many other treebank parsers is part-of-speech backoff, which is quite effective, affording an F-score of 93% over dependencies in §00 in the optimal configuration. It is difficult to say how backing off affects dependency errors, but when we examine category match accuracy of the CCGBank-trained parser, we find that POS backoff has been used on 19.6% of tokens, which means that those tokens are unseen, or too infrequent in the training data to be included in the lexicon. Of the 3320 items the parser labelled incorrectly, 675 (20.3%) are words that are missing from the lexicon entirely.[1] In the best case, if we were able to learn lexical entries for those 675, we could transfer them to lexical treatment, which is 93.5% accurate, rather than POS backoff, which is 89.3% accurate. Under these conditions, we predict a further 631 word/category pairs to be tagged correctly by the parser, reducing the error rate from 7.4% to 6% on §00. Further to reducing parsing error, a robust method for learning words from unlabelled data would result in the recovery of interesting and important category types that are missing from our standard lexical resources.

This paper introduces Chart Inference (CI) as a strategy for deducing a ranked set of possible categories for an unknown word using the partial chart formed from the known words that surround it. CCG (Steedman, 2000) is particularly suited to this problem, because category types can be inferred from the types of the surrounding constituents. CI is designed to take advantage of this property of generative CCGBank-trained parser, and of access to the full inventory of CCG combinators and non-combinatory unary rules from the trained model. It is capable of learning category types that are completely missing from the lexicon, and is superior to existing learning systems in both precision and efficiency.

Four experiments are discussed in this paper. The first compares three word-learning methods for their ability to converge to a toy target lexicon. The sec-

[1] A further 269 (8%) are cases where the word is known, but has not been seen with the correct category.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1246–1256,
Edinburgh, Scotland, UK, July 27–31, 2011.

ond and third compare the three methods based on their ability to correctly tag the all the words in a small natural language corpus. The final experiment shows how Chart Induction can be effectively used in a domain adaptation task where a small number of category types are known to be missing from the lexicon.

2 Learning Words

The methods used in this paper all operate under a restricted learning setting, over sentences where all but one word is in the lexicon. Since the learning portion of the algorithm is unsupervised, it has access to an essentially unlimited amount of unlabelled data, and it can afford to skip any sentence that does not conform to the one-unseen-word restriction. Attempting two or more OOL words at a time from one sentence would compound the search space and the error rate. We do not address the much harder problem of hypothesising missing categories for known words, which should presumably be handled by quite other methods, such as prior offline generalization of the lexicon.

2.1 A Brute-force System

One of the early lexical acquisition systems using Categorial Grammar was that of Watkinson and Manandhar (1999; 2000; 2001a; 2001b). This system attempted to simultaneously learn a CG lexicon and annotate unlabelled text with parse derivations. Using a stripped-down parser that only utilised the forward- and backward-application rules, they iteratively learned the lexicon from the feedback from online parsing. The system decided which parse was best based on the lexicon, and then decided which additions to the lexicon to make based on principles of compression. After each change, the system reexamined the parses for previous sentences and updated them to reflect the new lexicon.

They report fully convergent results on two toy corpora, but the parsing accuracy of the system trained on natural language data was far below the state of the art. However, they do show categorial grammar to be a promising basis for artificial language acquisition, because CCG makes learning the lexicon and learning the grammar the same task (Watkinson and Manandhar, 1999). They also showed that seeding the lexicon with examples of lexical items (closed-class words in their case), rather than just a list of possible category types, increased its chances of converging. This approach of automating the learning process differs from the previous language learning methods described, in that it doesn't require the specification of any particular patterns, only knowledge of the grammar formalism.

For this paper, as a baseline, we implement a generalised version of Watkinson and Manandhar's mechanism for determining the category γ of a single OOL word in a sentence where the rest of the words $C_1 ... C_N$ are in the lexicon: $\gamma = arg\max Parse(C_1 ... C_n, \gamma)$. This is equivalent to backing off to the set of all known category types; the learner returns the category that maximises the probability of the completed parse tree. We ignore the optimisation and compression steps of the original system.

2.2 A Rule-based System

Yao et al. (2009a; 2009b) developed a learning system based on handwritten translation rules for deducing the category (X) of a single unknown word in a sentence consisting of a sequence of partially-parsed constituents (A..N).

Their system was based on a small inventory of inference rules that eliminated ambiguity in the ordering of arguments. For example, one of the Level 3 inference rules specifies the order of the arguments in the deduced category:

$A\ \mathbf{X}\ B\ C \rightarrow D \Rightarrow \mathbf{X} = ((D\backslash A)/C)/B$

Without this inductive bias the learner would have to deal with the ambiguity of the options $((D/C)/B)\backslash A$ and $((D/C)\backslash A)/B$ at minimum. In addition they limited their learner to CG-compatible parse structures and their constituent strings to length 4.

Their argument is that only this minimal bias is needed to learn syntactic structures, including the fronting of polar interrogative auxiliaries and auxiliary word order (should $>$ have $>$ been), from a training set that did not explicitly contain full evidence for them.

Although Yao et al. (2009b) used the full set of CCG combinators to generate learned categories, they employed a post-processing step to filter spurious categories by checking whether the category

$\text{DERIVE}([C_1 ... C_n], \beta, \gamma)$

if $\beta = \emptyset$
then return (γ)
else if $C_1 = C_n = X$
then $\begin{cases} \gamma = \gamma + \beta; \\ \text{DERIVE}(X, \emptyset, \gamma) \end{cases}$
else $\begin{cases} \textbf{if } C_1 \notin S, X \\ \quad \textbf{then } \text{DERIVE}([C_2 ... C_n], \beta \backslash C_1, \gamma) \\ \textbf{if } C_n \notin S, X \\ \quad \textbf{then } \text{DERIVE}([C_1 ... C_{n-1}], \beta / C_n, \gamma) \\ \textbf{if } \beta \equiv B \textbf{ and } C_1 \equiv B/A \textbf{ and } C_1 \notin S, X \\ \quad \textbf{then } \text{DERIVE}([C_2 ... C_n], A, \gamma) \\ \textbf{if } \beta \equiv B \textbf{ and } C_n \equiv B \backslash A \textbf{ and } C_n \notin S, X \\ \quad \textbf{then } \text{DERIVE}([C_1 ... C_{n-1}], A, \gamma) \end{cases}$

Figure 1: Generalised recursive rule-based algorithm, where $[C_1 ... C_n]$ is a sequence of categories, one of which is X, β is a result category, and γ is the (initially empty) category set.

participated in a CG-only derivation (using application rules only). This is effective in limiting spurious derivations, but at the expense of reduced recall on those sentences for whose analysis CCG rules of composition etc. are crucial.

Their rules were effective for their toy-scale datasets, but for the purposes of this paper we have implemented a generalised version of the recursive algorithm for use in wide-coverage parsing. This algorithm is outlined in Figure 1. It takes a sequence of categorial constituents, all known except one (**X**), and builds a candidate set of categories (γ) for the unknown word by recursively applying Yao's Level 0 and Level 1 inference rules.

2.3 Chart Inference

Both Watkinson's and Yao's experiments were fully convergent over toy datasets, but did not scale to realistic corpora. Watkinson attempted to learn from the LLL corpus (Kazakov et al., 1998), but attributed the failure to the small amount of training data relative to the corpus, and the naive initial category set. Yao's method was only ever designed as a proof-of-concept to show how much of the language can be learned from partial evidence, and was not meant to be run in earnest in a real-world learning setting. For one, the rules do not cover the full set of partial parse conditions, and further to that, they do not allow for partial parses to be reanalysed within the learning framework.

To that end, we have developed a learning algorithm that is capable of operating within the one-unknown-word-per-sentence learning setting established by the two baseline systems, that is able to invent new category types, and that is able to take advantage of the full generality of CCG. This section shows that it performs as well as the previous two systems on a toy corpus, and the next section proves that it more readily scales to natural language domains.

Mellish (1989) established a two-stage bidirectional chart parser for diagnosing errors in input text. His method relied heavily on heuristic rules, and the only evaluation he did was on number of cycles needed for each type of error, and number of solutions produced. His method was designed for use in producing parses where the original parser failed, dealing with omissions, insertions, and misspelled/unknown words. The only method used to rank the possible solutions was heuristic scores.

Kato (1994) implemented a revised system that used a generalised top-down parser, rather than a chart, and was able to get the number of cycles to decrease.

In both cases the evaluation was only on a toy corpus, and they did not evaluate on whether the systems diagnosed the errors correctly, or whether the solution they offered was accurate. They also had to deal with cases where the error was ambiguous, for example, where an inserted word could be interpreted as a misspelling or vice-versa.

Where Mellish uses the two-stage parsing process to complete malformed parses, we use it to diagnose unknown lexical items. In addition, we work on the scale of a full grammar and wide-coverage parser, using modern lexical corpora.

Our method is a wrapper for a naive generative CCG parser StatOpenCCG (Christodoulopoulos, 2008), a statistical extension to OpenCCG (White and Baldridge, 2003). In the general case, the parser is trained on all the labelled data available in a particular learning setting, then the learner discovers new lexical items from unlabelled text. Like the brute force and rule-based systems, it is vulnerable

$$P(HeadLeft|R)=\left\{\begin{array}{r}P[outside](R)*\\P[inside](S)*\\P(exp=right|R)*\\P(S|R,exp=right)*\\P(C|R,exp=right,S)\end{array}\right\}$$

Figure 3: CI probability that the target is category C, given possible categories for result (R) and sister (S).

to attachment errors and ambiguity from adverbials.

The learning step consists in presenting the parser with sentences all of whose words but one are in-lexicon. The parser must have a statistical parsing model, which contains a seed lexicon, a set of CCG combinators, and an optional set of unary and binary rules learned from the training corpus.

First the baseline bottom-up parser is called upon to produce a partial parse chart. The learner takes this partial chart and fills the top right cell with a distribution for the result category based on the end punctuation.[2]

Using this partial chart that contains at least one entry for every leaf cell (except the one OOL target cell) and at least one entry for the result, the learner steps through the chart in a top-down version of CYK (Younger, 1967). For the top-down process, the standard combinators have to be reformulated to take an argument and a result as inputs, rather than two arguments as in the standard bottom-up case. In addition, the learner has access to the non-combinator rules from the parse model, which have been similarly inverted for top-down use. This process continues until the target cell has been filled, and the ranked set of categories is returned.

The probability that the target has a given category is calculated as the greater of the right- or left-headed derivations, according to Figure 3. At training time, the StatOpenCCG parser creates a head-dependency model from the training corpus, in which we can look up the values for the expansion probabilities. Where a value is unavailable, it backs off to a pre-specified value (default 0.0001).[3] The system requires a pruning parameter that limits each cell to the top N most probable categories. Here, we set N=10, to limit the search space and complexity. [4]

Figure 2 sets out the inventory of inverse combinators used in the top-down learning step. Each standard binary CCG combinator motivates two inverse combinators: one for each possible missing item. In the two permissive instances where the sister category's form is the unrestricted B, we limit the sister's valency to 1, in order to keep the learner from generating spurious categories that could result from these two rules being overapplied.

Figure 4 illustrates the workings of the learning

[2]For simple corpora, only S is required, but realistic corpora necessitate a distribution over all result types, including noun phrases and fragments.

[3]This backoff parameter allows adjustment of the expectation of new category types and could be replaced with another smoothing method in subsequent implementations.

[4]Further testing on the McGuffey corpus has shown the average rank of correct tags in the category set to be 1.4.

algorithm for the sentence *The cat* ***X*** *her*. The grey cells are filled as a partial chart by the parser, and the white cells are filled by the top-down learner. Note that taking rule probabilities into account makes the algorithm robust to ambiguity. The highest-ranking lexical category for *her* is $NP[nb]/N$, but the next highest (NP) is preferred in the derivation of the highest-ranking category for the unknown word **X**.

3 Experiment I: Convergence

In the following experiments, we compare Chart Inference to the two baseline methods: Brute Force (BF), derived from Watkinson and Manandhar, and Rule-Based (RB), derived from Yao et al. This section investigates how robust the three systems are to changes in theoriginal seed lexicon.

3.1 Corpus

For this experiment we test the three systems on a reconstructed version of Corpus 1 from Watkinson and Manandhar's experiments.[5] The lexicon contains 40 word-category pairs, including the full stop ($S\backslash S$), which was not in Watkinson's experiment, and one example of noun-verb ambiguity (*saw*). The test sentences are randomly generated from a simple PCFG over the lexicon, and are always presented to the learners in the same order.

3.2 Methods

In order to directly compare the three learning methods, we use the evaluation setting from Watkinson and Manandhar (1999), which consists of a 40-entry target lexicon and a PCFG language model used to randomly generate 1000 sentences. We then specify a seed lexicon and run the learner incrementally, so that it deals with one sentence at a time, then feeds the learned material back into the lexicon. Watkinson's system was shown to fully convergent (they defined convergence as cosine similarity between the seed lexicon ($\vec{S}$) and the target lexicon ($\vec{T}$) exceeding 0.99), whenever the seed lexicon contained at least one instance of each of the category types in the target lexicon (Watkinson and Manandhar, 1999)

[5]The full corpus was not included in any of Watkinson's papers, but its properties were outlined to such an extent that it was straightforward to recreate, though the reconstruction may differ from the original in the distribution of category types. The reconstructed corpus will be released shortly.

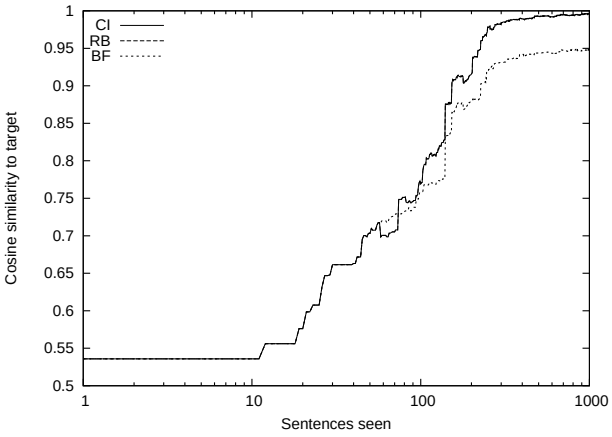

Figure 5: Learning curve for all three methods when the seed contains no ditransitives. CI and RB are identical.

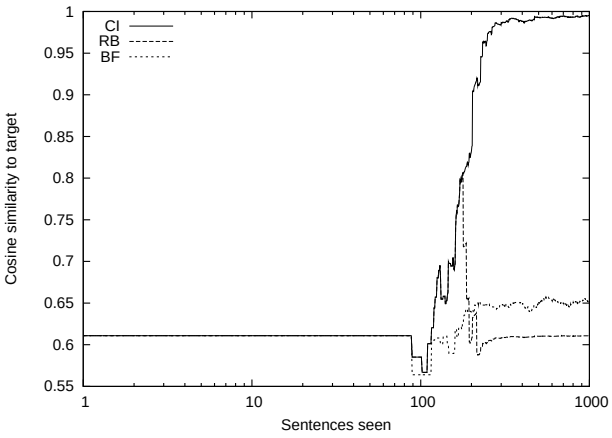

Figure 6: Learning curve for all three methods when seed contains only three determiners and one noun.

3.3 Results

When run incrementally over this toy corpus, both the RB and CI algorithms converge to the target lexicon in an identical sigmoid learning curve (not shown). However, when we start with an impoverished seed, the algorithms' behaviours start to diverge. Figure 5 shows the learning curve for the three methods when the seed lexicon omits all instances of the ditransitive category type $((S\backslash NP)/NP)/NP$. Both RB and CI converge identically as expected, but BF, the lower curve, cannot learn any category types that are not attested in the seed, so it plateaus at 95% similarity.

When the seed is reduced to only three determiners and a noun, CI can still learn the complete

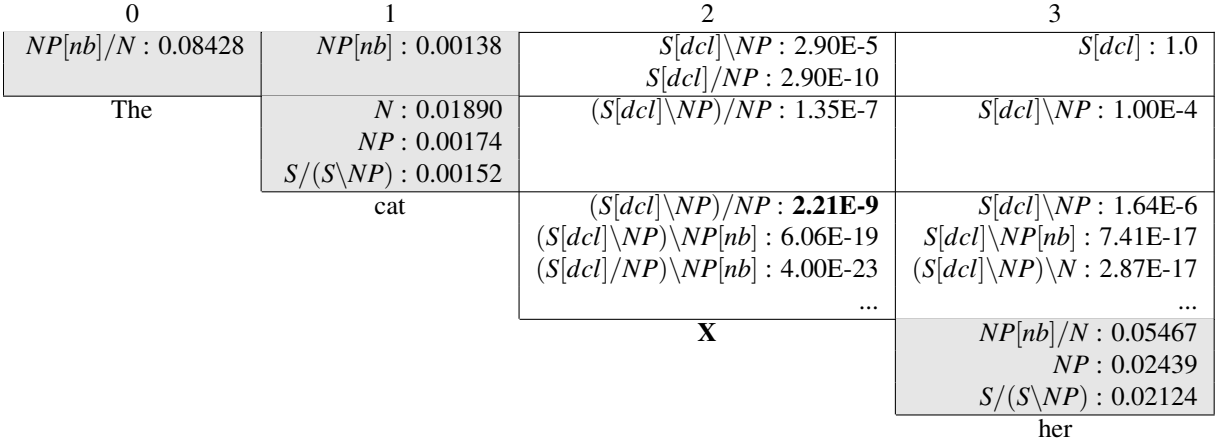

Figure 4: Example of a two-stage derivation using Chart Inference: Grey boxes are filled bottom-up by the partial parser; white boxes top-down by the learner. The target cell (2,2) shows the correct category type as the highest probability solution.

lexicon, despite some initial missteps and a steeper curve. However, the other two methods fail catastrophically (Figure 6). BF never gets going, since it can only correctly learn the remaining nouns. RB is partially successful, but is thwarted by a bad decision at 80% that quickly compounds to diverge from the target lexicon, ending up with higher coverage in the form of more lexical entries, but lower precision, as the final similarity plateaus at the same level as the original seed.

4 Experiments II and III: Coverage

Next, we compare the three learning methods on a larger corpus of natural language, to investigate how well they perform at recovering a wide range of category types in complex settings.

4.1 Corpus

We have constructed a small natural language lexicon based on the first volume of a 6-volume 1836 children's primer, McGuffey's Eclectic Reader.[6] Volume 1 of the McGuffey corpus (MG1) consists of 546 sentences that have been manually annotated with CCG categories, automatically parsed, and then corrected. Volume 2 (MG2) comprises 801 sentences, annotated in the same manner as Volume 1, though not as reliably. The McGuffey corpus makes an ideal seed for development purposes, as it contains a high proportion of simple declarative sentences, but also touches on questions, quotations, passives, and other complex constructions.

[6]The raw text of William Holmes McGuffey's Eclectic Reader is available as an e-book from Project Gutenberg at http://www.gutenberg.org/ebooks/14640. The annotated corpus will be released shortly.

4.2 Methods

In the first of these two experiments we train and test on the same corpus in one pass, attempting to learn each word token in turn and comparing the learned category set to the gold standard annotation. Because we know that the lexicon contains all the necessary entries to correctly parse all the sentences, this addresses the lexical coverage problem discussed in Section 1 of this paper.

The second of these two experiments looks at a more realistic environment for word learning: the parser is initially trained on MG1, then tested on MG2. We evaluate on the gold standard categories in MG2. Since we are not guaranteed to have access to all the necessary word/category pairs in the seed lexicon, the precision and recall values for this second experiment will inevitably be lower than the first.

Figure 7 outlines the process of producing new parsed sentences out of raw text. The process begins like the previous experiment, but then the category set generated by the learner is passed back to the parser, so it can incorporate this new information into its lexicon and produce a full parse. The Hypothesis lexicon is cleared after every sentence.

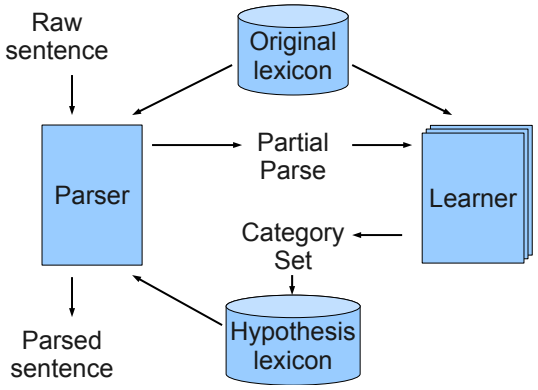

Figure 7: Learning framework for Experiments II-IV.

4.3 Results

Table 1 compares the category match accuracy across the three systems in experiment II, as well as the baseline that chose the the most probable category for the target word's POS. Two tasks are scored: *Top One*, where we evaluate the single highest-scoring category against the gold-standard tag, and *Top Ten*, where we check to see if the gold tag is in the set of the ten highest-probability categories returned by the learner.

CI achieves the best F-scores in both tasks, reaching 76% for *Top One* and 94% for *Top Ten*. POS backoff has an advantage in the *Top Ten* task, especially in recall, since it returns an answer in every case, but CI still outperforms it on F-score. BF achieves the highest precision in the *Top One* task, but takes 30 hours to do so, since it is searching over all possible categories. RB is markedly worse in both precision and recall, but also remarkably fast. CI combines the merits of both BF and RB, yielding a higher F-score than BF and a processing time similar to RB.

In Experiment III, to test the limits of the learners on truly OOL words, we again train on MG1, but test instead on MG2. We can then perform a meaningful error analysis on the results, showing how the three word-learning methods compare in actual practice, in a realistic setting.

Out of its 801 sentences in MG2, only 32 present learning opportunities for the learners, being between 2 and 10 tokens long, containing no internal punctuation or coordination, and containing only one OOL word.

Table 2 shows the category match results of the three systems on MG2. Recall is calculated over the set of learning opportunities, of which there are only 32. BF performs best in all metrics, but the CI results are reasonable. The underlying reason for this behaviour is that the 32 learning targets are all of common categories: over half of them are N or NP. Since the Brute Force learner seeks simply to maximise the tree probability, N and NP are its most common guesses in general.

5 Experiment IV: Domain Adaptation

Clark et al. (2004) identified the problem with using news data to train a parser for a question answering task as the lack of lexical support for question words. Some lexical types were missing entirely. The lexicon for CCGBank §02-21 contains 12 WH-question types, notably lacking some important ones. Clark et al. note the absence of one category in particular: $(S[wq]/(S[dcl]\backslash NP))/N$, the category needed for *What President became Chief Justice after his presidency?*

They attempt to adapt the discriminative C&C parser (Clark and Curran, 2007) to the QA domain by retraining on 500 hand-labelled question sentences, then automatically parsing and hand-correcting an additional 671. The entire set was then used in conjunction with CCGBank §02-21 to train a final parsing model. Their per-word accuracy rose from a 68.5% baseline to 94.6% for the newly trained model.

In this experiment, we examine how close we can get to those results by using Chart Inference to learn WH-question words from the *unlabelled* question corpus. If successful, this would eliminate the human-annotation step for domain adaptation of the kind investigated by (Clark et al., 2004).

5.1 Corpora

We trained the initial parser on the CCGBank (Hockenmaier and Steedman, 2007; Hockenmaier, 2003) training set (§02-21), consisting of 39603 sentences of Wall Street Journal text (Marcus et al., 1993). It is important to note that this training corpus contains only 93 questions in total, so it is not surprising that several category types for question words are entirely unrepresented. It also rein-

Table 2: Exp. III: Category match results for the three systems on the McGuffey corpus, training on MG1 and testing on MG2. Common categories (N, NP, N/N) are overrepresented in the test data, leading to higher BF scores. POS tags not available for MG2, so no POS baseline is reported.

forces the fact that this is a domain-adaptation task.

We use the same 500-sentence test set as Rimell and Clark (2008b). The test corpus consists of 488 questions, each starting with *What*, *When*, *How*, *Who* or *Where*. The learning corpus contains 1328 questions in a similar distribution.

Only three out of the five categories needed to parse What-questions are present in the CCGBank seed lexicon: $S[wq]/(S[q]/NP)$,[7], $S[wq]/(S[dcl]\backslash NP)$,[8] and $S[wq]/(S[q]/NP)/N$.[9] For this experiment we focus on the subject WH-element extraction category $(S[wq]/(S[dcl]\backslash NP))/N$, as in *Which cat is the grandmother?*. This particular category was chosen as a point of investigation because it is OOL in CCGBank and is common enough to meaningfully evaluate.

5.2 Methods

The baseline is the original StatCCG parser and lexicon. We also employ self-training (Charniak, 1997), in which a parser is used to parse a set of sentences, and then retrained using those output trees. Self-training has had very little success in CCG applications hitherto. McClosky et al (2006) attribute success in self-training to a confluence of circumstances particular to their learning setting, which has the benefit of a discriminative re-ranker, both in the parsing case and in the learning case (McClosky et al., 2008). We follow their recommendations that the best performance is achieved when all the training sentences are parsed at once, rather than incrementally.

We evaluate the success of CI in bootstrapping Wh-question categories from the out-of-domain corpus in two ways. First, we compare the CI output to the gold standard categories labelled in Rimmell and Clark (2008a). Second, we add the parsed questions into the training set, then retrain and finally retest the parser.

The parser was initially trained on CCGBank §02-21 with a word frequency threshold of 5.[10] It produces partial parse charts in the cases where all words in the sentence are in-lexicon, except for the WH-word target, for which the learner attempts to return a category motivated by that context.

We run the learner on the set of 149 sentences from the TREC Question-Answering corpus (Rimell and Clark, 2008b) that contain the word/category pair *What*:$(S[wq]/(S[dcl]\backslash NP))/N$. For this experiment the end-punctuation distribution derived from the training corpus is replaced with a single value: $P(S[wq]|?) = 1$.

[7] Object question category as in *What is the Keystone State?*

[8] Subject question category as in *What lays blue eggs?*

[9] Object WH-element extraction category as in *What continent is Scotland in?*

[10] StatCCG requires a parameter to trade off between training the lexicon and the POS-backoff.

Cat=SubjExt	7.84	**52.94**	**58.82**

Table 3: F-score over individual category matches. Bold means significantly different from the Baseline.

5.3 Results

Table 3 shows the change in F-score throughout this experiment. BL is the baseline condition, where the accuracy is predictably high over all the words in the sentence, but lower when we examine the question words only. It is most telling that the baseline F-score over words that should be tagged with the subject WH-element-extraction category $((S[wq]/(S[dcl]\backslash NP))/N)$ is extremely low. In fact, that seven percent represents only a handful of instances of *Which*, and none of *What*. Applying Chart Inference to the problem results in statistically significant increases in all metrics, but the biggest gain is in the last. When we first apply CI, then self-train over the full training corpus, we further increase all metrics, and again the largest gain is over the target category type specifically. [11] The reason for this can be clearly seen when we evaluate the lexicons created by each method.

Table 4 shows the differences in the impact on the lexicon between baseline (BL), Chart Induction (CI), and the combined method of CI and self-training (CI+ST).[12] CI leaves the initial distribution unchanged while adding seven more category types. One of these is the category we are interested in: $(S[wq]/(S[dcl]\backslash NP))/N$, which is previously associated with *Which* in the baseline lexicon. The other six are spurious categories, and have low counts. Combining the learning mechanisms by running first CI, and then ST, has the effect of introducing the category we need, and then elevating the counts. The probability for $S[wq]$ is elevated as well, as a result of misparses, but the whole process results in better category matches over the test set, as we saw in Table 3.

5.4 Error Analysis

Of the previously known categories, the ST step overwhelmingly prefers three categories: one subject extraction category $S[wq]/(S[dcl]\backslash NP)$ and two object extraction $S[wq]/(S[q]/NP)$ and $(S[wq]/(S[q]/NP))/N$. The remaining categories are classified in Table 4 as either rare (R), spurious (*), or duplicate (D). Rare categories, like $S[wq]$ are used for specialised cases (the sentence *What?*) which occur in PTB, but not in the QA corpus. Spurious categories, like $(S[wq]/PP)/N$ exist in the baseline parser, arising from errors in either the original PTB, or the translation to CCGBank. $S[wq]/S[q]$ is only used where $S[wq]/(S[q]/NP)$ is meant, but fails to capture the extraction. $S[wq]/(S[dcl]/NP)$ is a misinterpretation of sentences requiring $(S[wq]/(S[dcl]\backslash NP))/N$, but without capturing the extracted N.

Five spurious categories are also introduced by the CI learning step. $(S[wq]/S[dcl])/N$ and $(S[wq]/((S[dcl]\backslash NP[expl])/NP))/N$ are spurious forms of $(S[wq]/(S[dcl]\backslash NP))/N$ that arise when the constituent directly right of the target is misparsed; the former misses the extraction and the latter adds an extra dummy subject. $S[wq]/N$ occurs when the main verb of the sentence is treated as a participle, forming a complex nominal argument. $(S[wq]/N)/N$ and $(S[wq]/(S[dcl]/(S[pt]\backslash NP)))/N$ are caused by similar verbal ambiguity.

The classification of $(S[wq]/S[inv])/N$ as a duplicate category is linguistically motivated. Rather than interpret the embedded sentence as declarative, the parser uses *has*:$S[inv]/NP$ to interpret it instead as an inverted sentence. In essence, it cannot see the difference between *What companies have them?* and *What choice have they?* when the NPs lack a case distinction. As such, it duplicates the work of the target $(S[wq]/(S[dcl]\backslash NP))/N$, because the constituents $S[dcl]\backslash NP$ and $S[inv]$ are often synonymous in practice.

As seen in Table 4, the distinction between rare and spurious categories cannot be made on frequency alone, but the best categories are the ones with the highest frequency. Duplicate categories can be considered spurious for the sake of parsing, but

[11] We also ran the experiment using ST only, which performed better than CI alone, but only over a different set consisting entirely of seen categories. We do not report those figures here because they are not commensurable with the CI results.

[12] *What* has 31 categories in total in the baseline lexicon; here we show only the [wq] types.

Table 4: Exp. IV: Lexical category distribution for the word *What* in the baseline §02-21 of CCGBank (BL), after Chart Inference (CI), and after first applying Chart Inference, then self-training (CI+ST). Column 1 classifies low-frequency categories as rare (R), spurious (*) or duplicate (D). Cateogories above the middle line are present in the Baseline lexicon; below are induced.

are linguistically interesting, and if they are frequent enough, that is possibly an indication that the structure of the lexicon or the grammar is non-optimal.

6 Conclusion and Future Work

Chart Inference is a useful tool for finding OOL categories. It has been shown to outperform both the brute-force and rule-based systems. When used in conjunction with self-training, CI presents a valuable framework for domain adaptation in the case where whole category types are missing from the lexicon.

It remains to put Chart Inference into an appropriate framework for improving coverage over the baseline WSJ-trained StatCCG parser. We estimate an upper bound of 20% error reduction possible over CCGBank §00, if the lexicon is expanded to cover all the necessary word/category pairs. Improving global F-score for §23 is of course very difficult. The lexical entries CI finds are by definition rare and at the scale we are running, they are unlikely to occur in those 2000 sentences. We believe our analysis of the lexical items themselves shows that we are learning a high proportion of good lexical entries.

The problem of discovering missing categories for known words remains. We have shown through adapting to the question domain that it is possible to make focused improvements when we can identify the gaps in coverage (as in wh-question words), but in order to address the challenge of automatic lexicon extension fully, quite different techniques for generalising lexical entries for seen words will be require.

Acknowledgements

The authors would like to thank Steve Clark and Laura Rimell for provision of the annotated QA corpus, Christos Christodoulopoulos for the StatOpenCCG parser, Tejaswini Deoskar for editorial advice, and Luke Zettlemoyer for considerable mathematical assistance. A Fast, Accurate, Non-Projective, Semantically-Enriched Parser

Abstract

Dependency parsers are critical components within many NLP systems. However, currently available dependency parsers each exhibit at least one of several weaknesses, including high running time, limited accuracy, vague dependency labels, and lack of non-projectivity support. Furthermore, no commonly used parser provides additional shallow semantic interpretation, such as preposition sense disambiguation and noun compound interpretation. In this paper, we present a new dependency-tree conversion of the Penn Treebank along with its associated fine-grain dependency labels and a fast, accurate parser trained on it. We explain how a non-projective extension to shift-reduce parsing can be incorporated into non-directional easy-first parsing. The parser performs well when evaluated on the standard test section of the Penn Treebank, outperforming several popular open source dependency parsers; it is, to the best of our knowledge, the first dependency parser capable of parsing more than 75 sentences per second at over 93% accuracy.

1 Introduction

Parsers are critical components within many natural language processing (NLP) systems, including systems for information extraction, question answering, machine translation, recognition of textual entailment, summarization, and many others. Unfortunately, currently available dependency parsers suffer from at least one of several weaknesses including high running time, limited accuracy, vague dependency labels, and lack of non-projectivity support. Furthermore, few parsers include any sort of additional semantic interpretation, such as interpretations for prepositions, possessives, or noun compounds.

In this paper, we describe 1) a new dependency conversion (Section 3) of the Penn Treebank (Marcus, et al., 1993) along with the associated dependency label scheme, which is based upon the Stanford parser's popular scheme (de Marneffe and Manning, 2008), and a fast, accurate dependency parser with non-projectivity support (Section 4) and additional integrated semantic annotation modules for automatic preposition sense disambiguation and noun compound interpretation (Section 5). We show how Nivre's (2009) swap-based reordering technique for non-projective shift-reduce-style parsing can be integrated into the non-directional easy-first framework of Goldberg and Elhadad (2010) to support non-projectivity, and we report the results of our parsing experiments on the standard test section of the PTB, providing comparisons with several freely available parsers, including Goldberg and Elhadad's (2010) implementation, MALTPARSER (Nivre et al., 2006), MSTPARSER (McDonald et al., 2005; McDonald and Pereira, 2006), the Charniak (2000) parser, and the Berkeley parser (Petrov et al., 2006; Petrov and Klein, 2007).

The experimental results show that the parser is substantially more accurate than Goldberg and Elhadad's original implementation, with fairly similar overall speed. Furthermore, the results prove that Stanford-granularity dependency labels can be learned by modern dependency parsing systems when using our Treebank conversion, unlike the Stanford conversion, for which Cer et al. (2010) show that this isn't the case.

The optional semantic annotation modules also

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1257–1268,
Edinburgh, Scotland, UK, July 27–31, 2011.

perform well, with the preposition sense disambiguation module exceeding the accuracy of the previous best reported result for fine-grained preposition sense disambiguation (85.7% vs Hovy et al.'s (2010) 84.8%), the possessives interpretation system achieving over 85% accuracy, and the noun compound interpretation system performing similarly to an earlier version described by Tratz and Hovy (2010) at just over 79% accuracy.

2 Background

The NLP community has recently seen a surge of interest in dependency parsing, with several CoNLL shared tasks focusing on it (Buchholz and Marsi, 2006; Nivre et al., 2007). One of the main advantages of dependency parsing is the relative ease with which it can handle non-projectivity[1]. Additionally, since each word is linked directly to its head via a link that, ideally, indicates the syntactic dependency type, there is no difficulty in determining either the syntactic head of a particular word or the syntactic relation type, whereas these issues often arise when dealing with constituent parses[2].

Unfortunately, most currently available dependency parsers produce relatively vague labels or, in many cases, produce no labels at all. While the Stanford fine-grain dependency scheme (de Marneffe and Manning, 2008) has proven to be popular, recent experiments by Cer et al. (2010) using the Stanford conversion of the Penn Treebank indicate that it is difficult for current dependency parsers to learn. Indeed, the highest scoring parsers trained using the MSTPARSER (McDonald and Pereira, 2006) and MALTPARSER (Nivre et al., 2006) parsing suites achieved only 78.8 and 81.1 labeled attachment F_1, respectively. This contrasted with the much higher performance obtained using a constituent-to-dependency conversion approach with accurate, but much slower, constituency parsers such as the Charniak and Johnson (2005) and Berkeley (Petrov et al., 2006; Petrov and Klein, 2007) parsers, which achieved 89.1 and 87.9 labeled F_1 scores, respectively.

[1] A tree is non-projective if the sequence of words visited in a left-to-right, depth-first traversal of the sentence's parse tree is different than the actual word order of the sentence.

[2] These latter two issues are not problems for constituent parses with binarized output and functional tags.

Though there are many syntactic parsers than can reconstruct the grammatical structure of a text, there are few, if any, accurate and widely accepted systems that also produce shallow semantic analysis of the text. For example, a parser may indicate that, in the case of 'ice statue', 'ice' modifies 'statue' but will not indicate that 'ice' is the *substance* of the statue. Similarly, a parser will indicate which words a preposition connects but will not give any semantic interpretation (e.g., 'the boy *with* the pirate hat' $\rightarrow$ *wearing or carrying*, 'wash *with* cold water' $\rightarrow$ *means*, 'shave *with* the grain' $\rightarrow$ *in the same direction as*). While, in some cases, it may be possible to use the output from a separate system for this purpose, doing so is often difficult in practice due to a wide variety of complications, including programming language differences, alternative data formats, and, sometimes, other parsers.

3 Dependency Conversion

3.1 Relations and Structure

Most recent English dependency parsers produce one of three sets of dependency types: unlabeled, some variant of the coarse labels used by the CoNLL dependency parsing shared-tasks (Buchholz and Marsi, 2006; Nivre et al., 2007) (e.g., ADV, NMOD, PMOD), or Stanford's dependency labels (de Marneffe and Manning, 2008). Unlabeled dependencies are clearly too impoverished for many tasks. Similarly, the coarse labels of the CoNLL tasks are not very specific; for example, the same relation, NMOD, is used for determiners, adjectives, nouns, participle modifiers, relative clauses, etc. that modify nouns. In contrast, the Stanford relations provide a more reasonable level of granularity.

Our dependency relation scheme is similar to Stanford's basic scheme but has several differences. It introduces several new relations including *ccinit* "initial coordinating conjunction", *cleft* "cleft clause", *combo* "combined term", *extr* "extraposed element", *infmark* "infinitive marker 'to' ", *objcomp* "object complement", *postloc* "post-modifying location", *sccomp* "clausal complement of 'so' ", *vch* "verbal chain" and *whadvmod* "wh- adverbial modifier". The *nsubjpass*, *csubjpass*, and *auxpass* relations of Stanford's are left out because adding them up front makes learning more difficult and the fact

abbrev	abbreviation	*csubjpass*	clausal subject (passive)	pobj	prepositional object
acomp	adjectival complement	det	determiner	poss	possessive
advcl	adverbial clause	dobj	direct object	possessive	possessive marker
advmod	adverbial modifier	**extr**	extraposed element	**postloc**	post-modifying location
agent	'by' agent	expl	'there' expletive	preconj	pre conjunct
amod	adjectival modifier	**infmark**	infinitive marker ('to')	predet	predeterminer
appos	appositive	infmod	infinite modifier	prep	preposition
attr	attributive	iobj	indirect object	prt	particle
aux	auxillary	mark	subordinate clause marker	punct	punctuation
auxpass	auxillary (passive)	measure	measure modifier	purpcl	purpose clause
cleft	cleft clause	neg	negative	quantmod	quantifier modifier
cc	coordination	nn	noun compound	rcmod	relative clause
ccinit	initial CC	nsubj	nominal subject	*rel*	relative
ccomp	clausal complement	*nsubjpass*	nominal subject (passive)	**sccomp**	clausal complement of 'so'
combo	combination term	num	numeric modifier	tmod	temporal modifier
compl	complementizer	number	compound number	**vch**	verbal chain
conj	conjunction	**objcomp**	object complement	**whadvmod**	wh- adverbial
cop	copula complement	parataxis	parataxis	xcomp	clausal complement w/o subj
csubj	clausal subject	partmod	participle modifier		

Table 1: Dependency scheme with differences versus basic Stanford dependencies highlighted. Bold indicates the relation does not exist in the Stanford scheme. Italics indicate the relation appears in Stanford's scheme but not ours.

that a *nsubj*, *csubj*, or *aux* is passive can easily be determined from the final tree. Stanford's *aux* dependencies are replaced using verbal chain (*vch*) links; conversion of these to Stanford-style *aux* dependencies is also trivial as a post-processing step.[3] The *attr* dependency is excluded because it is redundant with the *cop* relation due to different handling of copula, and the dependency scheme does not have an *abbrev* label because this information is not provided by the Penn Treebank. The dependency scheme with differences with Stanford highlighted is presented in Table 1.

In addition to using a slightly different set of dependency names, a handful of relations, notably *cop*, *conj*, and *cc*, are treated in a different manner. These differences are illustrated by Figure 1. The Stanford scheme's treatment of copula may be one reason why dependency parsers have trouble learning and applying it. Normally, the head of the clause is a verb, but, under Stanford's scheme, if the verb happens to be a copula, the complement of the copula (*cop*) is treated as the head of the clause instead.

[3]The parsing system includes an optional script that can convert *vch* arcs into *aux* and *auxpass* and the subject relations into *csubjpass* and *nsubjpass*.

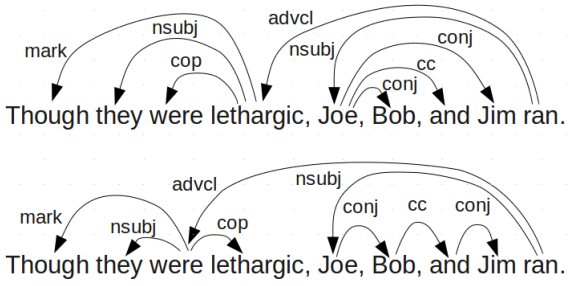

Figure 1: Example comparing Stanford's (top) handling of copula and coordinating conjunctions with ours (bottom).

3.2 Conversion Process

A three-step process is used to convert the Penn Treebank (Marcus, et al., 1993) from constituent parses into dependency trees labeled according to the dependency scheme presented in the prior section. The first step is to apply the noun phrase structure patch created by Vadas and Curran (2007), which adds structure to the otherwise flat noun phrases (NPs) of the Penn Treebank (e.g., '(metal soup pot cover)' would become '(metal (soup pot) cover)'). The second step is to apply a version of Johansson and Nugues' (2007) constituent-to-dependency converter with some head-finding rule modifications; these rules, with changes highlighted

Figure 2: Modified head-finding rules. Underline indicates that the search is performed in a left-to-right fashion instead of the default right-to-left order. NML and JJP are both products of Vadas and Curran's (2007) patch. Bold indicates an added or moved element; for the original rules, see the paper by Johansson and Nugues (2007).

in bold, are provided in Figure 2. Finally, an additional script makes additional changes and converts the intermediate output into the dependency scheme.

This dependency conversion has several advantages to it. Using the modified head-finding rules for Johansson and Nugues' (2007) converter results in fewer buggy trees than were present in the CoNLL shared tasks, including fewer trees in which words are headed by punctuation marks. For sections 2–21, there are far fewer generic *dep/DEP* relations (2,765) than with the Stanford conversion (34,134) or the CoNLL 2008 shared task conversion (23,811). Also, the additional conversion script contains various rules for correcting part-of-speech (POS) errors using the syntactic structure as well as additional rules for some specific word forms, mostly common words with inconsistent taggings. Many of these changes cover part-of-speech problems discussed by Manning (2011), including VBD/VBN, VBZ/NNS, NNP/NNPS, and IN/WDT/DT issues. In total, the script changes over 9,500 part-of-speech tags, with the most common change being to change preposition tags (IN) into adverb tags (RB) for cases where there is no prepositional complement/object. The top fifteen of these changes are presented in Table 2. The conversion script contains a variety of additional rules for modifying the parse structure and fixing erroneous trees as well, including cases where one or more POS tags were incorrect and, as such, the initial dependency parse was flawed. Quick manual inspections of the changes suggested that the vast majority are accurate.

In the final output from the conversion, the number of sentences with one or more words dependent on non-projective arcs in sections 2–21 is 3,245—about 8.1% of the dataset. About 1.3% of this, or 556 of sentences, is due to the secondary conversion script, with sentences containing approximate currency amounts (e.g., *about $ 10*) comprising the bulk of difference. For these, the quantifying text (e.g., *about*, *over*, *nearly*), is linked to the number following the currency symbol instead of to the currency symbol as it was in the CoNLL 2008 task.

4 Parser

4.1 Algorithm

The parsing approach is based upon the *non-directional easy-first* algorithm recently presented by Goldberg and Elhadad (2010). Their original algorithm behaves as follows. For a sentence of length n, the algorithm performs a total of n steps. In each step, one of the unattached tokens is added as a child to one of its current neighbors and is then removed from the list of unprocessed tokens. When only one token remains unprocessed, it is designated as the root. Provided that only a constant number of potential attachments need to be re-evaluated after each step, which is the case if one restricts the context for feature generation to a constant number of neighboring tokens, the algorithm can be implemented to run in O($n \log n$). However, since only O(n) dot products must be calculated by the parser and these have a large constant associated with them, the running time will rival O(n) parsers for any reasonable n, and, thus, a naive O(n^2) implementation will be nearly as fast as a priority queue implementation in practice.[4]

The algorithm has a couple potential advantages over standard shift-reduce style parsing algorithms. The first advantage is that performing easy actions first may make the originally difficult decisions easier. The second advantage is that performing parse actions in a more flexible order than left-to-right/right-to-left shift-reduce parsing reduces the chance of error propagation.

Unfortunately, the original algorithm does not support non-projective trees. To extend the algorithm to support non-projective trees, we introduce *move-right* and *move-left* operations similar to the stack-to-buffer *swaps* proposed by Nivre (2009) for shift-reduce style parsing. Thus, instead of attaching a token to one of its neighbors at each step, the algorithm may instead decide to *move* a token past one of its neighbors. Provided that no node is allowed to be moved past a token in such a way that a previous *move* operation is undone, there can be at most O(n^2) *moves* and the overall worst-case complexity becomes O($n^2 \log n$). While theoretically slower, this has a limited impact upon actual parsing times in practice, especially for languages with relatively fixed word order such as English.[5] Though Goldberg and Elhadad's (2010) original implementation only supports unlabeled dependencies, the algorithm itself is in no way limited in this regard, and it is simple enough to add labeled dependency support by treating each dependency label as a specific type of *attach* operation (e.g., *attach_as_nsubj*), which is the method used by this implementation. Pseudocode for the non-directional easy-first algorithm with non-projective support is given in Algorithm 1.

```
input : w_1 ... w_n, #the sentence
        m, #the model
        k, #the context width
        actions, #the list of parse actions
        φ, #the feature generator
output: tree #a collection of dependency arcs
words = copyOf(s);
stale = copyOf(s);
cache; #cache of action scores
while |words| > 1 do
    for w ∈ stale do
        for act ∈ actions do
            cache[w,act] = score(act, φ(w,...),
            m);
        stale.remove(w);
    best = argmax_{a∈actions&valid(a),w∈words} cache[w, a]
    if isMove(best) then
        i =
            words.index(getTokenToMove(best));
        words.move(i, isMoveLeft(best) ? -1
        : 1);
    else
        arc = createArc(best);
        tree.add(arc);
        i = words.index(getChild(arc));
        words.remove(i);
    for x ∈ -k,...,k do
        stale.add(words.get(index+x));
return tree
```

Algorithm 1: Modified version of Goldberg and Elhadad's (2010) Easy-First Algorithm with non-projective support.

[4] See Goldberg and Elhadad (2010) for more explanation.

[5] See Nivre (2009) for more information on the effect of reordering operations on parse time.

4.2 Features

One of the key aspects of the parser is the complex set of features used. The feature set is based off the features used by Goldberg and Elhadad (2010) but has a significant number of extensions. Various feature templates are specifically designed to produce features that help with several syntactic issues including preposition attachment, coordination, adverbial clauses, clausal complements, and relative clauses. Unfortunately, there is insufficient space in this paper to describe them all here. However, a list of feature templates will be provided with the parser download.

Several of the feature templates use unsupervised word clusters created with the Brown et al. (1992) hierarchical clustering algorithm. The use of this algorithm was inspired by Koo et al. (2008), who used the top branches of the cluster hierarchy as features. However, unlike Koo et al.'s (2008) parser, the fine-grained cluster identifiers are used instead of just the top 4-6 branches of the cluster hierarchy. The 175 word clusters utilized by the parser were created from the New York Times corpus (Sandhaus, 2008). Some examples from the clusters are presented in Figure 3. The ideal number of such clusters was not thoroughly investigated.

Figure 3: High frequency examples from 15 of the Brown clusters.

4.3 Training

The parsing model is trained using a variant of the structured perceptron training algorithm used in the original Goldberg and Elhadad (2010) implementation. The general idea of the algorithm is to iterate over the sentences and, whenever the model predicts an incorrect action, update the model weights. Following Goldberg and Elhadad, parameter averaging is used to reduce overfitting.

Our implementation varies slightly from that of Goldberg and Elhadad (2010). The difference is that, at any particular step for a given sentence, the algorithm continues to update the weight vector as long as *any* invalid action is scored higher than *any* valid action, not just the highest scoring valid action; unfortunately, this change significantly slowed down the training process. In early experiments, this change produced a slight improvement in accuracy though it also slowed training significantly. In later experiments using additional feature templates, this change ceased to have any notable impact on the overall accuracy, but it was kept anyway. [6]

The oracle used to determine whether a *move* operation should be considered legal during the training phase is similar to Nivre et al.'s (2009) improved oracle based upon *maximal projective subcomponents*. As an additional restriction, during training, *move* actions were only considered valid either if no other action was valid or if the token to be moved already had all its children attached and moving it caused it to be adjacent to its parent. This fits with Nivre et al.'s (2009) intuition that it is best to delay word reordering as long as possible.

4.4 Speed Enhancements

To enhance the speed for practical use, the parser uses constraints based upon the part-of-speech tags of the adjacent word pairs to eliminate invalid dependencies from even being evaluated. A relation is only considered between a pair of words if such a relation was observed in the training data between a pair of words with the same parts-of-speech (with the exception of the generic *dep* dependency, which is permitted between any POS tag pair). Early experiments utilizing similar constraints showed an improvement in parsing speed of about 16% with no significant impact on accuracy, regardless of whether the constraints were enforced during training.

[6] See Goldberg and Elhadad (2010) for more description of the general training procedure.

System	Arc Accuracy		Perfect Sentences		Non-Proj Arcs

Results in parentheses were produced using gold POS tags. †Eisner (1996) algorithm with non-projective rewriting and second order features. ‡Results not directly comparable; see text. *Labeled dependencies not available/comparable.

4.5 Evaluation

The following split of the Penn Treebank (Marcus, et al., 1993) was used for the experiments: sections 2–21 for training, 22 for development, and 23 for testing.

For part-of-speech (POS) tagging, we used an in-house SVM-based POS tagger modeled after the work of Giménez and Márquez (2004) [7]. The training data was tagged in a 10-fold fashion; each fold was tagged using a tagger trained from the nine remaining folds. The development and test sections were tagged by an instance of the tagger trained using the entire training set. The full details of the POS tagger are outside the scope of this paper; it is included with the parser download.

The final parser was trained for 31 iterations, which is the point at which its performance on the development set peaked. One test run was performed with non-projectivity support disabled in order to get some idea of the impact of the *move* operations on the parser's overall performance; also, since the parsers used for comparison had no access to the unsupervised word clusters, an additional instance of the parser was trained with every word treated as belonging to the same cluster so as to facilitate a more fair comparison.

Seven different dependency parsing models were trained for comparison using the following open source parsing packages: Goldberg and Elhadad's (2010)'s *non-directional easy-first* parser, MALTPARSER (Nivre et al., 2006), and MSTPARSER (McDonald and Pereira, 2006)[8]. The model trained using Goldberg and Elhadad's (2010) easy-first parser serves as something of a baseline. The four MALTPARSER parsing models used the *arc-eager*, *arc-standard*, *stack-eager*, and *stack-lazy* algorithms. One of the MSTPARSER models used the Chu-Liu-Edmonds maximum spanning tree approach, and the other used the Eisner (1996) algorithm with second order features and a non-projective rewriting post-processing step.

Unfortunately, it is not possible to directly compare the parser's accuracy with most popular constituent parsers such as the Charniak (2000) and Berkeley (Petrov et al., 2006; Petrov and Klein, 2007) parsers[9] both because they do not produce functional tags for subjects, direct objects, etc., which are required for the final script of the constituent-to-dependency conversion routine, and because they determine part-of-speech tags in conjunction with the parsing. However, it is possible to compute approximate unlabeled accuracy scores by training the constituent parsers on the NP-patched (Vadas and Curran, 2007) version of the data and then running the test output through just the first conversion script—that is, the modified version of Johansson and Nugues' (2007) converter.

[7] 97.42% accuracy on traditional POS evaluation (Penn Treebank WSJ sections 22-24).

The results of the experiment are given in Table 3, including accuracy for individual arcs, non-projective arcs only, and full sentence match. Punctuation is excluded in all the result computations. To determine whether an arc is non-projective, the following heuristic was used. Traverse the sentence in a depth-first search, starting from the imaginary root node and pursuing child arcs in order of increasing absolute distance from their parent. Whenever an arc being traversed is found to cross a previously traversed arc, mark it as non-projective and continue. To evaluate the impact of part-of-speech tagging error, results for parsing using the gold standard part-of-speech tags are also included.

We also measured the speed of the parser on the various sentences in the test collection. For reasonable sentence lengths, the parser scales quite well. The scatterplot depicting the relation between sentence length and parsing time is presented in Figure 5.

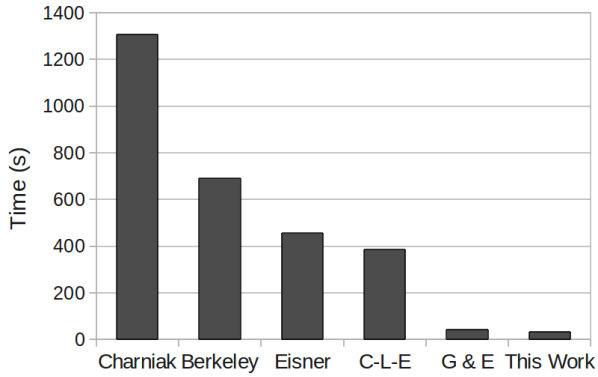

Figure 4: Parse times for Penn Treebank section 23 for the parsers on a PC with a 2.4Ghz Q6600 processor and 8GB RAM. MALTPARSER ran substantially slower than the others, perhaps due to its use of polynomial kernels, and isn't shown. (C-L-E - Chu-Liu-Edmonds, G&E - Goldberg and Elhadad (2010)).

4.5.1 Results Discussion

The parser achieves 92.1% labeled and 93.7% unlabeled accuracy on the evaluation, a solid result and about 2.5% higher than the original easy-first implementation of Goldberg and Elhadad (2010). Furthermore, the parser processed the entire test section in just over 30 seconds—a rate of over 75 sentences per second, substantially faster than most of the other parsers.

Not surprisingly, the results for non-projective arcs are substantially lower than the results for all arcs, and the systems that are designed to handle them outperformed the strictly projective parsers in this regard.

The negative effect of part-of-speech tagging error appears to impact the different parsers about the same amount, with a loss of .6% to .8% in unlabeled accuracy and 1.1% to 1.3% in labeled accuracy.

The 93.2% and 93.3% accuracy scores achieved by the Charniak and Berkeley parsers are not too different from the 93.7% result, but, of course, it is important to remember that these scores are not directly comparable.

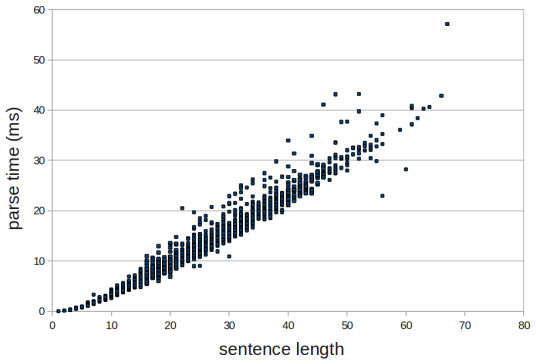

Figure 5: Sentence length versus parse time. Median times for five runs over section 23.

5 Shallow Semantic Annotation

To create a more informative parse, the parser includes four optional modules, a preposition sense disambiguation (PSD) system, a work-in-progress *'s*-possessive interpretation system, a noun compound interpretation system, and a PropBank-based semantic role labeling system[10]. Taken together, these integrated modules enable the parsing system to produce substantially more informative output than a traditional parser.

Preposition Sense Disambiguation The PSD system is a newer version of the system described

[8] Versions 1.4.1, 0.4.3b, and 0.2, respectively

[9] Versions 1.1 and 05Aug16, respectively

[10] Lack of space prohibits a sufficiently thorough discussion of these individual components and their evaluations, but additional information will be available with the system download.

by Tratz and Hovy (2009) and Hovy et al. (2010); it achieves 85.7% accuracy on the SemEval-2007 fine-grain PSD task (Litkowski and Hargraves, 2007), which is a statistically significant ($p<=0.05$; upper-tailed z test) increase over the previous best reported result for this dataset, Hovy et al.'s (2010) 84.8%.

Noun Compound Interpretation The noun compound interpretation system is a newer version of the system described by Tratz and Hovy (2010) with similar accuracy (79.6% vs 79.3% using 10-fold cross-validation[11]).

Possessives Interpretation The possessive interpretation system assigns interpretations to *'s* possessives (e.g., John's arm → PART-OF, Mowgli's capture → PATIENT/THEME). The current system achieves over 85.0% accuracy, but it is important to note that the annotation scheme, automatic classifier, and dataset are all still under active development.

PropBank SRL The PropBank-based semantic role labeling system achieves 86.8 combined F_1 measure for automatically-generated parse trees calculated over both predicate disambiguation and argument/adjunct classification (89.5 F_1 on predicate disambiguation, 85.6 F_1 on argument and adjuncts corresponding to dependency links, and 86.8 F_1); this score is not directly comparable to any previous work due to some differences, including differences in both the parse tree conversion and the PropBank conversion. The most similar work is that of the CoNLL shared task work (Surdeanu et al., 2008; Hajič et al., 2009).

6 Related Work

Non-projectivity. There are two main approaches used in recent NLP literature for handling non-projectivity in parse trees. The first is to use an algorithm, like the one presented in this paper, that has inherent support for non-projective trees. Examples of this include the Chu-Liu-Edmonds' approach for maximum spanning tree (MST) parsing (McDonald et al., 2005) and Nivre's (2009) swap-based reordering method for shift-reduce parsing. The second approach is to create an initial projective parse and then apply transformations to introduce non-projectivity into it. Examples of this include McDonald and Pereira's (2006) rewriting of projective trees produced by the Eisner (1996) algorithm, and Nivre and Nilsson's (2005) pseudo-projective approach that creates projective trees with specially marked arcs that are later transformed into non-projective dependencies.

Descriptive dependency labels. While most recent dependency parsing research has used either vague labels, such as those of the CoNLL shared tasks, or no labels at all, some descriptive dependency label schemes exist. By far the most prominent of these is the Stanford typed dependency scheme (de Marneffe and Manning, 2008). Another descriptive scheme that exists, but which is less widely used in the NLP community, is the one used by Tapanainen and Järvinen's parser (1997). Unfortunately, the Stanford dependency conversion of the Penn Treebank has proven difficult to learn for current dependency parsers (Cer et al., 2010), and there is no publicly available dependency conversion according to Tapanainen and Järvinen's scheme.

Faster parsing. While the fastest reasonable parsing algorithms are the $O(n)$ shift-reduce algorithms, such as Nivre's (2003) algorithm and an expected linear time dynamic programming approach presented by Huang and Sagae (2010), a few other fast alternatives exist. Goldberg and Elhadad's (2010) easy-first algorithm is one such example. Another example, is Roark and Hollingshead's (2009) work that uses chart constraints to achieve linear time complexity for constituency parsing.

Effective features for parsing. A variety of work has investigated the use of more informative features for parsing. This includes work that integrates second and even third order features (McDonald et al., 2006; Carreras, 2007; Koo and Collins, 2010). Also, some work has incorporated unsupervised word clusters as features, including that of Koo et al. (2008) and Suzuki et al. (2009), who utilized unsupervised word clusters created using the Brown et al. (1992) hierarchical clustering algorithm.

Semantically-enriched output. The 2008 and 2009 CoNLL shared tasks (Surdeanu et al., 2008; Hajič et al., 2009), which required participants to build systems capable of both syntactic parsing and Semantic Role Labeling (SRL) (Gildea and Jurafsky, 2002), are the most notable attempts to encour-

[11] These accuracy figures are higher than what should be expected for unseen datasets; see Tratz and Hovy (2010) for more detail.

age the development of parsers with additional semantic annotation. These tasks relied upon PropBank (2005) and NomBank (2004) for the semantic roles. A variety of other systems have focused on FrameNet-based (1998) SRL instead, including those that participated in the SemEval-2007 Task 19 (Baker et al., 2007) and work by Das et al. (2010).

7 Conclusion

In this paper, we have described a new high-quality dependency tree conversion of the Penn Treebank (Marcus, et al., 1993) along with its labeled dependency scheme and presented a parser that is fast, accurate, supports non-projective trees and provides rich output, including not only informative dependency labels similar to Stanford's but also additional semantic annotation for prepositions, possessives, and noun compound relations. We showed how the easy-first algorithm of Goldberg and Elhadad (Goldberg and Elhadad, 2010) can be extended to support non-projective trees by adding *move* actions similar to Nivre's (2009) swap-based reordering for shift-reduce parsing and evaluated our parser on the standard test section of the Penn Treebank, comparing with several other freely available parsers.

The Penn Treebank conversion process fixes a number of buggy trees and part-of-speech tags and produces dependency trees with a relatively small percentage of generic *dep* dependencies. The experimental results show that dependency parsers can generally produce Stanford-granularity labels with high accuracy when using the new dependency conversion of the Penn Treebank, something which, according to the findings of Cer et al. (2010), does not appear to be the case when training and testing dependency parsers on the Stanford conversion.

The parser achieves high labeled and unlabeled accuracy in the evaluation, 92.1% and 93.7%, respectively. The 93.7% result represents a 2.5% increase over the accuracy of Goldberg and Elhadad's (2010) implementation. Also, the parser proves to be quite fast, processing section 23 of the Penn Treebank in just over 30 seconds (a rate of over 75 sentences per second).

The parsing system is capable of not only producing fine-grained dependency relations, but can also produce shallow semantic annotations for prepositions, possessives, and noun compounds by using several optional integrated modules. The preposition sense disambiguation (PSD) module achieves 85.7% accuracy on the SemEval-2007 PSD task, exceeding the previous best published result of 84.8% by a statistically significant margin, the possessives module is over 85% accurate, the noun compound interpretation module achieves 79.6% accuracy on Tratz and Hovy's (2010) dataset. The PropBank SRL module achieves 89.5 F_1 on predicate disambiguation and 85.6 F_1 on argument and adjuncts corresponding to dependency links, for an overall F_1 of 86.8. Combined with the core parser, these modules allow the system to produce a substantially more informative textual analysis than a standard parser.

8 Future Work

There are a variety of ways to extend and improve upon this work. We would like to change our handling of coordinating conjunctions to treat the coordinating conjunction as the head because this has fewer ambiguities than the current approach and also add the ability to produce traces for WH- words. It would also be interesting to examine the impact on final parsing accuracy of the various differences between our dependency conversion and Stanford's.

To aid future NLP research work, the code, including the treebank converter, part-of-speech tagger, parser, and semantic annotation add-ons, will be made publicly available for download via http://www.isi.edu.

Acknowledgements

We would like to thank Richard Johansson for providing us with the code for the *pennconverter* consituent-to-dependency converter. We would also like to thank Dirk Hovy and Anselmo Peñas for many valuable dicussions and suggestions.

Abstract

We present new training methods that aim to mitigate local optima and slow convergence in unsupervised training by using additional imperfect objectives. In its simplest form, *lateen EM* alternates between the two objectives of ordinary "soft" and "hard" expectation maximization (EM) algorithms. Switching objectives when stuck can help escape local optima. We find that applying a single such alternation already yields state-of-the-art results for English dependency grammar induction. More elaborate lateen strategies track *both* objectives, with each validating the moves proposed by the other. Disagreements can signal earlier opportunities to switch or terminate, saving iterations. De-emphasizing fixed points in these ways eliminates some guesswork from tuning EM. An evaluation against a suite of unsupervised dependency parsing tasks, for a variety of languages, showed that lateen strategies significantly speed up training of both EM algorithms, and improve accuracy for hard EM.

1 Introduction

Expectation maximization (EM) algorithms (Dempster et al., 1977) play important roles in learning latent linguistic structure. Unsupervised techniques from this family excel at core natural language processing (NLP) tasks, including segmentation, alignment, tagging and parsing. Typical implementations specify a probabilistic framework, pick an initial model instance, and iteratively improve parameters using EM. A key guarantee is that subsequent model instances are no worse than the previous, according to training data likelihood in the given framework.

Another attractive feature that helped make EM instrumental (Meng, 2007) is its initial efficiency: Training tends to begin with large steps in a parameter space, sometimes bypassing many local optima at once. After a modest number of such iterations, however, EM lands close to an attractor. Next, its convergence rate necessarily suffers: Disproportionately many (and ever-smaller) steps are needed to finally approach this fixed point, which is almost invariably a local optimum. Deciding when to terminate EM often involves guesswork; and finding ways out of local optima requires trial and error. We propose several strategies that address both limitations.

Unsupervised objectives are, at best, loosely correlated with extrinsic performance (Pereira and Schabes, 1992; Merialdo, 1994; Liang and Klein, 2008, *inter alia*). This fact justifies (occasionally) deviating from a prescribed training course. For example, since *multiple* equi-plausible objectives are usually available, a learner could cycle through them, optimizing alternatives when the primary objective function gets stuck; or, instead of trying to escape, it could aim to avoid local optima in the first place, by halting search early if an improvement to one objective would come at the expense of harming another.

We test these general ideas by focusing on non-convex likelihood optimization using EM. This setting is standard and has natural and well-understood objectives: the classic, "soft" EM; and Viterbi, or "hard" EM (Kearns et al., 1997). The name "lateen" comes from the sea — triangular *lateen* sails can take wind on either side, enabling sailing vessels to *tack* (see Figure 1). As a captain can't count on favorable winds, so an unsupervised learner can't rely on co-operative gradients: soft EM maximizes

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1269–1280,
Edinburgh, Scotland, UK, July 27–31, 2011.

Figure 1: A triangular sail atop a traditional Arab sailing vessel, the *dhow* (right). Older square sails permitted sailing only before the wind. But the efficient *lateen* sail worked like a wing (with high pressure on one side and low pressure on the other), allowing a ship to go almost directly into a headwind. By *tacking*, in a zig-zag pattern, it became possible to sail in any direction, provided there was some wind at all (left). For centuries seafarers expertly combined both sails to traverse extensive distances, greatly increasing the reach of medieval navigation.[1]

likelihoods of observed data across assignments to hidden variables, whereas hard EM focuses on most likely completions.[2] These objectives are plausible, yet both can be provably "wrong" (Spitkovsky et al., 2010a, §7.3). Thus, it is permissible for lateen EM to maneuver between their gradients, for example by tacking around local attractors, in a zig-zag fashion.

2 The Lateen Family of Algorithms

We propose several strategies that use a secondary objective to improve over standard EM training. For hard EM, the secondary objective is that of soft EM; and vice versa if soft EM is the primary algorithm.

2.1 Algorithm #1: Simple Lateen EM

Simple lateen EM begins by running standard EM to convergence, using a user-supplied initial model, primary objective and definition of convergence. Next, the algorithm alternates. A single lateen alternation involves two phases: (i) retraining using the secondary objective, starting from the previous converged solution (once again iterating until convergence, but now of the secondary objective); and (ii) retraining using the primary objective again, starting from the latest converged solution (once more to convergence of the primary objective). The algorithm stops upon failing to sufficiently improve the primary objective across alternations (applying the standard convergence criterion end-to-end) and returns the best of all models re-estimated during training (as judged by the primary objective).

2.2 Algorithm #2: Shallow Lateen EM

Same as algorithm #1, but switches back to optimizing the primary objective after a *single* step with the secondary, during phase (i) of all lateen alternations. Thus, the algorithm alternates between optimizing a primary objective to convergence, then stepping away, using one iteration of the secondary optimizer.

2.3 Algorithm #3: Early-Stopping Lateen EM

This variant runs standard EM but quits early if the secondary objective suffers. We redefine convergence by "or"-ing the user-supplied termination criterion (i.e., a "small-enough" change in the primary objective) with *any* adverse change of the secondary (i.e., an increase in its cross-entropy). Early-stopping lateen EM does *not* alternate objectives.

2.4 Algorithm #4: Early-Switching Lateen EM

Same as algorithm #1, but with the new definition of convergence, as in algorithm #3. Early-switching lateen EM halts primary optimizers as soon as they hurt the secondary objective and stops secondary optimizers once they harm the primary objective. This algorithm terminates when it fails to sufficiently improve the primary objective across a full alternation.

2.5 Algorithm #5: Partly-Switching Lateen EM

Same as algorithm #4, but again iterating primary objectives to convergence, as in algorithm #1; secondary optimizers still continue to terminate early.

3 The Task and Study #1

We chose to test the impact of these five lateen algorithms on unsupervised dependency parsing — a task in which EM plays an important role (Paskin, 2001; Klein and Manning, 2004; Gillenwater et al., 2010, *inter alia*). This entailed two sets of experiments: In study #1, we tested whether single alternations of simple lateen EM (as defined in §2.1,

[2] See Brown et al.'s (1993, §6.2) definition of *Viterbi training* for a succinct justification of hard EM; in our case, the corresponding objective is Spitkovsky et al.'s (2010a, §7.1) $\hat{\theta}_{\text{VIT}}$.

System	*DDA (%)*
(Blunsom and Cohn, 2010)	**55.7**
(Gillenwater et al., 2010)	53.3
(Spitkovsky et al., 2010b)	50.4
+ soft EM + hard EM	52.8 (+**2.4**)
lexicalized, using hard EM	54.3 (+1.5)
+ soft EM + hard EM	**55.6** (+**1.3**)

Table 1: Directed dependency accuracies (DDA) on Section 23 of WSJ (all sentences) for recent state-of-the-art systems and our two experiments (one unlexicalized and one lexicalized) with a single alternation of lateen EM.

Algorithm #1) improve our recent publicly-available system for English dependency grammar induction. In study #2, we introduced a more sophisticated methodology that uses factorial designs and regressions to evaluate lateen strategies with unsupervised dependency parsing in many languages, after also controlling for other important sources of variation.

For study #1, our base system (Spitkovsky et al., 2010b) is an instance of the popular (unlexicalized) Dependency Model with Valence (Klein and Manning, 2004). This model was trained using hard EM on WSJ45 (WSJ sentences up to length 45) until successive changes in per-token cross-entropy fell below 2^{-20} bits (Spitkovsky et al., 2010b; 2010a, §4).[3]

We confirmed that the base model had indeed converged, by running 10 steps of hard EM on WSJ45 and verifying that its objective did not change much. Next, we applied a single alternation of simple lateen EM: first running soft EM (this took 101 steps, using the same termination criterion), followed by hard EM (again to convergence — another 23 iterations). The result was a decrease in hard EM's cross-entropy, from 3.69 to 3.59 bits per token (bpt), accompanied by a 2.4% jump in accuracy, from 50.4 to 52.8%, on Section 23 of WSJ (see Table 1).[4]

Our first experiment showed that lateen EM holds promise for simple models. Next, we tested it in a more realistic setting, by re-estimating *lexicalized* models,[5] starting from the unlexicalized model's parses; this took 24 steps with hard EM. We then applied another single lateen alternation: This time, soft EM ran for 37 steps, hard EM took another 14, and the new model again improved, by 1.3%, from 54.3 to 55.6% (see Table 1); the corresponding drop in (lexicalized) cross-entropy was from 6.10 to 6.09 bpt. This last model is competitive with the state-of-the-art; moreover, gains from single applications of simple lateen alternations (2.4 and 1.3%) are on par with the increase due to lexicalization alone (1.5%).

4 Methodology for Study #2

Study #1 suggests that lateen EM can improve grammar induction in English. To establish statistical significance, however, it is important to test a hypothesis in many settings (Ioannidis, 2005). We therefore use a factorial experimental design and regression analyses with a variety of lateen strategies. Two regressions — one predicting accuracy, the other, the number of iterations — capture the effects that lateen algorithms have on performance and efficiency, relative to standard EM training. We controlled for important dimensions of variation, such as the underlying language: to make sure that our results are not English-specific, we induced grammars in 19 languages. We also explored the impact from the quality of an initial model (using both uniform and ad hoc initializers), the choice of a primary objective (i.e., soft or hard EM), and the quantity and complexity of training data (shorter versus both short and long sentences). Appendix A gives the full details.

4.1 Data Sets

We use all 23 train/test splits from the 2006/7 CoNLL shared tasks (Buchholz and Marsi, 2006; Nivre et al., 2007),[6] which cover 19 different languages.[7] We splice out all punctuation labeled in the data, as is standard practice (Paskin, 2001; Klein and Manning, 2004), introducing new arcs from grandmothers to grand-daughters where necessary, both in train- and test-sets. Evaluation is always against the

[3] `http://nlp.stanford.edu/pubs/markup-data.tar.bz2: dp.model.dmv`

[4] It is standard practice to convert gold labeled constituents from Penn English Treebank's Wall Street Journal (WSJ) portion (Marcus et al., 1993) into unlabeled reference dependency parses using deterministic "head-percolation" rules (Collins, 1999); sentence root symbols (but not punctuation) arcs count towards accuracies (Paskin, 2001; Klein and Manning, 2004).

[5] We used Headden et al.'s (2009) method (also the approach taken by the two stronger state-of-the-art systems): for words seen at least 100 times in the training corpus, gold part-of-speech tags are augmented with lexical items.

[6] These disjoint splits require smoothing; in the WSJ setting, training and test sets overlapped (Klein and Manning, 2004).

[7] We down-weigh languages appearing in both years — Arabic, Chinese, Czech and Turkish — by 50% in all our analyses.

entire resulting test sets (i.e., all sentence lengths).[8]

4.2 Grammar Models

In all remaining experiments we model grammars via the original DMV, which ignores punctuation; all models are unlexicalized, with gold part-of-speech tags for word classes (Klein and Manning, 2004).

4.3 Smoothing Mechanism

All unsmoothed models are smoothed immediately prior to evaluation; some of the baseline models are also smoothed during training. In both cases, we use the "add-one" (a.k.a. Laplace) smoothing algorithm.

4.4 Standard Convergence

We always halt an optimizer once a change in its objective's consecutive cross-entropy values falls below 2^{-20} bpt (at which point we consider it "stuck").

4.5 Scoring Function

We report directed accuracies — fractions of correctly guessed (unlabeled) dependency arcs, including arcs from sentence root symbols, as is standard practice (Paskin, 2001; Klein and Manning, 2004). Punctuation does not affect scoring, as it had been removed from all parse trees in our data (see §4.1).

5 Experiments

We now summarize our baseline models and briefly review the proposed lateen algorithms. For details of the default systems (standard soft and hard EM), all control variables and both regressions (against final accuracies and iteration counts) see Appendix A.

5.1 Baseline Models

We tested a total of six baseline models, experimenting with two types of alternatives: (i) strategies that perturb stuck models directly, by *smoothing*, ignoring secondary objectives; and (ii) *shallow* applications of a single EM step, ignoring convergence.

Baseline $B1$ alternates running standard EM to convergence and smoothing. A second baseline, $B2$, smooths after every step of EM instead. Another shallow baseline, $B3$, alternates single steps of soft and hard EM.[9] Three such baselines begin with hard EM (marked with the subscript h); and three more start with soft EM (marked with the subscript s).

5.2 Lateen Models

Ten models, $A\{1,2,3,4,5\}_{\{h,s\}}$, correspond to our lateen algorithms #1–5 (§2), starting with either hard or soft EM's objective, to be used as the primary.

6 Results

		Soft EM		Hard EM	
	Model	Δa	Δi	Δa	Δi
Baselines	$B3$	**-2.7**	$\times$**0.2**	**-2.0**	$\times$**0.3**
	$B2$	+0.6	$\times$**0.7**	+0.6	$\times$1.2
	$B1$	0.0	$\times$**2.0**	+0.8	$\times$**3.7**
Algorithms	$A1$	0.0	$\times$**1.3**	**+5.5**	$\times$**6.5**
	$A2$	-0.0	$\times$**1.3**	+1.5	$\times$**3.6**
	$A3$	0.0	$\times$**0.7**	-0.1	$\times$**0.7**
	$A4$	0.0	$\times$**0.8**	**+3.0**	$\times$**2.1**
	$A5$	0.0	$\times$**1.2**	**+2.9**	$\times$**3.8**

Table 2: Estimated additive changes in directed dependency accuracy (Δa) and multiplicative changes in the number of iterations before terminating (Δi) for all baseline models and lateen algorithms, relative to standard training: soft EM (left) and hard EM (right). Bold entries are statistically different ($p < 0.01$) from zero, for Δa, and one, for Δi (details in Table 4 and Appendix A).

Not one baseline attained a statistically significant performance improvement. Shallow models $B3_{\{h,s\}}$, in fact, significantly lowered accuracy: by 2.0%, on average ($p \approx 7.8 \times 10^{-4}$), for $B3_h$, which began with hard EM; and down 2.7% on average ($p \approx 6.4 \times 10^{-7}$), for $B3_s$, started with soft EM. They were, however, 3–5x faster than standard training, on average (see Table 4 for all estimates and associated p-values; above, Table 2 shows a preview of the full results).

6.1 $A1_{\{h,s\}}$ — Simple Lateen EM

$A1_h$ runs 6.5x slower, but scores 5.5% higher, on average, compared to standard Viterbi training; $A1_s$ is only 30% slower than standard soft EM, but does not impact its accuracy at all, on average.

Figure 2 depicts a sample training run: Italian '07 with $A1_h$. Viterbi EM converges after 47 iterations,

[8] With the exception of Arabic '07, from which we discarded a single sentence containing 145 non-punctuation tokens.

[9] It approximates a mixture (the average of soft and hard objectives) — a natural comparison, computable via gradients and standard optimization algorithms, such as L-BFGS (Liu and Nocedal, 1989). We did not explore exact interpolations, however, because replacing EM is itself a significant confounder, even with unchanged objectives (Berg-Kirkpatrick et al., 2010).

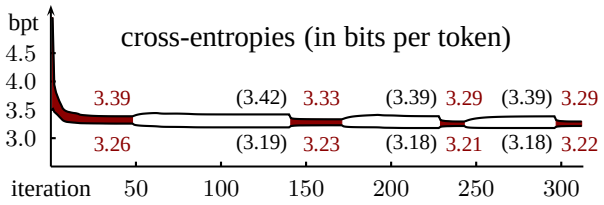

Figure 2: Cross-entropies for Italian '07, initialized uniformly and trained on sentences up to length 45. The two curves are primary and secondary objectives (soft EM's lies below, as sentence yields are at least as likely as parse trees): shaded regions indicate iterations of hard EM (primary); and annotated values are measurements upon each optimizer's convergence (soft EM's are parenthesized).

reducing the primary objective to 3.39 bpt (the secondary is then at 3.26); accuracy on the held-out set is 41.8%. Three alternations of lateen EM (totaling 265 iterations) further decrease the primary objective to 3.29 bpt (the secondary also declines, to 3.22) and accuracy increases to 56.2% (14.4% higher).

6.2 $A2_{\{h,s\}}$ — Shallow Lateen EM

$A2_h$ runs 3.6x slower, but scores only 1.5% higher, on average, compared to standard Viterbi training; $A2_s$ is again 30% slower than standard soft EM and also has no measurable impact on parsing accuracy.

6.3 $A3_{\{h,s\}}$ — Early-Stopping Lateen EM

Both $A3_h$ and $A3_s$ run 30% faster, on average, than standard training with hard or soft EM; and neither heuristic causes a statistical change to accuracy.

Table 3 shows accuracies and iteration counts for 10 (of 23) train/test splits that terminate early with $A3_s$ (in one particular, example setting). These runs are nearly twice as fast, and only two score (slightly) lower, compared to standard training using soft EM.

6.4 $A4_{\{h,s\}}$ — Early-Switching Lateen EM

$A4_h$ runs only 2.1x slower, but scores only 3.0% higher, on average, compared to standard Viterbi training; $A4_s$ is, in fact, 20% faster than standard soft EM, but still has no measurable impact on accuracy.

6.5 $A5_{\{h,s\}}$ — Partly-Switching Lateen EM

$A5_h$ runs 3.8x slower, scoring 2.9% higher, on average, compared to standard Viterbi training; $A5_s$ is 20% slower than soft EM, but, again, no more accurate. Indeed, $A4$ strictly dominates both $A5$ variants.

Table 3: Directed dependency accuracies (DDA) and iteration counts for the 10 (of 23) train/test splits affected by early termination (setting: soft EM's primary objective, trained using shorter sentences and ad-hoc initialization).

7 Discussion

Lateen strategies improve dependency grammar induction in several ways. Early stopping offers a clear benefit: 30% higher efficiency yet same performance as standard training. This technique could be used to (more) fairly compare learners with radically different objectives (e.g., lexicalized and unlexicalized), requiring quite different numbers of steps (or magnitude changes in cross-entropy) to converge.

The second benefit is improved performance, but only starting with hard EM. Initial local optima discovered by soft EM are such that the impact on accuracy of all subsequent heuristics is indistinguishable from noise (it's not even negative). But for hard EM, lateen strategies consistently improve accuracy — by 1.5, 3.0 or 5.5% — as an algorithm follows the secondary objective longer (a single step, until the primary objective gets worse, or to convergence).

Our results suggest that soft EM should use early termination to improve efficiency. Hard EM, by contrast, could use any lateen strategy to improve either efficiency or performance, or to strike a balance.

8 Related Work

8.1 Avoiding and/or Escaping Local Attractors

Simple lateen EM is similar to Dhillon et al.'s (2002) refinement algorithm for text clustering with spherical k-means. Their "ping-pong" strategy alternates batch and incremental EM, exploits the strong points of each, and improves a *shared* objective at every

step. Unlike generalized (GEM) variants (Neal and Hinton, 1999), lateen EM uses multiple objectives: it sacrifices the primary in the short run, to escape local optima; in the long run, it also does no harm, by construction (as it returns the best model seen).

Of the meta-heuristics that use more than a standard, scalar objective, deterministic annealing (DA) (Rose, 1998) is closest to lateen EM. DA perturbs objective functions, instead of manipulating solutions directly. As other continuation methods (Allgower and Georg, 1990), it optimizes an easy (e.g., convex) function first, then "rides" that optimum by gradually morphing functions towards the difficult objective; each step reoptimizes from the previous approximate solution. Smith and Eisner (2004) employed DA to improve part-of-speech disambiguation, but found that objectives had to be further "skewed," using domain knowledge, before it helped (constituent) grammar induction. (For this reason, we did not experiment with DA, despite its strong similarities to lateen EM.) Smith and Eisner (2004) used a "temperature" β to anneal a flat uniform distribution ($\beta = 0$) into soft EM's non-convex objective ($\beta = 1$). In their framework, hard EM corresponds to $\beta \longrightarrow \infty$, so the algorithms differ only in their β-schedule: DA's is continuous, from 0 to 1; lateen EM's is a discrete alternation, of 1 and $+\infty$.[10]

8.2 Terminating Early, Before Convergence

EM is rarely run to (even numerical) convergence. Fixing a modest number of iterations a priori (Klein, 2005, §5.3.4), running until successive likelihood ratios become small (Spitkovsky et al., 2009, §4.1) or using a combination of the two (Ravi and Knight, 2009, §4, Footnote 5) is standard practice in NLP. Elworthy's (1994, §5, Figure 1) analysis of part-of-speech tagging showed that, in most cases, a small number of iterations is actually preferable to convergence, in terms of final accuracies: "regularization by early termination" had been suggested for image deblurring algorithms in statistical astronomy (Lucy, 1974, §2); and validation against held-out data — a strategy proposed much earlier, in psychology (Larson, 1931), has also been used as a halting criterion in NLP (Yessenalina et al., 2010, §4.2, 5.2). Early-stopping lateen EM tethers termination to a *sign* change in the direction of a secondary objective, similarly to (cross-)validation (Stone, 1974; Geisser, 1975; Arlot and Celisse, 2010), but without splitting data — it trains using all examples, at all times.[11,12]

8.3 Training with Multiple Views

Lateen strategies may seem conceptually related to co-training (Blum and Mitchell, 1998). However, bootstrapping methods generally begin with some labeled data and gradually label the rest (discriminatively) as they grow more confident, but do not optimize an explicit objective function; EM, on the other hand, can be fully unsupervised, relabels all examples on each iteration (generatively), and guarantees not to hurt a well-defined objective, at every step.[13] Co-training classically relies on two views of the data — redundant feature sets that allow different algorithms to label examples for each other, yielding "probably approximately correct" (PAC)-style guarantees under certain (strong) assumptions. In contrast, lateen EM uses the same data, features, model and essentially the same algorithms, changing only their objective functions: it makes no assumptions, but guarantees not to harm the primary objective.

Some of these distinctions have become blurred with time: Collins and Singer (1999) introduced an objective function (also based on agreement) into co-training; Goldman and Zhou (2000), Ng and Cardie (2003) and Chan et al. (2004) made do without redundant views; Balcan et al. (2004) relaxed other strong assumptions; and Zhou and Goldman (2004) generalized co-training to accommodate three and more algorithms. Several such methods have been applied to dependency parsing (Søgaard and Rishøj, 2010), constituent parsing (Sarkar,

[10] One can think of this as a kind of "beam search" (Lowerre, 1976), with soft EM expanding and hard EM pruning a frontier.

[11] We see in it a milder contrastive estimation (Smith and Eisner, 2005a; 2005b), agnostic to implicit negative evidence, but caring *whence* learners push probability mass towards training examples: when most likely parse trees begin to benefit at the expense of their sentence yields (or vice versa), optimizers halt.

[12] For a recently proposed instance of EM that uses cross-validation (CV) to optimize *smoothed* data likelihoods (in learning synchronous PCFGs, for phrase-based machine translation), see Mylonakis and Sima'an's (2010, §3.1) CV-EM algorithm.

[13] Some authors (Nigam and Ghani, 2000; Ng and Cardie, 2003; Smith and Eisner, 2005a, §5.2, 7; §2; §6) draw a hard line between bootstrapping algorithms, such as self- and co-training, and probabilistic modeling using EM; others (Dasgupta et al., 2001; Chang et al., 2007, §1; §5) tend to lump them together.

2001) and parser reranking (Crim, 2002). Fundamentally, co-training exploits redundancies in unlabeled data and/or learning algorithms. Lateen strategies *also* exploit redundancies: in noisy objectives. Both approaches use a second vantage point to improve their perception of difficult training terrains.

9 Conclusions and Future Work

Lateen strategies can improve performance and efficiency for dependency grammar induction with the DMV. Early-stopping lateen EM is 30% faster than standard training, without affecting accuracy — it reduces guesswork in terminating EM. At the other extreme, simple lateen EM is slower, but significantly improves accuracy — by 5.5%, on average — for hard EM, escaping some of its local optima.

It would be interesting to apply lateen algorithms to advanced parsing models (Blunsom and Cohn, 2010; Headden et al., 2009, *inter alia*) and learning algorithms (Gillenwater et al., 2010; Cohen and Smith, 2009, *inter alia*). Future work could explore other NLP tasks — such as clustering, sequence labeling, segmentation and alignment — that often employ EM. Our meta-heuristics are multi-faceted, featuring aspects of iterated local search, deterministic annealing, cross-validation, contrastive estimation and co-training. They may be generally useful in machine learning and non-convex optimization.

Appendix A. Experimental Design

Statistical techniques are vital to many aspects of computational linguistics (Johnson, 2009; Charniak, 1997; Abney, 1996, *inter alia*). We used factorial designs,[14] which are standard throughout the natural and social sciences, to assist with experimental design and statistical analyses. Combined with ordinary regressions, these methods provide succinct and interpretable summaries that explain which settings meaningfully contribute to changes in dependent variables, such as running time and accuracy.

[14] We used *full* factorial designs for clarity of exposition. But many fewer experiments would suffice, especially in regression models without interaction terms: for the more efficient *fractional* factorial designs, as well as for randomized block designs and full factorial designs, see Montgomery (2005, Ch. 4–9).

9.1 Dependent Variables

We constructed two regressions, for two types of dependent variables: to summarize performance, we predict accuracies; and to summarize efficiency, we predict (logarithms of) iterations before termination.

In the performance regression, we used four different scores for the dependent variable. These include both directed accuracies and *undirected* accuracies, each computed in two ways: (i) using a best parse tree; and (ii) using all parse trees. These four types of scores provide different kinds of information. Undirected scores ignore polarity of parent-child relations (Paskin, 2001; Klein and Manning, 2004; Schwartz et al., 2011), partially correcting for some effects of alternate analyses (e.g., systematic choices between modals and main verbs for heads of sentences, determiners for noun phrases, etc.). And *integrated* scoring, using the inside-outside algorithm (Baker, 1979) to compute expected accuracy across all — not just best — parse trees, has the advantage of incorporating probabilities assigned to individual arcs: This metric is more sensitive to the margins that separate best from next-best parse trees, and is not affected by tie-breaking. We tag scores using two binary predictors in a simple (first order, multi-linear) regression, where having multiple relevant quality assessments improves goodness-of-fit.

In the efficiency regression, dependent variables are logarithms of the numbers of iterations. Wrapping EM in an inner loop of a heuristic has a multiplicative effect on the total number of models re-estimated prior to termination. Consequently, logarithms of the final counts better fit the observed data.

9.2 Independent Predictors

All of our predictors are binary indicators (a.k.a. "dummy" variables). The *undirected* and *integrated* factors only affect the regression for accuracies (see Table 4, left); remaining factors participate also in the running times regression (see Table 4, right). In a default run, all factors are zero, corresponding to the intercept estimated by a regression; other estimates reflect changes in the dependent variable associated with having that factor "on" instead of "off."

- *adhoc* — This setting controls initialization. By default, we use the uninformed uniform initializer (Spitkovsky et al., 2010a); when it is

	Goodness-of-Fit:		Regression for **Accuracies** ($R^2_{adj} \approx 76.2\%$)		Regression for ln(**Iterations**) ($R^2_{adj} \approx 82.4\%$)

Table 4: Regressions for accuracies and natural-log-iterations, using 86 binary predictors (all p-values jointly adjusted for simultaneous hypothesis testing; {*langyear*} indicators not shown). Accuracies' estimated coefficients $\hat{\beta}$ that are statistically different from 0 — and iteration counts' multipliers $e^{\hat{\beta}}$ significantly different from 1 — are shown in bold.

on, we use Klein and Manning's (2004) "adhoc" harmonic heuristic, bootstrapped using sentences up to length 10, from the training set.

- *sweet* — This setting controls the length cutoff. By default, we train with all sentences containing up to 45 tokens; when it is on, we use Spitkovsky et al.'s (2009) "sweet spot" cutoff of 15 tokens (recommended for English, WSJ).
- *viterbi* — This setting controls the primary objective of the learning algorithm. By default, we run soft EM; when it is on, we use hard EM.
- $\{\textit{langyear}_i\}_{i=1}^{22}$ — This is a set of 22 mutually-exclusive selectors for the language/year of a train/test split; default (all zeros) is English '07.

Due to space limitations, we exclude *langyear* predictors from Table 4. Further, we do not explore (even two-way) interactions between predictors.[15]

9.3 Statistical Significance

Our statistical analyses relied on the R package (R Development Core Team, 2011), which does not, by default, adjust statistical significance (p-values) for multiple hypotheses testing.[16] We corrected this using the Holm-Bonferroni method (Holm, 1979), which is uniformly more powerful than the older (Dunn-)Bonferroni procedure; since we tested many fewer hypotheses ($44 + 42$ — one per intercept/coefficient $\hat{\beta}$) than settings combinations, its adjustments to the p-values are small (see Table 4).[17]

[15] This approach may miss some interesting facts, e.g., that the *adhoc* initializer is exceptionally good for English, with soft EM. Instead it yields coarse summaries of regularities supported by overwhelming evidence across data and training regimes.

[16] Since we would *expect* $p\%$ of randomly chosen hypotheses to appear significant at the $p\%$ level simply by *chance*, we must take precautions against these and other "data-snooping" biases.

[17] We adjusted the p-values for all 86 hypotheses jointly, using `http://rss.acs.unt.edu/Rdoc/library/multtest/html/mt.rawp2adjp.html`.

Table 5: Performance (directed dependency accuracies measured against all sentences in the evaluation sets) and efficiency (numbers of iterations) for standard training (soft and hard EM), early-stopping lateen EM ($A3$) and simple lateen EM with hard EM's primary objective ($A1_h$), for all 23 train/test splits, with *adhoc* and *sweet* settings on.

9.4 Interpretation

Table 4 shows the estimated coefficients and their (adjusted) p-values for both intercepts and most predictors (excluding the language/year of the data sets) for all 1,840 experiments. The default (English) system uses soft EM, trains with both short and long sentences, and starts from an uninformed uniform initializer. It is estimated to score 30.9%, converging after approximately 256 iterations (both intercepts are statistically different from zero: $p < 2.0 \times 10^{-16}$).

As had to be the case, we detect a gain from *undirected* scoring; *integrated* scoring is slightly (but significantly: $p \approx 7.0 \times 10^{-7}$) negative, which is reassuring: best parses are scoring higher than the rest and may be standing out by large margins. The *adhoc* initializer boosts accuracy by 1.2%, overall (also significant: $p \approx 3.1 \times 10^{-13}$), without a measurable impact on running time ($p \approx 1.0$). Training with fewer, shorter sentences, at the *sweet* spot gradation, adds 1.0% and shaves 20% off the total number of iterations, on average (both estimates are significant).

We find the *viterbi* objective harmful — by 4.0%, on average ($p \approx 5.7 \times 10^{-16}$) — for the CoNLL sets. Spitkovsky et al. (2010a) reported that it helps on WSJ, at least with long sentences and uniform initializers. Half of our experiments are with shorter sentences, and half use ad hoc initializers (i.e., three quarters of settings are not ideal for Viterbi EM), which may have contributed to this negative result; still, our estimates do confirm that hard EM is significantly (80%, $p < 2.0 \times 10^{-16}$) faster than soft EM.

9.5 More on Viterbi Training

The overall negative impact of Viterbi objectives is a cause for concern: On average, $A1_h$'s estimated gain of 5.5% should more than offset the expected 4.0% loss from starting with hard EM. But it is, nevertheless, important to make sure that simple lateen EM with hard EM's primary objective is in fact an improvement over *both* standard EM algorithms.

Table 5 shows performance and efficiency numbers for $A1_h$, $A3_{\{h,s\}}$, as well as standard soft and hard EM, using settings that are least favorable for

Table 6: Performance (directed dependency accuracies measured against all sentences in the evaluation sets) and efficiency (numbers of iterations) for standard training (soft and hard EM), early-stopping lateen EM ($A3$) and simple lateen EM with hard EM's primary objective ($A1_h$), for all 23 train/test splits, with setting *adhoc* off and *sweet* on.

Viterbi training: *adhoc* and *sweet* on. Although $A1_h$ scores 7.1% higher than hard EM, on average, it is only slightly better than soft EM — up 0.1% (and worse than $A1_s$). Without *adhoc* (i.e., using uniform initializers — see Table 6), however, hard EM still improves, by 3.2%, on average, whereas soft EM drops nearly 10%; here, $A1_h$ further improves over hard EM, scoring 38.2% (up 5.0), higher than soft EM's accuracies from *both* settings (27.3 and 37.0).

This suggests that $A1_h$ is indeed better than both standard EM algorithms. We suspect that our experimental set-up may be disadvantageous for Viterbi training, since half the settings use ad hoc initializers, and because CoNLL sets are small. (Viterbi EM works best with more data and longer sentences.)

Abstract

We show that categories induced by unsupervised word clustering can surpass the performance of gold part-of-speech tags in dependency grammar induction. Unlike classic clustering algorithms, our method allows a word to have different tags in different contexts. In an ablative analysis, we first demonstrate that this context-dependence is crucial to the superior performance of gold tags — requiring a word to always have the same part-of-speech significantly degrades the performance of manual tags in grammar induction, eliminating the advantage that human annotation has over unsupervised tags. We then introduce a sequence modeling technique that combines the output of a word clustering algorithm with context-colored noise, to allow words to be tagged differently in different contexts. With these new induced tags as input, our state-of-the-art dependency grammar inducer achieves 59.1% directed accuracy on Section 23 (all sentences) of the Wall Street Journal (WSJ) corpus — 0.7% higher than using gold tags.

1 Introduction

Unsupervised learning — machine learning without manually-labeled training examples — is an active area of scientific research. In natural language processing, unsupervised techniques have been successfully applied to tasks such as word alignment for machine translation. And since the advent of the web, algorithms that induce structure from unlabeled data have continued to steadily gain importance. In this paper we focus on unsupervised part-of-speech tagging and dependency parsing — two related problems of syntax discovery. Our methods are applicable to vast quantities of unlabeled monolingual text.

Not all research on these problems has been fully unsupervised. For example, to the best of our knowledge, every new state-of-the-art dependency grammar inducer since Klein and Manning (2004) relied on gold part-of-speech tags. For some time, multi-point performance degradations caused by switching to automatically induced word categories have been interpreted as indications that "good enough" parts-of-speech induction methods exist, justifying the focus on grammar induction with supervised part-of-speech tags (Bod, 2006), pace (Cramer, 2007). One of several drawbacks of this practice is that it weakens any conclusions that could be drawn about how computers (and possibly humans) learn in the absence of explicit feedback (McDonald et al., 2011).

In turn, not all unsupervised taggers actually induce word categories: Many systems — known as part-of-speech *disambiguators* (Merialdo, 1994) — rely on external dictionaries of possible tags. Our work builds on two older part-of-speech *inducers* — word clustering algorithms of Clark (2000) and Brown et al. (1992) — that were recently shown to be more robust than other well-known fully unsupervised techniques (Christodoulopoulos et al., 2010).

We investigate which properties of gold part-of-speech tags are useful in grammar induction and parsing, and how these properties could be introduced into induced tags. We also explore the number of word classes that is good for grammar induction: in particular, whether categorization is needed at all. By removing the "unrealistic simplification" of using gold tags (Petrov et al., 2011, §3.2, Footnote 4), we will go on to demonstrate why grammar induction from plain text is no longer "still too difficult."

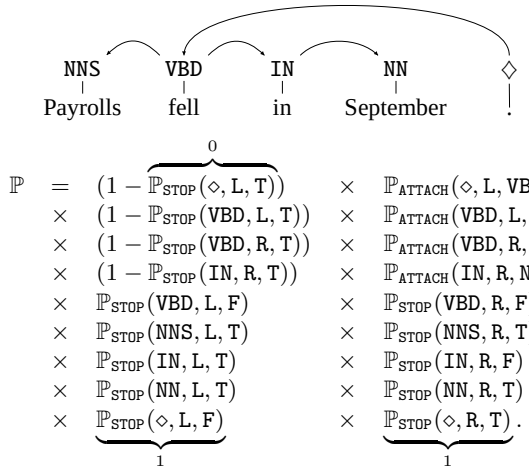

Figure 1: A dependency structure for a short WSJ sentence and its probability, factored by the DMV, using gold tags, after summing out $\mathbb{P}_{\text{ORDER}}$ (Spitkovsky et al., 2009).

2 Methodology

In all experiments, we model the English grammar via Klein and Manning's (2004) Dependency Model with Valence (DMV), induced from subsets of not-too-long sentences of the Wall Street Journal (WSJ).

2.1 The Model

The original DMV is a single-state head automata model (Alshawi, 1996) over lexical word classes $\{c_w\}$ — gold part-of-speech tags. Its generative story for a sub-tree rooted at a head (of class c_h) rests on three types of independent decisions: (i) initial direction $dir \in \{\text{L}, \text{R}\}$ in which to attach children, via probability $\mathbb{P}_{\text{ORDER}}(c_h)$; (ii) whether to seal dir, stopping with probability $\mathbb{P}_{\text{STOP}}(c_h, dir, adj)$, conditioned on $adj \in \{\text{T}, \text{F}\}$ (true iff considering dir's first, i.e., *adjacent*, child); and (iii) attachments (of class c_a), according to $\mathbb{P}_{\text{ATTACH}}(c_h, dir, c_a)$. This recursive process produces only projective trees. A root token $\diamond$ generates the head of the sentence as its left (and only) child (see Figure 1 for a simple, concrete example).

2.2 Learning Algorithms

The DMV lends itself to unsupervised learning via inside-outside re-estimation (Baker, 1979). Klein and Manning (2004) initialized their system using an "ad-hoc harmonic" completion, followed by training using 40 steps of EM (Klein, 2005). We reproduce this set-up, iterating without actually verifying convergence, in most of our experiments (#1–4, §3–4).

Experiments #5–6 (§5) employ our new state-of-the-art grammar inducer (Spitkovsky et al., 2011), which uses constrained Viterbi EM (details in §5).

2.3 Training Data

The DMV is usually trained on a customized subset of Penn English Treebank's Wall Street Journal portion (Marcus et al., 1993). Following Klein and Manning (2004), we begin with reference constituent parses, prune out all empty sub-trees and remove punctuation and terminals (tagged # and $) that are not pronounced where they appear. We then train only on the remaining sentence *yields* consisting of no more than fifteen tokens (WSJ15), in most of our experiments (#1–4, §3–4); by contrast, Klein and Manning's (2004) original system was trained using less data: sentences up to length ten (WSJ10).[1]

Our final experiments (#5–6, §5) employ a simple scaffolding strategy (Spitkovsky et al., 2010a) that follows up initial training at WSJ15 ("less is more") with an additional training run ("leapfrog") that incorporates most sentences of the data set, at WSJ45.

2.4 Evaluation Methods

Evaluation is against the training set, as is standard practice in unsupervised learning, in part because Klein and Manning (2004, §3) did not smooth the DMV (Klein, 2005, §6.2). For most of our experiments (#1–4, §3–4), this entails starting with the reference trees from WSJ15 (as modified in §2.3), automatically converting their labeled constituents into unlabeled dependencies using deterministic "head-percolation" rules (Collins, 1999), and then computing (directed) dependency accuracy scores of the corresponding induced trees. We report overall percentages of correctly guessed arcs, including the arcs from sentence root symbols, as is standard practice (Paskin, 2001; Klein and Manning, 2004).

For a meaningful comparison with previous work, we also test some of the models from our earlier experiments (#1,3) — and both models from final experiments (#5,6) — against Section 23 of WSJ$^\infty$, after applying Laplace (a.k.a. "add one") smoothing.

[1] WSJ15 contains 15,922 sentences up to length fifteen (a total of 163,715 tokens, not counting punctuation) — versus 7,422 sentences of at most ten words (only 52,248 tokens) comprising WSJ10 — and is a better trade-off between the quantity and complexity of training data in WSJ (Spitkovsky et al., 2009).

	Accuracy		Viable
1. **manual** tags	*Unsupervised*	*Sky*	*Groups*
gold	50.7	*78.0*	36
mfc	**47.2**	74.5	34

ua	44.3	**78.4**	328
2. tagless **lexicalized** models			
full	25.8	**97.3**	49,180
partial	29.3	60.5	176
none	**30.7**	*24.5*	1
3. tags from a **flat** (Clark, 2000) clustering			
	47.8	**83.8**	197
4. prefixes of a **hierarchical** (Brown et al., 1992) clustering			
first 7 bits	46.4	73.9	96
8 bits	**48.0**	77.8	165
9 bits	46.8	**82.3**	262

Table 1: Directed accuracies for the "less is more" DMV, trained on WSJ15 (after 40 steps of EM) and evaluated also against WSJ15, using various lexical categories in place of gold part-of-speech tags. For each tag-set, we include its effective number of (non-empty) categories in WSJ15 and the oracle skylines (supervised performance).

3 Motivation and Ablative Analyses

The concepts of polysemy and synonymy are of fundamental importance in linguistics. For words that can take on multiple parts of speech, knowing the gold tag can reduce ambiguity, improving parsing by limiting the search space. Furthermore, pooling the statistics of words that play similar syntactic roles, as signaled by shared gold part-of-speech tags, can simplify the learning task, improving generalization by reducing sparsity. We begin with two sets of experiments that explore the impact that each of these factors has on grammar induction with the DMV.

3.1 Experiment #1: Human-Annotated Tags

Our first set of experiments attempts to isolate the effect that replacing gold part-of-speech tags with deterministic *one class per word* mappings has on performance, quantifying the cost of switching to a monosemous clustering (see Table 1: manual; and Table 4). Grammar induction with gold tags scores 50.7%, while the oracle skyline (an ideal, supervised instance of the DMV) could attain 78.0% accuracy.

It may be worth noting that only 6,620 (13.5%) of 49,180 unique tokens in WSJ appear with multiple part-of-speech tags. Most words, like *it*, are always tagged the same way (5,768 times PRP). Some words, like *gains*, usually serve as one part of speech (227 times NNS, as in *the gains*) but are occasionally used differently (5 times VBZ, as in *he gains*). Only 1,322 tokens (2.7%) appear with three or more different gold tags. However, this minority includes the most frequent word — *the* (50,959 times DT, 7 times JJ, 6 times NNP and once as each of CD, NN and VBP).[2]

token	*mfc*	*mfp*	*ua*
it	{PRP}	{PRP}	{PRP}
gains	{NNS}	{VBZ, NNS}	{VBZ, NNS}
the	{DT}	{JJ, DT}	{VBP, NNP, NN, JJ, DT, CD}

Table 2: Example most frequent class, most frequent pair and union all reassignments for tokens *it*, *the* and *gains*.

We experimented with three natural reassignments of part-of-speech categories (see Table 2). The first, *most frequent class* (mfc), simply maps each token to its most common gold tag in the entire WSJ (with ties resolved lexicographically). This approach discards two gold tags (types PDT and RBR are not most common for any of the tokens in WSJ15) and costs about three-and-a-half points of accuracy, in both supervised and unsupervised regimes.

Another reassignment, *union all* (ua), maps each token to the set of all of its observed gold tags, again in the entire WSJ. This inflates the number of groupings by nearly a factor of ten (effectively lexicalizing the most ambiguous words),[3] yet improves the oracle skyline by half-a-point over actual gold tags; however, learning is harder with this tag-set, losing more than six points in unsupervised training.

Our last reassignment, *most frequent pair* (mfp), allows up to two of the most common tags into a token's label set (with ties, once again, resolved lexicographically). This intermediate approach performs strictly worse than *union all*, in both regimes.

3.2 Experiment #2: Lexicalization Baselines

Our next set of experiments assesses the benefits of categorization, turning to lexicalized baselines that avoid grouping words altogether. All three models discussed below estimated the DMV *without* using the gold tags in any way (see Table 1: lexicalized).

[2] Some of these are annotation errors in the treebank (Banko and Moore, 2004, Figure 2): such (mis)taggings can severely degrade the accuracy of part-of-speech disambiguators, without additional supervision (Banko and Moore, 2004, §5, Table 1).

[3] Kupiec (1992) found that the 50,000-word vocabulary of the Brown corpus similarly reduces to ∼400 ambiguity classes.

First, not surprisingly, a fully-lexicalized model over nearly 50,000 unique words is able to essentially memorize the training set, supervised. (Without smoothing, it is possible to deterministically attach most rare words in a dependency tree correctly, etc.) Of course, local search is unlikely to find good instantiations for so many parameters, causing unsupervised accuracy for this model to drop in half.

For our next experiment, we tried an intermediate, partially-lexicalized approach. We mapped frequent words — those seen at least 100 times in the training corpus (Headden et al., 2009) — to their own individual categories, lumping the rest into a single "unknown" cluster, for a total of under 200 groups. This model is significantly worse for supervised learning, compared even with the monosemous clusters derived from gold tags; yet it is only slightly more learnable than the broken fully-lexicalized variant.

Finally, for completeness, we trained a model that maps every token to the same one "unknown" category. As expected, such a trivial "clustering" is ineffective in supervised training; however, it outperforms both lexicalized variants unsupervised,[4] strongly suggesting that lexicalization alone may be insufficient for the DMV and hinting that some degree of categorization is essential to its learnability.

Cluster #173		*Cluster #188*	
1.	open	1.	get
2.	free	2.	make
3.	further	3.	take
4.	higher	4.	find
5.	lower	5.	give
6.	similar	6.	keep
7.	leading	7.	pay
8.	present	8.	buy
9.	growing	9.	win
10.	increased	10.	sell
⋮		⋮	
37.	cool	42.	improve
⋮		⋮	
1,688.	up-wind	2,105.	zero-out

Table 3: Representative members for two of the flat word groupings: cluster #173 (left) contains adjectives, especially ones that take comparative (or other) complements; cluster #188 comprises bare-stem verbs (infinitive stems). (Of course, many of the words have other syntactic uses.)

[4]Note that it also beats supervised training. That isn't a bug: Spitkovsky et al. (2010b, §7.2) explain this paradox in the DMV.

4 Grammars over Induced Word Clusters

We have demonstrated the need for grouping similar words, estimated a bound on performance losses due to monosemous clusterings and are now ready to experiment with induced part-of-speech tags. We use two sets of established, publicly-available hard clustering assignments, each computed from a much larger data set than WSJ (approximately a million words). The first is a flat mapping (200 clusters) constructed by training Clark's (2000) distributional similarity model over several hundred million words from the British National and the English Gigaword corpora.[5] The second is a hierarchical clustering — binary strings up to eighteen bits long — constructed by running Brown et al.'s (1992) algorithm over 43 million words from the BLLIP corpus, minus WSJ.[6]

4.1 Experiment #3: A Flat Word Clustering

Our main purely unsupervised results are with a flat clustering (Clark, 2000) that groups words having similar context distributions, according to Kullback-Leibler divergence. (A word's context is an ordered pair: its left- and right-adjacent neighboring words.)

To avoid overfitting, we employed an implementation from previous literature (Finkel and Manning, 2009). The number of clusters (200) and the sufficient amount of training data (several hundred-million words) were tuned to a task (NER) that is not directly related to dependency parsing. (Table 3 shows representative entries for two of the clusters.)

We added one more category (#0) for unknown words. Now every token in WSJ could again be replaced by a coarse identifier (one of at most 201, instead of just 36), in both supervised and unsupervised training. (Our training code did not change.)

The resulting supervised model, though not as good as the fully-lexicalized DMV, was more than five points more accurate than with gold part-of-speech tags (see Table 1: flat). Unsupervised accuracy was lower than with gold tags (see also Table 4) but higher than with *all* three derived hard assignments. This suggests that polysemy (i.e., ability to

[5]`http://nlp.stanford.edu/software/stanford-postagger-2008-09-28.tar.gz:models/egw.bnc.200`

[6]`http://people.csail.mit.edu/maestro/papers/bllip-clusters.gz`

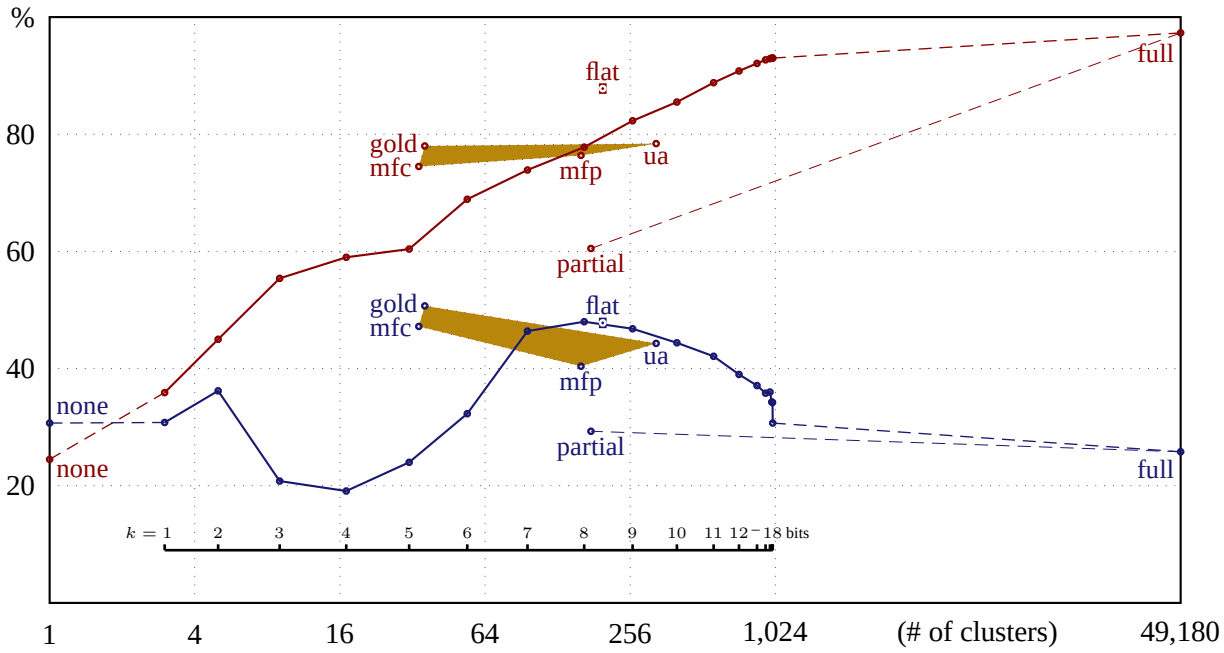

Figure 2: Parsing performance (accuracy on WSJ15) as a "function" of the number of syntactic categories, for all prefix lengths — $k \in \{1, \ldots, 18\}$ — of a hierarchical (Brown et al., 1992) clustering, connected by solid lines (dependency grammar induction in blue; supervised oracle skylines in red, above). Tagless lexicalized models (*full*, *partial* and *none*) connected by dashed lines. Models based on *gold* part-of-speech tags, and derived monosemous clusters (*mfc*, *mfp* and *ua*), shown as vertices of gold polygons. Models based on a *flat* (Clark, 2000) clustering indicated by squares.

tag a word differently in context) may be the primary advantage of manually constructed categorizations.

4.2 Experiment #4: A Hierarchical Clustering

The purpose of this batch of experiments is to show that Clark's (2000) algorithm isn't unique in its suitability for grammar induction. We found that Brown et al.'s (1992) older information-theoretic approach, which does not explicitly address the problems of rare and ambiguous words (Clark, 2000) and was designed to induce large numbers of plausible syntactic *and* semantic clusters, can perform just as well.

Once again, the sufficient amount of data (43 million words) was tuned in earlier work (Koo, 2010). His task of interest was, in fact, dependency parsing. But since this algorithm is hierarchical (i.e., there isn't a parameter for the number of categories), we doubt that there was a strong enough risk of overfitting to question the clustering's unsupervised nature.

As there isn't a set number of categories, we used binary prefixes of length k from each word's address in the computed hierarchy as cluster labels. Results for $7 \leq k \leq 9$ bits (approximately 100–250 non-empty clusters, close to the 200 we used before) are similar to those of flat clusters (see Table 1: hierarchical). Outside of this range, however, performance can be substantially worse (see Figure 2), consistent with earlier findings: Headden et al. (2008) demonstrated that (constituent) grammar induction, using the singular-value decomposition (SVD-based) tagger of Schütze (1995), also works best with 100–200 clusters. Important future research directions may include learning to automatically select a good number of word categories (in the case of flat clusterings) and ways of using multiple clustering assignments, perhaps of different granularities/resolutions, in tandem (e.g., in the case of a hierarchical clustering).

4.3 Further Evaluation

It is important to enable easy comparison with previous and future work. Since WSJ15 is not a standard test set, we evaluated two key experiments — "less is more" with gold part-of-speech tags (#1, Table 1: gold) and with Clark's (2000) clusters (#3, Table 1: flat) — on all sentences (not just length fifteen and shorter), in Section 23 of WSJ (see Table 4). This required smoothing both final models (§2.4).

We showed that two classic unsupervised word

	System Description		*Accuracy*
#1 (§3.1)	"less is more"	(Spitkovsky et al., 2009)	44.0
#3 (§4.1)	"less is more" with monosemous induced tags		41.4 (-2.6)

Table 4: Directed accuracies on Section 23 of WSJ (all sentences) for two experiments with the base system.

clusterings — one flat and one hierarchical — can be better for dependency grammar induction than monosemous syntactic categories derived from gold part-of-speech tags. And we confirmed that the unsupervised tags are worse than the actual gold tags, in a simple dependency grammar induction system.

5 State-of-the-Art without Gold Tags

Until now, we have deliberately kept our experimental methods simple and nearly identical to Klein and Manning's (2004), for clarity. Next, we will explore how our main findings generalize beyond this toy setting. A preliminary test will simply quantify the effect of replacing gold part-of-speech tags with the monosemous flat clustering (as in experiment #3, §4.1) on a modern grammar inducer. And our last experiment will gauge the impact of using a polysemous (but still unsupervised) clustering instead, obtained by executing standard sequence labeling techniques to introduce context-sensitivity into the original (independent) assignment or words to categories.

These final experiments are with our latest state-of-the-art system (Spitkovsky et al., 2011) — a partially lexicalized extension of the DMV that uses constrained Viterbi EM to train on nearly all of the data available in WSJ, at WSJ45 (48,418 sentences; 986,830 non-punctuation tokens). The key contribution that differentiates this model from its predecessors is that it incorporates punctuation into grammar induction (by turning it into parsing constraints, instead of ignoring punctuation marks altogether). In training, the model makes a simplifying assumption — that sentences can be split at punctuation and that the resulting fragments of text could be parsed independently of one another (these parsed fragments are then reassembled into full sentence trees, by parsing the sequence of their own head words). Furthermore, the model continues to take punctuation marks into account in inference (using weaker, more accurate constraints, than in training). This system scores 58.4% on Section 23 of WSJ$^\infty$ (see Table 5).

5.1 Experiment #5: A Monosemous Clustering

As in experiment #3 (§4.1), we modified the base system in exactly one way: we swapped out gold part-of-speech tags and replaced them with a flat distributional similarity clustering. In contrast to simpler models, which suffer multi-point drops in accuracy from switching to unsupervised tags (e.g., 2.6%), our new system's performance degrades only slightly, by 0.2% (see Tables 4 and 5). This result improves over substantial performance degradations previously observed for unsupervised dependency parsing with induced word categories (Klein and Manning, 2004; Headden et al., 2008, *inter alia*).[7]

One risk that arises from using gold tags is that newer systems could be finding cleverer ways to exploit manual labels (i.e., developing an over-reliance on gold tags) instead of actually learning to acquire language. Part-of-speech tags are *known* to contain significant amounts of information for unlabeled dependency parsing (McDonald et al., 2011, §3.1), so we find it reassuring that our latest grammar inducer is *less* dependent on gold tags than its predecessors.

5.2 Experiment #6: A Polysemous Clustering

Results of experiments #1 and 3 (§3.1, 4.1) suggest that grammar induction stands to gain from relaxing the *one class per word* assumption. We next test this conjecture by inducing a polysemous unsupervised word clustering, then using it to induce a grammar.

Previous work (Headden et al., 2008, §4) found that simple bitag hidden Markov models, classically trained using the Baum-Welch (Baum, 1972) variant of EM (HMM-EM), perform quite well,[8] on average, across different grammar induction tasks. Such sequence models incorporate a sensitivity to context via state transition probabilities $\mathbb{P}_{\texttt{TRAN}}(t_i \mid t_{i-1})$, capturing the likelihood that a tag t_i immediately follows the tag t_{i-1}; emission probabilities $\mathbb{P}_{\texttt{EMIT}}(w_i \mid t_i)$ capture the likelihood that a word of type t_i is w_i.

[7] We also briefly comment on this result in the "punctuation" paper (Spitkovsky et al., 2011, §7), published concurrently.

[8] They are also competitive with Bayesian estimators, on larger data sets, with cross-validation (Gao and Johnson, 2008).

	System Description		*Accuracy*
(§5)	"punctuation"	(Spitkovsky et al., 2011)	58.4
#5 (§5.1)	"punctuation" with monosemous induced tags		58.2 (-0.2)
#6 (§5.2)	"punctuation" with **context-sensitive** induced tags		**59.1** (+**0.7**)

Table 5: Directed accuracies on Section 23 of WSJ (all sentences) for experiments with the state-of-the-art system.

We need a context-sensitive tagger, and HMM models are good — relative to other tag-inducers. However, they are not better than gold tags, at least when trained using a modest amount of data.[9] For this reason, we decided to relax the monosemous flat clustering, plugging it in as an initializer for the HMM. The main problem with this approach is that, at least without smoothing, every monosemous labeling is trivially at a local optimum, since $\mathbb{P}(t_i \mid w_i)$ is deterministic. To escape the initial assignment, we used a "noise injection" technique (Selman et al., 1994), inspired by the contexts of Clark (2000). First, we collected the MLE statistics for $\mathbb{P}_{\text{R}}(t_{i+1} \mid t_i)$ and $\mathbb{P}_{\text{L}}(t_i \mid t_{i+1})$ in WSJ, using the flat monosemous tags. Next, we replicated the text of WSJ 100-fold. Finally, we retagged this larger data set, as follows: with probability 80%, a word kept its monosemous tag; with probability 10%, we sampled a new tag from the left context ($\mathbb{P}_{\text{L}}$) associated with the original (monosemous) tag of its rightmost neighbor; and with probability 10%, we drew a tag from the right context ($\mathbb{P}_{\text{R}}$) of its leftmost neighbor.[10] Given that our initializer — and later the input to the grammar inducer — are hard assignments of tags to words, we opted for (the faster and simpler) Viterbi training.

In the spirit of reproducibility, we again used an off-the-shelf component for tagging-related work.[11] Viterbi training converged after just 17 steps, replacing the original monosemous tags for 22,280 (of 1,028,348 non-punctuation) tokens in WSJ. For example, the first changed sentence is #3 (of 49,208):

> *Some "circuit breakers" installed after the October 1987 crash failed their first test, traders say, unable to **cool** the selling panic in both stocks and futures.*

Above, the word *cool* gets relabeled as #188 (from #173 — see Table 3), since its context is more suggestive of an infinitive verb than of its usual grouping with adjectives. (A proper analysis of all changes, however, is beyond the scope of this work.)

Using this new context-sensitive hard assignment of tokens to unsupervised categories our grammar inducer attained a directed accuracy of 59.1%, nearly a full point better than with the monosemous hard assignment (see Table 5). To the best of our knowledge it is also the first state-of-the-art unsupervised dependency parser to perform better with induced categories than with gold part-of-speech tags.

6 Related Work

Early work in dependency grammar induction already relied on gold part-of-speech tags (Carroll and Charniak, 1992). Some later models (Yuret, 1998; Paskin, 2001, *inter alia*) attempted full lexicalization. However, Klein and Manning (2004) demonstrated that effort to be worse at recovering dependency arcs than choosing parse structures at random, leading them to incorporate gold tags into the DMV.

Klein and Manning (2004, §5, Figure 6) had also tested their own models with induced word classes, constructed using a distributional similarity clustering method (Schütze, 1995). Without gold part-of-speech tags, their combined DMV+CCM model was about five points worse, both in (directed) unlabeled dependency accuracy (42.3% vs. 47.5%)[12] and unlabeled bracketing F_1 (72.9% vs. 77.6%), on WSJ10.

In constituent parsing, earlier Seginer (2007a, §6, Table 1) built a fully-lexicalized grammar inducer

[9] All of Headden et al.'s (2008) grammar induction experiments with induced parts-of-speech were worse than their best results using gold part-of-speech tags, most likely because they used a very small corpus (half of WSJ10) to cluster words.

[10] We chose the sampling split (80:10:10) and replication parameter (100) somewhat arbitrarily, so better results could likely be obtained with tuning. However, we suspect that the real gains would come from using soft clustering techniques (Hinton and Roweis, 2003; Pereira et al., 1993, *inter alia*) and propagating (joint) estimates of tag distributions into a parser. Our ad-hoc approach is intended to serve solely as a proof of concept.

[11] David Elworthy's `C+ tagger`, with options `-i t -G -l`, available from `http://friendly-moose.appspot.com/code/NewCpTag.zip`.

[12] On the same evaluation set (WSJ10), our context-sensitive system without gold tags (Experiment #6, §5.2) scores 66.8%.

that was competitive with DMV+CCM despite not using gold tags. His CCL parser has since been improved via a "zoomed learning" technique (Reichart and Rappoport, 2010). Moreover, Abend et al. (2010) reused CCL's internal distributional representation of words in a cognitively-motivated part-of-speech inducer. Unfortunately their tagger did not make it into Christodoulopoulos et al.'s (2010) excellent and otherwise comprehensive evaluation.

Outside monolingual grammar induction, fully-lexicalized statistical dependency transduction models have been trained from unannotated parallel bitexts for machine translation (Alshawi et al., 2000). More recently, McDonald et al. (2011) demonstrated an impressive alternative to grammar induction by projecting reference parse trees from languages that have annotations to ones that are resource-poor.[13] It uses graph-based label propagation over a bilingual similarity graph for a sentence-aligned parallel corpus (Das and Petrov, 2011), inducing part-of-speech tags from a universal tag-set (Petrov et al., 2011).

Even in supervised parsing we are starting to see a shift away from using gold tags. For example, Alshawi et al. (2011) demonstrated good results for mapping text to underspecified semantics via dependencies without resorting to gold tags. And Petrov et al. (2010, §4.4, Table 4) observed only a small performance loss "going POS-less" in question parsing.

We are not aware of any systems that induce both syntactic trees and their part-of-speech categories. However, aside from the many systems that induce trees from gold tags, there are also unsupervised methods for inducing syntactic categories from gold trees (Finkel et al., 2007; Pereira et al., 1993), as well as for inducing dependencies from gold constituent annotations (Sangati and Zuidema, 2009; Chiang and Bikel, 2002). Considering that Headden et al.'s (2008) study of part-of-speech taggers found no correlation between standard tagging metrics and the quality of induced grammars, it may be time for a unified treatment of these very related syntax tasks.

[13] When the target language is English, however, their best accuracy (projected from Greek) is low: 45.7% (McDonald et al., 2011, §4, Table 2); tested on the same CoNLL 2007 evaluation set (Nivre et al., 2007), our "punctuation" system with context-sensitive induced tags (trained on WSJ45, without gold tags) performs substantially better, scoring 51.6%. Note that this is also an improvement over our system trained on the CoNLL set using gold tags: 50.3% (Spitkovsky et al., 2011, §8, Table 6).

7 Discussion and Conclusions

Unsupervised word clustering techniques of Brown et al. (1992) and Clark (2000) are well-suited to dependency parsing with the DMV. Both methods outperform gold parts-of-speech in supervised modes. And both can do better than monosemous clusters derived from gold tags in unsupervised training. We showed how Clark's (2000) flat tags can be relaxed, using context, with the resulting polysemous clustering outperforming gold part-of-speech tags for the English dependency grammar induction task.

Monolingual evaluation is a significant flaw in our methodology, however. One (of many) take-home points made in Christodoulopoulos et al.'s (2010) study is that results on one language do not necessarily correlate with other languages.[14] Assuming that our results do generalize, it will still remain to remove the present reliance on gold tokenization and sentence boundary labels. Nevertheless, we feel that eliminating gold tags is an important step towards the goal of fully-unsupervised dependency parsing.

We have cast the utility of a categorization scheme as a combination of two effects on parsing accuracy: a synonymy effect and a polysemy effect. Results of our experiments with both full and partial lexicalization suggest that grouping similar words (i.e., synonymy) is vital to grammar induction with the DMV. This is consistent with an established viewpoint, that simple tabulation of frequencies of words participating in certain configurations cannot be reliably used for comparing their likelihoods (Pereira et al., 1993, §4.2): "The statistics of natural languages is inherently ill defined. Because of Zipf's law, there is never enough data for a reasonable estimation of joint object distributions." Seginer's (2007b, §1.4.4) argument, however, is that the Zipfian distribution — a property of words, not parts-of-speech — should allow frequent words to successfully guide

[14] Furthermore, it would be interesting to know how sensitive different head-percolation schemes (Yamada and Matsumoto, 2003; Johansson and Nugues, 2007) would be to gold versus unsupervised tags, since the Magerman-Collins rules (Magerman, 1995; Collins, 1999) agree with gold dependency annotations only 85% of the time, even for WSJ (Sangati and Zuidema, 2009). Proper intrinsic evaluation of dependency grammar inducers is not yet a solved problem (Schwartz et al., 2011).

parsing and learning: "A relatively small number of frequent words appears almost everywhere and most words are never too far from such a frequent word (this is also the principle behind successful part-of-speech induction)." We believe that it is important to thoroughly understand how to reconcile these only seemingly conflicting insights, balancing them both in theory and in practice. A useful starting point may be to incorporate frequency information in the parsing models directly — in particular, capturing the relationships between words of various frequencies.

The polysemy effect appears smaller but is less controversial: Our experiments suggest that the primary drawback of the classic clustering schemes stems from their *one class per word* nature — and not a lack of supervision, as may be widely believed. Monosemous groupings, even if they are themselves derived from human-annotated syntactic categories, simply cannot disambiguate words the way gold tags can. By relaxing Clark's (2000) flat clustering, using contextual cues, we improved dependency grammar induction: directed accuracy on Section 23 (all sentences) of the WSJ benchmark increased from 58.2% to 59.1% — from slightly worse to better than with gold tags (58.4%, previous state-of-the-art).

Since Clark's (2000) word clustering algorithm is already context-sensitive in training, we suspect that one could do better simply by preserving the polysemous nature of its internal representation. Importing the relevant distributions into a sequence tagger directly would make more sense than going through an intermediate monosemous summary. And exploring other uses of *soft* clustering algorithms — perhaps as inputs to part-of-speech disambiguators — may be another fruitful research direction. We believe that a *joint* treatment of grammar and parts-of-speech induction could fuel major advances in both tasks.

Abstract

We propose a novel way of incorporating dependency parse and word co-occurrence information into a state-of-the-art web-scale n-gram model for spelling correction. The syntactic and distributional information provides extra evidence in addition to that provided by a web-scale n-gram corpus and especially helps with data sparsity problems. Experimental results show that introducing syntactic features into n-gram based models significantly reduces errors by up to 12.4% over the current state-of-the-art. The word co-occurrence information shows potential but only improves overall accuracy slightly.

1 Introduction

The function of context-sensitive text correction is to identify word-choice errors in text (Bergsma et al., 2009). It can be viewed as a lexical disambiguation task (Lapata and Keller, 2005), where a system selects from a predefined confusion word set, such as {affect, effect} or {complement, compliment}, and provides the most appropriate word choice given the context. Typically, one determines if a word has been used correctly based on lexical, syntactic and semantic information from the context of the word. One of the top performing models of spelling correction (Bergsma et al., 2010) is based on web-scale n-gram counts, which reflect both syntax and meaning. However, even with a large-scale n-gram corpus, data sparsity can hurt performance in two ways. First, n-gram based methods require exact word and order matches. If there is a low frequency word in the context, such as a person's name, there will be little, if any, evidence in the n-gram data to support the usage. Second, if the target confusable word is rare, there will not be enough n-gram support or training data to render a confident decision. Because of the data sparsity problem, language modeling is not always sufficient to capture the meaning of the sentence and the correct usage of the word.

Take a sentence from The New York Times (NYT) for example: "'This fellow's won a war,' the dean of the capital's press corps, David Broder, announced on 'Meet the Press' after **complimenting** the president on the 'great sense of authority and command' he exhibited in a flight suit." Unfortunately, neither the phrase "complementing the president" nor "complimenting the president" exists in the web-scale Google N-gram corpus (Brants and Franz, 2006). The n-gram models decide solely based on the frequency of the bi-grams "after comple(i)menting" and "comple(i)menting the", which are common usages for both words. The real question is whether we are more likely to "compliment" or "complement" a person, the "president". Several clues could help us answer that question. A dependency parser can identify the word "president" as the subject of "compliment" or "complement" which also may be the case in some of the training data. Lexical co-occurrence (Edmonds, 1997) and semantic word relatedness measurements, such as Random Indexing (Sahlgren, 2006), could provide evidence that "compliment" is more likely to co-occur with "president" than "complement". Fur-

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1291–1300,
Edinburgh, Scotland, UK, July 27–31, 2011.

thermore, some important clues can be quite distant from the target word, e.g. outside the 9-word context window Bergsma et al. (2010) and Carlson (2007) used. Consider another sentence in the NYT corpus, "GM says the addition of OnStar, which includes a system that automatically notifies an OnStar operator if the vehicle is involved in a collision, **complements** the Vue's top five-star safety rating for the driver and front passenger in both front- and side-impact crash tests." The dependency parser finds the object of "complement" is "rating", which is outside the 9-word window.

We propose enhancing state-of-the-art web-scale n-gram models for spelling correction with syntactic structures and distributional information. For our work, we build on a baseline system that combines n-gram and lexical features (Bergsma et al., 2010). Specifically, this paper makes the following contributions:

1. We show that the baseline system can be improved by augmenting it with dependency parse features.

2. We show that the impact of parse features can be further augmented when combined with distributional information, specifically word co-occurrence information.

In the following section, we describe related work and how our approach differs from these approaches. In Sections 3 and 4, we discuss our methods for using parse features and word co-occurrence information. In Section 5, we present experimental results and analysis.

2 Related Work

A variety of approaches have been proposed for context-sensitive spelling correction ranging from semantic methods to machine learning classifiers to large-scale n-gram models.

Some semantics-based systems have been developed based on an intuitive assumption that the intended word is more likely to be semantically coherent with the context than is a spelling error. Jones and Martin (1997) made use of the semantic similarity produced by Latent Semantic Analysis. Budanitsky and Hirst (2001) investigated the effectiveness of predicting words based on different semantic similarity/distance measures in WordNet. Both systems report performance that is lower than systems developed more recently.

A variety of machine-learning methods have been proposed in spelling correction and preposition and article error correction fields, such as Bayesian classifiers (Golding, 1995; Golding and Roth, 1996), Winnow-based learning (Golding and Roth, 1999), decision lists (Golding, 1995), transformation-based learning (Mangu and Brill, 1997), augmented mixture models (Cucerzan and Yarowsky, 2002) and maximum entropy classifiers (Izumi et al., 2003; Han et al., 2006; Chodorow et al., 2007; Tetreault and Chodorow, 2008; Felice and Pulman, 2008). Despite their differences, these approaches mainly use contextual features to capture the lexical, semantic and/or syntactic environment of the target word.

The use of distributional similarity measures for spelling correction has been previously explored in (Mohammad and Hist, 2006). In our work, distributional similarity is not the primary contribution but we show the impact it can have when used in conjunction with a large scale n-gram model and with parse features, which allows the system to select words outside the local window for distributional similarity. In the prior work, the words for distributional similarity are constrained to the local window, and positional information of the words is not encoded.

Recent work (Carlson and Fette, 2007; Gamon et al., 2008; Bergsma et al., 2009) has demonstrated that large-scale language modeling is extremely helpful for contextual spelling correction and other lexical disambiguation tasks. These systems make the word choice depending on how frequently each candidate word has been seen in the given context in web-scale data. As n-gram data has become more readily available, such as the Google N-gram Corpus, the likelihood of a word being used in a certain context can be better estimated.

Bergsma et al. (2009; 2010) presented a series of simple but powerful models which relied heavily on web-scale n-gram counts. From the Google Web N-gram Corpus, they retrieve counts of n-grams of different sizes (2-5) and positions that span the target word w0 within a window of 9 words. For example, for the following sentence: "The system tried to decide {among, between} the two confus-

able words.", the method would extract the five 5-gram patterns, shown below in Figure 2, where $w0$ can be either word in the confusion set {among, between} in this particular example. Similarly, there are four 4-grams, three 3-grams, and two 2-grams, in total, 14 n-grams for each of the words in the confusion set.

system tried to decide $w0$
tried to decide $w0$ the
to decide $w0$ the two
decide $w0$ the two confusable
$w0$ the two confusable words

We briefly describe three of Bergsma et al.'s (2009; 2010) best systems below, which are reported to achieve state-of-the-art accuracy (NG = n-gram; LEX = lexical).

1. **sumLM**: For each candidate word, (Bergsma et al., 2009) sum the log-counts of all 14 patterns filled with the candidate, and choose the candidate with the highest total.

2. **NG**: Bergsma et al. (2009) exploit each candidate's 14 log-counts of n-gram patterns as features in a Support Vector Machine (SVM) model.

3. **NG+LEX**: Bergsma et al. (2010) augment the NG model with lexical features (described in detail in Section 3.1).

Bergsma et al. (2009; 2010) restricted their experiments to only five confusion sets where the reported performance in (Golding and Roth, 1999) was below 90%: {among, between}, {amount, number}, {cite, sight, site}, {peace, piece} and {raise, rise}. They reported that the SVM model with NG features outperformed its unsupervised version, sumLM. However, the limited confusion word sets they evaluated may not comprehensively represent the word usage errors that writers typically make. In this paper, we test nine additional commonly confused word pairs to expand the scope of the evaluation. These words were selected based on their lower frequencies compared to the five pairs in the above work (as shown later in Table 2).

3 Enhanced N-gram Models with Parse Features

To our knowledge, only (Elmi and Evans, 1998) have used parsing for spell correction. They focus on using a parser as a filter to discriminate between possible real-world corrections where the part-of-speech differs. In our work, we show that parse features are effective when used directly in the classification mode (as opposed to as a final filter) to select the best correction regardless of whether or not the part-of-speech of the choices differ.

Statistical parsers have also seen limited use in the sister tasks of preposition and article error detection (Hermet et al., 2008; Lee and Knutsson, 2008; Felice and Pulman, 2009; Tetreault et al., 2010) and verb sense disambiguation (Dligach and Palmer, 2008). In those instances where parsers have been used, they have mainly provided shallow analyses or relations involving specific target words, such as a preposition or verb. Unlike preposition errors, spelling errors can occur in any word.

In this paper, we propose a novel way to incorporate the parse into spelling correction, applying the parser to sentences filled by each candidate word equivalently and extracting salient features. This overcomes two problem in the existing methods: 1) the parse trees of the same sentence filled by different confusion words can be different. However, in the test phase, we do not know which word should be put in the sentences to create parse features for test examples. Previous studies (Tetreault et al., 2010) failed to discuss this issue. 2) Some existing work (Whitelaw et al., 2009; Rozovskaya and Roth, 2010) in the text correction field introduced artificial errors into training data to adapt the system to better handle ill-formed text. But this method will encounter serious data sparsity problems when facing rare words.

3.1 Baseline System

We chose one of the leading spelling correction systems, (Bergsma et al., 2010), as our primary baseline. As noted earlier, it is an SVM-based system combining web-scale n-gram counts (NG) and contextual words (LEX) as features. To simplify the explanation, throughout the paper, we will only consider the situation with two confusion words. The

problem with more than two words in pre-defined confusion sets can be solved similarly by using a one-vs.-all strategy. As we mentioned in Section 2, NG features include log-counts of 3-to-5-gram patterns for each candidate word with the given context. LEX features can be broken down into three subcategories: 1) bag-of-words (words at all positions in a 9-word window around the target word), 2) indicators for the words preceding or following the target word, and 3) indicators for all n-grams and their positions. For the sentence "The system tried to decide {among, between} the two confusable words.", examples of bag-of-word features would be "tried", "two", etc., the two positional bigrams would be "decide" and "the", and examples of the n-gram features would be right-trigram = "among the two" and left-4-gram = "tried to decide between".

3.2 Parse Features

The benefit of introducing dependency parse features is that 1) parse features capture contextual information in a larger context window; 2) parse features specify which words in the context are salient to the usage of the target word while purely lexically based approaches treat all words in the context equally. We use the Stanford dependency parser (de Marneffe et al., 2006) to extract six relevant feature classes.

Parse Features (PAR):

1. relation names (target word as head)
2. complement of the target word
3. combination of 1 and 2
4. relation names (target word as complement)
5. head of the target word
6. combination of 4 and 5

Each of these six classes of PAR features can contain zero to many values, since the target word can be involved in none to multiple grammatical relations and features of different filler words are merged together. The PAR features, like the LEX features, are binary. In Table 1, we present the parse features for an example sentence. The parse features here are listed as string values, but are later converted into binary numbers in the vectors for the SVM model.

4 Distributional Word Co-occurrence

Though lexical and parse features are complementary to n-gram models, they are learned from a normal training corpus and may not have enough coverage due to data sparsity. Take a sentence from the NYT for example: "An economist, he began his career as a professor – he is still called 'the professor,' by friends as a compliment and by foes as an insult – and taught at Harvard and Stanford ." If the most indicative word "friends" does not appear or does not appear enough times in the local context or dependencies with "compliment" as compared to "complement" in the training corpus, then the classifier may be unable to make the correct selection.

It is impractical and computationally costly to enlarge the training corpus without limit to include all possible language phenomena. A good compromise is to use word co-occurrence information from web-scale data. The other option is to make use of high-order word co-occurrence, which is included in many semantic word relatedness measures, such as Latent Semantic Analysis (LSA) (Landauer et al., 1998; Deerwester et al., 1990) or Random Indexing, both of which can be estimated from a moderate-size corpus.

Our intuition is to choose the confusion word which is most relevant to a given context. We define the salient words in context as a set M=m1, m2, m3, ..., and the relevance between two words as a function Relevance(w1, w2), which can either be calculated from word co-occurrence or Random Indexing. The score of each candidate word c in the confusion set given a context with meaningful words M is calculated by the following formula:

$$Score(c) = \sum_{m \in M} Relevance(c, m)$$

In this paper, we experiment with first-order word co-occurrence and Random Indexing as relevance measures. And we define salient contextual words as heads or complements in the dependency relations with the target word. In this way, we use the parse information to constrain the two distribution models. Thus the word co-occurrence information

Feature Name	PAR Features (compliment)	PAR Features (complement)
1. Head Relation Name	ccomp	appos
2. Head of Relation	says	collisions
3. Head Combination	ccomp_says	appos_collisions
4. Comp Relation Name	nsubj	dep
5. Comp of Relation	addition	rating
6. Comp Combination	nsub_addition	dep_rating

Table 1: Parse Feature Example for the sentence: "GM says the addition of OnStar, which includes a system that automatically notifies an OnStar operator if the vehicle is involved in a collision, **complements** the Vue's top five-star safety rating for the driver and front passenger in both front- and side-impact crash tests."

considerably overlaps with some values of the PAR features, but provides extra evidence from web-scale data rather than a limited amount of training data.

4.1 First-order Word Co-occurrence

The relevance based on first-order word co-occurrence is calculated from the Google Web 5-gram Corpus in a fashion similar to how we dealt with n-gram counts in the previous section. Given two words, w1 and w2, we consider all 8 possible patterns that appear in a local context (5-word window), where we use wildcard (*) to indicate any token:

w1 w2
w1 * w2
w1 * * w2
w1 * * * w2
w2 w1
w2 * w1
w2 * * w1
w2 * * * w1

The relevance is then calculated by summing the logarithm of each of the 8 different counts. Finally, we compare the score of each candidate word and output the one with higher score.

4.2 Random Indexing

The relevance scores based on Random Indexing are provided by a tool FRanI (Higgins, 2004) and a model trained on the Touchstone Applied Science Associates (TASA) corpus which contains 750k sentences and covers diverse topics (from a diversity of textbooks up to the college level). Take the sentence at the beginning of this section for example, where only the words "a" and "friends" are related to the target word (either "complement" or "compliment") by either relevance measure. The relevance based on Random Indexing for (complement, friends) is 0.08, (compliment, friends) is 0.19 and both (compliment, a) and (complement, a) are 0 because "a" is in the stop word list. Meanwhile, the relevance based on first order word co-occurrence for (compliment, friends) is 7.39, (complement, friends) is 5.38, (compliment, a) is 13.25, and (complement, a) is 13.42. The system with either kind of relevance outputs "compliment".

4.3 System Combination

Since the numeric measurement of word co-occurrence is not as specific as the PAR features and less trustworthy, adding word co-occurrence information as features into the classifier along with n-gram counts, lexical and parse features will hurt the overall performance. It is more practical to combine the two approaches in the following fashion:

1. When the SVM classifier (using NG, LEX and PAR features) has high confidence (over a certain threshold) in the output label, output that label;

2. Otherwise, output the results of the word relatedness/co-occurrence-based system.

5 Evaluation

We evaluate the effectiveness of syntactic and distributional information on spelling correction. The performance of the system is measured by accuracy: the percentage of sentences in the test data for which the system chooses the correct word. We compare our results against two baselines: 1) MAJOR chooses the most frequent candidate from the

confusion set in the training corpus, and 2) Bergsma et al.'s (2010) best systems, NG+LEX. We include inflectional variants ("-ing", "-ed", "-s", "-ly") of confusion words in the evaluation, such as complementing, complimenting in addition to complement, compliment, because this better corresponds to the range of errors that may be encountered in actual use and thus increases the scope of the system as a real world application. Also following Bergsma et al. (2010), we use a linear SVM, more exactly, the L2-regularized L2-loss dual SVM in LIBLINEAR (Fan et al., 2008). Unlike Bergsma et al., who used development data to optimize parameters, we always use default parameters, since training data is limited for many of the words we are dealing with.

5.1 Data

Following Bergsma et al. (2009; 2010), the test examples are extracted from The New York Times (NYT) portion of Gigaword[1], but constrained to a 9-month publication time frame from October 2005 to July 2006. Unlike Bergsma et al. who use the same source as training data for the lexical features, our training data (for both lexical and parse features) comes from larger and more diverse news sources. We use the very large database from Sekine's n-gram search engine (Sekine, 2008) as training data, which consists of 1.9B words of newspaper text spanning 89 years from NYT, BBC, WSJ, Xinhua, etc.

We evaluate our systems on 5 confusion sets from Bergsma et al. (2009; 2010) and 9 commonly confused word pairs with moderate frequency in daily usage (randomly selected from those listed in English educational resources[2]). Shown in Table 2, these 9 sets of words appear much less frequently than the words selected by Bergsma et al., even given the fact that we are using a considerably large training corpus.

For each confusable word pair, sentences that contain either of the words are extracted to form training and test data. The word that appears in the original sentences of the news article is treated as the gold standard. For frequently occurring confusion word sets used by Bergsma et al., we extract up to 10k examples for testing, and up to 100k examples for training. For the 9 less frequent confusion word sets, we extract all the unique examples for training and testing from the above sources. The spelling correction system is evaluated by measuring its accuracy in comparison to the gold standard in test data. The error rate is the complement of accuracy.

discreet / discrete	0.7k / 2.4k
elicit / illicit	1.9k / 10.0k
stationary / stationery	2.5k/2.3k
wander / wonder	3.3k / 39.5k

Table 2: Training Data Sizes for Common ESL Confused Words

Following Carlson et al. (2007) and Bergsma et al. (2009; 2010), we obtain the n-gram counts from the Google Web 1T 5-gram Corpus (Brants and Franz, 2006).

5.2 Experimental Results

We present the results for each set separately because each set may behave very differently, depending upon its frequency, part-of-speech, number of senses and other differences between the words in each confusion set. The overall accuracy across confusion sets is also presented to show the effectiveness of different approaches. The results are tested for statistical significance using McNemar's test of correlated proportions. The performance differences are marked as significant when $p < 0.05$.

5.2.1 Effectiveness of Parse Features

We exploit the n-gram counts (NG), lexical features (LEX) of Bergsma et al. (2010) and our own parse features (PAR) in linear SVM models.

The first comparison is between the supervised learning systems with LEX and LEX+PAR. As shown in Table 3, by exploiting our unique parse features, for the total 14 confusion sets, the accuracy increases on 12 sets and decreases on 2 sets. Overall, the spelling correction accuracy improves an ab-

solute 1.35% for our 9 confusion sets and 0.60% for Bergsma et al.'s 5 confusion sets.

The second comparison is to see how parse features interact with n-gram count features in a supervised classifier. The best system from (Bergsma et al., 2010) is listed in the table as "NG+LEX". As shown in Table 3, the parse features proved to be beneficial when augmenting this baseline, except for the decrease in accuracy on adverse, averse by only 2 cases out of 368, and among, between by 2 cases out of 10227. For all other confusion sets, parse features decrease the error rate by as much as 2.74% (absolute) and as much as 38.5% (relative). Improvements are statistically significant on all confusion sets together, although for each separate set, improvements are significant on only 5 sets, in part due to an insufficient number of test cases.

The reason that parse features are occasionally not helpful is because they sometimes include an uncommon word in dependencies, which happens to appear once with the wrong word but not with the correct word in the training data; or they sometimes include too common words, which bias the classifier in favor of the more frequent word in the confusion set. We also noticed that lexical features are not always helpful when added to n-gram count features, even for in-domain applications (i.e., with training data and test data coming from the same domain or corpus), as marked by underlines. However, lexical and parse features together show more significant and constant improvement over n-gram count-based models, as marked by α.

Of the six systems, every system that uses parse features gets the example correct in Section 1, "complementing the president"; LEX by itself also gets the example correct, but NG and NG+LEX fail.

In summary, our system NG+LEX+PAR outperforms the state-of-the-art system NG+LEX. It reduces the error rate by 12.4% across our 9 confusion sets and by 8.4% across Bergsma et al.'s 5 confusion sets. Both improvements are significant ($p < 0.05$) by the McNemar test. In addition, while NG+LEX is not always better than NG, NG+LEX+PAR is consistently better than NG.

5.2.2 Impact of Word Co-occurrence

The LIBLINEAR tool does not provide probability estimates for SVM models but Logistic Regression can. In this set of experiments, we train a Logistic Regression model with NG+LEX+PAR features and empirically set the confidence threshold at 0.6, as described in Section 4, based on the performance on two word pairs. In the combined system, when the Logistic Regression model estimates a probability higher than the threshold we output its results, otherwise we output the result of the system based on word co-occurrence.

Surprisingly, although Random Indexing takes into account more information than first-order word co-occurrence, it lowered overall performance substantially. Thus in Table 4, we only present results of using first-order word co-occurrence rather than Random Indexing. For all 12 confusion sets, distributional word co-occurrence information improves 9 sets and hurts 5 sets. Overall, it reduces the error rate slightly by 0.2% for our 9 sets and 1.5% for Bergsma et al.'s sets.

We believe there are two reasons why Random Indexing fared worse than first-order word co-occurrence: 1) Random Indexing considers co-occurrence on a document level, while our first-order word co-occurrence is limited to a 5-word window context. The latter is more suitable to context-sensitive spelling correction. 2) The model for Random Indexing is trained on a relatively small size corpus compared to the web-scale data we used to get n-gram count features for the classifier and thus is not able to introduce much new evidence besides the information carried by NG+LEX+PAR features.

Reason 2) also suggests why first-order co-occurrence helps on some occasions while not on other occasions. Its impact is limited because the word co-occurrence information overlaps with some of the PAR feature values as mentioned earlier. It improves some cases because it provides some new evidence from web-scale data to the system based on NG+LEX+PAR features. It introduces new errors because it simply favors the word that co-occurred more often regardless of other factors. Its impact is also limited because it is only considered when classifiers with NG+LEX+PAR features are not confident.

CONFUSION SET	# TEST	MAJOR	LEX	LEX+PAR	NG	NG+LEX	NG+LEX+PAR (&)

6 Conclusions

We propose a novel approach that uses parse features and lexical features together to improve the performance of web-scale n-gram models for spelling correction. This method is especially adaptive when less training data are available, which is the case for confusable words that are not very frequently used. We also investigate the effectiveness of incorporating web-scale word co-occurrence and corpus-based semantic word relatedness (Random Indexing).

For future work, we will investigate using semantic information (e.g. WordNet) to extend n-gram models. It will be interesting to see if the usage of the word "compliment" in "complimenting the president" can be estimated by considering similar usages in the corpus, such as "complimenting the student" or by creating an n-gram database of synset patterns. We will investigate extending, to other applications, this general methodology combining distributional, semantic and syntactic information with language models.

Acknowledgments

We wish to thank Michael Flor of Educational Testing Service for his TrendStream tool, which provides fast access and easy manipulation of the Google N-gram Corpus. We also thank Derrick Higgins of Educational Testing Service for his Random Indexing support. We also thank Satoshi Sekine of New York University, Matthew Snover of City University of New York, and Jing Jiang of Singapore Management University for their advice.

Abstract

Accurate prediction of demographic attributes from social media and other informal online content is valuable for marketing, personalization, and legal investigation. This paper describes the construction of a large, multilingual dataset labeled with gender, and investigates statistical models for determining the gender of uncharacterized Twitter users. We explore several different classifier types on this dataset. We show the degree to which classifier accuracy varies based on tweet volumes as well as when various kinds of profile metadata are included in the models. We also perform a large-scale human assessment using Amazon Mechanical Turk. Our methods significantly out-perform both baseline models and almost all humans on the same task.

1 Introduction

The rapid growth of social media in recent years, exemplified by Facebook and Twitter, has led to a massive volume of user-generated informal text. This in turn has sparked a great deal of research interest in aspects of social media, including automatically identifying latent demographic features of online users. Many latent features have been explored, but gender and age have generated great interest (Schler et al., 2006; Burger and Henderson, 2006; Argamon et al., 2007; Mukherjee and Liu, 2010; Rao et al., 2010). Accurate prediction of these features would be useful for marketing and personalization concerns, as well as for legal investigation.

In this work, we investigate the development of high-performance classifiers for identifying the gender of Twitter users. We cast gender identification as the obvious binary classification problem, and explore the use of a number of text-based features. In Section 2, we describe our Twitter corpus, and our methods for labeling a large subset of this data for gender. In Section 3 we discuss the features that are used in our classifiers. We describe our Experiments in Section 4, including our exploration of several different classifier types. In Section 5 we present and analyze performance results, and discuss some directions for acquiring additional data by simple self-training techniques. Finally in Section 6 we summarize our findings, and describe extensions to the work that we are currently exploring.

2 Data

Twitter is a social networking and micro-blogging platform whose users publish short messages or *tweets*. In late 2010, it was estimated that Twitter had 175 million registered users worldwide, producing 65 million tweets per day (Miller, 2010). Twitter is an attractive venue for research into social media because of its large volume, diverse and multilingual population, and the generous nature of its Terms of Service. This has led many researchers to build corpora of Twitter data (Petrovic et al., 2010; Eisenstein et al., 2010). In April 2009, we began sampling data from Twitter using their API at a rate of approximately 400,000 tweets per day. This represented approximately 2% of Twitter's daily volume at the time, but this fraction has steadily decreased to less than 1% by 2011. This decrease is because we sample roughly the same number of tweets every day while Twitter's overall volume has increased markedly. Our corpus thus far contains approximately 213 million tweets from 18.5 million users, in many different languages.

In addition to the tweets that they produce, each Twitter user has a profile with the following free-text fields:

- Screen name (e.g., *jsmith92*, *kingofpittsburgh*)
- Full name (e.g., *John Smith*, *King of Pittsburgh*)
- Location (e.g., *Earth*, *Paris*)
- URL (e.g., the user's web site, Facebook page, etc.)
- Description (e.g., *Retired accountant and grandfather*)

All of these except screen name are completely optional, and all may be changed at any time. Note that none

Test	18,424	418,072

Figure 1: Dataset Sizes

of the demographic attributes we might be interested in are present, such as gender or age. Thus, the existing profile elements are not directly useful when we wish to apply supervised learning approaches to classify tweets for these target attributes. Other researchers have solved this problem by using labor-intensive methods. For example, Rao et al. (2010) use a focused search methodology followed by manual annotation to produce a dataset of 500 English users labeled with gender. It is infeasible to build a large multilingual dataset in this way, however.

Previous research into gender variation in online discourse (Herring et al., 2004; Huffaker, 2004) has found it convenient to examine blogs, in part because blog sites often have rich profile pages, with explicit entries for gender and other attributes of interest. Many Twitter users use the URL field in their profile to link to another facet of their online presence. A significant number of users link to blogging websites, and many of these have well-structured profile pages indicating our target attributes. In many cases, these are not free text fields. Users on these sites must select gender and other attributes from drop-down menus in order to populate their profile information. Accordingly, we automatically followed the Twitter URL links to several of the most represented blog sites in our dataset, and sampled the corresponding profiles. By attributing this blogger profile information to the associated Twitter account, we created a corpus of approximately 184,000 Twitter users labeled with gender.

We partitioned our dataset by user into three distinct subsets, training, development, and test, with sizes as indicated in Figure 1. That is, all the tweets from each user are in a single one of the three subsets. This is the corpus we use in the remainder of this paper.

This method of gleaning supervised labels for our Twitter data is only useful if the blog profiles are in turn accurate. We conducted a small-scale quality assurance study of these labels. We randomly selected 1000 Twitter users from our training set and manually examined the description field for obvious indicators of gender, e.g., *mother to 3 boys* or *just a dude*. Only 150 descriptions (15% of the sample) had such an explicit gender cue. 136 of these also had a blog profile with the gender selected, and in all of these the gender cue from the user's Twitter description agreed with the corresponding blog profile. This may only indicate that people who misrepresent their gender are simply consistent across different aspects of their online presence. However, the effort involved in maintaining this deception in two different places suggests that the blog labels on the Twitter data are largely reliable.

Initial analysis using the blog-derived labels showed that our corpus is composed of 55% females and 45% males. This is consistent with the results of an earlier study which used name/gender correlations to estimate that Twitter is 55% female (Heil and Piskorski, 2009). Figure 2 shows several statistics broken down by gender, including the Twitter users who did not indicate their gender on their blog profile. In our dataset females tweet at a higher rate than males and in general users who provide their gender on their blog profile produce more tweets than users who do not. Additionally, of the 150 users who provided a gender cue in their Twitter user description, 105 were female (70%). Thus, females appear more likely to provide explicit indicators about their gender in our corpus.

The average number of tweets per user is 22 and is fairly consistent across our traing/dev/test splits. There is wide variance, however, with some users represented by only a single tweet, while the most prolific user in our sample has nearly 4000 tweets.

It is worth noting that many Twitter users do not tweet in English. Table 3 presents an estimated breakdown of language use in our dataset. We ran automatic language ID on the concatenated tweet texts of each user in the training set. The strong preponderance of English in our dataset departs somewhat from recent studies of Twitter language use (Wauters, 2010). This is likely due in part to sampling methodology differences between the two studies. The subset of Twitter users who also use a blog site may be different from the Twitter population as a whole, and may also be different from the users tweeting during the three days of Wauters's study. There are also possible longitudinal differences: English was the dominant language on Twitter when the online service began in 2006, and this was still the case when we began sampling tweets in 2009, but the proportion of English tweets had steadily dropped to about 50% in late 2010. Note that we do not use any explicit encoding of language information in any of the experiments described below.

Our Twitter-blog dataset may not be entirely representative of the Twitter population at general, but this has at least one advantage. As with any part of the Internet, spam is endemic to Twitter. However by sampling only Twitter users with blogs we have largely filtered out spammers from our dataset. Informal inspection of a few thousand tweets revealed a negligible number of commercial tweets.

3 Features

Tweets are tagged with many sources of potentially discriminative metadata, including timestamps, user color

	Users		Tweets		Mean tweets
	Count	Percentage	Count	Percentage	per user
Female	100,654	42.3%	2,429,621	47.7%	24.1
Male	83,075	35.0	1,672,813	32.8	20.1
Not provided	53,817	22.7	993,671	19.5	18.5

Figure 2: Gender distribution in our blog-Twitter dataset

Language	Users	Percentage
English	98,004	66.7%
Portuguese	21,103	14.4
Spanish	8,784	6.0
Indonesian	6,490	4.4
Malay	1,401	1.0
German	1,220	0.8
Chinese	985	0.7
Japanese	962	0.7
French	878	0.6

Other	4,377	3.0

Figure 3: Language ID statistics from training set

preferences, icons, and images. We have restricted our experiments to a subset of the textual sources of features as listed in Figure 4.

We use the content of the tweet text as well as three fields from the Twitter user profile described in Section 2: full name, screen name, and description. For each user in our dataset, a field is in general a *set* of text strings. This is obviously true for tweet texts but is also the case for the profile-based fields since a Twitter user may change any part of their profile at any time. Because our sample spans points in time where users have changed their screen name, full name or description, we include all of the different values for those fields as a set. In addition, a user may leave their description and full name blank, which corresponds to the empty set.

In general, our features are quite simple. Both word- and character-level ngrams from each of the four fields are included, with and without case-folding. Our feature functions do not count multiple occurrences of the same ngram. Initial experiments with count-valued feature functions showed no appreciable difference in performance. Each feature is a simple Boolean indicator representing presence or absence of the word or character ngram in the set of text strings associated with the particular field. The extracted set of such features represents the item to the classifier.

For word ngrams, we perform a simple tokenization

	Feature extraction		
	Char ngrams	Word ngrams	Distinct features
Screen name	1–5	*none*	432,606
Full name	1–5	1	432,820
Description	1–5	1–2	1,299,556
Tweets	1–5	1–2	13,407,571
Total			15,572,522

Figure 4: Feature types and counts

that separates words at transitions between alphanumeric characters and non-alphanumeric.[1] We make no attempt to tokenize unsegmented languages such as Chinese, nor do we perform morphological analysis on language such as Korean; we do no language-specific processing at all. We expect the character-level ngrams to extract useful information in the case of such languages.

Figure 4 indicates the details and feature counts for the fields from our training data. We ignore all features exhibited by fewer than three users.

4 Experiments

We formulate gender labeling as the obvious binary classification problem. The sheer volume of data presents a challenge for many of the available machine learning toolkits, e.g. WEKA (Hall et al., 2009) or MALLET (McCallum, 2002). Our 4.1 million tweet training corpus contains 15.6 million distinct features, with feature vectors for some experiments requiring over 20 gigabytes of storage. To speed experimentation and reduce the memory footprint, we perform a one-time feature generation preprocessing step in which we convert each feature pattern (such as "caseful screen name character trigram: Joh") to an integer codeword. The learning algorithms do not access the codebook at any time and instead deal solely with vectors of integers. We compress the data further by concatenating all of a user's features into a single vector that represents the union of every tweet produced by that user. This condenses the dataset to about 180,000 vectors occupying 11 gigabytes of storage.

We performed initial feasibility experiments using a wide variety of different classifier types, including Support Vector Machines, Naive Bayes, and Balanced Win-

[1] We use the standard regular expression pattern `\b`.

now2 (Littlestone, 1988). These initial experiments were based only on caseful word unigram features from tweet texts, which represent less than 3% of the total feature space but still include large numbers of irrelevant features. Performance as measured on the development set ranged from Naive Bayes at 67.0% accuracy to Balanced Winnow2 at 74.0% accuracy. A LIBSVM (Chang and Lin, 2001) implementation of SVM with a linear kernel achieved 71.8% accuracy, but required over fifteen hours of training time while Winnow needed less than seven minutes. No classifier that we evaluated was able to match Winnow's combination of accuracy, speed, and robustness to increasing amounts of irrelevant features.

We built our own implementation of the Balanced Winnow2 algorithm which allowed us to iterate repeatedly over the training data on disk rather than caching the entire dataset in memory. This reduced our memory requirements to the point that we were able to train on the entire dataset using a single machine with 8 gigabytes of RAM.

We performed a grid search to select learning parameters by measuring their affect on Winnow's performance on the development set. We found that two sets of parameters were required: a low learning rate (0.03) was effective when using only one type of input feature (such as only screen name features, or only tweet text features), and a higher learning rate (0.20) was required when mixing multiple types of features in one classifier. In both cases we used a relatively large margin (35%) and cooled the learning rate by 50% after each iteration.

These learning parameters were used during all of the experiments that follow. All gender prediction models were trained using data from the training set and evaluated on data from the development set. The test set was held out entirely until we finalized our best performing models.

4.1 Field combinations

We performed a number of experiments with the Winnow algorithm described above. We trained it on the training set and evaluated on the development set for each of the four user fields in isolation, as well as various combinations, in order to simulate different use cases for systems that perform gender prediction from social media sources. In some cases we may have all of the metadata fields available above, while in other cases we may only have a sample of a user's tweet content or perhaps just one tweet. We simulated the latter condition by randomly selecting a single tweet for each dev and test user; this tweet was used for all evaluations of that user under the single-tweet condition. Note, however, that for training the single tweet classifier, we do not concatenate all of a user's tweets as described above. Instead, we pair each user in the training set with each of their tweets in turn, in order to take advantage of all the training data. This amounted to over 3 million training instances for the single tweet condition.

We paid special attention to three conditions: single tweet, all fields, and all tweets. For these conditions, we evaluated the learned models on the training data, the development set, and the test set, to study over-training and generalization. Note that for all experiments, the evaluation includes some users who have left their full name or description fields blank in their profile.

In all cases, we compare results to a maximum likelihood baseline that simply labels all users female.

4.2 Human performance

We wished to compare our classifier's efficacy to human performance on the same task. A number of researchers have recently experimented with the use of Amazon Mechanical Turk (AMT) to create and evaluate human language data (Callison-Burch and Dredze, 2010). AMT and other crowd-sourcing platforms allow simple tasks to be posted online for large numbers of anonymous workers to complete.

We used AMT to measure human performance on gender determination for the all tweets condition. Each AMT worker was presented with all of the tweet texts from a single Twitter user in our development set and asked whether the author was male or female. We redundantly assigned five workers to each Twitter user, for a total of 91,900 responses from 794 different workers. We experimented with a number of ways to combine the five human labels for each item, including a simple majority vote and a more sophisticated scheme using an expectation maximization algorithm.

4.3 Self-training

Our final experiments were focused on exploring the use of unlabeled data, of which we have a great deal. We performed some initial experiments on a self-training approach to labeling more data. We trained the all-fields classifier on half of our training data, and applied it to the other half. We trained a new classifier on this full training set, which now included label errors introduced by the limitations of the first classifier. This provided a simulation of a self-training setup using half the training data. Any robust gains due to self-training should be revealed by this setup.

5 Results

5.1 Field combinations

Figure 5 shows development set performance on various combinations of the user fields, all of which outperform the maximum likelihood baseline that classifies all users as female. The single most informative field with respect

Baseline (F)	54.9%
One tweet text	67.8
Description	71.2
All tweet texts	75.5
Screen name (e.g. *jsmith92*)	77.1
Full name (e.g. *John Smith*)	89.1
Tweet texts + screen name	81.4
Tweet texts + screen name + description	84.3
All four fields	92.0

Figure 5: Development set accuracy using various fields

Condition	Train	Dev	Test
Baseline (F)	54.8%	54.9	54.3
One tweet text	77.8	67.8	66.5
Tweet texts	77.9	75.5	74.5
All fields	98.6	92.0	91.8

Figure 6: Accuracy on the training, development and test sets

to gender is the user's full name, which provides an accuracy of 89.1%. Screen name is often a derivative of full name, and it too is informative (77.1%), as is the user's self-assigned description (71.2).

Using only tweet texts performs better than using only the user description (75.5% vs. 71.2). Tweet texts are sufficient to decrease the error by nearly half over the all-female prior. It appears that the tweet texts convey more about a Twitter user's gender than their own self-descriptions. Even a single (randomly selected) tweet text contains some gender-indicative information (67.2%). These results are similar to previous work. Rao et al. (2010) report results of 68.7% accuracy on gender from tweet texts alone using an ngram-only model, rising to 72.3 with hand-crafted "sociolinguistic-based" features. Test set differences aside, this is comparable with the "All tweet texts" line in Figure 5, where we achieve an accuracy of 75.5%.

Performance of models built from various aggregates of the four basic fields are shown in Figure 5 as well. The combination of tweet texts and a screen name represents a use case common to many different social media sites, such as chat rooms and news article comment streams. The performance of this combination (81.4%) is significantly higher than either of the individual components. As we have observed, full name is the single most informative field. It out-performs the combination of the other three fields, which perform at 84.3%. Finally, the classifier that has access to features from all four fields is able to achieve an accuracy of 92.0%.

The final test set accuracy is shown in Figure 6. This test set was held out entirely during development and has been evaluated only with the four final models reported

Figure 7: A selection of tweet text features, ranked by mutual information. Character ngrams in Courier, words in **bold**. Underscores are spaces, $ matches the end of the tweet text. ♂ marks "male" features.

in this figure. The difference between the scores on the train and development sets show how well the model can fit the data. There are features in the user name and user screen name fields that make the data trivially separable. The tweet texts, however, present more ambiguity for the learners. The difference between the development and test set scores suggest that only minimal hill-climbing occurred during our development.

We have performed experiments to better understand how performance scales with training data size. Figure 8 shows how performance increases for both the all-fields and tweet-texts-only classifiers as we train on more users, with little indication of leveling off.

As discussed in Section 2, there is wide variance in the number of tweets available from different users. In Figure 9 we show how the tweet text classifier's accuracy increases as the number of tweets from the user increases. Each point is the average classifier accuracy for the user cohort with exactly that many tweets in our dev set. Performance increases given more tweets, although the averages get noisy for the larger tweet sets, due to successively smaller cohort sizes.

Some of the most informative features from tweet texts are shown in Figure 7, ordered by mutual information with gender. There are far more of these strong features for the female category than the male: only five of the top 1000 features are associated more strongly with males, i.e. they have lower $P(Female|feature)$ than the prior, $P(Female) = 0.55$.

Some of these features are content-based (*hair*, and several fragments of *love*), while others are stylistic (*ooo*, several emoticons). The presence of *http* as a strong male feature might be taken to indicate that men include links in their tweet texts far more often than women, but a cursory examination seems to show instead that women are simply more likely to include "bare" links, e.g., `emnlp.org` vs. `http://emnlp.org`.

5.2 Human performance

Figure 10 shows the results of the human performance benchmarks using Amazon Mechanical Turk. The raw per-response performance is 60.4%, only moderately better than the all-female baseline. When averaged across workers, however, this improves substantially, to 68.7. This would seem to indicate that there were a few poor workers who did many annotations, and in fact when we limit the performance average to those workers who produced 100 or more responses, we do see a degradation to 62.2.

The problem of poor quality workers is endemic to anonymous crowd sourcing platforms like Mechanical Turk. A common way to combat this is to use redundancy, with a simple majority vote to choose among multiple responses for each item. This allows us to treat the five workers who responded to each item as an ensemble. As Figure 10 indicates, this provides some improvement over the raw result (65.7% vs. 60.4). A different approach, first proposed by Dawid and Skene (1979), is to use an expectation maximization algorithm to estimate the quality of each source of labels, as well as estimate the posterior for each item. In this case, the first is an AMT worker's capability and the second is the distribution of gender labels for each Twitter user.

Baseline	54.9
Average response	60.4
Average worker	68.7
Average worker (100 or more responses)	62.2
Worker ensemble, majority vote	65.7
Worker ensemble, EM-adjusted vote	67.3
Winnow all-tweet-texts classifier	75.5

Figure 10: Comparing with humans on the all tweet texts task

The Dawid and Skene approach has previously been applied to Mechanical Turk responses (Ipeirotis et al., 2010). We used their implementation on our AMT results but with only moderate improvement over the simple majority ensemble (67.3% vs. 65.7). All of the aggregate human results are substantially below the all-tweet-texts classifier score, suggesting that this is a difficult task for people to perform. As Figure 11 indicates, most workers perform below 80% accuracy, and less than 5% of the prolific workers out-perform the automatic classifier. These high-scoring workers may indeed be good at the task, or they may have simply been assigned a less-difficult subset of the data. Figure 12 illustrates this by showing aligned worker performance and classifier performance on the precise set of items that each worker performed on. Here we see that, with few exceptions, the automatic classifier performs as well or better than the AMT workers on their subset.

5.3 Self-training

Finally, as described in Section 4.3, we performed some initial experiments on a self-training approach to labeling more data. As described above the all-fields classifier achieves an accuracy of 92% on the development set when trained on the full training set. Training on half of the training data results in a drop to 91.1%. The second classifier trained on the full training set, but with some label errors introduced by the first, had further degraded performance of 90.9%. Apparently the errorful labels introduced by the simplistic self-training procedure overwhelmed any new information that might have been gained from the additional data. We are continuing to explore ways to use the large amounts of unsupervised data in our corpus.

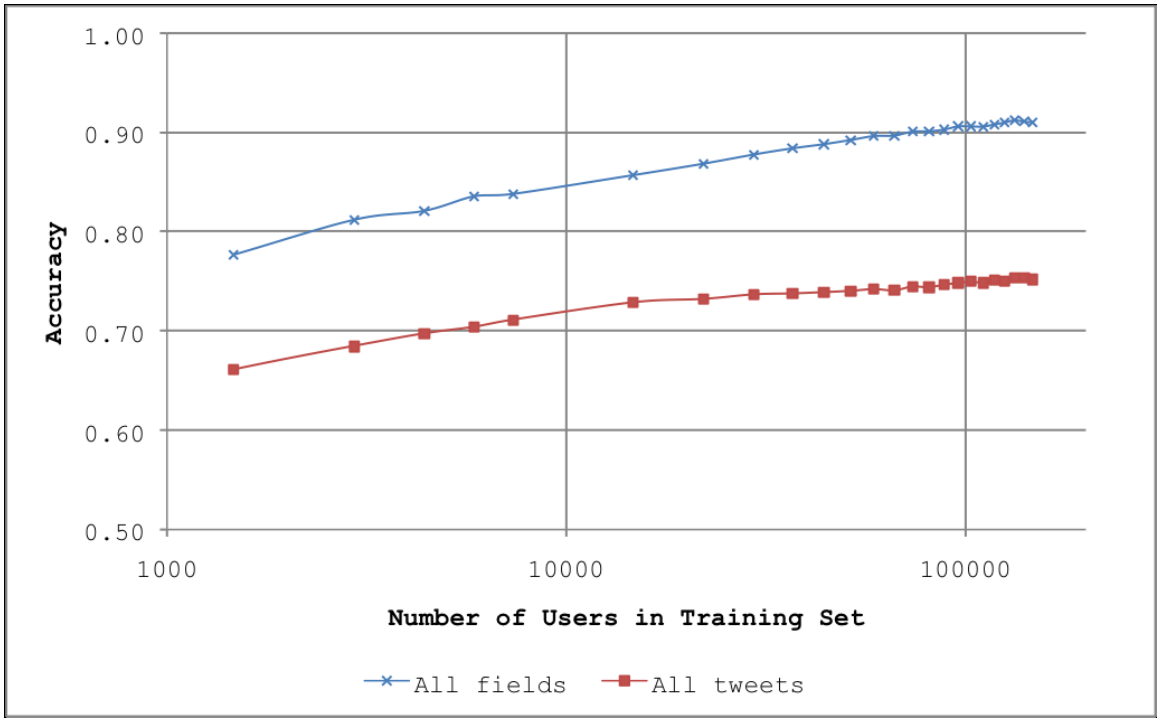

Figure 8: Performance increases when training with more users

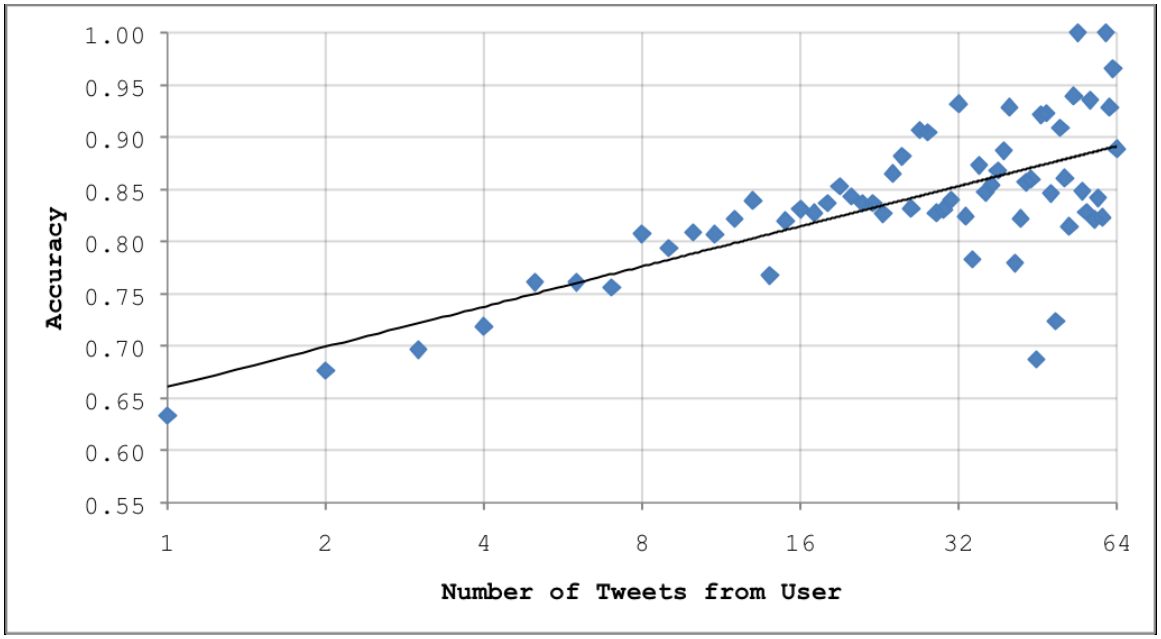

Figure 9: Performance increases with more tweets from target user

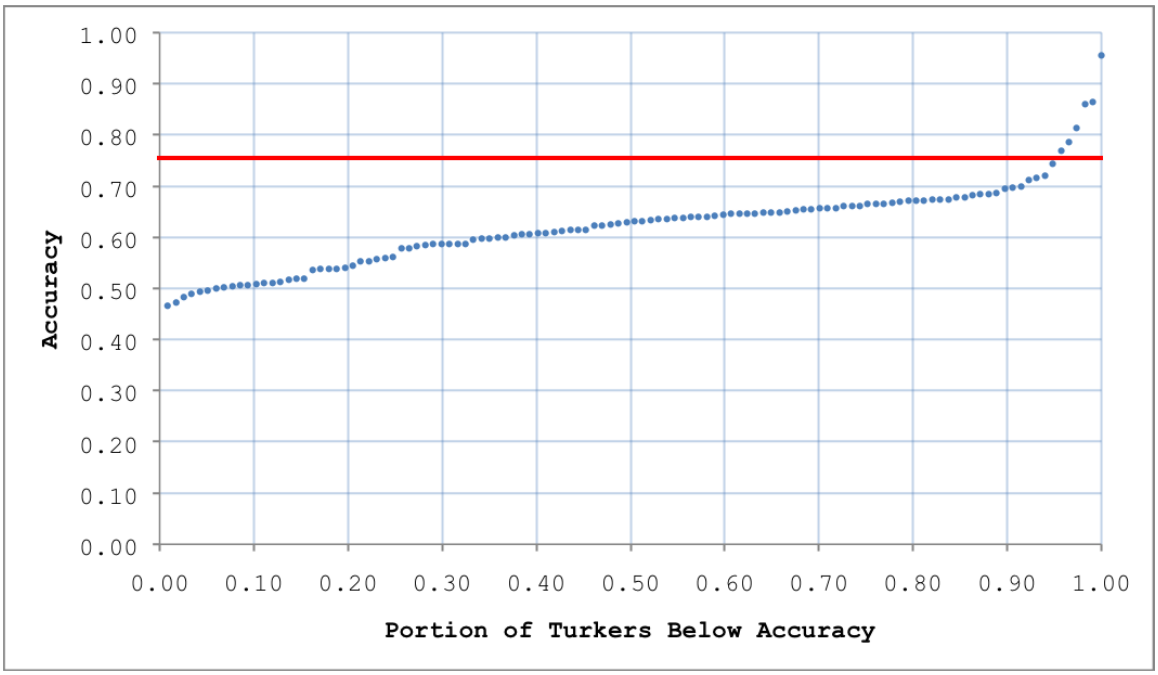

Figure 11: Human accuracy in rank order (100 responses or more), with classifier performance (line)

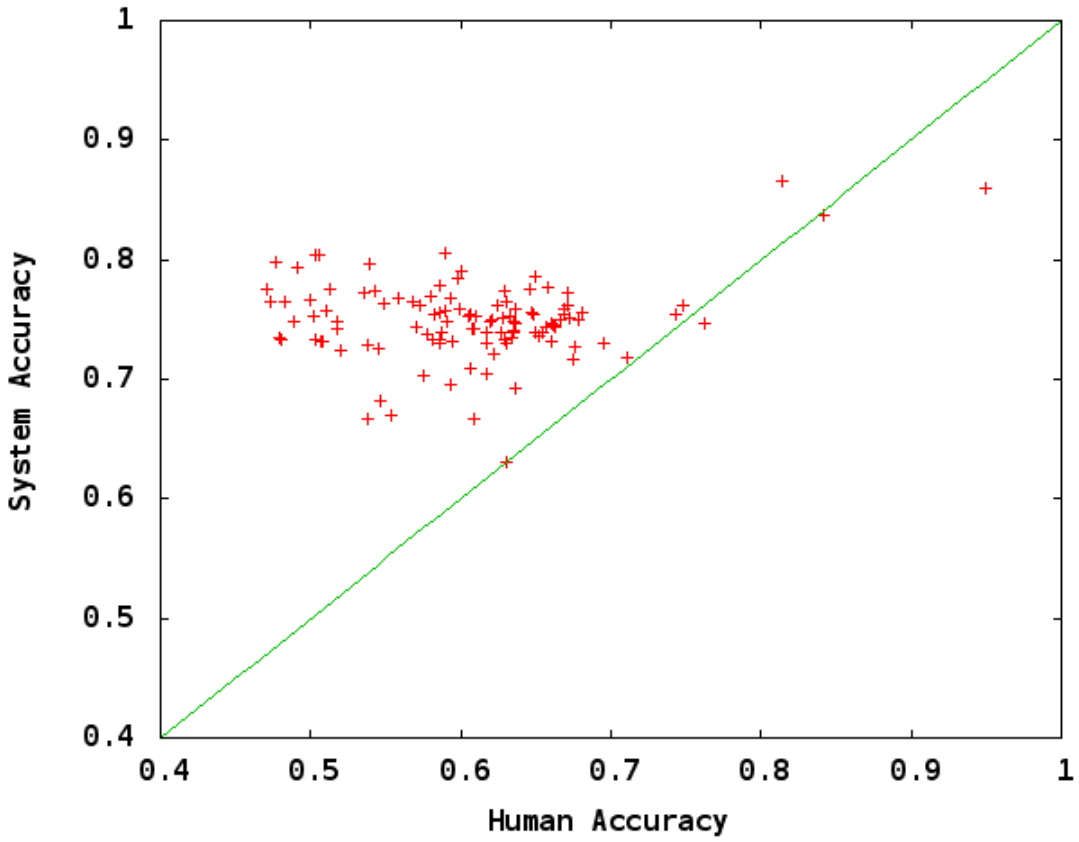

Figure 12: Classifier vs. human accuracy on the same subsets (100 responses or more)

6 Conclusion

In this paper, we have presented several configurations of a language-independent classifier for predicting the gender of Twitter users. The large dataset used for construction and evaluation of these classifiers was drawn from Twitter users who also completed blog profile pages.

These classifiers were tested on the largest set of gender-tagged tweets to date that we are aware of. The best classifier performed at 92% accuracy, and the classifier relying only on tweet texts performed at 76% accuracy. Human performance was assessed on this latter condition, and only 5% of 130 humans performed 100 or more classifications with higher accuracy than this machine.

In future work, we will explore how well such models carry over to gender identification in other informal online genres such as chat and forum comments. Furthermore, we have been able to assign demographic features beside gender, including age and location, to our Twitter dataset. We have begun to build classifiers for these features as well.

Identifying and Following Expert Investors in Stock Microblogs

Abstract

Information published in online stock investment message boards, and more recently in stock microblogs, is considered highly valuable by many investors. Previous work focused on aggregation of sentiment from all users. However, in this work we show that it is beneficial to distinguish expert users from non-experts. We propose a general framework for identifying expert investors, and use it as a basis for several models that predict stock rise from stock microblogging messages (stock tweets). In particular, we present two methods that combine expert identification and per-user unsupervised learning. These methods were shown to achieve relatively high precision in predicting stock rise, and significantly outperform our baseline. In addition, our work provides an in-depth analysis of the content and potential usefulness of stock tweets.

1 Introduction

Online investment message boards such as Yahoo! Finance and Raging Bull allow investors to share trading ideas, advice and opinions on public companies. Recently, stock microblogging services such as StockTwits (which started as a filtering service over the Twitter platform) have become very popular. These forums are considered by many investors as highly valuable sources for making their trading decisions.

This work aims to mine useful investment information from messages published in stock microblogs. We shall henceforth refer to these messages as *stock tweets*. Ultimately, we would like to transform those tweets into buy and sell decisions. Given a set of stock-related messages, this process typically comprises two steps:

1. Classify each message as "bullish" (having a positive outlook on the stock), "bearish" (having a negative outlook on the stock), or neutral.
2. Make trading decisions based on these message classifications.

Previous work on stock investment forums and microblogs usually regarded the first step (message classification) as a sentiment analysis problem, and aligned *bullish* with positive sentiment and *bearish* with negative sentiment. Messages were classified by matching positive and negative terms from sentiment lexicons, learning from a hand-labeled set of messages, or some combination of the two (Das and Chen, 2007; Antweiler and Frank, 2004; Chua et al., 2009; Zhang and Skiena, 2010; Sprenger and Welpe, 2010). Trading decisions were made by aggregating the sentiment for a given stock over all the tweets, and picking stocks with strongest sentiment signal (buying the most bullish stocks and short-selling the most bearish ones).

Sentiment aggregation reflects the opinion of the investors community as a whole, but overlooks the variability in user expertise. Clearly, not all investors are born equal, and if we could tell experts from non-experts, we would reduce the noise in these forums and obtain high-quality signals to follow. This paper presents a framework for identifying experts in stock microblogs by monitoring their performance in a training period. We show that following the experts results in more precise predictions.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1310–1319,
Edinburgh, Scotland, UK, July 27–31, 2011.

Based on the expert identification framework, we experiment with different methods for deriving predictions from stock tweets. While previous work largely aligned bullishness with message sentiment, our in-depth content analysis of stock tweets (to be presented in section 2.2) suggests that this view is too simplistic. To start with, one important difference between bullishness/bearishness and positive/negative sentiment is that while the former represents belief about the future, the latter may also refer to the past or present. For example, a user reporting on making profit from a buying stock yesterday and selling it today is clearly positive about the stock, but does not express any prediction about its future performance. Furthermore, messages that do refer to the future differ considerably in their significance. A tweet reporting on buying a stock by the user conveys a much stronger bullishness signal than a tweet that merely expresses an opinion. Overall, it would seem that judging bullishness is far more elusive than judging sentiment.

We therefore propose and compare two alternative approaches that sidestep the complexities of assessing tweets bullishness. These two approaches can be viewed as representing two extremes. The first approach restricts our attention to the most explicit signals of bullishness and bearishness, namely, tweets that report actual buy and sell transactions performed by the user. In the second approach we learn directly the relation between tweets content and stock prices, following previous work on predicting stock price movement from factual sources such as news articles (Lavrenko et al., 2000; Koppel and Shtrimberg, 2004; Schumaker and Chen, 2010). This approach poses no restrictions on the tweets content and avoids any stipulated tweet classification. However, user-generated messages are largely subjective, and their correlation with the stock prices depends on user's expertise. This introduces much noise into the learning process. We show that by making the learning user-sensitive we can improve the results substantially. Overall, our work illustrates the feasibility of finding expert investors, and the utility of following them.

2 Stock Tweets

2.1 Stock Tweets Language

Stock tweets, as Twitter messages in general, are short textual messages of up to 140 characters. They are distinguished by having one or more references to stock symbols (tickers), prefixed by a dollar sign. For instance, the stock of *Apple, Inc.* is referenced as $AAPL. Two other noteworthy Twitter conventions that are also found in stock tweets are *hashtags*, user-defined labels starting with *'#'*, and references to other users, starting with *'@'*. Table 1 lists some examples of stock tweets.

As common with Twitter messages, stock tweets are typically abbreviated and ungrammatical utterances. The language is informal and includes many slang expressions, many of which are unique to the stock tweets community. Thus, many positive and negative expressions common to stock tweets are not found in standard sentiment lexicons. Their unique language and terminology often make stock tweets hard to understand for an outsider. Many words are abbreviated and appear in several non-standard forms. For example, the word *bought* may also appear as *bot* or *bght*, and *today* may appear as *2day*. Stock tweets also contain many sentiment expressions which may appear in many variations, e.g. *wow, woooow, wooooooooow* and so on. These characteristics make the analysis of stock tweets a particularly challenging task.

2.2 Content Analysis

A preliminary step of this research was an extensive data analysis, aimed to gain better understanding of the major types of content conveyed in stock tweets. First, we developed a taxonomy of tweet categories while reading a few thousands of tweets. Based on this taxonomy we then tagged a sample of 350 tweets to obtain statistics on the frequency of each category. The sample contained only tweets that mention exactly one ticker. The following types of tweets were considered irrelevant:

- Tweets that express question. These tweets were labeled as *Question*.
- Obscure tweets, e.g. *"$AAPL fat"*, tweets that contain insufficient information (e.g. *"http://url.com $AAPL"*) and tweets that seem

		Example	%
Fact	News	$KFRC: Deutsche Bank starts at Buy	14.3%
	Chart Pattern	$C (Citigroup Inc) $3.81 crossed its 2nd Pivot Point Support http://empirasign.com/s/x4c	10.9%
	Trade	bot back some $AXP this morning	12.9%
	Trade Outcome	Sold $CELG at 55.80 for day-trade, +0.90 (+1.6%)X	2.9%
Opinion	Speculation	thinking of hedging my shorts by buying some oil. thinking of buying as much $goog as i can in my IRA. but i need more doing, less thinking.	4.0%
	Chart Prediction	http://chart.ly/wsy5ny $GS - not looking good for this one - breaks this support line on volume will nibble a few short	12.9%
	Recommendation	$WFC if you have to own financials, WFC would be my choice. http://fsc.bz/448 #WORDEN	1.7%
	Sentiment	$ivn is rocking	8.6%
Question		$aapl breaking out but in this mkt should wait till close?	7.1%
Irrelevant		$CLNE follow Mr. Clean $$	24.9%

Table 1: Tweets categories and their relative frequencies

to contain no useful information (e.g *"Even Steve Jobs is wrong sometimes... $AAPL http://ow.ly/1Tw0Z"*). These tweets were labeled *Irrelevant*.

The rest of the tweets were classified into two major categories: *Facts* and *Opinions*.

Facts can be divided into four main subcategories:

1. *News:* such tweets are generally in the form of a tweeted headline describing news or a current event generally drawn from mass media. As such they are reliable but, since the information is available in far greater detail elsewhere, their added value is limited.

2. *Chart Pattern:* technical analysis aims to provide insight into trends and emerging patterns in a stock's price. These tweets describe patterns in the stock's chart without the inclusion of any predicted or projected movement, an important contrast to *Chart Prediction*, which is an opinion tweet described below. Chart pattern tweets, like news, are a condensed form of information already available through more in-depth sources and as such their added value is limited.

3. *Trade:* reports an actual purchase or sale of a stock by the user. We consider this as the most valuable form of tweet.

4. *Trade Outcome:* provides details of an "inverse trade", the secondary trade to exit the initial position along with the outcome of the overall trade (profit/loss). The value of these tweets is debatable since although they provide details of a trade, they generally describe the "exit" transaction. This creates a dilemma for analysts since traders will often exit not because of a perceived change in the stock's potential but as a result of many short-term trading activities. For this reason *trade outcome* provides a moderate insight into a user's position which should be viewed with some degree of caution.

Opinions can also be divided into four main subcategories:

1. *Speculation:* provides individual predictions of future events relating to a company or actions of the company. These are amongst the least reliable categories, as the individual user is typically unable to justify his or her insight into the predicted action.

2. *Chart Prediction:* describes a user's prediction of a future chart movement based on technical analysis of the stock's chart.

3. *Recommendation:* As with analyst recommendations, this category represents users who summarize their understanding and insight into

a stock with a simple and effective recommendation to take a certain course of action with regard to a particular share. *Recommendation* is the less determinate counterpart to *Trade*.

4. *Sentiment:* These tweets express pure sentiment toward the stock, rather than any factual content.

Table 1 shows examples for each of the tweet categories, as well as their relative frequency in the analyzed sample.

3 An Expert Finding Framework

In this section we present a general procedure for finding experts in stock microblogs. Based on this procedure, we will develop in the next sections several models for extracting reliable trading signals from tweets.

We assume that a stock tweet refers to exactly one stock, and therefore there is a one-to-one mapping between tweets and stocks. Other tweets are discarded. We define *expertise* as the ability to predict stock rise with high precision. Thus, a user is an *expert* if a high percentage of his or her *bullish* tweets is followed by a stock rise. In principle, we could analogously follow *bearish* tweets, and see if they are followed by a stock fall. However, bearish tweets are somewhat more difficult to interpret: for example, selling a share may indicate a negative outlook on the stock, but it may also result from other considerations, e.g. following a trading strategy that holds the stock for a fixed period (cf. the discussion on *Trade Outcome* tweets in the previous section).

We now describe a procedure that determines whether a user u is an expert. The procedure receives a training set $\mathcal{T}$ of tweets posted by u, where each tweet is annotated with its posting time. It is also given a classifier $\mathcal{C}$, which classifies each tweet as *bullish* or *not bullish* (either bearish or neutral).

The procedure first applies the classifier $\mathcal{C}$ to identify the bullish tweets in $\mathcal{T}$. It then determines the *correctness* of each bullish tweet. Given a tweet t, we observe the price change of the stock referenced by t over a one day period starting at the next trading day. The exact definition of mapping tweets to stock prices is given in section 5.1. A one-day holding period was chosen as it was found to perform well in previous works on tweet-based trading (Zhang and Skiena, 2010; Sprenger and Welpe, 2010), in particular for long positions (buy transactions). A bullish tweet is considered *correct* if it is followed by a stock rise, and as *incorrect* otherwise[1]. Given a set of tweets, we define its *precision* as the percentage of correct tweets in the set. Let C_u, I_u denote the number of correct and incorrect bullish tweets of user u, respectively. The precision of u's bullish tweets is therefore:

$$P_u = \frac{C_u}{C_u + I_u}$$

Let P_{bl} be the baseline precision. In this work we chose the baseline precision to be the proportion of tweets that are followed by a stock rise in the whole training set (including all the users). This represents the expected precision when picking tweets at random. Clearly, if $P_u \leq P_{bl}$ then u is not an expert. If $P_u > P_{bl}$, we apply the following statistical test to assess whether the difference is statistically significant. First, we compute the expected number of correct and incorrect transactions C_{bl}, I_{bl} according to the baseline:

$$C_{bl} = P_{bl} \times (C_u + I_u)$$

$$I_{bl} = (1 - P_{bl}) \times (C_u + I_u)$$

We then compare the observed counts (C_u, I_u) to the expected counts (C_{bl}, I_{bl}), using Pearson's Chi-square test. Since it is required for this test that C_{bl} and I_{bl} are at least 5, cases that do not meet this requirement are discarded. If the resulting p-value satisfies the required significance level α, then u is considered an expert. In this work we take $\alpha = 0.05$. Note that since the statistical test takes into account the number of observations, it will reject cases where the number of the observations is very small, even if the precision is very high. The output of the procedure is a classification of u as expert/non-expert, as well as the p-value (for experts). The expert finding procedure is summarized in Algorithm 1.

In the next two sections we propose several alternatives for the classifier $\mathcal{C}$.

[1] For about 1% of the tweets the stock price did not change in the next trading day. These tweets are also considered *correct* throughout this work.

Algorithm 1 Determine if a user u is an expert

Input: set of tweets $\mathcal{T}$ posted by u, bullishness classifier $\mathcal{C}$, baseline probability P_{bl}, significance level α

Output: NON-EXPERT/(EXPERT, p-value)

$\mathcal{T}_{bullish} \leftarrow$ tweets in $\mathcal{T}$ classified by $\mathcal{C}$ as *bullish*
$C_u \leftarrow 0$; $I_u \leftarrow 0$
for each $t \in \mathcal{T}_{bullish}$ **do**
  if t is followed by a stock rise **then**
    C_u++
  else
    I_u++
  end if
end for
$P_u = \frac{C_u}{C_u + I_u}$
if $P_u \leq P_{bl}$ **then**
  return NON-EXPERT
else
  $C_{bl} \leftarrow P_{bl} \times (C_u + I_u)$
  $I_{bl} \leftarrow (1 - P_{bl}) \times (C_u + I_u)$
  $p \leftarrow$ *ChiSquareTest*(C_u, I_u, C_{bl}, I_{bl})
  if $p > \alpha$ **then**
    return NON-EXPERT
  else
    return (EXPERT, p)
  end if
end if

4 Following Explicit Transactions

The first approach we attempt for classifying bullish (and bearish) tweets aims to identify only tweets that report buy and sell transactions (that is, tweets in the *Trade* category). According to our data analysis (reported in section 2.2), about 13% of the tweets belong to this category. There are two reasons to focus on these tweets. First, as we already noted, actual transactions are clearly the strongest signal of bulishness/bearishness. Second, the buy and sell actions are usually reported using a closed set of expressions, making these tweets relatively easy to identify. A few examples for buy and sell tweets are shown in Table 2.

While buy and sell transactions can be captured reasonably well by a relatively small set of patterns, the examples in Table 2 show that stock tweets have their unique language for reporting these transactions, which must be investigated in order to come by these patterns. Thus, in order to develop a classifier for these tweets, we created a training and test corpora as follows. Based on our preliminary analysis of several thousand tweets, we composed a vocabulary of keywords which trade tweets must include[2]. This vocabulary contained words such as *in, out, bot, bght, sld* and so on. Filtering out tweets that match none of the keywords removed two thirds of the tweets. Out of the remaining tweets, about 5700 tweets were tagged. The training set contains about 3700 tweets, 700 of which are transactions. The test set contains about 2000 tweets, 350 of which are transactions.

sell	sold sum $OMNI 2.14 +12%
buy	bot $MSPD for earnings testing new indicator as well.
sell	Out 1/2 $RIMM calls @ 1.84 (+0.81)
buy	added to $joez 2.56
buy	I picked up some $X JUL 50 Puts @ 3.20 for gap fill play about an hour ago.
buy	long $BIDU 74.01
buy	$$ Anxiously sitting at the bid on $CWCO @ 11.85 It seems the ask and I are at an impasse. 20 min of this so far. Who will budge? (not me)
buy	In 300 $GOOG @ 471.15.
sell	sold $THOR 41.84 for $400 the FreeFactory is rocking
sell	That was quick stopped out $ICE
sell	Initiated a short position in $NEM.

Table 2: Buy and sell tweets

Since the transaction tweets can be characterized by a closed set of recurring patterns, we developed a classifier that is based on a few dozens of manually composed pattern matching rules, formulated as regular expressions. The classifier works in three stages:

1. *Normalization:* The tweet is transformed into a canonical form. For example, user name

[2]That is, we did not come across any trade tweet that does not include at least one of the keywords in the large sample we analyzed, so we assume that such tweets are negligible.

Dataset	Transaction	P	R	F1
Train	Buy	94.0%	84.0%	0.89
	Sell	96.0%	83.0%	0.89
Test	Buy	85.0%	70.0%	0.77
	Sell	88.5%	79.0%	0.84

Table 3: Results for buy/sell transactition classifier. Precision (P), Recall (R), and F-measure (F1) are reported.

is transformed into USERNAME; ticker name is transformed into TICKER; *buy, buying, bought, bot, bght* are transformed into BUY, and so on.

2. *Matching:* Trying to match one of the buy/sell patterns in the normalized tweet.

3. *Filtering:* Filtering out tweets that match "disqualifying" patterns. The simplest examples are a tweet starting with an "if" or a tweet containing a question mark.

The results of the classifier on the train and test set are summarized in Table 3. The results show that our classifier identifies buy/sell transactions with a good precision and a reasonable recall.

5 Unsupervised Learning from Stock Prices

The drawback of the method presented in the previous section is that it only considers a small part of the available tweets. In this section we propose an alternative method, which considers all the available tweets, and does not require any tagged corpus of tweets. Instead, we use actual stock price movements as our labels.

5.1 Associating Tweets with Stock Prices

We used stock prices to label tweets as follows. Each tweet message has a time stamp (eastern time), indicating when it was published. Our policy is to buy in the opening price of the next trading day (P_B), and sell on the opening price of the following trading day (P_S). Tweets that are posted until 9:25 in the morning (market hours begin at 9:30) are associated with the same day, while those are posted after that time are associated with the next trading date.

5.2 Training

Given the buy and sell prices associated with each tweet, we construct positive and negative training examples as follows: positive examples are tweets where $\frac{P_S - P_B}{P_B} \geq 3\%$, and negative examples are tweets where $\frac{P_S - P_B}{P_B} \leq -3\%$.

We used the SVM-light package (Joachims, 1999), with the following features:

- The existence of the following elements in the message text:
  - Reference to a ticker
  - Reference to a user
  - URL
  - Number
  - Hashtag
  - Question mark
- The case-insensitive words in the message after dropping the above elements.
- The 3, 4, 5 letter prefixes of each word.
- The name of the user who authored the tweet, if it is a frequent user (at least 50 messages in the training data). Otherwise, the user name is taken to be "anonymous".
- Whether the stock price was up or down 1% or more in the previous trading day.
- 2, 3, 4-word expressions which are typical to tweets (that is, their relative frequency in tweets is much higher than in general news text).

6 Empirical Evaluation

In this section we focus on the empirical task of *tweet ranking*: ordering the tweets in the test set according to their likelihood to be followed by a stock rise. This is similar to the common IR task of ranking documents according to their relevance. A perfect ranking would place all the correct tweets before all the incorrect ones.

We present several ranking models that use the expert finding framework and the bullishness classification methods discussed in the previous sections as building blocks. The performance of these models is evaluated on the test set. By considering the

precision at various points along the list of ranked tweets, we can compare the precision-recall tradeoffs achieved by each model.

Before we discuss the ranking models and the empirical results, we describe the datasets used to train and test these models.

6.1 Datasets

Stock tweets were downloaded from the StockTwits website[3], during two periods: from April 25, 2010 to November 1, 2011, and from December 14, 2010 to February 3, 2011. A total of 700K tweets messages were downloaded. Tweets that do not contain exactly one stock ticker (traded in NYSE or NASDAQ) were filtered out. The remaining 340K tweets were divided as follows:

- *Development set:* April 25, 2010 to August 31, 2010: 124K messages
- *Held out set*: September 1, 2010 to November 1, 2010: 110K messages
- *Test set:* December 14, 2010 to February 3, 2011: 106K messages

We consider the union of the development and held out sets as our training set.

6.2 Ranking Models

6.2.1 Joint-All Model

This is our baseline model, as it does not attempt to identify experts. It learns a single SVM model as described in Section 5 from all the tweets in the training set. It then applies the SVM model to each tweet in the test set, and ranks them according to the SVM classification score.

6.2.2 Transaction Model

This model finds expert users in the training set (Algorithm 1), using the buy/sell classifier described in Section 4. Tweets classified as *buy* are considered *bullish*, and the rest are considered non-bullish. Expert users are ranked according to their p value (in ascending order). The same classifier is then applied to the tweets of the expert users in the test set. The tweets classified as bullish are ordered according to the ranking of their author (first all the bullish tweets of the highest-ranked expert user, then all the bullish tweets of the expert ranked second, and so on).

6.2.3 Per-User Model

The *joint all* model suffers from the tweets of non-experts twice: at training time, these tweets introduce much noise into the training of the SVM model. At test time, we follow these unreliable tweets along with the more reliable tweets of the experts. The *per-user* model addresses both problems.

This model learns from the development set a separate SVM model $\mathcal{C}_u$ for each user u, based solely on the user's tweets. We then optimize the classification threshold of the learnt SVM model $\mathcal{C}_u$ as follows. Setting the threshold to θ results in a new classifier $\mathcal{C}_{u,\theta}$. Algorithm 1 is applied to u's tweets in the held-out set (denoted $\mathcal{H}_u$), using the classifier $\mathcal{C}_{u,\theta}$. For the ease of presentation, we define *ExpertPValue($\mathcal{H}_u$, $\mathcal{C}_{u,\theta}$,P_{bl},α)* as a function that calls Algorithm 1 with the given parameters, and returns the obtained p-value if u is an expert and 1 otherwise. We search exhaustively for the threshold $\hat{\theta}$ for which this function is minimized (in other words, the threshold that results in the best p-value). The threshold of $\mathcal{C}_u$ is then set to $\hat{\theta}$, and the user's p-value is set to the best p-value found. If u is a non-expert for all of the attempted θ values then u is discarded. Otherwise, u is identified as an expert.

The rest of the process is similar to the transaction model: the tweets of each expert u in the test set are classified using the optimized per-user classifier C_u. The final ranking is obtained by sorting the tweets that were classified as bullish according to the p-value of their author. The per-user ranking procedure is summarized in Algorithm 2.

6.2.4 Joint-Experts Model

The *joint experts* model makes use of the experts identified by the *per-user* model, and builds a single joint SVM model from the tweets of these users. This results in a model that is trained on more examples than in the previous per-user method, but unlike the *joint all* method, it learns only from high-quality users. As with the *joint all* model, test tweets are ranked according to the SVM's score. However, the model considers only the tweets of expert users in the test set.

end for
$\mathcal{R} \leftarrow$ tweets in $\bigcup_u \mathcal{S}_{bullish,u}$ sorted by p_u
return $\mathcal{R}$

6.3 Results

Figure 1 summarizes the results obtained for the various models. Each model was used to rank the tweets according to the confidence that they predict a positive stock price movement. Each data point corresponds to the precision obtained for the first k tweets ranked by the model, and the results for varying k values illustrate the precision/recall tradeoff of the model. These data points were obtained as follows:

- For methods that learn a single SVM model (*joint all* and *joint experts*), the graph was obtained by decreasing the threshold of the SVM classifier, at fixed intervals of 0.05. For each threshold value, k is the number of tweets classified as bullish by the model.

- For methods that rank the users by their p value and order the tweets accordingly (*transaction* and *per user*), the i-th data point corresponds to the cumulative precision for the tweets classified as bullish by the first i users. For the *per user* method we show the cumulative results for the first 20 users. For the *transaction* method we show all the users that were identified as experts.

The *random* line is our baseline. It shows the expected results for randomly ordering the tweets in the test set. The expected precision at any point is equal to the percentage of tweets in the test set that were followed by a stock rise, which was found to be 51.4%.

We first consider the *joint all* method, which learns a single model from all the tweets. The only

Correct	Incorrect	P	p
87	46	65.4	0.001
142	86	62.3	0.001
162	103	61.1	0.002
220	158	58.2	0.008
232	168	58.0	0.008
244	176	58.1	0.006
299	229	56.6	0.016
335	255	56.8	0.009
338	268	55.8	0.031
344	269	56.1	0.019

481	430	52.8	0.398
487	435	52.8	0.388
675	564	54.5	0.030
683	569	54.6	0.026
690	573	54.6	0.022
720	591	54.9	0.011

Table 4: Per user model: cumulative results for first 20 users. The table lists the number of correct and incorrect tweets, the precision P and the significance level p.

per-user information available to this model is a feature fed to the SVM classifier, which, as we found, does not contribute to the results. Except for the first 58 tweets, which achieved precision of 55%, the precision quickly dropped to a level of around 52%, which is just a little better than the random baseline. Next, we consider the *transaction* configuration, which is based on detecting *buy* transactions. Only 10 users were found to be experts according to this method, and in the test period these users had a total of 173 tweets. These 173 tweets achieve good precision (57.1% for the first 161 tweets, and 54.9% for the first 173 tweets). However this method resulted in a low number of transactions. This happens because it is able to utilize only a small fraction of the tweets (explicit buy transactions).

Remarkably, *per user* and *joint experts*, the two methods which rely on identifying the experts via unsupervised learning are by far the best methods. Both models seem to have comparable performance, where the results of the *join experts* model are somewhat smoother, as expected. Table 4 shows cumulative results for the first 20 users in the per-user model. The results show that this model achieves good precision for a relatively large number of tweets, and for most of the data points reported in the table the results significantly outperform the baseline (as indicated by the p value). Overall, these results show the effectiveness of our methods for finding experts through unsupervised learning.

7 Related Work

A growing body of work aims at extracting sentiment and opinions from tweets, and exploit this information in a variety of application domains. Davidov et al. (2010) propose utilizing twitter hashtag and smileys to learn enhanced sentiment types. O'Connor et al. (2010) propose a sentiment detector based on Twitter data that may be used as a replacement for public opinion polls. Bollen et al. (2011) measure six different dimensions of public mood from a very large tweet collection, and show that some of these dimensions improve the predication of changes in the Dow Jones Industrial Average (DJIA).

Sentiment analysis of news articles and financial blogs and their application for stock prediction were the subject of several studies in recent years. Some of these works focus on document-level sentiment classification (Devitt and Ahmad, 2007; O'Hare et al., 2009). Other works also aimed at predicting stock movement (Lavrenko et al., 2000; Koppel and Shtrimberg, 2004; Schumaker and Chen, 2010). All these methods rely on predefined sentiment lexicons, manually classified training texts, or their combination. Lavrenko et al. (2000), Koppel and Shtrimberg (2004), and Schumaker and Chen (2010) exploit stock prices for training, and thus save the need in supervised learning.

Previous work on stock message boards include (Das and Chen, 2007; Antweiler and Frank, 2004; Chua et al., 2009). (Sprenger and Welpe, 2010) is, to the best of our knowledge, the first work to address specifically stock microblogs. All these works take a similar approach for classifying message bullishness: they train a classifier (Naïve Bayes, which Das and Chen combined with additional classifiers and a sentiment lexicon, and Chua et al. presented improvement for) on a collection of manually labeled messages (classified into *Buy, Sell, Hold*). Interestingly, Chua et al. made use of an Australian mes-

sage board (HotCopper), where, unlike most of the stock message boards, these labels are added by the message author. Another related work is (Zhang and Skiena, 2010), who apply lexicon-based sentiment analysis to several sources of news and blogs, including tweets. However, their data set does not include stock microblogs, but tweets mentioning the official company name.

Our work differs from previous work on stock messages in two vital aspects. Firstly, these works did not attempt to distinguish between experts and non-expert users, but aggregated the sentiment over all the users when studying the relation between sentiment and the stock market. Secondly, unlike these works, our best-performing methods are completely unsupervised, and require no manually tagged training data or sentiment lexicons.

8 Conclusion

This paper investigated the novel task of finding expert investors in online stock forums. In particular, we focused on stock microblogs. We proposed a framework for finding expert investors, and experimented with several methods for tweet classification using this framework. We found that combining our framework with user-specific unsupervised learning allows us to predict stock price movement with high precision, and the results were shown to be statistically significant. Our results illustrate the importance of distinguishing experts from non-experts. An additional contribution of this work is an in-depth analysis of stock tweets, which sheds light on their content and its potential utility.

In future work we plan to improve the features of the SVM classifier, and further investigate the usefulness of our approach for trading.

Abstract

In this paper we present a method for *unsupervised* semantic role induction which we formalize as a graph partitioning problem. Argument instances of a verb are represented as vertices in a graph whose edge weights quantify their role-semantic similarity. Graph partitioning is realized with an algorithm that iteratively assigns vertices to clusters based on the cluster assignments of neighboring vertices. Our method is algorithmically and conceptually simple, especially with respect to how problem-specific knowledge is incorporated into the model. Experimental results on the CoNLL 2008 benchmark dataset demonstrate that our model is competitive with other unsupervised approaches in terms of F1 whilst attaining significantly higher cluster purity.

1 Introduction

Recent years have seen increased interest in the *shallow semantic analysis* of natural language text. The term is most commonly used to describe the automatic identification and labeling of the semantic roles conveyed by sentential constituents (Gildea and Jurafsky, 2002). Semantic roles describe the semantic relations that hold between a predicate and its arguments (e.g., "who" did "what" to "whom", "when", "where", and "how") abstracting over surface syntactic configurations.

In the example sentences below, *window* occupies different syntactic positions — it is the object of *broke* in sentences (1a,b), and the subject in (1c) — while bearing the same semantic role, i.e., the physical object affected by the breaking event. Analogously, *ball* is the instrument of *break* both when realized as a prepositional phrase in (1a) and as a subject in (1b).

(1) a. [Jim]$_{A0}$ **broke** the [window]$_{A1}$ with a [ball]$_{A2}$.
b. The [ball]$_{A2}$ **broke** the [window]$_{A1}$.
c. The [window]$_{A1}$ **broke** [last night]$_{TMP}$.

The semantic roles in the examples are labeled in the style of PropBank (Palmer et al., 2005), a broad-coverage human-annotated corpus of semantic roles and their syntactic realizations. Under the PropBank annotation framework (which we will assume throughout this paper) each predicate is associated with a set of core roles (named *A*0, *A*1, *A*2, and so on) whose interpretations are specific to that predicate[1] and a set of adjunct roles such as *location* or *time* whose interpretation is common across predicates (e.g., *last night* in sentence (1c)).

The availability of PropBank and related resources (e.g., FrameNet; Ruppenhofer et al. (2006)) has sparked the development of great many semantic role labeling systems most of which conceptualize the task as a supervised learning problem and rely on role-annotated data for model training. Most of these systems implement a two-stage architecture consisting of *argument identification* (determining the arguments of the verbal predicate) and *argument classification* (labeling these arguments with semantic roles). Despite being relatively shallow, se-

[1] More precisely, *A*0 and *A*1 have a common interpretation across predicates as *proto-agent* and *proto-patient* in the sense of Dowty (1991).

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1320–1331,
Edinburgh, Scotland, UK, July 27–31, 2011.

mantic role analysis has the potential of benefiting a wide spectrum of applications ranging from information extraction (Surdeanu et al., 2003) and question answering (Shen and Lapata, 2007), to machine translation (Wu and Fung, 2009) and summarization (Melli et al., 2005).

Current approaches have high performance — a system will recall around 81% of the arguments correctly and 95% of those will be assigned a correct semantic role (see Màrquez et al. (2008) for details), however only on languages and domains for which large amounts of role-annotated training data are available. For instance, systems trained on PropBank demonstrate a marked decrease in performance (approximately by 10%) when tested on out-of-domain data (Pradhan et al., 2008). Unfortunately, the reliance on role-annotated data which is expensive and time-consuming to produce for every language and domain, presents a major bottleneck to the widespread application of semantic role labeling.

In this paper we argue that unsupervised methods offer a promising yet challenging alternative. If successful, such methods could lead to significant savings in terms of annotation effort and ultimately yield more portable semantic role labelers that require overall less engineering effort. Our approach formalizes semantic role induction as a graph partitioning problem. Given a verbal predicate, it constructs a weighted graph whose vertices correspond to argument instances of the verb and whose edge weights quantify the similarity between these instances. The graph is partitioned into vertex clusters representing semantic roles using a variant of Chinese Whispers, a graph-clustering algorithm proposed by Biemann (2006). The algorithm iteratively assigns cluster labels to graph vertices by greedily choosing the most common label amongst the neighbors of the vertex being updated. Beyond extending Chinese Whispers to the semantic role induction task, we also show how it can be understood as a type of Gibbs sampling when our graph is interpreted as a Markov random field.

Experimental results on the CoNLL 2008 benchmark dataset demonstrate that our method, despite its simplicity, improves upon competitive approaches in terms of F1 and achieves significantly higher cluster purity.

2 Related Work

Although the bulk of previous work on semantic role labeling has primarily focused on supervised methods (Màrquez et al., 2008), a few semi-supervised and unsupervised approaches have been proposed in the literature. The majority of semi-supervised models have been developed within a framework known as *annotation projection*. The idea is to combine labeled and unlabeled data by projecting annotations from a labeled source sentence onto an unlabeled target sentence within the same language (Fürstenau and Lapata, 2009) or across different languages (Padó and Lapata, 2009). Outwith annotation projection, Gordon and Swanson (2007) propose to increase the coverage of PropBank to unseen verbs by finding syntactically similar (labeled) verbs and using their annotations as surrogate training data.

Swier and Stevenson (2004) were the first to introduce an unsupervised semantic role labeling system. Their algorithm induces role labels following a bootstrapping scheme where the set of labeled instances is iteratively expanded using a classifier trained on previously labeled instances. Their method starts with a dataset containing no role annotations at all, but crucially relies on VerbNet (Kipper et al., 2000) for identifying the arguments of predicates and making initial role assignments. VerbNet is a manually constructed lexicon of verb classes each of which is explicitly associated with argument realization and semantic role specifications.

Subsequent work has focused on unsupervised methods for argument identification and classification. Abend et al. (2009) recognize the arguments of predicates by relying solely on part of speech annotations whereas Abend and Rappoport (2010) distinguish between core and adjunct roles, using an unsupervised parser and part-of-speech tagger. Grenager and Manning (2006) address the role induction problem and propose a directed graphical model which relates a verb, its semantic roles, and their possible syntactic realizations. Latent variables represent the semantic roles of arguments and role induction corresponds to inferring the state of these latent variables.

Following up on this work, Lang and Lapata (2010) formulate role induction as the process of de-

tecting alternations and finding a canonical syntactic form for them. Verbal arguments are then assigned roles, according to their position in this canonical form, since each position references a specific role. Their model extends the logistic classifier with hidden variables and is trained in a manner that takes advantage of the close relationship between syntactic functions and semantic roles. More recently, Lang and Lapata (2011) propose a clustering algorithm which first splits the argument instances of a verb into fine-grained clusters based on syntactic cues and then executes a series of merge steps (mainly) based on lexical cues. The split phase creates a large number of small clusters with high purity but low collocation, i.e., while the instances in a particular cluster typically belong to the same role the instances for a particular role are commonly scattered amongst many clusters. The subsequent merge phase conflates clusters with the same role in order to increase collocation.

Like Grenager and Manning (2006) and Lang and Lapata (2010; 2011), this paper describes an unsupervised method for semantic role induction, i.e., one that does not require any role annotated data or additional semantic resources for training. Contrary to these previous approaches, we conceptualize role induction in a novel way, as a graph partitioning problem. Our method is simple, computationally efficient, and does not rely on hidden variables. Moreover, the graph-based representation for verbs and their arguments affords greater modeling flexibility. A wide range of methods exist for finding partitions in graphs (Schaeffer, 2007), besides Chinese Whispers (Biemann, 2006), which could be easily applied to the semantic role induction problem. However, we leave this to future work.

Graph-based methods are popular in natural language processing, especially with unsupervised learning problems (Chen and Ji, 2010). The Chinese Whispers algorithm itself (Biemann, 2006) has been previously applied to several tasks including word sense induction (Klapaftis and M., 2010) and unsupervised part-of-speech tagging (Christodoulopoulos et al., 2010). The same algorithm is also described in Abney (2007, pp. 146-147) under the name "clustering by propagation". The term makes explicit the algorithm's connection to label propagation, a general framework[2] for semi-supervised learning (Zhu et al., 2003) with applications to machine translation (Alexandrescu and Kirchhoff, 2009), information extraction (Talukdar and Pereira, 2010) and structured part-of-speech tagging (Subramanya et al., 2010). The basic idea behind label propagation is to represent labeled and unlabeled instances as vertices in an undirected graph with edges whose weights express similarity (and possibly dissimilarity) between the instances. Label information is then propagated between the vertices in such a way that similar instances tend to be assigned the same label. Analogously, Chinese Whispers works by propagating cluster membership information along the edges of a graph, even though the graph does not contain any human-labeled instance vertices.

3 Problem Setting

We adopt the standard architecture of supervised semantic role labeling systems where argument identification and argument classification are treated separately. Our role labeler is fully unsupervised with respect to both tasks — it does not rely on any role annotated data or semantic resources. However, our system does not learn from raw text. In common with most semantic role labeling research, we assume that the input is syntactically analyzed in the form of dependency trees.

We view argument identification as a syntactic processing step that can be largely undertaken deterministically through structural analysis of the dependency tree. We therefore use a small set of rules to detect arguments with high precision and recall (see Section 4). Argument classification is more challenging and must take into account syntactic *as well as* lexical-semantic information. Both types of information are incorporated into our model through a similarity function that assigns similarity scores to pairs of argument instances. Following previous work (Lang and Lapata, 2010; Grenager and Manning, 2006), our system outputs verb-specific roles by grouping argument instances into clusters and labeling each argument instance with an identifier cor-

[2]For example, Haffari and Sarkar (2007) use label propagation to analyze other semi-supervised algorithms such as the Yarowsky (1995) algorithm.

responding to the cluster it has been assigned to. Such identifiers are similar to PropBank-style core labels (e.g., *A*0, *A*1).

4 Argument Identification

Supervised semantic role labelers often employ a classifier in order to decide for each node in the parse tree whether or not it represents a semantic argument. Nodes classified as arguments are then assigned a semantic role. In the unsupervised setting, we slightly reformulate argument identification as the task of discarding as many non-semantic arguments as possible. This means that the argument identification component does not make a final positive decision for any of the argument candidates; instead, a final decision is only made in the subsequent argument classification stage.

We discard or select argument candidates using the set of rules developed in Lang and Lapata (2011). These are mainly based on the parts of speech and syntactic relations encountered when traversing a dependency tree from the predicate node to the argument node. For each candidate, rules are considered in a prespecified order and the first matching rule is applied. When evaluated on its own, the argument identification component obtained 88.1% precision (percentage of semantic arguments out of those identified) and 87.9% recall (percentage of identified arguments out of all gold arguments).

5 Argument Classification

After identifying likely arguments for each verb, the next step is to infer a label for each argument instance. Since we aim to induce verb-specific roles (see Section 3), we construct an undirected, weighted graph *for each verb*. Vertices correspond to verb argument instances and edge weights quantify the similarities between them. This argument-instance graph is then partitioned into clusters of vertices representing semantic roles and each argument instance is assigned a label that indicates the cluster it belongs to. In what follows we first describe how the graph is constructed and then provide the details of our graph partitioning algorithm.

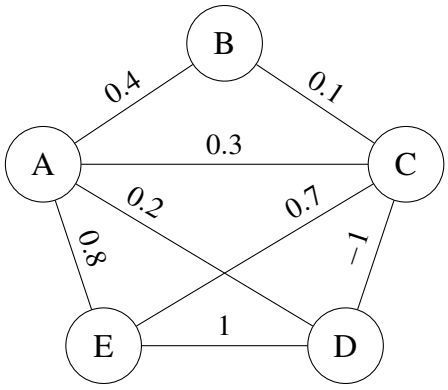

Figure 1: Simplified example of an argument-instance graph. All pairs of vertices with non-zero similarity are connected through edges that are weighted with a similarity score $\phi(v_i, v_j)$. Upon updating the label for a vertex all neighboring vertices propagate their label to the vertex being updated. The score for each label is determined by summing together the weighted votes for that label and the label with the maximal score is chosen.

5.1 Graph Construction

For each verb we construct an undirected, weighted graph $G = (V, E, \phi)$ with vertices V, edges E, and edge weight function ϕ as follows. Each argument instance in the corpus that belongs to the verb is added as a vertex. Then, for each possible pair of vertices (v_i, v_j) we compute a weight $\phi(v_i, v_j) \in \mathbb{R}$ according to the function ϕ. If the weight is non-zero, an undirected edge $e = (v_i, v_j)$ with weight $\phi(v_i, v_j)$ is added to the graph. The function ϕ quantifies the similarity or dissimilarity between instances; positive values indicate that roles are likely to be the same, negative values indicate that roles are likely to differ, and zero values indicate that there is no evidence for either case. Our similarity function is symmetric, i.e., $\phi(v_i, v_j) = \phi(v_j, v_i)$ and permits negative values (see Section 5.4 for a detailed description).

Figure 1 shows an example of a graph for a verb with five argument instances (vertices A–E). Edges are drawn between pairs of vertices with non-zero similarity values. For instance, vertex D is connected to vertex A with weight 0.2, to vertex E with 1, and vertex C with -1. Since edges are drawn between all pairs of vertices with non-zero similarity, the resulting graphs tend to be densely connected, which for large datasets may be prohibitively

inefficient. A solution would be to sample a subset from all possible pairs, but we did not make use of any kind of edge pruning in our experiments.

5.2 Graph Partitioning

Graph partitioning is realized with a variant of Chinese Whispers (Biemann, 2006) whose details are given below. In addition, we discuss how our algorithm relates to other graph-based models in order to help provide a better theoretical understanding.

We assume each vertex v_i is assigned a label $l_i \in \{1 \dots L\}$ indicating the cluster it belongs to. Initially, each vertex belongs to its own cluster, i.e., we let the number of clusters $L = |V|$ and set $l_i \leftarrow i$. Given this initial vertex labeling, the algorithm proceeds by iteratively updating the label for each vertex. The update is based on the labels of neighboring vertices and reflects their similarity to the vertex being updated. Intuitively, each neighboring vertex votes for the cluster it is currently assigned to, where the strength of the vote is determined by the similarity (i.e., edge weight) to the vertex being updated. The label l_i of vertex v_i is thus updated according to the following equation:

$$l_i \leftarrow \arg \max_{l \in \{1 \dots L\}} \sum_{v_j \in \mathcal{N}_i(l)} \phi(v_i, v_j) \tag{2}$$

where $\mathcal{N}_i(l) = \{v_j | (v_i, v_j) \in E \wedge l = l_j\}$ denotes the set of v_i's neighbors with label l. In other words, for each label we compute a score by summing together the weights of edges to neighboring vertices with that label and select the label with the maximal score. Note that negative edges decrease the score for a particular label, thus demoting the label.

Consider again Figure 1. Assume we wish to update vertex A. In addition, assume that B and E are currently assigned the same label (i.e., they belong to the same cluster) whereas C and D are each in different clusters. The score for cluster $\{B,E\}$ is $0.4 + 0.8 = 1.2$, the score for cluster $\{C\}$ is 0.3 and the score for cluster $\{D\}$ is 0.2. We would thus assign A to cluster $\{B,E\}$ as it has the highest score.

The algorithm is run for several iterations. At each iteration it passes over all vertices, and the update order of the vertices is chosen randomly. As the updates proceed, labels can disappear from the graph, whereby the number of clusters decreases. Empirically, we observe that for sufficiently many iterations the algorithm converges to a fixed labeling or oscillates between labelings that differ only in a few vertices. The result of the algorithm is a hard partitioning of the given graph, where the number of clusters is determined automatically.

5.3 Propagation Prioritization

We make one important modification to the basic algorithm described so far based on the intuition that higher scores for a label indicate more reliable propagations. More precisely, when updating vertex v_i to label l we define the confidence of the update as the average similarity to neighbors with label l:

$$conf(l_i \leftarrow l) = \frac{1}{|\mathcal{N}_i(l)|} \sum_{v_j \in \mathcal{N}_i(l)} \phi(v_i, v_j) \tag{3}$$

We can then prioritize high-confidence updates by setting a threshold θ and allowing only updates with confidence greater or equal to θ. The threshold is initially set to 1 (i.e., the maximal possible confidence) and then lowered by some small constant Δ after each iteration until it reaches a minimum θ_{min}, at which point the algorithm terminates. This improves the resulting clustering, since it promotes reliable updates in earlier phases of the algorithm which in turn has a positive effect on successive updates.

5.4 Argument-Instance Similarity

As described earlier, the edge weights in our graph are similarity scores, with positive values indicating similarity and negative values indicating dissimilarity. Determining the similarity function ϕ without access to labeled training data poses a major difficulty which we resolve by relying on prior linguistic knowledge. Specifically, we measure the similarity of argument instances based on three simple and intuitive criteria: (1) whether the instances are lexically similar; (2) whether the instances occur in the same syntactic position; and (3) whether the instances occur in the same frame (i.e., are arguments in the same clause). The same criteria were used in (Lang and Lapata, 2011) and shown effective in quantifying role-semantic similarity between *clusters* of argument instances. Lexical and syntactic similarity are scored through functions $lex(v_i, v_j)$ and $syn(v_i, v_j)$ with range $[-1, 1]$, whereas the third criterion enters the scoring function directly:

$$\phi(v_i, v_j) = \begin{cases} -\infty \text{ if } v_i \text{ and } v_j \text{ are in same frame} \\ \alpha lex(v_i, v_j) + (1-\alpha) syn(v_i, v_j) \text{ otherwise.} \end{cases} \quad (4)$$

The first case in the function expresses a common linguistic assumption, i.e., that two argument instances v_i and v_j occurring in the same frame cannot have the same semantic role. The function implements this constraint by returning $-\infty$.[3] The syntactic similarity function $s(v_i, v_j)$ indicates whether two argument instances occur in a similar syntactic position. We define syntactic positions through four cues: the relation of the argument head word to its governor, verb voice (active/passive), the linear position of the argument relative to the verb (left/right) and the preposition used for realizing the argument (if any). The score is $\frac{S}{4}$ where S is the number of cues which agree, i.e., have the same value. The syntactic score is set to zero when the governor relation of the arguments is not the same. Lexical similarity $l(v_i, v_j)$ is measured in terms of the cosine of the angle between vectors h_i and h_j representing the argument head words:

$$lex(v_i, v_j) = cos(h_i, h_j) = \frac{h_i \cdot h_j}{\|h_i\| \|h_j\|} \quad (5)$$

We obtain h_i and h_j from a simple semantic space model (Turney and Pantel, 2010) which requires no supervision (Section 6 describes the details of the model used in our experiments).

Our similarity function weights the contribution of syntax vs. semantics equally, i.e., α is set to 0.5. This reflects the linguistic intuition that lexical and syntactic information are roughly of equal importance.

5.5 Relation to Other Models

This section briefly points out some connections to related models. The averaging procedure used for updating the graph vertices (Equation 2) appears in some form in most label propagation algorithms (see Talukdar (2010) for details). Label propagation algorithms are commonly interpreted as random walks on graphs. In our case such an interpretation is not directly possible due to the presence of negative edge weights. This could be changed by transforming the edge weights onto a non-negative scale, but we find the current setup more expedient for modeling dissimilarity.

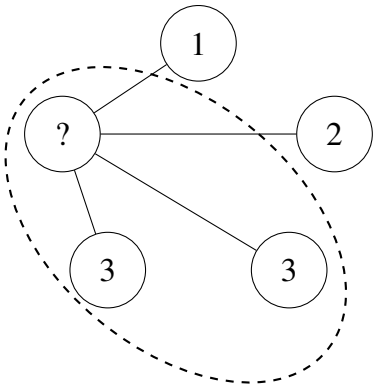

Figure 2: The update rule (Equation 2) can be understood as choosing a minimal edge-cut, thereby greedily maximizing intra-cluster similarity and minimizing inter-cluster similarity. Assuming equal weight for all edges above, label 3 is chosen for the vertex being updated such that the sum of weights of edges crossing the cut is minimal.

Our model could be also transformed into a probabilistic graphical model that specifies a distribution over vertex labels. In the transformed model each vertex corresponds to a random variable over labels and edges are associated with binary potential functions over vertex-pairs. Let $\mathbf{1}(v_i = v_j)$ denote an indicator function which takes value 1 iff. $l_i = l_j$ and value 0, otherwise. Then pairwise potentials can be defined in terms of the original edge weights[4] as $\psi(v_i, v_j) = \exp(\mathbf{1}(v_i = v_j)\phi(v_i, v_j))$. A Gibbs sampler used to sample from the distribution of the resulting pairwise Markov random field (Bishop, 2006; Wainwright and Jordan, 2008) would employ almost the same update procedure as in Equation 2, the difference being that labels would be sampled according to their probabilities, rather than chosen deterministically based on scores.

A third way of understanding the update rule is as a heuristic for maximizing intra-cluster similarity and minimizing inter-cluster similarity. By

[3] Formally, ϕ has range $ran(\phi) = [-1, 1] \cup \{-\infty\}$ and for $x \in ran(\phi)$ we define $x + (-\infty) = -\infty$. This means that the overall score computed for a label (Equation 2) is $-\infty$ if one of the summands is $-\infty$.

[4] Including weights with value zero and thus connecting all vertex pairs.

assigning the label with maximal score to v_i, we greedily maximize the sum of intra-cluster edge weights while minimizing the sum of inter-cluster edge weights, i.e., the weight of the edge-cut. This is illustrated in Figure 2. Cut-based methods are a common method in graph clustering (Schaeffer, 2007) and are also used for inference in pairwise Markov random fields like the one described in the previous paragraph (Boykov et al., 2001).

Note that while it would be possible to transform our model into a model with a formal probabilistic interpretation (either as a graph random walk or as a probabilistic graphical model) this would not change the non-empirical nature of the similarity function, which is unavoidable in the unsupervised setting and is also common in the semi-supervised methods discussed in Section 2.

6 Experimental Setup

In this section we describe how we assessed the performance of our model. We discuss the dataset on which our experiments were carried out, explain how our system's output was evaluated and present the methods used for comparison with our approach.

Data We compared the output of our model against the PropBank gold standard annotations contained in the CoNLL 2008 shared task dataset (Surdeanu et al., 2008). The latter was taken from the Wall Street Journal portion of the Penn Treebank and converted into a dependency format (Surdeanu et al., 2008). In addition to gold standard dependency parses, the dataset also contains automatic parses obtained from the MaltParser (Nivre et al., 2007). The dataset provides annotations for verbal and nominal predicate-argument constructions, but we only considered the former, following previous work on semantic role labeling (Màrquez et al., 2008). All the experiments described in this paper use the CoNLL 2008 training dataset.

Evaluation Metrics For each verb, we determine the extent to which argument instances in the clusters share the same gold standard role (purity) and the extent to which a particular gold standard role is assigned to a single cluster (collocation).

More formally, for each group of verb-specific clusters we measure the purity of the clusters as the percentage of instances belonging to the majority gold class in their respective cluster. Let N denote the total number of instances, G_j the set of instances belonging to the j-th gold class and C_i the set of instances belonging to the i-th cluster. Purity can be then written as:

$$PU = \frac{1}{N} \sum_i \max_j |G_j \cap C_i| \tag{6}$$

Collocation is defined as follows. For each gold role, we determine the cluster with the largest number of instances for that role (the role's *primary* cluster) and then compute the percentage of instances that belong to the primary cluster for each gold role:

$$CO = \frac{1}{N} \sum_j \max_i |G_j \cap C_i| \tag{7}$$

Per-verb scores are aggregated into an overall score by averaging over all verbs. We use the micro-average obtained by weighting the scores for individual verbs proportionately to the number of instances for that verb.

Finally, we use the harmonic mean of purity and collocation as a single measure of clustering quality:

$$F_1 = \frac{2 \cdot CO \cdot PU}{CO + PU} \tag{8}$$

Model Parameters Recall that our algorithm prioritizes updates with confidence higher than a threshold θ. Initially, θ is set to 1 and its value decreases at each iteration by a small constant Δ which we set to 0.0025. The algorithm terminates when a minimum confidence θ_{min} is reached. While choosing a value for Δ is straightforward — it simply has to be a small fraction of the maximal possible confidence — specifying θ_{min} on the basis of objective prior knowledge is less so. And although a human judge could determine the optimal termination point based on several criteria such as clustering quality or the number of clusters, we used a development set instead for the sake of reproducibility and comparability. Specifically, we optimized θ_{min} on the CoNLL test set and obtained best results with $\theta_{min} = \frac{1}{3}$. This value was used for all our experiments and was also kept fixed for all verbs. Importantly, the development set was not used for any kind of supervised training.

Table 1: Evaluation of the output of our graph partitioning algorithm compared to our previous models and a baseline that assigns arguments to clusters based on their syntactic function.

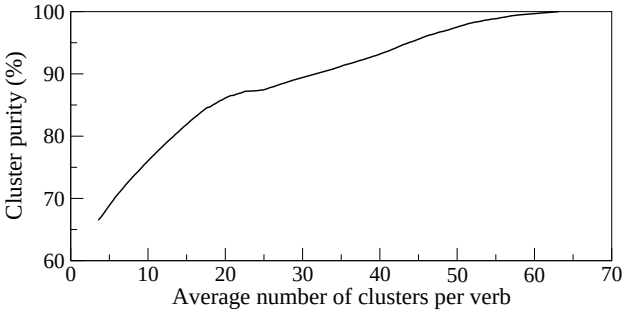

Figure 3: Purity (vertical axis) against average number of clusters per verb (horizontal axis) on the auto/auto dataset.

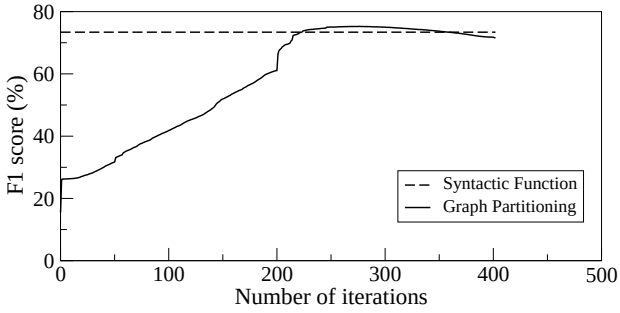

Figure 4: F1 (vertical axis) against number of iterations (horizontal axis) on the auto/auto dataset.

Recall that one of the components in our similarity function is lexical similarity which we measure using a vector-based model (see Section 5.4). We created such a model from the Google *N*-Grams corpus (Brants and Franz, 2006) using a context window of two words on both sides of the target word and co-occurrence frequencies as vector components (no weighting was applied). The large size of this corpus allows us to use bigram frequencies, rather than frequencies of individual words and to distinguish between left and right bigrams. We used randomized algorithms (Ravichandran et al., 2005) to build the semantic space efficiently.

Comparison Models We compared our graph partitioning algorithm against three competitive approaches. The first one assigns argument instances to clusters according to their syntactic function (e.g., subject, object) as determined by a parser. This baseline has been previously used as a point of comparison by other unsupervised semantic role induction systems (Grenager and Manning, 2006; Lang and Lapata, 2010) and shown difficult to outperform. Our implementation allocates up to $N = 21$ clusters[5] for each verb, one for each of the 20 most frequent syntactic functions and a default cluster for all other functions. We also compared our approach to Lang and Lapata (2010) using the same model settings (with 10 latent variables) and feature set proposed in that paper. Finally, our third comparison model is Lang and Lapata's (2011) split-merge clustering algorithm. Again we used the same parameters and number of clusters (on average 10 per verb). Our graph partitioning method uses identical cues for assessing role-semantic similarity as the method described in Lang and Lapata (2011).

7 Results

Our results are summarized in Table 1. We report cluster purity (PU), collocation (CO) and their harmonic mean (F1) for the baseline (Syntactic Function), our two previous models (the Latent Logistic classifier and Split-Merge) and the graph partitioning algorithm on four datasets. These result from the combination of automatic parses with automatically identified arguments (auto/auto), gold parses with

[5] This is the number of gold standard roles.

Table 2: Clustering results for individual verbs on the auto/auto dataset with our graph partitioning algorithm and the syntactic function baseline; the scores were taken from a single run.

automatic arguments (gold/auto), automatic parses with gold arguments (auto/gold) and gold parses with gold arguments (gold/gold). Table 1 reports averages across multiple runs. This was necessary in order to ensure that the results of our randomized graph partitioning algorithm are stable.[6] The arguments for the auto/auto and gold/auto datasets were identified using the rules described in Lang and Lapata (2011) (see Section 4). Bold-face is used to highlight the best performing system under each measure (PU, CO, or F1) on each dataset.

Compared to the Syntactic Function baseline, the Graph Partitioning algorithm has higher F1 on the auto/auto and auto/gold datasets but lags behind by 0.5 points on the gold/auto dataset and by 0.9 points on the gold/gold dataset. It attains highest purity on all datasets except for gold/gold, where it is 0.1 points below Split-Merge. When considering F1 in conjunction with purity and collocation, we observe that Graph Partitioning can attain higher purity than the comparison models by trading off collocation. If we were to hand label the clusters output by our system, purity would correspond to the quality of the resulting labeling, while collocation would determine the labeling effort. The relationship is illustrated more explicitly in Figure 3, which plots purity against the average number of clusters per verb on the auto/auto dataset. As the algorithm proceeds the number of clusters is reduced which results in a decrease of purity. The latter decreases more rapidly once the number of 20 clusters per verb is reached. This is accompanied by a decreasing tradeoff ratio between collocation and purity: at this stage decreasing purity by one point increases collocation by roughly one point, whereas in earlier iterations a decrease of purity by one point goes together with several points increase in collocation. This is most likely due to the fact that the number of gold standard classes is around 20.

Figure 4 shows the complete learning curve of our graph partitioning method on the auto/auto dataset (F1 is plotted against the number of iterations). The algorithm naturally terminates at iteration 266 (when $\theta_{min} = 1/3$), but we have also plotted iterations beyond that point. Since lower values of θ permit unreliable propagations, F1 eventually falls below the baseline (see Section 5.2). The importance of our propagation prioritization mechanism is further underlined by the fact that when it is not employed (i.e., when using the vanilla Chinese Whispers algorithm without any modifications), it performs substantially worse than the comparison models. On the auto/auto dataset, F1 converges to 59.1 (purity is 55.5 and collocation 63.2) within 10 iterations.

Finally, Table 2 shows how performance varies across verbs. We report results for the Syntactic Function baseline and Graph Partitioning on the auto/auto dataset for 12 verbs. These were selected so as to exhibit varied occurrence frequencies and alternation patterns. As can be seen, the macro-

[6] For example, on the auto/auto dataset and over 10 runs, the standard deviation in F1 was 0.11 points in collocation 0.16 points and in purity 0.08 points. The worst F1 was 0.20 points below the average, the worst collocation was 0.32 points below the average and the worst purity was 0.17 points below the average.

scopic result — increase in F1 and purity — also holds across verbs.

8 Conclusions

In this paper we described an unsupervised method for semantic role induction, in which argument-instance graphs are partitioned into clusters representing semantic roles. The approach is conceptually and algorithmically simple and novel in its formalization of role induction as a graph partitioning problem. We believe this constitutes an interesting alternative for two reasons. Firstly, eliciting and encoding problem-specific knowledge in the form of instance-wise similarity judgments can be easier than encoding it into model structure e.g., by making statistical independence assumptions or assumptions about latent structure. Secondly, the approach is general and amenable to other graph partitioning algorithms and relates to well-known graph-based semi-supervised learning methods.

The similarity function in this paper is by necessity rudimentary, since it cannot be estimated from data. Nevertheless, the resulting system attains competitive F1 and notably higher purity than the comparison models. Arguably, performance could be improved by developing a better similarity function. Therefore, in the future we intend to investigate how our system performs in a weakly supervised setting, where the similarity function is estimated from a small amount of labeled instances, since this would allow us to incorporate richer syntactic features and result in more precise similarity scores.

Structural Opinion Mining for Graph-based Sentiment Representation

Yuanbin Wu, Qi Zhang, Xuanjing Huang, Lide Wu

Abstract

Based on analysis of on-line review corpus we observe that most sentences have complicated opinion structures and they cannot be well represented by existing methods, such as frame-based and feature-based ones. In this work, we propose a novel graph-based representation for sentence level sentiment. An integer linear programming-based structural learning method is then introduced to produce the graph representations of input sentences. Experimental evaluations on a manually labeled Chinese corpus demonstrate the effectiveness of the proposed approach.

1 Introduction

Sentiment analysis has received much attention in recent years. A number of automatic methods have been proposed to identify and extract opinions, emotions, and sentiments from text. Previous researches on sentiment analysis tackled the problem on various levels of granularity including document, sentence, phrase and word (Pang et al., 2002; Riloff et al., 2003; Dave et al., 2003; Takamura et al., 2005; Kim and Hovy, 2006; Somasundaran et al., 2008; Dasgupta and Ng, 2009; Hassan and Radev, 2010). They mainly focused on two directions: sentiment classification which detects the overall polarity of a text; sentiment related information extraction which tries to answer the questions like "*who* expresses *what* opinion on *which* target".

Most of the current studies on the second direction assume that an opinion can be structured as a frame which is composed of a fixed number of slots. Typical slots include opinion holder, opinion expression, and evaluation target. Under this representation, they defined the task as a slots filling problem for each of the opinions. Named entity recognition and relation extraction techniques are usually applied in this task (Hu and Liu, 2004; Kobayashi et al., 2007; Wu et al., 2009).

However, through data analysis, we observe that 60.5% of sentences in our corpus do not follow the assumption used by them. A lot of important information about an opinion may be lost using those representation methods. Consider the following examples, which are extracted from real online reviews:

Example 1: *The interior is a bit noisy on the freeway*[1].

Example 2: *Takes good pictures during the daytime. Very poor picture quality at night*[2].

Based on the definition of opinion unit proposed by Hu and Liu (2004), from the first example, the information we can get is the author's negative opinion about "interior" using an opinion expression "noisy". However, the important restriction "on the freeway", which narrows the scope of the opinion, is ignored. In fact, the tuple ("noisy","on the freeway") cannot correctly express the original opinion: it is negative but under certain condition. The second example is similar. If the conditions "during the daytime" and "at night" are dropped, the extracted elements cannot correctly represent user's opinions.

Example 3: *The camera is actually quite good for outdoors because of the software*.

Besides that, an opinion expression may induce other opinions which are not expressed directly. In example 3, the opinion expression is "good" whose

[1] http://reviews.carreview.com/blog/2010-ford-focus-review-the-compact-car-that-can/

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1332–1341,
Edinburgh, Scotland, UK, July 27–31, 2011.

target is "camera". But the "software" which triggers the opinion expression "good" is also endowed with a positive opinion. In practice, this induced opinion on "software" is actually more informative than its direct counterpart. Mining those opinions may help to form a complete sentiment analysis result.

Example 4: *The image quality is in the middle of its class, but it can still be a reasonable choice for students.*

Furthermore, the relations among individual opinions also provide additional information which is lost when they are considered separately. Example 4 is such a case that the whole positive comment of camera is expressed by a transition from a negative opinion to a positive one.

In order to address those issues, this paper describes a novel sentiment representation and analysis method. Our main contributions are as follows:

1. We investigate the use of graphs for representing sentence level sentiment. The vertices are evaluation target, opinion expression, modifiers of opinion. The Edges represent relations among them. The semantic relations among individual opinions are also included. Through the graph, various information on opinion expressions which is ignored by current representation methods can be well handled. And the proposed representation is language-independent.

2. We propose a supervised structural learning method which takes a sentence as input and the proposed sentiment representation for it as output. The inference algorithm is based on integer linear programming which helps to concisely and uniformly handle various properties of our sentiment representation. By setting appropriate prior substructure constraints of the graph, the whole algorithm achieves reasonable performances.

The remaining part of this paper is organized as follows: In Section 2 we discuss the proposed representation method. Section 3 describes the computational model used to construct it. Experimental results in test collections and analysis are shown in Section 4. In Section 5, we present the related work and Section 6 concludes the paper.

2 Graph-based Sentiment Representation

In this work, we propose using directed graph to represent sentiments. In the graph, vertices are text spans in the sentences which are opinion expressions, evaluation targets, conditional clauses etc. Two types of edges are included in the graph: (1) relations among opinion expressions and their modifiers; (2) relations among opinion expressions. The edges of the first type exist within individual opinions. The second type of the edges captures the relations among individual opinions. The following sections detail the definition.

2.1 Individual Opinion Representation

Let r be an opinion expression in a sentence, the representation unit for r is a set of relations $\{(r, d_k)\}$. For each relation (r, d_k), d_k is a *modifier* which is a span of text specifying the change of r's meaning.

The relations between modifier and opinion expression can be the type of any kind. In this work, we mainly consider two basic types:

- *opinion restriction*. (r, d_k) is called an opinion restriction if d_k narrows r's scope, adds a condition, or places limitations on r's original meaning.

- *opinion expansion*. (r, d_k) is an opinion expansion if r's scope expands to d_k, r induces another opinion on d_k, or the opinion on d_k is implicitly expressed by r.

Mining the opinion restrictions can help to get accurate meaning of an opinion, and the opinion expansions are useful to cover more indirect opinions. As with previous sentiment representations, we actually consider the third type of modifier which d_k is the evaluation target of r.

Figure 1 shows a concrete example. In this example, there are three opinion expressions: "good", "sharp", "slightly soft". The modifiers of "good" are "indoors" and "Focus accuracy", where relation ("good","indoors") is an opinion restriction because "indoors" is the condition under which "Focus accuracy" is good. On the other hand, the relation

("sharp", "little 3x optical zooms") is an opinion expansion because the "sharp" opinion on "shot" implies a positive opinion on "little 3x optical zooms".

It is worth to remark that: 1) a modifier d_k can relate to more than one opinion expression. For example, multiple opinion expressions may share a same condition; 2) d_k itself can employ a set of relations, although the case appears occasionally. The following is an example:

Example 5: *The camera wisely get rid of many redundant buttons.*

In the example, "redundant buttons" is the evaluation target of opinion expression "wisely get rid of", but itself is a relation between "redundant" and "buttons". Such nested semantic structure is described by a path: "wisely get rid of" $\xrightarrow{target}$ ["redundant" $\xrightarrow{target}$ "buttons"]$_{\text{nested target}}$.

2.2 Relations between Individual Opinion Representation

Assume $\langle r_i \rangle$ are opinion expressions ordered by their positions in sentence, and each of them has been represented by relations $\{(r_i, d_{ik})\}$ individually (the nested relations for d_{ik} have also been determined). Then we define two relations on adjacent pair r_i, r_{i+1}: *coordination* when the polarities of r_i and r_{i+1} are consistent, and *transition* when they are opposite. Those relations among r_i form a set B called *opinion thread*. In Figure 1, the opinion thread is: {("good", "sharp"), ("sharp", "slightly soft")}.

The whole sentiment representation for a sentence can be organized by a direct graph $G = (V, E)$. Vertex set V includes all opinion expressions and modifiers. Edge set E collects both relations of each individual opinion and relations in opinion thread. The edges are labeled with relation types in label set $\mathcal{L}$={"restriction", "expansion", "target", "coordination", "transition"} [3].

Compared with previous works, the advantages of using G as sentiment representation are: 1) for individual opinions, the modifiers will collect more information than using opinion expression alone.

[3]We don't define any "label" on vertices: if two span of text satisfy a relation in $\mathcal{L}$, they are chosen to be vertices and an edge with proper label will appear in E. In other words, vertices are identified by checking whether there exist relations among them.

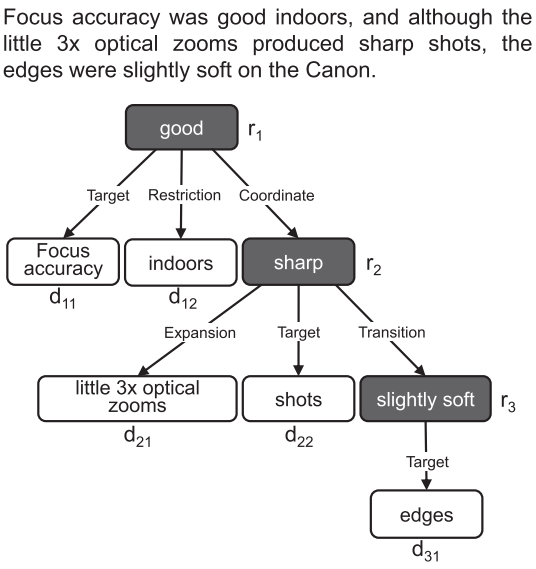

Figure 1: Sentiment representation for an example sentence

Thus G is a relatively complete and accurate representation; 2) the opinion thread can help to catch global sentiment information, for example the general polarity of a sentence, which is dropped when the opinions are separately represented.

3 System Description

To produce the representation graph G for a sentence, we need to extract candidate vertices and build the relations among them to get a graph structure. For the first task, the experimental results in Section 4 demonstrate that the standard sequential labeling method with simple features can achieve reasonable performance. In this section, we focus on the second task, and assume the vertices in the graph have already been correctly collected in the following formulation of algorithm.

3.1 Preliminaries

In order to construct graph G, we use a structural learning method. The framework is from the first order discriminative dependency parsing model (Mcdonald and Pereira, 2005). A sentence is denoted by s; $\mathbf{x}$ are text spans which will be vertices of graph; x_i is the ith vertex in $\mathbf{x}$ ordered by their positions in s. For a set of vertices $\mathbf{x}$, $\mathbf{y}$ is the graph of its sentiment representation, and $e = (x_i, x_j) \in \mathbf{y}$ is the direct edge from x_i to x_j in $\mathbf{y}$. In addition, x_0 is a

virtual root node without inedge. $\mathcal{G} = \{(\mathbf{x}_n, \mathbf{y}_n)\}_n^N$ is training set.

Following the edge based factorization, the score of a graph is the sum of its edges' scores,

$$\begin{aligned} \text{score}(\mathbf{x}, \mathbf{y}) &= \sum_{(x_i,x_j)\in\mathbf{y}} \text{score}(x_i, x_j) \\ &= \sum_{(x_i,x_j)\in\mathbf{y}} \alpha^T \mathbf{f}(x_i, x_j), \end{aligned} \quad (1)$$

$\mathbf{f}(x_i, x_j)$ is a high dimensional feature vector of the edge (x_i, x_j). The components of $\mathbf{f}$ are either 0 or 1. For example the k-th component could be

$$\mathbf{f}_k(x_i, x_j) = \begin{cases} 1 & \text{if } x_i\text{.POS} = \text{JJ and } x_j\text{.POS} = \text{NN} \\ & \quad \text{and label of } (x_i, x_j) \text{is restriction .} \\ 0 & \text{otherwise} \end{cases}$$

Then the score of an edge is the linear combination of $\mathbf{f}$'s components, and the coefficients are in vector α.

Algorithm 1 shows the parameter learning process. It aims to get parameter α which will assign the correct graph $\mathbf{y}$ with the highest score among all possible graphs of $\mathbf{x}$ (denoted by $\mathcal{Y}$).

Algorithm 1 Online structural learning

Training Set:$\mathcal{G} = \{(\mathbf{x}_n, \mathbf{y}_n)\}_n^N$

for $t = 0$ to T **do**
  for $n = 0$ to N **do**
    $\hat{\mathbf{y}} = \arg\max_{\mathbf{y}\in\mathcal{Y}} \text{score}(\mathbf{x}_n, \mathbf{y})$ ▷ Inference
    if $\hat{\mathbf{y}} \neq \mathbf{y}_n$ **then**
      update α^t to α^{t+1} ▷ PA
      $r = r + \alpha^{t+1}$
    end if
  end for
end for
return $\alpha = r/(N * T)$

3.2 Inference

Like other structural learning tasks, the "$\arg\max$" operation in the algorithm (also called inference)

$$\begin{aligned} \hat{\mathbf{y}} &= \arg\max_{\mathbf{y}\in\mathcal{Y}} \text{score}(\mathbf{x}, \mathbf{y}) \\ &= \arg\max_{\mathbf{y}\in\mathcal{Y}} \sum_{(x_i,x_j)\in\mathbf{y}} \alpha^T \mathbf{f}(x_i, x_j) \end{aligned} \quad (2)$$

is hard because all possible values of $\mathbf{y}$ form a huge search space. In our case, $\mathcal{Y}$ is all possible directed acyclic graphs of the given vertex set, which number is exponential. Directly solving the problem of finding maximum weighted acyclic graph is equivalent to finding maximum feedback arc set, which is a NP-hard problem (Karp, 1972). We will use integer linear programming (ILP) as the framework for this inference problem.

3.2.1 Graph Properties

We first show some properties of graph G either from the definition of relations or corpus statistics.

Property 1. The graph is connected and without directed cycle. From individual opinion representation, each subgraph of G which takes an opinion expression as root is connected and acyclic. Thus the connectedness is guaranteed for opinion expressions are connected in opinion thread; the acyclic is guaranteed by the fact that if a modifier is shared by different opinion expressions, the inedges from them always keep (directed) acyclic.

Property 2. Each vertex can have one outedge labeled with coordination or transition at most. The opinion thread B is a directed path in graph.

Property 3. The graph is sparse. The average in-degree of a vertex is 1.03 in our corpus, thus the graph is almost a rooted tree. In other words, the cases that a modifier connects to more than one opinion expression rarely occur comparing with those vertices which have a single parent. An explaination for this sparseness is that opinions in online reviews always concentrate in local context and have local semantic connections.

3.2.2 ILP Formulation

Based on the property 3, we divide the inference algorithm into two steps: i) constructing G's spanning tree (arborescence) with property 1 and 2; ii) finding additional non-tree edges as a post processing task. The first step is close to the works on ILP formulations of dependency parsing (Riedel and Clarke, 2006; Martins et al., 2009). In the second step, we use a heuristic method which greedily adds non-tree edges. A similar approximation method is also used in (Mcdonald and Pereira, 2006) for acyclic dependency graphs.

Step 1. Find MST. Following the multicommodity

flow formulation of maximum spanning tree (MST) problem in (Magnanti and Wolsey, 1994), the ILP for MST is:

$$\text{max.} \sum_{i,j} y_{ij} \cdot \text{score}(x_i, x_j) \quad (3)$$

$$\text{s.t.} \quad \sum_{i,j} y_{ij} = |V| - 1 \quad (4)$$

$$\sum_i f_{ij}^u - \sum_k f_{jk}^u = \delta_j^u, 1 \le u, j \le |V| \quad (5)$$

$$\sum_k f_{0k}^u = 1, \qquad 1 \le u \le |V| \quad (6)$$

$$f_{ij}^u \le y_{ij}, \qquad 1 \le u, j \le |V|, \; 0 \le i \le |V| \quad (7)$$

$$f_{ij}^u \ge 0, \qquad 1 \le u, j \le |V|, \; 0 \le i \le |V| \quad (8)$$

$$y_{ij} \in \{0, 1\}, \qquad 0 \le i, j \le |V|. \quad (9)$$

In this formulation, y_{ij} is an edge indicator variable that (x_i, x_j) is a spanning tree edge when $y_{ij} = 1$, (x_i, x_j) is a non-tree edge when $y_{ij} = 0$. Then output $\mathbf{y}$ is represented by the set $\{y_{ij}, 0 \le i, j \le |V|\}$ [4]. Eq(4) ensures that there will be exactly $|V| - 1$ edges are chosen. Thus if the edges corresponding to those non zero y_{ij} is a connected subgraph, $\mathbf{y}$ is a well-formed spanning tree. Objective function just says the optimal solution of y_{ij} have the maximum weight.

The connectedness is guaranteed if for every vertex, there is exactly one path from root to it. It is formulated by using $|V| - 1$ flows $\{f^u, 1 \le u \le |V|\}$. f^u starts from virtual root x_0 towards vertex x_u. Each flow $f^u = \{f_{ij}^u, 0 \le i, j \le |V|\}$. f_{ij}^u indicates whether flow f^u is through edge (x_i, x_j). so it should be 0 if edge (x_i, x_j) does not exist (by (7)). The Kronecker's delta δ_j^u in (5) guarantees f^u is only assumed by vertex x_u, so f^u is a well-formed path from root to x_u. (6) ensures there is only one flow (path) from root to x_u. Thus the subgraph is connected. The following are our constraints:

c1: Constraint on edges in opinion thread (10)-(11).

From the definition of opinion thread, we impose a constraint on every vertex's outedges in opinion thread, which are labeled with "coordination" or "transition". Let $\mathbb{I}_{ob}$ be a characteristic function on edges: $\mathbb{I}_{ob}((j,k)) = 1$ when edge (x_j, x_k) is labeled with "coordination" or "transition", otherwise 0. We denote q variables for vertices:

$$q_j = \sum_k y_{jk} \cdot \mathbb{I}_{ob}((j,k)), \quad 0 \le j \le |V|. \quad (10)$$

Then following linear inequalities bound the number of outedges in opinion thread (≤ 1) on each vertex:

$$q_j \le 1, \qquad 0 \le j \le |V|. \quad (11)$$

c2: Constraint on target edge (12).

We also bound the number of evaluation targets for a vertex in a similar way. Let $\mathbb{I}_t$ be characteristic function on edges identifing whether it is labeled with "target",

$$\sum_k y_{jk} \cdot \mathbb{I}_t((j,k)) \le C_t, \quad 0 \le j \le |V|. \quad (12)$$

The parameter C_t can be adjusted according to the style of document. In online reviews, authors tend to use simple and short comments on individual targets, so C_t could be set small.

c3: Constraint on opinion thread (13)-(18).

From graph property 2, the opinion thread should be a directed path. It implies the number of connected components whose edges are "coordination" or "transition" should be less than 1. Two set of additional variables are needed: $\{c_j, 0 \le j \le |V|\}$ and $\{h_j, 0 \le j \le |V|\}$, where

$$c_j = \begin{cases} 1 & \text{if an opinion thread starts at } x_j \\ 0 & \text{otherwise} \end{cases},$$

and

$$h_j = \sum_i y_{ij} \cdot \mathbb{I}_{ob}((i,j)). \quad (13)$$

Then $c_j = \neg h_j \wedge q_j$, which can be linearized by

$$c_j \ge q_j - h_j, \quad (14)$$

$$c_j \le 1 - h_j, \quad (15)$$

$$c_j \le q_j, \quad (16)$$

$$c_j \ge 0. \quad (17)$$

If the sum of c_j is no more than 1, the opinion thread of graph is a directed path.

$$\sum_j c_j \le 1. \quad (18)$$

[4] For simplicity, we overload symbol $\mathbf{y}$ from the graph of the sentiment represetation to the MST of it.

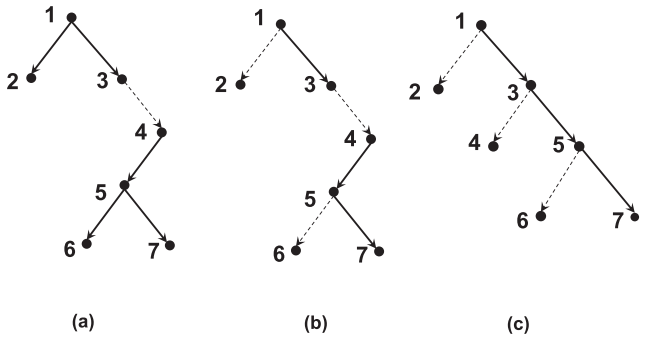

Figure 2: The effects of **c1** and **c3**. Assume solid lines are edges labeled with "coordination" and "transition", dot lines are edges labeled with other types. (a) is an arbitrary tree. (b) is a tree with **c1** constraints. (c) is a tree with **c1** and **c3**. It shows **c1** are not sufficient for graph property 2: the edges in opinion thread may not be connected.

Figure 2 illustrates the effects of **c1** and **c3**.

Equations (10)-(18), together with basic multicommodity flow model build up the inference algorithm. The entire ILP formulation involves $O(|V|^3)$ variables and $O(|V|^2)$ constraints. Generally, ILP falls into NPC, but as an important result, in the multicommodity flow formulation of maximum spanning tree problem, the integer constraints (9) on y_{ij} can be dropped. So the problem reduces to a linear programming which is polynomial solvable (Magnanti and Wolsey, 1994). Unfortunately, with our additional constraints the LP relaxation is not valid.

Step 2. Adding non-tree edges. We examine the case that a modifier attaches to different opinion expressions. That often occurs as the result of the sharing of modifiers among adjacent opinion expressions. We add those edges in the following heuristic way: If a vertex r_i in opinion thread does not have any modifier, we search the modifiers of its adjacent vertices r_{i+1}, r_{i-1} in the opinion thread, and add edge (r_i, d^*) where

$$d^* = \arg\max_{d \in S} \text{score}(r_i, d),$$

and S are the modifiers of r_{i-1} and r_{i+1}.

3.3 Training

We use online passive aggressive algorithm (PA) with Hamming cost of two graphs in training (Crammer et al., 2006).

Unigram Feature Template	
Inside Features	x_i.text w_0.text w_1.text
	w_0.POS w_1.POS
	w_{k-1}.text w_k.text
	w_{k-1}.POS w_k.POS
	x_i.hasDigital
	x_i.isSingleWord
	x_i.hasSentimentWord
	x_i.hasParallelPhrase

	c_{l+1}.POS c_{l+2}.POS
Other Features	
distance between parent and child	
dependency parsing relations	

Table 1: Feature set

3.4 Feature Construction

For each vertex x_i in graph, we use 2 sets of features: inside features which are extracted inside the text span of x_i; outside features which are outside the text span of x_i. A vertex x_i is described both in word sequence $(w_0, w_1, \cdots, w_k)$ and character sequence $(c_0, c_1, \cdots, c_l)$, for the sentences are in Chinese.

$$\cdots, w_{-1}, \underbrace{w_0, w_1, w_2, \cdots, w_{k-1}, w_k}_{x_i}, w_{k+1} \cdots$$
$$\cdots, c_{-1}, \underbrace{c_0, c_1, c_2, \cdots, c_{l-1}, c_l}_{x_i}, c_{l+1} \cdots$$

For an edge (x_i, x_j), the high dimensional feature vector $\mathbf{f}(x_i, x_j)$ is generated by using unigram features in Table 1 on x_i and x_j respectively. The distance between parent and child in sentence is also attached in features. In order to involve syntactic information, whether there is certain type of dependency relation between x_i and x_j is also used as a feature.

4 Experiments

4.1 Corpus

We constructed a Chinese online review corpus from Pcpop.com, Zol.com.cn, and It168.com, which have a large number of reviews about digital camera. The corpus contains 138 documents and 1735 sentences. Since some sentences do not contain any opinion, 1390 subjective sentences were finally chosen and manually labeled.

Two annotators labeled the corpus independently. The annotators started from locating opinion expressions, and for each of them, they annotated other modifiers related to it. In order to keep the reliability of annotations, another annotator was asked to check the corpus and determine the conflicts. Finally, we extracted 6103 elements, which are connected by 6284 relations.

Relation	Number
Target	2479
Coordinate	1173
Transition	154
Restriction	693
Expansion	386

Table 2: Statistics of relation types

Table 2 shows the number of various relation types appearing in the labeled corpus. We observe 60.5% of sentences and 32.1% of opinion expressions contain other modifiers besides "target". Thus only mining the relations between opinion expressions and evaluation target is actually at risk of inaccurate and incomplete results.

4.2 Experiments Configurations

In all the experiments below, we take 90% of the corpus as training set, 10% as test set and run 10 folder cross validation. In feature construction, we use an external Chinese sentiment lexicon which contains 4566 positive opinion words and 4370 negative opinion words. For Chinese word segment, we use ctbparser [5]. Stanford parser (Klein and Manning, 2003) is used for dependency parsing. In the settings of PA, the maximum iteration number is set to 2, which is chosen by maximizing the testing performances, aggressiveness parameter C is set to 0.00001. For parameters in inference algorithm, $C_t = 2$, the solver of ILP is lpsolve[6].

We evaluate the system from the following aspects: 1) whether the structural information helps to mining opinion relations. 2) How the proposed inference algorithm performs with different constraints. 3) How the various features affect the system. Except for the last one, the feature set used for different experiments are the same ("In+Out+Dep" in Table 5). The criteria for evaluation are similar to the unlabeled attachment score in parser evaluations, but due to the equation $|E| = |V| - 1$ is not valid if G is not a tree, we evaluate precision $P = \frac{\texttt{\#true edges in result graph}}{\texttt{\#edges in result graph}}$, recall $R = \frac{\texttt{\#true edges in result graph}}{\texttt{\#edges in true graph}}$, and F-score $F = \frac{2P \cdot R}{P+R}$.

4.3 Results

1. *The effects of structural information.* An alternative method to extract relations is directly using a classifier to judge whether there is a relation between any two elements. Those kinds of methods were used in previous opinion mining works (Wu et al., 2009; Kobayashi et al., 2007). To show the entire structural information is important for mining relations, we use SVM for binary classification on candidate pairs. The data point representing a pair (x_i, x_j) is the same as the high dimensional feature vectors $\mathbf{f}(x_i, x_j)$. The setting of our algorithm "MST+c1+c2+c3" is the basic MST with all the constraints. The results are shown in the Table 3.

	P	R	F
SVM	64.9	24.0	35.0
MST+c1+c2+c3-m	61.5	74.0	67.2
MST+c1+c2+c3	73.1	71.0	72.1

Table 3: Binary classifier and structural learning

From the results, the performance of SVM (especially recall) is relatively poor. A possible reason is that the huge imbalance of positive and negative training samples (only $\Theta(n)$ positive pairs among all n^2 pairs). And the absence of global structural

[5] http://code.google.com/p/ctbparser/

[6] http://sourceforge.net/projects/lpsolve/

knowledge makes binary classifier unable to use the information provided by classification results of other pairs.

In order to examine whether the complicated sentiment representation would disturb the classifier in finding relations between opinion expressions and its target, we evaluate the system by discarding the modifiers of opinion restriction and expansion from the corpus. The result is shown in the second row of Table 3. We observe that "MST+c1+c2+c3" is still better which means at least on overall performance the additional modifiers do not harm.

2. *The effect of constraints on inference algorithm*. In the inference algorithm, we utilized the properties of graph G and adapted the basic multicommodity flow ILP to our specific task. To evaluate how the constraints affect the system, we decompose the algorithm and combine them in different ways.

	P	R	F
MST	69.3	67.3	68.3
MST+c1	70.0	68.0	69.0
MST+c2	69.8	67.8	68.8
MST+c1+c2	70.6	68.6	69.6
MST+c1+c3	72.4	70.4	71.4
MST+c1+c2+c3	73.1	71.0	72.1
MST+c1+c2+c3+g	72.5	72.3	72.4

Table 4: Results on inference methods. "MST" is the basic multicommodity flow formulation of maximum spanning tree; c1, c2, c3 are groups of constraint from Section 3.2.2; "g" is our heuristic method for additional non spanning tree edges.

From Table 4, we observe that with any additional constraints the inference algorithm outperforms the basic maximum spanning tree method. It implies although we did not use high order model (e.g. involving grandparent and sibling features), prior structural constraints can also help to get a better output graph. By comparing with different constraint combinations, the constraints on opinion thread (c1, c3) are more effective than constraints on evaluation targets (c2). It is because opinion expressions are more important in the entire sentiment representation. The main structure of a graph is clear once the relations between opinion expressions are correctly determined.

3. *The effects of various features*. We evaluate the performances of different feature configurations in Table 5. From the results, the outside feature set is more effective than inside feature set, even if it does not use any external resource. A possible reason is that the content of a vertex can be very complicated (a vertex even can be a clause), but the features surrounding the vertex are relatively simple and easy to identify (for example, a single preposition can identify a complex condition). The dependency feature has limited effect, due to that lots of online review sentences are ungrammatical and parsing results are unreliable. And the complexity of vertices also messes the dependency feature.

	P	R	F
In-s	66.3	66.3	66.3
In	66.7	66.4	66.6
Out	67.8	67.4	67.6
In+Out	72.0	70.5	71.0
In+Out+Dep	72.5	72.3	72.4

Table 5: Results with different features. "In" represents the result of inside feature set; "In-s" is "In" without the external opinion lexicon feature; "Out" uses the outside feature set; "In+Out" uses both "In" and "Out", "In+Out+Dep" adds the dependency feature. The inference algorithm is "MST+c1+c2+c3+g" in Table 4.

We analyze the errors in test results. A main source of errors is the confusion of classifier between "target" relations and "coordination", "transition" relations. The reason may be that for a modification on opinion expression (r, d_k), we allow d_k recursively has its own modifiers (Example 5). Thus an opinion expression can be a modifier which brings difficulties to classifier.

4. *Extraction of vertices.* Finally we conduct an experiment on vertex extraction using standard sequential labeling method. The tag set is simply {B, I, O} which are signs of begin, inside, outside of a vertex. The underlying model is conditional random field [7]. Feature templates involved are in Table 6. We only use basic features in the experiment. 10 folder cross validation results are in table 7. We suspect that the performances (especially recall) could be improved if some external resources(i.e. ontology, domain related lexicon, etc.) are involved.

[7]We use CRF++ toolkit, http://crfpp.sourceforge.net/

Unigram Template	
c_i.char	character
c_i.isDigit	digit
c_i.isAlpha	english letter
c_i.isPunc	punctuation
c_i.inDict	in a sentiment word
c_i.BWord	start of a word
c_i.EWord	end of a word

Table 6: Features for vertex extraction. The sequential labeling is conducted on character level (c_i). The sentiment lexicon used in c_i.inDict is the same as Table1. We also use bigram feature templates on c_i.char, c_i.isAlpha, c_i.inDict with respect to c_{i-1} and c_{i+1}.

	P	R	F
E+Unigram	56.8	45.1	50.3
E+Unigram+Bigram	57.3	47.9	52.1
O+Unigram	71.9	57.2	63.7
O+Unigram+Bigram	72.3	60.2	65.6

Table 7: Results on vertices extraction with 10 folder cross validation. We use two criterion: 1) the vertex is correct if it is exactly same as ground truth("E"), 2) the vertex is correct if it overlaps with ground truth("O").

5 Related Work

Opinion mining has recently received considerable attentions. Large amount of work has been done on sentimental classification in different levels and sentiment related information extraction. Researches on different types of sentences such as comparative sentences (Jindal and Liu, 2006) and conditional sentences (Narayanan et al., 2009) have also been proposed.

Kobayashi et al. (2007) presented their work on extracting opinion units including: opinion holder, subject, aspect and evaluation. They used slots to represent evaluations, converted the task to two kinds of relation extraction tasks and proposed a machine learning-based method which used both contextual and statistical clues.

Jindal and Liu (2006) studied the problem of identifying comparative sentences. They analyzed different types of comparative sentences and proposed learning approaches to identify them.

Sentiment analysis of conditional sentences were studied by Narayanan et al. (2009). They aimed to determine whether opinions expressed on different topics in a conditional sentence are positive, negative or neutral. They analyzed the conditional sentences in both linguistic and computational perspectives and used learning method to do it. They followed the *feature-based sentiment analysis* model (Hu and Liu, 2004), which also use flat frames to represent evaluations.

Integer linear programming was used in many NLP tasks (Denis and Baldridge, 2007), for its power in both expressing and approximating various inference problems, especially in parsing (Riedel and Clarke, 2006; Martins et al., 2009). Martins etc. (2009) also applied ILP with flow formulation for maximum spanning tree, besides, they also handled dependency parse trees involving high order features(sibling, grandparent), and with projective constraint.

6 Conclusions

This paper introduces a representation method for opinions in online reviews. Inspections on corpus show that the information ignored in previous sentiment representation can cause incorrect or incomplete mining results. We consider opinion restriction, opinion expansions, relations between opinion expressions, and represent them with a directed graph. Structural learning method is used to produce the graph for a sentence. An inference algorithm is proposed based on the properties of the graph. Experimental evaluations with a manually labeled corpus are given to show the importance of structural information and effectiveness of proposed inference algorithm.

Abstract

Most traditional summarization methods treat their outputs as static and plain texts, which fail to capture user interests during summarization because the generated summaries are the same for different users. However, users have individual preferences on a particular source document collection and obviously a universal summary for all users might not always be satisfactory. Hence we investigate an important and challenging problem in summary generation, i.e., Interactive Personalized Summarization (IPS), which generates summaries in an interactive and personalized manner. Given the source documents, IPS captures user interests by enabling interactive clicks and incorporates personalization by modeling captured reader preference. We develop experimental systems to compare 5 rival algorithms on 4 instinctively different datasets which amount to 5197 documents. Evaluation results in ROUGE metrics indicate the comparable performance between IPS and the best competing system but IPS produces summaries with much more user satisfaction according to evaluator ratings. Besides, low ROUGE consistency among these user preferred summaries indicates the existence of personalization.

1 Introduction

In the era of information explosion, people need new information to update their knowledge whilst information on Web is updating extremely fast. Multi-document summarization has been proposed to address such dilemma by producing a summary delivering the majority of information content from a document set, and hence is a necessity.

Traditional summarization methods play an important role with the exponential document growth on the Web. However, for the readers, the impact of human interests has seldom been considered. Traditional summarization utilizes the same methodology to generate the same summary no matter who is reading. However, users may have bias on what they prefer to read due to their potential interests: they need *personalization*. Therefore, traditional summarization methods are to some extent insufficient.

Topic biased summarization tries for personalization by pre-defining human interests as several general categories, such as *health* or *science*. Readers are required to select their possible interests before summary generation so that the chosen topic has priority during summarization. Unfortunately, such topic biased summarization is not sufficient for two reasons: (1) interests cannot usually be accurately pre-defined by ambiguous topic categories and (2) user interests cannot always be foreknown. Often users do not really know what general ideas or detail information they are interested in until they read the summaries. Therefore, more flexible *interactions* are required to establish personalization.

Due to all the insufficiencies of existed summarization approaches, we introduce a new multi-document summarization task of Interactive Personalized Summarization (IPS) and a novel solution for the task. Taking a document collection as input, the system outputs a summary aligned both with source corpus and with user personalization, which is captured by flexible *human−system* interactions. We

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1342–1351,
Edinburgh, Scotland, UK, July 27–31, 2011.

build an experimental system on 4 real datasets to verify the effectiveness of our methods compared with 4 rivals. The contribution of IPS is manifold by addressing following challenges:

• The **1st challenge** for IPS is to integrate user interests into traditional summary components. We measure the utilities of these components and combine them. We formulate the task into a balanced optimization framework via iterative substitution to generate summaries with maximum overall utilities.

• The **2nd challenge** is to capture user interests through interaction. We develop an interactive mechanism of "click" and "examine" between readers and summaries and address sparse data by "click smoothing" under the scenario of few user clicks.

We start by reviewing previous works. In Section 3 we provide IPS overview, describe user interaction and optimize component combination with personalization. We conduct empirical evaluation and demonstrate the experimental system in Section 4. Finally we draw conclusions in Section 5.

2 Related Work

Multi-Document Summarization (MDS) has drawn much attention in recent years and gained emphasis in conferences such as ACL, EMNLP and SIGIR, etc. General MDS can either be extractive or abstractive. The former assigns salient scores to semantic units (e.g. sentences, paragraphs) of the documents indicating their importance and then extracts top ranked ones, while the latter demands information fusion(e.g. sentence compression and reformulation). Here we focus on extractive summarization.

Centroid-based method is one of the most popular extractive summarization method. MEAD (Radev et al., 2004) and NeATS (Lin and Hovy, 2002) are such implementations, using position and term frequency, etc. MMR (Goldstein et al., 1999) algorithm is used to remove redundancy. Most recently, the graph-based ranking methods have been proposed to rank sentences or passages based on the "votes" or "recommendations" between each other. The graph-based methods first construct a graph representing the sentence relationships at different granularities and then evaluate the saliency score of the sentences based on the graph. TextRank (Mihalcea and Tarau, 2005) and LexPageRank (Erkan and Radev, 2004) use algorithms similar to PageRank and HITS to compute sentence importance. Wan et al. improve the graph-ranking algorithm by differentiating intra-document and inter-document links between sentences (2007b) and incorporate cluster information in the graph model to evaluate sentences (2008).

To date, topics (or themes, clusters) in documents have been discovered and used for sentence selection for topic biased summarization (Wan and Yang, 2008; Gong and Liu, 2001). Wan et al. have proposed a manifold-ranking method to make uniform use of sentence-to-sentence and sentence-to-topic relationships to generate topic biased summaries (2007a). Leuski et al. in (2003) pre-define several topic concepts, assuming users will foresee their interested topics and then generate the topic biased summary. However, such assumption is not quite reasonable because user interests may not be forecasted, or pre-defined accurately as we have explained in last section.

The above algorithms are usually traditional extensions of generic summarizers. They do not involve interactive mechanisms to capture reader interests, nor do they utilize user preference for personalization in summarization. Wan et al. in (2008) have proposed a summarization biased to neighboring reading context through anchor texts. However, such scenario does not apply to contexts without human-edited anchor texts like Wikipedia they have used. Our approach can naturally and simultaneously take into account traditional summary elements and user interests and combine both in optimization under a wider practical scenario.

3 Interactive Personalized Summarization

Personalization based on user preference can be captured via various alternative ways, such as *eye-tracking* or *mouse-tracking* instruments used in (Guo and Agichtein, 2010). In this study, we utilize interactive user clicks/examinations for personalization.

Unlike traditional summarization, IPS supports *human−system* interaction by *clicking* into the summary sentences and *examining* source contexts. The implicit feedback of user clicks indicates what they are interested in and the system collects preference information to update summaries if readers wish to. We obtain an associated tuple $<q, c>$ between a

clicked sentence **q** and the examined contexts **c**.

As q has close semantic coherence with neighboring contexts due to consistency in human natural language, we consider a window of sentences centered at the clicked sentence q as c, which is a bag of sentences. The window size k is a parameter to set.

However, click data is often sparse: users are not likely to click more than 1/10 of total summary sentences within a single generation. We amplify these tiny hints of user interest by *click smoothing*.

We change the flat summary structure into a hierarchical organization by extracting important semantic units (denoted as **u**) and establishing linkage between them. If the clicked sentence q contains u, we diffuse the click impact to the correlated units, which makes a single click perform as multiple clicks and the sparse data is smoothed.

Problem Formulation

Input: Given the sentence collection D decomposed by documents, $D = \{s_1, s_2, \dots, s_{|D|}\}$ and the clicked sentence record $Q = \{q_1, q_2, \dots\}$, we generate summaries in sentences. A user click is associated with a tuple $<q, (u), c>$ where the existence of u depends on whether q contains u. The collection of semantic units is denoted as $M = \{u_1, u_2, \dots, u_{|M|}\}$.

Output: A summary S as a set of sentences $\{s_1, s_2, \dots, s_{|S|}\}$ and $S \subset D$ according to the prespecified compression rate ϕ ($0 < \phi < 1$).

After the overview and formulation of IPS problem, we move on to the major components of *User Interaction* and *Personalized Summarization*.

3.1 User Interaction

Hypertexify Summaries. We hypertexify the summary structure by establishing linkage between semantic units. There are several possible formats for semantic units, such as words or n-grams, etc. As single words are proved to be not illustrative of semantic meanings (Zhao et al., 2011) and n-grams are rigid in length, we choose to extract semantic units at a phrase granularity. Among all phrases from source texts, some are of higher importance to attract user interests, such as hot concepts or popular event names. We utilize the toolkit provided by (Zhao et al., 2011) based on graph proximity LDA (Blei et al., 2003) to extract key phrases and their corresponding topic. A topic T is represented by $\{(u_1, \pi(u_1, T)), (u_2, \pi(u_2, T)), \dots\}$ where $\pi(u, T)$ is the probability of u belonging to topic T. We invert the topic-unit representation in Table 1, where each u is represented as a topic vector. The correlation $corr(.)$ between u_i, u_j is measured by cosine similarity $sim(.)$ on topic distribution vector $\vec{u}_i$, $\vec{u}_j$.

$$corr(u_i, u_j) = sim_{\text{topic}}(\vec{u}_i, \vec{u}_j) \quad (1)$$

Table 1: Inverted representation of topic-unit vector.

$\vec{u}_1$	$\pi(u_1, T_1)$	$\pi(u_1, T_2)$	$\dots$	$\pi(u_1, T_n)$
$\vec{u}_2$	$\pi(u_2, T_1)$	$\pi(u_2, T_2)$	$\dots$	$\pi(u_2, T_n)$
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$
$\vec{u}_{\|M\|}$	$\pi(u_{\|M\|}, T_1)$	$\pi(u_{\|M\|}, T_2)$	$\dots$	$\pi(u_{\|M\|}, T_n)$

When the summary is *hypertexified* by established linkage, users click into the generated summary to examine what they are interested in. A single click on one sentence become multiple clicks via click smoothing when the indicative function $I(u|q) = 1$.

$$I(u|q) = \begin{cases} 1 & q \text{ contains } u; \\ 0 & \text{otherwise.} \end{cases} \quad (2)$$

The click smoothing brings pseudo clicks q' associated with u' and contexts c'. The entire user feedback texts $\mathcal{A}$ from q can be written as:

$$\mathcal{A}(q) = I(u|q) \sum_{j=1}^{|M|} corr(u', u)(u' + \gamma \cdot c') + \gamma \cdot c \quad (3)$$

where γ is the weight tradeoff between u and associated contexts c. If $I(u|q) = 0$, only the examined context c is feedbacked for user preference; otherwise, correlative contexts with u are taken into consideration, which is a process of impact diffusion.

3.2 Personalized Summarization

Traditional summarization involves two essential requirements: (1) **coverage**: the summary should keep alignment with the source collection, which is proved to be significant (Li et al., 2009). (2) **diversity**: according to MMR principle (Goldstein et al., 1999) and its applications (Wan et al., 2007b; Wan and Yang, 2008), a good summary should be concise and contain as few redundant sentences as possible, i.e., two sentences providing similar information should not both present. According to our

investigation, we observe that a well generated summary should properly consider a key component of (3) **user interests**, which captures user preference to summarize what they are interested in.

All above requirements involve a measurement of similarity between two word distributions Θ_1 and Θ_2. Cosine, Kullback-Leibler divergence D_{KL} and Jensen Shannon divergence D_{JS} are all able to measure the similarity, but (Louis and Nenkova, 2009) indicate the superiority of D_{JS} in summarization task. We also introduce a pair of decreasing/increasing logistic functions, $\mathcal{L}_1(x) = 1/(1 + e^x)$ and $\mathcal{L}_2(x) = e^x/(1 + e^x)$, to map the divergence into interval [0,1]. V is the vocabulary set and *tf* denotes the term frequency for word w.

$$D_{JS}(\Theta_1||\Theta_2) = \frac{1}{2}[D_{KL}(\Theta_1||\Theta_2)+D_{KL}(\Theta_2||\Theta_1)]$$

where

$$D_{KL}(\Theta_1||\Theta_2) = \sum_{k\in V} p(w|\Theta_1) log \frac{p(w|\Theta_1)}{p(w|\Theta_2)}$$

where

$$p(w|\Theta) = \frac{tf(w,\Theta)}{\sum_{w'} tf(w',\Theta)}.$$

Modeling Interest for User Utility. Given a generated summary S, users tend to scrutinize texts relevant to their interests. Texts related to user implicit feedback are collected as $\mathcal{A} = \sum_{i=1}^{|Q|} \mathcal{A}(q_i)$. Intuitively, the smaller distance between the word distribution of final summary (Θ_S) and the word distribution of user preference ($\Theta_{\mathcal{A}}$), the higher utility of user interests $\mathcal{U}_{user}(S)$ will be, i.e.,

$$\mathcal{U}_{user}(S) = \mathcal{L}_1(D_{JS}(\Theta_S||\Theta_{\mathcal{A}})). \quad (4)$$

We model the utility of traditional summarization $\mathcal{U}_{trad}(S)$ using a linear interpolation controlled by parameter δ between utility from *coverage* $\mathcal{U}_c(S)$ and utility $\mathcal{U}_d(S)$ from *diversity*:

$$\mathcal{U}_{trad}(S) = \mathcal{U}_c(S) + \delta \cdot \mathcal{U}_d(S). \quad (5)$$

Coverage Utility. The summary should share a closer word distribution with the source collection (Allan et al., 2001; Li et al., 2009). A good summary focuses on minimizing the loss of main information from the whole collection D. Utility from coverage $\mathcal{U}_c(S)$ is defined as follows and for coverage utility, smaller divergence is desired.

$$\mathcal{U}_c(S) = \mathcal{L}_1(D_{JS}(\Theta_S||\Theta_D)). \quad (6)$$

Diversity Utility. Diversity measures the novelty degree of any sentence s compared with all other sentences within S, i.e., the distances between all other sentences and itself. Diversity utility $\mathcal{U}_d(S)$ is an average novelty score for all sentences in S. For diversity utility, larger distance is desired, and hence we use the increasing function $\mathcal{L}_2$ as follows:

$$\mathcal{U}_d(S) = \frac{1}{|S|}\sum_{s\in S} \mathcal{L}_2(D_{JS}(\Theta_s||\Theta_{(S-s)})). \quad (7)$$

3.3 Balanced Optimization Framework

A well generated summary S should be sufficiently aligned with the original source corpus, and also be optimized given the user interests. The utility of an individual summary $\mathcal{U}(S)$ is evaluated by the weighted combination of these components, controlled by parameter λ for balanced weights.

$$\mathcal{U}(S) = \mathcal{U}_{trad}(S) + \lambda \cdot \mathcal{U}_{user}(S) \quad (8)$$

Given the sentence set D and the compression rate ϕ, there are $\phi \cdot |D|$ out of $|D|$ possibilities to generate S. The IPS task is to predict the optimized sentence subset of S^* from the space of all combinations. The objective function is as follows:

$$S^* = \underset{S}{\operatorname{argmax}}\, \mathcal{U}(S). \quad (9)$$

As $\mathcal{U}(S)$ is measured based on preferred interests from user interaction within a generation in our system, we extract S iteratively to approximate S^*, i.e, maximize $\mathcal{U}(S)$ based on the user feedbacks from the interaction sessions. Each session is an iteration. We use a similar framework as we have proposed in (Yan et al., 2011).

During every session, the top ranked sentences are strong candidates for the summary to generate and the rank methodology is based on the metrics $\mathcal{U}(.)$. The algorithm tends to highly rank sentences which are with both coverage utility and interest utility, and are diversified in balance: we rank each sentence s according to $\mathcal{U}(s)$ under such metrics.

Consider $S^{(n-1)}$ generated in the (*n-1*)-th session which consists of top $\phi|D|$ ranked sentences, as well

as the top $\phi|D|$ ranked sentences in the *n*-th iteration (denoted by $\mathcal{O}^{(n)}$), they have an intersection set of $\mathcal{Z}^{(n)} = S^{n-1} \cap \mathcal{O}^n$. There is a substitutable sentence set $\mathcal{X}^{(n)} = S^{(n-1)} - \mathcal{Z}^{(n)}$ and a new candidate sentence set $\mathcal{Y}^{(n)} = \mathcal{O}^{(n)} - \mathcal{Z}^{(n)}$. We substitute $\mathrm{x}^{(n)}$ sentences with $\mathrm{y}^{(n)}$, where $\mathrm{x}^{(n)} \subseteq \mathcal{X}^{(n)}$ and $\mathrm{y}^{(n)} \subseteq \mathcal{Y}^{(n)}$. During every iteration, our goal is to find a substitutive pair $<\mathrm{x}, \mathrm{y}>$ for S:

$$<\mathrm{x}, \mathrm{y}> : \mathcal{X} \times \mathcal{Y} \rightarrow \mathcal{R}.$$

To measure the performance of such a substitution, a discriminant utility gain function $\Delta\mathcal{U}_{\mathrm{x},\mathrm{y}}$

$$\begin{aligned}\Delta\mathcal{U}^{(n)}_{\mathrm{x}^{(n)},\mathrm{y}^{(n)}} &= \mathcal{U}(S^{(n)}) - \mathcal{U}(S^{(n-1)}) \\ &= \mathcal{U}((S^{(n-1)} - \mathrm{x}^{(n)}) \cup \mathrm{y}^{(n)}) - \mathcal{U}(S^{(n-1)})\end{aligned} \tag{10}$$

is employed to quantify the penalty. Therefore, we predict the substitutive pair by maximizing the gain function $\Delta\mathcal{U}_{\mathrm{x},\mathrm{y}}$ over the state set $\mathcal{R}$, with a size of $\sum_{k=0}^{\mathcal{Y}} A^k_{\mathcal{X}} C^k_{\mathcal{Y}}$, where $<\mathrm{x}, \mathrm{y}> \in \mathcal{R}$. Finally the objective function of Equation (9) changes into maximization of utility gain by substitute $\hat{\mathrm{x}}$ with $\hat{\mathrm{y}}$ during each iteration:

$$< \hat{\mathrm{x}}, \hat{\mathrm{y}} >= \underset{\mathrm{x}\subseteq\mathcal{X},\mathrm{y}\subseteq\mathcal{Y}}{\operatorname{argmax}} \Delta\mathcal{U}_{\mathrm{x},\mathrm{y}}. \tag{11}$$

Note that the objectives of interest utility optimization and traditional utility optimization are not always the same because the word distributions in these texts are usually different. The substitutive pair $<\mathrm{x}, \mathrm{y}>$ may perform well based on the user preference component while not on the traditional summary part and vice versa. There is a tradeoff between both user optimization and traditional optimization and hence we need to balance them by λ.

The objective Equation (11) is actually to maximize $\Delta\mathcal{U}(S)$ from all possible substitutive pairs between two iteration sessions to generate S. The algorithm is shown in Algorithm 1. The threshold ϵ is set at 0.001 in this study.

Algorithm 1 Regenerative Optimization

  end if
end while

4 Experiments and Evaluation

4.1 Datasets

IPS can be tested on any document set but a tiny corpus to summarize may not cover abundant effective interests to attract user clicks indicating their preference. Besides, the scenario of small corpus is not quite practical for the exponential growing web. Therefore, we test IPS on large real world datasets. We build 4 news story sets which consist of documents and reference summaries to evaluate our proposed framework empirically. We downloaded 5197 news articles from 10 selected sources. As shown in Table 2, three of the sources are in UK, one of them is in China and the rest are in US. We choose them because many of these websites provide handcrafted summaries for their special reports, which serve as reference summaries. These events belong to different categories of Rule of Interpretation (ROI) (Kumaran and Allan, 2004). Statistics are in Table 3.

4.2 Experimental System Setups

• **Preprocessing.** Given a collection of documents, we first decompose them into sentences. Stop-words are removed and words stemming is performed. Then the word distributions can be calculated.

• **User Interface Design.** Users are required to specify the overall compression rate ϕ and the system extracts $\phi|D|$ sentences according to user utility

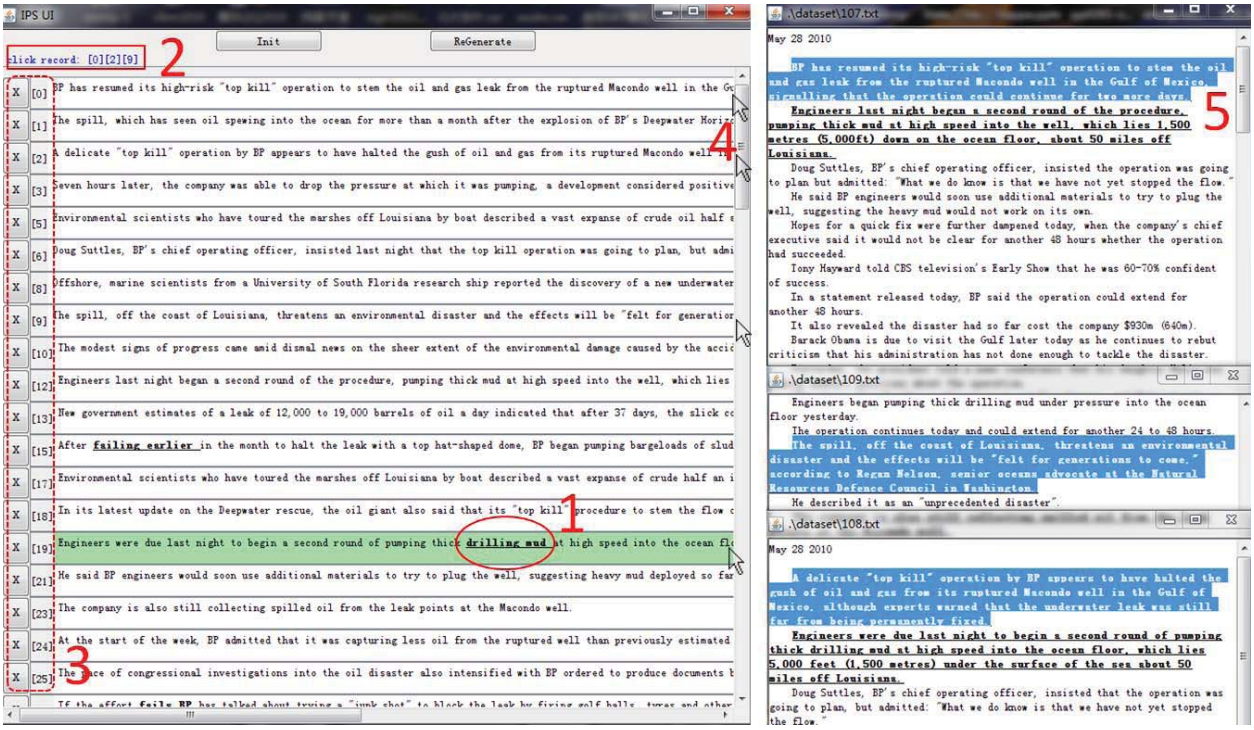

Figure 1: A demonstration system for Interactive Personalized Summarization when compression rate ϕ is specified (e.g. 5%). For convenience of browsing, we number the selected sentences (see in part 3). Extracted semantic units, such as "drilling mud", are in bold and underlined format (see in part 1). When the user clicks a sentence (part 4), the clicked sentence **ID** is kept in the *click record* (part 2). Mis-clicked records revocation can be operated by clicking the deletion icon "X" (see in part 3). Once a sentence is clicked, user can track the sentence into the popup source document to examine the contexts. The selected sentences are highlighted in the source documents (see in part 5).

Table 2: News sources of 4 datasets

News Sources	Nation	News Sources	Nation
BBC	UK	Fox News	US
Xinhua	China	MSNBC	US
CNN	US	Guardian	UK
ABC	US	New York Times	US
Reuters	UK	Washington Post	US

Table 3: Detailed basic information of 4 datasets.

4.Jackson Death	37819	925	3	64

#size: total sentence counts; #RS: the number of reference summaries; Avg.L: average length of reference summary measured in sentences.

and traditional utility. User utility is obtained from interaction. The system keeps the clicked sentence records and calculates the user feedback by Equation (3) during every session. Consider sometimes users click into the summary due to confusion or mis-operations, but not their real interests. The system supports click records revocation. More details of the user interface is demonstrated in Figure 1.

4.3 Evaluation Metrics

We include both subjective evaluation from 3 evaluators based on their personalized interests and preference, and the objective evaluation based on the widely used ROUGE metrics (Lin and Hovy, 2003).

Evaluator Judgments

Evaluators are requested to express an opinion over all summaries based on the sentences which they deem to be important for the news. In general a summary can be rated in a 5-point scale, where "1" for "terrible", "2" for "bad", "3" for "normal", "4" for "good" and "5" for "excellent". Evaluators are allowed to judge at any scores between 1 and 5, e.g. a score of "3.3" is adopted when the evaluator feels difficult to decide whether "3" or "4" is more

appropriate but with preference towards "3".

ROUGE Evaluation

The DUC usually officially employs ROUGE measures for summarization evaluation, which measures summarization quality by counting overlapping units such as the N-gram, word sequences, and word pairs between the candidate summary and the reference summary. We use ROUGE-N as follows:

$$\text{ROUGE-N} = \frac{\sum_{S \in \{\text{RefSum}\}} \sum_{\text{N-gram} \in S} \text{Count}_{\text{match}}(\text{N-gram})}{\sum_{S \in \{\text{RefSum}\}} \sum_{\text{N-gram} \in S} \text{Count (N-gram)}}$$

where N stands for the length of the N-gram and N-gram$\in$RefSum denotes the N-grams in the reference summaries while N-gram$\in$CandSum denotes the N-grams in the candidate summaries. $\text{Count}_{\text{match}}$(N-gram) is the maximum number of N-gram in the candidate summary and in the set of reference summaries. $\text{Count}_{\text{(N-gram)}}$ is the number of N-grams in the reference summaries or candidate summary.

According to (Lin and Hovy, 2003), among all sub-metrics in ROUGE, ROUGE-N (N=1, 2) is relatively simple and works well. In this paper, we evaluate our experiments using all methods provided by the ROUGE package (version 1.55) and only report ROUGE-1, since the conclusions drawn from different methods are quite similar. Intuitively, the higher the ROUGE scores, the similar two summaries are.

4.4 Algorithms for Comparison

We implement the following widely used multi-document summarization algorithms as the baseline systems, which are all designed for traditional summarization without user interaction. For fairness we conduct the same preprocessing for all algorithms.

Random: The method selects sentences randomly for each document collection.

Centroid: The method applies MEAD algorithm (Radev et al., 2004) to extract sentences according to the following parameters: centroid value, positional value, and first-sentence overlap.

GMDS: The Graph-based MDS proposed by (Wan and Yang, 2008) first constructs a sentence connectivity graph based on cosine similarity and then selects important sentences based on the concept of eigenvector centrality.

IPS_{ini}: The initial generated summary from IPS merely models *coverage* and *diversity* utility, which is similar to the previous work described in (Allan et al., 2001) with different goals and frameworks.

IPS: Our proposed algorithms with personalization component to capture *interest* by user feedbacks. IPS generates summaries via iterative sentence substitutions within user interactive sessions.

RefSum: As we have used multiple reference summaries from websites, we not only provide ROUGE evaluations of the competing systems but also of the reference summaries against each other, which provides a good indicator of not only the upper bound ROUGE score that any system could achieve, but also human inconsistency among reference summaries, indicating personalization.

4.5 Overall Performance Comparison

We take the average ROUGE-1 performance and human ratings on all sets. The overall results are shown in Figure 2 and details are listed in Tables 4$\sim$6.

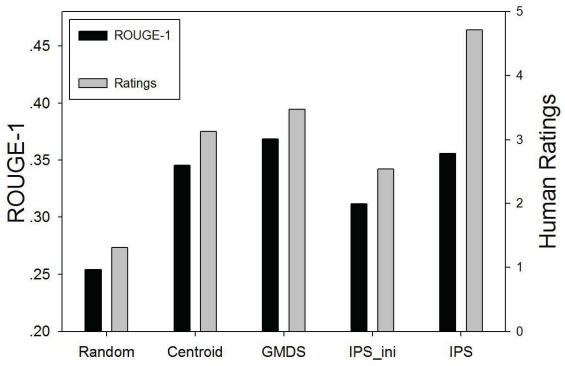

Figure 2: Overall performance on 6 datasets.

From the results, we have following observations:

• Random has the worst performance as expected, both in ROUGE-1 scores and human judgements.

• The ROUGE-1 and human ratings of Centroid and GMDS are better than those of Random. This is mainly because the Centroid based algorithm takes into account positional value and first-sentence overlap, which facilitates main aspects summarization and PageRank-based GMDS ranks the sentence using eigenvector centrality which implicitly accounts for information subsumption among all sentences.

• In general, the GMDS system slightly outperforms Centroid system in ROUGE-1, but the human judgements of GMDS and Centroid are of no significant difference. This is probably due to the difficulty

Table 4: Overall performance comparison on *Influenza A*. ROI* category: Science.

of human judgements on comparable summaries.

• The results of ROUGE-1 and ratings for IPS_{ini} are better than Random but worse than Centroid and GMDS. The reason in this case may be that IPS_{ini} does not capture sufficient attributes: coverage and diversity are merely fundamental requirements.

• Traditional summarization considers sentence selection based on corpus only, and hence neglects user interests. Many sentences are extracted due to arbitrary assumption of reader preference, which results in a low user satisfaction. Human judgements under our proposed IPS framework greatly outperform baselines, indicating that the appropriate use of human interests for summarization are beneficial.

Table 8: Ratings consistency between evaluators: mean ± standard deviation over the 4 datasets.

RefSum	Evaluator 1	Evaluator 2	Evaluator 3
Evaluator 1		0.35±0.09	0.30±0.33
Evaluator 2			0.50±0.14

Random	Evaluator 1	Evaluator 2	Evaluator 3
Evaluator 1		0.23±0.04	0.20±0.02
Evaluator 2			0.33±0.06

Centroid	Evaluator 1	Evaluator 2	Evaluator 3
Evaluator 1		0.45±0.03	0.50±0.12
Evaluator 2			0.55±0.11

GMDS	Evaluator 1	Evaluator 2	Evaluator 3
Evaluator 1		0.35±0.02	0.35±0.03
Evaluator 2			0.70±0.03

IPS_{ini}	Evaluator 1	Evaluator 2	Evaluator 3
Evaluator 1		0.45±0.01	0.25±0.04
Evaluator 2			0.30±0.06

IPS	Evaluator 1	Evaluator 2	Evaluator 3
Evaluator 1		0.35±0.01	0.18±0.02
Evaluator 2			0.28±0.04

The ROUGE-1 performance for IPS is not as ideal as that of GMDS. This situation may result from the divergence between user interests and general information provided by mass media propaganda, which again motivates the need for personalization.

Although the high disparities between different human evaluators have been observed in (Gong and Liu, 2001), we still examine the consistency among 3 evaluators and their preferred summaries to prove the motivation of personalization in our work.

4.6 Consistency Analysis for Personalization

The low ROUGE-1 scores of RefSum indicate the inconsistency among reference summaries. We conduct personalization analysis from two perspectives: (1) human rating consistency and (2) content consistency among human supervised summaries.

We calculate the mean and variance of rating variations among evaluator judgements, listed in Table

Table 9: Content consistency among evaluators supervised summaries.

	Evaluator 1	Evaluator 2	Evaluator 3
Evaluator 1		0.273	0.398
Evaluator 2	0.289		0.257
Evaluator 3	0.407	0.235	
RefSum	0.365	0.302	0.394

8. We see that for Random the average rating variation is 0.25, for IPS is 0.27, for IPS_{ini} is 0.33, for RefSum is 0.38, for GMDS is 0.47 and for Centroid is the highest, 0.50. Such phenomenon indicates for poor generated summaries, such as Random or IPS_{ini}, humans have consensus, but for normal summaries without personalized interests, they are likely to have disparities, surprisingly, even for RefSum. General summaries provided by mass media satisfy part of audiences, but obviously not all of them.

The high rating consistency of IPS indicates people tend to favor summaries generated according to their interests. We next examine content consistency of these summaries with high rating consistency.

As shown in Table 9, although highly scored, these human supervised summaries still have low content consistency (especially Evaluator 2). The low content consistency between RefSum and supervised summaries shows reader have individual personalization. Note that the inconsistency among evaluators is larger than that between RefSum and supervised summaries, indicating *interests* take a high proportion in evaluator supervised summaries.

4.7 Parameter Settings

δ controls coverage/diversity tradeoff. We tune δ on IPS_{ini} and apply the optimal δ directly in IPS. According to the statistics in (Yan et al., 2010), the semantic coherent context is about 7 sentences. Therefore, we empirically choose k=3 for the examined context window. The number of topics is set at n=50. We assign an equal weight ($\gamma = 1$) to semantic units and examined contexts according to analogical research of summarization from implicit feedbacks via clickthrough data (Sun et al., 2005).

λ is the key parameter in IPS approach, controlling the weight of user utility during the process of interactive personalized summarization.

Through Figure 3, we see that when λ is small

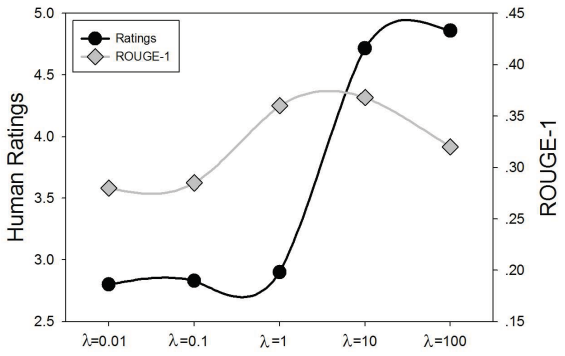

Figure 3: λ v.s. human ratings and ROUGE scores.

($\lambda \in [0.01, 0.1]$), both human judgements and ROUGE evaluation scores have little difference. When $\lambda \in [0.1, 1]$, ROUGE scores increase significantly but human satisfaction shows little response. $\lambda \in [1, 10]$ brings large user utility enhancement because user may find what they are interested in but ROUGE scores start to decay. When $\lambda \in [10, 100]$, ROUGE scores drop much because the emphasized user interests may guide the generated summaries divergent away from the original corpus.

In Figure 4 we examine how λ attracts user clicks and regeneration counts until satisfaction. As the result indicates, both counts increase as λ increases. When λ is small (from 0.01 to 0.1), readers find no more interesting aspects through clicks and regenerations and stop due to the bad user experience. As λ increases, the system mines more relevant sentences according to personalized interests and hence attracts user clicks and intention to regenerate.

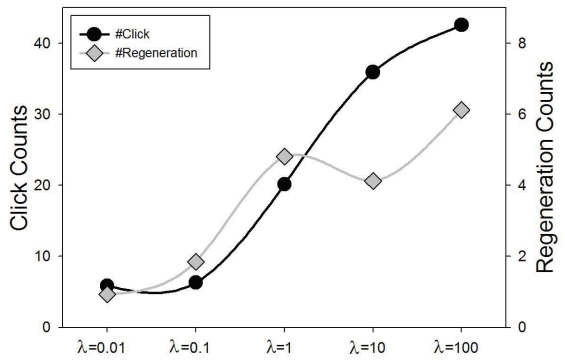

Figure 4: λ v.s. click counts and regeneration counts.

5 Conclusion

We present an important and novel summarization problem, Interactive Personalized Summarization (IPS), which generates summaries based on human−system interaction for "interests" and personalization. We formally formulate IPS as a combination of user utility and traditional summary utility, such as coverage and diversity. We implement a system under such framework for experiments on real web datasets to compare all approaches. Through our experiments we notice that user personalization of interests plays an important role in summary generation, which largely increase human ratings due to user satisfaction. Besides, our experiments indicate the inconsistency between user preferred summaries and reference summaries measured by ROUGE, and hence prove the effectiveness of personalization.

Tuning as Ranking

Mark Hopkins and Jonathan May

Abstract

We offer a simple, effective, and scalable method for statistical machine translation parameter tuning based on the pairwise approach to ranking (Herbrich et al., 1999). Unlike the popular MERT algorithm (Och, 2003), our pairwise ranking optimization (PRO) method is not limited to a handful of parameters and can easily handle systems with thousands of features. Moreover, unlike recent approaches built upon the MIRA algorithm of Crammer and Singer (2003) (Watanabe et al., 2007; Chiang et al., 2008b), PRO is easy to implement. It uses off-the-shelf linear binary classifier software and can be built on top of an existing MERT framework in a matter of hours. We establish PRO's scalability and effectiveness by comparing it to MERT and MIRA and demonstrate parity on both phrase-based and syntax-based systems in a variety of language pairs, using large scale data scenarios.

1 Introduction

The MERT algorithm (Och, 2003) is currently the most popular way to tune the parameters of a statistical machine translation (MT) system. MERT is well-understood, easy to implement, and runs quickly, but can behave erratically and does not scale beyond a handful of features. This lack of scalability is a significant weakness, as it inhibits systems from using more than a couple dozen features to discriminate between candidate translations and stymies feature development innovation.

Several researchers have attempted to address this weakness. Recently, Watanabe et al. (2007) and Chiang et al. (2008b) have developed tuning methods using the MIRA algorithm (Crammer and Singer, 2003) as a nucleus. The MIRA technique of Chiang et al. has been shown to perform well on large-scale tasks with hundreds or thousands of features (2009). However, the technique is complex and architecturally quite different from MERT. Tellingly, in the entire proceedings of ACL 2010 (Hajič et al., 2010), only one paper describing a statistical MT system cited the use of MIRA for tuning (Chiang, 2010), while 15 used MERT.[1]

Here we propose a simpler approach to tuning that scales similarly to high-dimensional feature spaces. We cast tuning as a ranking problem (Chen et al., 2009), where the explicit goal is to learn to correctly rank candidate translations. Specifically, we follow the *pairwise approach* to ranking (Herbrich et al., 1999; Freund et al., 2003; Burges et al., 2005; Cao et al., 2007), in which the ranking problem is reduced to the binary classification task of deciding between candidate translation pairs.

Of primary concern to us is the ease of adoption of our proposed technique. Because of this, we adhere as closely as possible to the established MERT architecture and use freely available machine learning software. The end result is a technique that scales and performs just as well as MIRA-based tuning, but which can be implemented in a couple of hours by anyone with an existing MERT implementation. Mindful that many would-be enhancements to the

[1] The remainder either did not specify their tuning method (though a number of these used the Moses toolkit (Koehn et al., 2007), which uses MERT for tuning) or, in one case, set weights by hand.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1352–1362,
Edinburgh, Scotland, UK, July 27–31, 2011.

state-of-the-art are false positives that only show improvement in a narrowly defined setting or with limited data, we validate our claims on both syntax and phrase-based systems, using multiple language pairs and large data sets.

We describe tuning in abstract and somewhat formal terms in Section 2, describe the MERT algorithm in the context of those terms and illustrate its scalability issues via a synthetic experiment in Section 3, introduce our pairwise ranking optimization method in Section 4, present numerous large-scale MT experiments to validate our claims in Section 5, discuss some related work in Section 6, and conclude in Section 7.

2 Tuning

In Figure 1, we show an example *candidate space*, defined as a tuple $\langle \Delta, I, J, f, e, \mathbf{x} \rangle$ where:

- Δ is a positive integer referred to as the *dimensionality* of the space
- I is a (possibly infinite) set of positive integers, referred to as *sentence indices*
- J maps each sentence index to a (possibly infinite) set of positive integers, referred to as *candidate indices*
- f maps each sentence index to a sentence from the source language
- e maps each pair $\langle i, j \rangle \in I \times J(i)$ to the j^{th} target-language *candidate translation* of source sentence $f(i)$
- $\mathbf{x}$ maps each pair $\langle i, j \rangle \in I \times J(i)$ to a Δ-dimension *feature vector* representation of $e(i, j)$

The example candidate space has two source sentences, three candidate translations for each source sentence, and feature vectors of dimension 2. It is an example of a *finite* candidate space, defined as a candidate space for which I is finite and J maps each index of I to a finite set.

A *policy* of candidate space $\langle \Delta, I, J, f, e, \mathbf{x} \rangle$ is a function that maps each member $i \in I$ to a member of $J(i)$. A policy corresponds to a choice of one candidate translation for each source sentence. For the example in Figure 1, policy $p_1 = \{1 \mapsto 2, 2 \mapsto 3\}$ corresponds to the choice of "he does not go" for the first source sentence and "I do not go" for the second source sentence. Obviously some policies are better than others. Policy $p_2 = \{1 \mapsto 3, 2 \mapsto 1\}$ corresponds to the inferior translations "she not go" and "I go not."

We assume the MT system distinguishes between policies using a scoring function for candidate translations of the form $h_{\mathbf{w}}(i, j) = \mathbf{w} \cdot \mathbf{x}(i, j)$, where $\mathbf{w}$ is a weight vector of the same dimension as feature vector $\mathbf{x}(i, j)$. This scoring function extends to a policy p by summing the cost of each of the policy's candidate translations: $H_{\mathbf{w}}(p) = \sum_{i \in I} h_{\mathbf{w}}(i, p(i))$. As can be seen in Figure 1, using $\mathbf{w} = [-2, 1]$, $H_{\mathbf{w}}(p_1) = 9$ and $H_{\mathbf{w}}(p_2) = -8$.

The goal of tuning is to learn a weight vector $\mathbf{w}$ such that $H_{\mathbf{w}}(p)$ assigns a high score to good policies, and a low score to bad policies.[2] To do so, we need information about which policies are good and which are bad. This information is provided by a "gold" scoring function G that maps each policy to a real-valued score. Typically this gold function is BLEU (Papineni et al., 2002), though there are several common alternatives (Lavie and Denkowski, 2009; Melamed et al., 2003; Snover et al., 2006; Chiang et al., 2008a).

We want to find a weight vector $\mathbf{w}$ such that $H_{\mathbf{w}}$ behaves "similarly" to G on a candidate space s. We assume a loss function $l_s(H_{\mathbf{w}}, G)$ which returns the real-valued loss of using scoring function $H_{\mathbf{w}}$ when the gold scoring function is G and the candidate space is s. Thus, we may say the goal of tuning is to find the weight vector $\mathbf{w}$ that minimizes loss.

3 MERT

In general, the candidate space may have infinitely many source sentences, as well as infinitely many candidate translations per source sentence. In practice, tuning optimizes over a finite subset of source sentences[3] and a finite subset of candidate translations as well. The classic tuning architecture used in the dominant MERT approach (Och, 2003) forms the translation subset and learns weight vector $\mathbf{w}$ via

[2] Without loss of generality, we assume that a higher score indicates a better translation.

[3] See Section 5.2 for the tune sets used in this paper's experiments.

Source Sentence		Candidate Translations				
i	$f(i)$	j	$e(i,j)$	$\mathbf{x}(i,j)$	$h_{\mathbf{w}}(i,j)$	$g(i,j)$
1	"il ne va pas"	1	"he goes not"	[2 4]	0	0.28
		2	"he does not go"	[3 8]	2	0.42
		3	"she not go"	[6 1]	-11	0.12
2	"je ne vais pas"	1	"I go not"	[-3 -3]	3	0.15
		2	"we do not go"	[1 -5]	-7	0.18
		3	"I do not go"	[-5 -3]	7	0.34

Figure 1: Example candidate space of dimensionality 2. Note: $I = \{1, 2\}$, $J(1) = J(2) = \{1, 2, 3\}$. We also show a local scoring function $h_{\mathbf{w}}(i, j)$ (where $\mathbf{w} = [-2, 1]$) and a local gold scoring function $g(i, j)$.

Algorithm TUNE(s, G):

1: **initialize pool:** let $s' = \langle \Delta, I', J', f, e, \mathbf{x} \rangle$, where $I' \subseteq I$ and $J' = \emptyset$
2: **for** the desired number of iterations **do**
3: **candidate generation:** choose index pairs (i, j); for each, add j to $J'(i)$
4: **optimization:** find vector $\mathbf{w}$ that minimizes $l_{s'}(H_{\mathbf{w}}, G)$
5: **return** $\mathbf{w}$

Figure 2: Schema for iterative tuning of base candidate space $s = \langle \Delta, I, J, f, e, \mathbf{x} \rangle$ w.r.t. gold function G.

a feedback loop consisting of two phases. Figure 2 shows the pseudocode. During *candidate generation*, candidate translations are selected from a base candidate space s and added to a finite candidate space s' called the *candidate pool*. During *optimization*, the weight vector $\mathbf{w}$ is optimized to minimize loss $l_{s'}(H_{\mathbf{w}}, G)$.

For its candidate generation phase, MERT generates the k-best candidate translations for each source sentence according to $h_{\mathbf{w}}$, where $\mathbf{w}$ is the weight vector from the previous optimization phase (or an arbitrary weight vector for the first iteration).

For its optimization phase, MERT defines the loss function as follows:

$$l_s(H_{\mathbf{w}}, G) = \max_p G(p) - G(\arg\max_p H_{\mathbf{w}}(p))$$

In other words, it prefers weight vectors $\mathbf{w}$ such that the gold function G scores $H_{\mathbf{w}}$'s best policy as highly as possible (if $H_{\mathbf{w}}$'s best policy is the same as G's best policy, then there is zero loss). Typically the optimization phase is implemented using Och's line optimization algorithm (2003).

MERT has proven itself effective at tuning candidate spaces with low dimensionality. However, it is often claimed that MERT does not scale well with dimensionality. To test this claim, we devised the following synthetic data experiment:

1. We created a gold scoring function G that is *also* a linear function of the same form as $H_{\mathbf{w}}$, i.e., $G(p) = H_{\mathbf{w}^*}(p)$ for some gold weight vector $\mathbf{w}^*$. Under this assumption, the role of the optimization phase reduces to learning back the gold weight vector $\mathbf{w}^*$.

2. We generated a Δ-dimensionality candidate pool with 500 source "sentences" and 100 candidate "translations" per sentence. We created the corresponding feature vectors by drawing Δ random real numbers uniformly from the interval $[0, 500]$.

3. We ran MERT's line optimization on this synthetic candidate pool and compared the learned weight vector $\mathbf{w}$ to the gold weight vector $\mathbf{w}^*$ using cosine similarity.

We used line optimization in the standard way, by generating 20 random starting weight vectors and hill-climbing on each independently until no further progress is made, then choosing the final weight vector that minimizes loss. We tried various dimensionalities from 10 to 1000. We repeated each setting three times, generating different random data each time. The results in Figure 3 indicate that as the dimensionality of the problem increases MERT rapidly loses the ability to learn $\mathbf{w}^*$. Note that this synthetic problem is considerably easier than a real MT scenario, where the data is noisy and interdependent, and the gold scoring function is nonlinear. If

MERT cannot scale in this simple scenario, it has little hope of succeeding in a high-dimensionality deployment scenario.

4 Optimization via Pairwise Ranking

We would like to modify MERT so that it scales well to high-dimensionality candidate spaces. The most prominent example of a tuning method that performs well on high-dimensionality candidate spaces is the MIRA-based approach used by Watanabe et al. (2007) and Chiang et al. (2008b; 2009). Unfortunately, this approach requires a complex architecture that diverges significantly from the MERT approach, and consequently has not been widely adopted. Our goal is to achieve the same performance with minimal modification to MERT.

With MERT as a starting point, we have a choice: modify candidate generation, optimization, or both. Although alternative candidate generation methods have been proposed (Macherey et al., 2008; Chiang et al., 2008b; Chatterjee and Cancedda, 2010), we will restrict ourselves to MERT-style candidate generation, in order to minimize divergence from the established MERT tuning architecture. Instead, we focus on the optimization phase.

4.1 Basic Approach

While intuitive, the MERT optimization module focuses attention on $H_{\mathbf{w}}$'s best policy, and not on its overall prowess at ranking policies. We will create an optimization module that directly addresses $H_{\mathbf{w}}$'s ability to rank policies in the hope that this more holistic approach will generalize better to unseen data.

Assume that the gold scoring function G decomposes in the following way:

$$G(p) = \sum_{i \in I} g(i, p(i)) \tag{1}$$

where $g(i, j)$ is a local scoring function that scores the single candidate translation $e(i, j)$. We show an example g in Figure 1. For an arbitrary pair of candidate translations $e(i, j)$ and $e(i, j')$, the local gold function g tells us which is the better translation. Note that this induces a ranking on the candidate translations for each source sentence.

We follow the *pairwise approach* to ranking (Herbrich et al., 1999; Freund et al., 2003; Burges et al., 2005; Cao et al., 2007). In the pairwise approach, the learning task is framed as the classification of candidate pairs into two categories: correctly ordered and incorrectly ordered. Specifically, for candidate translation pair $e(i, j)$ and $e(i, j')$, we want: $g(i, j) > g(i, j') \Leftrightarrow h_{\mathbf{w}}(i, j) > h_{\mathbf{w}}(i, j')$. We can re-express this condition:

$$\begin{aligned} g(i, j) > g(i, j') &\Leftrightarrow h_{\mathbf{w}}(i, j) > h_{\mathbf{w}}(i, j') \\ &\Leftrightarrow h_{\mathbf{w}}(i, j) - h_{\mathbf{w}}(i, j') > 0 \\ &\Leftrightarrow \mathbf{w} \cdot \mathbf{x}(i, j) - \mathbf{w} \cdot \mathbf{x}(i, j') > 0 \\ &\Leftrightarrow \mathbf{w} \cdot (\mathbf{x}(i, j) - \mathbf{x}(i, j')) > 0 \end{aligned}$$

Thus optimization reduces to a classic binary classification problem. We create a labeled training instance for this problem by computing difference vector $\mathbf{x}(i, j) - \mathbf{x}(i, j')$, and labeling it as a positive or negative instance based on whether, respectively, the first or second vector is superior according to gold function g. To ensure balance, we consider both possible difference vectors from a pair. For example, given the candidate space of Figure 1, since $g(1, 1) > g(1, 3)$, we would add $([-4, 3], +)$ and $([4, -3], -)$ to our training set. We can then feed this training data directly to any off-the-shelf classification tool that returns a linear classifier, in order to obtain a weight vector $\mathbf{w}$ that optimizes the above condition. This weight vector can then be used directly by the MT system in the subsequent candidate generation phase. The exact loss function $l_{s'}(H_{\mathbf{w}}, G)$ optimized depends on the choice of classifier.[4]

Typical approaches to pairwise ranking enumerate all difference vectors as training data. For tuning however, this means $O(|I| * J_{max}^2)$ vectors, where J_{max} is the cardinality of the largest $J(i)$. Since I and J_{max} commonly range in the thousands, a full enumeration would produce billions of feature vectors. Out of tractability considerations, we sample from the space of difference vectors, using the sampler template in Figure 4. For each source sentence i, the sampler generates Γ candidate translation pairs $\langle j, j' \rangle$, and accepts each pair with probability $\alpha_i(|g(i, j) - g(i, j')|)$. Among the accepted pairs, it keeps the Ξ with greatest g differential, and adds their difference vectors to the training data.[5]

[4] See (Chen et al., 2009) for a brief survey.

[5] The intuition for biasing toward high score differential is

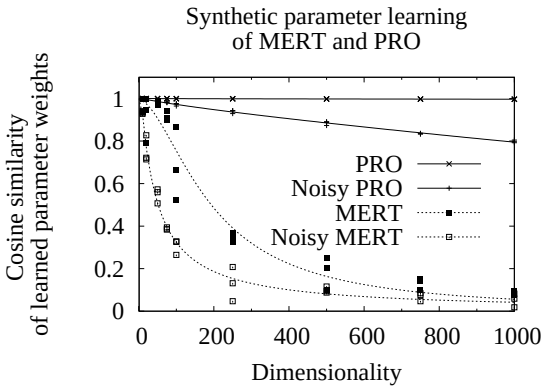

Figure 3: Result of synthetic data learning experiment for MERT and PRO, with and without added noise. As the dimensionality increases MERT is unable to learn the original weights but PRO still performs adequately.

Algorithm SAMPLER$_{s,g}$(Γ, Ξ, i, α_i):

1: $V = \langle\rangle$
2: **for** Γ samplings **do**
3: Choose $\langle j, j' \rangle \in J(i) \times J(i)$ uniformly at random.
4: With probability $\alpha_i(|g(i,j)\text{-}g(i,j')|)$, add $(\mathbf{x}(i,j), \mathbf{x}(i,j'), |g(i,j)\text{-}g(i,j')|)$ to V.
5: Sort V decreasingly by $|g(i,j)\text{-}g(i,j')|$.
6: **return** $(\mathbf{x}(i,j) - \mathbf{x}(i,j'), \mathsf{sign}(g(i,j)\text{-}g(i,j'))$ and $(\mathbf{x}(i,j')\text{-}\mathbf{x}(i,j), \mathsf{sign}(g(i,j')\text{-}g(i,j)))$ for each of the first Ξ members of V.

Figure 4: Pseudocode for our sampler. Arguments: $s = \langle \Delta, I, J, f, e, \mathbf{x} \rangle$ is a finite candidate space; g is a scoring function; Γ, Ξ, i are nonnegative integers; α_i is a function from the nonnegative real numbers to the real interval $[0, 1]$.

4.2 Scalability

We repeated the scalability study from Section 3, now using our pairwise ranking optimization (hereafter, PRO) approach. Throughout all experiments with PRO we choose $\Gamma = 5000$, $\Xi = 50$, and the following step function α for each α_i: [6]

$$\alpha(n) = \begin{cases} 0 \text{ if } n < 0.05 \\ 1 \text{ otherwise} \end{cases}$$

We used MegaM (Daumé III, 2004) as a binary classifier in our contrasting synthetic experiment and ran it "out of the box," i.e., with all default settings for binary classification.[7] Figure 3 shows that PRO is able to learn $\mathbf{w}^*$ nearly perfectly at all dimensionalities from 10 to 1000.

As noted previously, though, this is a rather simple task. To encourage a disconnect between g and $h_{\mathbf{w}}$ and make the synthetic scenario look more like MT reality, we repeated the synthetic experiments but added noise to each feature vector, drawn from a zero-mean Gaussian with a standard deviation of 500. The results of the noisy synthetic experiments, also in Figure 3 (the lines labeled "Noisy"), show that the pairwise ranking approach is less successful than before at learning $\mathbf{w}^*$ at high dimensionality, but still greatly outperforms MERT.

4.3 Discussion

The idea of learning from difference vectors also lies at the heart of the MIRA-based approaches (Watanabe et al., 2007; Chiang et al., 2008b) and the approach of Roth et al. (2010), which, similar to our method, uses sampling to select vectors. Here, we isolate these aspects of those approaches to create a simpler tuning technique that closely mirrors the ubiquitous MERT architecture. Among other simplifications, we abstract away the choice of MIRA as the classification method (our approach can use any classification technique that learns a separating hyperplane), and we eliminate the need for oracle translations.

An important observation is that BLEU does not satisfy the decomposability assumption of Equation (1). An advantage of MERT is that it can directly optimize for non-decomposable scoring functions like BLEU. In our experiments, we use the BLEU+1 approximation to BLEU (Liang et al., 2006) to determine class labels. We will nevertheless use BLEU to evaluate the trained systems.

that our primary goal is to ensure good translations are preferred to bad translations, and not to tease apart small differences.

[6] We obtained these parameters by trial-and-error experimentation on a single MT system (Urdu-English SBMT), then held them fixed throughout our experiments. We obtained similar results using $\Gamma = \Xi = 100$, and for each α_i, a logistic sigmoid function centered at the mean g differential of candidate translation pairs for the i^{th} source sentence. This alternative approach has the advantage of being agnostic about which gold scoring function is used.

[7] With the sampling settings previously described and MegaM as our classifier we were able to optimize two to three times faster than with MERT's line optimization.

PBMT					SBMT

Table 1: Machine translation performance for the experiments listed in this paper. Scores are case-sensitive IBM BLEU. For every choice of system, language pair, and feature set, PRO performs comparably with the other methods.

5 Experiments

We now turn to real machine translation conditions to validate our thesis: We can cleanly replace MERT's line optimization with pairwise ranking optimization and immediately realize the benefits of high-dimension tuning. We now detail the three language pairs, two feature scenarios, and two MT models used for our experiments. For each language pair and each MT model we used MERT, MIRA, and PRO to tune with a standard set of baseline features, and used the latter two methods to tune with an extended set of features.[8] At the end of every experiment we used the final feature weights to decode a held-out test set and evaluated it with case-sensitive BLEU. The results are in Table 1.

5.1 Systems

We used two systems, each based on a different MT model. Our syntax-based system (hereafter, SBMT) follows the model of Galley et al. (2004). Our phrase-based system (hereafter, PBMT) follows the model of Och and Ney (2004). In both systems we learn alignments with GIZA++ (Och and Ney, 2000) using IBM Model 4; for Urdu-English and Chinese-English we merged alignments with the refined method, and for Arabic-English we merged with the union method.

5.2 Data

Table 2 notes the sizes of the datasets used in our experiments. All tune and test data have four English reference sets for the purposes of scoring.

Data		U-E	A-E	C-E
Train	lines	515K	6.5M	7.9M
	words	2.2M	175M	173M
Tune	lines	923	1994	1615
	words	16K	65K	42K
Test	lines	938	1357	1357
	words	18K	47K	37K

Table 2: Data sizes for the experiments reported in this paper (English words shown).

[8] MERT could not run to a satisfactory completion in any extended feature scenario; as implied in the synthetic data experiment of Section 3, the algorithm makes poor choices for its weights and this leads to low-quality k-best lists and dismal performance, near 0 BLEU in every iteration.

Table 3: Summary of features used in experiments in this paper.

5.2.1 Urdu-English

The training data for Urdu-English is that made available in the constrained track in the NIST 2009 MT evaluation. This includes many lexicon entries and other single-word data, which accounts for the large number of lines relative to word count. The NIST 2008 evaluation set, which contains newswire and web data, is split into two parts; we used roughly half each for tune and test. We trained a 5-gram English language model on the English side of the training data.

5.2.2 Arabic-English

The training data for Arabic English is that made available in the constrained track in the NIST 2008 MT evaluation. The tune set, which contains only newswire data, is a mix from NIST MT evaluation sets from 2003–2006 and from GALE development data. The test set, which contains both web and newswire data, is the evaluation set from the NIST 2008 MT evaluation. We trained a 4-gram English language model on the English side of the training data.

5.2.3 Chinese-English

For Chinese-English we used 173M words of training data from GALE 2008. For SBMT we used a 32M word subset for extracting rules and building a language model, but used the entire training data for alignments, and for all PBMT training. The tune and test sets both contain web and newswire data. The tune set is selected from NIST MT evaluation sets from 2003–2006. The test set is the evaluation set from the NIST 2008 MT evaluation. We trained a 3-gram English language model on the English side of the training data.

5.3 Features

For each of our systems we identify two feature sets: *baseline*, which correspond to the typical small feature set reported in current MT literature, and *extended*, a superset of baseline, which adds hundreds or thousands of features. Specifically, we use 15 baseline features for PBMT, similar to the baseline features described by Watanabe et al. (2007). We use 19 baseline features for SBMT, similar to the baseline features described by Chiang et al. (2008b).

We used the following feature classes in SBMT and PBMT extended scenarios:

- Discount features for rule frequency bins (cf. Chiang et al. (2009), Section 4.1)
- Target word insertion features[9]

We used the following feature classes in SBMT extended scenarios only (cf. Chiang et al. (2009), Section 4.1):[10]

- Rule overlap features
- Node count features

[9]For Chinese-English and Urdu-English SBMT these features only fired when the inserted target word was unaligned to any source word.

[10]The parser used for Arabic-English had a different nonterminal set than that used for the other two SBMT systems, accounting for the wide disparity in feature count for these feature classes.

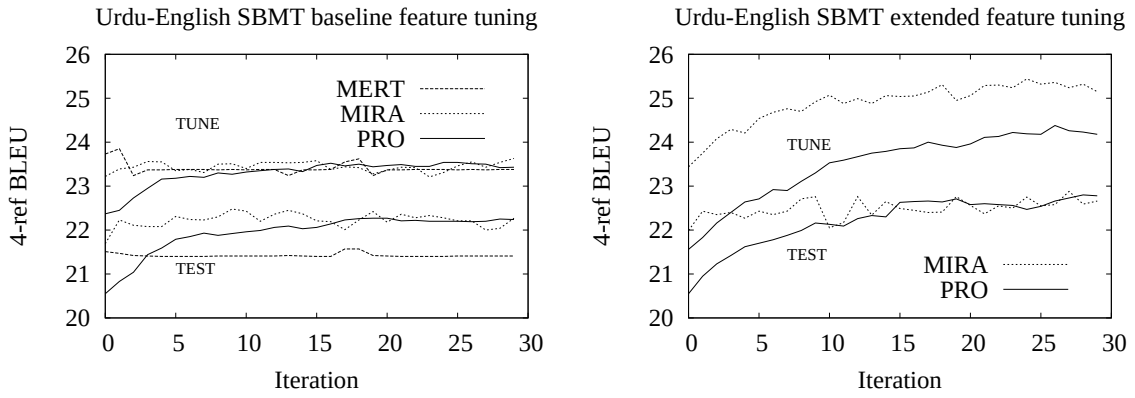

Figure 5: Comparison of MERT, PRO, and MIRA on tuning Urdu-English SBMT systems, and test results at every iteration. PRO performs comparably to MERT and MIRA.

We used the following feature classes in PBMT extended scenarios only:

- Unigram word pair features for the 80 most frequent words in both languages plus tokens for unaligned and all other words (cf. Watanabe et al. (2007), Section 3.2.1)[11]
- Source, target, and joint phrase length features from 1 to 7, e.g. "tgt=4", "src=2", and "src/tgt=2,4"

The feature classes and number of features used within those classes for each language pair are summarized in Table 3.

5.4 Tuning settings

Each of the three approaches we compare in this study has various details associated with it that may prove useful to those wishing to reproduce our results. We list choices made for the various tuning methods here, and note that all our decisions were made in keeping with best practices for each algorithm.

5.4.1 MERT

We used David Chiang's CMERT implementation of MERT that is available with the Moses system (Koehn et al., 2007). We ran MERT for up to 30 iterations, using $k = 1500$, and stopping early when the accumulated k-best list does not change in an iteration. In every tuning iteration we ran MERT once with weights initialized to the last iteration's chosen weight set and 19 times with random weights, and chose the the best of the 20 ending points according to G on the development set. The G we optimize is tokenized, lower-cased 4-gram BLEU (Papineni et al., 2002).

5.4.2 MIRA

We for the most part follow the MIRA algorithm for machine translation as described by Chiang et al. (2009)[12] but instead of using the 10-best of each of the best $h_{\mathbf{w}}$, $h_{\mathbf{w}}$ +g, and $h_{\mathbf{w}}$-g, we use the 30-best according to $h_{\mathbf{w}}$.[13] We use the same sentence-level BLEU calculated in the context of previous 1-best translations as Chiang et al. (2008b; 2009). We ran MIRA for 30 iterations.

5.4.3 PRO

We used the MegaM classifier and sampled as described in Section 4.2. As previously noted, we used BLEU+1 (Liang et al., 2006) for g. MegaM was easy to set up and ran fairly quickly, however any linear binary classifier that operates on real-valued features can be used, and in fact we obtained similar results

[11] This constitutes 6,723 features in principle ($82^2 - 1$ since "unaligned-unaligned" is not considered) but in practice far fewer co-occurrences were seen. Table 3 shows the number of actual unigram word pair features observed in data.

[12] and acknowledge the use of David Chiang's code

[13] This is a more realistic scenario for would-be implementers of MIRA, as obtaining the so-called "hope" and "fear" translations from the lattice or forest is significantly more complicated than simply obtaining a k-best list. Other tests comparing these methods have shown between 0.1 to 0.3 BLEU drop using 30-best $h_{\mathbf{w}}$ on Chinese-English (Wang, 2011).

using the support vector machine module of WEKA (Hall et al., 2009) as well as the Stanford classifier (Manning and Klein, 2003). We ran for up to 30 iterations and used the same k and stopping criterion as was used for MERT, though variability of sampling precluded list convergence.

While MERT and MIRA use each iteration's final weights as a starting point for hill-climbing the next iteration, the pairwise ranking approach has no explicit tie to previous iterations. To incorporate such stability into our process we interpolated the weights $\mathbf{w}'$ learned by the classifier in iteration t with those from iteration $t-1$ by a factor of Ψ, such that $\mathbf{w}_t = \Psi \cdot \mathbf{w}' + (1 - \Psi) \cdot \mathbf{w}_{t-1}$. We found $\Psi = 0.1$ gave good performance across the board.

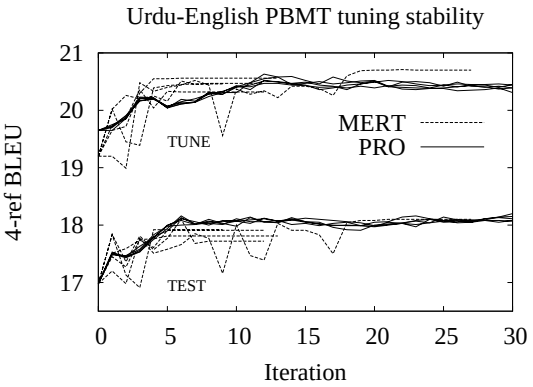

Figure 6: Tune and test curves of five repetitions of the same Urdu-English PBMT baseline feature experiment. PRO is more stable than MERT.

5.5 Discussion

We implore the reader to avoid the natural tendency to compare results using baseline vs. extended features or between PBMT and SBMT on the same language pair. Such discussions are indeed interesting, and could lead to improvements in feature engineering or sartorial choices due to the outcome of wagers (Goodale, 2008), but they distract from our thesis. As can be seen in Table 1, for each of the 12 choices of system, language pair, and feature set, the PRO method performed nearly the same as or better than MIRA and MERT on test data.

In Figure 5 we show the tune and test BLEU using the weights learned at every iteration for each Urdu-English SBMT experiment. Typical of the rest of the experiments, we can clearly see that PRO appears to proceed more monotonically than the other methods. We quantified PRO's stability as compared to MERT by repeating the Urdu-English baseline PBMT experiment five times with each configuration. The tune and test BLEU at each iteration is depicted in Figure 6. The standard deviation of the final test BLEU of MERT was 0.13 across the five experiment instances, while PRO had a standard deviation of just 0.05.

6 Related Work

Several works (Shen et al., 2004; Cowan et al., 2006; Watanabe et al., 2006) have used discriminative techniques to re-rank k-best lists for MT. Tillmann and Zhang (2005) used a customized form of multi-class stochastic gradient descent to learn feature weights for an MT model. Och and Ney (2002) used maximum entropy to tune feature weights but did not compare pairs of derivations. Ittycheriah and Roukos (2005) used a maximum entropy classifier to train an alignment model using hand-labeled data. Xiong et al. (2006) also used a maximum entropy classifier, in this case to train the reordering component of their MT model. Lattice- and hypergraph-based variants of MERT (Macherey et al., 2008; Kumar et al., 2009) are more stable than traditional MERT, but also require significant engineering efforts.

7 Conclusion

We have described a simple technique for tuning an MT system that is on par with the leading techniques, exhibits reliable behavior, scales gracefully to high-dimension feature spaces, and is remarkably easy to implement. We have demonstrated, via a litany of experiments, that our claims are valid and that this technique is widely applicable. It is our hope that the adoption of PRO tuning leads to fewer headaches during tuning and motivates advanced MT feature engineering research.

Abstract

We propose a general method to watermark and probabilistically identify the structured outputs of machine learning algorithms. Our method is robust to local editing operations and provides well defined trade-offs between the ability to identify algorithm outputs and the quality of the watermarked output. Unlike previous work in the field, our approach does not rely on controlling the inputs to the algorithm and provides probabilistic guarantees on the ability to identify collections of results from one's own algorithm. We present an application in statistical machine translation, where machine translated output is watermarked at minimal loss in translation quality and detected with high recall.

1 Motivation

Machine learning algorithms provide structured results to input queries by simulating human behavior. Examples include automatic machine translation (Brown et al., 1993) or automatic text and rich media summarization (Goldstein et al., 1999). These algorithms often estimate some portion of their models from publicly available human generated data. As new services that output structured results are made available to the public and the results disseminated on the web, we face a daunting new challenge: Machine generated structured results contaminate the pool of naturally generated human data. For example, machine translated output and human generated translations are currently both found extensively on the web, with no automatic way of distinguishing between them. Algorithms that mine data from the web (Uszkoreit et al., 2010), with the goal of learning to simulate human behavior, will now learn models from this contaminated and potentially self-generated data, reinforcing the errors committed by earlier versions of the algorithm.

It is beneficial to be able to identify a set of encountered structured results as having been generated by one's own algorithm, with the purpose of filtering such results when building new models.

Problem Statement: We define a structured result of a query q as $r = \{z_1 \cdots z_L\}$ where the order and identity of elements z_i are important to the quality of the result r. The structural aspect of the result implies the existence of alternative results (across both the order of elements and the elements themselves) that might vary in their quality.

Given a collection of N results, $\mathcal{C}_N = r_1 \cdots r_N$, where each result r_i has k ranked alternatives $D_k(q_i)$ of relatively similar quality and queries $q_1 \cdots q_N$ are arbitrary and not controlled by the watermarking algorithm, we define the watermarking task as:

Task. *Replace r_i with $r'_i \in D_k(q_i)$ for some subset of results in $\mathcal{C}_N$ to produce a watermarked collection $\mathcal{C}'_N$*

such that:

- $\mathcal{C}'_N$ is probabilistically identifiable as having been generated by one's own algorithm.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1363–1372,
Edinburgh, Scotland, UK, July 27–31, 2011.

- the degradation in quality from $\mathcal{C}_N$ to the watermarked $\mathcal{C}'_N$ should be analytically controllable, trading quality for detection performance.
- $\mathcal{C}'_N$ should not be detectable as watermarked content without access to the generating algorithms.
- the detection of $\mathcal{C}'_N$ should be robust to simple edit operations performed on individual results $r \in \mathcal{C}'_N$.

2 Impact on Statistical Machine Translation

Recent work(Resnik and Smith, 2003; Munteanu and Marcu, 2005; Uszkoreit et al., 2010) has shown that multilingual parallel documents can be efficiently identified on the web and used as training data to improve the quality of statistical machine translation.

The availability of free translation services (Google Translate, Bing Translate) and tools (Moses, Joshua), increase the risk that the content found by parallel data mining is in fact generated by a machine, rather than by humans. In this work, we focus on statistical machine translation as an application for watermarking, with the goal of discarding documents from training if they have been generated by one's own algorithms.

To estimate the magnitude of the problem, we used parallel document mining (Uszkoreit et al., 2010) to generate a collection of bilingual document pairs across several languages. For each document, we inspected the page content for source code that indicates the use of translation modules/plug-ins that translate and publish the translated content.

We computed the proportion of the content within our corpus that uses these modules. We find that a significant proportion of the mined parallel data for some language pairs is generated via one of these translation modules. The top 3 languages pairs, each with parallel translations into English, are Tagalog (50.6%), Hindi (44.5%) and Galician (41.9%). While these proportions do not reflect impact on each language's monolingual web, they are certainly high enough to affect machine translations systems that train on mined parallel data. In this work, we develop a general approach to watermark structured outputs and apply it to the outputs of a statistical machine translation system with the goal of identifying these same outputs on the web. In the context of the watermarking task defined above, we output selecting alternative translations for input source sentences. These translations often undergo simple edit and formatting operations such as case changes, sentence and word deletion or post editing, prior to publishing on the web. We want to ensure that we can still detect watermarked translations despite these edit operations. Given the rapid pace of development within machine translation, it is also important that the watermark be robust to improvements in underlying translation quality. Results from several iterations of the system within a single collection of documents should be identifiable under probabilistic bounds.

While we present evaluation results for statistical machine translation, our proposed approach and associated requirements are applicable to any algorithm that produces structured results with several plausible alternatives. The alternative results can arise as a result of inherent task ambiguity (for example, there are multiple correct translations for a given input source sentence) or modeling uncertainty (for example, a model assigning equal probability to two competing results).

3 Watermark Structured Results

Selecting an alternative r' from the space of alternatives $D_k(q)$ can be stated as:

$$r' = \arg\max_{r \in D_k(q)} w(r, D_k(q), h) \quad (1)$$

where w ranks $r \in D_k(q)$ based on r's presentation of a watermarking signal computed by a hashing operation h. In this approach, w and its component operation h are the only *secrets* held by the watermarker. This selection criterion is applied to all system outputs, ensuring that watermarked and non-watermarked version of a collection will never be available for comparison.

A specific implementation of w within our watermarking approach can be evaluated by the following metrics:

- False Positive Rate: how often non-watermarked collections are *falsely* identified as watermarked.
- Recall Rate: how often watermarked collections are *correctly* identified as watermarked.
- Quality Degradation: how significantly does $\mathcal{C}'_N$ differ from $\mathcal{C}_N$ when evaluated by task specific quality metrics.

While identification is performed at the collection level, we can scale these metrics based on the size of each collection to provide more task sensitive metrics. For example, in machine translation, we count the number of words in the collection towards the false positive and recall rates.

In Section 3.1, we define a random hashing operation h and a task independent implementation of the selector function w. Section 3.2 describes how to classify a collection of watermarked results. Section 3.3 and 3.4 describes refinements to the selection and classification criteria that mitigate quality degradation. Following a comparison to related work in Section 4, we present experimental results for several languages in Section 5.

3.1 Watermarking: $\mathcal{C}_N \rightarrow \mathcal{C}'_N$

We define a random hashing operation h that is applied to result r. It consists of two components:

- A hash function applied to a structured result r to generate a bit sequence of a fixed length.
- An optional mapping that maps a single candidate result r to a set of sub-results. Each sub-result is then hashed to generate a concatenated bit sequence for r.

A good hash function produces outputs whose bits are independent. This implies that we can treat the bits for any input structured results as having been generated by a binomial distribution with equal probability of generating 1s vs 0s. This condition also holds when accumulating the bit sequences over a collection of results as long as its elements are selected uniformly from the space of possible results. Therefore, *the bits generated from a collection of unwatermarked results will follow a binomial distribution with parameter* $p = 0.5$. This result provides a null hypothesis for a statistical test on a given bit sequence, testing whether it is likely to have been generated from a binomial distribution binomial(n, p) where $p = 0.5$ and n is the length of the bit sequence.

For a collection $\mathcal{C}_N = r_1 \cdots r_N$, we can define a watermark ranking function w to systematically select alternatives $r'_i \in D_k(q)$, such that the resulting $\mathcal{C}'_N$ is *unlikely* to produce bit sequences that follow the $p = 0.5$ binomial distribution. A straightforward biasing criteria would be to select the candidate whose bit sequence exhibits the highest ratio of 1s. w can be defined as:

$$w(r, D_k(q), h) = \frac{\#(1, h(r))}{|h(r)|} \qquad (2)$$

where $h(r)$ returns the randomized bit sequence for result r, and $\#(x, \vec{y})$ counts the number of occurrences of x in sequence $\vec{y}$. Selecting alternatives results to exhibit this bias will result in watermarked collections that exhibit this same bias.

3.2 Detecting the Watermark

To classify a collection $\mathcal{C}_N$ as watermarked or non-watermarked, we apply the hashing operation h on each element in $\mathcal{C}_N$ and concatenate the sequences. This sequence is tested against the null hypothesis that it was generated by a binomial distribution with parameter $p = 0.5$. We can apply a Fisherian test of statistical significance to determine whether the observed distribution of bits is unlikely to have occurred by chance under the null hypothesis (binomial with $p = 0.5$).

We consider a collection of results that *rejects* the null hypothesis to be watermarked results generated by our own algorithms. The p-value under the null hypothesis is efficiently computed

by:

$$p - value = P_n(X \geq x) \quad (3)$$

$$= \sum_{i=x}^{n} \binom{n}{i} p^i (1-p)^{n-i} \quad (4)$$

where x is the number of 1s observed in the collection, and n is the total number of bits in the sequence. Comparing this p-value against a desired significance level α, we reject the null hypothesis for collections that have $P_n(X \geq x) < \alpha$, thus deciding that such collections were generated by our own system.

This classification criteria has a fixed false positive rate. Setting $\alpha = 0.05$, we know that 5% of *non-watermarked* bit sequences will be *falsely* labeled as watermarked. This parameter α can be controlled on an application specific basis. By biasing the selection of candidate results to produce more 1s than 0s, we have defined a watermarking approach that exhibits a fixed false positive rate, a probabilistically bounded detection rate and a task independent hashing and selection criteria. In the next sections, we will deal with the question of robustness to edit operations and quality degradation.

3.3 Robustness and Inherent Bias

We would like the ability to identify watermarked collections to be robust to simple edit operations. Even slight modifications to the elements within an item r would yield (by construction of the hash function), completely different bit sequences that no longer preserve the biases introduced by the watermark selection function.

To ensure that the distributional biases introduced by the watermark selector are preserved, we can optionally map individual results into a set of sub-results, each one representing some local structure of r. h is then applied to each sub-result and the results concatenated to represent r. This mapping is defined as a component of the h operation.

While a particular edit operation might affect a small number of sub-results, the majority of the bits in the concatenated bit sequence for r would remain untouched, thereby limiting the damage to the biases selected during watermarking. This is of course no defense to edit operations that are applied globally across the result; our expectation is that such edits would either significantly degrade the quality of the result or be straightforward to identify directly.

For example, a sequence of words $r = z_1 \cdots z_L$ can be mapped into a set of consecutive n-gram sequences. Operations to edit a word z_i in r will only affect events that consider the word z_i. To account for the fact that alternatives in $D_k(q)$ might now result in bit sequences of different lengths, we can generalize the biasing criteria to directly reflect the expected contribution to the watermark by defining:

$$w(r, D_k(q), h) = P_n(X \geq \#(1, h(r))) \quad (5)$$

where P_n gives probabilities from binomial($n = |h(r)|, p = 0.5$).

Inherent collection level biases: Our null hypothesis is based on the assumption that collections of results draw uniformly from the space of possible results. This assumption might not always hold and depends on the type of the results and collection. For example, considering a text document as a collection of sentences, we can expect that some sentences might repeat more frequently than others.

This scenario is even more likely when applying a mapping into sub-results. n-gram sequences follow long-tailed or Zipfian distributions, with a small number of n-grams contributing heavily toward the total number of n-grams in a document.

A random hash function guarantees that inputs are distributed uniformly at random over the output range. However, the same input will be assigned the same output deterministically. Therefore, if the distribution of inputs is heavily skewed to certain elements of the input space, the output distribution will not be uniformly distributed. The bit sequences resulting from the high frequency sub-results have the potential to generate inherently biased distributions when accumulated at the collection level. We want to choose a mapping that tends towards generating uniformly from the space of sub-results. We can empirically measure the quality of a sub-result mapping for a specific task by computing the

false positive rate on non-watermarked collections. For a given significance level α, an ideal mapping would result in false positive rates close to α as well.

Figure 1 shows false positive rates from 4 alternative mappings, computed on a large corpus of French documents (see Table 1 for statistics). Classification decisions are made at the collection level (documents) but the contribution to the false positive rate is based on the number of words in the classified document. We consider mappings from a result (sentence) into its 1-grams, $1-5$-grams and $3-5$ grams as well as the non-mapping case, where the full result is hashed.

Figure 1 shows that the 1-grams and $1-5$-gram generate sub-results that result in heavily biased false positive rates. The $3-5$ gram mapping yields false positive rates close to their theoretically expected values. [1] Small deviations are expected since documents make different contributions to the false positive rate as a function of the number of words that they represent. For the remainder of this work, we use the 3-5 gram mapping and the full sentence mapping, since the alternatives generate inherently distributions with very high false positive rates.

3.4 Considering Quality

The watermarking described in Equation 3 chooses alternative results on a per result basis, with the goal of influencing collection level bit sequences. The selection criteria as described will choose the most biased candidates available in $D_k(q)$. The parameter k determines the extent to which lesser quality alternatives can be chosen. If all the alternatives in each $D_k(q)$ are of relatively similar quality, we expect minimal degradation due to watermarking.

Specific tasks however can be particularly sensitive to choosing alternative results. Discriminative approaches that optimize for arg max selection like (Och, 2003; Liang et al., 2006; Chiang et al., 2009) train model parameters such that the top-ranked result is well *separated* from its competing alternatives. Different queries also differ in the inherent ambiguity expected from their results; sometimes there really is just one correct result for a query, while for other queries, several alternatives might be equally good.

By generalizing the definition of the w function to interpolate the estimated loss in quality and the gain in the watermarking signal, we can trade-off the ability to identify the watermarked collections against quality degradation:

$$\begin{aligned} w(r, D_k(q), f_w) = \lambda * \text{gain}(r, D_k(q), f_w) \\ -(1-\lambda) * \text{loss}(r, D_k(q)) \end{aligned} \quad (6)$$

Loss: The $\text{loss}(r, D_k(q))$ function reflects the quality degradation that results from selecting alternative r as opposed to the best ranked candidate in $D_k(q)$). We will experiment with two variants:

$$loss_{rank}(r, D_k(q)) = (\text{rank}(r) - k)/k$$

$$loss_{cost}(r, D_k(q)) = (\text{cost}(r) - \text{cost}(r^1))/\,\text{cost}(r^1)$$

where:

- $\text{rank}(r)$: returns the rank of r within $D_k(q)$.
- $\text{cost}(r)$: a weighted sum of features (not normalized over the search space) in a log-linear model such as those mentioned in (Och, 2003).
- r^1: the highest ranked alternative in $D_k(q)$.

loss_{rank} provides a generally applicable criteria to select alternatives, penalizing selection from deep within $D_k(q)$. This estimate of the quality degradation does not reflect the generating model's opinion on relative quality. loss_{cost} considers the relative increase in the generating model's cost assigned to the alternative translation.

Gain: The $\text{gain}(r, D_k(q), f_w)$ function reflects the gain in the watermarking signal by selecting candidate r. We simply define the gain as the $P_n(X \geq \#(1, h(r)))$ from Equation 5.

[1] In the final version of this paper we will perform sampling to create a more reliable estimate of the false positive rate that is not overly influenced by document length distributions.

4 Related Work

Using watermarks with the goal of transmitting a hidden message within images, video, audio and monolingual text media is common. For structured text content, linguistic approaches like (Chapman et al., 2001; Gupta et al., 2006) use language specific linguistic and semantic expansions to introduce hidden watermarks. These expansions provide alternative candidates within which messages can be encoded. Recent publications have extended this idea to machine translation, using multiple systems and expansions to generate alternative translations. (Stutsman et al., 2006) uses a hashing function to select alternatives that encode the hidden message in the lower order bits of the translation. In each of these approaches, the watermarker has control over the collection of results into which the watermark is to be embedded.

These approaches seek to embed a hidden message into a collection of results that is *selected* by the watermarker. In contrast, we address the condition where the input queries are not in the watermarker's control.

The goal is therefore to introduce the watermark into all generated results, with the goal of probabilistically identifying such outputs. Our approach is also task independent, avoiding the need for templates to generate additional alternatives. By addressing the problem directly within the search space of a dynamic programming algorithm, we have access to high quality alternatives with well defined models of quality loss. Finally, our approach is robust to local word editing. By using a sub-result mapping, we increase the level of editing required to obscure the watermark signal; at high levels of editing, the quality of the results themselves would be significantly degraded.

5 Experiments

We evaluate our watermarking approach applied to the outputs of statistical machine translation under the following experimental setup.

A repository of parallel (aligned source and target language) web documents is sampled to produce a large corpus on which to evaluate the watermarking *classification* performance. The

corpora represent translations into 4 diverse target languages, using English as the source language. Each document in this corpus can be considered a collection of un-watermarked structured results, where source sentences are queries and each target sentence represents a structured result.

Using a state-of-the-art phrase-based statistical machine translation system (Och and Ney, 2004) trained on parallel documents identified by (Uszkoreit et al., 2010), we generate a set of 100 alternative translations for each source sentence. We apply the proposed watermarking approach, along with the proposed refinements that address task specific loss (Section 3.4) and robustness to edit operations (Section 3.3) to generate watermarked corpora.

Each method is controlled via a single parameter (like k or λ) which is varied to generate alternative watermarked collections. For each parameter value, we evaluate the Recall Rate and Quality Degradation with the goal of finding a setting that yields a high recall rate, minimal quality degradation. False positive rates are evaluated based on a fixed classification significance level of $\alpha = 0.05$. The false positive and recall rates are evaluated on the word level; a document that is misclassified or correctly identified contributes its length in words towards the error calculation. In this work, we use $\alpha = 0.05$ during classification corresponding to an expected 5% false positive rate. The false positive rate is a function of h and the significance level α and therefore constant across the parameter values k and λ.

We evaluate quality degradation on human translated test corpora that are more typical for machine translation evaluation. Each test corpus consists of 5000 source sentences randomly selected from the web and translated into each respective language.

We chose to evaluate quality on test corpora to ensure that degradations are not hidden by imperfectly matched web corpora and are consistent with the kind of results often reported for machine translation systems. As with the classification corpora, we create watermarked versions at each parameter value. For a given parameter value, we measure false positive and recall rates on the classification corpora and quality degradation on the evaluation corpora.

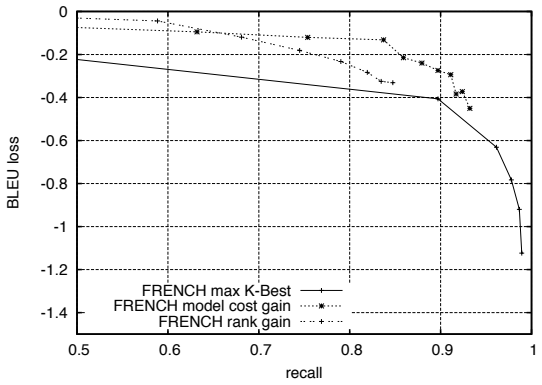

Figure 2: BLEU loss against recall of watermarked content for the baseline approach (max K-best), rank and cost interpolation.

Table 1 shows corpus statistics for the classification and test corpora and non-watermarked BLEU scores for each target language. All source texts are in English.

5.1 Loss Interpolated Experiments

Our first set of experiments demonstrates baseline performance using the watermarking criteria in Equation 5 versus the refinements suggested in Section 3.4 to mitigate quality degradation. The h function is computed on the full sentence result r with no sub-event mapping. The following methods are evaluated in Figure 2.

- Baseline method (labeled "max K-best"): selects r' purely based on gain in watermarking signal (Equation 5) and is parameterized by k: the number of alternatives considered for each result.
- Rank interpolation: incorporates rank into w, varying the interpolation parameter λ.
- Cost interpolation: incorporates cost into w, varying the interpolation parameter λ.

The observed false positive rate on the French classification corpora is 1.9%.

	Classification			Quality		
Target	**# words**	**# sentences**	**# documents**	**# words**	**# sentences**	**BLEU %**
Arabic	200107	15820	896	73592	5503	12.29
French	209540	18024	600	73592	5503	26.45
Hindi	183676	13244	1300	73409	5489	20.57
Turkish	171671	17155	1697	73347	5486	13.67

Table 1: Content statistics for classification and quality degradation corpora. Non-watermarked BLEU scores are reported for the quality corpora.

We consider 0.2% BLEU loss as a threshold for acceptable quality degradation. Each method is judged by its ability to achieve high recall below this quality degradation threshold.

Applying cost interpolation yields the best results in Figure 2, achieving a recall of 85% at 0.2% BLEU loss, while rank interpolation achieves a recall of 76%. The baseline approach of selecting the highest gain candidate within a depth of k candidates does not provide sufficient parameterization to yield low quality degradation. At $k = 2$, this method yields almost 90% recall, but with approximately 0.4% BLEU loss.

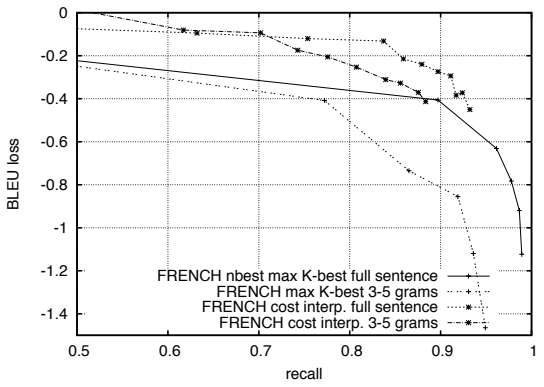

Figure 3: BLEU loss against recall of watermarked content for the baseline and cost interpolation methods using both result level and 3-5 gram mapped events.

5.2 Robustness Experiments

In Section 5.2, we proposed mapping results into sub-events or features. We considered alternative feature mappings in Figure 1, finding that mapping sentence results into a collection of 3-5 grams yields acceptable false positive rates at varied levels of α.

Figure 3 presents results that compare moving from the result level hashing to the 3-5 gram sub-result mapping. We show the impact of the mapping on the baseline max K-best method as well as for cost interpolation. There are substantial reductions in recall rate at the 0.2% BLEU loss level when applying sub-result mappings in cases. The cost interpolation method recall drops from 85% to 77% when using the 3-5 grams event mapping. The observed false positive rate of the 3-5 gram mapping is 4.7%.

By using the 3-5 gram mapping, we expect to increase robustness against local word edit operations, but we have sacrificed recall rate due to the inherent distributional bias discussed in Section 3.3.

5.3 Multilingual Experiments

The watermarking approach proposed here introduces no language specific watermarking operations and it is thus broadly applicable to translating into all languages. In Figure 4, we report results for the baseline and cost interpolation methods, considering both the result level and 3-5 gram mapping. We set $\alpha = 0.05$ and measure recall at 0.2% BLEU degradation for translation from English into Arabic, French, Hindi and Turkish. The observed false positive rates for full sentence hashing are: Arabic: 2.4%, French: 1.8%, Hindi: 5.6% and Turkish: 5.5%, while for the 3-5 gram mapping, they are: Arabic: 5.8%, French: 7.5%, Hindi:3.5% and Turkish: 6.2%. Underlying translation quality plays an important role in translation quality degradation when watermarking. Without a sub-result mapping, French (BLEU: 26.45%)

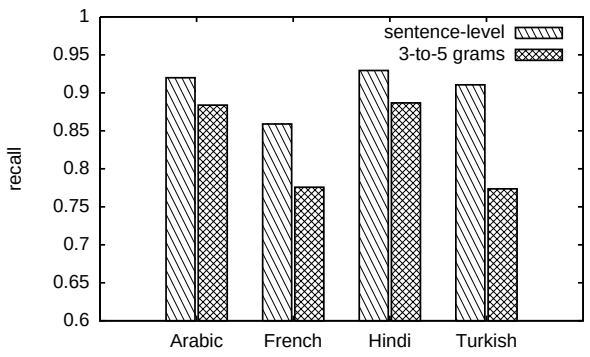

Figure 4: Loss of recall when using 3-5 gram mapping vs sentence level mapping for Arabic, French, Hindi and Turkish translations.

achieves recall of 85% at 0.2% BLEU loss, while the other languages achieve over 90% recall at the same BLEU loss threshold. Using a sub-result mapping degrades quality for each language pair, but changes the relative performance. Turkish experiences the highest relative drop in recall, unlike French and Arabic, where results are relatively more robust to using sub-sentence mappings. This is likely a result of differences in n-gram distributions across these languages. The languages considered here all use space separated words. For languages that do not, like Chinese or Thai, our approach can be applied at the character level.

6 Conclusions

In this work we proposed a general method to watermark and probabilistically identify the structured outputs of machine learning algorithms. Our method provides probabilistic bounds on detection ability, analytic control on quality degradation and is robust to local editing operations. Our method is applicable to any task where structured outputs are generated with ambiguities or ties in the results. We applied this method to the outputs of statistical machine translation, evaluating each refinement to our approach with false positive and recall rates against BLEU score quality degradation.

Our results show that it is possible, across several language pairs, to achieve high recall rates (over 80%) with low false positive rates (between 5 and 8%) at minimal quality degradation (0.2% BLEU), while still allowing for local edit operations on the translated output. In future work we will continue to investigate methods to mitigate quality loss.

Abstract

This paper compares several translation representations for a synchronous context-free grammar parse including CFGs/hypergraphs, finite-state automata (FSA), and pushdown automata (PDA). The representation choice is shown to determine the form and complexity of target LM intersection and shortest-path algorithms that follow. Intersection, shortest path, FSA expansion and RTN replacement algorithms are presented for PDAs. Chinese-to-English translation experiments using HiFST and HiPDT, FSA and PDA-based decoders, are presented using admissible (or exact) search, possible for HiFST with compact SCFG rulesets and HiPDT with compact LMs. For large rulesets with large LMs, we introduce a two-pass search strategy which we then analyze in terms of search errors and translation performance.

1 Introduction

Hierarchical phrase-based translation, using a *synchronous context-free translation grammar* (SCFG) together with an n-gram target language model (LM), is a popular approach in machine translation (Chiang, 2007). Given a SCFG G and an n-gram language model M, this paper focuses on how to *decode* with them, i.e. how to apply them to the source text to generate a target translation. Decoding has three basic steps, which we first describe in terms of the formal languages and relations involved, with data representations and algorithms to follow.

1. *Translating the source sentence s with G to give target translations:* $\mathcal{T} = \{s\} \circ \mathcal{G}$, a (weighted) context-free language resulting from the composition of a finite language and the algebraic relation $\mathcal{G}$ for SCFG G.
2. *Applying the language model to these target translations:* $\mathcal{L} = \mathcal{T} \cap \mathcal{M}$, a (weighted) context-free language resulting from the intersection of a context-free language and the regular language $\mathcal{M}$ for M.
3. *Searching for the translation and language model combination with the highest-probablity path:* $\hat{\mathcal{L}} = \mathrm{argmax}_{l \in \mathcal{L}} L$

Of course, decoding requires explicit data representations and algorithms for combining and searching them. In common to the approaches we will consider here, s is applied to G by using the CYK algorithm in Step 1 and M is represented by a finite automaton in Step 2. The choice of the representation of $\mathcal{T}$ in many ways determines the remaining decoder representations and algorithms needed. Since $\{s\}$ is a finite language and we assume throughout that G does not allow unbounded insertions, $\mathcal{T}$ and $\mathcal{L}$ are, in fact, regular languages. As such, $\mathcal{T}$ and $\mathcal{L}$ have finite automaton representations T_f and L_f. In this case, weighted finite-state intersection and single-source shortest path algorithms (using negative log probabilities) can be used to solve Steps 2 and 3 (Mohri, 2009). This is the approach taken in (Iglesias et al., 2009a; de Gispert et al., 2010). Instead $\mathcal{T}$ and $\mathcal{L}$ can be represented by *hypergraphs* T_h and L_h (or very similarly context-free rules, and-or trees, or deductive systems). In this case, hypergraph intersection with a finite automaton and hypergraph shortest path algorithms can be used to solve Steps 2 and 3 (Huang, 2008). This is the approach taken by Chiang (2007). In this paper, we will consider another representation for context-free languages $\mathcal{T}$ and $\mathcal{L}$ as well, *pushdown automata* (PDA) T_p and L_p, familiar from formal

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1373–1383,
Edinburgh, Scotland, UK, July 27–31, 2011.

language theory (Aho and Ullman, 1972). We will describe PDA intersection with a finite automaton and PDA shortest-path algorithms in Section 2 that can be used to solve Steps 2 and 3. It cannot be over-emphasized that the CFG, hypergraph and PDA representations of $\mathcal{T}$ are used for their compactness rather than for expressing non-regular languages.

As presented so far, the search performed in Step 3 is *admissible* (or *exact*) – the true shortest path is found. However, the search space in MT can be quite large. Many systems employ aggressive pruning during the shortest-path computation with little theoretical or empirical guarantees of correctness. Further, such pruning can greatly complicate any complexity analysis of the underlying representations and algorithms. In this paper, we will exclude any inadmissible pruning in the shortest-path algorithm itself. This allows us in Section 3 to compare the computational complexity of using these different representations. We show that the PDA representation is particularly suited for decoding with large SCFGs and compact LMs.

We present Chinese-English translation results under the FSA and PDA translation representations. We describe a two-pass translation strategy which we have developed to allow use of the PDA representation in large-scale translation. In the first pass, translation is done using a lattice-generating version of the shortest path algorithm. The full translation grammar is used but with a compact, entropy-pruned version (Stolcke, 1998) of the full language model. This first-step uses admissible pruning and lattice generation under the compact language model. In the second pass, the original, unpruned LM is simply applied to the lattices produced in the first pass. We find that entropy-pruning and first-pass translation can be done so as to introduce very few search errors in the overall process; we can identify search errors in this experiment by comparison to exact translation under the full translation grammar and language model using the FSA representation. We then investigate a translation grammar which is large enough that exact translation under the FSA representation is not possible. We find that translation is possible using the two-pass strategy with the PDA translation representation and that gains in BLEU score result from using the larger translation grammar.

1.1 Related Work

There is extensive prior work on computational efficiency and algorithmic complexity in hierarchical phrase-based translation. The challenge is to find algorithms that can be made to work with large translation grammars and large language models.

Following the original algorithms and analysis of Chiang (2007), Huang and Chiang (2007) developed the cube-growing algorithm, and more recently Huang and Mi (2010) developed an incremental decoding approach that exploits left-to-right nature of the language models.

Search errors in hierarchical translation, and in translation more generally, have not been as extensively studied; this is undoubtedly due to the difficulties inherent in finding exact translations for use in comparison. Using a relatively simple phrase-based translation grammar, Iglesias et al. (2009b) compared search via cube-pruning to an exact FST implementation (Kumar et al., 2006) and found that cube-pruning suffered significant search errors. For Hiero translation, an extensive comparison of search errors between the cube pruning and FSA implementation was presented by Iglesias et al. (2009a) and de Gispert et al. (2010). Relaxation techniques have also recently been shown to finding exact solutions in parsing (Koo et al., 2010) and in SMT with tree-to-string translation grammars and trigram language models (Rush and Collins, 2011), much smaller models compared to the work presented in this paper.

Although entropy-pruned language models have been used to produce real-time translation systems (Prasad et al., 2007), we believe our use of entropy-pruned language models in two-pass translation to be novel. This is an approach that is widely-used in automatic speech recognition (Ljolje et al., 1999) and we note that it relies on efficient representation of very large search spaces $\mathcal{T}$ for subsequent rescoring, as is possible with FSAs and PDAs.

2 Pushdown Automata

In this section, we formally define pushdown automata and give intersection, shortest-path and related algorithms that will be needed later.

Informally, pushdown automata are finite automata that have been augmented with a stack. Typ-

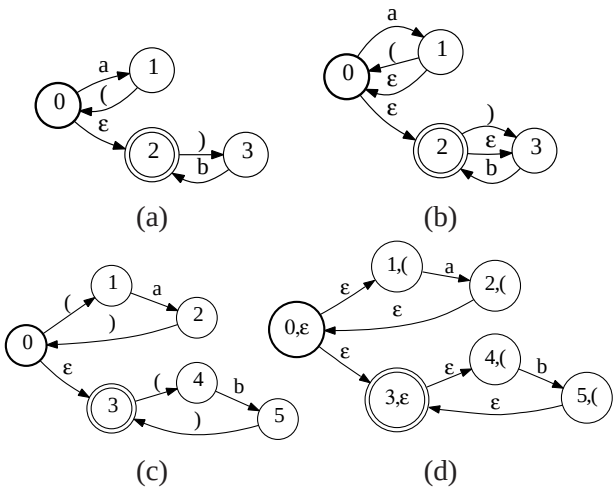

Figure 1: PDA Examples: (a) Non-regular PDA accepting $\{a^n b^n | n \in \mathbb{N}\}$. (b) Regular (but not bounded-stack) PDA accepting a^*b^*. (c) Bounded-stack PDA accepting a^*b^* and (d) its expansion as an FSA.

ically this is done by adding a stack alphabet and labeling each transition with a stack operation (a stack symbol to be pushed onto, popped or read from the stack) in additon to the usual input label (Aho and Ullman, 1972; Berstel, 1979) and weight (Kuich and Salomaa, 1986; Petre and Salomaa, 2009). Our equivalent representation allows a transition to be labeled by a stack operation or a regular input symbol but not both. Stack operations are represented by pairs of open and close parentheses (pushing a symbol on and popping it from the stack). The advantage of this representation is that is identical to the finite automaton representation except that certain symbols (the parentheses) have special semantics. As such, several finite-state algorithms either immediately generalize to this PDA representation or do so with minimal changes. The algorithms described in this section have been implemented in the PDT extension (Allauzen and Riley, 2011) of the OpenFst library (Allauzen et al., 2007).

2.1 Definitions

A (restricted) Dyck language consist of "well-formed" or "balanced" strings over a finite number of pairs of parentheses. Thus the string ([( ) ( )] { } [ ]) ( ) is in the Dyck language over 3 pairs of parentheses.

More formally, let A and $\overline{A}$ be two finite alphabets such that there exists a bijection f from A to $\overline{A}$. Intuitively, f maps an open parenthesis to its corresponding close parenthesis. Let $\bar{a}$ denote $f(a)$ if $a \in A$ and $f^{-1}(a)$ if $a \in \overline{A}$. The *Dyck language* D_A over the alphabet $\widehat{A} = A \cup \overline{A}$ is then the language defined by the following context-free grammar: $S \to \epsilon$, $S \to SS$ and $S \to aS\bar{a}$ for all $a \in A$. We define the mapping $c_A : \widehat{A}^* \to \widehat{A}^*$ as follow. $c_A(x)$ is the string obtained by iteratively deleting from x all factors of the form $a\bar{a}$ with $a \in A$. Observe that $D_A = c_A^{-1}(\epsilon)$.

Let A and B be two finite alphabets such that $B \subseteq A$, we define the mapping $r_B : A^* \to B^*$ by $r_B(x_1 \dots x_n) = y_1 \dots y_n$ with $y_i = x_i$ if $x_i \in B$ and $y_i = \epsilon$ otherwise.

A *weighted pushdown automaton* (PDA) T over the tropical semiring $(\mathbb{R} \cup \{\infty\}, \min, +, \infty, 0)$ is a 9-tuple $(\Sigma, \Pi, \overline{\Pi}, Q, E, I, F, \rho)$ where Σ is the finite input alphabet, Π and $\overline{\Pi}$ are the finite open and close parenthesis alphabets, Q is a finite set of states, $I \in Q$ the initial state, $F \subseteq Q$ the set of final states, $E \subseteq Q \times (\Sigma \cup \widehat{\Pi} \cup \{\epsilon\}) \times (\mathbb{R} \cup \{\infty\}) \times Q$ a finite set of transitions, and $\rho : F \to \mathbb{R} \cup \{\infty\}$ the final weight function. Let $e = (p[e], i[e], w[e], n[e])$ denote a transition in E.

A path π is a sequence of transitions $\pi = e_1 \dots e_n$ such that $n[e_i] = p[e_{i+1}]$ for $1 \leq i < n$. We then define $p[\pi] = p[e_1]$, $n[\pi] = n[e_n]$, $i[\pi] = i[e_1] \cdots i[e_n]$, and $w[\pi] = w[e_1] + \ldots + w[e_n]$.

A path π is accepting if $p[\pi] = I$ and $n[\pi] \in F$. A path π is balanced if $r_{\widehat{\Pi}}(i[\pi]) \in D_\Pi$. A balanced path π accepts the string $x \in \Sigma^*$ if it is a balanced accepting path such that $r_\Sigma(i[\pi]) = x$.

The *weight associated by* T to a string $x \in \Sigma^*$ is $T(x) = \min_{\pi \in P(x)} w[\pi] + \rho(n[\pi])$ where $P(x)$ denotes the set of balanced paths accepting x. A weighted language is recognizable by a weighted pushdown automaton iff it is context-free. We define the *size* of T as $|T| = |Q| + |E|$.

A PDA T has *a bounded stack* if there exists $K \in \mathbb{N}$ such that for any sub-path π of any balanced path in T: $|c_\Pi(r_{\widehat{\Pi}}(i[\pi]))| \leq K$. If T has a bounded stack, then it represents a regular language. Figure 1 shows non-regular, regular and bounded-stack PDAs.

A *weighted finite automaton* (FSA) can be viewed as a PDA where the open and close parentheses alphabets are empty, see (Mohri, 2009) for a standalone definition.

2.2 Expansion Algorithm

Given a bounded-stack PDA T, the *expansion* of T is the FSA T' equivalent to T defined as follows.

A state in T' is a pair (q, z) where q is a state in T and $z \in \Pi^*$. A transition (q, a, w, q') in T results in a transition $((q, z), a', w, (q', z'))$ in T' only when: (a) $a \in \Sigma \cup \{\epsilon\}$, $z' = z$ and $a' = a$, (b) $a \in \Pi$, $z' = za$ and $a' = \epsilon$, or (c) $a \in \overline{\Pi}$, z' is such that $z = z'\overline{a}$ and $a' = \epsilon$. The initial state of T' is $I' = (I, \epsilon)$. A state (q, z) in T' is final if q is final in T and $z = \epsilon$ ($\rho'((q, \epsilon)) = \rho(q)$). The set of states of T' is the set of pairs (q, z) that can be reached from an initial state by transitions defined as above. The condition that T has a bounded stack ensures that this set is finite (since it implies that for any (q, z), $|z| \leq K$).

The complexity of the algorithm is linear in $O(|T'|) = O(e^{|T|})$. Figure 1d show the result of the algorithm when applied to the PDA of Figure 1c.

2.3 Intersection Algorithm

The class of weighted pushdown automata is closed under intersection with weighted finite automata (Bar-Hillel et al., 1964; Nederhof and Satta, 2003). Considering a pair (T_1, T_2) where one element is an FSA and the other element a PDA, then there exists a PDA $T_1 \cap T_2$, the *intersection* of T_1 and T_2, such that for all $x \in \Sigma^*$: $(T_1 \cap T_2)(x) = T_1(x) + T_2(x)$. We assume in the following that T_2 is an FSA. We also assume that T_2 has no input-ϵ transitions. When T_2 has input-ϵ transitions, an epsilon filter (Mohri, 2009; Allauzen et al., 2011) generalized to handle parentheses can be used.

A state in $T = T_1 \cap T_2$ is a pair (q_1, q_2) where q_1 is a state of T_1 and q_2 a state of T_2. The initial state is $I = (I_1, I_2)$. Given a transition $e_1 = (q_1, a, w_1, q_1')$ in T_1, transitions out of (q_1, q_2) in T are obtained using the following rules.

If $a \in \Sigma$, then e_1 can be matched with a transition (q_2, a, w_2, q_2') in T_2 resulting a transition $((q_1, q_2), a, w_1 + w_2, (q_1', q_2'))$ in T.

If $a = \epsilon$, then e_1 is matched with staying in q_2 resulting in a transition $((q_1, q_2), \epsilon, w_1, (q_1', q_2))$.

Finally, if $a \in \widehat{\Pi}$, e_1 is also matched with staying in q_2, resulting in a transition $((q_1, q_2), a, w_1, (q_1', q_2))$ in T.

A state (q_1, q_2) in T is final when both q_1 and q_2 are final, and then $\rho((q_1, q_2)) = \rho_1(q_1) + \rho_2(q_2)$.

The complexity of the algorithm is in $O(|T_1||T_2|)$.

2.4 Shortest Distance and Path Algorithms

A *shortest path* in a PDA T is a balanced accepting path with minimal weight and the *shortest distance* in T is the weight of such a path. We show that when T has a bounded stack, shortest distance and shortest path can be computed in $O(|T|^3 \log |T|)$ time (assuming T has no negative weights) and $O(|T|^2)$ space.

Given a state s in T with at least one incoming open parenthesis transition, we denote by C_s the set of states that can be reached from s by a balanced path. If s has several incoming open parenthesis transitions, a naive implementation might lead to the states in C_s to be visited up to exponentially many times. The basic idea of the algorithm is to memoize the shortest distance from s to states in C_s. The

pseudo-code is given in Figure 2.

GETDISTANCE(T, s) starts a new instance of the shortest-distance algorithm from s using the queue $\mathcal{S}_s$, initially containing s. While the queue is not empty, a state is dequeued and its outgoing transitions examined (line 5-9). Transitions labeled by non-parenthesis are treated as in Mohri (2009) (line 9-10). When the considered transition e is labeled by a close parenthesis, it is remembered that it balances all incoming open parentheses in s labeled by $\overline{i[e]}$ by adding e to $B[s, \overline{i[e]}]$ (line 11-12). Finally, when e is labeled with an open parenthesis, if its destination has not already been visited, a new instance is started from $n[e]$ (line 14-15). The destination states of all transitions balancing e are then relaxed (line 16-18).

The space complexity of the algorithm is quadratic for two reasons. First, the number of non-infinity $d[q, s]$ is $|Q|^2$. Second, the space required for storing B is at most in $O(|E|^2)$ since for each open parenthesis transition e, the size of $|B[n[e], i[e]]|$ is $O(|E|)$ in the worst case. This last observation also implies that the cumulated number of transitions examined at line 16 is in $O(N|Q|\ |E|^2)$ in the worst case, where N denotes the maximal number of times a state is inserted in the queue for a given call of GETDISTANCE. Assuming the cost of a queue operation is $\Gamma(n)$ for a queue containing n elements, the worst-case time complexity of the algorithm can then be expressed as $O(N|T|^3\ \Gamma(|T|))$. When T contains no negative weights, using a shortest-first queue discipline leads to a time complexity in $O(|T|^3 \log |T|)$. When all the C_s's are acyclic, using a topological order queue discipline leads to a $O(|T|^3)$ time complexity.

In effect, we are solving a k-sources shortest-path problem with k single-source solutions. A potentially better approach might be to solve the k-sources or k-pairs problem directly (Hershberger et al., 2003).

When T has been obtained by converting an RTN or an hypergraph into a PDA (Section 2.5), the polynomial dependency in $|T|$ becomes a linear dependency both for the time and space complexities. Indeed, for each q in T, there exists a unique s such that $d[q, s]$ is non-infinity. Moreover, for each close parenthesis transistion e, there exists a unique open parenthesis transition e' such that $e \in B[n[e'], i[e']]$. When each component of the RTN is acyclic, the complexity of the algorithm is hence in $O(|T|)$ in time and space.

The algorithm can be modified to compute the shortest path by keeping track of parent pointers.

2.5 Replacement Algorithm

A *recursive transition network* (RTN) can be specified by $(N, \Sigma, (T_\nu)_{\nu \in N}, S)$ where N is an alphabet of nonterminals, Σ is the input alphabet, $(T_\nu)_{\nu \in N}$ is a family of FSAs with input alphabet $\Sigma \cup N$, and $S \in N$ is the root nonterminal.

A string $x \in \Sigma^*$ is accepted by R if there exists an accepting path π in T_S such that recursively replacing any transition with input label $\nu \in N$ by an accepting path in T_ν leads to a path π^* with input x. The weight associated by R is the minimum over all such π^* of $w[\pi^*] + \rho_S(n[\pi^*])$.

Given an RTN R, the *replacement* of R is the PDA T equivalent to R defined by the 9-tuple $(\Sigma, \Pi, \overline{\Pi}, Q, E, I, F, \sigma, \rho)$ with $\Pi = Q = \bigcup_{\nu \in N} Q_\nu$, $I = I_S$, $F = F_S$, $\rho = \rho_S$, and $E = \bigcup_{\nu \in N} \bigcup_{e \in E_\nu} E^e$ where $E^e = \{e\}$ if $i[e] \notin N$ and $E^e = \{(p[e], n[e], w[e], I_\mu), (f, \overline{n[e]}, \rho_\mu(f), n[e]) | f \in F_\mu\}$ with $\mu = i[e] \in N$ otherwise.

The complexity of the construction is in $O(|T|)$. If $|F_\nu| = 1$, then $|T| = O(\sum_{\nu \in N} |T_\nu|) = O(|R|)$. Creating a superfinal state for each T_ν would lead to a T whose size is always linear in the size of R.

3 Hierarchical Phrase-Based Translation Representation

In this section, we compare several different representations for the target translations $\mathcal{T}$ of the source sentence s by synchronous CFG G prior to language model M application. As discussed in the introduction, $\mathcal{T}$ is a context-free language. For example, suppose it corresponds to:

$$S \rightarrow abXdg,\ S \rightarrow acXfg,\ \text{and}\ X \rightarrow bc.$$

Figure 3 shows several alternative representations of $\mathcal{T}$: Figure 3a shows the hypergraph representation of this grammar; there is a 1:1 correspondence between each production in the CFG and each hyperedge in the hypergraph. Figure 3b shows the RTN representation of this grammar with a 1:1 correspondence between each production in the CFG and each path in the RTN; this is the translation representation pro-

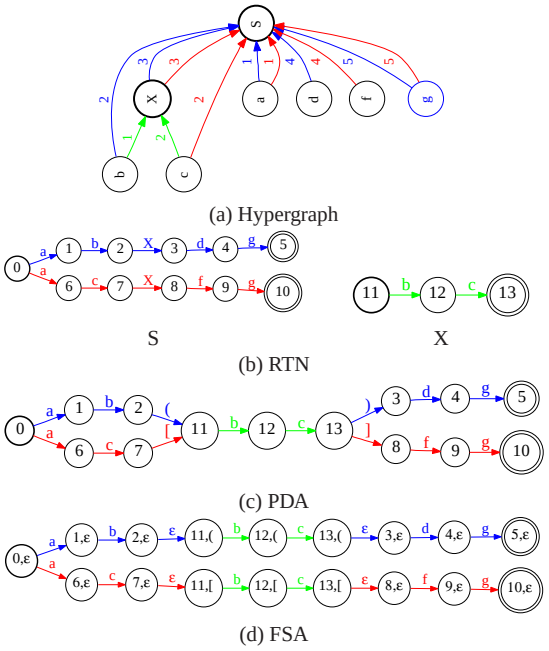

Figure 3: Alternative translation representations

duced by the HiFST decoder (Iglesias et al., 2009a; de Gispert et al., 2010). Figure 3c shows the push-down automaton representation generated from the RTN with the replacement algorithm of Section 2.5. Since s is a finite language and G does not allow unbounded insertion, T_p has a bounded stack and $\mathcal{T}$ is, in fact, a regular language. Figure 3d shows the finite-state automaton representation of $\mathcal{T}$ generated by the PDA using the expansion algorithm of Section 2.2. The HiFST decoder converts its RTN translation representation immediately into the finite-state representation using an algorithm equivalent to converting the RTN into a PDA followed by PDA expansion.

As shown in Figure 4, an advantage of the RTN, PDA, and FSA representations is that they can benefit from FSA epsilon removal, determinization and minimization algorithms applied to their components (for RTNs and PDAs) or their entirety (for FSAs). For the complexity discussion below, however, we disregard these optimizations. Instead we focus on the complexity of each MT step described in the introduction:

1. *SCFG Translation:* Assuming that the parsing of the input is performed by a CYK parse, then the CFG, hypergraph, RTN and PDA representations can be generated in $O(|s|^3|G|)$ time and space (Aho and Ullman, 1972). The FSA representation can require an additional $O(e^{|s|^3|G|})$ time and space since the PDA expansion can be exponential.
2. *Intersection:* The intersection of a CFG T_h with a finite automaton M can be performed by the classical Bar-Hillel algorithm (Bar-Hillel et al., 1964) with time and space complexity $O(|T_h||M|^3)$.[1] The PDA intersection algorithm from Section 2.3 has time and space complexity $O(|T_p||M|)$. Finally, the FSA intersection algorithm has time and space complexity $O(|T_f||M|)$ (Mohri, 2009).
3. *Shortest Path:* The shortest path algorithm on the hypergraph, RTN, and FSA representations requires linear time and space (given the underlying acyclicity) (Huang, 2008; Mohri, 2009). As presented in Section 2.4, the PDA representation can require time cubic and space quadratic in $|M|$.[2]

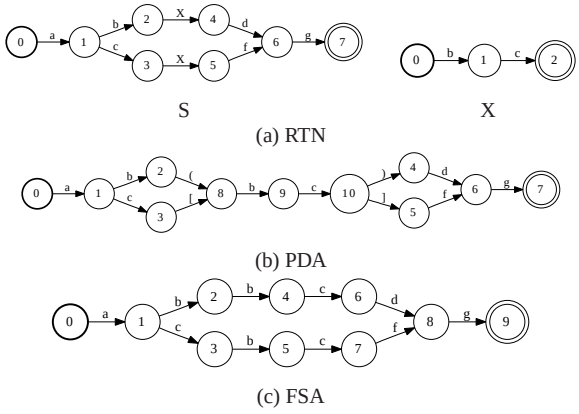

Figure 4: Optimized translation representations

Table 1 summarizes the complexity results. Note the PDA representation is equivalent in time and superior in space to the CFG/hypergraph representation, in general, and it can be superior in both space

[1]The modified Bar-Hillel construction described by Chiang (2007) has time and space complexity $O(|T_h||M|^4)$; the modifications were introduced presumably to benefit the subsequent pruning method employed (but see Huang et al. (2005)).

[2]The time (resp. space) complexity is not cubic (resp. quadratic) in $|T_p||M|$. Given a state q in T_p, there exists a unique s_q such that q belongs to C_{s_q}. Given a state (q_1, q_2) in $T_p \cap M$, $(q_1, q_2) \in C_{(s_1,s_2)}$ only if $s_1 = s_{q_1}$, and hence (q_1, q_2) belongs to at most $|M|$ components.

Representation	Time Complexity	Space Complexity
CFG/hypergraph	$O(\|s\|^3 \, \|G\| \, \|M\|^3)$	$O(\|s\|^3 \, \|G\| \, \|M\|^3)$
PDA	$O(\|s\|^3 \, \|G\| \, \|M\|^3)$	$O(\|s\|^3 \, \|G\| \, \|M\|^2)$
FSA	$O(e^{\|s\|^3 \|G\|} \, \|M\|)$	$O(e^{\|s\|^3 \|G\|} \, \|M\|)$

Table 1: Complexity using various target translation representations.

and time to the FSA representation depending on the relative SCFG and LM sizes. The FSA representation favors smaller target translation sets and larger language models. Should a better complexity PDA shortest path algorithm be found, this conclusion could change. In practice, the PDA and FSA representations benefit hugely from the optimizations mentioned above, these optimizations improve the time and space usage by one order of magnitude.

4 Experimental Framework

We use two hierarchical phrase-based SMT decoders. The first one is a lattice-based decoder implemented with weighted finite-state transducers (de Gispert et al., 2010) and described in Section 3. The second decoder is a modified version using PDAs as described in Section 2. In order to distinguish both decoders we call them HiFST and HiPDT, respectively. The principal difference between the two decoders is where the finite-state *expansion* step is done. In HiFST, the RTN representation is immediately expanded to an FSA. In HiPDT, this expansion is delayed as late as possible - in the output of the shortest path algorithm. Another possible configuration is to expand after the LM intersection step but before the shortest path algorithm; in practice this is quite similar to HiFST.

In the following sections we report experiments in Chinese-to-English translation. For translation model training, we use a subset of the GALE 2008 evaluation parallel text;[3] this is 2.1M sentences and approximately 45M words per language. We report translation results on a development set *tune-nw* (1,755 sentences) and a test set *test-nw* (1,671 sentences). These contain translations produced by the GALE program and portions of the newswire sections of MT02 through MT06. In tuning the systems, standard MERT (Och, 2003) iterative parameter estimation under IBM BLEU[4] is performed on the development set.

[3]See http://projects.ldc.upenn.edu/gale/data/catalog.html. We excluded the UN material and the LDC2002E18, LDC2004T08, LDC2007E08 and CUDonga collections.

207.5	20.2	4.1	0.9

Table 2: Number of ngrams (in millions) in the 1st pass 4-gram language models obtained with different θ values (top row).

The parallel corpus is aligned using MTTK (Deng and Byrne, 2008) in both source-to-target and target-to-source directions. We then follow standard heuristics (Chiang, 2007) and filtering strategies (Iglesias et al., 2009b) to extract hierarchical phrases from the union of the directional word alignments. We call a translation grammar the set of rules extracted from this process. We extract two translation grammars:

- A restricted grammar where we apply the following additional constraint: rules are only considered if they have a forward translation probability $p > 0.01$. We call this G_1. As will be discussed later, the interest of this grammar is that decoding under it can be exact, that is, without any pruning in search.
- An unrestricted one without the previous constraint. We call this G_2. This is a superset of the previous grammar, and exact search under it is not feasible for HiFST: pruning is required in search.

The initial English language model is a Kneser-Ney 4-gram estimated over the target side of the parallel text and the AFP and Xinhua portions of monolingual data from the English Gigaword Fourth Edition (LDC2009T13). This is a total of 1.3B words. We will call this language model M_1. For large language model rescoring we also use the LM M_2 obtained by interpolating M_1 with a zero-cutoff stupid-backoff (Brants et al., 2007) 5-gram estimated using 6.6B words of English newswire text.

We next describe how we build translation systems using entropy-pruned language models.

1. We build a baseline HiFST system that uses M_1 and a hierarchical grammar G, parameters being optimized with MERT under BLEU.

[4]See ftp://jaguar.ncsl.nist.gov/mt/resources/mteval-v13.pl

2. We then use entropy-based pruning of the language model (Stolcke, 1998) under a relative perplexity threshold of θ to reduce the size of M_1. We will call the resulting language model as M_1^θ. Table 2 shows the number of n-grams (in millions) obtained for different θ values.
3. We translate with M_1^θ using the same parameters obtained in MERT in step 1, except for the word penalty, tuned over the lattices under BLEU performance. This produces a translation lattice in the topmost cell that contains hypotheses with exact scores under the translation grammar and M_1^θ.
4. Translation lattices in the topmost cell are pruned with a likelihood-based beam width β.
5. We remove the M_1^θ scores from the pruned translation lattices and reapply M_1, moving the word penalty back to the original value obtained in MERT. These operations can be carried out efficiently via standard FSA operations.
6. Additionally, we can rescore the translation lattices obtained in steps 1 or 5 with the larger language model M_2. Again, this can be done via standard FSA operations.

Note that if $\beta = \infty$ or if $\theta = 0$, the translation lattices obtained in step 1 should be identical to the ones of step 5. While the goal is to increase θ to reduce the size of the language model used at Step 3, β will have to increase accordingly so as to avoid pruning away desirable hypotheses in Step 4. If β defines a sufficiently wide beam to contain the hypotheses which would be favoured by M_1, faster decoding with M_1^θ would be possible without incurring search errors M_1. This is investigated next.

5 Entropy-Pruned LM in Rescoring

In Table 3 we show translation performance under grammar G_1 for different values of θ. Performance is reported after first-pass decoding with M_1^θ (see step 3 in Section 4), after rescoring with M_1 (see step 5) and after rescoring with M_2 (see step 6). The baseline (experiment number 1) uses $\theta = 0$ (that is, M_1) for decoding.

Under translation grammar G_1, HiFST is able to generate an FSA with the entire space of possible candidate hypotheses. Therefore, any degradation in performance is only due to the M_1^θ involved in decoding and the β applied prior to rescoring.

As shown in row number 2, for $\theta \leq 10^{-9}$ the system provides the same performance to the baseline when $\beta > 8$, while decoding time is reduced by roughly 40%. This is because M_1^θ is 10% of the size of the original language model M_1, as shown in Table 2. As M_1^θ is further reduced by increasing θ (see rows number 3 and 4), decoding time is also reduced. However, the beam width β required in order to recover the good hypotheses in rescoring increases, reaching 12 for experiment 3 and 15 for experiment 4.

Regarding rescoring with the larger M_2 (step 6 in Section 4), the system is also able to match the baseline performance as long as β is wide enough, given the particular M_1^θ used in first-pass decoding. Interestingly, results show that a similar β value is needed when rescoring either with M_1 or M_2.

The usage of entropy-pruned language models increments speed at the risk of search errors. For instance, comparing the outputs of systems 1 and 2 with $\beta = 10$ in Table 3 we find 45 different 1-best hypotheses, even though the BLEU score is identical. In other words, we have 45 cases in which system 2 is not able to recover the baseline output because the 1st-pass likelihood beam β is not wide enough. Similarly, system 3 fails in 101 cases ($\beta = 12$) and system 4 fails in 95 cases. Interestingly, some of these sentences would require impractically huge beams. This might be due to the Kneser-Ney smoothing, which interacts badly with entropy pruning (Chelba et al., 2010).

6 Hiero with PDAs and FSAs

In this section we contrast HiFST with HiPDT under the same translation grammar and entropy-pruned language models. Under the constrained grammar G_1 their performance is identical as both decoders can generate the entire search space which can then be rescored with M_1 or M_2 as shown in the previous section.

Therefore, we now focus on the unconstrained grammar G_2, where exact search is not feasible for HiFST. In order to evaluate this problem, we run both decoders over *tune-nw*, restricting memory usage to 10 gigabytes. If this limit is reached in decod-

HiFST (G_1 + M_1^θ)						+M_1		+M_2	
#	θ	*tune-nw*	*test-nw*	*time*	β	*tune-nw*	*test-nw*	*tune-nw*	*test-nw*
1	**0 (M_1)**	**34.3**	**34.5**	**0.68**	-	-	-	**34.8**	**35.6**
2	7.5×10^{-9}	32.0	32.8	0.38	*10*	34.3	34.5	34.8	35.6
					9			34.9	35.5
					8				
3	7.5×10^{-8}	29.5	30.0	0.28	*12*	34.2	34.5	34.7	35.6
					9	34.3	34.4	34.8	35.2
					8	34.2			35.1
4	7.5×10^{-7}	26.0	26.4	0.20	*15*	34.2	34.5	34.7	35.6
					12		34.4		35.5

Table 3: Results (lowercase IBM BLEU scores) under G_1 with various M_1^θ as obtained with several values of θ. Performance in subsequent rescoring with M_1 and M_2 after likelihood-based pruning of the translation lattices for various β is also reported. Decoding time, in seconds/word over *test-nw*, refers strictly to first-pass decoding.

Exact search for G_2 + M_1^θ with memory usage under 10 GB							
#	θ	HiFST			HiPDT		
		Success	**Failure**		**Success**	**Failure**	
			Expand	*Compose*		*Compose*	*Expand*
2	7.5×10^{-9}	12	51	37	40	8	52
3	7.5×10^{-8}	16	53	31	76	1	23
4	7.5×10^{-7}	18	53	29	99.8	0	0.2

Table 4: Percentage of success in producing the 1-best translation under G_2 with various M_1^θ when applying a hard memory limitation of 10 GB, as measured over *tune-nw* (1755 sentences). If decoder fails, we report what step was being done when the limit was reached. HiFST could be expanding into an FSA or composing the FSA with M_1^θ; HiPDT could be PDA composing with M_1^θ or PDA expanding into an FSA.

HiPDT (G_2 + M_1^θ)				+M_1		+M_2	
θ	*tune-nw*	*test-nw*	β	*tune-nw*	*test-nw*	*tune-nw*	*test-nw*
7.5×10^{-7}	25.7	26.3	15	34.6	34.8	35.2	36.1

Table 5: HiPDT performance on grammar G_2 with $\theta = 7.5 \times 10^{-7}$. Exact search with HiFST is not possible under these conditions: pruning during search would be required.

ing, the process is killed[5]. We report what internal decoding operation caused the system to crash. For HiFST, these include expansion into an FSA (*Expand*) and subsequent intersection with the language model (*Compose*). For HiPDT, these include PDA intersection with the language model (*Compose*) and subsequent expansion into an FSA (*Expand*), using algorithms described in Section 2.

Table 4 shows the number of times each decoder succeeds in finding a hypothesis given the memory limit, and the operations being carried out when they fail to do so, when decoding with various M_1^θ. With $\theta = 7.5 \times 10^{-9}$ (row 2), HiFST can only decode 218 sentences, while HiPDT succeeds in 703 cases. The differences between both decoders increase as the M_1^θ is more reduced, and for $\theta = 7.5 \times 10^{-7}$ (row 4), HiPDT is able to perform exact search over all but three sentences.

Table 5 shows performance using the latter configuration (Table 4, row 4). After large language model rescoring, HiPDT improves 0.5 BLEU over baseline with G_1 (Table 3, row 1).

7 Discussion and Conclusion

HiFST fails to decode mainly because the expansion into an FST leads to far too big search spaces (e.g. fails 938 times under $\theta = 7.5 \times 10^{-8}$). If it succeeds in expanding the search space into an FST, the decoder still has to compose with the language model, which is also critical in terms of memory us-

[5]We used *ulimit* command. The experiment was carried out over machines with different configurations and load. Therefore, these numbers must be considered as approximate values.

age (fails 536 times). In contrast, HiPDT creates a PDA, which is a more compact representation of the search space and allows efficient intersection with the language model before expansion into an FST. Therefore, the memory usage is considerably lower. Nevertheless, the complexity of the language model is critical for the PDA intersection and very specially the PDA expansion into an FST (fails 403 times for $\theta = 7.5 \times 10^{-8}$).

With the algorithms presented in this paper, decoding with PDAs is possible for any translation grammar as long as an entropy pruned LM is used. While this allows exact decoding, it comes at the cost of making decisions based on less complex LMs, although this has been shown to be an adequate strategy when applying compact CFG rulesets. On the other hand, HiFST cannot decode under large translation grammars, thus requiring pruning during lattice construction, but it can apply an unpruned LM in this process. We find that with carefully designed pruning strategies, HiFST can match the performance of HiPDT reported in Table 5. But without pruning in search, expansion directly into an FST would lead to an explosion in terms of memory usage. Of course, without memory constraints both strategies would reach the same performance.

Overall, these results suggest that HiPDT is more robust than HiFST when using complex hierarchical grammars. Conversely, FSTs might be more efficient for search spaces described by more constrained hierarchical grammars. This suggests that a hybrid solution could be effective: we could use PDAs or FSTs e.g. depending on the number of states of the FST representing the expanded search space, or other conditions.

Abstract

Mining of transliterations from comparable or parallel text can enhance natural language processing applications such as machine translation and cross language information retrieval. This paper presents an enhanced transliteration mining technique that uses a generative graph reinforcement model to infer mappings between source and target character sequences. An initial set of mappings are learned through automatic alignment of transliteration pairs at character sequence level. Then, these mappings are modeled using a bipartite graph. A graph reinforcement algorithm is then used to enrich the graph by inferring additional mappings. During graph reinforcement, appropriate link reweighting is used to promote good mappings and to demote bad ones. The enhanced transliteration mining technique is tested in the context of mining transliterations from parallel Wikipedia titles in 4 alphabet-based languages pairs, namely English-Arabic, English-Russian, English-Hindi, and English-Tamil. The improvements in F1-measure over the baseline system were 18.7, 1.0, 4.5, and 32.5 basis points for the four language pairs respectively. The results herein outperform the best reported results in the literature by 2.6, 4.8, 0.8, and 4.1 basis points for the four language pairs respectively.

Introduction

Transliteration Mining (TM) is the process of finding transliterated word pairs in parallel or comparable corpora. TM has many potential applications such as mining training data for transliteration, improving lexical coverage for machine translation, and cross language retrieval via translation resource expansion. TM has been gaining some attention lately with a shared task in the ACL 2010 NEWS workshop (Kumaran, et al. 2010).

One popular statistical TM approach is performed in two stages. First, a generative model is trained by performing automatic character level alignment of parallel transliterated word pairs to find character segment mappings between source and target languages. Second, given comparable or parallel text, the trained generative model is used to generate possible transliterations of a word in the source language while constraining the transliterations to words that exist in the target language.

However, two problems arise in this approach:

1. Many possible character sequence mappings between source and target languages may not be observed in training data, particularly when limited training data is available – hurting recall.
2. Conditional probability estimates of obtained mappings may be inaccurate, because some mappings and some character sequences may not

appear a sufficient number of times in training to properly estimate their probabilities – hurting precision.

In this paper we focus on overcoming these two problems to improve overall TM. To address the first problem, we modeled the automatically obtained character sequence mappings (from alignment) as a bipartite graph and then we performed graph reinforcement to enrich the graph and predict possible mappings that were not directly obtained from training data. The example in Figure 1 motivates graph reinforcement. In the example, the Arabic letter "ق" (pronounced as "qa") was not aligned to the English letter "c" in training data. Such a mapping seems probable given that another Arabic letter, "ك" (pronounced as "ka"), maps to two English letters, "q" and "k", to which "ق" also maps. In this case, there are multiple paths that would lead to a mapping between the Arabic letter "ق" and the English letter "c", namely ق ➔ q ➔ ك ➔ c and ق ➔ k ➔ ك ➔ c. By using multiple paths as sources of evidence, we can infer the new mapping and estimate its probability.

Another method for overcoming the missing mappings problem entails assigning small smoothing probabilities to unseen mappings. However, from looking at the graph, it is evident that some mappings could be inferred and should be assigned probabilities that are higher than a small smoothing probability.

The second problem has to do primarily with some characters in one language, typically vowels, mapping to many character sequences in the other language, with some of these mappings assuming very high probabilities (due to limited training data). To overcome this problem, we used link reweighting in graph reinforcement to scale down the likelihood of mappings to target character sequences in proportion to how many source sequences map to them.

We tested the proposed method using the ACL 2010 NEWS workshop data for English-Arabic, English-Russian, English-Hindi, and English-Tamil (Kumaran et al., 2010). For each language pair, the standard ACL 2010 NEWS workshop data contained a base set of 1,000 transliteration pairs for training, and set of 1,000 parallel Wikipedia titles for testing.

The contributions of the paper are:

1. Employing graph reinforcement to improve the coverage of automatically aligned data – as they apply to transliteration mining. This positively affects recall.
2. Applying link reweighting to overcome situations where certain tokens – character sequences in the case of transliteration – tend to have many mappings, which are often erroneous. This positively affects precision.

The rest of the paper is organized as follows: Section 2 surveys prior work on transliteration mining; Section 3 describes the baseline TM approach and reports on its effectiveness; Section 4 describes the proposed graph reinforcement along with link reweighting and reports on the observed improvements; and Section 5 concludes the paper.

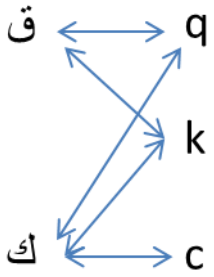

Figure 1: Example mappings seen in training

Background

Much work has been done on TM for different language pairs such as English-Chinese (Kuo et al., 2006; Kuo et al., 2007; Kuo et al., 2008; Jin et al. 2008;), English-Tamil (Saravanan and Kumaran, 2008; Udupa and Khapra, 2010), English-Korean (Oh and Isahara, 2006; Oh and Choi, 2006), English-Japanese (Qu et al., 2000; Brill et al., 2001; Oh and Isahara, 2006), English-Hindi (Fei et al., 2003; Mahesh and Sinha, 2009), and English-Russian (Klementiev and Roth, 2006).

TM typically involves two main tasks, namely: finding character mappings between two languages, and given the mappings ascertaining whether two words are transliterations or not. When training with a limited number of transliteration pairs, two additional problems appear: many possible character sequence mappings between source and target languages may not be observed in training data, and conditional probability estimates of obtained

mappings may be inaccurate. These two problems affect recall and precision respectively.

1.1 Finding Character Mappings

To find character sequence mappings between two languages, the most common approach entails using automatic letter alignment of transliteration pairs. Akin to phrasal alignment in machine translation, character sequence alignment is treated as a word alignment problem between parallel sentences, where transliteration pairs are treated as if they are parallel sentences and the characters from which they are composed are treated as if they are words. Automatic alignment can be performed using different algorithms such as the EM algorithm (Kuo et al., 2008; Lee and Chang, 2003) or HMM based alignment (Udupa et al., 2009a; Udupa et al., 2009b). In this paper, we use automatic character alignment between transliteration pairs using an HMM aligner. Another method is to use automatic speech recognition confusion tables to extract phonetically equivalent character sequences to discover monolingual and cross lingual pronunciation variations (Kuo and Yang, 2005). Alternatively, letters can be mapped into a common character set using a predefined transliteration scheme (Oh and Choi, 2006).

1.2 Transliteration Mining

For the problem of ascertaining if two words can be transliterations of each other, a common approach involves using a generative model that attempts to generate all possible transliterations of a source word, given the character mappings between two languages, and restricting the output to words in the target language (Fei et al., 2003; Lee and Chang, 2003, Udupa et al., 2009a). This is similar to the baseline approach that we used in this paper. Noeman and Madkour (2010) implemented this technique using a finite state automaton by generating all possible transliterations along with weighted edit distance and then filtered them using appropriate thresholds and target language words. They reported the best TM results between English and Arabic with F1-measure of 0.915 on the ACL-2010 NEWS workshop standard TM dataset. A related alternative is to use back-transliteration to determine if one sequence could have been generated by successively mapping character sequences from one language into another (Brill et al., 2001; Bilac and Tanaka, 2005; Oh and Isahara, 2006).

Udupa and Khapra (2010) proposed a method in which transliteration candidates are mapped into a "low-dimensional common representation space". Then, similarity between the resultant feature vectors for both candidates can be computed. Udupa and Kumar (2010) suggested that mapping to a common space can be performed using context sensitive hashing. They applied their technique to find variant spellings of names.

Jiampojamarn et al. (2010) used classification to determine if a source language word and target language word are valid transliterations. They used a variety of features including edit distance between an English token and the Romanized versions of the foreign token, forward and backward transliteration probabilities, and character n-gram similarity. They reported the best results for Russian, Tamil, and Hindi with F1-measure of 0.875, 0.924, and 0.914 respectively on the ACL-2010 NEWS workshop standard TM datasets.

1.3 Training with Limited Training Data

When only limited training data is available to train a character mapping model, the resultant mappings are typically incomplete (due to sparseness in the training data). Further, resultant mappings may not be observed a sufficient of times and hence their mapping probabilities may be inaccurate.

Different methods were proposed to solve these two problems. These methods focused on making training data less sparse by performing some kind of letter conflation. Oh and Choi (2006) used a SOUNDEX like scheme. SOUNDEX is used to convert English words into a simplified phonetic representation, in which vowels are removed and phonetically similar characters are conflated. A variant of SOUNDEX along with iterative training was proposed by Darwish (2010). Darwish (2010) reported significant improvements in TM recall at the cost of limited drop in precision. Another method involved expanding character sequence maps by automatically mining transliteration pairs and then aligning these pairs to generate an expanded set of character sequence maps (Fei et al., 2003). In this work we proposed graph

reinforcement with link reweighting to address this problem. Graph reinforcement was used in the context of different problems such as mining paraphrases (Zhao et al., 2008; Kok and Brockett, 2010; Bannard and Callison-Burch 2005) and named entity translation extraction (You et al., 2010).

Baseline Transliteration Mining

1.4 Description of Baseline System

The basic TM setup that we employed in this work used a generative transliteration model, which was trained on a set of transliteration pairs. The training involved automatically aligning character sequences. The alignment was performed using a Bayesian learner that was trained on word dependent transition models for HMM based word alignment (He, 2007). Alignment produced mappings of source character sequences to target character sequences along with the probability of source given target and vice versa. Source character sequences were restricted to be 1 to 3 characters long.

For all the work reported herein, given an English-foreign language transliteration candidate pair, English was treated as the target language and the foreign language as the source. Given a foreign source language word sequence F_1^n and an English target word sequence E_1^m, $F_i \in F_1^n$ could be a potential transliteration of $E_j \in E_1^m$. An example of word sequences pair is the Tamil-English pair: (முதலாம் ஹைலி செலாசி, Haile Selassie I of Ethiopia), where "முதலாம்" could be transliteration for any or none of the English words {"Haile", "Selassie", "I", "of", "Ethiopia"}. The pseudo code below describes how transliteration mining generates candidates.

Basically, given a source language word, all possible segmentations, where each segment has a maximum length of 3 characters, are produced along with their associated mappings into the target language. Given all mapping combinations, combinations producing valid target words are retained and sorted according to the product of their mapping probabilities. If the product of the mapping probabilities for the top combination is above a certain threshold, then it is chosen as the transliteration candidate. Otherwise, no candidate is chosen. To illustrate how TM works, consider the following example: Given the Arabic word "من", all possible segmentations are (م ، ن) and (من). Given the target words {the, best, man} and the possible mappings for the segments and their probabilities:

مـ = {(m, 0.7), (me, 0.25), (ma, 0.05)}

ن = {n, 0.7), (nu, 0.2), (an, 0.1)}

من = {(men, 0.4), (man, 0.3), (mn, 0.3)}

The only combinations leading valid target words would be:

(من) ➔ {(man: 0.3)}

(مـ ، ن) ➔ {(m,an: 0.07), (ma, n: 0.035)}

Consequently, the algorithm would produce the tuple with the highest probability: (من , man, 0.3).

As the pseudo code suggests, the actual implementation is optimized via: incremental left to right processing of source words; the use of a Patricia trie to prune mapping combinations that don't lead to valid words; and the use of a priority queue to insure that the best candidate is always at the top of the queue.

1.5 Smoothing and Thresholding

We implemented the baseline system with and without assigning small smoothing probabilities for unseen source character to target character mappings. Subsequent to training, the smoothing probability was selected as the smallest observed mapping probability in training.

We used a threshold on the minimum acceptable transliteration score to filter out unreliable transliterations. We couldn't fix a minimum score for reliable transliterations to a uniform value for all words, because this would have caused the model to filter out long transliterations. Thus, we tied the threshold to the length of transliterated words. We assumed a threshold d for single character mappings and the transliteration threshold for a target word of length l was computed as d^l. We selected d by sorting the mapping probabilities, removing the lowest 10% of mapping probabilities (which we assumed to be outliers), and then selecting the smallest observed probability to be the character threshold d. The choice of removing the lowest ranking 10% of mapping probabilities was based on intuition, because we did not have a validation set. The threshold was then applied to filter out transliteration with $TransliterationScore < d^l$.

1.6 Effectiveness of Baseline System

To test the effectiveness of the baseline system, we used the standard TM training and test datasets from the ACL-2010 NEWS workshop shared task. The datasets are henceforth collectively referred to as the NEWS dataset. The dataset included 4 alphabet-based language pairs, namely English-Arabic, English-Russian, English-Hindi, and English-Tamil. For each pair, a dataset included a list of 1,000 parallel transliteration word pairs to train a transliteration model, and a list of 1,000 parallel word sequences to test TM. The parallel sequences in the test sets were extracted titles from Wikipedia article for which cross language links exist between both languages.

We preprocessed the different languages as follows:

- Russian: characters were case-folded
- Arabic: the different forms of alef (alef, alef maad, alef with hamza on top, and alef with hamza below it) were normalized to alef, ya and alef maqsoura were normalized to ya, and ta marbouta was mapped to ha.
- English: letters were case-folded and the following letter conflations were performed:
  ž, ż → z á, â, ä, à, ã, ā, ą, æ → a
  é, ę, è → e ć, č, ç →c
  ł →l ï, í, ì, î → i
  ó, ō, ö, õ → o ń, ñ, ṅ → n
  ș, ś, ß, š → s ř → r
  ý → y ū, ü, ú, û → u
- Tamil and Hindi: no preprocessing was performed.

English/	P		R		F	
Arabic	0.988	0.983	0.583	0.603	0.733	0.748
Russian	0.975	0.967	0.831	0.862	0.897	0.912
Hindi	0.986	0.981	0.693	0.796	0.814	0.879
Tamil	0.984	0.981	0.274	0.460	0.429	0.626

Table 1: Baseline results for all language pairs. Results with smoothing are shaded.

Table 1 reports the precision, recall, and F1-measure results for using the baseline system in TM between English and each of the 4 other languages in the NEWS dataset with and without smoothing. As is apparent in the results, without smoothing, precision is consistently high for all languages, but recall is generally poor, particularly for Tamil. When smoothing is applied, we observed a slight drop in precision for Arabic, Hindi, and Tamil and a significant drop of 5.6

basis points for Russian. However, the application of smoothing increased recall dramatically for all languages, particularly Tamil. For the remainder of the paper, the results with smoothing are used as the baseline results.

Background

1.7 Description of Graph Reinforcement

In graph reinforcement, the mappings deduced from the alignment process were represented using a bipartite graph G = (S, T, M), where S was the set of source language character sequences, T was the set of target language character sequences, and M was the set of mappings (links or edges) between S and T. The score of each mapping m(v1|v2), where m(v1|v2) ∈ M, was initially set to the conditional probability of target given source p(v1|v2). Graph reinforcement was performed by traversing the graph from S ➔ T ➔ S ➔ T in order to deduce new mappings. Given a source sequence s' ∈ S and a target sequence t' ∈ T, the deduced mapping probabilities were computed as follows (Eq.1):

$$m(t'|s') = 1 - \prod_{\forall s \in S, t \in T} \left(1 - m(t'|s)m(s|t)m(t|s')\right)$$

where the term $\left(1 - m(t'|s)m(s|t)m(t|s')\right)$ computed the probability that a mapping is not correct. Hence, the probability of an inferred mapping would be boosted if it was obtained from multiple paths. Given the example in Figure 1, m(c|ق) would be computed as follows:

$$1 - \left(1 - m(c|ك)m(ك|q)m(q|ق)\right)\left(1 - m(c|ك)m(ك|k)m(k|ق)\right)$$

We were able to apply reinforcement iteratively on all mappings from S to T to deduce previously unseen mappings (graph edges) and to update the probabilities of existing mappings.

1.8 Link Reweighting

The basic graph reinforcement algorithm is prone to producing irrelevant mappings by using character sequences with many different possible mappings as a bridge. Vowels were the most obvious examples of such character sequences. For example, automatic alignment produced 26 Hindi character sequences that map to the English letter "a", most of which were erroneous such as the mapping between "a" and "व" (pronounced va). Graph reinforcement resulted in many more such mappings. After successive iterations, such character sequences would cause the graph to be fully connected and eventually the link weights will tend to be uniform in their values. To illustrate this effect, we experimented with basic graph reinforcement on the NEWS dataset. The figures of merit were precision, recall, and F1-measure. Figures 3, 4, 5, and 6 show reinforcement results for Arabic, Russian, Hindi, and Tamil respectively. The figures show that: recall increased quickly and nearly saturated after several iterations; precision continued to drop with more iterations; and F1-measure peaked after a few iterations and began to drop afterwards. This behavior was undesirable because overall F1-measure values did not converge with iterations, necessitating the need to find clear stopping conditions.

To avoid this effect and to improve precision, we applied link reweighting after each iteration. Link reweighting had the effect of decreasing the weights of target character sequences that have many source character sequences mapping to them and hence reducing the effect of incorrectly inducing mappings. Link reweighting was performed as follows (Eq. 2):

$$m'(s|t) = \frac{m(s|t)}{\sum_{s_i \in S} m(s_i|t)}$$

Where $s_i \in S$ is a source character sequence that maps to *t*. So in the case of "a" mapping to the "व" character in Hindi, the link weight from "a" to "व" is divided by the sum of link weights from "a" to all 26 characters to which "a" maps.

We performed multiple experiments on the NEWS dataset to test the effect of graph reinforcement with link reweighting with varying number of reinforcement iterations. Figures 7, 8, 9, and 10 compare baseline results with smoothing to results with graph reinforcement at different iterations.

As can be seen in the figures, the F1-measure values stabilized as we performed multiple graph reinforcement iterations. Except for Russian, the results across different languages behaved in a similar manner.

For Russian, graph reinforcement marginally affected TM F1-measure, as precision and recall

marginally changed. The net improvement was 1.1 basis points. English and Russian do not share the same alphabet, and the number of initial mappings was bigger compared to the other language pairs. Careful inspection of the English-Russian test set, with the help of a Russian speaker, suggests that:
1) the test set reference contained many false negatives;
2) Russian names often have multiple phonetic forms (or spellings) in Russian with a single standard transliteration in English. For example, the Russian name "Olga" is often written and pronounced as "Ola" and "Olga" in Russian; and
3) certain English phones do not exist in Russian, leading to inconsistent character mappings in Russian. For example, the English phone for "g", as in "George", does not exist in Russian.

For the other languages, graph reinforcement yielded steadily improving recall and consequently steadily improving F1-measure. Most improvements were achieved within the first 5 iterations, and improvements beyond 10 iterations were generally small (less than 0.5 basis points in F1-measure). After 15 iterations, the improvements in overall F1-measure above the baseline with smoothing were 19.3, 5.3, and 32.8 basis points for Arabic, Tamil, and Hindi respectively. The F1-measure values seemed to stabilize with successive iterations. The least improvements were observed for Hindi. This could be attributed to the fact that Hindi spelling is largely phonetic, making letters in words pronounceable in only one way. This fact makes transliteration between Hindi and English easier than Arabic and Tamil. In the case of Tamil, the phonetics of letters change depending on the position of letters in words. As for Arabic, multiple letters sequences in English can map to single letters in Arabic and vice versa. Also, Arabic has diacritics which are typically omitted, but commonly transliterate to English vowels. Thus, the greater the difference in phonetics between two languages and the greater the phonetic complexity of either, the more TM can gain from the proposed technique.

1.9 When Graph Reinforcement Worked

An example where reinforcement worked entails the English-Arabic transliteration pair (Seljuq, سلاجقه). In the baseline runs with 1,000 training examples, both were not mapped to each other because there were no mappings between the letter "q" and the Arabic letter sequence "قه" (pronounced as "qah"). The only mappings that were available for "q" were "كه" (pronounced as "kah"), "ق" (pronounced as "q"), and "ك" (pronounced as "k") with probabilities 54.0, 0.10, and 5452 respectively. Intuitively, the third mapping is more likely than the second. After 3 graph reinforcement iterations, the top 5 mappings for "q" were "ق" (pronounced as "q"), "قه" (pronounced as "qah"), "كه" (pronounced as "kah"), "ك" (pronounced as "k"), and "الق" (pronounced as "alq") with mapping probabilities of 0.22, 0.19, 0.15, 0.05, and 0.05 respectively. In this case, graph reinforcement was able to find the missing mapping and properly reorder the mappings. Performing 10 iterations with link reweighting for Arabic led to 17 false positives. Upon examining them, we found that: 9 were actually correct, but erroneously labeled as false in the test set; 6 were phonetically similar like "اسبانيا" (pronounced espanya) and "Spain" and "التكنولوجيا" (pronounced alteknologya) and "technology"; and the remaining 2 were actually wrong, which were "بيتشي" (pronounced beatchi) and "medici" and "سيدي" (pronounced sidi) and "taya". This seems to indicate that graph reinforcement generally introduced more proper mappings than improper ones.

1.10 Comparing to the State-of-the-Art

Table 2 compares the best reported results in ACL-2010 NEWS TM shared task for Arabic (Noeman and Madkour, 2010) and for the other languages (Jiampojamarn et al. 2010) and the results obtained by the proposed technique using 10 iterations, with link reweighting. The comparison shows that the proposed algorithm yielded better results than the best reported results in the literature by 2.6, 4.8, 0.8 and 4.1 F1-measure points in Arabic, Russian, Hindi and Tamil respectively. For Arabic, the improvement over the previously reported result was due to improvement in precision, while for the other languages the improvements were due to improvements in both recall and precision.

Russian	0.880	0.869	0.875	0.921	0.925	0.923
Hindi	0.954	0.895	0.924	0.972	0.895	0.932
Tamil	0.923	0.906	0.914	0.964	0.945	0.955

Table 2: Best results obtained in ACL-2010 NEWS TM shared task compared to graph reinforcement with link reweighting after 10 iterations

Conclusion

In this paper, we presented a graph reinforcement algorithm with link reweighting to improve transliteration mining recall and precision by systematically inferring mappings that were unseen in training. We used the improved technique to extract transliteration pairs from parallel Wikipedia titles. The proposed technique solves two problems in transliteration mining, namely: some mappings may not be seen in training data – hurting recall, and certain mappings may not be seen a sufficient number of times to appropriate estimate mapping probabilities – hurting precision. The results showed that graph reinforcement yielded improved transliteration mining from parallel Wikipedia titles for all four languages on which the technique was tested.

Generally iterative graph reinforcement was able to induce unseen mappings in training data – improving recall. Link reweighting favored precision over recall counterbalancing the effect of graph reinforcement. The proposed system outperformed the best reported results in the literature for the ACL-2010 NEWS workshop shared task for Arabic, Russian, Hindi and Tamil. To extend the work, we would like to try transliteration mining from large comparable texts. The test parts of the NEWS dataset only contained short parallel fragments. For future work, graph reinforcement could be extended to MT to improve the coverage of aligned phrase tables. In doing so, it is reasonable to assume that there are multiple ways of expressing a singular concept and hence multiple translations are possible. Using graph reinforcement can help discover such translation though they may never be seen in training data. Using link reweighting in graph reinforcement can help demote unlikely translations while promoting likely ones. This could help clean MT phrase tables. Further, when dealing with transliteration, graph reinforcement can help find phonetic variations within a single language, which can have interesting applications in spelling correction and information retrieval. Applying the same to machine translation phrase tables can help identify paraphrases automatically.

Abstract

Modelling compositional meaning for sentences using empirical distributional methods has been a challenge for computational linguists. We implement the abstract categorical model of Coecke et al. (2010) using data from the BNC and evaluate it. The implementation is based on unsupervised learning of matrices for relational words and applying them to the vectors of their arguments. The evaluation is based on the word disambiguation task developed by Mitchell and Lapata (2008) for intransitive sentences, and on a similar new experiment designed for transitive sentences. Our model matches the results of its competitors in the first experiment, and betters them in the second. The general improvement in results with increase in syntactic complexity showcases the compositional power of our model.

1 Introduction

As competent language speakers, we humans can almost trivially make sense of sentences we've never seen or heard before. We are naturally good at understanding ambiguous words given a context, and forming the meaning of a sentence from the meaning of its parts. But while human beings seem comfortable doing this, machines fail to deliver. Search engines such as Google either fall back on bag of words models—ignoring syntax and lexical relations—or exploit superficial models of lexical semantics to retrieve pages with terms related to those in the query (Manning et al., 2008).

However, such models fail to shine when it comes to processing the semantics of phrases and sentences. Discovering the process of meaning assignment in natural language is among the most challenging and foundational questions of linguistics and computer science. The findings thereof will increase our understanding of cognition and intelligence and shall assist in applications to automating language-related tasks such as document search.

Compositional type-logical approaches (Montague, 1974; Lambek, 2008) and distributional models of lexical semantics (Schutze, 1998; Firth, 1957) have provided two partial orthogonal solutions to the question. Compositional formal semantic models stem from classical ideas from mathematical logic, mainly Frege's principle that the meaning of a sentence is a function of the meaning of its parts (Frege, 1892). Distributional models are more recent and can be related to Wittgenstein's later philosophy of 'meaning is use', whereby meanings of words can be determined from their context (Wittgenstein, 1953). The logical models relate to well known and robust logical formalisms, hence offering a scalable theory of meaning which can be used to reason inferentially. The distributional models have found their way into real world applications such as thesaurus extraction (Grefenstette, 1994; Curran, 2004) or automated essay marking (Landauer, 1997), and have connections to semantically motivated information retrieval (Manning et al., 2008). This two-sortedness of defining properties of meaning: 'logical form' versus 'contextual use', has left the quest for 'what is the foundational structure of meaning?' even more of a challenge.

Recently, Coecke et al. (2010) used high level cross-disciplinary techniques from logic, category

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1394–1404,
Edinburgh, Scotland, UK, July 27–31, 2011.

theory, and physics to bring the above two approaches together. They developed a unified mathematical framework whereby a sentence vector is by definition a function of the Kronecker product of its word vectors. A concrete instantiation of this theory was exemplified on a toy hand crafted corpus by Grefenstette et al. (2011). In this paper we implement it by training the model over the entire BNC. The highlight of our implementation is that words with relational types, such as verbs, adjectives, and adverbs are matrices that *act* on their arguments. We provide a general algorithm for building (or indeed learning) these matrices from the corpus.

The implementation is evaluated against the task provided by Mitchell and Lapata (2008) for disambiguating intransitive verbs, as well as a similar new experiment for transitive verbs. Our model improves on the best method evaluated in Mitchell and Lapata (2008) and offers promising results for the transitive case, demonstrating its scalability in comparison to that of other models. But we still feel there is need for a different class of experiments to showcase merits of compositionality in a statistically significant manner. Our work shows that the categorical compositional distributional model of meaning permits a practical implementation and that this opens the way to the production of large scale compositional models.

2 Two Orthogonal Semantic Models

Formal Semantics To compute the meaning of a sentence consisting of n words, meanings of these words must *interact* with one another. In formal semantics, this further interaction is represented as a function derived from the grammatical structure of the sentence, but meanings of words are amorphous objects of the domain: no distinction is made between words that have the same type. Such models consist of a pairing of syntactic interpretation rules (in the form of a grammar) with semantic interpretation rules, as exemplified by the simple model presented in Figure 1.

The parse of a sentence such as "cats like milk" typically produces its semantic interpretation by substituting semantic representation for their grammatical constituents and applying β-reduction where needed. Such a derivation is shown in Figure 2.

Syntactic Analysis	Semantic Interpretation
S $\rightarrow$ NP VP	$\|VP\|(\|NP\|)$
NP $\rightarrow$ cats, milk, etc.	$\|\text{cats}\|$, $\|\text{milk}\|$, ...
VP $\rightarrow$ Vt NP	$\|Vt\|(\|NP\|)$
Vt $\rightarrow$ like, hug, etc.	$\lambda yx.\|\text{like}\|(x, y)$, ...

Figure 1: A simple model of formal semantics.

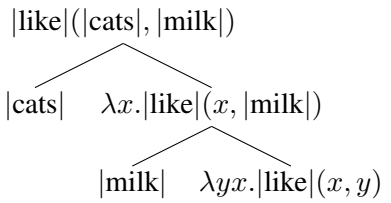

Figure 2: A parse tree showing a semantic derivation.

This methodology is used to translate sentences of natural language into logical formulae, then use computer-aided automation tools to reason about them (Alshawi, 1992). One major drawback is that the result of such analysis can only deal with truth or falsity as the meaning of a sentence, and says nothing about the closeness in meaning or topic of expressions beyond their truth-conditions and what models satisfy them, hence do not perform well on language tasks such as search. Furthermore, an underlying domain of objects and a valuation function must be provided, as with any logic, leaving open the question of how we might *learn* the meaning of language using such a model, rather than just use it.

Distributional Models Distributional models of semantics, on the other hand, dismiss the interaction between syntactically linked words and are solely concerned with lexical semantics. Word meaning is obtained empirically by examining the *contexts*[1] in which a word appears, and equating the meaning of a word with the distribution of contexts it shares. The intuition is that context of use is what we appeal to in learning the meaning of a word, and that words that frequently have the same sort of context in common are likely to be semantically related.

For instance, beer and sherry are both drinks, alcoholic, and often cause a hangover. We expect these facts to be reflected in a sufficiently large corpus: the words 'beer' and 'sherry' occur within the

[1] *E.g.* words which appear in the same sentence or n-word window, or words which hold particular grammatical or dependency relations to the word being learned.

context of identifying words such as 'drink', 'alcoholic' and 'hangover' more frequently than they occur with other content words.

Such context distributions can be encoded as vectors in a high dimensional space with contexts as basis vectors. For any word vector $\overrightarrow{\text{word}}$, the scalar weight c_i^{word} associated with each context basis vector $\overrightarrow{n_i}$ is a function of the number of times the word has appeared in that context. Semantic vectors $(c_1^{word}, c_2^{word}, \cdots, c_n^{word})$ are also denoted by sums of such weight/basis vector pairs:

$$\overrightarrow{\text{word}} = \sum_i c_i^{word} \overrightarrow{n_i}$$

Learning a semantic vector is just learning its basis weights from the corpus. This setting offers geometric means to reason about semantic similarity (*e.g.* via cosine measure or k-means clustering), as discussed in Widdows (2005).

The principal drawback of such models is their non-compositional nature: they ignore grammatical structure and logical words, and hence cannot compute the meanings of phrases and sentences in the same efficient way that they do for words. Common operations discussed in (Mitchell and Lapata, 2008) such as vector addition ($+$) and componentwise multiplication ($\odot$, *cf.* §4 for details) are commutative, hence if $\overrightarrow{vw} = \overrightarrow{v} + \overrightarrow{w}$ or $\overrightarrow{v} \odot \overrightarrow{w}$, then $\overrightarrow{vw} = \overrightarrow{wv}$, leading to unwelcome equalities such as

$$\overrightarrow{\text{the dog bit the man}} = \overrightarrow{\text{the man bit the dog}}$$

Non-commutative operations, such as the Kronecker product (*cf.* §4 for definition) can take word-order into account (Smolensky, 1990) or even some more complex syntactic relations, as described in Clark and Pulman (2007). However, the dimensionality of sentence vectors produced in this manner differs for sentences of different length, barring all sentences from being compared in the same vector space, and growing exponentially with sentence length hence quickly becoming computationally intractable.

3 A Hybrid Logico-Distributional Model

Whereas semantic compositional mechanisms for set-theoretic constructions are well understood, there are no obvious corresponding methods for vector spaces. To solve this problem, Coecke et al. (2010) use the abstract setting of category theory to turn the grammatical structure of a sentence into a morphism compatible with the higher level logical structure of vector spaces.

One pragmatic consequence of this abstract idea is as follows. In distributional models, there is a meaning vector for each word, *e.g.* $\overrightarrow{\text{cats}}$, $\overrightarrow{\text{like}}$, and $\overrightarrow{\text{milk}}$. The logical recipe tells us to *apply* the meaning of the verb to the meanings of subject and object. But how can a vector *apply* to other vectors? The solution proposed above implies that one needs to have different levels of meaning for words with different types. This is similar to logical models where verbs are relations and nouns are atomic sets. So verb vectors should be built differently from noun vectors, for instance as matrices.

The general information as to which words should be matrices and which words atomic vectors is in fact encoded in the type-logical representation of the grammatical structure of the sentence. This is the linear map with word vectors as input and sentence vectors as output. Hence, at least theoretically, one should be able to build sentence vectors and compare their synonymity in exactly the same way as one measures word synonymity.

Pregroup Grammars The aforementioned linear maps turn out to be the grammatical reductions of a type-logic called a Lambek pregroup grammar (Lambek, 2008)[2]. Pregroups and vector spaces share the same high level mathematical structure, referred to as a *compact closed category*, for a proof and details of this claim see Coecke et al. (2010); for a friendly introduction to category theory, see Coecke and Paquette (2011). One consequence of this parity is that the grammatical reductions of a pregroup grammar can be directly transformed into linear maps that act on vectors.

In a nutshell, pregroup types are either atomic or compound. Atomic types can be simple (*e.g.* n for noun phrases, s for statements) or left/right superscripted—referred to as adjoint types (*e.g.* n^r and n^l). An example of a compound type is that of a verb $n^r s n^l$. The superscripted types express that the verb is a relation with two arguments of type n,

[2]The usage of pregroup types is not essential, the types of any other logic, for instance CCG can be used, but should be translated into the language of pregroups.

which have to occur to the *right* and to the *left* of it, and that it outputs an argument of the type s. A transitive sentence has types as shown in Figure 3.

Each type n cancels out with its right adjoint n^r from the right and its left adjoint n^l from the left; mathematically speaking these mean[3]

$$n^l n \leq 1 \qquad \text{and} \qquad n n^r \leq 1$$

Here 1 is the unit of concatenation: $1n = n1 = n$. The corresponding grammatical reduction of a transitive sentence is $nn^r sn^l \leq 1s1 = s$. Each such reduction can be depicted as a wire diagram. The diagram of a transitive sentence is shown in Figure 3.

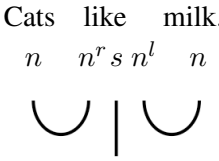

Figure 3: The pregroup types and reduction diagram for a transitive sentence.

Syntax-guided Semantic Composition According to Coecke et al. (2010) and based on a general completeness theorem between compact categories, wire diagrams, and vector spaces, the meaning of sentences can be canonically reduced to linear algebraic formulae. The following is the meaning vector of our transitive sentence:

$$\overrightarrow{\text{cats like milk}} = (f)\Big(\overrightarrow{\text{cats}} \otimes \overrightarrow{\text{like}} \otimes \overrightarrow{\text{milk}}\Big) \qquad (\mathbf{I})$$

Here f is the linear map that encodes the grammatical structure. The categorical morphism corresponding to it is denoted by the tensor product of 3 components: $\epsilon_V \otimes 1_S \otimes \epsilon_W$, where V and W are subject and object spaces, S is the sentence space, the ϵ's are the cups, and 1_S is the straight line in the diagram. The cups stand for taking inner products, which when done with the basis vectors imitate substitution. The straight line stands for the identity map that does nothing. By the rules of the category, equation **(I)** reduces to the following linear algebraic formula with lower dimensions, hence the dimensional explosion problem for Kronecker products is avoided:

$$\sum_{itj} c_{itj} \langle \overrightarrow{\text{cats}} | \overrightarrow{v_i} \rangle \, \overrightarrow{s_t} \, \langle \overrightarrow{w_j} | \overrightarrow{\text{milk}} \rangle \in S \qquad (\mathbf{II})$$

$\overrightarrow{v_i}, \overrightarrow{w_j}$ are basis vectors of V and W. The inner product $\langle \overrightarrow{\text{cats}} \mid \overrightarrow{v_i} \rangle$ substitutes the weights of $\overrightarrow{\text{cats}}$ into the first argument place of the verb (similarly for object and second argument place). $\overrightarrow{s_t}$ is a basis vector of the sentence space S in which meanings of sentences live, regardless of their grammatical structure.

The degree of synonymity of sentences is obtained by taking the cosine measure of their vectors. S is an abstract space: it needs to be instantiated to provide concrete meanings and synonymity measures. For instance, a truth-theoretic model is obtained by taking the sentence space S to be the 2-dimensional space with basis vectors $|1\rangle$ (True) and $|0\rangle$ (False).

4 Building Matrices for Relational Words

In this section we present a general scheme to build matrices for relational words. Recall that given a vector space A with basis $\{\overrightarrow{n_i}\}_i$, the Kronecker product of two vectors $\overrightarrow{v} = \sum_i c_i^a \overrightarrow{n_i}$ and $\overrightarrow{w} = \sum_i c_i^b \overrightarrow{n_i}$ is defined as follows:

$$\overrightarrow{v} \otimes \overrightarrow{w} = \sum_{ij} c_i^a c_j^b \, (\overrightarrow{n_i} \otimes \overrightarrow{n_j})$$

where $(\overrightarrow{n_i} \otimes \overrightarrow{n_j})$ is just the pairing of the basis of A, *i.e.* $(\overrightarrow{n_i}, \overrightarrow{n_j})$. The Kronecker product vectors belong in the tensor product of A with itself: $A \otimes A$, hence if A has dimension r, these will be of dimensionality $r \times r$. The point-wise multiplication of these vectors is defined as follows

$$\overrightarrow{v} \odot \overrightarrow{w} = \sum_i c_i^a c_i^b \, \overrightarrow{n_i}$$

The intuition behind having a matrix for a relational word is that any relation R on sets X and Y, *i.e.* $R \subseteq X \times Y$ can be represented as a matrix, namely one that has as row-bases $x \in X$ and as column-bases $y \in Y$, with weight $c_{xy} = 1$ where $(x, y) \in R$ and 0 otherwise. In a distributional setting, the weights, which are natural or real numbers,

[3] The relation $\leq$ is the partial order of the pregroup. It corresponds to implication $\Longrightarrow$ in a logical reading thereof. If these inequalities are replaced by equalities, *i.e.* if $n^l n = 1 = n n^r$, then the pregroup collapses into a group where $n^l = n^r$.

will represent more: 'the extent according to which x and y are related'. This can be determined in different ways.

Suppose X is the set of animals, and 'chase' is a relation on it: $chase \subseteq X \times X$. Take $x =$ 'dog' and $y =$ 'cat': with our type-logical glasses on, the obvious choice would be to take c_{xy} to be the number of times 'dog' has chased 'cat', *i.e.* the number of times the sentence 'the dog chases the cat' has appeared in the corpus. But in the distributional setting, this method will be too syntactic and dismissive of the actual *meaning* of 'cat' and 'dog'. If instead the corpus contains the sentence 'the hound hunted the wild cat', c_{xy} will be 0, restricting us to only assign meaning to sentences that have directly appeared in the corpus. We propose to, instead, use a level of abstraction by taking words such as verbs to be distributions over the semantic information in the vectors of their context words, rather than over the context words themselves.

Start with an r-dimensional vector space N with basis $\{\overrightarrow{n}_i\}_i$, in which meaning vectors of atomic words, such as nouns, live. The basis vectors of N are in principle all the words from the corpus, however in practice and following Mitchell and Lapata (2008) we had to restrict these to a subset of the most occurring words. These basis vectors are not restricted to nouns: they can as well be verbs, adjectives, and adverbs, so that we can define the meaning of a noun in all possible contexts—as is usual in context-based models—and not only in the context of other nouns. Note that basis words with relational types are treated as pure lexical items rather than as semantic objects represented as matrices. In short, we count how many times a noun has occurred close to words of other syntactic types such as 'elect' and 'scientific', rather than count how many times it has occurred close to their corresponding matrices: it is the lexical tokens that form the context, not their meaning.

Each relational word P with grammatical type π and m adjoint types $\alpha_1, \alpha_2, \cdots, \alpha_m$ is encoded as an $(r \times \ldots \times r)$ matrix with m dimensions. Since our vector space N has a fixed basis, each such matrix is represented in vector form as follows:

$$\overrightarrow{\mathrm{P}} = \sum_{\underbrace{ij\cdots\zeta}_{m}} c_{ij\cdots\zeta} \underbrace{(\overrightarrow{n}_i \otimes \overrightarrow{n}_j \otimes \cdots \otimes \overrightarrow{n}_\zeta)}_{m}$$

This vector lives in the tensor space $\underbrace{N \otimes N \otimes \cdots \otimes N}_{m}$. Each $c_{ij\cdots\zeta}$ is computed according to the procedure described in Figure 4.

1) Consider a sequence of words containing a relational word 'P' and its arguments w_1, w_2, $\cdots$, w_m, occurring in the same order as described in P's grammatical type π. Refer to these sequences as 'P'-relations. Suppose there are k of them.
2) Retrieve the vector $\overrightarrow{\mathrm{w}}_l$ of each argument w_l.
3) Suppose w_1 has weight c_i^1 on basis vector $\overrightarrow{n}_i$, w_2 has weight c_j^2 on basis vector $\overrightarrow{n}_j$, $\cdots$, and w_m has weight c_ζ^m on basis vector $\overrightarrow{n}_\zeta$. Multiply these weights

$$c_i^1 \times c_j^2 \times \cdots \times c_\zeta^m$$

4) Repeat the above steps for all the k 'P'-relations, and sum[a] the corresponding weights

$$c_{ij\cdots\zeta} = \sum_k \left(c_i^1 \times c_j^2 \times \cdots \times c_\zeta^m\right)_k$$

[a] We also experimented with multiplication, but the sparsity of noun vectors resulted in most verb matrices being empty.

Figure 4: Procedure for learning weights for matrices of words 'P' with relational types π of m arguments.

Linear algebraically, this procedure corresponds to computing the following

$$\overrightarrow{\mathrm{P}} = \sum_k \left(\overrightarrow{\mathrm{w}}_1 \otimes \overrightarrow{\mathrm{w}}_2 \otimes \cdots \otimes \overrightarrow{\mathrm{w}}_m\right)_k$$

Type-logical examples of relational words are verbs, adjectives, and adverbs. A transitive verb is represented as a 2 dimensional matrix since its type is $n^r s n^l$ with two adjoint types n^r and n^l. The corresponding vector of this matrix is

$$\overrightarrow{\mathrm{verb}} = \sum_{ij} c_{ij} \left(\overrightarrow{n}_i \otimes \overrightarrow{n}_j\right)$$

The weight c_{ij} corresponding to basis vector $\overrightarrow{n}_i \otimes \overrightarrow{n}_j$, is the extent according to which words that have co-occurred with $\overrightarrow{n}_i$ have been the subject of the 'verb' and words that have co-occurred with $\overrightarrow{n}_j$ have been the object of the 'verb'. This example computation is demonstrated in Figure 5.

1) Consider phrases containing 'verb', its subject w_1 and object w_2. Suppose there are k of them.
2) Retrieve vectors $\overrightarrow{\mathrm{w}}_1$ and $\overrightarrow{\mathrm{w}}_2$.
3) Suppose $\overrightarrow{\mathrm{w}}_1$ has weight c_i^1 on $\overrightarrow{n}_i$ and $\overrightarrow{\mathrm{w}}_2$ has c_j^2 on $\overrightarrow{n}_j$. Multiply these weights $c_i^1 \times c_j^2$.
4) Repeat the above steps for all k 'verb'-relations and sum the corresponding weights $\sum_k (c_i^1 \times c_j^2)_k$

Figure 5: Procedure for learning weights for matrices of transitive verbs.

Linear algebraically, we are computing

$$\overrightarrow{\text{verb}} \quad = \quad \sum_k \left(\overrightarrow{\mathrm{w}}_1 \otimes \overrightarrow{\mathrm{w}}_2\right)_k$$

As an example, consider the verb 'show' and suppose there are two 'show'-relations in the corpus:

s_1 = table show result
s_2 = map show location

The vector of 'show' is

$$\overrightarrow{\text{show}} = \overrightarrow{\text{table}} \otimes \overrightarrow{\text{result}} + \overrightarrow{\text{map}} \otimes \overrightarrow{\text{location}}$$

Consider an N space with four basis vectors 'far', 'room', 'scientific', and 'elect'. The TF/IDF-weighted values for vectors of the above four nouns (built from the BNC) are as shown in Table 1.

i	$\overrightarrow{\mathbf{n_i}}$	table	map	result	location
1	far	6.6	5.6	7	5.9
2	room	27	7.4	0.99	7.3
3	scientific	0	5.4	13	6.1
4	elect	0	0	4.2	0

Table 1: Sample weights for selected noun vectors.

Part of the matrix of 'show' is presented in Table 2.

As a sample computation, the weight c_{11} for vector $(1,1)$, *i.e.* $(\overrightarrow{\text{far}}, \overrightarrow{\text{far}})$ is computed by multiplying weights of 'table' and 'result' on $\overrightarrow{\text{far}}$, *i.e.* 6.6×7,

	far	room	scientific	elect
far	79.24	47.41	119.96	27.72
room	232.66	80.75	396.14	113.2
scientific	32.94	31.86	32.94	0
elect	0	0	0	0

Table 2: Sample semantic matrix for 'show'.

multiplying weights of 'map' and 'location' on $\overrightarrow{\text{far}}$, *i.e.* 5.6×5.9 then adding these $46.2 + 33.04$ and obtaining the total weight 79.24.

The same method is applied to build matrices for ditransitive verbs, which will have 3 dimensions, and adjectives and adverbs, which will be of 1 dimension each.

5 Computing Sentence Vectors

Meaning of sentences are vectors computed by taking the variables of the categorical prescription of meaning (the linear map f obtained from the grammatical reduction of the sentence) to be determined by the matrices of the relational words. For instance the meaning of the transitive sentence 'sub verb obj' is:

$$\overrightarrow{\text{sub verb obj}} = \sum_{itj} \langle \overrightarrow{\text{sub}} \mid \overrightarrow{v}_i \rangle \langle \overrightarrow{w}_j \mid \overrightarrow{\text{obj}} \rangle \, c_{itj} \, \overrightarrow{s}_t$$

We take $V := W := N$ and $S = N \otimes N$, then $\sum_{itj} c_{itj} \overrightarrow{s}_t$ is determined by the matrix of the verb, *i.e.* substitute it by $\sum_{ij} c_{ij} (\overrightarrow{n}_i \otimes \overrightarrow{n}_j)$[4]. Hence $\overrightarrow{\text{sub verb obj}}$ becomes:

$$\sum_{ij} \langle \overrightarrow{\text{sub}} \mid \overrightarrow{n}_i \rangle \langle \overrightarrow{n}_j \mid \overrightarrow{\text{obj}} \rangle c_{ij} (\overrightarrow{n}_i \otimes \overrightarrow{n}_j) \quad = \quad \sum_{ij} c_i^{sub} c_j^{obj} c_{ij} (\overrightarrow{n}_i \otimes \overrightarrow{n}_j)$$

This can be decomposed to point-wise multiplication of two vectors as follows:

$$\left(\sum_{ij} c_i^{sub} c_j^{obj} (\overrightarrow{n}_i \otimes \overrightarrow{n}_j) \right) \odot \left(\sum_{ij} c_{ij} (\overrightarrow{n}_i \otimes \overrightarrow{n}_j) \right)$$

[4]Note that by doing so we are also reducing the verb space from $N \otimes (N \otimes N) \otimes N$ to $N \otimes N$, since for our construction we only need tuples of the form $\overrightarrow{n}_i \otimes \overrightarrow{n}_i \otimes \overrightarrow{n}_j \otimes \overrightarrow{n}_j$ which are isomorphic to pairs $(\overrightarrow{n}_i \otimes \overrightarrow{n}_j)$.

The left argument is the Kronecker product of subject and object vectors and the right argument is the vector of the verb, so we obtain

$$\left(\overrightarrow{\text{sub}} \otimes \overrightarrow{\text{obj}}\right) \odot \overrightarrow{\text{verb}}$$

Since $\odot$ is commutative, this provides us with a distributional version of the type-logical meaning of the sentence: point-wise multiplication of the meaning of the verb to the Kronecker product of its subject and object:

$$\overrightarrow{\text{sub verb obj}} \quad = \quad \overrightarrow{\text{verb}} \odot \left(\overrightarrow{\text{sub}} \otimes \overrightarrow{\text{obj}}\right)$$

This mathematical operation can be informally described as a structured 'mixing' of the information of the subject and object, followed by it being 'filtered' through the information of the verb applied to them, in order to produce the information of the sentence.

In the transitive case, $S = N \otimes N$, hence $\overrightarrow{s}_t = \overrightarrow{n}_i \otimes \overrightarrow{n}_j$. More generally, the vector space corresponding to the abstract sentence space S is the concrete tensor space $(N \otimes \ldots \otimes N)$ for m the dimension of the matrix of the 'verb'. As we have seen above, in practice we do not need to build this tensor space, as the computations thereof reduce to point-wise multiplications and summations.

Similar computations yield meanings of sentences with adjectives and adverbs. For instance the meaning of a transitive sentence with a modified subject and a modified verb we have

$$\overrightarrow{\text{adj sub verb obj adv}} = \left(\overrightarrow{\text{adv}} \odot \overrightarrow{\text{verb}}\right) \odot \left(\left(\overrightarrow{\text{adj}} \odot \overrightarrow{\text{sub}}\right) \otimes \overrightarrow{\text{obj}}\right)$$

After building vectors for sentences, we can compare their meaning and measure their degree of synonymy by taking their cosine measure.

6 Evaluation

Evaluating such a framework is no easy task. What to evaluate depends heavily on what sort of application a practical instantiation of the model is geared towards. In (Grefenstette et al., 2011), it is suggested that the simplified model we presented and expanded here could be evaluated in the same way as lexical semantic models, measuring compositionally built sentence vectors against a benchmark dataset such as that provided by Mitchell and Lapata (2008). In this section, we briefly describe the evaluation of our model against this dataset. Following this, we present a new evaluation task extending the experimental methodology of Mitchell and Lapata (2008) to transitive verb-centric sentences, and compare our model to those discussed by Mitchell and Lapata (2008) within this new experiment.

First Dataset Description The first experiment, described in detail by Mitchell and Lapata (2008), evaluates how well compositional models disambiguate ambiguous words given the context of a potentially disambiguating noun. Each entry of the dataset provides a noun, a target verb and landmark verb (both intransitive). The noun must be composed with both verbs to produce short phrase vectors the similarity of which is measured by the candidate. Also provided with each entry is a classification ("High" or "Low") indicating whether or not the verbs are indeed semantically close within the context of the noun, as well as an evaluator-set similarity score between 1 and 7 (along with an evaluator identifier), where 1 is low similarity and 7 is high.

Evaluation Methodology Candidate models provide a similarity score for each entry. The scores of high similarity entries and low similarity entries are averaged to produce a mean High score and mean Low score for the model. The correlation of the model's similarity judgements with the human judgements is also calculated using Spearman's ρ, a metric which is deemed to be more scrupulous, and ultimately that by which models should be ranked, by Mitchell and Lapata (2008). The mean for each model is on a $[0, 1]$ scale, except for UpperBound which is on the same $[1, 7]$ scale the annotators used. The ρ scores are on a $[-1, 1]$ scale. It is assumed that inter-annotator agreement provides the theoretical maximum ρ for any model for this experiment. The cosine measure of the verb vectors, ignoring the noun, is taken to be the baseline (no composition).

Other Models The other models we compare ours to are those evaluated by Mitchell and Lapata (2008). We provide a selection of the results

from that paper for the worst (Add) and best[5] (Multiply) performing models, as well as the previous second-best performing model (Kintsch). The additive and multiplicative models are simply applications of vector addition and component-wise multiplication. We invite the reader to consult (Mitchell and Lapata, 2008) for the description of Kintsch's additive model and parametric choices.

Model Parameters To provide the most accurate comparison with the existing multiplicative model, and exploiting the aforementioned feature that the categorical model can be built "on top of" existing lexical distributional models, we used the parameters described by Mitchell and Lapata (2008) to reproduce the vectors evaluated in the original experiment as our noun vectors. All vectors were built from a lemmatised version of the BNC. The noun basis was the 2000 most common context words, basis weights were the probability of context words given the target word divided by the overall probability of the context word. Intransitive verb function-vectors were trained using the procedure presented in §4. Since the dataset only contains intransitive verbs and nouns, we used $S = N$. The cosine measure of vectors was used as a similarity metric.

First Experiment Results In Table 3 we present the comparison of the selected models. Our categorical model performs significantly better than the existing second-place (Kintsch) and obtains a ρ quasi-identical to the multiplicative model, indicating significant correlation with the annotator scores.

There is not a large difference between the mean High score and mean Low score, but the distribution in Figure 6 shows that our model makes a non-negligible distinction between high similarity phrases and low similarity phrases, despite the absolute scores not being different by more than a few percentiles.

[5]The multiplicative model presented here is what is qualified as best in (Mitchell and Lapata, 2008). However, they also present a slightly better performing ($\rho = 0.19$) model which is a combination of their multiplicative model and a weighted additive model. The difference in ρ is qualified as "not statistically significant" in the original paper, and furthermore the mixed model requires parametric optimisation hence was not evaluated against the entire test set. For these reasons, we chose not to include it in the comparison.

Model	High	Low	ρ
Baseline	0.27	0.26	0.08
Add	0.59	0.59	0.04
Kintsch	0.47	0.45	0.09
Multiply	0.42	0.28	0.17
Categorical	**0.84**	**0.79**	**0.17**
UpperBound	4.94	3.25	0.40

Table 3: Selected model means for High and Low similarity items and correlation coefficients with human judgements, first experiment (Mitchell and Lapata, 2008). $p < 0.05$ for each ρ.

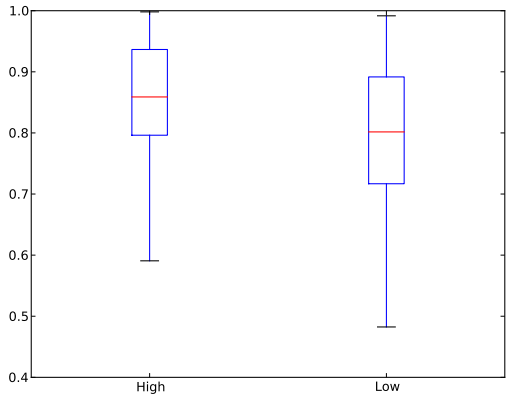

Figure 6: Distribution of predicted similarities for the categorical distributional model on High and Low similarity items.

Second Dataset Description The second dataset[6], developed by the authors, follows the format of the (Mitchell and Lapata, 2008) dataset used for the first experiment, with the exception that the target and landmark verbs are transitive, and an object noun is provided in addition to the subject noun, hence forming a small transitive sentence. The dataset comprises 200 entries consisting of sentence pairs (hence a total of 400 sentences) constructed by following the procedure outlined in §4 of (Mitchell and Lapata, 2008), using transitive verbs from CELEX[7]. For examples of these sentences, see Table 4. The dataset was split into four sections of 100 entries each, with guaranteed 50% exclusive overlap with

[6]http://www.cs.ox.ac.uk/activities/CompDistMeaning/GS2011data.txt

[7]http://celex.mpi.nl/

exactly two other datasets. Each section was given to a group of evaluators, with a total of 25, who were asked to form simple transitive sentence pairs from the verbs, subject and object provided in each entry; for instance 'the table showed the result' from 'table show result'. The evaluators were then asked to rate the semantic similarity of each verb pair within the context of those sentences, and offer a score between 1 and 7 for each entry. Each entry was given an arbitrary classification of HIGH or LOW by the authors, for the purpose of calculating mean high/low scores for each model. For example, the first two pairs in table 4 were classified as HIGH, whereas the second two pairs as LOW.

Sentence 1	Sentence 2
table show result	table express result
map show location	map picture location
table show result	table picture result
map show location	map express location

Table 4: Example entries from the transitive dataset without annotator score, second experiment.

Evaluation Methodology The evaluation methodology for the second experiment was identical to that of the first, as are the scales for means and scores. Here also, Spearman's ρ is deemed a more rigorous way of determining how well a model tracks difference in meaning. This is both because of the imprecise nature of the classification of verb pairs as HIGH or LOW; and since the objective similarity scores produced by a model that distinguishes sentences of different meaning from those of similar meaning can be renormalised in practice. Therefore the delta between HIGH means and LOW mean cannot serve as a definite indication of the practical applicability (or lack thereof) of semantic models; the means are provided just to aid comparison with the results of the first experiment.

Model Parameters As in the first experiment, the lexical vectors from (Mitchell and Lapata, 2008) were used for the other models evaluated (additive, multiplicative and baseline)[8] and for the noun vectors of our categorical model. Transitive verb vectors were trained as described in §4 with $S = N \otimes N$.

Second Experiment Results The results for the models evaluated against the second dataset are presented in Table 5.

Model	High	Low	ρ
Baseline	0.47	0.44	0.16
Add	0.90	0.90	0.05
Multiply	0.67	0.59	0.17
Categorical	**0.73**	**0.72**	**0.21**
UpperBound	4.80	2.49	0.62

Table 5: Selected model means for High and Low similarity items and correlation coefficients with human judgements, second experiment. $p < 0.05$ for each ρ.

We observe a significant (according to $p < 0.0.5$) improvement in the alignment of our categorical model with the human judgements, from 0.17 to 0.21. The additive model continues to make little distinction between senses of the verb during composition, and the multiplicative model's alignment does not change, but becomes statistically indistinguishable from the non-compositional baseline model.

Once again we note that the high-low means are not very indicative of model performance, as the difference between high mean and the low mean of the categorical model is much smaller than that of the both the baseline model and multiplicative model, despite better alignment with annotator judgements.

7 Discussion

In this paper, we described an implementation of the categorical model of meaning (Coecke et al., 2010), which combines the formal logical and the empirical distributional frameworks into a unified semantic model. The implementation is based on building matrices for words with relational types (adjectives, verbs), and vectors for words with atomic types (nouns), based on data from the BNC. We then show how to apply verbs to their subject/object, in order to compute the meaning of intransitive and transitive sentences.

[8] Kintsch was not evaluated as it required optimising model parameters against a held-out segment of the test set, and we could not replicate the methodology of Mitchell and Lapata (2008) with full confidence.

Other work uses matrices to model meaning (Baroni and Zamparelli, 2010; Guevara, 2010), but only for adjective-noun phrases. Our approach easily applies to such compositions, as well as to sentences containing combinations of adjectives, nouns, verbs, and adverbs. The other key difference is that they learn their matrices in a top-down fashion, *i.e.* by regression from the composite adjective-noun context vectors, whereas our model is bottom-up: it learns sentence/phrase meaning compositionally from the vectors of the compartments of the composites. Finally, very similar functions, for example a verb with argument alternations such as 'break' in 'Y breaks' and 'X breaks Y', are not treated as unrelated. The matrix of the intransitive 'break' uses the corpus-observed information about the subject of break, including that of 'Y', similarly the matrix of the transitive 'break' uses information about its subject and object, including that of 'X' and 'Y'. We leave a thorough study of these phenomena, which fall under providing a modular representation of passive-active similarities, to future work.

We evaluated our model in two ways: first against the word disambiguation task of Mitchell and Lapata (2008) for intransitive verbs, and then against a similar new experiment for transitive verbs, which we developed.

Our findings in the first experiment show that the categorical method performs on par with the leading existing approaches. This should not surprise us given that the context is so small and our method becomes similar to the multiplicative model of Mitchell and Lapata (2008). However, our approach is sensitive to grammatical structure, leading us to develop a second experiment taking this into account and differentiating it from models with commutative composition operations.

The second experiment's results deliver the expected qualitative difference between models, with our categorical model outperforming the others and showing an increase in alignment with human judgements in correlation with the increase in sentence complexity. We use this second evaluation principally to show that there is a strong case for the development of more complex experiments measuring not only the disambiguating qualities of compositional models, but also their syntactic sensitivity, which is not directly measured in the existing experiments.

These results show that the high level categorical distributional model, uniting empirical data with logical form, can be implemented just like any other concrete model. Furthermore it shows better results in experiments involving higher syntactic complexity. This is just the tip of the iceberg: the mathematics underlying the implementation ensures that it uniformly scales to larger, more complicated sentences and enables it to compare synonymity of sentences that are of different grammatical structure.

8 Future Work

Treatment of function words such as 'that', 'who', as well as logical words such as quantifiers and conjunctives are left to future work. This will build alongside the general guidelines of Coecke et al. (2010) and concrete insights from the work of Widdows (2005). It is not yet entirely clear how existing set-theoretic approaches, for example that of discourse representation and generalised quantifiers, apply to our setting. Preliminary work on integration of the two has been presented by Preller (2007) and more recently also by Preller and Sadrzadeh (2009).

As mentioned by one of the reviewers, our pregroup approach to grammar flattens the sentence representation, in that the verb is applied to its subject and object at the same time; whereas in other approaches such as CCG, it is first applied to the object to produce a verb phrase, then applied to the subject to produce the sentence. The advantages and disadvantages of this method and comparisons with other systems, in particular CCG, constitutes ongoing work.

Abstract

Context-dependent word similarity can be measured over multiple *cross-cutting* dimensions. For example, *lung* and *breath* are similar thematically, while *authoritative* and *superficial* occur in similar syntactic contexts, but share little semantic similarity. Both of these notions of similarity play a role in determining word meaning, and hence lexical semantic models must take them both into account. Towards this end, we develop a novel model, Multi-View Mixture (MVM), that represents words as multiple *overlapping clusterings*. MVM finds multiple data partitions based on different subsets of features, subject to the marginal constraint that feature subsets are distributed according to Latent Dirichlet Allocation. Intuitively, this constraint favors feature partitions that have coherent topical semantics. Furthermore, MVM uses soft feature assignment, hence the contribution of each data point to each clustering view is variable, isolating the impact of data only to views where they assign the most features. Through a series of experiments, we demonstrate the utility of MVM as an inductive bias for capturing relations between words that are intuitive to humans, outperforming related models such as Latent Dirichlet Allocation.

1 Introduction

Humans categorize objects using multiple orthogonal taxonomic systems, where category generalization depends critically on what features are relevant to one particular system. For example, foods can be organized in terms of their nutritional value (high in fiber) or situationally (commonly eaten for Thanksgiving; Shafto et al. (2006)). Human knowledgebases such as Wikipedia also exhibit such multiple clustering structure (e.g. people are organized by occupation or by nationality). The effects of these overlapping categorization systems manifest themselves at the lexical semantic level (Murphy, 2002), implying that lexicographical word senses and traditional computational models of word-sense based on clustering or exemplar activation are too impoverished to capture the rich dynamics of word usage.

In this work, we introduce a novel probabilistic clustering method, Multi-View Mixture (MVM), based on *cross-cutting categorization* (Shafto et al., 2006) that generalizes traditional *vector-space* or *distributional* models of lexical semantics (Curran, 2004; Padó and Lapata, 2007; Schütze, 1998; Turney, 2006). Cross-cutting categorization finds multiple feature subsets (categorization systems) that produce high quality clusterings of the data. For example words might be clustered based on their part of speech, or based on their thematic usage. Context-dependent variation in word usage can be accounted for by leveraging multiple latent categorization systems. In particular, cross-cutting models can be used to capture both *syntagmatic* and *paradigmatic* notions of word relatedness, breaking up word features into multiple categorization systems and then computing similarity separately for each system.

MVM leverages primitives from Dirichlet-Process Mixture Models (DPMMs) and Latent Dirichlet Allocation (LDA). Each clustering (*view*) in MVM consists of a distribution over features and data and views are further subdivided into clusters based on a DPMM. View marginal distributions are determined by LDA, allowing data features to be distributed over multiple views, explaining subsets of features.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1405–1415,
Edinburgh, Scotland, UK, July 27–31, 2011.

We evaluate MVM against several other model-based clustering procedures in a series of human evaluation tasks, measuring its ability to find meaningful syntagmatic and paradigmatic structure. We find that MVM finds more semantically and syntactically coherent fine-grained structure, using both common and rare n-gram contexts.

2 Mixture Modeling and Lexical Semantics

Distributional, or *vector space* methods attempt to model word meaning by embedding words in a common metric space, whose dimensions are derived from, e.g., word collocations (Schütze, 1998), syntactic relations (Padó and Lapata, 2007), or latent semantic spaces (Finkelstein et al., 2001; Landauer and Dumais, 1997; Turian et al., 2010). The distributional hypothesis addresses the problem of modeling word similarity (Curran, 2004; Miller and Charles, 1991; Schütze, 1998; Turney, 2006), and can be extended to selectional preference (Resnik, 1997) and lexical substitution (McCarthy and Navigli, 2007) as well. Such methods are highly scalable (Gorman and Curran, 2006) and have been applied in information retrieval (Manning et al., 2008), large-scale taxonomy induction (Snow et al., 2006), and knowledge acquisition (Van Durme and Paşca, 2008).

Vector space models fail to capture the richness of word meaning since similarity is not a globally consistent metric. It violates, e.g., the triangle inequality: the sum of distances from *bat* to *club* and *club* to *association* is less than the distance from *bat* to *association* (Griffiths et al., 2007; Tversky and Gati, 1982).[1] Erk (2007) circumvents this problem by representing words as multiple exemplars derived directly from word occurrences and embedded in a common vector space to capture context-dependent usage. Likewise Reisinger and Mooney (2010) take a similar approach using mixture modeling combined with a background variation model to generate multiple prototype vectors for polysemous words.

Both of these approaches still ultimately embed all words in a single metric space and hence argue for globally consistent metrics that capture human intuitive notions of "similarity." Rather than assuming a global metric embedding exists, in this work we simply leverage the *cluster assumption*, e.g. that similar words should appear in the same clusters, in particular extending it to multiple clusterings. The cluster assumption is a natural fit for lexical semantics, as partitions can account for metric violations. The end result is a model capable of representing multiple, overlapping similarity metrics that result in disparate valid clusterings leveraging the

> **Subspace Hypothesis**: For any pair of words, the set of "active" features governing their apparent similarity differs. For example *wine* and *bottle* are similar and *wine* and *vinegar* are similar, but it would not be reasonable to expect that the features governing such similarity computations to overlap much, despite occurring in similar documents.

MVM can extract multiple competing notions of similarity, for example both *paradigmatic*, or thematic similarity, and *syntagmatic* or syntactic similarity, in addition to more fine grained relations.

3 Multi-View Clustering with MVM

As feature dimensionality increases, the number of ways the data can exhibit interesting structure goes up exponentially. Clustering is commonly used to explain data, but often there are several equally valid, competing clusterings, keying off of different subsets of features, especially in high-dimensional settings such as text mining (Niu et al., 2010). For example, company websites can be clustered by sector or by geographic location, with one particular clustering becoming predominant when a majority of features correlate with it. In fact, informative features in one clustering may be noise in another, e.g. the occurrence of *CEO* is not necessarily discriminative when clustering companies by industry sector, but may be useful in other clusterings. Multiple clustering is one approach to inferring feature subspaces that lead to high quality data partitions. Multiple clustering also improves the flexibility of generative clustering models, as a single model is no longer required to explain all the variance in the feature dimensions (Mansinghka et al., 2009).

[1] Similarity also has been shown to violate symmetry (e.g. people have the intuition that *China* is more similar to *North Korea* than *North Korea* is to *China*).

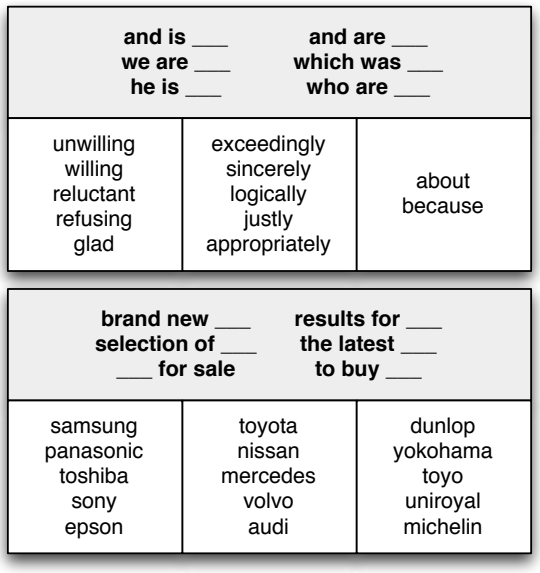

Figure 1: Example clusterings from MVM applied to Google n-gram data. Top contexts (features) for each view are shown, along with examples of word clusters. Although these particular examples are interpretable, in general the relationship captured by the view's context subspace is not easily summarized.

MVM is a multinomial-Dirichlet multiple clustering procedure for distributional lexical semantics that fits multiple, overlapping Dirichlet Process Mixture Models (DPMM) to a set of word data. Features are distributed across the set of clusterings (views) using LDA, and each DPMM is fit using a subset of the features. This reduces clustering noise and allows MVM to capture multiple ways in which the data can be partitioned. Figure 1 shows a simple example, and Figure 2 shows a larger sample of feature-view assignments from a 3-view MVM fit to contexts drawn from the Google n-gram corpus.

We implement MVM using generative model primitives drawn from Latent Dirichlet Allocation (LDA) and the Dirichlet Process (DP). $|M|$ disparate clusterings (views) are inferred jointly from a set of data $\mathcal{D} = \{\mathbf{w}_d | d \in [1 \dots D]\}$. Each data vector $\mathbf{w}_d$ is associated with a probability distribution over views $\boldsymbol{\theta}_d^{|M|}$. Empirically, $\boldsymbol{\theta}_d^{|M|}$ is represented as a set of *feature-view* assignments $\mathbf{z}_d$, sampled via the standard LDA collapsed Gibbs sampler. Hence, each view maintains a separate distribution over features. The generative model for feature-view assignment is given by

$$\begin{aligned}
\boldsymbol{\theta}_d^{|M|} | \boldsymbol{\alpha} &\sim \text{Dirichlet}(\boldsymbol{\alpha}), & d &\in D, \\
\boldsymbol{\phi}_m | \boldsymbol{\beta} &\sim \text{Dirichlet}(\boldsymbol{\beta}), & m &\in |M|, \\
z_{dn} | \boldsymbol{\theta}_d &\sim \text{Discrete}(\boldsymbol{\theta}_d), & n &\in |\mathbf{w}_d|, \\
w_{dn} | \boldsymbol{\phi}_{z_{dn} m} &\sim \text{Discrete}(\boldsymbol{\phi}_{z_{dn} m}), & n &\in |\mathbf{w}_d|,
\end{aligned}$$

where $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ are hyperparameters smoothing the per-document topic distributions and per-topic word distributions respectively.

Conditional on the feature-view assignment $\{\mathbf{z}\}$, a clustering is inferred for each view using the Chinese Restaurant Process representation of the DP. The clustering probability is given by

$$\begin{aligned}
p(\mathbf{c} | \mathbf{z}, \mathbf{w}) &\propto p(\{\mathbf{c}_m\}, \mathbf{z}, \mathbf{w}) \\
&= \prod_{m=1}^{M} \prod_{d=1}^{|D|} p(\mathbf{w}_d^{[\mathbf{z}=m]} | \mathbf{c}_m, \mathbf{z}) p(\mathbf{c}_m | \mathbf{z}).
\end{aligned}$$

where $p(\mathbf{c}_m | \mathbf{z})$ is a prior on the clustering for view m, i.e. the DPMM, and $p(\mathbf{w}_d^{[\mathbf{z}=m]} | \mathbf{c}_m, \mathbf{z})$ is the likelihood of the clustering $\mathbf{c}_m$ given the data point $\mathbf{w}_d$ restricted to the features assigned to view m:

$$\mathbf{w}_d^{[\mathbf{z}=m]} \stackrel{\text{def}}{=} \{w_{id} | z_{id} = m\}.$$

Thus, we treat the m clusterings $\mathbf{c}_m$ as conditionally independent given the feature-view assignments.

The feature-view assignments $\{\mathbf{z}\}$ act as a set of marginal constraints on the multiple clusterings, and the impact that each data point can have on each clustering is limited by the number of features assigned to it. For example, in a two-view model, $z_{id} = 1$ might be set for all syntactic features (yielding a syntagmatic clustering) while $z_{id} = 2$ is set for document features (paradigmatic clustering).

By allowing the clustering model capacity to vary via the DPMM, MVM can naturally account for the semantic variance of the view. This provides a novel mechanism for handling feature noise: noisy features can be assigned to a separate view with potentially a small number of clusters. This phenomenon is apparent in cluster 1, view 1 in the example in figure 2, where place names and adjectives are clustered together using rare contexts

From a topic modeling perspective, MVM finds topic refinements within each view, similar to hierarchical methods such as the nested Chinese Restaurant Process (Blei et al., 2003). The main difference is that the features assigned to the second "refined topics" level are constrained by the higher

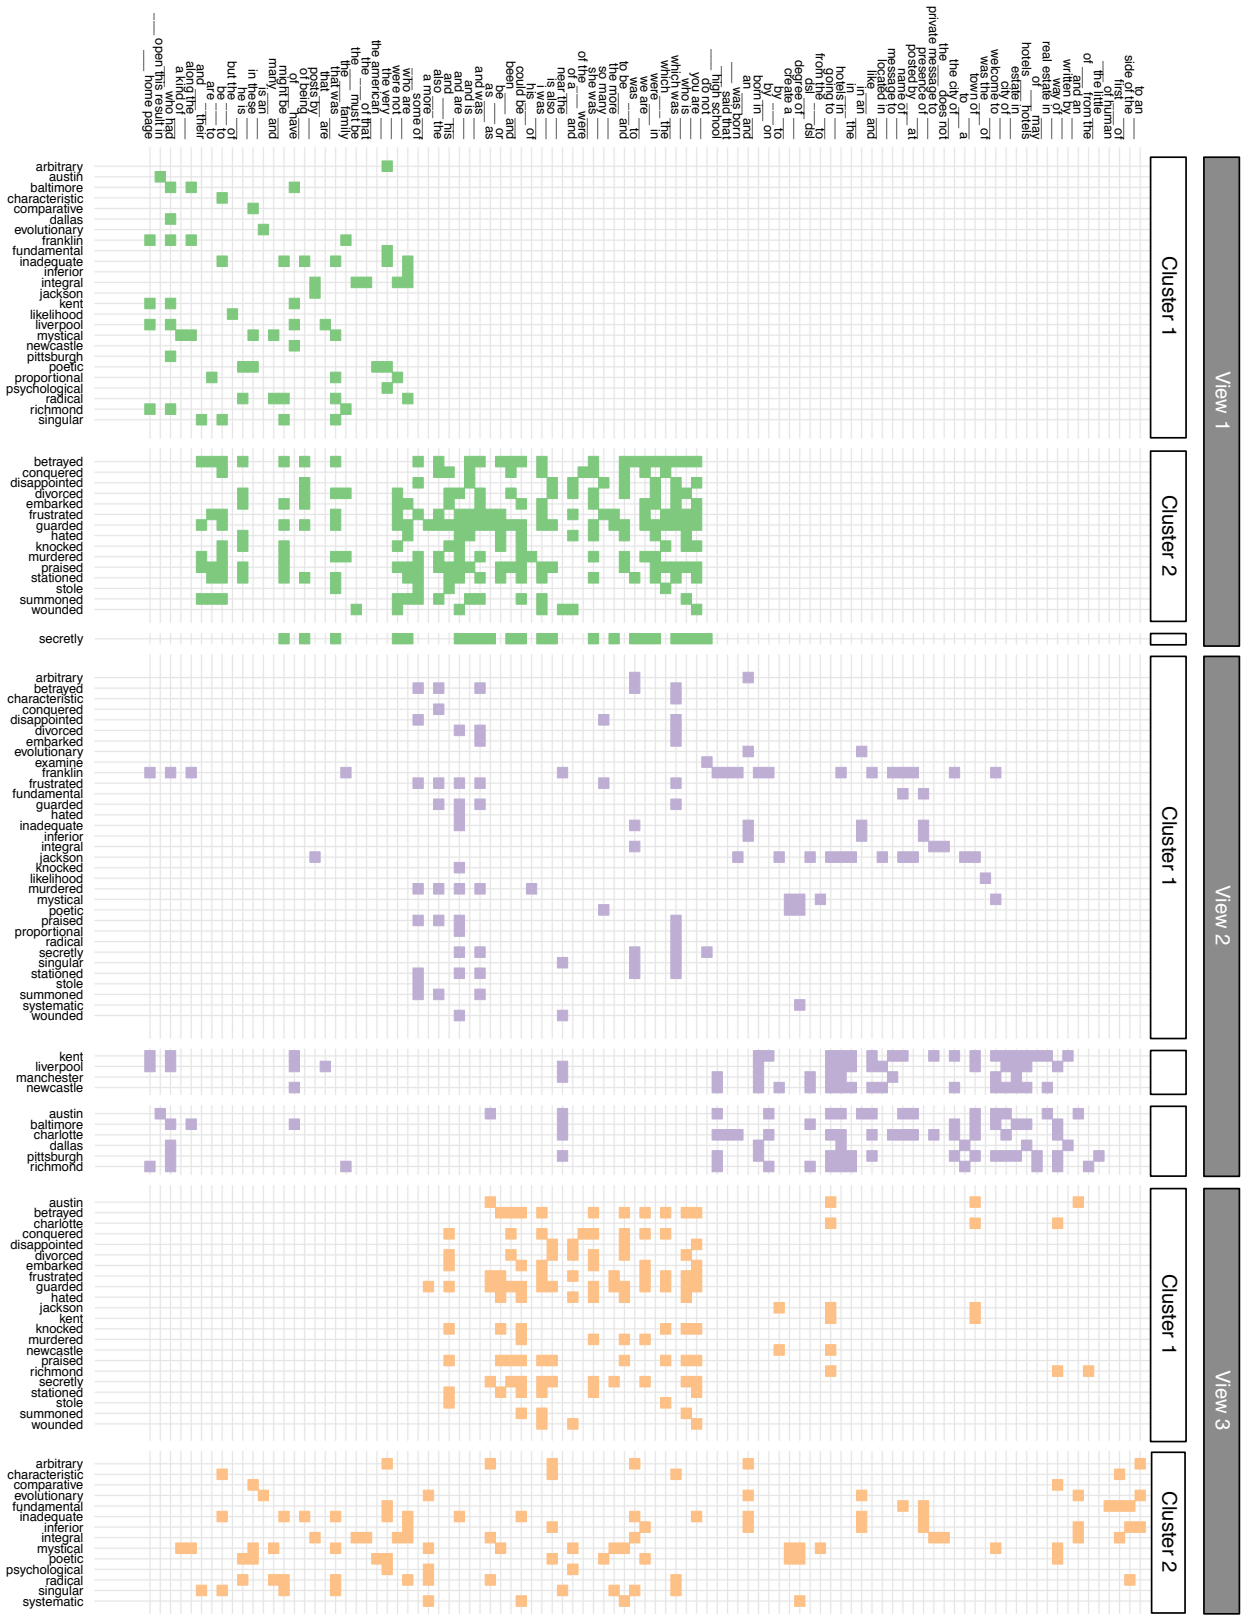

Figure 2: **Topics with Senses**: Shows top 20% of features for each view in a 3-view MVM fit to Google n-gram context data; different views place different mass on different sets of features. Cluster groupings within each view are shown. View 1 cluster 2 and View 3 cluster 1 both contain past-tense verbs, but only overlap on a subset of syntactic features.

level, similar to hierarchical clustering. Unlike hierarchical clustering, however, the top level topics/views form an admixture, allowing individual features from a single data point to be assigned to multiple views.

The most similar model to ours is *Cross-cutting categorization* (CCC), which fits multiple DPMMs to non-overlapping partitions of features (Mansinghka et al., 2009; Shafto et al., 2006). Unlike MVM, CCC *partitions* features among multiple DPMMs, hence all occurrences of a particular feature will end up in a single clustering, instead of assigning them softly using LDA. Such hard feature partitioning does not admit an efficient sampling procedure, and hence Shafto et al. (2006) rely on Metropolis-Hastings steps to perform feature assignment, making the model less scalable.

3.1 Word Representation

MVM is trained as a lexical semantic model on Web-scale n-gram and semantic context data. N-gram contexts are drawn from a combination of the Google n-gram and Google books n-gram corpora, with the head word removed: e.g. for the term *architect*, we collect contexts such as *the __ of the house*, *an __ is a*, and *the __ of the universe*. Semantic contexts are derived from word occurrence in Wikipedia documents: each document a word appears in is added as a potential feature for that word. This co-occurrence matrix is the transpose of the standard bag-of-words document representation.

In this paper we focus on two representations:

1. **Syntax-only** – Words are represented as bags of ngram contexts derived slot-filling procedure described above.

2. **Syntax+Documents** – The syntax-only representation is augmented with additional document contexts drawn from Wikipedia.

Models trained on the **syntax-only** set are only capable of capturing *syntagmatic* similarity relations, that is, words that tend to appear in similar contexts. In contrast, the **syntax+documents** set broadens the scope of modelable similarity relations, allowing for *paradigmatic* similarity (e.g. words that are topically related, but do not necessarily share common syntactic contexts).

Given such word representation data, MVM generates a fixed set of M context views corresponding to dominant eigenvectors in local syntactic or semantic space. Within each view, MVM partitions words into clusters based on each word's *local representation* in that view; that is, based on the set of context features it allocates to the view. Words have a non-uniform affinity for each view, and hence may not be present in every clustering (Figure 2). This is important as different ways of drawing distinctions between words do not necessarily apply to all words. In contrast, LDA finds locally consistent collections of contexts but does not further subdivide words into clusters given that set of contexts. Hence, it may miss more fine-grained structure, even with increased model complexity.

4 Experimental Setup

4.1 Corpora

We derive word features from three corpora: (1) the English **Google Web n-gram** corpus, containing n-gram contexts up to 5-gram that occur more than 40 times in a 1T word corpus of Web text, (2) the English **Google Books n-gram** corpus[2], consisting of n-gram contexts up to 5-gram that occur more than 40 times in a 500B word corpus of books, and (3) a snapshot of the English Wikipedia[3] taken on October 11, 2010 containing over 3M articles.

MVM is trained on a sample of 20k English words drawn uniformly at random from the top 200k English terms appearing in Wikipedia (different parts of speech were sampled from the Google n-gram corpus according to their observed frequency). Two versions of the **syntax-only** dataset are created from different subsets of the Google n-gram corpora: (1) the *common* subset contains all syntactic contexts appearing more than 200 times in the combined corpus, and (2) the *rare* subset, containing only contexts that appear 50 times or fewer.

4.2 Human Evaluation

Our main goal in this work is to find models that capture aspects of the syntactic and semantic organization of word in text that are intuitive to humans.

Palestinian cuisine	Joachim von Ribbentrop	Conquest of Wu by Jin
Field ration	World War I	Mongolia

Table 1: Example questions from the three intrusion tasks, in order of difficulty (left to right, easy to hard; computed from inter-annotator agreement). *Italics* show intruder items.

According to the *use theory* of meaning, lexical semantic knowledge is equivalent to knowing the contexts that words appear in, and hence being able to form reasonable hypotheses about the relatedness of syntactic contexts.

Vector space models are commonly evaluated by comparing their similarity predictions to a nominal set of human similarity judgments (Curran, 2004; Padó and Lapata, 2007; Schütze, 1998; Turney, 2006). In this work, since we are evaluating models that potentially yield many different similarity scores, we take a different approach, scoring clusters on their semantic and syntactic *coherence* using a *set intrusion* task (Chang et al., 2009).

In set intrusion, human raters are shown a set of options from a coherent group and asked to identify a single *intruder* drawn from a different group. We extend intrusion to three different lexical semantic tasks: (1) *context intrusion*, where the top contexts from each cluster are used, (3) *document intrusion*, where the top document contexts from each cluster are used, and (2) *word intrusion*, where the top words from each cluster are used. For each cluster, the top four contexts/words are selected and appended with another context/word from a different cluster.[4] The resulting set is then shuffled, and the human raters are asked to identify the intruder, after being given a short introduction (with common examples) to the task. Table 1 shows sample questions of varying degrees of difficulty. As the semantic coherence and distinctness from other clusters increases, this task becomes easier.

Set intrusion is a more robust way to account for human similarity judgments than asking directly for a numeric score (e.g., the Miller and Charles (1991) set) as less calibration is required across raters. Furthermore, the additional cluster context significantly reduces the variability of responses.

Human raters were recruited from *Amazon's Mechanical Turk*. A total of 1256 raters completed 30438 evaluations for 5780 unique intrusion tasks (5 evaluations per task). 2736 potentially fraudulent evaluations from 11 raters were rejected.[5] Table 3 summarizes inter-annotator agreement. Overall we found $\kappa \approx 0.4$ for most tasks; a set of comments about the task difficulty is given in Table 2, drawn from an anonymous public message board.

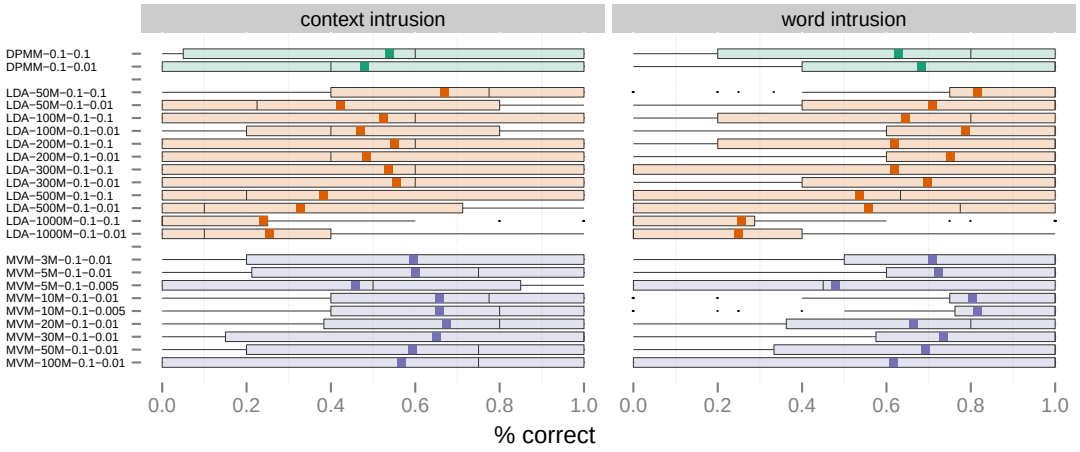
5 Results

We trained DPMM, LDA and MVM models on the **syntax-only** and **syntax+documents** data across a wide range of settings for $M \in \{3, 5, 7, 10, 20, 30, 50, 100, 200, 300, 500, 1000\}$,[6]

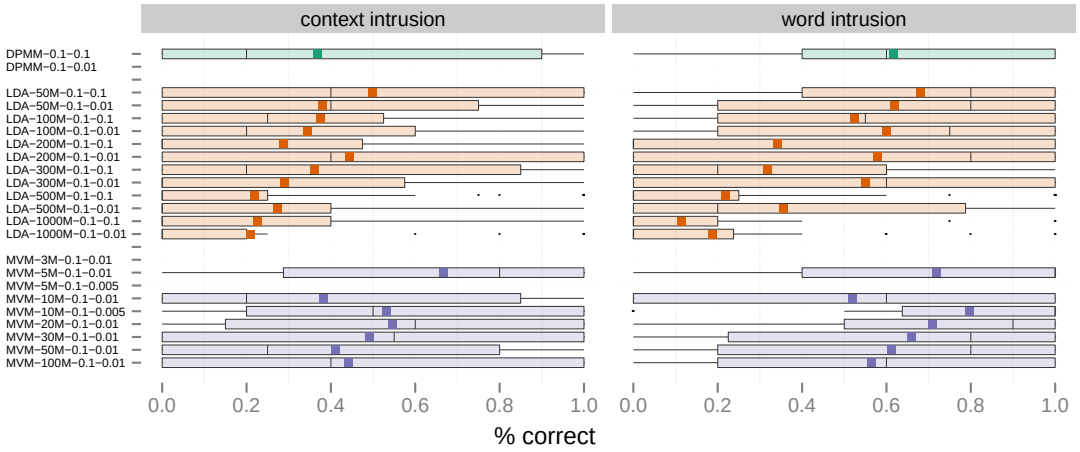
[4] Choosing four elements from the cluster uniformly at random instead of the top by probability led to lower performance across all models.

[5] (**Rater Quality**) Fraudulent Turkers were identified using a combination of average answer time, answer entropy, average agreement with other raters, and adjusted answer accuracy.

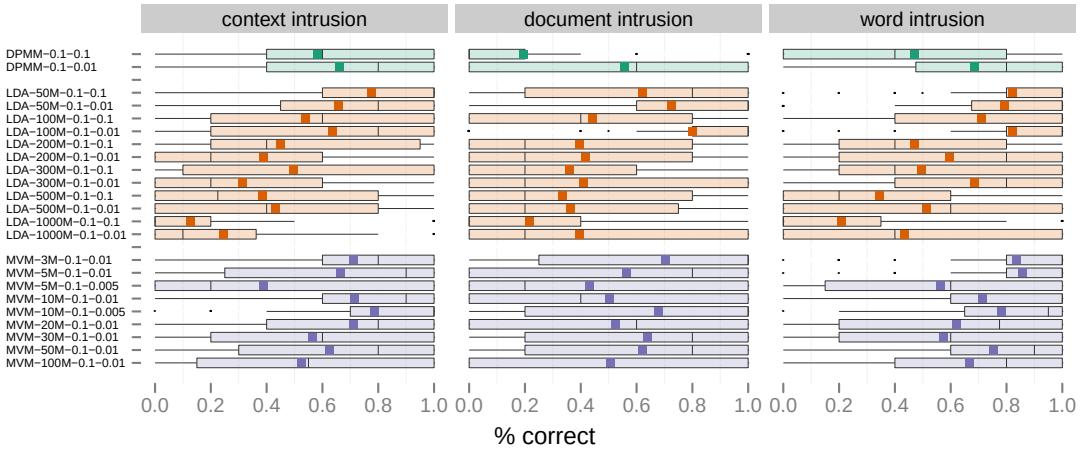
[6] LDA is run on a different range of M settings from MVM (50-1000 vs 3-100) in order to keep the effective number of



(a) **Syntax-only**, common n-gram contexts.



(b) **Syntax-only**, rare n-gram contexts.



(c) **Syntax+Documents**, common n-gram contexts.

Figure 3: Average scores for each model broken down by parameterization and data source. Error bars depict 95% confidence intervals. X-axis labels show **Model-views**-α-β. Dots show average rater scores; bar-charts show standard quantile ranges and median score.

U1	I just tried 30 of the what doesn't belong ones. They took about 30 seconds each due to thinking time so not worth it for me.
U2	I don't understand the fill in the blank ones to be honest. I just kinda pick one,since I don't know what's expected lol
U3	Your not filling in the blank just ignore the blank and think about how the words they show relate to each other and choose the one that relates least. Some have just words and no blanks.
U4	These seem very subjective to mw. i hope there isn't definite correct answers because some of them make me go [emoticon of head-scratching]
U5	I looked and have no idea. I guess I'm a word idiot because I don't see the relation between the words in the preview HIT - too scared to try any of these.
U6	I didn't dive in but I did more than I should have they were just too easy. Most of them I could tell what did not belong, some were pretty iffy though.

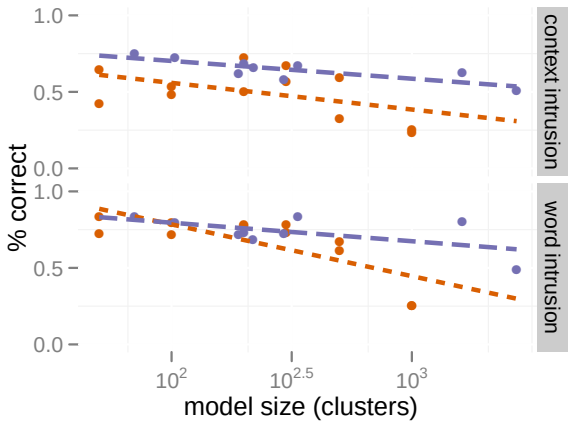
Table 2: Sample of comments about the task taken verbatim from a public Mechanical Turk user message board (TurkerNation). Overall the raters report the task to be difficult, but engaging.

$\alpha \in \{0.1, 0.01\}$, and $\beta \in \{0.1, 0.05, 0.01\}$ in order to understand how they perform relatively on the intrusion tasks and also how sensitive they are to various parameter settings.[7] Models were run until convergence, defined as no increase in log-likelihood on the training set for 100 Gibbs samples. Average runtimes varied from a few hours to a few days, depending on the number of clusters or topics. There is little computational overhead for MVM compared to LDA or DPMM with a similar number of clusters.

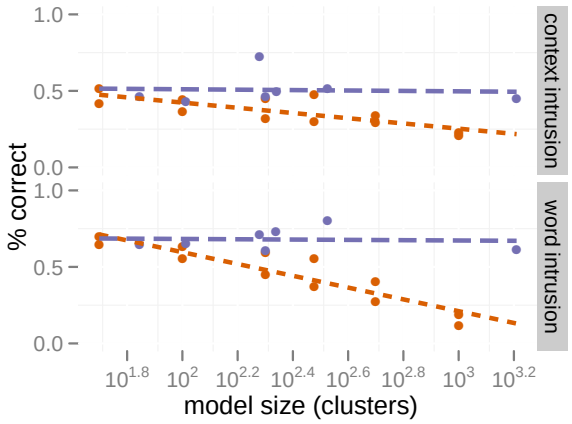
Overall, MVM significantly outperforms both LDA and DPMM (measured as % of intruders correctly identified) as the number of clusters increases. Coarse-grained lexical semantic distinctions are easy for humans to make, and hence models with fewer clusters tend to outperform models with more clusters. Since high granularity predictions are more useful for downstream tasks, we focus on the interplay between model complexity and performance.

clusters (and hence model capacity) roughly comparable.

[7]We did not compare directly to Cross-cutting categorization, as the Metropolis-Hasting steps required that model were too prohibitively expensive to scale to the Google n-gram data.



(a) **Syntax-only**, common n-gram contexts.



(b) **Syntax-only**, rare n-gram contexts.

Figure 4: Scatterplot of model size vs. avg score for MVM (dashed, purple) and LDA (dotted, orange).

5.1 Syntax-only Model

For common n-gram context features, MVM performance is significantly less variable than LDA on both the word intrusion and context intrusion tasks, and furthermore significantly outperforms DPMM (Figure 3(a)). For context intrusion, DPMM, LDA, and MVM average 57.4%, 49.5% and 64.5% accuracy respectively; for word intrusion, DPMM, LDA, and MVM average 66.7%, 66.1% and 73.6% accuracy respectively (averaged over all parameter settings). These models vary significantly in the average number of clusters used: 373.5 for DPMM, 358.3 for LDA and 639.8 for MVM, i.e. the MVM model is signifi-

Model	Syntax	Syntax+Documents	Overall
DPMM	0.30	0.40	**0.33**
LDA	0.33	0.39	**0.35**
MVM	0.44	0.49	**0.46**
Overall	**0.37**	**0.43**	**0.39**

Table 3: Fleiss' κ scores for various model and data combinations. Results from MVM have higher κ scores than LDA or DPMM; likewise **Syntax+Documents** data yields higher agreement, primarily due to the relative ease of the document intrusion task.

cantly more granular. Figure 4(a) breaks out model performance by model complexity, demonstrating that MVM has a significant edge over LDA as model complexity increases.

For rare n-gram contexts, we obtain similar results, with MVM scores being less variable across model parameterizations and complexity (Figure 3(b)). In general, LDA performance degrades faster as model complexity increases for rare contexts, due to the increased data sparsity (Figure 4(b)). For context intrusion, DPMM, LDA, and MVM average 45.9%, 36.1% and 50.9% accuracy respectively; for word intrusion, DPMM, LDA, and MVM average 67.4%, 45.6% and 67.9% accuracy; MVM performance does not differ significantly from DPMM, but both outperform LDA. Average cluster sizes are more uniform across model types for rare contexts: 384.0 for DPMM, 358.3 for LDA and 391 for MVM.

Human performance on the context intrusion task is significantly more variable than on the word-intrusion task, reflecting the additional complexity.

In all models, there is a high correlation between rater scores and per-cluster likelihood, indicating that model confidence reflects noise in the data.

5.2 Syntax+Documents Model

With the **syntax+documents** training set, MVM significantly outperforms LDA across a wide range of model settings. MVM also outperforms DPMM for word and document intrusion. For context intrusion, DPMM, LDA, and MVM average 68.0%, 51.3% and 66.9% respectively;[8] for word intrusion, DPMM, LDA, and MVM average 56.3%, 64.0% and 74.9% respectively; for document intrusion, DPMM, LDA,

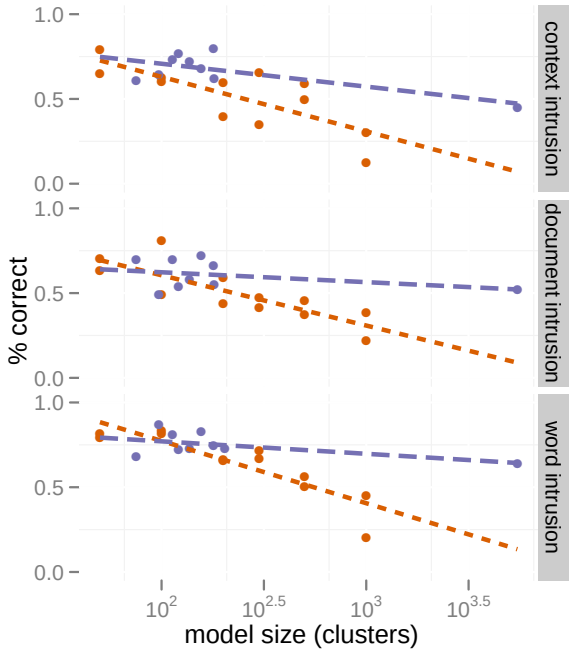


Figure 5: Scatterplot of model size vs. avg score for MVM (dashed, purple) and LDA (dotted, orange); **Syntax+Documents** data.

and MVM average 41.5%, 49.7% and 60.6% respectively. Qualitatively, models trained on **syntax+document** yield a higher degree of paradigmatic clusters which have intuitive thematic structure. Performance on document intrusion is significantly lower and more variable, reflecting the higher degree of world knowledge required. As with the previous data set, performance of MVM models trained on **syntax+documents** data degrades less slowly as the cluster granularity increases (Figure 5).

One interesting question is to what degree MVM *views* partition syntax and document features versus LDA topics. That is, to what degree do the MVM views capture purely syntagmatic or purely paradigmatic variation? We measured *view entropy* for all three models, treating syntactic features and document features as different class labels. MVM with $M = 50$ views obtained an entropy score of 0.045, while LDA with $M = 50$ obtained 0.073, and the best DPMM model 0.082.[9] Thus MVM views may indeed capture pure syntactic or thematic clusterings.

[8] High DPMM accuracy is driven by the low number of clusters: 46.5 for DPMM vs. 358.3 for LDA and 725.6 for MVM.

[9] The low entropy scores reflect the higher percentage of syntactic contexts overall.

5.3 Discussion

As cluster granularity increases, we find that MVM accounts for feature noise better than either LDA or DPMM, yielding more coherent clusters. (Chang et al., 2009) note that LDA performance degrades significantly on a related task as the number of topics increases, reflecting the increasing difficulty for humans in grasping the connection between terms in the same topic. This suggests that as topics become more ne-grained in models with larger number of topics, they are less useful for humans. In this work, we find that although MVM and LDA perform similarity on average, MVM clusters are significantly more interpretable than LDA clusters as the granularity increases (Figures 4 and 5). We argue that models capable of making such fine-grained semantic distinctions are more desirable.

The results presented in the previous two sections hold both for unbiased cluster selection (e.g. where clusters are drawn uniformly at random from the model) *and* when cluster selection is biased based on model probability (results shown). Biased selection potentially gives an advantage to MVM, which generates many more small clusters than either LDA or DPMM, helping it account for noise.

6 Future Work

Models based on cross-cutting categorization is a novel approach to lexical semantics and hence should be evaluated on standard baseline tasks, e.g. contextual paraphrase or *lexical substitution* (McCarthy and Navigli, 2007). Additional areas for future work include:

(**Latent Relation Modeling**) Clusterings formed from feature partitions in MVM can be viewed as a form of *implicit* relation extraction; that is, instead of relying on explicit surface patterns in text, relations between words or concepts are identified indirectly based on common syntactic patterns. For example, clusterings that divide cities by geography or clusterings partition adjectives by their polarity.

(**Latent Semantic Language Modeling**) Generative models such as MVM can be used to build better priors for class-based language modeling (Brown et al., 1992). The rare n-gram results demonstrate that MVM is potentially useful for tail contexts; i.e. inferring tail probabilities from low counts.

(**Explicit Feature Selection**) In this work we rely on smoothing to reduce the noise of over-broad extraction rather than performing feature selection explicitly. All of the models in this paper can be combined with feature selection methods to remove noisy features, and it would be particularly interesting to draw parallels to models of "clutter" in vision.

(**Hierarchical Cross-Categorization**) Human concept organization consists of multiple overlapping local ontologies, similar to the loose ontological structure of Wikipedia. Furthermore, each ontological system has a different set of salient properties. It would be interesting to extend MVM to model hierarchy explicitly, and compare against baselines such as *Brown clustering* (Brown et al., 1992), the nested Chinese Restaurant Process (Blei et al., 2003) and the hierarchical Pachinko Allocation Model (Mimno et al., 2007).

7 Conclusion

This paper introduced MVM, a novel approach to modeling lexical semantic organization using multiple *cross-cutting* clusterings capable of capturing multiple lexical similarity relations jointly in the same model. In addition to robustly handling homonymy and polysemy, MVM naturally captures both *syntagmatic* and *paradigmatic* notions of word similarity. MVM performs favorably compared to other generative lexical semantic models on a set of human evaluations, over a wide range of model settings and textual data sources.

Abstract

It is often assumed that 'grounded' learning tasks are beyond the scope of grammatical inference techniques. In this paper, we show that the grounded task of learning a semantic parser from ambiguous training data as discussed in Kim and Mooney (2010) can be reduced to a Probabilistic Context-Free Grammar learning task in a way that gives state of the art results. We further show that additionally letting our model learn the language's canonical word order improves its performance and leads to the highest semantic parsing f-scores previously reported in the literature.[1]

1 Introduction

One of the most fundamental ideas about language is that we use it to express our thoughts. Learning a natural language, then, amounts to (at least) learning a mapping between the things we utter and the things we think, and can therefore be seen as the task of learning a semantic parser, i.e. something that maps natural language expressions such as sentences into meaning representations such as logical forms. Obviously, this learning can neither take place in a fully supervised nor in a fully unsupervised fashion: the learner does not 'hear' the meanings of the sentences she observes, but she is also not treating them as merely meaningless strings. Rather, it seems plausible to assume that she uses extra-linguistic context to assign certain meanings to the linguistic input she is confronted with.

In this sense, learning a semantic parser seems to go beyond the well-studied task of unsupervised grammar induction. It involves not only learning a grammar for the form-side of language, i.e. language expressions such as sentences, but also the 'grounding' of this structure in meaning representations. It requires going beyond the mere linguistic input to incorporate, for example, perceptual information that provides a clue to the meaning of the observed forms. Essentially, it seems as if 'grounded' learning tasks like this require dealing with two different kinds of information, the purely formal (phonemic) and meaningful (semantic) aspects of language. Grammatical inference seems to be limited to dealing with one level of formal information (Chang and Maia, 2001). For this reason, probably, approaches to the task of learning a semantic parser employ a variety of sophisticated and task-specific techniques that go beyond (but often elaborate on) the techniques used for grammatical inference (Lu et al., 2008; Chen and Mooney, 2008; Liang et al., 2009; Kim and Mooney, 2010; Chen et al., 2010).

In this paper, we show that one can reduce the task of learning a semantic parser to a Probabilistic Context Free Grammar (PCFG) learning task, and more generally, that grounded learning tasks are not in principle beyond the scope of grammatical inference techniques. In particular, we show how to formulate the task of learning a semantic parser as discussed by Chen, Kim and Mooney (2008, 2010) as the task of learning a PCFG from strings. Our model does not only constitute a proof of concept that this

[1] The source code used for our experiments and the evaluation is available as supplementary material for this article.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1416–1425,
Edinburgh, Scotland, UK, July 27–31, 2011.

reduction is possible for certain cases, it also yields highly competitive results.[2]

By reducing the problem to the well understood PCFG formalism, it also becomes easy to consider extensions, leading to our second contribution. We demonstrate that a slight modification to our model so that it also learns the language's canonical word order improves its performance even beyond the best results previously reported in the literature. This language-independent and linguistically well motivated elaboration allows the model to learn a global fact about the language's syntax, its canonical word order.

Our contribution is two-fold. We provide an illustration of how to reduce grounded learning tasks to grammatical inference. Secondly, we show that extending the model so that it can learn linguistically well motivated generalizations such as the canonical word order can lead to better results.

The structure of the paper is as follows. First we give a short overview of the previous work by Chen, Kim and Mooney and describe their dataset. Then, we show how to reduce the parsing task addressed by them to a PCFG-learning task. Finally, we explain how to let our model additionally learn the language's canonical word order.

2 Previous Work by Chen, Kim and Mooney

In a series of recent papers, Chen, Kim and Mooney approach the task of learning a semantic parser from *ambiguous* training data (Chen and Mooney, 2008; Kim and Mooney, 2010; Chen et al., 2010). This goes beyond previous work on semantic parsing such as Lu et al. (2008) or Zettlemoyer and Collins (2005) which rely on *unambiguous* training data where every sentence is paired only with its meaning. In contrast, Chen, Kim and Mooney allow their training examples to exhibit the kind of uncertainty about sentence meanings human learners are likely to have to deal with by allowing for sentences to be associated with a *set* of candidate-meanings, and the correct meaning might not even be in this set. They create the training data by first collecting humanly generated written language comments on four different RoboCup games. The comments are recorded with a time-stamp and then associated with all game events automatically extracted from the games which occured up to five seconds before the comment was made. This leads to an ambiguous pairing of comments with candidate meanings that can be considered similar to the "linguistic input in the context of a rich, relevant, perceptual environment" to which real language learners probably have access (Chen and Mooney, 2008). For evaluation purposes, they manually create a gold-standard which contains unambiguous natural language comment / event pairs. Due to the fact that some comments refer to events not detected by their extraction-algorithm, not every natural language sentence has a gold matching meaning representation. In addition to the inherent ambiguity of the training examples, the learner therefore has to somehow deal with those examples which only have 'wrong' meanings associated with them.

Datasets exist for both Korean and English, each comprising training and gold data for four games.[3] Some details about this data are given in Table 1, such as the number of examples, their average ambiguity and the number of misleading examples.

For the following short discussion of previous approaches, we mainly focus on Kim and Mooney (2010). This is the most recent publication and reports the highest scores.

2.1 The parsing task

Learning a semantic parser from the ambiguous data is, in fact, just one of three tasks discussed by Kim and Mooney (2010), henceforth KM. In addition to parsing, they discuss matching and natural language generation. We are ignoring the generation task as we are currently only interested in the parsing problem, and we treat the matching task, picking the correct meaning from the set of candidates, merely as a byproduct of parsing, rather than as a completely separate task: parsing implicitly requires the model to disambiguate the data it is learning from.

[2] It has been pointed out to us by one reviewer that the task we address falls short of what is often called 'grounded learning'. We acknowledge that semantic parsing constitutes a very limited kind of grounded learning but want to point out that the task has been introduced as an instance of grounded learning in the previous literature such as Chen and Mooney (2008).

[3] The datasets are freely available at `http://www.cs.utexas.edu/~ml/clamp/sportscasting/`. We retrieved the data used here on March 29th, 2011.

	Number of comments				Ambiguity	
	# Training	# Training with Gold Match	# Training with correct MR	# Gold	Noise	Avg. # of MRs
English dataset						
total	1872	1492	1360	1539	0.2735	2.20
Korean dataset						
total	1914	1763	1733	1763	0.0946	2.39

Table 1: Statistics for the Korean and the English datasets. The numbers are basically identical to those reported in Chen et al. (2010) except for minimal differences in the number of training examples (we give one more for every English training set, and one more for the 2004 Korean training set). In addition, our calculation of the average sentential ambiguity (Avg. # of MRs) differs because we assume that mutiple occurences of the same event in a context do not add to the overall ambiguity, and our calculation of the noise (fraction of training examples without the correct meaning in their context) takes into account that there are training examples which do not have their gold meaning associated with them in the training data and is therefore slightly higher than the one reported in Chen et al. (2010).

KM's model builds on previous work by Lu et al. (2008) and is a generative model which defines a joint probability distribution over natural language sentences (NLs), meaning representations (MRs) and hybrid trees. The NLs are the natural language comments to the games, the MRs are simple logical formulae describing game events and playing the role of sentence meanings, and a hybrid tree is a tree structure that represents the correspondence between a sentence and its meaning. More specifically, if some NL w has as its meaning an MR m, and m has been generated by a meaning grammar (MG) G, the hybrid tree corresponding to the pair $\langle$w,m$\rangle$ has as its internal nodes those rules of G used in the derivation of m, and as its leaves the words making up w.[4] An example hybrid tree for the pair $\langle$THE PINK GOALIE PASSES THE BALL TO PINK11,pass(pink1,pink11)$\rangle$ is given in Figure 1. Their model is trained by a variant of the Inside-Outside algorithm which deals with the hybrid tree structure and takes into account the ambiguity of the training examples.

In addition to learning directly from the ambiguous training data, they also train a semantic parser in a supervised fashion on data that has been previously disambiguated by their matching model. This slightly improves their system's performance. Consequently, there are two scores for each of the two languages (English and Korean) with which we compare our own model: those of the parsers trained directly from the ambiguous data, and those of the 'supervised' parsers which constitute the current state of the art. The details of their evaluation method are disccused in Section 3.3, and their scores are given in Table 2, together with our own scores.

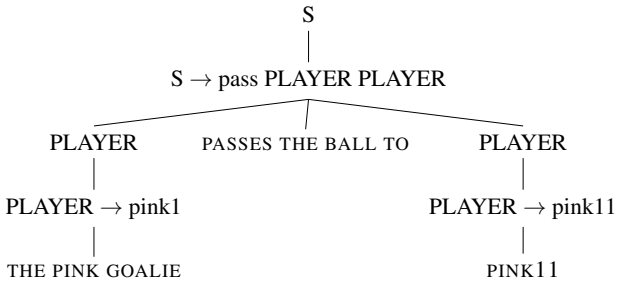

Figure 1: A hybrid tree for the sentence-meaning pair $\langle$THE PINK GOALIE PASSES THE BALL TO PINK11,pass(pink1,pink11)$\rangle$. The internal nodes correspond to the rules used to derive pass(pink1,pink11) from a given Meaning Grammar, and the leaves correspond to the words or substrings that make up the sentence.

3 Learning a Semantic Parser as a PCFG-learning problem

Given that one can effectively represent both a sentence's form and its meaning in a hybrid tree, it is interesting to ask whether one can do with a structure that can be learned by grammatical inference tech-

[4] We use SMALL CAPS for words, sans serif for MRs and MR constituents (concepts), and *italics* for non-terminals and Grammars.

niques from strings which incorporate the contextual information. In this section, we show how to reduce hybrid trees to such 'standard' trees. In effect, we show via construction that 'grounded' learning tasks such as learning a semantic parser from semantically enriched and ambiguous data can be reduced to 'ungrounded' tasks such as grammatical inference.

Instead of taking the internal nodes of the trees generated by our model as corresponding to MG *production rules*, we take them to correspond to MR *constituents*. The MR pass(pink1,pink11), for example, has 4 constituents: the whole MR, the predicate pass, and the two arguments pink1 and pink11. Figure 2 gives the tree we assume instead of Figure 1 for the sentence-meaning pair ⟨THE PINK GOALIE PASSES THE BALL TO PINK11,pass(pink1,pink11)⟩. Its root is assumed to correspond to the whole MR and is labeled $S_{pass(pink1,pink11)}$. The remaining three MR constituents correspond to the root's daughters which we label $Phrase_{pink1}$, $Phrase_{pass}$ and $Phrase_{pink11}$. Generally speaking, we assume a special non-terminal S_m for every MR m generated by the MG, and a special non-terminal $Phrase_{con}$ for each of the terminals of the MG (which loosely correspond to concepts). This is only possible for MGs which create a finite set of MRs, but the MG used by Kim and Mooney (2010) obeys this restriction.[5]

The tree's terminals are the words that make up the sentence, and we assume them to be dominated by concept-specific pre-terminals $Word_{con}$ which correspond to concept-specific probability distributions over the language's vocabulary. Since each $Phrase_{con}$ may span multiple words, we give trees rooted in $Phrase_{con}$ a left-recursive structure that corresponds to a unigram Markov-process. This process generates an arbitrary sequence of words semantically related to con, dominated by the corresponding pre-terminal $Word_{con}$ in our model, and words not directly semantically related to con, dominated by a special word pre-terminal $Word_{\emptyset}$. The sole further restriction is that every $Phrase_{con}$ must contain at least one $Word_{con}$.

Trees like the one in Figure 2 can be generated by a Context-Free Grammar (CFG) which, in turn, can be trained on strings to yield a PCFG which embodies a semantic parser as will be discussed in Section 3.3. We now describe how to set up such a CFG in a systematic way and how to train it on the data used by KM.

3.1 Setting up the PCFG

The training data expresses information of two different kinds – form and meaning. Every training example consists of a natural language string (the formal information) and a set of candidate meanings for the string (the semantic information, its context), allowing for the possibility that none of the meanings in the context is the correct one. In order to learn from data like this within a grammatical inference framework, we have to encode the semantic information as part of the string. Assigning a specific MR m to a string corresponds, in our framework, to analyzing it as a tree with S_m as its root. A sentence's context constrains which of the many possible meanings might be expressed by the string. Thus the role played by the context is adequately modelled if we ensure that if a string w is associated with a context $\{m_1,...,m_n\}$, the model only considers the possibilities that this string might be analyzed as $S_{m_1},...,S_{m_n}$.

There are 959 different contexts, i.e. 959 different sets of MRs, in the English data set (984 for the Korean data), and we therefore introduce 959 new terminal symbols which play the role of context-identifiers, for example c_1 to c_{959}.[6] Formally speaking, a context-identifier is a terminal like any other word of the language and we can therefore prefix every comment in the training data with the context-identifier standing for the set of MRs associated with this comment, an idea taken from previous work such as Johnson et al. (2010). Thus having incorporated the contextual information into the string, we go on to show how our model makes use of this information, considering the MR pass(pink1,pink11) as an example. A formal description of the model is given Figure 3.

Assume that pass(pink1,pink11) is associated with only one training example and therefore occurs only in one specific context. If the context-identifier introduced for this context is c_1, we require the

[5]This grammar is given in the Appendix to Chen et al. (2010) and generates a total of 2048 MRs.

[6]If we were to consider every possible context, we would have to consider 2^{2048} contexts because the MG generates 2048 MRs.

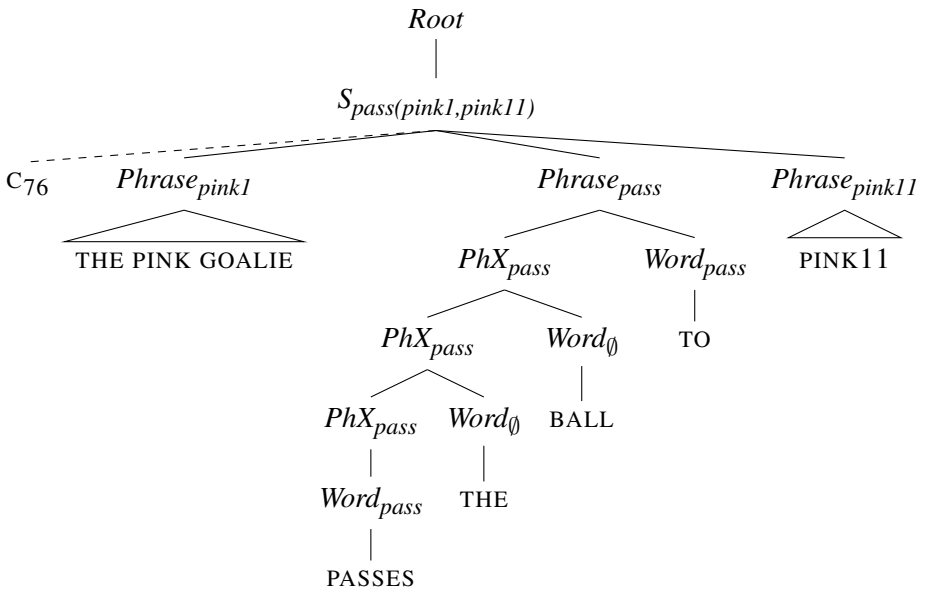

Figure 2: The tree-structure we propose instead of the Hybrid Tree structure used by (Kim and Mooney, 2010). The non-terminal nodes do not correspond to MG productions, but to MR constituents. The internal structure of the $Phrase_{con}$ constituents, shown in full detail for $Phrase_{pass}$, corresponds to a Markov process that generates the words that make up the sentence. The terminal C_{76} is a context-identifier that restricts the range of S_m non-terminals that might dominate the sentence and is only used during training, as described in Section 3.1. The grammar that generates this trees is described in Figure 3.

right-hand side of all rules with $S_{pass(pink1,pink11)}$ on their left-hand side to begin with C_1. More generally, if an MR m occurs in the contexts associated with the context-identifiers C_K,...,C_L, we require the right-hand side of all rules with S_m on their left-hand side to begin with exactly one of C_K,...,C_L.

In this sense, the *context-identifiers* can be seen as providing the model with a *top-down constraint* – if it encounters a context-identifier, it can only try analyses leading to MRs which are licensed by this context-identifier. On the other hand, the words have to be generated by concept-specific word-distributions, and the concepts that are present restrict the range of possible S_m non-terminals which might dominate the whole string. In this sense, the *words* the model observes provide it with a *bottom-up constraint* – if it sees words which are semantically related to certain concepts con_1,...,con_n, it has to arrive at an MR which licenses the presence of the corresponding $Phrase_{con_x}$ non-terminals. Of course, the model has to also learn which words are semantically related to which concepts. To enable it to do this, our grammar allows every $Word_x$ non-terminal to be rewritten as every word of the language.

Since there are sentences in the training data without the correct meaning in their context, we want to give our model the possibility of not assigning to a sentence any of the MRs licensed by its context-identifier. To do this, we employ another trick of previous work by Johnson et. al and assume a special null meaning $\emptyset$ to be present in every context. $S_\emptyset$ may only span words generated by $Word_\emptyset$, the language-specific distribution for words not directly related to any concept; this also has to be learned by the model.

As a last complication, we deal with the fact that syntactic constituents are linearized with respect to each other. For example, if an MR has 3 proper constituents (i.e. excluding the MR itself), our grammar allows the corresponding 3 syntactic constituents – which we might label $Phrase_{predicate}$, $Phrase_{arg1}$ and $Phrase_{arg2}$ – to occur in any of the 6 possible orders. Therefore, we have an S_m rule for every context in which m occurs and for every possible order of the proper constituents of m.

A formally explicit description of the rule

schemata used to generate the CFG is given in Figure 3.[7] Instantiating all those schemata leads to a grammar with 33,101 rules for the English data and 30,731 rules for the Korean data. The difference in size is due to differences in the size of the vocabulary and the different number of contexts in the data sets.

These CFGs can now be trained on the training data using the Inside-Outside algorithm (Lari and Young, 1990). After training, the resulting PCFG embodies a semantic parser in the sense that, with a slight modification we describe in section 3.3, it can be used to parse a string into its meaning representation by determining the most likely syntactic analysis and reading off the meaning assigned by our model at the S_m-node.

3.2 Possible objections to our reduction

Before we go on to discuss the details of training and evaluation of our model, we want to address an objection that might seem tempting. Isn't our reduction impractical and unrealistic as even a highly abstract model of language learning – after all, setting up the huge CFG requires knowledge about the vocabulary, the MG and all the complicated rules discussed which, presumably, is more knowledge than we want to provide a language learner with, lest we trivialize the task. To this we reply firstly, that it is true that our reduction only works for *offline* or *batch grounded learning tasks* where all the data is available to the model before the actual learning begins so that it 'knows' the words, the meanings and the contexts present in the data. This offline constraint is, however, true of all models which are trained by iterating multiple times over training data such as KM's model. Secondly, the intimidating CFG can in principle be reduced to a hand-full of intuitive principles and is easy to generate automatically.

First of all, the many specific S_m-rewrite rules reduce to the heuristic that every semantic constituent should correspond to a syntactic constituent, and the fact that natural language expressions are linearly ordered. Note that our model does not contain knowledge about the specific word order of the language. It simply allows for the constituents of an MR to occur in every possible order which is a very unbiased and empiricist assumption. Of course, this leads to some limited kind of 'implicit learning' of word order in the sense that for every meaning and for every context, our model might (and in most cases will) assign different probabilities to the different rules for every word order; so it can learn that certain specific MRs such as pass(pink1,pink11) are more often linearized in one way than in any other. It cannot, however, generalize this to other (or even unseen) MRs, i.e. it does not learn a global fact about the language. In a way, it lacks the knowledge that there is such a thing as word order, a point which we will elaborate on in Section 4.

The many re-write rules for the pre-terminal $Word_x$s are nothing but an explicit version of the assumption that every word the model encounters might, in principle, be semantically related to every concept it knows. Again, this seems to us to be a reasonable assumption.

Finally, the complicated looking set of rules for the internal structure of $Phrase_x$s corresponds to a simple unigram Markov-process for generating strings. All in all, we do not see that we make any more assumptions than other approaches; our formulation may make explicit how rich those assumptions are but we have not qualitatively changed them.

3.3 Training and Evaluation

The CFG described in the previous section is trained on the same training data used by KM, except that we reduce it to strings (without changing the information present in the original data) by prefixing every sentence with a context-identifier. For training we run the Inside-Outside algorithm[8] with uniform initialization weights until convergence. For English, this results in an average number of 76 iterations for each fold, for Korean the average number of iterations is 50. To deal with the fact that the model might not observe certain meanings during training, we apply a simple smoothing technique by using a Dirichlet prior of α=0.1 on the rule probabilities. In effect, this provides our system with a small number of pseudo-observations for each rule which prevents

[7] In our description, we use context-identifiers such as c_1 with a systematic ambiguity, letting them stand for the terminal symbol representing a context and, in contexts such as $m \in c_1$, for the represented context itself.

[8] We use Mark Johnson's freely available implementation, available at `http://web.science.mq.edu.au/~mjohnson/Software.htm`.

$\text{Root} \rightarrow S_m$	$m \in M \cup \{\emptyset\}$
$S_m \rightarrow c\, Phrase_{p(m)}$	$c \in C, m \in c, m \in Pred0(M)$
$S_m \rightarrow c\, \{Phrase_{p(m)}, Phrase_{a1(m)}\}$	$c \in C, m \in c, m \in Pred1(M)$
$S_m \rightarrow c\, \{Phrase_{p(m)}, Phrase_{a1(m)}, Phrase_{a2(m)}\}$	$c \in C, m \in c, m \in Pred2(M)$
$S_\emptyset \rightarrow c\, Phrase_\emptyset$	$c \in C$
$Phrase_\emptyset \rightarrow Word_\emptyset$	
$Phrase_\emptyset \rightarrow Phrase_\emptyset\, Word_\emptyset$	
$Phrase_x \rightarrow Word_x$	$x \in T$

$PhX_x \rightarrow Word_r$	$x \in T, r \in \{x, \emptyset\}$
$PhX_x \rightarrow PhX_x\, Word_r$	$x \in T, r \in \{x, \emptyset\}$
$Ph_x \rightarrow PhX_x\, Word_x$	$x \in T$
$Ph_x \rightarrow Ph_x\, Word_\emptyset$	$x \in T$
$Ph_x \rightarrow Word_x$	$x \in T$
$Word_x \rightarrow v$	$x \in T \cup \{\emptyset\}, v \in V$

Figure 3: The rule-schemata used to generate the NoWo-PCFG. Root is the unique start-symbol, M is the set of all MRs present in the corpus, C is set the of all context-identifiers present in the corpus, T is the set of terminals of the MG, V is the vocabulary of the corpus. $Pred0(M)$ is the subset of all MRs in M of the form predicate, $Pred1(M)$ is the subset of all MRs in M of the form predicate(arg1) and $Pred2(M)$ is the subset of all MRs in M of the form predicate(arg1,arg2). $p(m)$ is the predicate of the MR m, $a1(m)$ is the first argument of the MR m, $a2(m)$ is the second argument of the MR m. The rules expanding $Phrase_x$ ensure that it contains at least one $Word_x$. A set on the right-hand side of a rule is shorthand for all possible orderings of the elements of the set.

the automatic assignment of zero probability to rules not used during training.[9]

For parsing, the resulting PCFG is slightly modified by removing the context-identifiers. This is done because the task of a semantic parser is to establish a mapping between NLs and MRs, irrespective of contexts which were only used for learning the parser and should not play a role in its final performance. To do this, we add up the probability of all rules which differ only in the context-identifier which can be thought of as marginalizing out the different contexts, giving our first model which we call NoWo-PCFG.[10]

Note that the context-deletion (and the simple smoothing) enables NoWo-PCFG to parse sentences into meanings not present in the data it was trained on which, in fact, happens. For example, there are 81 meanings in the training data for the first English match that are not present in any of the other games' training data. The PCFG trained on games 2, 3 and 4 is still able to correctly assign 12 of those 81 meanings which it has not seen during the training phase which shows the effectiveness of the bottom-up constraint.

For evaluation, we employ 4-fold cross validation as described in detail in Chen and Mooney (2008) and used by KM: the model is trained on all possible combinations of 3 of the 4 games and is then used to produce an MR for all sentences of the held-out game *for which there is a matching gold-standard meaning*. For an NL w, our model produces an MR m by finding the *most probable* parse of w with the CKY algorithm and reading off m at the S_m-node.[11] An MR is considered correct if and only if it matches the gold-standard MR *exactly*; the final evaluation result is averaged over all 4 folds. Our evaluation results for NoWo-PCFG are given in Table 2. All scores are reported in F-measure which is the harmonic mean of Precision and Recall. In this specific case, precision is the fraction of correct parses out

[9] We experimented with α=0.1, α=0.5 and α=1.0 and found that overall, 0.1 yields the best results. We also tried jittering the initial rule weights during training and found that our results are very robust and seem to be independent of a specific initialization.

[10] NoWo because this model, unlike the one described in Section 4, does **no**t make explicit use of **w**ord **o**rder generalisations.

[11] For parsing, we use Mark Johnson's freely available CKY implementation which can be downloaded at `http://web.science.mq.edu.au/~mjohnson/Software.htm`.

	English	Korean
KM	0.742	0.764
KM 'supervised'	0.810	0.808
Chen et al. (2010)	0.801	0.812
NoWo-PCFG	0.742	0.718
WO-PCFG	**0.860**	**0.829**

Table 2: A summary of results for the parsing task, in F-measure. We also show the results of Chen et al. (2010), as given in Kim and Mooney (2010), which to our knowledge are the highest previously reported scores for Korean. WO-PCFG, described in Section 4 performs better than all previously reported models, but only slightly so for Korean.

of the total number of parses the model returns. Recall is the fraction of correct parses out of the total number of test sentences.[12]

NoWo-PCFG performs a little worse than KM's model. Its scores are virtually identical for English (0.742) and worse for Korean (0.718 vs 0.764). We are not sure as to why our model performs worse on the Korean data, but it might have to do with the fact that the Korean average ambiguity is higher than for the English data.

This shows that it is not only possible to reduce the task of learning a semantic parser to standard grammatical inference, but that this way of approaching the problem yields comparable results.

The remainder of the paper focuses on our second main point: that letting the model learn additional kinds of information, such as the language's canonical word order, can further improve its performance. In order to do this we propose a model that learns the word order as well as the mapping from NLs to MRs, and compare its performance to that of the other models.

4 Extending NoWo-PCFG to WO-PCFG

We already pointed out that our model considers every possible linear order of syntactic constituents. Our NoWo-PCFG model considers each of the possible word orders for every meaning and context in isolation: it is unable to infer from the fact that most meanings it has observed are most likely to be expressed with a certain word order that new meanings it will encounter are also more likely to be expressed with this word order. It seems, however, to be at least a soft fact about languages that they *do* have a canonical word order that is more likely to be realized in its sentences than any other possible word order. In order to test whether trying to learn this order helps our model, we modify the CFG used for NoWo-PCFG so it can learn word order generalizations, and train it in the same way to yield another semantic parser, WO-PCFG.

4.1 Setting up WO-PCFG

For every possible ordering of the constituents corresponding to an MR, our grammar contains a rule. In NoWo-PCFG, these different rules all share the same parent which prevents the model from learning the probability of the different word orders corresponding to the many rules. A straight-forward way to overcome this is to annotate every S_m node with the word order of its daughter. We split every S_m non-terminal in multiple S_{wo_m} non-terminals, where $wo \in$ {v,sv,vs,svo,sov,osv,ovs,vso,vos} indicates the linear order of the constituents the non-terminal rewrites as.[13]

This in itself does not yet allow our model to *use* word order as a means of generalization. To model that whenever it *encounters a specific example* that is indicative of a certain word order, this word order becomes slightly more probable *for every other example as well*, we have to make a further slight change to the CFG which we now describe. A formally explicit description of the necessary changes which we go on to describe is given in Figure 4.

We introduce six new non-terminals, corresponding to the six possible word orders SVO, SOV, VSO, VOS, OSV and OVS and require every S_{wo_m} non-terminal to be dominated by the non-terminal compatible with its daughters linear order. As an example, consider the two syntactic non-terminals corresponding to the MR kick(pink1), $S_{vs\_kick(pink11)}$ and $S_{sv\_kick(pink11)}$. Whenever an example is successfully analyzed as $S_{vs\_kick(pink11)}$, this should strengthen our model's expectation of encountering

[12] Because our model parses every sentence, for it Recall and Precision are identical and F-measure is identical to Accuracy.

[13] We assume, somewhat simplifying, that an MR's predicate corresponds to a V(erb), its first argument corresponds to the S(ubject) and its second argument corresponds to the O(bject). These are purely formal categories that are not constrained to correspond to specific linguistic categories.

$\text{Root} \rightarrow wo$	$wo \in WO$
$wo \rightarrow S_{x\_m}$	$wo \in WO, x \in WOS, x \subset wo, m \in M$
$S_{v\_m} \rightarrow c\, Phrase_{p(m)}$	$c \in C, m \in c, m \in Pred0(M)$
$S_{x\_m} \rightarrow c\, \{Phrase_{p(m)}, Phrase_{a1(m)}\}$	$c \in C, m \in c, m \in Pred1(M), x \in \{sv, vs\}$
$S_{x\_m} \rightarrow c\, \{Phrase_{p(m)}, Phrase_{a1(m)}, Phrase_{a2(m)}\}$	$c \in C, m \in c, m \in Pred2(M), x \in WOS$
$S_{v\_\emptyset} \rightarrow c\, Phrase_{\emptyset}$	$c \in C$

Figure 4: In order to turn NoWo-PCFG described in Figure 3 into the WO-PCFG described in the text, substitute the first five rule-schemata with the schemata given here. WO is the set of word order non-terminals $\{SVO, SOV, OSV, OVS, VSO, VOS\}$, WOS is the set of word order annotations $\{v, sv, vs, svo, svo, ovs, osv, vso, vos\}$. We take $x \subset wo$ to mean that x is compatible with wo, where v is compatible with all word orders, sv is compatible with SVO,SOV and OSV, and so on. For rule-schemata 4 and 5, the choice of x determines the order of the elements of the set on the right-hand side. All other symbols have the same meaning as explained in Figure 3.

more examples where the verb precedes the subject, i.e. of the language being pre-dominantly VSO, VOS or OVS. Therefore, we allow *VSO*, *VOS* and *OVS* to be rewritten as $S_{vs\_kick(pink11)}$. More generally, every word order non-terminal can rewrite as any of the S_{wo_m} non-terminals that are compatible with it. Adding this additional layer of word order abstraction leads to a grammar with 36,019 rules for English and a grammar with 33,715 rules for Korean.

4.2 Evaluation of WO-PCFG

Training and evaluating WO-PCFG in exactly the same way as the previous grammar gives an F-measure of 0.860 for English and an F-measure of 0.829 for Korean. Those scores are, to our knowledge, the highest scores previously reported for this parsing task and establish our second main point: letting the model learn the language's word order in addition to learning the mapping from sentences to MR increases semantic parsing accuracy.[14]

An intuitive explanation for the increase in performance is that by allowing the model to learn word order, we are providing it with a new dimension along which it can generalize.

In this sense, we can look at our refinement as providing the model with abstract linguistic knowledge, namely that languages tend to have a canonical word order. The usefulness of this kind of information is impressive – for English, it improves the accuracy of semantic parsing by almost 12% in F-measure and for Korean by 11.1%. In addition, our model correctly learns that English's predominant word order is SVO and that Korean is predominantly SOV, assigning by far the highest probability to the corresponding *Root* rewrite rule (0.91 for English and 0.98 for Korean). This kind of information is useful in its own right and could, for example, be exploited by coupling word order with other linguistic properties, perhaps following Greenberg (1966)'s implicational universals.

In this sense, the reduction of grounded learning problems to grammatical inference does not only make possible the application of a wide variety of tools and insights developed over years of research, it might also make it easier to bring abstract (and not so abstract) linguistic knowledge to bear on those tasks.

The overall slightly worse performance of our system on Korean data might stem from the fact that Korean, unlike English, has a rich morphology, and that our model does not learn anything about morphology at all. We plan on further investigating effects like this in the future, as well as applying more advanced grammatical inference algorithms.

5 Conclusion and Future Work

We have shown that certain grounded learning tasks such as learning a semantic parser from semantically enriched training data can be reduced to a grammatical inference problem over strings. This allows

[14] Liang et al. (2009)'s model can be seen as capturing something similar to our word order generalization with the help of a Field Choice Model which primarily captures discourse coherence and salience properties. It differs, however, in that it can only learn one generalization for each predicate type and no language wide generalization.

for the application of techniques and insights developed for grammatical inference to grounded learning tasks. In addition, we have shown that letting the model learn the language's canonical word order improves parsing performance, beyond the top scores previously reported, thus illustrating the usefullnes of linguistic knowledge for tasks like this.

In future research, we plan to address the limitation of our model to a finite set of meaning representations, in particular through the use of non-parametric Bayesian models such as the Infinite PCFG model of Liang et al. (2007) and the Infinite Tree model of Finkel et al. (2007); both allow for a potentially infinite set of non-terminals, hence directly addressing this problem. In addition, we are thinking about using an extension of the PCFG formalism that allows for some kind of 'feature-passing' which could lead to much smaller and more general grammars.

Abstract

This paper describes a novel approach to the semantic relation detection problem. Instead of relying only on the training instances for a new relation, we leverage the knowledge learned from previously trained relation detectors. Specifically, we detect a new semantic relation by projecting the new relation's training instances onto a lower dimension topic space constructed from existing relation detectors through a three step process. First, we construct a large relation repository of more than 7,000 relations from Wikipedia. Second, we construct a set of non-redundant relation topics defined at multiple scales from the relation repository to characterize the existing relations. Similar to the topics defined over words, each relation topic is an interpretable multinomial distribution over the existing relations. Third, we integrate the relation topics in a kernel function, and use it together with SVM to construct detectors for new relations. The experimental results on Wikipedia and ACE data have confirmed that background-knowledge-based topics generated from the Wikipedia relation repository can significantly improve the performance over the state-of-the-art relation detection approaches.

1 Introduction

Detecting semantic relations in text is very useful in both information retrieval and question answering because it enables knowledge bases to be leveraged to score passages and retrieve candidate answers. To extract semantic relations from text, three types of approaches have been applied. Rule-based methods (Miller et al., 2000) employ a number of linguistic rules to capture relation patterns. Feature-based methods (Kambhatla, 2004; Zhao and Grishman, 2005) transform relation instances into a large amount of linguistic features like lexical, syntactic and semantic features, and capture the similarity between these feature vectors. Recent results mainly rely on kernel-based approaches. Many of them focus on using tree kernels to learn parse tree structure related features (Collins and Duffy, 2001; Culotta and Sorensen, 2004; Bunescu and Mooney, 2005). Other researchers study how different approaches can be combined to improve the extraction performance. For example, by combining tree kernels and convolution string kernels, (Zhang et al., 2006) achieved the state of the art performance on ACE (ACE, 2004), which is a benchmark dataset for relation extraction.

Although a large set of relations have been identified, adapting the knowledge extracted from these relations for new semantic relations is still a challenging task. Most of the work on domain adaptation of relation detection has focused on how to create detectors from ground up with as little training data as possible through techniques such as bootstrapping (Etzioni et al., 2005). We take a different approach, focusing on how the knowledge extracted from the existing relations can be reused to help build detectors for new relations. We believe by reusing knowledge one can build a more cost effective relation detector, but there are several challenges associated with reusing knowledge.

The first challenge to address in this approach is how to construct a relation repository that has suffi-

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1426–1436,
Edinburgh, Scotland, UK, July 27–31, 2011.

cient coverage. In this paper, we introduce a method that automatically extracts the knowledge characterizing more than 7,000 relations from Wikipedia. Wikipedia is comprehensive, containing a diverse body of content with significant depth and grows rapidly. Wikipedia's infoboxes are particularly interesting for relation extraction. They are short, manually-created, and often have a relational summary of an article: a set of attribute/value pairs describing the article's subject.

Another challenge is how to deal with overlap of relations in the repository. For example, Wikipedia authors may make up a name when a new relation is needed without checking if a similar relation has already been created. This leads to relation duplication. We refine the relation repository based on an unsupervised multiscale analysis of the correlations between existing relations. This method is parameter free, and able to produce a set of non-redundant *relation topics* defined at multiple scales. Similar to the topics defined over words (Blei et al., 2003), we define relation topics as multinomial distributions over the existing relations. The relation topics extracted in our approach are interpretable, orthonormal to each other, and can be used as basis relations to re-represent the new relation instances.

The third challenge is how to use the relation topics for a relation detector. We map relation instances in the new domains to the relation topic space, resulting in a set of new features characterizing the relationship between the relation instances and existing relations. By doing so, background knowledge from the existing relations can be introduced into the new relations, which overcomes the limitations of the existing approaches when the training data is not sufficient. Our work fits in to a class of relation extraction research based on "distant supervision", which studies how knowledge and resources external to the target domain can be used to improve relation extraction. (Mintz et al., 2009; Jiang, 2009; Chan and Roth, 2010). One distinction between our approach and other existing approaches is that we represent the knowledge from distant supervision using automatically constructed topics. When we test on new instances, we do not need to search against the knowledge base. In addition, our topics also model the indirect relationship between relations. Such information cannot be directly found from the knowledge base.

The contributions of this paper are three-fold. Firstly, we extract a large amount of training data for more than 7,000 semantic relations from Wikipedia (Wikipedia, 2011) and DBpedia (Auer et al., 2007). A key part of this step is how we handle noisy data with little human effort. Secondly, we present an unsupervised way to construct a set of *relation topics* at multiple scales. This step is parameter free, and results in a non-redundant, multiscale relation topic space. Thirdly, we design a new kernel for relation detection by integrating the relation topics into the relation detector construction. The experimental results on Wikipedia and ACE data (ACE, 2004) have confirmed that background-knowledge-based features generated from the Wikipedia relation repository can significantly improve the performance over the state-of-the-art relation detection approaches.

2 Extracting Relations from Wikipedia

Our training data is from two parts: relation instances from DBpedia (extracted from Wikipedia infoboxes), and sentences describing the relations from the corresponding Wikipedia pages.

2.1 Collecting the Training Data

Since our relations correspond to Wikipedia infobox properties, we use an approach similar to that described in (Hoffmann et al., 2010) to collect positive training data instances. We assume that a Wikipedia page containing a particular infobox property is likely to express the same relation in the text of the page. We further assume that the relation is most likely expressed in the first sentence on the page which mentions the arguments of the relation. For example, the Wikipedia page for "Albert Einstein" contains an infobox property "alma mater" with value "University of Zurich", and the first sentence mentioning the arguments is the following: "Einstein was awarded a PhD by the University of Zurich", which expresses the relation. When looking for relation arguments on the page, we go beyond (sub)string matching, and use link information to match entities which may have different surface forms. Using this technique, we are able to collect a large amount of positive training instances of DBpe-

dia relations.

To get precise type information for the arguments of a DBpedia relation, we use the DBpedia knowledge base (Auer et al., 2007) and the associated YAGO type system (Suchanek et al., 2007). Note that for every Wikipedia page, there is a corresponding DBpedia entry which has captured the infobox-properties as RDF triples. Some of the triples include type information, where the subject of the triple is a Wikipedia entity, and the object is a YAGO type for the entity. For example, the DBpedia entry for the entity "Albert Einstein" includes YAGO types such as Scientist, Philosopher, Violinist etc. These YAGO types are also linked to appropriate WordNet concepts, providing for accurate sense disambiguation. Thus, for any entity argument of a relation we are learning, we obtain sense-disambiguated type information (including super-types, sub-types, siblings etc.), which become useful generalization features in the relation detection model. Given a common noun, we can also retrieve its type information by checking against WordNet (Fellbaum, 1998).

2.2 Extracting Rules from the Training Data

We use a set of rules together with their popularities (occurrence count) to characterize a relation. A rule representing the relations between two arguments has five components (ordered): argument_1 type, argument_2 type, noun, preposition and verb. A rule example of *ActiveYearsEndDate* relation (about the year that a person retired) is:

person100007846|year115203791|-|in|retire.

In this example, argument_1 type is *person100007846*, argument_2 type is *year115203791*, both of which are from YAGO type system. The key words connecting these two arguments are *in* (preposition) and *retire* (verb). This rule does not have a noun, so we use a '-' to take the position of noun. The same relation can be represented in many different ways. Another rule example characterizing the same relation is

person100007846|year115203791|retirement|-|announce.

This paper only considers three types of words: *noun*, *verb* and *preposition*. It is straightforward to expand or simplify the rules by including more or removing some word types. The keywords are extracted from the shortest path on the dependency tree between the two arguments. A dependency tree (Figure 1) represents grammatical relations between words in a sentence. We used a slot grammar parser (McCord, 1995) to generate the parse tree of each sentence. Note that there could be multiple paths between two arguments in the tree. We only take the shortest path into consideration. The popularity value corresponding to each rule represents how many times this rule applies to the given relation in the given data. Multiple rules can be constructed from one relation instance, if multiple argument types are associated with the instance, or multiple nouns, prepositions or verbs are in the dependency path.

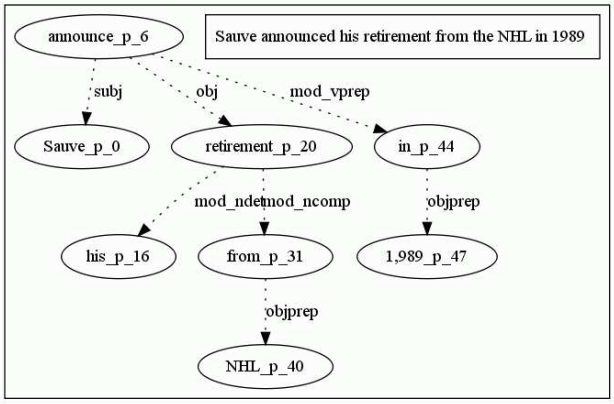

Figure 1: A dependency tree example.

2.3 Cleaning the Training Data

To find a sentence on the Wikipedia page that is likely to express a relation in its infobox, we consider the first sentence on the page that mentions both arguments of the relation. This heuristic approach returns reasonably good results, but brings in about 20% noise in the form of false positives, which is a concern when building an accurate statistical relation detector. To address this issue, we have developed a two-step technique to automatically remove some of the noisy data. In the first step, we extract popular argument types and keywords for each DBpedia relation from the given data, and then use the combinations of those types and words to create initial rules. Many of the argument types and keywords introduced by the noisy data are often not very popular, so they can be filtered out in the first step. Not all initial rules make sense. In the second step, we

check each rule against the training data to see if that rule really exists in the training data or not. If it does not exist, we filter it out. If a sentence does not have a single rule passing the above procedure, that sentence will be removed. Using the above techniques, we collect examples characterizing 7,628 DBpedia relations.

3 Learning Multiscale Relation Topics

An extra step extracting knowledge from the raw data is needed for two reasons: Firstly, many DBpedia relations are inter-related. For example, some DBpedia relations have a subclass relationship, e.g. "AcademyAward" and "Award"; others overlap in their scope and use, e.g., "Composer" and "Artist"; while some are equivalent, e.g., "DateOfBirth" and "BirthDate". Secondly, a fairly large amount of the noisy labels are still in the training data.

To reveal the intrinsic structure of the current DBpedia relation space and filter out noise, we carried out a correlation analysis of relations in the training data, resulting in a relation topic space. Each relation topic is a multinomial distribution over the existing relations. We adapted diffusion wavelets (Coifman and Maggioni, 2006) for this task. Compared to the other well-known topic extraction methods like LDA (Blei et al., 2003) and LSI (Deerwester et al., 1990), diffusion wavelets can efficiently extract a hierarchy of interpretable topics without any user input parameter (Wang and Mahadevan, 2009).

3.1 An Overview of Diffusion Wavelets

The diffusion wavelets algorithm constructs a compressed representation of the dyadic powers of a square matrix by representing the associated matrices at each scale not in terms of the original (unit vector) basis, but rather using a set of custom generated bases (Coifman and Maggioni, 2006). Figure 2 summarizes the procedure to generate diffusion wavelets. Given a matrix T, the $\mathcal{QR}$ (a modified QR decomposition) subroutine decomposes T into an orthogonal matrix Q and a triangular matrix R such that $T \approx QR$, where $|T_{i,k} - (QR)_{i,k}| < \varepsilon$ for any i and k. Columns in Q are orthonormal basis functions spanning the column space of T at the finest scale. RQ is the new representation of T with respect to the space spanned by the columns of Q (this result is based on the matrix invariant subspace theory). At an arbitrary level j, $\mathcal{DWT}$ learns the basis functions from T^{2^j} using $\mathcal{QR}$. Compared to the number of basis functions spanning T^{2^j}'s original column space, we usually get fewer basis functions, since some high frequency information (corresponding to the "noise" at that level) can be filtered out. $\mathcal{DWT}$ then computes $T^{2^{j+1}}$ using the low frequency representation of T^{2^j} and the procedure repeats.

$\{[\phi_j]_{\phi_0}\} = \mathcal{DWT}(T, \varepsilon, J)$
//**INPUT**:
//T: The input matrix.
//ε: Desired precision, which can be set to a small number or simply machine precision.
//J: Number of levels (optional).
//**OUTPUT**:
//$[\phi_j]_{\phi_0}$: extended diffusion scaling functions at scale j.

$\phi_0 = I$;
$For\ j = 0\ to\ J-1\ \{$
  $([\phi_{j+1}]_{\phi_j}, [T^{2^j}]_{\phi_j}^{\phi_{j+1}}) \leftarrow \mathcal{QR}([T^{2^j}]_{\phi_j}^{\phi_j}, \varepsilon)$;
  $[\phi_{j+1}]_{\phi_0} = [\phi_{j+1}]_{\phi_j}[\phi_j]_{\phi_0}$;
  $[T^{2^{j+1}}]_{\phi_{j+1}}^{\phi_{j+1}} = ([T^{2^j}]_{\phi_j}^{\phi_{j+1}}[\phi_{j+1}]_{\phi_j})^2$;
$\}$

Figure 2: Diffusion Wavelets construct multiscale representations of the input matrix at different scales. $\mathcal{QR}$ is a modified QR decomposition. J is the max step number (this is optional, since the algorithm automatically terminates when it reaches a matrix of size 1×1). The notation $[T]_{\phi_a}^{\phi_b}$ denotes matrix T whose column space is represented using basis ϕ_b at scale b, and row space is represented using basis ϕ_a at scale a. The notation $[\phi_b]_{\phi_a}$ denotes basis ϕ_b represented on the basis ϕ_a. At an arbitrary scale j, we have p_j basis functions, and length of each function is l_j. The number of p_j is determined by the intrinsic structure of the given dataset in $\mathcal{QR}$ routine. $[T]_{\phi_a}^{\phi_b}$ is a $p_b \times l_a$ matrix, and $[\phi_b]_{\phi_a}$ is an $l_a \times p_b$ matrix.

3.2 Constructing Multiscale Relation Topics

Learning Relation Correlations

Assume we have M relations, and the i^{th} of them is characterized by m_i <*rule, popularity*> pairs. We use $s(a, b)$ to represent the similarity between the a^{th} and b^{th} relations. To compute $s(a, b)$, we first normalize the popularities for each relation, and then

look for the rules that are shared by both relation a and b. We use the product of corresponding popularity values to represent the similarity score between two relations with respect to each common rule. $s(a, b)$ is set to the sum of such scores over all common rules. The relation-relation correlation matrix S is constructed as follows:

$$S = \begin{bmatrix} s(1,1) & \cdots & s(1,M) \\ \cdots & \cdots & \cdots \\ s(M,1) & \cdots & s(M,M) \end{bmatrix}$$

We have more than $200,000$ argument types, tens of thousands of distinct nouns, prepositions, and verbs, so we potentially have trillions of distinct rules. One rule may appear in multiple relations. The more rules two relations share, the more related two relations should be. The rules shared across different relations offer us a novel way to model the correlations between different relations, and further allow us to create relation topics. The rules can also be simplified. For example, we may treat argument$_1$, argument$_2$, noun, preposition and verb separately. This results in simple rules that only involve in one argument type or word. The correlations between relations are then computed only based on one particular component like argument$_1$, noun, etc.

Theoretical Analysis

Matrix S models the correlations between relations in the training data. Once S is constructed, we adapt diffusion wavelets (Coifman and Maggioni, 2006) to automatically extract the basis functions spanning the original column space of S at multiple scales. The key strength of the approach is that it is data-driven, largely parameter-free and can automatically determine the number of levels of the topical hierarchy, as well as the topics at each level. However, to apply diffusion wavelets to S, we first need to show that S is a positive semi-definite matrix. This property guarantees that all eigenvalues of S are ≥ 0. Depending on the way we formalize the rules, the methods to validate this property are slightly different. When we treat argument$_1$, argument$_2$, noun, preposition and verb separately, it is straightforward to see the property holds. In Theorem 1, we show the property also holds when we use more complicated rules (using the 5-tuple rule in Section 2.2 as an example in the proof).

Theorem 1. *S is a Positive Semi-Definite matrix.*

Proof: An arbitrary rule r_i is uniquely characterized by a five tuple: *argument$_1$ type*| *argument$_2$ type*| *noun*| *preposition*| *verb*. Since the number of distinct argument types and words are constants, the number of all possible rules is also a constant: R.

If we treat each rule as a feature, then the set of rules characterizing an arbitrary relation r_i can be represented as a point $[p_i^1, \cdots, p_i^R]$ in a latent R dimensional rule space, where p_i^j represents the popularity of rule j in relation r_i in the given data.

We can verify that the way to compute $s(a, b)$ is the same as $s(a, b) =< [p_a^1 \cdots p_a^R], [p_b^1 \cdots p_b^R] >$, where $< \cdot, \cdot >$ is the cosine similarity (kernel). It follows directly from the definition of positive semi-definite matrix (PSD) that S is PSD (Schölkopf and Smola, 2002). □

In our approach, we construct multiscale relation topics by applying $\mathcal{DWT}$ to decompose $S/\lambda_{max}(S)$, where $\lambda_{max}(S)$ represents the largest eigenvalue of S. Theorem 2 shows that this decomposition will converge, resulting in a relation topic hierarchy with one single topic at the top level.

Theorem 2. *Let $\lambda_{max}(S)$ represent the largest eigenvalue of matrix S, then $\mathcal{DWT}(S/\lambda_{max}(S), \varepsilon)$ produces a set of nested subspaces of the column space of S, and the highest level of the resulting subspace hierarchy is spanned by one basis function.*

Proof: From Theorem 1, we know that S is a PSD matrix. This means $\lambda_{max}(S) \in [0, +\infty)$ (all eigenvalues of S are non-negative). This further implies that $\Lambda(S)/\lambda_{max}(S) \in [0, 1]$, where $\Lambda(S)$ represents any eigenvalue of S.

The idea underlying diffusion wavelets is based on decomposing the spectrum of an input matrix into various spectral bands, spanned by basis functions (Coifman and Maggioni, 2006). Let $T = S/\lambda_{max}(S)$. In Figure 2, we construct spectral bands of eigenvalues, whose associated eigenvectors span the corresponding subspaces. Define dyadic spatial scales t_j as

$$t_j = \sum_{t=0}^{j} 2^t = 2^{j+1} - 1, \;\; j \geq 0 \, .$$

At each spatial scale, the spectral band is defined as:

$$\Omega_j(T) = \{\lambda \in \Lambda(T), \lambda^{t_j} \geq \varepsilon\},$$

where $\Lambda(T)$ represents any eigenvalue of T, and $\varepsilon \in (0, 1)$ is a pre-defined threshold in Figure 2. We can now associate with each of the spectral bands a vector subspace spanned by the corresponding eigenvectors:

$$V_j = \langle \{\xi_\lambda : \lambda \in \Lambda(T), \lambda^{t_j} \geq \varepsilon\} \rangle, \;\; j \geq 0 \, .$$

In the limit, we obtain

$$\lim_{j \to \infty} V_j = \langle \{\xi_\lambda : \lambda = 1\} \rangle$$

That is, the highest level of the resulting subspace hierarchy is spanned by the eigenvector associated with the largest eigenvalue of T. □

This result shows that the multiscale analysis of the relation space will automatically terminate at the level spanned by one basis, which is the most popular relation topic in the training data.

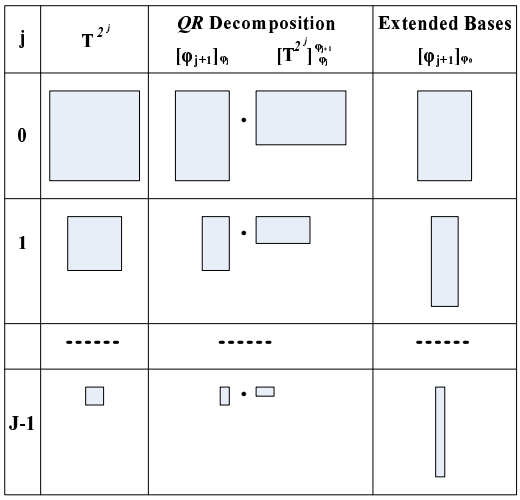

Figure 3: Learning Relation Topics at Multiple Scales.

3.3 High Level Explanation

We first create a set of rules to characterize each input relation. Since these rules may occur in multiple relations, they provide a way to model the co-occurrence relationship between different relations. Our algorithm starts with the relation co-occurrence matrix and then repeatedly applies QR decomposition to learn the topics at the current level while at the same time modifying the matrix to focus more on low-frequency indirect co-occurrences (between relations) for the next level. Running $\mathcal{DWT}$ is equivalent to running a Markov chain on the input data forward in time, integrating the local geometry and therefore revealing the relevant geometric structures of the whole data set at different scales. At scale j, the representation of $T^{2^{j+1}}$ is compressed based on the amount of remaining information and the desired precision. This procedure is illustrated in Figure 3. In the resulting topic space, instances with related relations will be grouped together. This approach may significantly help us detect new relations, since it potentially expands the information brought in by new relation instances from making use of the knowledge extracted from the existing relation repository.

3.4 Benefits

As shown in Figure 3, the topic spaces at different levels are spanned by a different number of basis functions. These numbers reveal the dimensions of the relevant geometric structures of data at different levels. These numbers are completely data-driven: the diffusion wavelets approach can automatically find the number of levels and simultaneously generate the topics at each level. Experiments show that most multiscale topics are interpretable (due to the sparsity of the scaling functions), such that we can interpret the topics at different scales and select the best scale for embedding. Compared to bootstrapping approach, our approach is accumulative; that is as the system learns more relations, it gets better at learning new relations. Because our approach takes advantage of the previously learned relations, and the topic space is enriched as we learn more and more relations.

We use diffusion wavelets (DWT) rather than other hierarchy topic models like hLDA (Blei et al., 2004) to extract relation topics for two reasons. First, DWT is parameter free while other models need some user-input parameters like hierarchy level. Second, DWT is more efficient than the other models. After the relation correlation matrix is constructed, DWT only needs a couple of minutes to extract multiscale topics on a regular computer. A direct experimental comparison between DWT and hLDA can be found in (Wang and Mahadevan, 2009).

4 Constructing Relation Detectors with Multiscale Relation Topics

4.1 Project Relation Instances onto Topics

When we design detectors for new relations, we treat arg_1, arg_2, $noun$, and $verb$ separately to get stronger correlations between relations. We do not directly use $preposition$. Any DBpedia relation $r \in \{1, \cdots, M\}$ is represented with 4 vectors $r_t = [r_t(1), \cdots, r_t(N_t)]$, where $t \in \{arg_1, arg_2, noun, verb\}$, N_t represents the size of the vocabulary set of the type t component in the Wikipedia training data, and $r_t(j)$ represents the occurrence count of type t component in relation r. For example, N_{verb} is the size of the verb vocabulary set in the training data and $r_{verb}(j)$ represents the occurrence count of the j^{th} verb in relation r. When a new relation instance x is given, we extract the dependency path between two arguments, and create four vectors x_t, where $t \in \{arg_1, arg_2, noun, verb\}$, following the same format as r_t. The projection result of x_t onto the DBpedia relation space X_t is as follows:

$X_t = [< r_t(1), x_t(1) >, \cdots, < r_t(M), x_t(M) >]$, where $< \cdot, \cdot >$ is the cosine similarity of two vectors. At level k, the embedding of x is $E^k_x = [E^k_{X_{arg_1}}, E^k_{X_{arg_2}}, E^k_{X_{noun}}, E^k_{X_{verb}}]$, where $E^k_{X_t} = ([\phi_k]_{\phi_0})^T X_t$, and $[\phi_k]_{\phi_0}$ is defined in Figure 2.

4.2 Design New Kernel Using Topic Features

We combine E^k_x with 3 existing kernels ($K_{Argument}$, K_{Path} and K_{BOW}) to create a new kernel for relation detection.

(1) $K_{Argument}$ matches two arguments, it returns the number of common argument types that the input arguments share.

(2) K_{Path} matches two dependency paths. This kernel is formally defined in (Zhao and Grishman, 2005). We extended this kernel by also matching the common nouns, prepositions and verbs in the dependency paths. We assign weight 1 to verbs, 0.5 to nouns and prepositions.

(3) K_{BOW} models the number of common nouns, prepositions and verbs in the given sentences but not in the dependency paths. Since these words are not as important as the words inside the dependency path, we assign weight 0.25 to them.

(4) $K_{TF_k}(x, y) =< E^k_x, E^k_y >$, where x, y are two input relation instances, and $< \cdot, \cdot >$ models the cosine similarity of two vectors. TF stands for topic feature.

(5) The final kernel used in this paper is

$\alpha_1 K_{Argument} + \alpha_2 K_{Path} + \alpha_3 K_{BOW} + \alpha_4 K_{TF_k}$, where α_i can be tuned for each individual domain. In this paper, we set $\alpha_i = 1$ for $i \in \{1, 2, 3, 4\}$.

4.3 Algorithm to Construct Relation Detectors

1. **Construct a relation repository from Wikipedia.**
   (a) Collect training data from Wikipedia and DBpedia (Section 2.1);
   (b) Clean the data representing each input relation (Section 2.2 and 2.3);
   (c) Create relation correlation matrix S following the approach described in Section 3.2, resulting in an $M \times M$ matrix.
2. **Create multiscale relation topics.**
   $[\phi_k]_{\phi_0} = \mathcal{DWT}(S/\lambda_{max}(S), \varepsilon)$, where $\mathcal{DWT}()$ is the diffusion wavelets implementation described in Section 3.1. $[\phi_k]_{\phi_0}$ are the scaling function bases at level k represented as an $M \times p_k$ matrix, $k = 1, \cdots, h$ represents the level in the topic hierarchy. The value of p_k is determined in $\mathcal{DWT}()$ based on the intrinsic structure of the given dataset. Columns of $[\phi_k]_{\phi_0}$ are used as relation topics at level k.
3. **Construct relation detectors for new relations.**
   Given the training data from a new relation, project the data onto level k of the multiscale topic hierarchy, where k is chosen by users (Section 4.1). Apply SVM classifiers together with our kernel (Section 4.2) to create detectors for new relations.

5 Experimental Results

We used SVMLight (Joachims, 1999) together with the user defined kernel setting in our approach. The trade-off parameter between training error and margin c is 1 for all experiments. Our approach to learn multiscale relation topics is largely parameter free. The only parameter to be set is the precision $\varepsilon = 10^{-5}$, which is also the default value in the diffusion wavelets implementation.

5.1 Learning Multiscale Relation Topics

Following the approach discussed in Section 2.1, we collect more than 620,000 training instances for

Table 1: Number of topics at different levels (DBpedia Relations) under 5 different settings: use args, noun, preposition and verb; arg_1 only; arg_2 only; noun only and verb only.

Level	args & words	arg_1	arg_2	noun	verb
1	7628	7628	7628	7628	7628
2	269	119	155	249	210
3	32	17	19	25	35
4	7	5	5	7	10
5	3	2	3	4	4
6	2	1	2	2	2
7	1		1	1	1

7,628 DBpedia relations. For any given topic vector v, we know it is a column vector of length M, where M is the size of the DBpedia relation set and $\|v\|$ = 1. The entry $v[i]$ represents the contribution of relation i to this topic. To explain the main concept of topic v, we sort the entries on v and print out the relations corresponding to the top entries. These relations summarize the topics in the relation repository. One topic example is as follows: [*doctoraladvisor (0.683366), doctoralstudents (0.113201), candidate (0.014662), academicadvisors (0.008623), notablestudents (0.003829), college (0.003021), operatingsystem (0.002964), combatant (0.002826), influences (0.002285), training (0.002148),* $\cdots$], where $doctoraladvisor$ is a DBpedia relation and 0.683366 is its contribution to the topic. The length of this relation vector is 7,628. We only list the top 10 relations here.

Our approach identifies 5 different topic hierarchies under different settings (use args, noun, preposition and verb; arg_1 only; arg_2 only; noun only and verb only). The number of the topics at each level is shown in Table 1. At the first level, each input relation is treated as a topic. At the second level, numbers of topics go down to reasonable numbers like 269. Finally at the top level, the number of topic is down to 1 (Theorem 2 also proves this). We show some topic examples under the first setting. The 3 topics at level 5 are shown in Table 2. They represent the most popular DBpedia relation topics. Almost all 269 topics at level 5 look semantically meaningful. They nicely capture the related relations. Some examples are in Table 3.

Table 2: 3 topics at level 5 (all word types and args).

Top 4 Relations and Their Contributions
starring 86.6%, writer 3.8%, producer 3.2%, director 1.6%
birthplace 75.3%, clubs 6.1%, deathplace 5.1%, location 4.1%

5.2 Relation Detection on Wikipedia Data

In previous experiment, 20,000 relation instances were held and not used to construct the topic space. These instances are randomly selected from 100 relations (200 instances from each relation). This set is used as a benchmark to compare different relation detection approaches. In this experiment, 100 instances from each relation are used for training, and the other 100 are for testing. In training, we try three different settings: $n = 5$, 20 and 100, where n is the size of the training set for each relation. When we train a model for one relation, we use the training positive instances from the other 99 relations as training negatives. For example, we use 5 training positive instances and 5*99=495 training negatives to train a detector for each relation.

We compare our approach against the regular rule-based approach (Lin and Pantel, 2001) and two other kernel-based approaches (presented in Section 4.2) for relation detection task. The comparison results are summarized in Table 4. The approach using relation topics (level 2) consistently outperforms the other three approaches in all three settings. When $n = 5$, it achieves the largest improvement over the other three. This indicates that using relation topics that integrate the knowledge extracted from the existing relations, can significantly benefit us when the training data is insufficient. This is reasonable, since the prior knowledge becomes more valuable in this scenario.

The users can select the level that is the most appropriate for their applications. In this example, we only have alignment results at 7 levels. Choosing the space at level 2 spanned by a couple of hundreds of basis functions is a natural choice, since the levels below and above this have too many or too few features, respectively. A user can also select the most appropriate level by checking if the related relation topics are meaningful for their applications.

5.3 Relation Detection on ACE Data

In this experiment, we use the news domain documents of the ACE 2004 corpus (ACE, 2004) to compare our approaches against the state-of-the-art approaches. This dataset includes 348 documents and around 4400 relation instances. 7 relation types, 7 entity types, numerous relation sub-types, entity sub-types, and mention types are defined on this set. The task is to classify the relation instances into one of the 7 relation types or "NONE", which means there is no relation. For comparison, we use the same setting as (Zhang et al., 2006), by applying a 5-fold cross-validation. The scores reported here are the average of all 5 folds. This is also how the other approaches are evaluated. In this test, we treat entity types, entity sub-types and mention types equally as argument types. Table 5 summarizes the performance after applying the kernels presented in Section 4.2 incrementally, showing the improvement from each individual kernel. We also compare our approaches to the other state-of-the-art approaches including Convolution Tree kernel (Collins and Duffy, 2001), Syntactic kernel (Zhao and Grishman, 2005), Composite kernel (linear) (Zhang et al., 2006) and the best kernel in (Nguyen et al., 2009). Our approach with relation topics at level 2 has the best performance, achieving a 73.24% F-measure. The impact of the relation topics is huge. They improve the F-measure from 61.15% to 73.24%. We also test our approach using the topics at level 3. The performance is slightly worse than using level 2, but still better than the others.

This paper studies how relation topics extracted from Wikipedia relation repository can help improve relation detection performance. We do not want to tune our approach to one particular relation detection task, like ACE 2004. In our experiments, no parameter tuning was taken and no domain specific heuristic rules were applied. We are aware of some methods that could stack on our approach to further improve the performance on ACE test. The Composite kernel result in Table 5 is based on a linear combination of the Argument kernel and Convolution Tree kernel. (Zhang et al., 2006) showed that by carefully choosing the weight of each component and using a polynomial expansion, they could achieve the best performance on this data: 72.1% F-measure. (Nguyen et al., 2009) further showed that the performance can be improved by taking syntactic and semantic structures into consideration. They used several types of syntactic information including constituent and dependency syntactic parse trees to improve the state of the art approaches to 71.5% on F-measure. Heuristic rules extracted from the target data can also help improve the performance. (Jiang and Zhai, 2007) reported that by taking several heuristic rules they can improve the F-measure of Composite Kernel to 70.4%. They also showed that using maximum entropy classifier rather than SVM achieved the best performance on this task: 72.9% F-measure. To the best of our knowledge, the most recent result was reported by (Zhou and Zhu, 2011), who extended their previous work in (Zhou et al., 2007). By using several heuristics to define an effective portion of constituent trees, and training the classifiers using ACE relation sub-types (rather than on types), they achieved an impressive 75.8% F-measure. However, as pointed out in (Nguyen et al., 2009), such heuristics are tuned on the target relation extraction task and might not be appropriate to compare against the automatic learning approaches. Even though we have not done any domain specific parameter tuning or applied any heuristics, our approach still achieve significant improvements over all approaches mentioned above except one, which is based on heuristics extracted from the target domain. This also implies that by combining some of the above ideas with relation topics, the performance on ACE data may be further improved.

6 Conclusions

This paper proposes a novel approach to create detectors for new relations integrating the knowledge extracted from the existing relations. The contributions of this paper are three-fold. Firstly, we pro-

Table 4: F-measure comparison of different approaches over 100 DBpedia relations with 5, 20 and 100 positive examples per relation. AG: $K_{Argument}$, DP: K_{Path}, BOW: K_{BOW}, TF_k: K_{TF_k}.

Approaches	100	20	5

vide an automatic way to collect training data for more than 7,000 relations from Wikipedia and DBpedia. Secondly, we present an unsupervised way to construct a set of relation topics at multiple scales. Different from the topics defined over words, relation topics are defined over the existing relations. Thirdly, we design a new kernel for relation detection by integrating the relation topics in the representation of the relation instances. By leveraging the knowledge extracted from the Wikipedia relation repository, our approach significantly improves the performance over the state-of-the-art approaches on ACE data. This paper makes use of all DBpedia relations to create relation topics. It is possible that using a subset of them (more related to the target relations) might improve the performance. We will explore this in future work.

Abstract

We report on empirical results in *extreme extraction*. It is extreme in that (1) from receipt of the ontology specifying the target concepts and relations, development is limited to one week and that (2) relatively little training data is assumed. We are able to surpass human recall and achieve an F1 of 0.51 on a question-answering task with less than 50 hours of effort using a hybrid approach that mixes active learning, bootstrapping, and limited (5 hours) manual rule writing. We compare the performance of three systems: extraction with handwritten rules, bootstrapped extraction, and a combination. We show that while the recall of the handwritten rules surpasses that of the learned system, the learned system is able to improve the overall recall and F1.

1 Introduction

Throughout the Automatic Content Extraction [1] (ACE) evaluations and the Message Understanding Conferences[2] (MUC), teams typically had a year or more from release of the target to submitting system results. One exception was MUC-6 (Grishman & Sundheim, 1996), in which scenario templates for changing positions were extracted given only one month. Our goal was to confine development to a calendar week, in fact, <50 person hours. This is significant in two ways: the less effort it takes to bring up a new domain, (1) the more broadly applicable the technology is and (2) the less effort required to run a diagnostic research experiment.

Our second goal concerned minimizing training data. Rather than approximately 250k words of entity and relation annotation as in ACE, only ~20 example pairs per relation-type were provided as training. Reducing the training requirements has the same two desirable outcomes: demonstrating that the technology can be broadly applicable and reducing the overhead for running experiments.

The system achieved recall of 0.49 and precision of 0.53 (for an F1 of 0.51) on a blind test set of 60 queries of the form $R_i(arg_1, arg_2)$, where R_i is one of the 5 new relations and exactly one of arg_1 or arg_2 is a free variable for each query.

Key to this achievement was a hybrid of:

- a variant of (Miller, et al., 2004) to learn two new classes of entities via automatically induced word classes and active learning (6 hours)
- bootstrap relation learning (Freedman et al, 2010) to learn 5 new relation classes (2.5 hours),
- handwritten patterns over predicate-argument structure (5 hours), and
- coreference (20 hours)

Our bootstrap learner is initialized with relation tuples (not annotated text) and uses LDC's Gigaword and Wikipedia as a background corpus to learn patterns for relation detection that are based on normalized predicate argument structure as well as surface strings.

These early empirical results suggest the following: (1) It is possible to specify a domain, adapt our system, and complete manual scoring, includ-

ing human performance, within a month. Experiments in machine reading (and in extraction) can be performed much more quickly and cheaply than ever before. (2) Through machine learning and limited human pattern writing (6 hours), we adapted a machine reading system within a week (using less than 50 person hours), achieving question answering performance with an F1 of 0.5 and with recall 11% higher (relative) to a human reader. (3) Unfortunately, machine learning, though achieving 80% precision,[3] significantly lags behind a gifted human pattern writer in recall. Thus, bootstrap learning with much higher recall at minimal sacrifice in precision is highly desirable.

2 Related Work

This effort is evaluated extrinsically via formal questions expressed as a binary relation with one free variable. This contrasts with TREC Question Answering,[4] where the questions are in natural language, and not restricted to a single binary relation. Like the "list" queries of TREC QA, the requirement is to find all answers, not just one. Though question interpretation is not required in our work, interpretation of the text corpus is.

The goal of rapid adaptation has been tested in other contexts. In 2003, a series of experiments in adapting to a new language in less than month tested system performance on Cebuano and Hindi. The primary goal was to adapt to a new language, rather than a new domain. The extraction participants focused on named-entity recognition, not relation extraction (May, et al, 2003; Sekine & Grishman, 2003; Li & McCallum, 2003; Maynard et al, 2003). The scenario templates of MUC-6 (Grishman & Sundheim, 1996) are more similar to our relation extraction task, although the domain is quite different. Our experiment allowed for 1 week of development time, while MUC-6 allowed a month. The core entities in the MUC-6 task (people and organizations) had been worked on previously. In contrast all of our relations included at least one novel class. While MUC-6 systems tended to use finite-state patterns, they did not incorporate bootstrapping or patterns based on the output of a statistical parser.

For learning entity classes, we follow Miller, et al., (2004), using word clustering and active learning to train a perceptron model, but unlike that work we apply the technique not just to names but also to descriptions. An alternative approach to learning classes, applying structural patterns to bootstrap description recognition without active learning, is seen in Riloff (1996) and Kozareva et al., (2008)

Much research (e.g. Ramshaw 2001) has focused on learning relation extractors using large amounts of supervised training, as in ACE. The obvious weakness of such approaches is the resulting reliance on manually annotated examples, which are expensive and time-consuming to create.

Others have explored bootstrap relation learning from seed examples. Agichtein & Gravano (2000) and Ravichandran & Hovy (2002) reported results for generating surface patterns for relation identification; others have explored similar approaches (e.g. Pantel & Pennacchiotti, 2006). Mitchell et al. (2009) showed that for macro-reading, precision and recall can be improved by learning a large set of interconnected relations and concepts simultaneously. None use coreference to find training examples; all use surface (word) patterns. Freedman et. al (2010) report improved performance from using predicate structure for bootstrappped relation learning.

Most approaches to automatic pattern generation have focused on precision, e.g., Ravichandran and Hovy (2002) report results in TREC QA, where extracting one instance of a relation can be sufficient, rather than detecting all instances. Mitchell et al. (2009), while demonstrating high precision, do not measure recall.

By contrast, our work emphasizes recall, not just precision. Our question answering task asks list-like questions that require multiple answers. We also include the results of a secondary, extraction evaluation which requires that the system identify every mention of the relations in a small set of documents. This evaluation is loosely based on the relation mention detection task in ACE.

3 Task Set-Up and Evaluation

Our effort was divided into four phases. During the first phase, a third party produced an ontology and the resources, which included: brief (~1 paragraph) guidelines for each relation and class in the ontolo-

[3] Handwritten patterns achieved 52% precision.
[4] http://trec.nist.gov/data/qamain.html

gy; ~20 examples for each relation in the ontology; 2K documents that are rich in domain relations.

Table 1 lists the 5 new relations and number of examples provided for each. Arguments in italics were known by the system prior to the evaluation.

Relation	Ex.
possibleTreatment(Substance, Condition)	23
expectedDateOnMarket(Substance, *Date*)	11
responsibleForTreatment(Substance, A*gent*)	19
studiesDisease(*Agent*, Condition)	16
hasSideEffect(Substance, Condition)	27

Table 1: New Relations and Number of Examples

In phase two, we spent one week extending our extraction system for the new ontology. During the third phase, we ran our system over 10K documents to extract all instances of domain relations from those documents. In the fourth phase, our question answering system used the extracted information to answer queries.

4 Approach to Domain Specialization

Our approach to extracting domain relations integrated novel relation and class detectors into an existing extraction system, designed primarily around the ACE tasks. The existing system uses a discriminatively trained classifier to detect the entity and value types of ACE. It also produces a syntactic parse for each sentence; normalizes these parses to find logical predicate argument structure; and detects and coreferences pronominal, nominal, and name mentions for each of the 7 ACE entity types (Person, Organization, Geopolitical Entity, Location, Facility, Weapon, and Vehicle).[5]

The extraction system has three components that allow for rapid adaptation to a new domain:

- Class detectors trained using word classes derived from unsupervised clustering and sentence-selected training data.
- A bootstrap relation learner which given a few seed examples learns patterns that indicate the presence of relations.
- An expressive pattern language which allows a developer to express rules for relation extraction in a simple, but fast manner.

Component	Approach	Effort
Class Recognizer	Active Learning	6 hrs
Class Recognizer	Web-Mined List	1 hrs
Relation Recognizer	Semi-supervised Bootstrapping	8.5 hrs
Relation Recognizer	Manual Patterns	5 hrs
Coreference	Heuristics	20 hrs

Table 2: Effort and Approach for New Domain

4.1 Class Extraction

Each of the relations in the new domain included at least one argument that was new. While question answering requires the system to identify the classes only when they appear in a relation, knowledge of when a class is present provides important information for relation extraction. For example in our ontology, Y is a treatment for X only if Y is a substance. Thus, '*Group counseling sessions are effective treatments for depression'* does not contain an instance of *possibleTreatment*(), while '*SSRIs are effective treatments for depression*' does. The bootstrap learner allows constraints based on argument type. To use this capability, we trained the recognizer at the beginning of the week of domain adaptation and used the predicted classes during learning.

We annotated 1064 sentences (~31K words) using active learning combined with unsupervised word clusters (Miller,et al., 2004) for the following classes: *Substance-Name, Substance-Description, Condition-Name, and Condition-Description*. Generic noun-phrases like *new drugs, the illness*, etc were labeled as descriptors. Because of the time frame, we did not develop extensive guidelines nor measure inter-annotator agreement. Annotation took 6 hours. We supplemented our annotation with lists of substances and treatments from the web, which took 1 hour.

4.2 Coreference

Providing a name reference is generally preferable to a non-specific string (e.g. *the drugs*), but not always feasible; for instance, reports of new research may appear without a name for the drug. Our existing system's coreference algorithms operate only on mentions of ACE entity types (persons, organizations, GPEs, other locations, facilities, vehicles, and weapons). During the week of domain adaption we developed new heuristics for coreference over non-ACE types. Most of our heuristics are domain independent (e.g. linking the parts of an appositive). Our decision to annotate names and descriptions separately was driven par-

[5] The extraction system detects relations and events in the ACE ontology, but these were not used in the current work.

tially by the need to select the best reference (i.e. name) for co-referent clusters. Adding coreference heuristics for the two new entity types was the single most time-consuming activity, taking 20 of the total 43 hours.

4.3 Relation Extraction

For relation extraction, we used both pattern learning and handwritten patterns. We initialized our bootstrap relation learner with the example instances provided with the domain ontology; Table 3 includes examples of the instances provided to the system as training. Our bootstrap relation learner finds instances of the relation argument pairs in text and then proposes both predicate-argument structure and word-based connections between the arguments as possible new patterns for the relation. The learner automatically prunes potential patterns using information about the number of known-to-be true and novel instances matched by a proposed pattern. By running the pattern extractor over a large corpus, the proposed patterns generate new seeds which are in turn are used to propose new patterns. For this experiment, we incorporated a small amount of supervision during the bootstrapping process (roughly 1 hour total per relation); we also performed ~30 minutes total in pruning domain patterns at the end of learning.

Relation	Arg-1	Arg-2
possTreatmnt	AZT	AIDS
studyDisease	Dr Henri Joyeux	cancer
studyDisease	Samir Khleif	cancer

Table 3: Sample Instances for Initializing Learner

We also used a small amount of human effort creating rules for detecting the relations. The pattern writer was given the guidelines, the examples, and a 2K document background corpus and spent 1 hour per relation writing rules.

The learned patterns use a subset of the full pattern language used by the pattern-writer. The language operates over surface-strings as well as predicate-argument structure. Figure 1 illustrates learned and handwritten patterns for *the possibleTreatmentRelation()*. The patterns in rectangles match surface-string patterns; the tree-like patterns match normalized predicate argument structure. The –WORD- token indicates a wild card of 1-3 words. The blue rectangles at the root of the trees in the handwritten patterns are sets of predicates that can be matched by the pattern.

5 Evaluation

Our question answering evaluation was inspired by the evaluation in DARPA's machine reading program, which requires systems to map the information in text into a formal ontology and answer questions based on that ontology. Unlike ACE, this allows evaluators to measure performance without exhaustively annotating documents, allows for balance between rare and common relations, and implicitly measures coreference without requiring explicit annotation of answer keys for coreference. However because the evaluation only measures performance on the set of queries, many relation instances will be unscored. Furthermore, the system is not rewarded for finding the same relation multiple times; finding 100 instances of *isPossibleTreatment(Penicillin, Strep Throat)* is the same as finding 1 (or 10) instances.

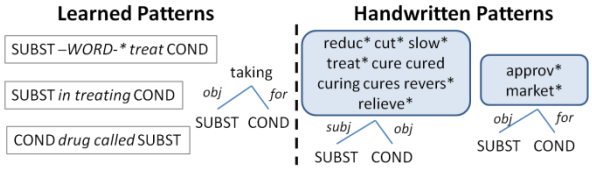

Figure 1: Sample Patterns for *possibleTreatment()*

The evaluation included only queries of the type *Find all instances for which the relation P(X, Z) is true* where one of X or Z is constant. For example, *Find possible treatments for diabetes*; or *What is expected date to market for Abilify?* There were 60 queries in the evaluation set to be answered from a 10K document corpus. To produce a preliminary answer key, annotators were given the queries and corpus indexed by Google Desktop. Annotators were given 1 hour to find potential answers to each query. If no answers were found after 1 hour, the annotators were given a second hour to look for answers. For two queries, both of the form *Find treatments with an expected date to market of MM-YYYY,* even after two hours of searching the annotators were unable to find any answers.[6]

Annotator answers served as the initial gold-standard. Given this initial answer key, annotators reviewed system answers and aligned them with gold-standard answers. System output not aligned with the initial gold standard was assessed as correct or incorrect. We assume that the final gold-standard constitutes a complete answer key, and

[6] Evaluators wanted some queries with no answers.

are thus able to calculate recall for our system and for humans[7]. Because we had only one annotator for each query and because we assumed that any answer found by an annotator was correct, we could not estimate human precision on this task.

Answers can be specific named concepts (e.g. *Penicillin*) or generic descriptions (e.g. *drug, illness*). Given the sentence, *ACME produces a wide range of drugs including treatments for malaria and athletes foot,*' our reading system would extract the relations *responsibleForTreatment(drugs, ACME), possibleTreatment(drugs, malaria), possibleTreatment(drugs, athletes foot).* When a name was available in the document, annotators marked the answer as correct, but underspecified. We calculated precision and recall treating underspecified answers as incorrect and separately calculated precision and recall counting underspecified answers as correct. When treated as correct, there was less than a 0.05 absolute increase in both precision and recall. Unless otherwise specified, all scores reported here use the stricter condition which treats underspecified answers as incorrect.

We also evaluated extracting all information in a small document collection (here human search of the 10k documents does not play a role in finding answers). Individuals were asked to annotate every instance of the 5 relations in a set of 102 documents. Recall, Precision, and F were calculated by aligning system responses to the answer key. System answers that aligned are correct; those that did not are incorrect; and answers in the key that were not found by the system are misses. Unlike the question answering evaluation, this evaluation measures the ability to find every instance of a fact. If the gold standard includes 100 instances of *isPossibleTreatment(Penicillin, Strep Throat),* recall will decrease for each instance missed. The "extraction" evaluation does not penalize systems for missing coreference.

6 Results

6.1 Class Detection

The recall, precision, and F1 for class detection using 10-fold cross validation of the ~1K annotated sentences appear in the 3-5th columns of Table 4. Given the amount of training, our results are lower than in Miller et al (2004) (an F1 of 90 with less than 25K words of training). Several factors could explain this: Finding boundaries and types for descriptions is more complex than for names in English.[8] Our classes, pharmaceutical substances and physiological conditions, may have been more difficult to learn. Our classes are less common in news reporting; as such, both word-class clusters and active learning may have been less effective. Finally, our evaluation was done on a 10-fold split of the active-learning selected data; bias in selecting the data could explain at least a part of our lower performance.

Type	# in GS	Without Lists			With Lists		
		R	P	F	R	P	F
Subst-D	789	77	85	80.8	78	85	81.3
Subst-N	410	70	82	75.5	77	81	78.9
Cond-D	427	72	78	74.9	72	77	74.4
Cond-N	963	80	87	83.4	84	83	83.5

Table 4: Cross Validation: Condition & Substance

We noticed that the system frequently reported country names to be substance-names. Surprisingly, we found that our well-trained name finder made the opposite mistake, occasionally reporting drugs as geo-political entities.

We incorporated lists of known substances and conditions to improve recall. Performance on the same cross-validation split is shown in the final three columns of Table 4. Incorporating the lists led to recall gains for both substance-name and condition-name. Because a false-alarm in class recognition only leads to an incorrect relation extraction if it appears in a context indicating a domain relation, false alarms of classes may be less important in the question answering and extraction evaluations.

6.2 Question Answering and Extraction

Figure 2 and Table 6 show system performance using only handwritten rules (HW), only learned patterns (L), and combining both (C). Figure 2 includes scores calculated with all of the systems' answers (in the dotted boxes), and with just those answers that were deemed useful (discussed be-

[7] The answer key may contain some answers that were found neither by the annotator nor by the systems described here, since the answer key includes answers pooled from other systems not reported in this paper. The system reported here was the highest performing of all those participating in the experiment. Furthermore, if a system answer is marked as correct, but underspecified, the specific answer is put in the key.

[8] English names are capitalized; person names have a typical form and are frequently signaled by titles; organization names frequently have clear signal words, such as Corp.

low). We include annotator recall. Handwritten patterns outperform learned patterns consistently with much higher recall. Encouragingly, however,

1. The combined system's recall and F-Score are noticeably higher for 3 of the relations.
2. The learned patterns generate answers not found by handwritten patterns.
3. The learned patterns have high precision.[9]

There is variation across the different relations. The two best performing relations *possibleTreatment*() and *studiesDisease*() have F1 more than twice as high as the two worst performing relations, *expectedDateToMarket()* and *hasSideEffect()*. This is primarily due to differences in recall.

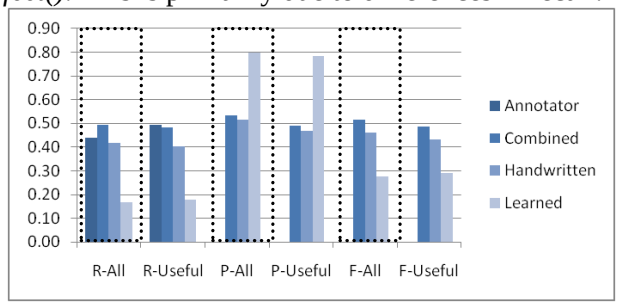

Figure 2: Overall Q/A Performance: All answers in dotted boxes; 'Useful Answers' unboxed

The combined system's recall (0.49), while low, is higher than that of the annotators (0.44). While hardly surprising that a machine can process information much more quickly than a person, it is encouraging that higher recall is achieved even with only one week's effort. In the context of our pooled answer-key, the relatively low recall of both the system and the annotator suggests that there was little overlap between the answers found by the annotator and those found by the system.

As already described, the system answers can include both specific references (e.g. *Prozac*) and more generic references (*the drug*). When a more specific answer is present in the document, generic references have been treated as incorrect. However, sometimes there is not a more specific reference; for example an article written before a drug has been released may never name the drug. Scores reported thus far treat such answers as correct. These answers would be useful when answering more complex queries. For example, given the sentence '*ACME spent 5 years developing a pill to treat the flu which it will release next week,'* extracting relations involving '*the pill'* would allow a system to answer questions that use multiple relations in the ontology to for example ask about *organizations developing treatments for the flu*, or *the expected date of release for ACME's drugs*. However, in our simple question answering framework such generic answers never convey novel information and thus were probably ignored by human annotators.

To measure the impact of treating these generic references as correct,[10] we did additional annotation on the correct answers, marking answers as 'useful' (specific) and 'not-useful' (generic). The unboxed bars in Figure 2 show performance when 'not-useful' answers are removed from the answer-key and the responses. For the four relations where there was a change Table 5 provides the relative change performance when only 'useful' answers are considered. The annotator's recall increases noticeably while the combined system's drops. This results in the overall recall of annotators surpassing that of the combined system.

Relation	Recall				Precision		
	A	C	H	L	C	H	L
possTreat	12	10	10	14	-10	-11	-3
respTreat	9	0	-5	8	-4	-4	-1
studyDis	12	-6	-9	13	-11	-13	0
hasSidEff	3	4	4	4	0	0	0
Total	11	-2	-4	6	-9	-10	-2

Table 5: Relative Change in Recall and Precision When Non-Useful Answers are Removed

Table 7 shows the total number of answers produced by annotators and by each system, as well as the percentage of queries with at least one correct answer for each system. For one relation *expectedDateOnMarket()*, the learned system did not find any answers. This relation had far fewer answers found by annotators and occurred far more rarely in the fully annotated extraction set (see Table 8). Anecdotally, extracting this relation frequently required co-referencing 'it' (e.g. "*It will be released in March 2011"*). Our heuristics for coreference of the new classes did not account for pronouns. Learning from such examples would require coreference during bootstrapping. Most likely, the learned system was unable to generate enough novel instances to continue bootstrapping

[9] The learned patterns' high precision is to be expected for two reasons. First, a few bad patterns were manually removed for each relation. More importantly, the learning algorithm strongly favors high precision patterns because it needs to maintain a seed set with low noise in order to learn effectively.

[10] Generic answers were treated as correct only if a more specific reference was not available in the document.

and was thus unable to learn the relation.

Relation Type (# Queries; # Correct Ans.)	Recall				Precision			F		
	A	C	HW	L	C	HW	L	C	HW	L
possTreatment (10;247)	0.27	0.63	0.50	0.34	0.51	0.47	0.83	0.56	0.48	0.48

Total	369	774	681	175	90.0%	60.0%	56.7%	43.3%

Table 7: Number of Answers and Number of Queries Answered

Overall, the system did better on relations having more correct answers. Bootstrap learning has an easier time discovering new instances and new patterns when there are more examples to work with. Even a human pattern writer will have more examples to generalize from for common relations.

While *possibleTreatment()* and *hasSideEffect()* have similar F-scores, their performance is very different at the query level. The system was able to find at least one correct answer to every *possibleTreatment*() query; however only 72.7% of the *studiesDisease*() queries were answered.

Table 8 presents results from the extraction evaluation where a set of ~100 documents were annotated for all mentions of the 5 relations. Because every mention in the document set must be found, the system cannot rely on finding the easiest answers for common relations. The results in Table 8 are significantly lower than for the question answering tasks; yet some of the same trends are present. Handwritten rules outperform learned patterns. For at least some relations, the combination of the two improves performance. The three relations for which the learned system has the lowest performance on the question-answering task have the fewest instances annotated in the document set. Fewer instance in the large corpus make bootstrapping more difficult—the learner is less able to generate novel instances to expand its pattern set.

7 Discussion

7.1 Sources of Error

The most common source of error is pattern coverage. In the following figure, the system identified responsibleForTreatment(Janssen Pharmaceutical, Sporanox), but missed the corresponding relation between Novartis and Lamisil.

> *Sporanox is made by Janssen Pharmaceutica Inc., of Titusville, N.J. Lamisil is a product of Novartis Pharmaceuticals of East Hanover, N.J.*

Relation Type	# Relations Found				Recall			Precision			F		
	GS	C	HW	L	C	HW	L	C	HW	L	C	HW	L
possibleTreatment	518	225	187	68	**0.15**	0.10	0.09	**0.34**	0.28	0.66	**0.21**	0.15	0.15
respForTreatment	387	101	77	36	**0.10**	0.08	0.05	**0.41**	0.40	0.50	**0.17**	0.13	0.08
expDateOnMarket	66	13	13	0	***0.06***	***0.06***	0.00	***0.31***	**0.31**	0.00	***0.10***	***0.10***	0.00
studiesDisease	136	95	91	4	0.08	***0.09***	0.00	0.12	**0.13**	0.00	0.10	**0.11**	0.00
hasSideEffect	256	26	25	2	***0.04***	***0.04***	0.00	0.39	0.40	0.50	***0.07***	***0.07***	0.01

Table 8: Extraction Results on the 102 Document Test Set Annotated for All Instances of the Relations

Missed class instances contribute to errors, sometimes originating in errors in tokenization (e.g. not removing the '_' in each drug name in a bulleted list of the form "*_Trovan, an antibiotic...; etc.)* However, many drug-names are simply missed:

> *Pfizer also hopes to introduce Pregabalin next year for treatment of neuropathic pain, epilepsy and anxiety…Other deals include co-promoting Rebif for multiple sclerosis with its discoverer, Serono, and marketing Aricept for Alzheimer's disease with its developer, Eisai Co.*

The system correctly identifies *Rebif* and *Aricept* as drugs, but misses *Pregabalin* and *Serono*. In both misses, the immediately preceding and following words provide little evidence that the word refers to a drug rather than some other product. Substance detection might be better served with a web-scale, list-learning approach like the doubly anchored patterns described in (Kozareva et al., 2008). Alternatively, our approach may need to be extended to include a larger context window.

7.2 Learned Patterns

One of the ways in which learned patterns supplement handwritten ones is learning highly specific surface-string patterns that are insensitive to errors in parsing. Figure 3 illustrates two examples of what appear to be easy cases of *possibleTreatment*(). Because the handwritten patterns are not exhaustive and make extensive use of syntactic structure, parse errors prevented the system based on handwritten rules from firing. Learned surface-string patterns were able to find these relations.

Even when the syntactic structure is correct, learned patterns capture expressions not common enough to have been noticed by the rule writer. For example, while the handwritten patterns included '*withdrew'* as a predicate indicating a company was responsible for a drug, they did not include '*pulled.'* By including '*pulled'*, learned patterns extracted *responsibleForTreatment()* from '*American Home Products pulled Duract, a painkiller.'* Similarly, the learned patterns include an explicit pattern '*CONDITION drug called SUBSTANCE'*, and thus extracted a *possibleTreatment()* relation from '*newly approved narcolepsy drug called modafinil'* without relying on the coreference component to link *drug* to *modafinil*.

Handwritten Patterns

Despite the examples above of successfully learned patterns, handwritten patterns perform significantly better. In the active-learning context used for these experiments, the handwritten rules also required *less* manual effort. This comparison is not entirely fair-- while learned patterns required more hours, supervising the bootstrapping algorithm requires no training. The handwritten patterns, in contrast, require a trained expert.

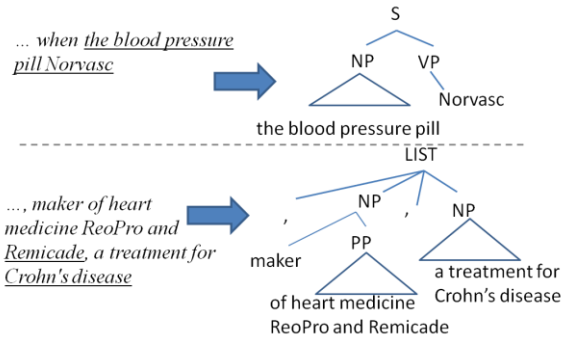

Figure 3: Extractions Missed by Handwritten Rules & the Erroneous Parses that Hid them

While handwritten rules and learned patterns use the same language, they make use of it differently. The handwritten patterns group similar concepts together. A human pattern writer adds relevant synonyms, as well as words that are not synonymous but in the pattern context can be used interchangeably. In Figure 4, the handwritten patterns include three word-sets: (*patient**, *people*, *participant**); (*given*, *taken*, *took*, *using*); and (*report**, *experience**, *develop**, *suffer**). The '*' serves as a wild-card to further generalize a pattern. The word-sets in Figure 4 illustrate challenges for a learned system: the words are not synonyms, but rather are words that can be used to imply the relation.

A human pattern writer frequently generates new classes not in the domain ontology. In Figure 4, the circled patterns form a class of 'people taking a substance.' The handwritten patterns for *studiesDisease*() include classes targeting scientists and researchers. These classes are not necessarily triggered by nouns. Such classes allow the pattern writer to include complex patterns as in Figure 4 and to write relatively precise, but open-ended patterns such as: *if there is a single named-drug and a named, non-side-effect disease in the same sentence, the drug is a treatment for the disease.*

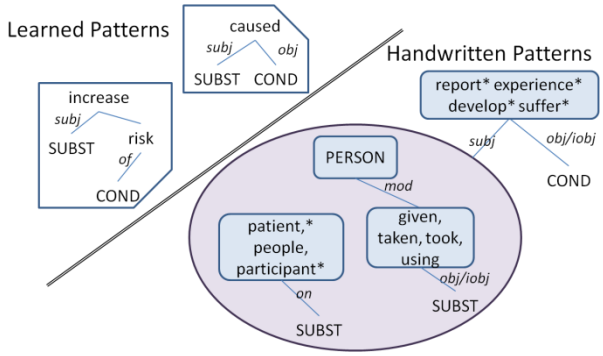

Figure 4: Learned and Handwritten Patterns for *hasSideEffect*()

A final difference between handwritten and learned patterns is the level of predicate-argument complexity used. In general, handwritten patterns account for larger spans of predicate argument structure while learned patterns tend to limit themselves to the connections between the arguments of the relation with minor extensions.

8 Conclusions and Lessons Learned

First, it is encouraging that the synthesis of learning algorithms and handwritten algorithms can achieve an F1 of 0.51 in a new domain in a week (<50 hours of effort). *Second*, it is exciting that so little training data is required: ~20 relation pairs out of context (~2.5 hours of effort) and ~6 hours of active learning for the new classes.

Third, the effectiveness of learning algorithms is still not competitive with handwritten patterns based on predicate-argument structure (~5 hours of effort on top of active learning for entities). Though the learned patterns have high precision (0.80 on average), recall is low (0.17) and varied greatly across the relations. Though the dominant factor in missing relations is pattern coverage, missing instances of classes contributed to low recall. Comparing learned patterns to manually written patterns, (1) synonyms or other lexical alternatives that a human pattern writer would include, (2) the creation of subclasses for argument types, and (3) the scope of patterns[11] are each major sources of the disparity in coverage. Research on learning approaches to raise recall without significant sacrifice in precision seems essential.

Fourth, despite the disparity in performance of learned versus manual patterns, and despite the low recall of learned patterns, the combined system's recall and F-Score are higher for three of the relations because the learned patterns generated answers not found by handwritten patterns. We found examples where highly specific, learned, surface-level patterns (lexical patterns) occasionally found information missed by handwritten patterns due to parsing errors or general low coverage.

Fifth, the effort for coreference was the most time-consuming, given that every new relation contained at least one of the new argument types. While we included this in our estimate of domain adaptation, the infrastructure we built is domain generic. Improving generic coreference will reduce domain specific effort in future.

Perhaps *most significant* of all, running a complete experiment from definition of the domain through creation of training data and measurement of end-to-end performance of the system can be completed in a month. The ability to rapidly, cheaply, and empirically measure the impact of extraction research could prove a significant spur to research across the board.

These experiments suggest three possible directions for improving the ability to quickly develop information extraction technology for a new set of relations: (1) reducing the amount of supervision provided to the bootstrap-learner; (2) improving the bootstrapping approach to reach the level of recall achieved by the human pattern writer eliminating the need for a trained expert during domain adaptation; and (3) focusing improvements to the bootstrapping approach on techniques that allow it to find more of the instances missed by the pattern writer, thus improving the accuracy of the hybrid system.

[11] Learned patterns tend to focus on the structure that appears between the two arguments, rather than structure surrounding the left and right arguments.

Abstract

Traditional approaches to Relation Extraction from text require manually defining the relations to be extracted. We propose here an approach to automatically discovering relevant relations, given a large text corpus plus an initial ontology defining hundreds of noun categories (e.g., Athlete, Musician, Instrument). Our approach discovers frequently stated relations between pairs of these categories, using a two step process. For each pair of categories (e.g., Musician and Instrument) it first co-clusters the text contexts that connect known instances of the two categories, generating a candidate relation for each resulting cluster. It then applies a trained classifier to determine which of these candidate relations is semantically valid. Our experiments apply this to a text corpus containing approximately 200 million web pages and an ontology containing 122 categories from the NELL system [Carlson et al., 2010b], producing a set of 781 proposed candidate relations, approximately half of which are semantically valid. We conclude this is a useful approach to semi-automatic extension of the ontology for large-scale information extraction systems such as NELL.

1 Introduction

The Never-Ending Language Learner (NELL) (Carlson et al., 2010b)) is a computer system that learns continuously to extract facts from the web. NELL is given as input an initial ontology that specifies the semantic categories (e.g. city, company, sportsTeam) and semantic relations (e.g. hasOfficesIn(company,city), teamPlaysInCity(sportsTeam,city)) it must extract from the web. In addition, it is provided 10-20 seed positive training examples for each of these categories and relations, along with hundreds of millions of unlabeled web page. Given this input, NELL applies a large-scale multitask, semisupervised learning method to learn to extract new instances of these categories (e.g., city("London")) and relations (e.g., teamPlaysInCity("Steelers","Pittsburgh")) from the web. During the past 17 months NELL has been running nearly continuously, learning to extract over 600 categories and relations, and populating a knowledge base containing over 700,000 instances of these categories and relations with a precision of approximately 0.85[1].

This paper considers the problem of automatically discovering new relations to extend the ontology of systems such as NELL, enabling them to increase over time their learning and extraction capabilities. More precisely, we consider the following problem:

Input:
- An ontology specifying a set of categories
- A knowledge base containing instances of these categories (perhaps including errors)
- A large text corpus

Output:
- A set of two-argument relations that are frequently mentioned in the text corpus, and whose argument types correspond to categories in the input ontology (e.g., RiverFlowsThroughCity(<River>,<City>).
- For each proposed relation, a set of instances (i.e. RiverFlowsThroughCity("Nile","Cairo")).
- For each proposed relation, a set of text extraction patterns that can be used to extract additional instances of the relation (e.g., the text "X in the heart of Y", where X is a known river, and Y a known City, suggests extracting RiverFlowsThroughCity(X,Y)).

Note the above inputs are easily available from NELL in the form of its existing ontology and extracted knowledge base. Note also that the outputs

Edinburgh, Scotland, UK, July 27–31, 2011.

of our system are sufficient to initiate NELL's learning of additional extraction methods to further populate each proposed relation. One goal of this research is to create a system that can provide NELL with an ongoing set of new learning and extraction tasks. The system is called OntExt (Ontology Extension System)

Table 1 shows a sample of successful relations and corresponding relation contexts and sample seed instances generated by OntExt.

Table 1. Examples of valid relations (generated by OntExt), their text extraction patterns and extracted instances.

name(category1-main context-category2)	Extraction patterns	Seed Instances
River -in heart of- City	'in heart of' 'in the center of' 'which flows through'	"Seine, Paris" "Nile, Cairo" "Tiber river, Rome" "River arno, Florence"
Food -to produce- Chemical	'to produce' 'to make' 'to form'	"Salt, Chlorine" "Sugar, Carbon dioxide" "Protein, Serotonin"
StadiumOrVenue -in downtown- City	'in downtown'	"Ford field, Detroit" "Superdome, New Orleans" "Turner field, Atlanta"
Disease -caused by- Bacteria	'caused by' 'is the causative agent of' 'is the cause of'	"pneumonia, legionella" "mastitis, staphylococcus aureus" "gonorrhea, neisseria gonorrhoeae"
Disease -destroys- CellType	'destroys' 'attacks'	"alzheimer, brain cells" "vitiligo", melanocytes" "aids, lymphocytes"
County -county- StateOrProvince	'county' 'county of' 'county in'	"sufolk, massachusetts" "marin, california" "sussex, delaware" "osceola, michigan"

2 Background

Traditional Relation Extraction

We define Traditional RE systems as those that require the user to specify information about the relations to be learned. For instance, SnowBall (Agichtein and Gravano 2000) & CPL (Carlson et al. 2009) are bootstrapped learning systems that require manual input of relation predicates. In these systems, for each relation predicate, the relation name (e.g. City 'Capital of' Country), the seed instances and the category type (e.g. City, Country, Celebrity etc) are provided (for domain and range). In CPL (Carlson et al. 2009), learning of relation/category instances is coupled by using constraints such as mutual exclusion relationships among the predicates. The authors show that this coupling reduces semantic drift, which commonly occurs with bootstrapping systems, thus leading to improved precision. CPL achieved 89% precision for the relation instances extracted (Carlson, Betteridge et al. 2009). KNOWITALL (Etzioni, Cafarella et al. 2005) is a web-scale relation extraction system, which requires as input the relation names. Hence, in these "traditional relation extraction" methods, the need to manually define the relations to be extracted makes it difficult to work in applications having thousands of possible relation predicates.

2.1 Open Relation Extraction

Open RE methods do not require a user to manually specify the information about the relations to be learned, such as their names, seed examples, etc. TextRunner (Banko, Cararella et al. 2007) is such an Open Information Extraction system that retrieves from the web millions of relational tuples between noun phrase entities. TextRunner uses a deep linguistic parser to perform self-supervised learning and extracts a positive set (i.e. valid relation between entities) and a negative set (i.e. invalid relationships) of relational tuples based on certain heuristics. Then, a Naive Bayes classifier is built having features such as part-of-speech tags of the words in the relation tuples, number of tokens, stopwords etc., and uses the labeled instances as the training set. This classifier runs on sentences from a web corpus to extract millions of relational tuples. However, of the 11 million high confident relational tuples extracted by this system only 1 million were concrete facts (Banko, Cararella et al. 2007). Of these concrete facts 88% were estimated to be correct. For instance, (Mountain View, headquarters of, Google) is a tuple representing a valid concrete fact. The remaining 90% of the tuples are abstract or do not have well-formed arguments or well-formed relations. For instance, (Einstein, derived, theory) is an abstract tuple as it does not

have enough information to indicate a concrete fact (Banko, Cararella et al. 2007) because the specific theory which Einstein derived is missing in that tuple. In the tuple (45, 'went to', 'Boston'), one of the arguments (i.e. 45) is not well formed.

In (Banko and Etzioni, 2008) a Conditional Random Field (CRF) classifier is used to perform Open Relation Extraction which improves by more than 60% the F-score achieved by the Naive Bayes model in the TextRunner system. However the CRF approach does not solve the problem associated with extraction of abstract/non-well formed tuples. Further, in the same work, it is shown that Open RE has a much lower recall in comparison to Traditional RE systems. On four common relations (Acquisition, Birthplace, InvetorOf, WonAward), Open RE attained a recall of 18.4% in comparison to 58.4% achieved by Traditional RE (Banko and Etzioni 2008). Both Open RE systems discussed (Banko, Cararella et al. 2007; Banko and Etzioni 2008) do not perform learning of the category type of the entities involved in the relations. They are single-pass and do not perform continuous learning to improve/extend on what has been learnt.

2.2 Unsupervised Methods to Extract Relations between Named Entities

In general, traditional RE methods extract concrete facts and have much higher recall for a given relation, than Open RE methods. This is due to the knowledge fed into Traditional RE methods such as the category type of the entities in the relation and seed instances for the relation. Traditional RE methods require the relations to be manually defined and extract instances only for them. Open RE methods, on the other hand, do not require any such domain specific knowledge to be manually input. They extract instances for a wide spectrum of relations that are not manually pre-defined.

To overcome the drawbacks of using Traditional and Open RE methods, some researchers have used unsupervised learning methods to automatically generate new relations (with seeds and contexts) between specific categories. These automatically generated relations can then be used as input to Traditional RE systems.

Hasegawa et.al (Hasegawa, Sekine et al. 2004), propose an unsupervised clustering based approach. One feature vector for each co-occurring NE pair is formed based on the context words in which the NE pair co-occurs. Then, a cosine-similarity metric is applied to each pair of feature vectors to generate a "NE-pair x NE-pair" matrix. Clustering is done on this matrix and each cluster of NE-pairs corresponds to a relation predicate.

The work by Zhang et.al (Zhang, Su et al. 2005) generates a shallow parse tree for each sentence containing a NE pair to generate relation instances. A tree similarity metric is used to cluster the relation instances. This method gives improved F-score over Hasegawa et.al (Hasegawa, Sekine et al. 2004). Further they use a specialized NE tagger built to recognize entities that belong to specific predefined categories. The aforementioned methods (Hasegawa, Sekine et al. 2004) (Zhang, Su et al. 2005) were tested on a news corpus to identify relations between only a couple of pairs of entity types (Person-GeoPoliticalEntity and Company-Company).

Both of these methods cluster NE-pairs primarily based on lexical similarity of the context words connecting the entities. Hence NE-pairs connected by lexically different but semantically similar context patterns (e.g. river 'in heart of' city and river 'flows through' city) would probably not get clustered together. The web data is, however, much noisier and has a larger number of entity types (i.e. category predicates), thus, another issue is that for web scale data *NE pairs X NE pairs* similarity matrix would not be scalable for many thousands of NE-pairs.

3 Ontology Extension System - OntExt

The OntExt system for ontology extension, proposed in this paper, combines characteristics from both "Traditional RE" and "Open RE," to discover new relations among categories that are already present in the ontology, and for which many instances have already been extracted.

Our proposed method for automatic relation extraction offers the following advantages over the methods discussed above.

- The key idea in our approach is to make use of redundancy of information in web data - the same relational fact is often stated multiple times in large text corpora, using different context patterns. We use this redundancy to cluster together context patterns which are semantically similar although they may be lexically dissimilar.

- Instead of clustering on the *'NE-pairs X NE-pairs'* matrix, clustering is done on a *'Context-pattern X Context-pattern'* matrix. This is much more scalable as the context patterns are fewer in number and since our method applies several criteria to prune out irrelevant patterns.
- To accommodate errors in the input category instances and ambiguity in web data, we build a classifier which learns to distinguish valid relations from semantically invalid relations.

OntExt has 3 components. 1) It starts exploring a large web corpus and 2) category instances extracted by CPL to generate new relations. After the relations are generated, 3) a classifier is developed to classify semantically valid relations.

3.1 Pre-processing

Following along the same strategy used in [Carlson et al., 2010], OntExt uses as input a corpus of 2 billion sentences, which was generated by using the OpenNLP[2] package to extract, tokenize, and POS-tag sentences from the 500 million web page English portion of the ClueWeb09 data [Callan and Hoy, 2009]. Before performing relation extraction, this corpus is preprocessed. First, sentences which contain a pair of known category instances are retrieved (e.g. the sentence "Ottawa is the capital of Canada.", where 'Ottawa' is a known instance of the 'City' category and 'Canada' is a known instance of 'Country'). For every category pair (e.g. <City, Country>) the sentences containing known instances of both categories are grouped into a set S. The text between the two instances is called the 'context pattern' (e.g. 'is the capital of' is a context pattern). Three types of pruning are done on this set S.

1. If the context pattern is a rare one (i.e. if the context pattern occurs in less than a threshold number of sentences), all sentences with that context pattern are removed. Thus we retain only frequently occurring contexts. We use a threshold requiring at least 5 sentences in the experiments presented in Section 4.
2. Context patterns which co-occur with very few instances of either category type are removed. For example, the category pair <Vehicle,SportsTeam> has several sentences such as 'Car was engulfed in flames', 'Truck was engulfed in flames' etc. Note that Flames (Calgary Flames) is a SportsTeam. But here flames clearly does not refer to a Sportsteam. This context 'was engulfed in' connects several instance of a 'Vehicle' category to a single instance of SportsTeam instance. Hence all sentences with this context are removed. Note this context would not have been removed in step 1 as that is just a threshold on the number of sentences in which any pair occurs. We use a threshold requiring at least 3 distinct instances of both the domain and the range, for each context.
3. Banko et.al, 2008 show that most binary relational contexts fall under certain types of lexico-synctatic patterns. They include context patterns like 'C1 Verb C2', 'C1 NP Prep C2', 'C1 Verb Prep C2' and 'C1 to Verb C2' (C1 and C2 are category instances). Hence context patterns which do not fall under the above types are removed from the set S as they are not likely to produce relation instances.

3.2 Relation Generation

From the previous pre-processing step OntExt retrieves for each category pair a pruned set S' of sentences. Each sentence has a pair of category instances and the context connecting them.

Algorithm 1: Relation Generator

Input: One pair of Categories (C1, C2) and set of sentences, each containing a pair of instances known to belong to C1 and C2. The phrase connecting the instances in the sentence is the context.
Output: Relations and their seed instances

Steps:

1. From the input sentences, build a Context by Context co-occurrence matrix (Shown in figure 1). The matrix is then normalized.
2. Apply K-means clustering on the matrix to cluster the related contexts together. Each cluster corresponds to a possible new relation between the two input categories. (Weka Machine Learning package [Hall et al., 2009] was used to perform K-means clustering. The value of K was set to 5 based on trial and error experiments.)

2 http://opennlp.sourceforge.net.

3. Rank the known instance pairs (belonging to C1,C2) for each cluster and take the top 50 as seed instances for the relation

The key data structure used by OntExt is a co-occurrence matrix of the contexts for each category pair, as shown in Figure 1. In this matrix, each cell corresponds to the number of pairs of category instances that both contexts co-occur with (e.g. the sentences "Vioxx can cure Arthritis" and "Vioxx is a treatment for Arthritis" provide a case where the 2 contexts 'can cure' and 'is a treatment for' co-occur with an instance pair [Vioxx, Arthritis]). Initially, the value of Matrix(I,j) is the number of category instance pairs that occur with both context i and context j. We then normalize each cell in the matrix, dividing it by by the total count for its row.

$$Matrix(i,j) = \frac{Matrix(i,j)}{\sum_{j=0}^{N} Matrix(i,j)}$$

We also give higher weight to contexts which co-occur with only a few contexts over ones which are generic and co-occur with most contexts.

$$Matrix(i,j) = Matrix(i,j) * \frac{N}{|\{Context(j) : Matrix(i,j) > 0\}|}$$

Where N is the total number of contexts, and |{Context(j) : Matrix(i,j) > 0}| refers to the number of cells in the row Matrix(i) which are greater than zero.

For example, for the <drug, disease> category pair after 122 contexts were obtained after preprocessing. Contexts such as 'to treat', 'for treatment of', 'medication' which all indicate the same relation (drug-to treat-disease) have high co-occurrence values (see Figure 1). Similarly contexts such as 'can cause', 'may cause', 'can lead to' (indicating the relation drug-can cause-disease) have high co-occurrence values (see Figure 1). When OntExt performs clustering on this co-occurrence matrix the contexts with large co-occurrences get clustered together. Each cluster is then used to propose a possible new relation. The centroid of each cluster is used to build the relation name. If the centroid of a cluster is the context 'for treatment of', then the relation name is 'drug-for-treatment-of-disease'.

OntExt next generates seed instances for the proposed relation. The seed instances which co-occur with contexts corresponding to the cluster centroid or close to centroid will be best representative of the relation. So the strength of the seed instance is inversely proportional to the standard deviation of the context from the centroid of the relation contexts cluster. Also the strength of the seed instance is directly proportional to the number of times it co-occurs with the context.

Contexts/ Contexts	may cause	can cause	can lead to	to treat	for treatment of	medication
may cause	0.176	0.074	0.030	0.015	0.011	0.000
can cause	0.051	0.150	0.039	0.018	0.013	0.010
can lead to	0.034	0.064	0.189	0.019	0.021	0.018
to treat	0.006	0.011	0.007	0.109	0.043	0.015
for treatment of	0.005	0.008	0.008	0.045	0.086	0.023
medication	0.000	0.011	0.009	0.030	0.036	0.111

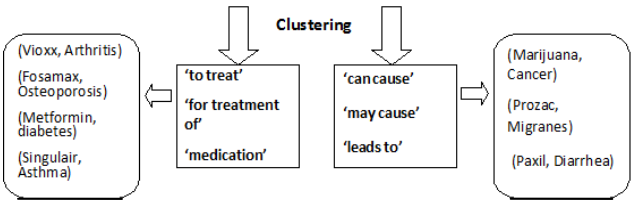

Figure 1: This figure shows the Context by Context sub-matrix (with 6 contexts) for the category pair (Drug, Disease) and the seed instances for each relation. As described in the text, each entry gives the normalized count of the number of known <drug, disease> pairs that occur with both the row context and the column context.

To summarize, each seed instance *s* (pair of category instances) is weighted as follows

$$\sum_{c \in Pattern\ cluster} Occ(c,s)/(1 + sd(c))$$

Where,

Pattern_cluster is the cluster of pattern contexts for this given relation

Occ(c,s) is the number of times instance 's' co-occurs with the pattern context 'c'

sd(c) is the standard deviation of the context from the centroid of the pattern cluster.

Using this metric the instances are ranked and the top 50 are output as initial seed instances for the proposed relation.

3.3 Classifying semantically valid relations

More than half of the relations generated in the previous step are invalid due to the following reasons

1. Error in category instances: The category instances input to OntExt come from NELL. In the version of the knowledge base used in these experiments, the accuracy of these instances was 78%. Due to the erroneous category instances some invalid relations are generated by OntExt. For instance the generated relation, 'condiment-wearing-clothing' with seeds (pig,dress), (rabbit,pants) etc. Here 'pig' and 'rabbit' were incorrectly identified by NELL as instances of 'condiment'.
2. Semantic Ambiguity: Consider the generated relation 'bakedgood-baking-magazine' with instances (cookies,time), (cupcakes, people), etc. Here the instances 'time' and 'people' do not refer to magazines, although they can in general. Due to the semantic ambiguity of these instances this invalid relation got generated
3. Semantically Incomplete relations: Some of the generated relations require a third entity or some more contextual information, in order to be considered semantically valid. For instance, 'personUs-said-company' or 'newspaper-is-reporting-that-company'. These don't stand by themselves as two-argument relational facts and need more information to be complete
4. Illogical relations: Some generated relations simply have no real semantic meaning. These relations are generated due to the category instances appearing together in some unrelated contexts. E.g. the generated relation 'date-starting-date' with seeds such as (Wednesday, June), (friday, July) and the relation 'country-minister-of- economicsector' with seeds (japan,agriculture), (india, industry).

The introduction of these invalid relations can adversely affect the performance of NELL. However, it is a challenging problem to develop automated ways to distinguish between valid and invalid relations without any domain specific knowledge. To approach this problem, we identified a set of features which can help characterizing valid and invalid relations, and which can be generated automatically. Below is a description of the features and the intuition behind their use for this classification task.

Each generated relation has a pair of category types (C1, C2), a corresponding set of seed instances (which are pairs of instances belonging to C1 and C2) and pattern contexts connecting C1 and C2. Let N be the number of seed instance pairs and N1 and N2 be number of unique instances (out of these N instance pairs) belonging to categories C1 and C2 respectively.

1. Normalized frequency count: The frequency count of each category instance is obtained from the corpus and normalized by the category instance with maximum count. For a given relation, a feature is generated by averaging the normalized frequency counts of the instances belonging to C1. Another similar feature is generated for C2 following the same strategy. For example the relation <Profession 'believe that' Movie> was generated due to common words like 'predator', 'earthquake' being identified as movie names out of context. These features can help identify such invalid relations.
2. Distribution of extraction patterns: NELL learns instances as well as extraction patterns for each category (e.g. the category Actor has extraction patterns such as '_ got an Oscar award', '_ is the movie's lead actor'). If a category instance co-occurs in the web corpus with several extraction patterns belonging to other categories, then that instance has large ambiguity. We measure ambiguity of an instance (i) belonging to category 'C' with respect to another category 'M' (where M is not a sub type or super type of 'C') as

   $$\text{Ambiguity}(i,M) = \frac{\#\text{ of extraction patterns in 'M' that 'i' co-occurs with}}{\#\text{ of extraction patterns in 'C' that 'i' co-occurs with}}$$

   We measure the average ambiguity for the set of instances (of size N) belonging to category C in the generated seeds as follows,

   $$Max_M\left(\sum_{i \in C} Ambiguity(i,M)/N\right)$$

   Two features are generated for categories C1 and C2 in the relation.
3. Relationship characteristics: We identified a few characteristics of the relation which help in identifying valid relations. If in the generated relation, most instances of C1 co-occur only

with very few instances of C2 (or vice versa) then the relation could be weak. For example, <Organization 'Provides' EconomicSector> - the instance 'Information' (of category EconomicSector) connects to a large percentage of items in the category 'Organization' but does not express a meaningful relation. So we consider the instance (in this example 'Information', let us call it 'maxconnect_instance') co-occurring with maximum number of instances of the other category. The percentage of instances it co-occurs with from among the total number of instances of the other category which are part of the seed instances is taken as a feature. Also if that instance is a very common word (like 'information' which in several contexts does not refer to 'EconomicSector') then this could indicate the presence of an invalid relation. So the normalized frequency count of this instance (maxconnect_instance) is taken as another feature.

4. Pattern Contexts: The number of pattern contexts attained through pattern clustering for the relation is taken as another feature. The presence of several pattern contexts connecting the instances between the two categories could indicate that the relation is a valid one. The presence of Hearst patterns (Hearst M, 1992) referring to a hyponym ("is-a") relation in pattern contexts indicates the possibility of a valid relation, and is taken as another feature

   Another feature is regarding how specific is the context pattern to this relation. If the same context connects say C1 instances to instances of several other categories apart from C2, then this context is not unique to this relation and might not indicate a meaningful valid relationship. So the ratio of the number of instances in C2 connected to C1 versus the number of instances from all categories connected to C1 by the most significant pattern context (i.e. centroid in pattern cluster) is taken as a feature. A similar feature is generated for C2 as well.

4 Experimental Setup and Results

4.1 CPL System

CPL (Carlson et al., 2010) is a semi-supervised learning system which takes in an input ontology (containing category and relation predicates and corresponding seed instances) and constraints (such as Mutual exclusion rules between predicates). The system iteratively extracts patterns and instances for the category/relation predicates from a web corpus of around 500 million web pages. CPL is one learning component in NELL (the Never Ending Language Learner) (Carlson et al., 2010b).

4.2 Relation Generation:

We use approximately 22,000 category instances belonging to 122 categories extracted by CPL at the end of its 20th iteration and the web corpus as input to perform the co-clustering described in Section 3.2 and generate the new relations. The process generated 781 relations. For each relation, the relation name, types of the categories involved in the relation and the seed instances and patterns for each relation were generated. Table 1 in section 1 shows a sample of valid relations generated by this method.

Tables 2, 3, 4 and 5 show invalid relations for each type of invalidity, "Error in the Category Instances", "Semantic Ambiguity", "Semantically Incomplete Relations" and "Illogical Relations" respectively. More specifically, Table 2 shows a sample of relations generated due to an entity being labeled incorrectly as to belong to a category. The incorrect category instances are in italics.

Table 3 presents a sample of relations which were generated because of semantic ambiguity. Instances with ambiguity are in italics.

Table 4 shows some of the generated relations which are semantically incomplete.

Table 5 presents samples of illogical relations which do not establish any concrete fact.

Table 2. Examples of Incorrect category instances.

name(category1 -main context- category2)	Relation Contexts	Seed Instances
SportsGame -Beating- Country	'beating'	"tournament,Sri Lanka" "champions, France" "match, canada"
Animal -will eat- Condiment	'will eat' 'eating'	"wolf, sheep" "fox, rabbit" "lion, lamb"

Table 3. Examples of Semantically Ambiguous relations.

Name	Relation Contexts	Seed Instances
Bird -play- City	‘play’	"Cardinals, Atlanta" "Ravens, Miami" "Eagles, Chicago"
BakedGood -baking- Magazine	‘baking’	"time, cakes" "people, cookies"

Table 4. Examples of semantically incomplete relations.

Name	Relation Contexts	Seed Instances
Personus acknowledged Date	‘acknowledged’ ‘warned’ ‘met’	"mr obama, tuesday" "george w . bush, tuesday" "al gore, thursday"
NewsPaper -is reporting that- Company	‘is reporting that’ ‘writes that’ ‘reported that’	"financial times, apple" "wall street journal, gm" "wall street journal, yahoo"

Table 5. Examples of relations representing facts that are not concrete.

Name	Relation Contexts	Seed Instances
Emotion -of living in- StateOrProvince	‘of living in’	"joy, california" "excitement, colorado" "fear, iowa"
BodyPart -to keep- BodyPart	‘to keep’ ‘guard’	“hand, eye” “nose, throat” “eye, brain” “elbow, hand”

4.3 Relation Classification:

To determine the feasibility of automatically classifying OntExt’s proposed relations as valid or invalid, we trained and tested a classifier using the features described above, using manually assigned class label for some of the generated relations (252 relations) as valid or invalid (the criteria for which was explained before). 115 of these 252 relations were found to be valid by manual evaluation. This shows the need for a machine learning classifier to identify valid/invalid relations. The various features described earlier (such as normalized frequency count, relationship characteristics, pattern context features, distribution of extraction patterns) were generated for each relation. Ten-fold cross validation experiments were carried out with various classifiers. A Random Forest classifier performed the best. Precision, recall and ROC-area is shown in the table below (ROC area is the area under the ROC curve which plots the classifier performance by having the True Positive Rate on the Y-axis and False Positive Rate on the X-axis).

Table 6. Classifier performance.

RelationType	Precision	Recall	ROC Area
Valid	71.6	72.2	0.804
Invalid	76.5	75.9	0.804
Weighted Avg.	74.2	74.2	0.804

These results indicate that the system is able to learn to identify semantically valid relations without using any manually input information. The valid relations generated can be input to NELL, allowing it to iteratively learn additional instances for each proposed relation.

5 Conclusion and Future work:

Open Relation Extraction and Traditional Relation Extraction have their respective strengths and weaknesses. The OntExt system proposed in this work combines the strengths of both of those methods. The relation predicates automatically generated by our approach are typed, have a meaningful name identifying the relation, and are accompanied by suggested context patterns and seed instances. These relations can be input to NELL to learn more instances for the relation. We propose in the future to integrate this relation generation system into NELL, to iteratively extend NELL’s initial ontology, providing an ongoing stream of new learning tasks. After every fixed set of NELL’s iterations, its growing knowledge base would be input to the relation generation system which will in turn feed NELL with new relation predicates. One additional area for future research is to extend OntExt to discover new categories in addition to new relations.

Abstract

We explore unsupervised approaches to relation extraction between two named entities; for instance, the semantic *bornIn* relation between a person and location entity. Concretely, we propose a series of generative probabilistic models, broadly similar to topic models, each which generates a corpus of observed triples of entity mention pairs and the surface syntactic dependency path between them. The output of each model is a clustering of observed relation tuples and their associated textual expressions to underlying semantic relation types. Our proposed models exploit entity type constraints within a relation as well as features on the dependency path between entity mentions. We examine effectiveness of our approach via multiple evaluations and demonstrate 12% error reduction in precision over a state-of-the-art weakly supervised baseline.

1 Introduction

Many NLP applications would benefit from large knowledge bases of relational information about entities. For instance, knowing that the entity *Steve Balmer* bears the *leaderOf* relation to the entity *Microsoft*, would facilitate question answering (Ravichandran and Hovy, 2002), data mining, and a host of other end-user applications. Due to these many potential applications, relation extraction has gained much attention in information extraction (Kambhatla, 2004; Culotta and Sorensen, 2004; Mintz et al., 2009; Riedel et al., 2010; Yao et al., 2010). We propose a series of generative probabilistic models, broadly similar to standard topic models, which generate a corpus of observed triples of entity mention pairs and the surface syntactic dependency path between them. Our proposed models exploit entity type constraints within a relation as well as features on the dependency path between entity mentions. The output of our approach is a clustering over observed relation paths (e.g. "X was born in Y" and "X is from Y") such that expressions in the same cluster bear the same semantic relation type between entities.

Past work has shown that standard supervised techniques can yield high-performance relation detection when abundant labeled data exists for a fixed inventory of individual relation types (e.g. *leaderOf*) (Kambhatla, 2004; Culotta and Sorensen, 2004; Roth and tau Yih, 2002). However, less explored are *open-domain* approaches where the set of possible relation types are not fixed and little to no labeled is given for each relation type (Banko et al., 2007; Banko and Etzioni, 2008). A more related line of research has explored inducing relation types via clustering. For example, DIRT (Lin and Pantel, 2001) aims to discover different representations of the same semantic relation using distributional similarity of dependency paths. Poon and Domingos (2008) present an Unsupervised semantic parsing (USP) approach to partition dependency trees into meaningful fragments (or "parts" to use their terminology). The combinatorial nature of this dependency partition model makes it difficult for USP to scale to large data sets despite several necessary approximations during learning and infer-

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1456–1466,
Edinburgh, Scotland, UK, July 27–31, 2011.

ence. Our work is similar to DIRT and USP in that we induce relation types from observed dependency paths, but our approach is a straightforward and principled generative model which can be efficiently learned. As we show empirically, our approach outperforms these related works when trained with the same amount of data and further gains are observed when trained with more data.

We evaluate our approach using 'intrinsic' clustering evaluation and 'extrinsic' evaluation settings.[1] The former evaluation is performed using subset of induced clusters against Freebase relations, a large manually-built entity and relational database. We also show some clusters which are not included as Freebase relations, as well as some entity clusters found by our approach. The latter evaluation uses the clustering induced by our models as features for relation extraction in distant supervision framework. Empirical results show that we can find coherent clusters. In relation extraction, we can achieve 12% error reduction in precision over a state-of-the-art weakly supervised baseline and we show that using features from our proposed models can find more facts for a relation without significant accuracy loss.

2 Problem and Experimental Setup

The task of relation extraction is mapping surface textual relations to underlying semantic relations. For instance, the textual expression "X was born in Y" indicates a semantic relation *bornIn* between entities "X" and "Y". This relation can be expressed textually in several ways: for instance, "X, a native of Y" or "X grew up in Y". There are several components to a coherent relation type, including a tight small number of textual expressions as well as constraints on the entities involved in the relation. For instance, in the *bornIn* relation "X" must be a person entity and "Y" a location (typically a city or nation). In this work, we present an unsupervised probabilistic generative model for inducing clusters of relation types and recognizing their textual expressions. The set of relation types is not pre-specified but induced from observed unlabeled data. See Table 4 for examples of learned semantic relations.

Our observed data consists of a corpus of documents and each document is represented by a bag of relation tuples. Each tuple represents an observed syntactic relationship between two Named Entities (NE) and consists of three components: the dependency path between two NE mentions, the source argument NE, and the destination argument NE. A dependency path is a concatenation of dependency relations (edges) and words (nodes) along a path in a dependency tree. For instance, the sentence "John Lennnon was born in Liverpool" would yield the relation tuple (*Lennon*, $[\uparrow -nsubjpass, born, \downarrow -in]$, *Liverpool*). This relation tuple reflects a semantic *bornIn* relation between the *John Lennon* and *Liverpool* entities. The dependency path in this example corresponds to the "X was born in Y" textual expression given earlier. Note that for the above example, the *bornIn* relation can only occur between a *person* and a *location*. The relation tuple is the primary observed random variable in our model and we construct our models (see Section 3) so that clusters consist of textual expressions representing the same underlying relation type.

3 Models

We propose three generative models for modeling tuples of entity mention pairs and the syntactic dependency path between them (see Section 2). The first two models, Rel-LDA and Rel-LDA1 are simple extensions of the standard LDA model (Blei et al., 2003). At the document level, our model is identical to standard LDA; a multinomial distribution is drawn over a fixed number of relation types R. Changes lie in the observations. In standard LDA, the atomic observation is a word drawn from a latent topic distribution determined by a latent topic indicator variable for that word position. In our approach, a document consists of an exchangeable set of relation tuples. Each relation tuple is drawn from a relation type 'topic' distribution selected by a latent relation type indicator variable. Relation tuples are generated using a collection of independent features drawn from the underlying relation type distribution. These changes to standard LDA are intended to have the effect that instead of representing semantically related words, the 'topic' latent variable represents a relation type.

Our third model exploits entity type constraints within a relation and induces clusters of relations

[1] See Section 4 for a fuller discussion of evaluation.

and entities jointly. For each tuple, a set of relation level features and two latent entity type indicators are drawn independently from the relation type distribution; a collection of entity mention features for each argument is drawn independently from the entity type distribution selected by the entity type indicator.

ϕ_{rx}	$p(x\|r)$
ϕ_t	$p(f_s\|T)$, $p(f_d\|T)$

Table 2: The notation used in our models

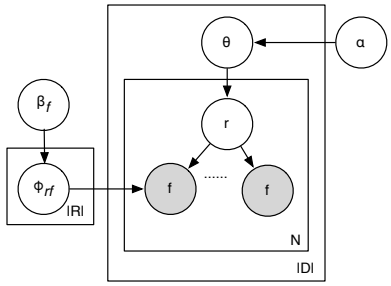

Figure 1: Rel-LDA model. Shaded circles are observations, and unshaded ones are hidden variables. A document consists of N tuples. Each tuple has a set of features. Each feature of a tuple is generated independently from a hidden relation variable r.

3.1 Rel-LDA Model

This model is an extension to the standard LDA model. At the document level, a multinomial distribution over relations θ_{doc} is drawn from a prior Dir(α). To generate a relation tuple, we first draw a relation 'topic' r from Multi(θ). Then we generate each feature f of a tuple independently from a multinomial distribution Multi(ϕ_{rf}) selected by r. In this model, each tuple has three features, i.e. its three components, shown in the first three rows in Table 1. Figure 1 shows the graphical representation of Rel-LDA. Table 2 lists all the notation used in describing our models.

The learning process of the models is an EM process. The procedure is similar to that used by the standard topic model. In the variational E-step (inference), we sample the relation type indicator for each tuple using $p(r|f)$:

$$P(r|f(p,s,d)) \propto p(r)\prod_f p(f|r)$$
$$\propto (\alpha_r + n_{r|d})\prod_f \frac{\beta_f + n_{f|r}}{\sum_{f'}(\beta_{f'} + n_{f'|r})}$$

$p(r)$ and $p(f|r)$ are estimated in the M-step:

$$\theta_{doc} = \frac{\alpha + n_{r|doc}}{\sum_{r'}(\alpha + n_{r'|doc})}$$
$$\phi_{rf} = \frac{\beta_f + n_{f|r}}{\sum_{f'}(\beta_{f'} + n_{f'|r})}$$

where $n_{f|r}$ indicates the number of times a feature f is assigned with r.

3.2 Rel-LDA1

Looking at results of Rel-LDA, we find the clusters sometimes are in need of refinement, and we can address this by adding more features. For instance, adding *trigger* features can encourage sparsity over dependency paths. We define trigger words as all the words on the dependency path except stop words. For example, from path "X, based in Y", "base" is extracted as a trigger word. The intuition

for using trigger words is that paths sharing the same set of trigger words should go to one cluster. Adding named entity tag pair can refine the cluster too. For example, a cluster found by Rel-LDA contains "X was born in Y" and "X lives in Y"; but it also contains "X, a company in Y". In this scenario, adding features 'PER-LOC' and 'ORG-LOC' can push the model to split the clusters into two and put the third case into a new cluster.

Hence we propose Rel-LDA1. It is similar to Rel-LDA, except that each tuple is represented with more features. Besides p, s, and d, we introduce trigger words, lexical pattern, POS tag pattern, the named entity pair and the syntactic category pair features for each tuple. Lexical pattern is the word sequence between the two arguments of a tuple and POS tag pattern is the POS tag sequence of the lexical pattern. See Table 1 as an example.

Following typical EM learning(Charniak and Elsner, 2009), we start with a much simpler generative model, expose the model to fewer features first, and iteratively add more features. First, we train a Rel-LDA model, i.e. the model only generates the dependency path, source and destination arguments. After each interval of 10 iterations, we introduce one additional feature. We add the features in the order of trigger, lexical pattern, POS, NER pair, and syntactic pair.

3.3 Type-LDA model

We know that relations can only hold between certain entity types, known as selectional preferences (Ritter et al., 2010; Seaghdha, 2010; Kozareva and Hovy, 2010). Hence we propose Type-LDA model. This model can capture the selectional preferences of relations to their arguments. In the mean time, it clusters tuples into relational clusters, and arguments into different entity clusters. The entity clusters could be interesting in many ways, for example, defining fine-grained entity types and finding new concepts.

We split the features of a tuple into relation level features and entity level features. Relation level features include the dependency path, trigger, lex and POS features; entity level features include the entity mention itself and its named entity tag.

The generative storyline is as follows. At the document level, a multinomial distribution over relations θ_{doc} is drawn from a Dirichlet prior. A document consists of N relation tuples. Each tuple is represented by relation level features (f) and entity level features of source argument (f_s) and destination argument (f_d). For each tuple, a relation r is drawn from Multi(θ_{doc}). The relation level features and two hidden entity types T_1 and T_2 are independently generated from r. Features f_s are generated from T_1 and f_d from T_2. Figure 2 shows the graphical representation of this model.

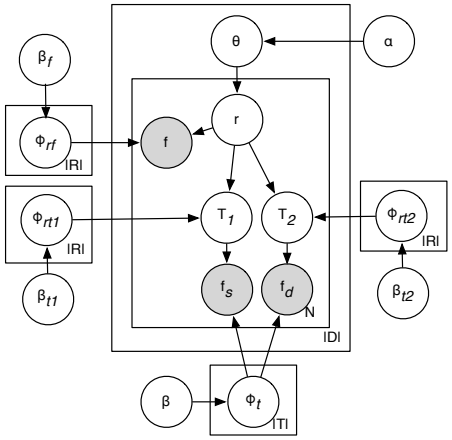

Figure 2: Type-LDA model. Each document consists of N tuples. Each tuple has a set of features, relation level features f and entity level features of source argument f_s and destination argument f_d. Relation level features and two hidden entity types T_1 and T_2 are generated from hidden relation variable r independently. Source entity features are generated from T_1 and destination features are generated from T_2.

At inference time, we sample r, T_1 and T_2 for each tuple. For efficient inference, we first initialize the model without T_1 and T_2, i.e. all the features are generated directly from r. Here the model degenerates to Rel-LDA1. After some iterations, we introduce T_1 and T_2. We sample the relation variable (r) and two mention types variables (T_1,T_2) iteratively for each tuple. We can sample them together, but this is not very efficient. In addition, we found that it does not improve performance.

4 Experiments

Our experiments are carried out on New York Times articles from year 2000 to 2007 (Sandhaus, 2008). We filter out some noisy documents, for example,

obituary content, lists and so on. Obituary articles often contain syntax that diverges from standard newswire text. This leads to parse errors with WSJ-trained parsers and in turn, makes extraction harder. We also filter out documents that contain lists or tables of items (such as books, movies) because this semi-structured information is not the focus of our current work. After filtering we are left with approximately 428K documents. They are preprocessed in several steps. First we employ Stanford tools to tokenize, sentence-split and Part-Of-Speech tag (Toutanova et al., 2003) a document. Next we recognize named entities (Finkel et al., 2005) by labelling tokens with PERSON, ORGANIZATION, LOCATION, MISC and NONE tags. Consecutive tokens which share the same category are assembled into entity mentions. They serve as source and destination arguments of the tuples we seek to model. Finally we parse each sentence of a document using MaltParser (Nivre et al., 2004) and extract dependency paths for each pair of named entity mentions in one sentence.

Following DIRT (Lin and Pantel, 2001), we filter out tuples that do not satisfy the following constraints. First, the path needs to be shorter than 10 edges, since longer paths occur less frequently. Second, the dependency relations in the path should connect two content words, i.e. nouns, verbs, adjectives and adverbs. For example, in phrase 'solve a problem', 'obj(solve, problem)' is kept, while 'det(problem, a)' is discarded. Finally, the dependency labels on the path must not be: 'conj', 'ccomp', 'parataxis', 'xcomp', 'pcomp', 'advcl', 'punct', and 'infmod'. This selection is based on the observation that most of the times the corresponding dependency relations do not explicitly state a relation between two candidate arguments.

After all entity mentions are generated and paths are extracted, we have nearly 2.5M tuples. After clustering (inference), each of these tuple will belong to one cluster/relation and is associated with its clusterID.

We experimented with the number of clusters and find that in a range of 50-200 the performance does not vary significantly with different numbers. In our experiments, we cluster the tuples into 100 relation clusters for all three models. For Type-LDA model, we use 50 entity clusters.

We evaluate our models in two ways. The first aims at measuring the clustering quality by mapping clusters to Freebase relations. The second seeks to assess the utility of our predicted clusters as features for relation extraction.

4.1 Relations discovered by different models

Looking closely at the clusters we predict, we find that some of them can be mapped to Freebase relations. We discover clusters that roughly correspond to the *parentCom* (parent company relation), *filmDirector*, *authorOf*, *comBase* (base of a company relation) and *dieIn* relations in Freebase. We treat Freebase annotations as ground truth and measure recall. We count each tuple in a cluster as true positive if Freebase states the corresponding relation between its argument pair. We find that precision numbers against Freebase are low, below 10%. However, these numbers are not reliable mainly because many correct instances found by our models are missing in Freebase. One reason why our predictions are missing in Freebase is coreference. For example, we predict *parentCom* relation between 'Linksys' and 'Cisco', while Freebase only considers 'Cisco Systems, Inc.' as the parent company of 'Linksys'. It does not corefer 'Cisco' to 'Cisco Systems, Inc.'. Incorporating coreference in our model may fix this problem and is a focus of future work. Instead of measuring precision against Freebase, we ask humans to label 50 instances for each cluster and report precision according to this annotated data. Table 3 shows the scores.

We can see that in most cases Rel-LDA1 and Type-LDA substantially outperform the Rel-LDA model. This is due to the fact that both models can exploit more features to make clustering decisions. For example, in Rel-LDA1 model, the NER pair feature restricts the entity types the two arguments can take.

In the following, we take *parentCom* relation as an example to analyze the behaviors of different models. Rel-LDA includes spurious instances such as 'A is the chief executive of B', while Rel-LDA1 has fewer such instances due to the NER pair feature. Similarly, by explicitly modeling entity type constraints, Type-LDA makes fewer such errors. All our models make mistakes when sentences have coordination structures on which the parser has failed.

Rel.	Sys.	Rec.	Prec.
parentCom	Rel-LDA	51.4	76.0
	Rel-LDA1	49.5	**78.0**
	Type-LDA	**55.3**	72.0
filmDirector	Rel-LDA	42.5	32.0
	Rel-LDA1	70.5	**40.0**
	Type-LDA	**74.2**	26.0
comBase	Rel-LDA	31.5	12.0
	Rel-LDA1	54.2	22.0
	Type-LDA	**57.1**	**30.0**
authorOf	Rel-LDA	25.2	**84.0**
	Rel-LDA1	**46.9**	86.0
	Type-LDA	20.2	68.0
dieIn	Rel-LDA	26.5	34.0
	Rel-LDA1	**55.9**	**40.0**
	Type-LDA	50.2	28.0

Table 3: Clustering quality evaluation (%), Rec. is measured against Freebase, Prec. is measured according to human annotators

For example, when a sentence has the following pattern "The winners are A, a part of B; C, a part of D; E, a part of F", our models may predict *parentCom*(A,F), because the parser connects A with F via the pattern 'a part of'.

Some clusters found by our models cannot be mapped to Freebase relations. Consider the Freebase relation *worksFor* as one example. This relation subsumes all types of employment relationships, irrespective of the role the employee plays for the employer. By contrast, our models discover clusters such as *leaderOf*, *editorOf* that correspond to more specific roles an employee can have. We show some example relations in Table 4. In the table, the 2nd row shows a cluster of employees of news media companies; the 3rd row shows leaders of companies; the last one shows birth and death places of persons. We can see that the last cluster is noisy since we do not handle antonyms in our models. The arguments of the clusters have noise too. For example, 'New York' occurs as a destination argument in the 2nd cluster. This is because 'New York' has high frequency in the corpus and it brings noise to the clustering results. In Table 5 some entity clusters found by Type-LDA are shown. We find different types of companies, such as financial companies and news companies. We also find subclasses of *person*, for example, *reviewer* and *politician*, because these different entity classes participate in different relations. The last cluster shown in the table is a mixture of news companies and government agencies. This may be because this entity cluster is affected by many relations.

4.2 Distant Supervision based Relation Extraction

Our generative models detect clusters of dependency paths and their arguments. Such clusters are interesting in their own right, but we claim that they can also be used to help a supervised relation extractor. We validate this hypothesis in the context of relation extraction with distant supervision using predicted clusters as features.

Following previous work (Mintz et al., 2009), we use Freebase as our distant supervision source, and align related entity pairs to the New York Times articles discussed earlier. Our training and test instances are pairs of entities for which both arguments appear in at least one sentence together. Features of each instance are extracted from all sentences in which both entities appear together. The gold label for each instance comes from Freebase. If a pair of entities is not related according to Freebase, we consider it a negative example. Note that this tends to create some amount of noise: some pairs may be related, but their relationships are not yet covered in Freebase.

After filtering out relations with fewer than 10 instances we have 65 relations and an additional "O" label for unrelated pairs of entities. We call related instances positive examples and unrelated instances negative examples.

We train supervised classifiers using maximum entropy. The baseline classifier employs features that Mintz et al. (2009) used. To extract features from the generative models we proceed as follows. For each pair of entities, we collect all tuples associated with it. For each of these tuples we extract its clusterID, and use this ID as a binary feature.

The baseline system without generative model features is called *Distant*. The classifiers with additional features from generative models are named after the generative models. Thus we have Rel-LDA, Rel-LDA1 and Type-LDA classifiers. We compare

Table 5: The entity clusters found by Type-LDA

these against Distant and the DIRT database. For the latter we parse our data using Minipar (Lin, 1998) and extract dependency paths between pairs of named entity mentions. For each path, the top 3 similar paths are extracted from DIRT database. The Minipar path and the similar paths are used as additional features.

For held-out evaluation, we construct the training data from half of the positive examples and half of the negative examples. The remaining examples are used as test data. Note that the number of negative instances is more than 10 times larger than the number of positive instances. At test time, we rank the predictions by the conditional probabilities obtained from the Maximum Entropy classifier. We report precision of top ranked 50 instances for each relation in table 6. From the table we can see that all systems using additional features outperform the Distant system. In average, our best model achieves 4.1% improvement over the distant supervision baseline, 12% error reduction. The precision of *bornIn* is low because in most cases we predict *bornIn* instances as *liveIn*.

We expect systems using generative model features to have higher recall than the baseline. This is difficult to measure, but precision in the high recall area is a signal. We look at top ranked 1000 instances of each system and show the precision in the last row of the table. We can see that our best model Type-LDA outperforms the distant supervision baseline by 4.5%.

Why do generative model features help to im-

Table 6: Precision (%) of some frequent relations

prove relation extraction? One reason is that generative models can transfer information from known patterns to unseen patterns. For example, given "Sidney Mintz, the great food anthropologist at Johns Hopkins University", we want to predict the relation between 'Sidney Mintz' and 'Johns Hopkins University'. The distant supervision system incorrectly predicts the pair as 'O' since it has not seen the path 'X, the anthropologist at Y' in the training data. By contrast, Rel-LDA can predict this pair correctly as *worksFor* because the dependency path of this pair is in a cluster which contains the path 'X, a professor at Y'.

In addition to held-out evaluation we also carry out manual evaluation. To this end, we use all the positive examples and randomly select five times the number of positive examples as negative examples to train a classifier. The remaining negative examples are candidate instances. We rank the predicted instances according to their classification scores. For each relation, we ask human annotators to judge its top ranked 50 instances.

Table 7 lists the manual evaluation results for some frequent relations. We also list how many instances are found for each relation. For almost all the relations, systems using generative model features find more instances. In terms of precision, our models perform comparatively to the baseline, even better for some relations.

We also notice that clustering quality is not consistent with distant supervision performance. Rel-LDA1 can find better clusters than Rel-LDA but it has lower precision in held-out evaluation. Type-LDA underperforms Rel-LDA in average precision but it gets higher precision in a higher recall area, i.e. precision at 1K. One possible reason for the inconsistency is that the baseline distant supervision system already employs features that are used in Rel-LDA1. Another reason may be that the clusters do not overlap with Freebase relations very well, see section 4.1.

4.3 Comparing against USP

We also try to compare against USP (Poon and Domingos, 2008). Due to memory requirements of USP, we are only able to run it on a smaller data set consisting of 1,000 NYT documents; this is three times the amount of data Poon and Domingos (2008) used to train USP.[2] For distant supervision based relation extraction, we only match about 500 Freebase instances to this small data set.

USP provides a parse tree for each sentence and for each mention pair we can extract a path from the tree. Since USP provides clusters of words and phrases, we use the USP clusterID associated with the words on the path as binary features in the classifier.

All models are less accurate when trained on this smaller dataset; we can do as well as USP does, even a little better. USP achieves 8.6% in F1, Rel-LDA 8.7%, Rel-LDA1 10.3%, Type-LDA 8.9% and Distant 10.3%. Of course, given larger datasets, the performance of Rel-LDA, Rel-LDA1, and Type-LDA improves considerably. In summary, comparing against USP, our approach scales much more easily to large data.

5 Related Work

Many approaches have been explored in relation extraction, including bootstrapping, supervised classification, distant supervision, and unsupervised approaches.

Bootstrapping employs a few labeled examples for each relation, iteratively extracts patterns from the labeled seeds, and uses the patterns to extract

[2]Using the publicly released USP code, training a model with 1,000 documents resulted in about 45 gigabytes of heap space in the JVM.

more seeds (Brin, 1998). This approach may suffer from low recall since the patterns can be too specific.

Supervised learning can discover more general patterns (Kambhatla, 2004; Culotta and Sorensen, 2004). However, this approach requires labeled data, and most work only carry out experiments on small data set.

Distant supervision for relation extraction requires no labeled data. The approach takes some existing knowledge base as supervision source, matches its relational instances against the text corpus to build the training data, and extracts new instances using the trained classifiers (Mintz et al., 2009; Bunescu and Mooney, 2007; Riedel et al., 2010; Yao et al., 2010).

All these approaches can not discover new relations and classify instances which do not belong to any of the predefined relations. Other past work has explored inducing relations using unsupervised approaches.

For example, DIRT (Lin and Pantel, 2001) aims to discover different representations of the same semantic relation, i.e. similar dependency paths. They employ the distributional similarity based approach while we use generative models. Both DIRT and our approach take advantage of the arguments of dependency paths to find semantic relations. Moreover, our approach can cluster the arguments into different types.

Unsupervised semantic parsing (USP) (Poon and Domingos, 2008) discovers relations by merging predicates which have similar meanings; it proceeds to recursively cluster dependency tree fragments (or "parts") to best explain the observed sentence. It is not focused on capturing any particular kind of relation between sentence constituents, but to capture repeated patterns. Our approach differs in that we are focused on capturing a narrow range of binary relations between named entities; some of our models (see Section 3) utilize entity type information to constraint relation type induction. Also, our models are built to be scalable and trained on a very large corpus. In addition, we use a distant supervision framework for evaluation.

Relation duality (Bollegala et al., 2010) employs co-clustering to find clusters of entity pairs and patterns. They identify each cluster of entity pairs as a relation by selecting representative patterns for that relation. This approach is related to our models, however, it does not identify any entity clusters.

Generative probabilistic models are widely employed in relation extraction. For example, they are used for in-domain relation discovery while incorporating constraints via posterior regularization (Chen et al., 2011). We are focusing on open domain relation discovery. Generative models are also applied to selectional preference discovery (Ritter et al., 2010; Seaghdha, 2010). In this scenario, the authors assume relation labels are given while we automatically discover relations. Generative models are also used in unsupervised coreference (Haghighi and Klein, 2010).

Clustering is also employed in relation extraction. Hasegawa et al. (2004) cluster pairs of named entities according to the similarity of context words intervening between them. Their approach is not probabilistic. Researchers also use topic models to perform dimension reduction on features when they cluster relations (Hachey, 2009). However, they do not explicitly model entity types.

Open information extraction aims to discover relations independent of specific domains and relations (Banko et al., 2007; Banko and Etzioni, 2008). A self-learner is employed to extract relation instances but the systems do not cluster the instances into relations. Yates and Etzioni (2009) present RESOLVER for discovering relational synonyms as a post processing step. Our approach integrates entity and relation discovery in a probabilistic model.

6 Conclusion

We have presented an unsupervised probabilistic generative approach to relation extraction between two named entities. Our proposed models exploit entity type constraints within a relation as well as features on the dependency path between entity mentions to cluster equivalent textual expressions. We demonstrate the effectiveness of this approach by comparing induced relation clusters against a large knowledge base. We also show that using clusters of our models as features in distant supervised framework yields 12% error reduction in precision over a weakly supervised baseline and outperforms other state-of-the art relation extraction techniques.

Closing the Loop: Fast, Interactive Semi-Supervised Annotation With Queries on Features and Instances

Burr Settles
Machine Learning Department
Carnegie Mellon University
Pittsburgh, PA 15213 USA
bsettles@cs.cmu.edu

Abstract

This paper describes DUALIST, an active learning annotation paradigm which solicits and learns from labels on both features (e.g., words) and instances (e.g., documents). We present a novel semi-supervised training algorithm developed for this setting, which is (1) fast enough to support real-time interactive speeds, and (2) at least as accurate as preexisting methods for learning with mixed feature and instance labels. Human annotators in user studies were able to produce near-state-of-the-art classifiers—on several corpora in a variety of application domains—with only a few minutes of effort.

1 Introduction

In active learning, a classifier participates in its own training process by posing *queries*, such as requesting labels for documents in a text classification task. The goal is to maximize the accuracy of the trained system in the most economically efficient way. This paradigm is well-motivated for natural language applications, where unlabeled data may be readily available (e.g., text on the Internet), but the annotation process can be slow and expensive.

Nearly all previous work in active learning, however, has focused on selecting queries from the *learner*'s perspective. For example, experiments are often run in simulation rather than with user studies, and results are routinely evaluated in terms of training set size rather than human annotation time or labor costs (which are more reasonable measures of labeling effort). Many state-of-the-art algorithms are also too slow to run or too tedious to implement to be useful for real-time interaction with human annotators, and few analyses have taken these factors into account. Furthermore, there is very little work on actively soliciting domain knowledge from humans (e.g., information about features) and incorporating this into the learning process.

While selecting good queries is clearly important, if our goal is to reduce actual annotation effort these human factors must be taken into account. In this work, we propose a new interactive annotation interface which addresses some of these issues; in particular it has the ability to pose queries on both features (e.g., words) and instances (e.g., documents). We present a novel semi-supervised learning algorithm that is fast, flexible, and accurate enough to support these interface design constraints interactively.

2 DUALIST: Utility for Active Learning with Instances and Semantic Terms

Figure 1 shows a screenshot of the DUALIST annotation tool, which is freely available as an open-source software project[1]. On the left panel, users are presented with unlabeled documents: in this case Usenet messages that belong to one of two sports-related topics: *baseball* and *hockey*. Users may label documents by clicking on the class buttons listed below each text. In cases of extreme ambiguity, users may ignore a document by clicking the "X" to remove it from the pool of possible queries.

On the right panel, users are given a list of feature queries organized into columns by class label.

[1] http://code.google.com/p/dualist/

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1467–1478,
Edinburgh, Scotland, UK, July 27–31, 2011.

Figure 1: A screenshot of DUALIST.

The rationale for these columns is that they should reduce cognitive load (i.e., once a user is in the *baseball* mindset, s/he can simply go down the list, labeling features in context: "plate," "pitcher," "bases," etc.). Within each column, words are sorted by how informative they are the to classifier, and users may click on words to label them. Each column also contains a text box, where users may "inject" domain knowledge by typing in arbitrary words (whether they appear in any of the columns or not). The list of previously labeled words appears at the bottom of each list (highlighted), and can be unlabeled at any time, if users later feel they made any errors.

Finally, a large submit button is located at the top of the screen, which users must click to re-train the classifier and receive a new set of queries. The learning algorithm is actually fast enough to do this automatically after each labeling action. However, we found such a dynamically changing interface to be frustrating for users (e.g., words they wanted to label would move or disappear).

2.1 A Generative Model for Learning from Feature and Instance Labels

For the underlying model in this system, we use multinomial naïve Bayes (MNB) since it is simple, fast, and known to work well for several natural language applications—text classification in particular—despite its simplistic and often violated independence assumptions (McCallum and Nigam, 1998; Rennie et al., 2003).

MNB models the distribution of features as a multinomial: documents are sequences of words, with the "naïve" assumption that words in each position are generated independently. Each document is treated as a mixture of classes, which have their own multinomial distributions over words. Let the model be parameterized by the vector θ, with $\theta_j = P(y_j)$ denoting the probability of class y_j, and $\theta_{jk} = P(f_k|y_j)$ denoting the probability of generating word f_k given class y_j. Note that for class priors $\sum_j \theta_j = 1$, and for per-class word multinomials $\sum_k \theta_{jk} = 1$. The likelihood of document x being generated by class y_j is given by:

$$P_\theta(x|y_j) = P(|x|) \prod_k (\theta_{jk})^{f_k(x)},$$

where $f_k(x)$ is the frequency count of word f_k in document x. If we assume $P(|x|)$ is distributed independently of class, and since document length $|x|$ is fixed, we can drop the first term for classification purposes. Then, we can use Bayes' rule to calculate the posterior probability under the model of a label, given the input document for classification:

$$P_\theta(y_j|x) = \frac{P_\theta(y_j)P_\theta(x|y_j)}{P_\theta(x)} = \frac{\theta_j \prod_k (\theta_{jk})^{f_k(x)}}{Z(x)}, \quad (1)$$

where $Z(x)$ is shorthand for a normalization constant, summing over all possible class labels.

The task of training such a classifier involves estimating the parameters in θ, given a set of labeled instances $\mathcal{L} = \{\langle x^{(l)}, y^{(l)} \rangle\}_{l=1}^{L}$. To do this, we use a Dirichlet prior and take the expectation of each parameter with respect to the posterior, which is a simple way to estimate a multinomial (Heckerman, 1995). In other words, we count the fraction of times the word f_k occurs in the labeled set among documents of class y_j, and the prior adds m_{jk} "hallucinated" occurrences for a smoothed version of the maximum likelihood estimate:

$$\theta_{jk} = \frac{m_{jk} + \sum_i P(y_j|x^{(i)}) f_k(x^{(i)})}{Z(f_k)}. \quad (2)$$

Here, m_{jk} is the prior for word f_k under class y_j, $P(y_j|x^{(i)}) \in \{0, 1\}$ indicates the true labeling of the ith document in the training set, and $Z(f_k)$ is a normalization constant summing over all words in the vocabulary. Typically, a uniform prior is used, such as the Laplacian (a value of 1 for all m_{jk}). Class parameters θ_j are estimated a similar way, by counting

the fraction of documents that are labeled with that class, subject to a prior m_j. This prior is important in the event that no documents are yet labeled with y_j, which can be quite common early on in the active learning process.

Recall that our scenario lets human annotators provide not only document labels, but feature labels as well. To make use of this additional information, we assume that labeling the word f_k with a class y_j increases the probability $P(f_k|y_j)$ of the word appearing in documents of that class. The natural interpretation of this under our model is to increase the prior m_{jk} for the corresponding multinomial. To do this we introduce a new parameter α, and define the elements of the Dirichlet prior as follows:

$$m_{jk} = \begin{cases} 1+\alpha & \text{if } f_k \text{ is labeled with } y_j, \\ 1 & \text{otherwise.} \end{cases}$$

This approach is extremely flexible, and offers three particular advantages over the previous "pooling multinomials" approach for incorporating feature labels into MNB (Melville et al., 2009). The pooling multinomials algorithm averages together two sets of θ_{jk} parameters: one that is estimated from labeled data, and another derived from feature labels under the assumption of a boolean output variable (treating labeled features are "polarizing" factors). Therefore, pooling multinomials can only be applied to binary classification tasks, while our method works equally well for problems with multiple classes. The second advantage is that feature labels need not be mutually exclusive, so the word "score" could be labeled with both *baseball* and *hockey*, if necessary (e.g., if the task also includes several non-sports labels). Finally, our framework allows users to conceivably provide feature-specific priors α_{jk} to, for example, imply that the word "inning" is a stronger indicator for *baseball* than the word "score" (which is a more general sports term). However, we leave this aspect for future work and employ the fixed-α approach as described above in this study.

2.2 Exploiting Unlabeled Data

In addition to document and feature labels, we usually have access to a large unlabeled corpus. In fact, these texts form the pool of possible instance queries in active learning. We can take advantage of this additional data in generative models like MNB by employing the Expectation-Maximization (EM) algorithm. Combining EM with pool-based active learning was previously studied in the context of instance labeling (McCallum and Nigam, 1998), and we extend the method to our interactive scenario, which supports feature labeling as well.

First, we estimate initial parameters θ' as in Section 2.1, but using *only* the priors (and no instances). Then, we apply the induced classifier on the unlabeled pool $\mathcal{U} = \{x^{(u)}\}_{u=1}^{U}$ (Eq. 1). This is the "E" step of EM. Next we re-estimate feature multinomials θ_{jk}, using both labeled instances from $\mathcal{L}$ and probabilistically-labeled instances from $\mathcal{U}$ (Eq. 2). In other words, $P(y_j|x) \in \{0,1\}$ for $x \in \mathcal{L}$, and $P(y_j|x) = P_{\theta'}(y_j|x)$ for $x \in \mathcal{U}$. We also weight the data in $\mathcal{U}$ by a factor of 0.1, so as not to overwhelm the training signal coming from true instance labels in $\mathcal{L}$. Class parameters θ_j are re-estimated in the analogous fashion. This is the "M" step.

For speed and interactivity, we actually stop training after this first iteration. When feature labels are available, we found that EM generally converges in four to 10 iterations, requiring more training time but rarely improving accuracy (the largest gains consistently come in the first iteration). Also, we ignore labeled data in the initial estimation of θ' because $\mathcal{L}$ is too small early in active learning to yield good results with EM. Perhaps this can be improved by using an ensemble (McCallum and Nigam, 1998), but that comes at further computational expense. Feature labels, on the other hand, seem generally more reliable for probabilistically labeling $\mathcal{U}$.

2.3 Selecting Instance and Feature Queries

The final algorithmic component to our system is the selection of informative queries (i.e., unlabeled words and documents) to present to the annotator.

Querying instances is the traditional mode of active learning, and is well-studied in the literature; see Settles (2009) for a review. In this work we use entropy-based uncertainty sampling, which ranks all instances in $\mathcal{U}$ by the posterior class entropy under the model $H_\theta(Y|x) = -\sum_j P_\theta(y_j|x) \log P_\theta(y_j|x)$, and asks the user to label the top D unlabeled documents. This simple heuristic is an approximation to querying the instance with the maximum information gain (since the class entropy, once labeled, is zero), under the assumption that each x is repre-

sentative of the underlying natural data distribution. Moreover, it is extremely fast to compute, which is important for our interactive environment.

Querying features, though, is a newer idea with significantly less research behind it. Previous work has either assumed that (1) features are not assigned to classes, but instead flagged for "relevance" to the task (Godbole et al., 2004; Raghavan et al., 2006), or (2) feature queries are posed just like instance queries: a word is presented to the annotator, who must choose among the labels (Druck et al., 2009; Attenberg et al., 2010). Recall from Figure 1 that we want to organize feature queries into columns by class label. This means our active learner must produce queries that are class-specific.

To select these feature queries, we first rank elements in the vocabulary by information gain (IG):

$$IG(f_k) = \sum_{\mathbf{I}_k} \sum_{j} P(\mathbf{I}_k, y_j) \log \frac{P(\mathbf{I}_k, y_j)}{P(\mathbf{I}_k)P(y_j)},$$

where $\mathbf{I}_k \in \{0, 1\}$ is a variable indicating the presence or absence of a feature. This is essentially the common feature-selection method for identifying the most salient features in text classification (Sebastiani, 2002). However, we use both $\mathcal{L}$ and probabilistically-labeled instances from $\mathcal{U}$ to compute $IG(f_k)$, to better reflect what the model believes it has learned. To organize queries into classes, we take the top V unlabeled features and pose f_k for the class y_j with which it occurs most frequently, as well as any other class with which it occurs at least 75% as often. Intuitively, this approach (1) queries features that the model believes are most informative, and (2) automatically identifies classes that seem most correlated. To our knowledge, DUALIST is the first active learning environment with both of these properties.

3 Experiments

We conduct four sets of experiments to evaluate our approach. The first two are "offline" experiments, designed to better understand (1) how our training algorithm compares to existing methods for feature-label learning, and (2) the effects of tuning the α parameter. The other experiments are user studies designed to empirically gauge how well human annotators make use of DUALIST in practice.

We use a variety of benchmark corpora in the following evaluations. Reuters (Rose et al., 2002) is a collection of news articles organized into topics, such as *acquisitions*, *corn*, *earnings*, etc. As in previous work (Raghavan et al., 2006) we use the 10 most frequent topics, but further process the corpus by removing ambiguous documents (i.e., that belong to multiple topics) so that all articles have a unique label, resulting in a corpus of 9,002 articles. WebKB (Craven et al., 1998) consists of 4,199 university web pages of four types: *course*, *faculty*, *project*, and *student*. 20 Newsgroups (Lang, 1995) is a set of 18,828 Usenet messages from 20 different online discussion groups. For certain experiments (such as the one shown in Figure 1), we also use topical subsets. Movie Reviews (Pang et al., 2002) is a set of 2,000 online movie reviews categorized as *positive* or *negative* in sentiment. All data sets were processed using lowercased unigram features, with punctuation and common stop-words removed.

3.1 Comparison of Learning Algorithms

An important question is how well our learning algorithm, "MNB/Priors," performs relative to existing baseline methods for learning with labeled features. We compare against two such approaches from the literature. "MaxEnt/GE" is a maximum entropy classifier trained using generalized expectation (GE) criteria (Druck et al., 2008), which are constraints used in training discriminative linear models. For labeled features, these take the form of expected "reference distributions" conditioned on the presence of the feature (e.g., 95% of documents containing the word "inning" should be labeled *baseball*). For each constraint, a term is added to the objective function to encourage parameter settings that yield predictions conforming to the reference distribution on unlabeled instances. "MNB/Pool" is naïve Bayes trained using the pooling multinomials approach (Melville et al., 2009) mentioned in Section 2.1. We also expand upon MNB/Pool using an EM variant to make it semi-supervised.

We use the implementation of GE training from the open-source MALLET toolkit[2], and implement both MNB variants in the same data-processing pipeline. Because the GE implementation available

Table 1: Accuracies and training times for different feature-label learning algorithms on benchmark corpora. Classification accuracy is reported for each model, using only the top 10 oracle-ranked features per label (and no labeled instances) for training. The best model for each corpus is highlighted in bold. Training time (in seconds) is shown in parentheses on the right side of each column. All results are averaged across 10 folds using cross-validation.

to us only supports labeled features (and not labeled instances as well), we limit the MNB methods to features for a fair comparison. To obtain feature labels in this experiment, we simulate a "feature oracle" as in previous work (Druck et al., 2008; Attenberg et al., 2010), which is essentially the query selection algorithm from Section 2.3, but using complete labeled data to compute $IG(f_k)$. We conservatively use only the top 10 features per class, which is meant to resemble a handful of very salient features that a human might brainstorm to jumpstart the learning process. We experiment with EM$_1$ (one-step EM) variants of both MNB/Pool and MNB/Priors, and set $\alpha = 50$ for the latter (see Section 3.2 for details on tuning this parameter). Results are averaged over 10 folds using cross-validation, and all experiments are conducted on a single 2.53GHz processor machine.

Results are shown in Table 1. As expected, adding one iteration of EM for semi-supervised training improves the accuracy of both MNB methods across all data sets. These improvements come without significant overhead in terms of time: training still routinely finishes in a fraction of a second per fold. MNB/Pool and MNB/Priors, where they can be compared, perform virtually the same as each other with or without EM, in terms of accuracy and speed alike. However, MNB/Pool is only applicable to binary classification problems. As explained in Section 2.1, MNB/Priors is more flexible, and preferable for a more general-use interactive annotation tool like DUALIST.

The semi-supervised MNB methods are also consistently more accurate than GE training—and are about 40 times faster as well. The gains of Priors+EM$_1$ over MaxEnt/GE are statistically significant in all cases but two: Autos/Motorcycles and Movie Reviews[3]. MNB is superior when using anywhere from five to 20 oracle-ranked features per class, but as the number of feature labels increases beyond 30, GE is often more accurate (results not shown). If we think of MaxEnt/GE as a discriminative analog of MNB/Priors+EM, this is consistent with what is known about labeled set size in supervised learning for generative/discriminative pairs (Ng and Jordan, 2002). However, the time complexity of GE training increases sharply with each new labeled feature, since it adds a new constraint to the objective function whose gradient must be computed using all the unlabeled data. In short, GE training is too slow and too inaccurate early in the active learning process (where labels are more scarce) to be appropriate for our scenario. Thus, we select MNB/Priors to power the DUALIST interface.

3.2 Tuning the Parameter α

A second question is how sensitive the accuracy of MNB/Priors is to the parameter α. To study this, we ran experiments varying α from from one to 2^{12}, using different combinations of labeled instances and/or features (again using the simulated oracle and 10-fold cross-validation).

[3]Paired 2-tailed t-test, $p < 0.05$, correcting for multiple tests using the Bonferroni method.

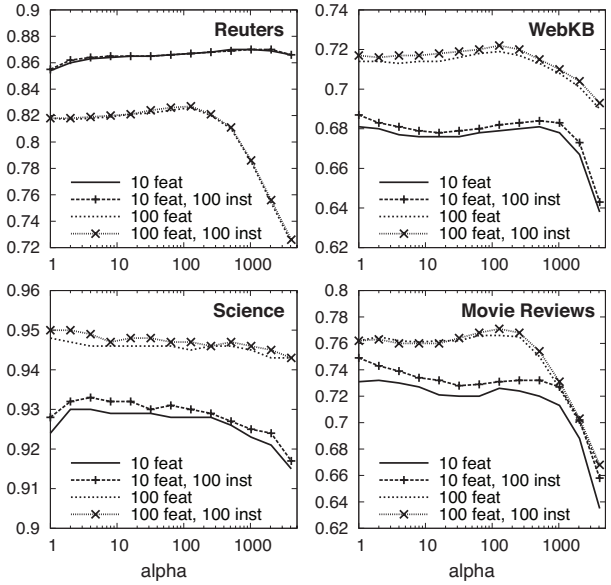

Figure 2: The effects of varying α on accuracy for four corpora, using differing amounts of training data (labeled features and/or instances). For clarity, vertical axes are scaled differently for each data set, and horizontal axes are plotted on a logarithmic scale. Classifier performance remains generally stable across data sets for $\alpha < 100$.

Figure 2 plots these results for four of the corpora. The first thing to note is that in all cases, accuracy is relatively stable for $\alpha < 100$, so tuning this value seems not to be a significant concern; we chose 50 for all other experiments in this paper. A second observation is that, for all but the Reuters corpus, labeling 90 additional features improves accuracy much more than labeling 100 documents. This is encouraging, since labeling features (e.g., words) is known to be generally faster and easier for humans than labeling entire instances (e.g., documents).

For Reuters, however, the additional feature labels appear harmful. The anomaly can be explained in part by previous work with this corpus, which found that a few expertly-chosen keywords can outperform machine learning methods (Cohen and Singer, 1996), or that aggressive feature selection—i.e., using only three or four features per class—helps tremendously (Moulinier, 1996). Corpora like Reuters may naturally lend themselves to feature selection, which is (in some sense) what happens when labeling features. The simulated oracle here was forced to label 100 features, some with very low information gain (e.g., "south" for *acquisitions*, or "proven" for *gold*); we would not expect humans annotators to provide such misleading information. Instead, we hypothesize that in practice there may be a limited set of features with high enough information content for humans to feel confident labeling, after which they switch their attention to labeling instance queries instead. This further indicates that the user-guided flexibility of annotation in DUALIST is an appropriate design choice.

3.3 User Experiments

To evaluate our system in practice, we conducted a series of user experiments. This is in contrast to most previous work, which simulates active learning by using known document labels and feature labels from a simulated oracle (which can be flawed, as we saw in the previous section). We argue that this is an important contribution, as it gives us a better sense of how well the approach actually works in practice. It also allows us to analyze behavioral results, which in turn may help inform future protocols for human interaction in active learning.

DUALIST is implemented as a web-based application in Java and was deployed online. We used three different configurations: *active dual* (as in Figure 1, implementing everything from Section 2), *active instance* (instance queries only, no features), and a *passive instance* baseline (instances only, but selected at random). We also began by randomly selecting instances in the active configurations, until every class has at least one labeled instance or one labeled feature. $D = 2$ documents and $V = 100$ features were selected for each round of active learning.

We recruited five members of our research group to label three data sets using each configuration, in an order of their choosing. Users were first allowed to spend a minute or two familiarizing themselves with DUALIST, but received no training regarding the interface or data sets. All experiments used a fixed 90% train, 10% test split which was consistent across all users, and annotators were not allowed to see the accuracy of the classifier they were training at any time. Each annotation action was timestamped and logged for analysis, and each experiment automatically terminated after six minutes.

Figure 3 shows learning curves, in terms of accuracy vs. annotation time, for each trial in the user study. The first thing to note is that the active

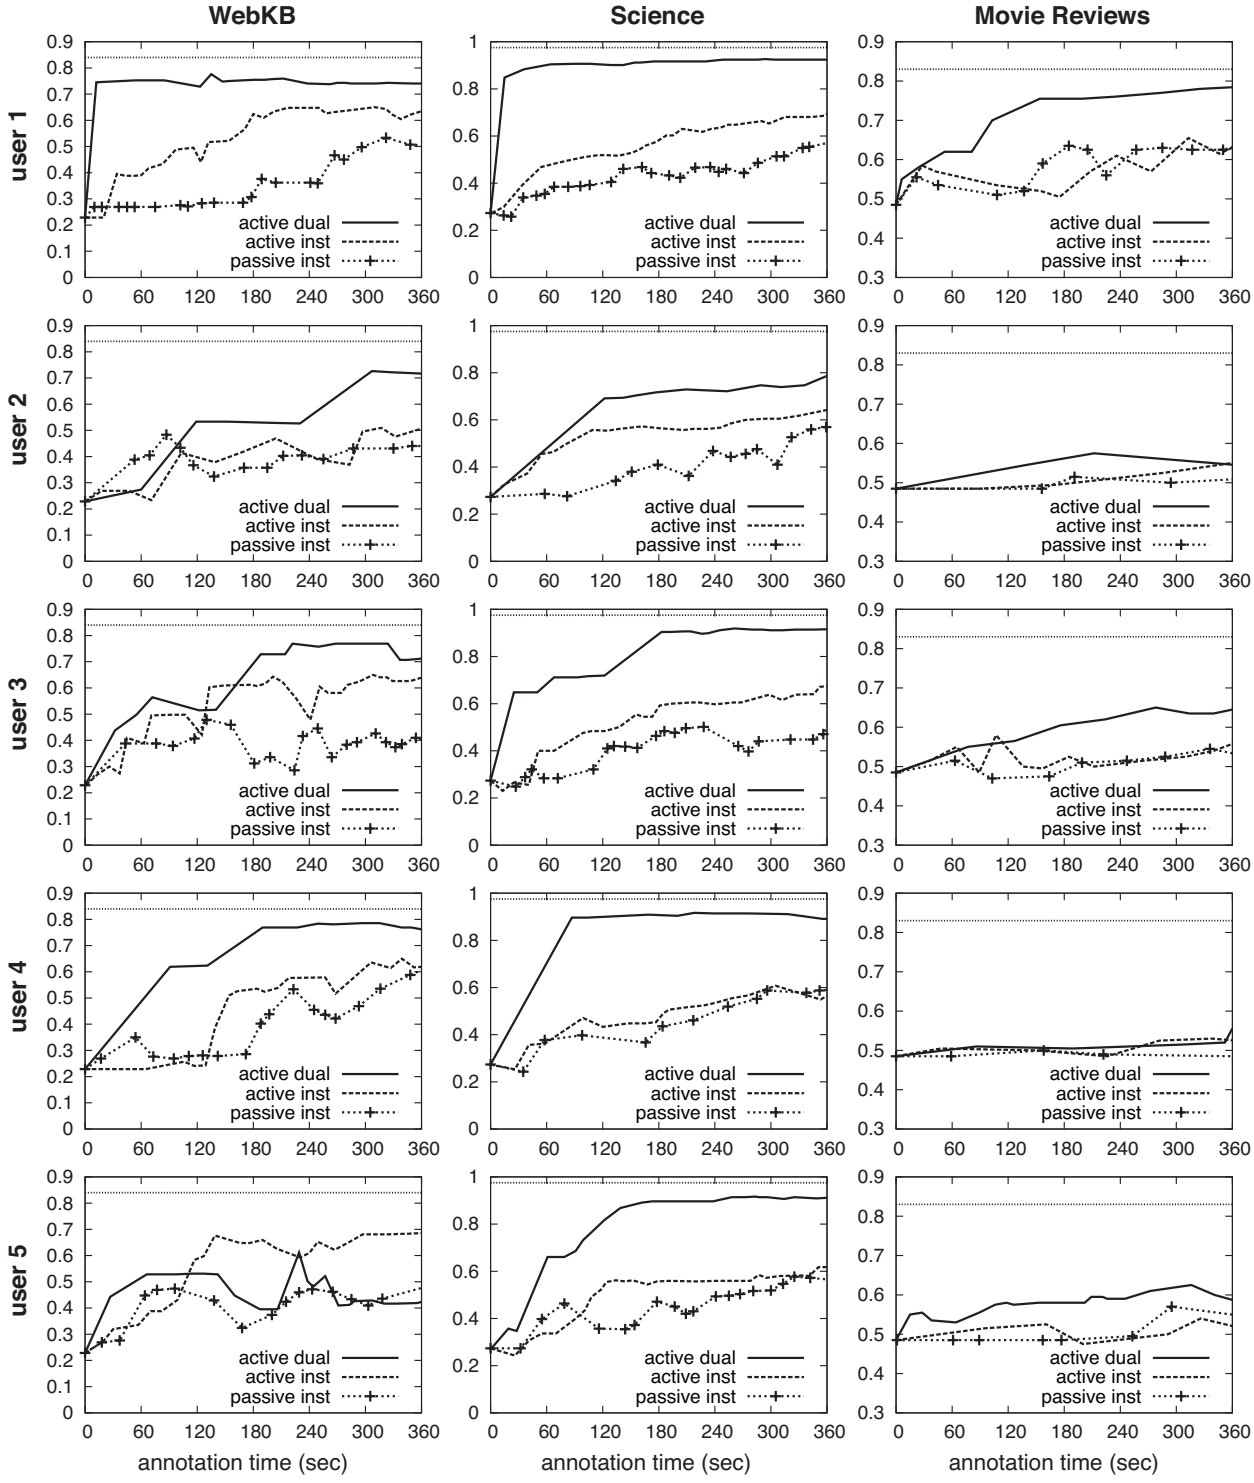

Figure 3: User experiments involving human annotators for text classification. Each row plots accuracy vs. time learning curves for a particular user (under all three experimental conditions) for each of the three corpora (one column per data set). For clarity, vertical axes are scaled differently for each corpus, but held constant across all users. The thin dashed lines at the top of each plot represents the idealized fully-supervised accuracy. Horizontal axes show labeling cost in terms of actual elapsed annotation time (in seconds).

dual configuration yields consistently better learning curves than either active or passive learning with instances alone, often getting within 90% of fully-supervised accuracy (in under six minutes). The only two exceptions make interesting (and different) case studies. User 4 only provided four labeled features in the Movie Review corpus, which partially explains the similarity in performance to the instance-only cases. Moreover, these were manually-added features, i.e., he never answered any of the classifier's feature *queries*, thus depriving the learner of the information it requested. User 5, on the other hand, never manually added features and only answered queries. With the WebKB corpus, however, he apparently found feature queries for the *course* label to be easier than the other classes, and 71% of all his feature labels came from that class (sometimes noisily, e.g., "instructor" might also indicate *faculty* pages). This imbalance ultimately biased the learner toward the *course* label, which led to classification errors. These pathological cases represent potential pitfalls that could be alleviated with additional user studies and training. However, we note that the active dual interface is not particularly worse in these cases, it is simply not significantly better, as in the other 13 trials.

Feature queries were less costly than instances, which is consistent with findings in previous work (Raghavan et al., 2006; Druck et al., 2009). The least expensive actions in these experiments were labeling (mean 3.2 seconds) and unlabeling (1.8s) features, while manually adding new features took only slightly longer (5.9s). The most expensive actions were labeling (10.8s) and ignoring (9.9s) instance queries. Interestingly, we observed that the human annotators spent most of the first three minutes performing feature-labeling actions ( ), and switched to more instance-labeling activity for the final three minutes ( ). As hypothesized in Section 3.2, it seems that the active learner is exhausting the most salient feature queries early on, and users begin to focus on more interpretable instance queries over time. However, more study (and longer annotation periods) are warranted to better understand this phenomenon, which may suggest additional user interface design improvements.

We also saw surprising trends in annotation quality. In active settings, users made an average of one instance-labeling error per trial (relative to the gold-standard labels), but in the passive case this rose to 1.6, suggesting they are more accurate on the active queries. However, they also explicitly ignored more instances in the active dual condition (7.7) than either active instance (5.9) or passive (2.5), indicating that they find these queries more ambiguous. This seems reasonable, since these are the instances the classifier is least certain about. But if we look at the *time* users spent on these actions, they are much faster to label/ignore (9.7s/7.5s) in the active dual scenario than in the active instance (10.0s/10.7s) or passive (12.3s/15.4s) cases, which means they are being more efficient. The differences in time between dual and passive are statistically significant[4].

3.4 Additional Use Cases

Here we discuss the application of DUALIST to a few other natural language processing tasks. This section is not meant to show its superiority relative to other methods, but rather to demonstrate the flexibility and potential of our approach in a variety of problems in human language technology.

3.4.1 Word Sense Disambiguation

Word Sense Disambiguation (WSD) is the problem of determining which meaning of a word is being used in a particular context (e.g., "hard" in the sense of a challenging task vs. a marble floor). We asked a user to employ DUALIST for 10 minutes for each of three benchmark WSD corpora (Mohammad and Pedersen, 2004): Hard (3 senses), Line (6 senses), and Serve (4 senses). Each instance represents a sentence using the ambiguous word, and features are lowercased unigram and bigram terms from the surrounding context in the sentence. The learned models' prediction accuracies (on the sentences *not* labeled by the user) were: 83.0%, 78.4%, and 78.7% for Hard, Line, and Serve (respectively), which appears to be comparable to recent supervised learning results in the WSD literature on these data sets. However, our results were achieved in less than 10 minutes of effort each, by labeling an average of 76 sentences and 32 words or phrases per task (compared to the thousands of labeled training sentences used in previous work).

[4] Kolmogorov-Smirnov test, $p < 0.01$.

3.4.2 Information Extraction

DUALIST is also well-suited to a kind of large-scale information extraction known as semantic class learning: given a set of semantic categories and a very large unlabeled text corpus, learn to populate a knowledge base with words or phrases that belong to each class (Riloff and Jones, 1999; Carlson et al., 2010). For this task, we first processed 500 million English Web pages from the ClueWeb09 corpus (Callan and Hoy, 2009) by using a shallow parser. Then we represented noun phrases (e.g., "Al Gore," "World Trade Organization," "upholstery") as instances, using a vector of their co-occurrences with heuristic contextual patterns (e.g., "visit to X" or "X's mission") as well as a few orthographic patterns (e.g., capitalization, head nouns, affixes) as features. We filtered out instances or contexts that occurred fewer than 200 times in the corpus, resulting in 49,923 noun phrases and 87,760 features.

We then had a user annotate phrases and patterns into five semantic classes using DUALIST: *person*, *location*, *organization*, *date/time*, and *other* (the background or null class). The user began by inserting simple hyponym patterns (Hearst, 1992) for their corresponding classes (e.g., "people such as X" for *person*, or "organizations like X" for *organization*) and proceeded from there for 20 minutes. Since there was no gold-standard for evaluation, we randomly sampled 300 predicted extractions for each of the four non-null classes, and hired human evaluators using the Amazon Mechanical Turk service[5] to estimate precision. Each instance was assigned to three evaluators, using majority vote to score for correctness.

Table 2 shows the estimated precision, total extracted instances, and the number of user-labeled features and instances for each class. While there is room for improvement (published results for this kind of task are often above 80% precision), it is worth noting that in this experiment the user did not provide any initial "seed examples" for each class, which is fairly common in semantic class learning. In practice, such additional seeding should help, as the active learner acquired 115 labeled instances for the null class, but fewer than a dozen for each non-null class (in the first 20 minutes).

Class	Prec.	# Ext.	# Feat.	# Inst.
person	74.7	6,478	37	6
location	76.3	5,307	47	5
organization	59.7	4,613	51	7
date/time	85.7	494	51	12
other	–	32,882	13	115

Table 2: Summary of results using DUALIST for web-scale information extraction.

3.4.3 Twitter Filtering and Sentiment Analysis

There is growing interest in language analysis for online social media services such as Twitter[6] (Petrović et al., 2010; Ritter et al., 2010), which allows users to broadcast short messages limited to 140 characters. Two basic but interesting tasks in this domain are (1) language filtering and (2) sentiment classification, both of which are difficult because of the extreme brevity and informal use of language in the messages.

Even though Twitter attempts to provide language metadata for its "tweets," English is the default setting for most users, so about 35% of English-tagged tweets are actually in a different language. Furthermore, the length constraints encourage acronyms, emphatic misspellings, and orthographic shortcuts even among English-speaking users, so many tweets in English actually contain no proper English words (e.g., "OMG ur sooo gr8!! #luvya"). This may render existing lexicon-based language filters—and possibly character n-gram filters—ineffective.

To quickly build an English-language filter for Twitter, we sampled 150,000 tweets from the Twitter Streaming API and asked an annotator spend 10 minutes with DUALIST labeling English and non-English messages and features. Features were represented as unigrams and bigrams without any stopword filtering, plus a few Twitter-specific features such as emoticons (text-based representations of facial expressions such as :) or :(used to convey feeling or tone), the presence of anonymized usernames (preceded by '@') or URL links, and hashtags (compound words preceded by '#' and used to label messages, e.g., "#loveit"). Following the same methodology as Section 3.4.2, we evaluated 300 random predictions using the Mechanical Turk service. The

[5] http://www.mturk.com

[6] http://twitter.com

estimated accuracy of the trained language filter was 85.2% (inter-annotator agreement among the evaluators was 94.3%).

We then took the 97,813 tweets predicted to be in English and used them as the corpus for a sentiment classifier, which attempts to predict the mood conveyed by the author of a piece of text (Liu, 2010). Using the same feature representation as the language filter, the annotator spent 20 minutes with DUALIST, labeling tweets and features into three mood classes: *positive*, *negative*, and *neutral*. The annotator began by labeling emoticons, by which the active learner was able to uncover some interesting domain-specific salient terms, e.g., "cant wait" and "#win" for *positive* tweets or "#tiredofthat" for *negative* tweets. Using a 300-instance Mechanical Turk evaluation, the estimated accuracy of the sentiment classifier was 65.9% (inter-annotator agreement among the evaluators was 77.4%).

4 Discussion and Future Work

We have presented DUALIST, a new type of dual-strategy annotation interface for semi-supervised active learning. To support this dual-query interface, we developed a novel, fast, and practical semi-supervised learning algorithm, and demonstrated how users can employ it to rapidly develop useful natural language systems for a variety of tasks. For several of these applications, the interactively-trained systems are able to achieve 90% of state-of-the-art performance after only a few minutes of labeling effort on the part of a human annotator. By releasing DUALIST as an open-source tool, we hope to facilitate language annotation projects and encourage more user experiments in active learning.

This represents one of the first studies of an active learning system designed to compliment the strengths of both learner and annotator. Future directions along these lines include user studies of efficient annotation behaviors, which in turn might lead to new types of queries or improvements to the user interface design. An obvious extension in the natural language domain is to go beyond classification tasks and query domain knowledge for structured prediction in this way. Another interesting potential application is human-driven active feature induction and engineering, after Della Pietra et al. (1997).

From a machine learning perspective, there is an open empirical question of how useful the labels gathered by DUALIST's internal naïve Bayes model might be in later training machine learning systems with different inductive biases (e.g., MaxEnt models or decision trees), since the data are not IID. So far, attempts to "reuse" active learning data have yielded mixed results (Lewis and Catlett, 1994; Baldridge and Osborne, 2004). Practically speaking, DUALIST is designed to run on a single machine, and supports a few hundred thousand instances and features at interactive speeds on modern hardware. Distributed data storage (Chang et al., 2008) and parallelized learning algorithms (Chu et al., 2007) may help scale this approach into the millions.

Finally, modifying the learning algorithm to better cope with violated independence assumptions may be necessary for interesting language applications beyond those presented here. TAN-Trees (Friedman et al., 1997), for example, might be able to accomplish this while retaining speed and interactivity. Alternatively, one could imagine online stochastic learning algorithms for discriminatively-trained classifiers, which are semi-supervised and can exploit feature labels. To our knowledge, such flexible and efficient learning algorithms do not currently exist, but they could be easily incorporated into the DUALIST framework in the future.

Acknowledgments

Thanks to members of Carnegie Mellon's "Read the Web" research project for helpful discussions and participation in the user studies. This work is supported in part by DARPA (under contracts FA8750-08-1-0009 and AF8750-09-C-0179), the National Science Foundation (IIS-0968487), and Google.

Abstract

We propose a novel *forest reranking* algorithm for discriminative dependency parsing based on a variant of Eisner's generative model. In our framework, we define two kinds of generative model for reranking. One is learned from training data offline and the other from a forest generated by a baseline parser on the fly. The final prediction in the reranking stage is performed using linear interpolation of these models and discriminative model. In order to efficiently train the model from and decode on a hypergraph data structure representing a forest, we apply extended *inside/outside* and *Viterbi* algorithms. Experimental results show that our proposed forest reranking algorithm achieves significant improvement when compared with conventional approaches.

1 Introduction

Recently, much of research on statistical parsing has been focused on k-best (or forest) reranking (Collins, 2000; Charniak and Johnson, 2005; Huang, 2008). Typically, reranking methods first generate a list of top-k candidates (or a forest) from a baseline system, then rerank the candidates with arbitrary features that are intractable within the baseline system. In the reranking framework, the baseline system is usually modeled with a generative model, and a discriminative model is used for reranking. Sangati et al. (2009) reversed the usual order of the two models for dependency parsing by employing a generative model to rescore the k-best candidates provided by a discriminative model. They use a variant of Eisner's generative model C (Eisner, 1996b; Eisner, 1996a) for reranking and extend it to capture higher-order information than Eisner's second-order generative model. Their reranking model showed large improvements in dependency parsing accuracy. They reported that the discriminative model is very effective at filtering out bad candidates, while the generative model is able to further refine the selection among the few best candidates.

In this paper, we propose a *forest generative reranking* algorithm, opposed to Sangati et al. (2009)'s approach which reranks only k-best candidates. Forests usually encode better candidates more compactly than k-best lists (Huang, 2008). Moreover, our reranking uses not only a generative model obtained from training data, but also a sentence specific generative model learned from a forest. In the reranking stage, we use linearly combined model of these models. We call this *variational reranking* model. The model proposed in this paper is factored in the third-order structure, therefore, its non-locality makes it difficult to perform the reranking with an usual 1-best *Viterbi* search. To solve this problem, we also propose a new search algorithm, which is inspired by the third-order dynamic programming parsing algorithm (Koo and Collins, 2010). This algorithm enables us an exact 1-best reranking without any approximation. We summarize our contributions in this paper as follows.

- To extend k-best to forest generative reranking.
- We introduce *variational reranking* which is a combination approach of generative reranking and variational decoding (Li et al., 2009).
- To obtain 1-best tree in the reranking stage, we

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1479–1488,
Edinburgh, Scotland, UK, July 27–31, 2011.

propose an exact 1-best search algorithm with the third-order model.

In experiments on English Penn Treebank data, we show that our proposed methods bring significant improvement to dependency parsing. Moreover, our variational reranking framework achieves consistent improvement, compared to conventional approaches, such as simple k-best and forest-based generative reranking algorithms.

2 Dependency Parsing

Given an input sentence $x \in \mathcal{X}$, the task of statistical dependency parsing is to predict output dependencies $\hat{y}$ for x. The task is usually modeled within a discriminative framework, defined by the following equation:

$$\begin{aligned} \hat{y} &= \operatorname*{argmax}_{y \in \mathcal{Y}} s(x, y) \\ &= \operatorname*{argmax}_{y \in \mathcal{Y}} \boldsymbol{\lambda}^{\top} \cdot \mathbf{F}(y, x) \end{aligned} \quad (1)$$

where $\mathcal{Y}$ is the output space, $\boldsymbol{\lambda}$ is a parameter vector, and $\mathbf{F}()$ is a set of feature functions.

We denote a set of candidates as $G(x)$. By using $G(x)$, the conditional probability $p(y|x)$ is typically derived as follows:

$$p(y|x) = \frac{e^{\gamma \cdot s(x,y)}}{Z(x)} = \frac{e^{\gamma \cdot s(x,y)}}{\sum_{y \in G(x)} e^{\gamma \cdot s(x,y)}} \quad (2)$$

where $s(x, y)$ is the score function shown in Eq.1 and γ is a scaling factor to adjust the sharpness of the distribution and $Z(x)$ is a normarization factor.

2.1 Hypergraph Representation

We propose to encode many hypotheses in a compact representation called dependency forest. While there may be exponentially many dependency trees, the forest represents them in polynomial space. A dependency forest (or tree) can be defined as a hypergraph data strucure $\mathbf{HG}$ (Tu et al., 2010).

Figure 1 shows an example of a hypergraph for a dependency tree. A shaded hyperedge e is defined as the following form:

$$e : \langle (\mathrm{I}_{1,2}, \mathrm{girl}_{3,5}, \mathrm{with}_{5,8}), \mathrm{saw}_{1,8} \rangle.$$

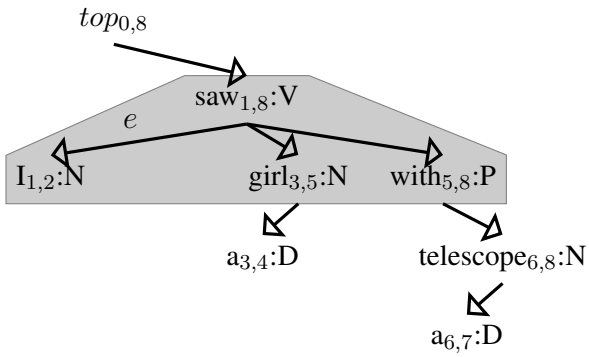

Figure 1: An example of dependency tree for a sentence "I saw a girl with a telescope".

The node saw$_{1,8}$ is a head node of e. The nodes, I$_{1,2}$, girl$_{3,5}$ and with$_{5,8}$, are tail nodes of e. The hyperedge e is an incoming edge for saw$_{1,8}$ and outgoing edge for each of I$_{1,2}$, girl$_{3,5}$ and with$_{5,8}$[1].

More formally, $\mathbf{HG}(x)$ of a forest is a pair $\langle V, E \rangle$, where V is a set of nodes and E is a set of hyperedges. Given a length m sentence $x = (w_1 \dots w_m)$, each node $v \in V$ is in the form of $w_{i,j}$ $(= (w_i \dots w_{j+1}))$ which denotes that a word w dominates the substring from positions i to j. In our implementation, each word is paired with POS-tag $tag(w)$. We denote the root node of dependency tree y as top. Each hyperedge $e \in E$ is a pair $\langle tails(e), head(e) \rangle$, where $head(e) \in V$ is the head and $tails(e) \in V^+$ are its dependants. For notational brevity of algorithmic description, we do not distinguish left and right tails in the definition, but, our implementation implicitly distinguishes left tails $tails_L(e)$ and right tails $tails_R(e)$. We define the set of incoming edges of a node v as $IE(v)$ and the set of outgoing edges of a node v as $OE(v)$.

3 Forest Reranking

3.1 Generative Model for Reranking

Given a node v in a dependency tree y, the left and right children are generated as two separate Markov sequences, each conditioned on ancestral and sibling information (context). Like a variation of Eisner's generative model C (Eisner, 1996b; Eisner, 1996a),

[1] In Figure 1, according to custom of dependency tree description, the direction of hyperedge is written as from head to tail nodes. However, in this paper, "incoming" and "outgoing" have the same meanings as those in (Huang, 2006).

Table 1: An event list of tri-sibling model whose event space is $v|h, sib, tsib, dir$, extracted from hyperedge e in Figure 1. EOC is an end symbol of sequence.

event space
I | saw NONE NONE L
EOC | saw I NONE L
girl | saw NONE NONE R
with | saw girl NONE R
EOC | saw with girl R

the probability of our model q is defined as follows:

$$q(v) = \prod_{l=1}^{|tails_L(e)|} q(v_l|\mathrm{C}(v_l)) \cdot q(v_l) \times \prod_{r=1}^{|tails_R(e)|} q(v_r|\mathrm{C}(v_r)) \cdot q(v_r) \quad (3)$$

where $|tails_L(e)|$ and $|tails_R(e)|$ are the number of left and right children of v, v_l and v_r are the left and right child of position l and r in each side. $\mathrm{C}(v)$ is a context event space of v. We explain the context event space later in more detail. The probability of the entire dependency tree y is recursively computed by $q(y(top))$ where $y(top)$ denotes a top node of y.

The probability $q(v|\mathrm{C}(v))$ is dependent on a context space $\mathrm{C}(v)$ for a node v. We define two kinds of context spaces. First, we define a tri-sibling model whose context space consists of the head node, sibling node, tri-sibling node and direction of a node v:

$$q_1(v|\mathrm{C}(v)) = q_1(v|h, sib, tsib, dir) \quad (4)$$

where h, sib and $tsib$ are head, sibling and tri-sibling node of v, and dir is a direction of v from h. Table 1 shows an example of an event list of the tri-sibling model, which is extracted from hyperedge e in Figure 1. EOC indicates the end of the left or right child sequence. This is factored in a tri-sibling structure shown in the left side of Figure 2.

Eq.4 is further decomposed into a product of the form consisting of three terms:

$$\begin{aligned} & q_1(v|h, sib, tsib, dir) \quad (5) \\ & = q_1(dist(v,h), wrd(v), tag(v)|h, sib, tsib, dir) \\ & = q_1(tag(v)|h, sib, tsib, dir) \\ & \times q_1(wrd(v)|tag(v), h, sib, tsib, dir) \\ & \times q_1(dist(v,h)|wrd(v), tag(v), h, sib, tsib, dir) \end{aligned}$$

where $tag(v)$ and $wrd(v)$ are the POS-tag and word of v and $dist(v,h)$ is the distance between positions of v and h. The values of $dist(v,h)$ are partitioned into 4 categories: $1, 2, 3-6, 7-\infty$.

Second, following Sangati et al. (2009), we define a grandsibling model whose context space consists of the head node, sibling node, grandparent node and direction of a node v.

$$q_2(v|\mathrm{C}(v)) = q_2(v|h, sib, g, dir) \quad (6)$$

where g is a grandparent node of v. Analogous to Eq.5, Eq.6 is decomposed into three terms:

$$\begin{aligned} & q_2(v|h, sib, g, dir) \quad (7) \\ & = q_2(dist(v,h), wrd(v), tag(v)|h, sib, g, dir) \\ & = q_2(tag(v)|h, sib, g, dir) \\ & \times q_2(wrd(v)|tag(v), h, sib, g, dir) \\ & \times q_2(dist(v,h)|wrd(v), tag(v), h, sib, g, dir) \end{aligned}$$

where notations are the same as those in Eq.5 with the exception of tri-sibling $tsib$ and grandparent g. This model is factored in a grandsibling structure shown in the right side of Figure 2.

The direct estimation of tri-sibling and grandsibling models from a corpus suffers from serious data sparseness issues. To overcome this, Eisner (1996a) proposed a back-off strategy which reduces the conditioning of a model. We show the reductions list for each term of two models in Table 2. The usage of reductions list is identical to Eisner (1996a) and readers may refer to it for further details.

The final prediction is performed using a log-linear interpolated model. It interpolates the baseline discriminative model and two (tri-sibling and grandsibling) generative models.

$$\hat{y} = \operatorname*{argmax}_{y \in G(x)} \sum_{n=1}^{2} \log q_n(top(y))^{\theta_n} + \log p(y|x)^{\theta_{base}} \quad (8)$$

where $\boldsymbol{\theta}$ are parameters to adjust the weight of each term in prediction. These parameters are tuned using *MERT* algorithm (Och, 2003) on development data using a criterion of accuracy maximization. The reason why we chose *MERT* is that it effectively tunes dense parameters with a line search algorithm.

Table 2: Reduction lists for tri-sibling and grandsibling models: $wt()$, $w()$ and $t()$ mean word and POS-tag, word, POS-tag for a node. d indicates the direction. The first reduction on the list keeps all or most of the original condition; later reductions throw away more and more of this information.

first-order	McDonald et al. (2005)
second-order (sibling)	Eisner (1996a) McDonald et al. (2005)
third-order (tri-sibling)	tri-sibling model Model 2 (Koo and Collins, 2010)
third-order (grandsibling)	grandsibling model (Sangati et al., 2009) Model 1 (Koo and Collins, 2010)

3.2 Exact Search Algorithm

Our baseline discriminative model uses first- and second-order features provided in (McDonald et al., 2005; McDonald and Pereira, 2006). Therefore, both our tri-sibling model and baseline discriminative model integrate local features that are factored in one hyperedge. On the other hand, the grandsibling model has non-local features because the grandparent is not factored in one hyperedge. We summarize the order of each model in Table 3. Our reranking models are generative versions of Koo and Collins (2010)'s third-order factorization model.

Non-locality of weight function makes it difficult to perform the search of Eq.8 with an usual exact *Viterbi* 1-best algorithm. One solution to resolve the intractability is an approximate k-best *Viterbi* search. For a constituent parser, Huang (2008) applied *cube pruning* techniques to forest reranking with non-local features. Cube pruning is originally proposed for the decoding of *statistical machine translation* (SMT) with an integrated n-gram language model (Chiang, 2007). It is an approximate k-best *Viterbi* search algorithm using beam search and lazy computation (Huang and Chiang, 2005).

In the case of a dependency parser, Koo and Collins (2010) proposed dynamic-programming-based third-order parsing algorithm, which enumerates all grandparents with an additional loop. Our hypergraph based search algorithm for Eq.8 share the same spirit to their third-order parsing algorithm since the grandsibling model is similar to their model 1 in that it is factored in grandsibling structure. Algorithm 1 shows the search algorithm. This is almost the same bottom-up 1-best *Viterbi* algorithm except an additional loop in line 4. Line 4 references outgoing edge e' of node h from a set of outgoing edges $OE(h)$. $tails(e)$ contains a node v, the sibling node sib and tri-sibling node $tsib$ of v, moreover, the head of e' ($head(e')$) is the grandparent for v and sib. Thus, in line 5, we can capture tri-sibling and grandsibling information and compute the current inside estimate of Eq.8.

In our actual implementation, each score of components in Eq.8 is represented as a cost. This is written as a shortest path search algorithm with a tropical (real) semiring framework (Mohri, 2002; Huang, 2006). Therefore, $\oplus$ denotes the $\min$ operater and $\otimes$ denotes the $+$ operater. The function f is defined as follows:

$$f(d(v_1, e), \ldots, d(v_{|e|}, e))) = \bigotimes_{i=1}^{|e|} d(v_i, e) \qquad (9)$$

where $d(v_i, e)$ denotes the current estimate of the best cost for a pair of node v_i and a hyperedge e. $\bigotimes$ sums the best cost of a pair of a sub span node and hyperedge e. Each c_{tsib} and c_{gsib} in line 5 and 7 indicates the cost of tri-sibling and grandsibling

Algorithm 1 Exact DP-Search Algorithm($\mathbf{HG}(x)$)

3: // $tails(e)$ is $\{v_1, \ldots, v_{|e|}\}$.
4: **for** $e' \in OE(h)$ **do**
5: $d(h, e') = \oplus f(d(v_1, e), \ldots, d(v_{|e|}, e)) \otimes w_e \otimes c_{tsib}(h, tails(e)) \otimes c_{gsib}(head(e'), h, tails(e))$
6: **if** $h == top$ **then**
7: $d(h) = \oplus f(d(v_1, e), \ldots, d(v_{|e|}, e)) \otimes w_e \otimes c_{tsib}(h, tails(e))$

model. w_e indicates the cost of hyperedge e computed from a baseline discriminative model. Lines 6-7 denote the calculation of the best cost for a top node. We do not compute the cost of the grandsibling model when h is top node because top node has no outgoing edges.

Our baseline k-best second-order parser is implemented using Huang and Chiang (2005)'s algorithm 2 whose time complexity is $O(m^3 + mk \log k)$. Koo and Collins (2010)'s third-order parser has $O(m^4)$ time complexity and is theoretically slower than our baseline k-best parser for a long sentence. Our search algorithm is based on the third-order parsing algorithm, but, the search space is previously shrank by a baseline parser's k-best approximation and a forest pruning algorithm presented in the next section. Therefore, the time efficiency of our reranking is unimpaired.

3.3 Forest Pruning

Charniak and Johnson (2005) and Huang (2008) proposed forest pruning algorithms to reduce the size of a forest. Huang (2008)'s pruning algorithm uses a 1-best *Viterbi inside/outside* algorithm to compute an inside probability $\beta(v)$ and an outside probability $\alpha(v)$, while Charniak and Johnson (2005) use the usual *inside/outside* algorithm.

In our experiments, we use Charniak and Johnson (2005)'s forest pruning criterion because the variational model needs traditional *inside/outside* probabilities for its ML estimation. We prune away all hyperedges that have $score < \rho$ for a threshold ρ.

$$score = \frac{\alpha\beta(e)}{\beta(top)}. \tag{10}$$

Following Huang (2008), we also prune away nodes with all incoming and outgoing hyperedges pruned.

4 Variational Reranking Model

In place of a *maximum a posteriori* (MAP) decision based on Eq.2, the *minimum Bayes risk* (MBR) decision rule (Titov and Henderson, 2006) is commonly used and defined as following equation:

$$\hat{y} = \operatorname*{argmin}_{y \in G(x)} \sum_{y' \in G(x)} loss(y, y') p(y'|x) \tag{11}$$

where $loss(y, y')$ represents a loss function[2]. As an alternative to the MBR decision rule, Li et al. (2009) proposed a variational decision rule that rescores candidates with an approximate distribution $q^* \in \mathcal{Q}$.

$$\hat{y} = \operatorname*{argmax}_{y \in G(x)} q^*(y) \tag{12}$$

where q^* minimizes the KL divergence $\mathrm{KL}(p||q)$

$$\begin{aligned} q^* &= \operatorname*{argmin}_{q \in \mathcal{Q}} \mathrm{KL}(p||q) \\ &= \operatorname*{argmax}_{q \in \mathcal{Q}} \sum_{y \in G(x)} p \log q \end{aligned} \tag{13}$$

where each p and q represents $p(y|x)$ and $q(y)$. For SMT systems, q^* is modeled by n-gram language model over output strings. While the decoding based on q^* is an approximation of intractable MAP decoding[3], it works as a rescoring function for candidates generated from a baseline model. Here, we propose to apply the variational decision rule to dependency parsing. For dependency parsing, we can choose to model q^* as the tri-sibling and grandsibling generative models in section 3.

[2] In case of dependency parsing, Titov and Henderson (2006) proposed that a loss function is simply defined using a dependency attachment score.

[3] In SMT, a marginalization of all derivations which yield a paticular translation needs to be carried out for each translation. This makes the MAP decoding NP-hard in SMT. This variational approximate framework can be applied to other tasks collapsing *spurious ambiguity*, such as latent-variable parsing (Matsuzaki et al., 2005).

```

4.1 ML Estimation from a Forest

$q^*(v|\mathrm{C}(v))$ is estimated from a forest using a *maximum likelihood estimation* (MLE). The count of events is no longer an integer count, but an expected count under p, which is formulated as follows:

$$q^*(v|\mathrm{C}(v)) = \frac{\overline{c}(v|\mathrm{C}(v))}{\overline{c}(\mathrm{C}(v))} = \frac{\sum_y p(y|x) c_{v|\mathrm{C}(v)}(y)}{\sum_y p(y|x) c_{\mathrm{C}(v)}(y)} \quad (14)$$

where $c_{\mathrm{e}}(y)$ is the number of event e in y. The estimation of Eq.14 can be efficiently performed on a hypergraph data structure $\mathbf{HG}(x)$ of a forest.

Algorithm 2 shows the estimation algorithm. First, it runs the *inside/outside* algorithm on $\mathbf{HG}(x)$. We denote inside weight for a node v as $\beta(v)$ and outside weight as $\alpha(v)$. For each hyperedge e, we denote c_{tsib} as the posterior weight for computing expected count $\overline{c}_1$ of events in the tri-sibling model q_1^*. Lines 16-18 compute $\overline{c}_1$ for all events occuring in a hyperedge e.

The expected count $\overline{c}_2$ needed for the estimation of grandsibling model q_2^* is extracted in lines 7-15. $\overline{c}_2$ for a grandsibling model must be extracted over two hyperedges e and e' because it needs grandparent information. Lines 8-12 show the algorithm to compute the posterior weight c_{gsib} of e and e', which is similar to that to compute the posterior weight of rules of *tree substitution grammars* used in tree-based MT systems (Mi and Huang, 2008). Lines 13-15 compute expected counts $\overline{c}_2$ of events occuring over two hyperedges e and e'. Finally, line 19 estimates q_1^* and q_2^* using the form in Eq.14.

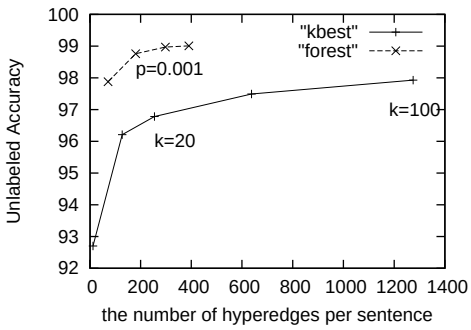

Figure 3: The relationship between tha data size (the number of hyperedges) and oracle scores on development data: Forests encode candidates with high accuracy scores more compactly than k-best lists.

Li et al. (2009) assumes n-gram locality of the forest to efficiently train the model, namely, the baseline n-gram model has larger n than that of variational n-gram model. In our case, grandsibling locality is not embedded in the forest generated from the baseline parser. Therefore, we need to reference incoming hyperedges of tail nodes in line 7.

y^* of Eq.12 may be locally appropriate but globally inadequate because q^* only approximates p. Therefore, we log-linearly combine q^* with a global generative model estimated from the training data and the baseline discriminative model.

$$\hat{y} = \operatorname*{argmax}_{y \in G(x)} \sum_{n=1}^{2} \log q_n(top(y))^{\theta_n} + \sum_{n=1}^{2} \log q_n^*(top(y))^{\theta_n^*} + \log p(y|x)^{\theta_{base}} \quad (15)$$

Algorithm1 is also applicable to the decoding of Eq.15. Note that this framework is a combination of variational decoding and generative reranking. We call this framework *variational reranking*.

Table 4: The statistics of forests and 20-best lists on development data: this shows the average number of hyperedges and nodes per sentence and oracle scores.

	forest	20-best
pruning threshold	$\rho = 10^{-3}$	—
ave. num of hyperedges	180.67	255.04
ave. num of nodes	135.74	491.42
oracle scores	98.76	96.78

5 Experiments

Experiments are performed on English Penn Treebank data. We split WSJ part of the Treebank into sections 02-21 for training, sections 22 for development, sections 23 for testing. We use Yamada and Matsumoto (2003)'s head rules to convert phrase structure to dependency structure. We obtain k-best lists and forests generated from the baseline discriminative model which has the same feature set as provided in (McDonald et al., 2005), using the second-order Eisner algorithms. We use MIRA for training as it is one of the learning algorithms that achieves the best performance in dependency parsing. We set the scaling factor $\gamma = 1.0$.

We also train a generative reranking model from the training data. To reduce the data sparseness problem, we use the back-off strategy proposed in (Eisner, 1996a). Parameters $\boldsymbol{\theta}$ are trained using MERT (Och, 2003) and for each sentence in the development data, 300-best dependency trees are extracted from its forest. Our variational reranking does not need much time to train the model because the training is performed over not the training data (39832 sentences) but the development data (1700 sentences)[4]. After MERT was performed until the convergence, the variational reranking finally achieved a 94.5 accuracy score on development data.

5.1 k-best Lists vs. Forests

Figure 3 shows the relationship between the size of data structure (the number of hyperedges) and accuracy scores on development data. Obviously, forests can encode a large number of potential candidates more compactly than k-best lists. This means that for reranking, there is more possibility of selecting good candidates in forests than k-best lists.

Table 4 shows the statistics of forests and 20-best lists on development data. This setting, threshold $\rho = 10^{-3}$ for pruning, is also used for testing. Forests, which have an average of 180.67 hyperedges per sentence, achieve oracle score of 98.76, which is about 1.0% higher than the 96.78 oracle score of 20-best lists with 255.04 hyperedges per sentence. Though the size of forests is smaller than that of k-best lists, the oracle scores of forests are much higher than those of k-best lists.

5.2 The Performance of Reranking

First, we compare the performance of variational decoding with that of MBR decoding. The results are shown in Table 5. Variational decoding outperforms MBR decodings. However, compared with baseline, the gains of variational and MBR decoding are small. Second, we also compare the performance of variational reranking with k-best and forest generative reranking algorithms. Table 6 shows that our variational reranking framework achieves the highest accuracy scores.

Being different from the decoding framework, reranking achieves significant improvements. This result is intuitively reasonable because the reranking model obtained from training data has the ability to select a globally consistent candidate, while the variational approximate model obtained from a forest only supports selecting a locally consistent candidate. On the other hand, the fact that variational reranking achieves the best results clearly indicates that the combination of sentence specific generative model and that obtained from training data is successful in selecting both locally and globally appropriate candidate from a forest.

Table 7 shows the parsing time (on 2.66GHz Quad-Core Xeon) of the baseline k-best, generative reranking and variational reranking parsers (java implemented). The variational reranking parser contains the following procedures.

1. k-best forest creation (baseline)
2. Estimation of variational model
3. Forest pruning
4. Search with the third-order model

Our reranking parser incurred little overhead to the

[4]To generate forests, sentences are parsed only once before the training. MERT is performed over the forests. We can also apply a more efficient hypergraph MERT algorithm (Kumar et al., 2009) to the training than a simple MERT algorithm.

Table 5: The comparison of the decoding frameworks: MBR decoding seeks a candidate which has the highest accuracy scores over a forest (Kumar et al., 2009). Variational decoding is performed based on Eq.8.

baseline parser in terms of runtime. This means that our reranking parser can parse sentences at reasonable times.

5.3 The Effects of Third-order Factors and Error Analysis

From results in section 5.2, our variational reranking model achieves higher accuracy scores than the others. To analyze the factors that improve accuracy scores, we further investigate whether variational reranking is performed better with the tri-sibling or grandsibling model. Table 8 indicates that grandsibling model achieves a larger gain than that of tri-sibling model. Table 9 shows the examples whose accuracy scores improved by the grandsibling model. For example, the dependency relationship from *Verb* to *Noun phrase* was corrected by our proposed model.

On the other hand, many errors remain still in our results. In our experiments, 48% of sentences which contain errors have *Prepositional* word errors. In fact, well-known *PP-Attachment* is a problem to be solved for natural language parsers. Other remaining errors are caused by symbols such as .,:“”(). 45% sentences contain such a dependency mistake. Adding features to solve these problems may potentially improve our parser more.

5.4 Comparison with Other Systems

Table 10 shows the comparison of the performance of variational reranking (16-best forests) with that of other systems. Our method outperforms supervised parsers with second-order features, and achieves comparable results compared to a parser with third-order features (Koo and Collins, 2010). We can not directly compare our method with semi-supervised parsers such as Koo et al. (2008)'s semi-sup and Suzuki et al. (2009), because ours does not use additional unlabeled data for training. The model trained from unlabeled data can be easily incorporated into our reranking framework. We plan to investigate semi-supervised learning in future work.

Table 9: Examples of outputs for input sentence No.148 and No.283 in section 23 from baseline and variational reranking parsers. The underlined portions show the effect of the grandsibling model.

6 Related Work

Collins (2000) and Charniak and Johnson (2005) proposed a reranking algorithm for constituent parsers. Huang (2008) extended it to a forest reranking algorithm with non-local features. Our framework is for a dependency parser and the decoding in the reranking stage is done with an exact 1-best dynamic programming algorithm. Sangati et al. (2009) proposed a k-best generative reranking algorithm for dependency parsing. In this paper, we use a similar generative model, but combined with a variational model learned on the fly. Moreover, our framework is applicable to forests, not k-best lists.

Koo and Collins (2010) presented third-order dependency parsing algorithm. Their model 1 is defined by an enclosing grandsibling for each sibling or grandchild part used in Carreras (2007). Our grandsibling model is similar to the model 1, but ours is defined by a generative model. The decoding in the reranking stage is also similar to the parsing algorithm of their model 1. In order to capture grandsibling factors, our decoding calculates inside probablities for not the current head node but each pair of the node and its outgoing edges.

Titov and Henderson (2006) reported that the MBR approach could be applied to a projective dependency parser. In the field of SMT, for an approximation of MAP decoding, Li et al. (2009) proposed variational decoding and Kumar et al. (2009) presented hypergraph MBR decoding. Our variational model is inspired by the study of Li et al. (2009) and we apply it to a dependency parser in order to select better candidates with third-order information. We also propose an efficient algorithm to estimate the non-local third-order model structure.

7 Conclusions

In this paper, we propose a novel forest reranking algorithm for dependency parsing. Our reranking algorithm is a combination approach of generative reranking and variational decoding. The search algorithm in the reranking stage can be performed using dynamic programming algorithm. Our variational reranking is aimed at selecting a candidate from a forest, which is correct both in local and global. Our experimental results show more significant improvements than conventional approaches, such as k-best and forest generative reranking.

In the future, we plan to investigate more appropriate generative models for reranking. *PP-Attachment* is one of the most difficult problems for a natural language parser. We plan to examine to model such a complex structure (granduncle) (Goldberg and Elhadad, 2010) or higher-order structure than third-order for reranking which is computationally expensive for a baseline parser. As we mentioned in Section 5.4, we also plan to incorporate semi-supervised learning into our framework, which may potentially improve our reranking performance.

Training dependency parsers by jointly optimizing multiple objectives

Keith Hall Ryan McDonald Jason Katz-Brown Michael Ringgaard

Abstract

We present an online learning algorithm for training parsers which allows for the inclusion of multiple objective functions. The primary example is the extension of a standard supervised parsing objective function with additional loss-functions, either based on intrinsic parsing quality or task-specific extrinsic measures of quality. Our empirical results show how this approach performs for two dependency parsing algorithms (graph-based and transition-based parsing) and how it achieves increased performance on multiple target tasks including reordering for machine translation and parser adaptation.

1 Introduction

The accuracy and speed of state-of-the-art dependency parsers has motivated a resumed interest in utilizing the output of parsing as an input to many downstream natural language processing tasks. This includes work on question answering (Wang et al., 2007), sentiment analysis (Nakagawa et al., 2010), MT reordering (Xu et al., 2009), and many other tasks. In most cases, the accuracy of parsers degrades when run on out-of-domain data (Gildea, 2001; McClosky et al., 2006; Blitzer et al., 2006; Petrov et al., 2010). But these accuracies are measured with respect to gold-standard out-of-domain parse trees. There are few tasks that actually depend on the complete parse tree. Furthermore, when evaluated on a downstream task, often the optimal parse output has a model score lower than the best parse as predicted by the parsing model. While this means that we are not properly modeling the downstream task in the parsers, it also means that there is some information from small task or domain-specific data sets which could help direct our search for optimal parameters during parser training. The goal being not necessarily to obtain better parse performance, but to exploit the structure induced from human labeled treebank data while targeting specific extrinsic metrics of quality, which can include task specific metrics or external weak constraints on the parse structure.

One obvious approach to this problem is to employ parser reranking (Collins, 2000). In such a setting, an auxiliary reranker is added in a pipeline following the parser. The standard setting involves training the base parser and applying it to a development set (this is often done in a cross-validated jack-knife training framework). The reranker can then be trained to optimize for the downstream or extrinsic objective. While this will bias the reranker towards the target task, it is limited by the oracle performance of the original base parser.

In this paper, we propose a training algorithm for statistical dependency parsers (Kübler et al., 2009) in which a single model is jointly optimized for a regular supervised training objective over the treebank data as well as a task-specific objective – or more generally an extrinsic objective – on an additional data set. The case where there are both gold-standard trees and a task-specific objective for the entire training set is a specific instance of the larger problem that we address here. Specifically, the algorithm takes the form of an online learner where a training instance is selected and the param-

Edinburgh, Scotland, UK, July 27–31, 2011.

eters are optimized based on the objective function associated with the instance (either intrinsic or extrinsic), thus jointly optimizing multiple objectives. An update schedule trades-off the relative importance of each objective function. We call our algorithm *augmented-loss training* as it optimizes multiple losses to augment the traditional supervised parser loss.

There have been a number of efforts to exploit weak or external signals of quality to train better prediction models. This includes work on generalized expectation (Mann and McCallum, 2010), posterior regularization (Ganchev et al., 2010) and constraint driven learning (Chang et al., 2007; Chang et al., 2010). The work of Chang et al. (2007) on constraint driven learning is perhaps the closest to our framework and we draw connections to it in Section 5. In these studies the typical goal is to use the weak signal to improve the structured prediction models on the intrinsic evaluation metrics. For our setting this would mean using weak application specific signals to improve dependency parsing. Though we explore such ideas in our experiments, in particular for semi-supervised domain adaptation, we are primarily interested in the case where the weak signal is precisely what we wish to optimize, but also desire the benefit from using both data with annotated parse structures and data specific to the task at hand to guide parser training.

In Section 2 we outline the augmented-loss algorithm and provide a convergence analysis. In Section 3 and 4 we present a set of experiments defining diffent augmented losses covering a task-specific extrinsic loss (MT reordering), a domain adaptation loss, and an alternate intrinsic parser loss. In all cases we show the augmented-loss framework can lead to significant gains in performance. In Section 5 we tie our augmented-loss algorithm to other frameworks for encoding auxiliary information and/or joint objective optimization.

2 Methodology

We present the augmented-loss algorithm in the context of the structured perceptron. The structured perceptron (Algorithm 1) is an on-line learning algorithm which takes as input: 1) a set of training examples $d_i = (x_i, y_i)$ consisting of an input sentence x_i and an output y_i; and 2) a loss-function, $L(\hat{y}, y)$, that measures the cost of predicting output $\hat{y}$ relative to the gold standard y and is usually the 0/1 loss (Collins, 2002). For dependency parser training, this set-up consists of input sentences x and the corresponding gold dependency tree $y \in \mathcal{Y}_x$, where $\mathcal{Y}_x$ is the space of possible parse trees for sentence x. In the perceptron setting, $F_\theta(x) = \arg\max_{y \in \mathcal{Y}_x} \theta \cdot \Phi(y)$ where Φ is mapping from a parse tree y for sentence x to a high dimensional feature space. Learning proceeds by predicting a structured output given the current model, and if that structure is incorrect, updating the model: rewarding features that fire in the gold-standard $\Phi(y_i)$, and discounting features that fire in the predicted output, $\Phi(\hat{y}_i)$.

Algorithm 1 Structured Perceptron

```
{Input data sets: D = {d_1 = (x_1, y_1) ... d_N = (x_N, y_N)}}
{Input 0/1 loss: L(F_θ(x), y) = [F_θ(x) ≠ y ? 1 : 0]}
{Let: F_θ(x) = arg max_{y∈Y} θ · Φ(y)}
{Initialize model parameters: θ = 0⃗}
repeat
  for i = 1 ... N do
    {Compute structured loss}
    ŷ_i = F_θ(x_i)
    if L(ŷ_i, y_i) > 0 then
      {Update model Parameters}
      θ = θ + Φ(y_i) − Φ(ŷ_i)
    end if
  end for
until converged
{Return model θ}
```

The structured perceptron, as given in Algorithm 1, only updates when there is a positive loss, meaning that there was a prediction mistake. For the moment we will abstract away from details such as the precise definition of $F(x)$ and $\Phi(y)$. We will show in the next section that our augmented-loss method is general and can be applied to any dependency parsing framework that can be trained by the perceptron algorithm, such as transition-based parsers (Nivre, 2008; Zhang and Clark, 2008) and graph-based parsers (McDonald et al., 2005).

2.1 Augmented-Loss Training

The augmented-loss training algorithm that we propose is based on the structured perceptron; however, the augmented-loss training framework is a general

mechanism to incorporate multiple loss functions in online learner training. Algorithm 2 is the pseudo-code for the augmented-loss structured perceptron algorithm. The algorithm is an extension to Algorithm 1 where there are 1) multiple loss functions being evaluated $L^1, \ldots, L^M$; 2) there are multiple datasets associated with each of these loss functions $D^1, \ldots, \mathcal{D}^M$; and 3) there is a schedule for processing examples from each of these datasets, where Sched(j, i) is true if the j^{th} loss function should be updated on the i^{th} iteration of training. Note that for data point $d_i^j = (x, y)$, which is the i^{th} training instance of the j^{th} data set, that y does not necessarily have to be a dependency tree. It can either be a task-specific output of interest, a partial tree, or even null, in the case where learning will be guided strictly by the loss L^j. The training algorithm is effectively the same as the perceptron, the primary difference is that if L^j is an extrinsic loss, we cannot compute the standard updates since we do not necessarily know the correct parse (the line indicated by †). Section 2.2 shows one method for updating the parser parameters for extrinsic losses.

In the experiments in this paper, we only consider the case where there are two loss functions: a supervised dependency parsing labeled-attachment loss; and an additional loss, examples of which are presented in Section 3.

Algorithm 2 Augmented-Loss Perceptron

```
{Input data sets}:
  D^1 = {d_1^1 = (x_1^1, y_1^1) ... d_{N^1}^1 = (x_{N^1}^1, y_{N^1}^1)},
  ...
  D^M = {d_1^M = (x_1^M, y_1^M) ... d_{N^M}^M = (x_{N^M}^M, y_{N^M}^M)}
{Input loss functions: L^1 ... L^M}
{Initialize indexes: c_1 ... c_M = 0⃗}
{Initialize model parameters: θ = 0⃗}
i = 0
repeat
  for j = 1 ... M do
    {Check whether to update L^j on iteration i}
    if Sched(j, i) then
      {Compute index of instance – reset if c_j ≡ N^j}
      c_j = [(c_j ≡ N^j) ? 0 : c_j + 1]
      {Compute structured loss for instance}
      if L^j is intrinsic loss then
        ŷ = F_θ(x_{c_j}^j)
        if L^j(ŷ, y_{c_j}^j) > 0 then
          θ = θ + Φ(y_{c_j}^j) − Φ(ŷ)      {y_{c_j}^j is a tree}
        end if
      else if L^j is an extrinsic loss then
        {See Section 2.2}†
      end if
    end if
  end for
  i = i + 1
until converged
{Return model θ}
```

2.2 Inline Ranker Training

In order to make Algorithm 2 more concrete, we need a way of defining the loss and resulting parameter updates for the case when L^j is not a standard supervised parsing loss († from Algorithm 2). Assume that we have a cost function $C(x_i, \hat{y}, y_i)$ which, given a training example (x_i, y_i) will give a score for a parse $\hat{y} \in \mathcal{Y}_{x_i}$ relative to some output y_i. While we can compute the score for any parse, we are unable to determine the features associated with the optimal parse, as y_i need not be a parse tree. For example, consider a machine translation reordering system which uses the parse $\hat{y}$ to reorder the words of x_i, the optimal reordering being y_i. Then $C(x_i, \hat{y}, y_i)$ is a reordering cost which is large if the predicted parse induces a poor reordering of x_i.

We propose a general purpose loss function which is based on parser k-best lists. The inline reranker uses the currently trained parser model θ to parse the external input, producing a k-best set of parses: $F_\theta^{\text{k-best}}(x_i) = \{\hat{y}_1, \ldots, \hat{y}_k\}$. We can compute the cost function $C(x_i, \hat{y}, y_i)$ for all $\hat{y} \in F_\theta^{\text{k-best}}(x_i)$. If the 1-best parse, $\hat{y}_1$, has the lowest cost, then there is no lower cost parse in this k-best list. Otherwise, the lowest-cost parse in $F_\theta^{\text{k-best}}(x_i)$ is taken to be the *correct* output structure y_i, and the 1-best parse is taken to be an incorrect prediction. We can achieve this by substituting the following into Algorithm 2 at line †.

Algorithm 3 Reranker Loss

```
{ŷ_1, ..., ŷ_k} = F_θ^{k-best}(x_i)
τ = min_τ C(x_{c_j}^j, ŷ_τ, y_{c_j}^j)    {τ is min const index}
L^j(ŷ_1, y_{c_j}^j) = C(x_{c_j}^j, ŷ_1, y_{c_j}^j) − C(x_{c_j}^j, ŷ_τ, y_{c_j}^j)
if L^j(ŷ_1, y_{c_j}^j) > 0 then
  θ = θ + Φ(ŷ_τ) − Φ(ŷ_1)
end if
```

Again the algorithm only updates when there is an error – when the 1-best output has a higher cost than any other output in the k-best list – resulting

in positive L^j. The intuition behind this method is that in the presence of only a cost function and a k-best list, the parameters will be updated towards the parse structure that has the lowest cost, which over time will move the parameters of the model to a place with low extrinsic loss.

We exploit this formulation of the general-purpose augmented-loss function as it allows one to include any extrinsic cost function which is dependent of parses. The scoring function used does not need to be factored, requiring no internal knowledge of the function itself. Furthermore, we can apply this to any parsing algorithm which can generate k-best lists. For each parse, we must retain the features associated with the parse (e.g., for transition-based parsing, the features associated with the transition sequence resulting in the parse).

There are two significant differences from the inline reranker loss function and standard reranker training. First, we are performing this decision per example as each data item is processed (this is done in the inner loop of the Algorithm 2). Second, the feedback function for selecting a parse is based on an external objective function. The second point is actually true for many minimum-error-rate training scenarios, but in those settings the model is updated as a post-processing stage (after the base-model is trained).

2.3 Convergence of Inline Ranker Training

A training set $\mathcal{D}$ is loss-separable with margin $\gamma > 0$ if there exists a vector u with $\|u\| = 1$ such that for all $y', y'' \in \mathcal{Y}_x$ and $(x, y) \in \mathcal{D}$, if $L(y', y) < L(y'', y)$, then $u \cdot \Phi(y') - u \cdot \Phi(y'') \geq \gamma$. Furthermore, let $R \geq ||\Phi(y) - \Phi(y')||$, for all y, y'.

Assumption 1. *Assume training set $\mathcal{D}$ is loss-separable with margin γ.*

Theorem 1. *Given Assumption 1. Let m be the number of mistakes made when training the perceptron (Algorithm 2) with inline ranker loss (Algorithm 3) on $\mathcal{D}$, where a mistake occurs for $(x, y) \in \mathcal{D}$ with parameter vector θ when $\exists \hat{y}_j \in F_\theta^{k\text{-best}}(x)$ where $\hat{y}_j \neq \hat{y}_1$ and $L(\hat{y}_j, y) < L(\hat{y}_1, y)$. If training is run indefinitely, then $m \leq \frac{R^2}{\gamma^2}$.*

Proof. Identical to the standard perceptron proof, e.g., Collins (2002), by inserting in loss-separability for normal separability. □

Like the original perceptron theorem, this implies that the algorithm will converge. However, unlike the original theorem, it does not imply that it will converge to a parameter vector θ such that for all $(x, y) \in \mathcal{D}$, if $\hat{y} = \arg\max_{\hat{y}} \theta \cdot \Phi(\hat{y})$ then $L(\hat{y}, y) = 0$. Even if we assume for every x there exists an output with zero loss, Theorem 1 still makes no guarantees. Consider a training set with one instance (x, y). Now, set $k = 2$ for the k-best output list and let $\hat{y}_1$, $\hat{y}_2$, and $\hat{y}_3$ be the top-3 scoring outputs and let $L(\hat{y}_1, y) = 1$, $L(\hat{y}_2, y) = 2$ and $L(\hat{y}_3, y) = 0$. In this case, no updates will ever be made and $\hat{y}_1$ will remain unchanged even though it doesn't have minimal loss. Consider the following assumption:

Assumption 2. *For any parameter vector θ that exists during training, either 1) for all $(x, y) \in \mathcal{D}$, $L(\hat{y}_1, y) = 0$ (or some optimal minimum loss), or 2) there exists at least one $(x, y) \in \mathcal{D}$ where $\exists \hat{y}_j \in F_\theta^{k\text{-best}}(x)$ such that $L(\hat{y}_j, y) < L(\hat{y}_1, y)$.*

Assumption 2 states that for any θ that exists during training, but before convergence, there is at least one example in the training data where k is large enough to include one output with a lower loss when $\hat{y}_1$ does not have the optimal minimal loss. If $k = \infty$, then this is the standard perceptron as it guarantees the optimal loss output to be in the k-best list. But we are assuming something much weaker here, i.e., not that the k-best list will include the minimal loss output, only a single output with a lower loss than the current best guess. However, it is strong enough to show the following:

Theorem 2. *Given Assumption 1 and Assumption 2. Training the perceptron (Algorithm 2) with inline ranker loss (Algorithm 3) on $\mathcal{D}$ 1) converges in finite time, and 2) produces parameters θ such that for all $(x, y) \in \mathcal{D}$, if $\hat{y} = \arg\max_{\hat{y}} \theta \cdot \Phi(\hat{y})$ then $L(\hat{y}, y) = 0$ (or equivalent minimal loss).*

Proof. It must be the case for all $(x, y) \in \mathcal{D}$ that $L(\hat{y}_1, y) = 0$ (and $\hat{y}_1$ is the argmax) after a finite amount of time. Otherwise, by Assumption 2, there exists some x, such that when it is next processed, there would exist an output in the k-best list that had a lower loss, which will result in an additional mistake. Theorem 1 guarantees that this can not continue indefinitely as the number of mistakes is bounded. □

Thus, the perceptron algorithm will converge to optimal minimal loss under the assumption that k is large enough so that the model can keep improving. Note that this does not mean k must be large enough to include a zero or minimum loss output, just large enough to include a better output than the current best hypothesis. Theorem 2, when coupled with Theorem 1, implies that augmented-loss learning will make at most R^2/γ^2 mistakes at training, but does not guarantee the rate at which these mistakes will be made, only that convergence is finite, providing that the scheduling time (defined by Sched()) between seeing the same instance is always finite, which is always true in our experiments.

This analysis does not assume anything about the loss L. Every instance (x, y) can use a different loss. It is only required that the loss for a specific input-output pair is fixed throughout training. Thus, the above analysis covers the case where some training instances use an extrinsic loss and others an intrinsic parsing loss. This also suggests more efficient training methods when extracting the k-best list is prohibitive. One can parse with $k = 2, 4, 8, 16, \ldots$ until an k is reached that includes a lower loss parse. It may be the case that for most instances a small k is required, but the algorithm is doing more work unnecessarily if k is large.

3 Experimental Set-up

3.1 Dependency Parsers

The augmented-loss framework we present is general in the sense that it can be combined with any loss function and any parser, provided the parser can be parameterized as a linear classifier, trained with the perceptron and is capable of producing a k-best list of trees. For our experiments we focus on two dependency parsers.

- **Transition-based**: An implementation of the transition-based dependency parsing framework (Nivre, 2008) using an arc-eager transition strategy and are trained using the perceptron algorithm as in Zhang and Clark (2008) with a beam size of 8. Beams with varying sizes can be used to produce k-best lists. The features used by all models are: the part-of-speech tags of the first four words on the buffer and of the top two words on the stack; the word identities of the first two words on the buffer and of the top word on the stack; the word identity of the syntactic head of the top word on the stack (if available); dependency arc label identities for the top word on the stack, the left and rightmost modifier of the top word on the stack, and the left most modifier of the first word in the buffer (if available). All feature conjunctions are included.

- **Graph-based**: An implementation of graph-based parsing algorithms with an arc-factored parameterization (McDonald et al., 2005). We use the non-projective k-best MST algorithm to generate k-best lists (Hall, 2007), where $k = 8$ for the experiments in this paper. The graph-based parser features used in the experiments in this paper are defined over a word, w_i at position i; the head of this word $w_{\rho(i)}$ where $\rho(i)$ provides the index of the head word; and part-of-speech tags of these words t_i. We use the following set of features similar to McDonald et al. (2005):

isolated features:	$w_i, t_i, w_{\rho(i)}, t_{\rho(i)}$
word-tag pairs:	$(w_i, t_i); (w_{\rho(i)}, t_{\rho(i)})$
word-head pairs:	$(w_i, w_{\rho(i)}), (t_i, t_{\rho(i)})$
word-head-tag triples:	$(t_{\rho(i)}, w_i, t_i)$
	$(w_{\rho(i)}, w_i, t_i)$
	$(w_{\rho(i)}, t_{\rho(i)}, t_i)$
	$(w_{\rho(i)}, t_{\rho(i)}, w_i)$
tag-neighbourhood:	$(t_{\rho(i)}, t_{\rho(i)+1}, t_{i-1}, t_i)$
	$(t_{\rho(i)}, t_{\rho(i)+1}, t_{i+1}, t_i)$
	$(t_{\rho(i)}, t_{\rho(i)-1}, t_{i-1}, t_i)$
	$(t_{\rho(i)}, t_{\rho(i)-1}, t_{i+1}, t_i)$
between features:	$\forall_j\, i < j < \rho(i) \,\|\|\, \rho(i) < j < i$
	$(t_{\rho(i)}, t_j, t_i)$
arc-direction/length :	$(i - \rho(i) > 0, \|i - \rho(i)\|)$

3.2 Data and Tasks

In the next section, we present a set of scoring functions that can be used in the inline reranker loss framework, resulting in a new augmented-loss for each one. Augmented-loss learning is then applied to target a downstream task using the loss functions to measure gains. We show empirical results for two extrinsic loss-functions (optimizing for the downstream task): machine translation and domain adaptation; and for one intrinsic loss-function: an arc-length parsing score. For some experiments we also

measure the standard intrinsic parser metrics unlabeled attachment score (UAS) and labeled attachment score (LAS) (Buchholz and Marsi, 2006).

In terms of treebank data, the primary training corpus is the Penn Wall Street Journal Treebank (PTB) (Marcus et al., 1993). We also make use of the Brown corpus, and the Question Treebank (QTB) (Judge et al., 2006). For PTB and Brown we use standard training/development/testing splits of the data. For the QTB we split the data into three sections: 2000 training, 1000 development, and 1000 test. All treebanks are converted to dependency format using the Stanford converter v1.6 (de Marneffe et al., 2006).

4 Experiments

4.1 Machine Translation Reordering Score

As alluded to in Section 2.2, we use a reordering-based loss function to improve word order in a machine translation system. In particular, we use a system of source-side reordering rules which, given a parse of the source sentence, will reorder the sentence into a target-side order (Collins et al., 2005). In our experiments we work with a set of English-Japanese reordering rules[1] and gold reorderings based on human generated correct reordering of an aligned target sentences. We use a reordering score based on the reordering penalty from the METEOR scoring metric. Though we could have used a further downstream measure like BLEU, METEOR has also been shown to directly correlate with translation quality (Banerjee and Lavie, 2005) and is simpler to measure.

$$\text{reorder-score} = 1 - \frac{\#\text{ chunks} - 1}{\#\text{ unigrams\_matched} - 1}$$

$$\text{reorder-cost} = 1 - \text{reorder-score}$$

All reordering augmented-loss experiments are run with the same treebank data as the baseline (the training portions of PTB, Brown, and QTB). The extrinsic reordering training data consists of 10930 examples of English sentences and their correct Japanese word-order. We evaluate our results on an evaluation set of 6338 examples of similarly created reordering data. The reordering cost, evaluation criteria and data used in our experiments are based on the work of Talbot et al. (2011).

[1] Our rules are similar to those from Xu et al. (2009).

	Exact	Reorder
trans–PTB + Brown + QTB	35.29	76.49
trans–0.5×aug.-loss	38.71	78.19
trans–1.0×aug.-loss	39.02	78.39
trans–2.0×aug.-loss	39.58	78.67
graph–PTB + Brown + QTB	25.71	69.84
graph–0.5× aug.-loss	28.99	72.23
graph–1.0×aug.-loss	29.99	72.88
graph–2.0×aug.-loss	30.03	73.15

Table 1: Reordering scores for parser-based reordering (English-to-Japanese). Exact is the number of correctly reordered sentences. All models use the same treebank-data (PTB, QTB, and the Brown corpus). Results for three augmented-loss schedules are shown: 0.5 where for every two treebank updates we make one augmented-loss update, 1 is a 1-to-1 mix, and 2 is where we make twice as many augmented-loss updates as treebank updates.

Table 1 shows the results of using the reordering cost as an augmented-loss to the standard treebank objective function. Results are presented as measured by the reordering score as well as a coarse exact-match score (the number of sentences which would have correct word-order given the parse and the fixed reordering rules). We see continued improvements as we adjust the schedule to process the extrinsic loss more frequently, the best result being when we make two augmented-loss updates for every one treebank-based loss update.

4.2 Semi-supervised domain adaptation

Another application of the augmented-loss framework is to improve parser domain portability in the presence of partially labeled data. Consider, for example, the case of questions. Petrov et al. (2010) observed that dependency parsers tend to do quite poorly when parsing questions due to their limited exposure to them in the news corpora from the PennTreebank. Table 2 shows the accuracy of two parsers (LAS, UAS and the F1 of the root dependency attachment) on the QuestionBank test data. The first is a parser trained on the standard training sections of the PennTreebank (PTB) and the second is a parser trained on the training portion of the QuestionBank (QTB). Results for both

	LAS	UAS	Root-F1
trans–PTB	67.97	73.52	47.60
trans–QTB	84.59	89.59	91.06
trans–aug.-loss	76.27	86.42	83.41
graph–PTB	65.27	72.72	43.10
graph–QTB	82.73	87.44	91.58
graph–aug.-loss	72.82	80.68	86.26

Table 2: Domain adaptation results. Table shows (for both transition and graph-based parsers) the labeled accuracy score (LAS), unlabeled accuracy score (UAS) and Root-F1 for parsers trained on the PTB and QTB and tested on the QTB. The augmented-loss parsers are trained on the PTB but with a partial tree loss on QTB that considers only root dependencies.

transition-based parsers and graph-based parsers are given. Clearly there is significant drop in accuracy for a parser trained on the PTB. For example, the transition-based PTB parser achieves a LAS of 67.97% relative to 84.59% for the parser trained on the QTB.

We consider the situation where it is possible to ask annotators a single question about the target domain that is relatively easy to answer. The question should be posed so that the resulting answer produces a partially labeled dependency tree. Root-F1 scores from Table 2 suggest that one simple question is "what is the main verb of this sentence?" for sentences that are questions. In most cases this task is straight-forward and will result in a single dependency, that from the root to the main verb of the sentence. We feel this is a realistic partial labeled training setting where it would be possible to quickly collect a significant amount of data.

To test whether such weak information can significantly improve the parsing of questions, we trained an augmented-loss parser using the training set of the QTB stripped of all dependencies except the dependency from the root to the main verb of the sentence. In other words, for each sentence, the parser may only observe a single dependency at training from the QTB – the dependency to the main verb. Our augmented-loss function in this case is a simple binary function: 0 if a parse has the correct root dependency and 1 if it does not. Thus, the algorithm will select the first parse in the k-best list that has the correct root as the proxy to a gold standard parse.[2]

The last row in each section of Table 2 shows the results for this augmented-loss system when weighting both losses equally during training. By simply having the main verb annotated in each sentence – the sentences from the training portion of the QTB – the parser can eliminate half of the errors of the original parser. This is reflected by both the Root-F1 as well as LAS/UAS. It is important to point out that these improvements are not limited to simply better root predictions. Due to the fact that parsing algorithms make many parsing decisions jointly at test time, all such decisions influence each other and improvements are seen across the board. For example, the transition-based PTB parser has an F1 score of 41.22% for verb subjects (nsubj), whereas the augmented-loss parser has an F1 of 73.52%. Clearly improving just a single (and simple to annotate) dependency leads to general parser improvements.

4.3 Average Arc Length Score

The augmented-loss framework can be used to incorporate multiple treebank-based loss functions as well. Labeled attachment score is used as our base model loss function. In this set of experiments we consider adding an additional loss function which weights the lengths of correct and incorrect arcs, the average (labeled) arc-length score:

$$\text{ALS} = \frac{\sum_i \delta(\hat{\rho}_i, \rho_i)(i - \rho_i)}{\sum_i (i - \rho_i)}$$

For each word of the sentence we compute the distance between the word's position i and the position of the words head ρ_i. The arc-length score is the summed length of all those with correct head assignments ($\delta(\hat{\rho}_i, \rho_i)$ is 1 if the predicted head and the correct head match, 0 otherwise). The score is normalized by the summed arc lengths for the sentence. The labeled version of this score requires that the labels of the arc are also correct. Optimizing for dependency arc length is particularly important as parsers tend to do worse on longer dependencies (McDonald and Nivre, 2007) and these dependencies are typically the most meaningful for downstream tasks, e.g., main verb dependencies for tasks

[2] For the graph-based parser one can also find the higest scoring tree with correct root by setting the score of all competing arcs to $-\infty$.

	LAS	UAS	ALS
trans–PTB	88.64	91.64	82.96
trans–unlabeled aug.-loss	88.74	91.91	83.65
trans–labeled aug.-loss	88.84	91.91	83.46
graph–PTB	85.75	88.70	73.88
graph–unlabeled aug.-loss	85.80	88.81	74.26
graph–labeled aug.-loss	85.85	88.93	74.40

Table 3: Results for both parsers on the development set of the PTB. When training with ALS (labeled and unlabeled), we see an improvement in UAS, LAS, and ALS. Furthermore, if we use a labeled-ALS as the metric for augmented-loss training, we also see a considerable increase in LAS.

like information extraction (Yates and Etzioni, 2009) and textual entailment (Berant et al., 2010).

In Table 3 we show results for parsing with the ALS augmented-loss objective. For each parser, we consider two different ALS objective functions; one based on unlabeled-ALS and the other on labeled-ALS. The arc-length score penalizes incorrect long-distance dependencies more than local dependencies; long-distance dependencies are often more destructive in preserving sentence meaning and can be more difficult to predict correctly due to the larger context on which they depend. Combining this with the standard attachment scores biases training to focus on the difficult head dependencies.

For both experiments we see that by adding the ALS augmented-loss we achieve an improvement in LAS and UAS in addition to ALS. The augmented-loss not only helps us improve on the longer dependencies (as reflected in the increased ALS), but also in the main parser objective function of LAS and UAS. Using the labeled loss function provides better reinforcement as can be seen in the improvements over the unlabeled loss-function. As with all experiments in this paper, the graph-based parser baselines are much lower than the transition-based parser due to the use of arc-factored features. In these experiments we used an inline-ranker loss with 8 parses. We experimented with larger sizes (16 and 64) and found very similar improvements: for example, the transition parser's LAS for the labeled loss is 88.68 and 88.84, respectively).

We note that ALS can be decomposed locally and could be used as the primary objective function for parsing. A parse with perfect scores under ALS and LAS will match the gold-standard training tree. However, if we were to order incorrect parses of a sentence, ALS and LAS will suggest different orderings. Our results show that by optimizing for losses based on a combination of these metrics we train a more robust parsing model.

5 Related Work

A recent study by Katz-Brown et al. (2011) also investigates the task of training parsers to improve MT reordering. In that work, a parser is used to first parse a set of manually reordered sentences to produce k-best lists. The parse with the best reordering score is then fixed and added back to the training set and a new parser is trained on resulting data. The method is called *targeted self-training* as it is similar in vein to self-training (McClosky et al., 2006), with the exception that the new parse data is targeted to produce accurate word reorderings. Our method differs as it does not statically fix a new parse, but dynamically updates the parameters and parse selection by incorporating the additional loss in the inner loop of online learning. This allows us to give guarantees of convergence. Furthermore, we also evaluate the method on alternate extrinsic loss functions.

Liang et al. (2006) presented a perceptron-based algorithm for learning the phrase-translation parameters in a statistical machine translation system. Similar to the inline-ranker loss function presented here, they use a k-best lists of hypotheses in order to identify parameters which can improve a global objective function: BLEU score. In their work, they are interested in learning a parameterization over translation phrases (including the underlying word-alignment) which optimizes the BLEU score. Their goal is considerably different; they want to incorporate additional features into their model and define an objective function which allows them to do so; whereas, we are interested in allowing for multiple objective functions in order to adapt the parser model parameters to downstream tasks or alternative intrinsic (parsing) objectives.

The work that is most similar to ours is that of Chang et al. (2007), who introduced the Constraint Driven Learning algorithm (CODL). Their algorithm specifically optimizes a loss function with

the addition of constraints based on unlabeled data (what we call extrinsic datasets). For each unlabeled example, they use the current model along with their set of constraints to select a set of k automatically labeled examples which best meet the constraints. These induced examples are then added to their training set and, after processing each unlabeled dataset, they perform full model optimization with the concatenation of training data and newly generated training items. The augmented-loss algorithm can be viewed as an online version of this algorithm which performs model updates based on the augmented-loss functions directly (rather than adding a set of examples to the training set). Unlike the CODL approach, we do not perform complete optimization on each iteration over the unlabeled dataset; rather, we incorporate the updates in our online learning algorithm. As mentioned earlier, CODL is one example of learning algorithms that use weak supervision, others include Mann and McCallum (2010) and Ganchev et al. (2010). Again, these works are typically interested in using the extrinsic metric – or, in general, extrinsic information – to optimize the intrinsic metric in the absence of any labeled intrinsic data. Our goal is to optimize both simultaneously.

The idea of jointly training parsers to optimize multiple objectives is related to joint learning and inference for tasks like information extraction (Finkel and Manning, 2009) and machine translation (Burkett et al., 2010). In such works, a large search space that covers both the space of parse structures and the space of task-specific structures is defined and parameterized so that standard learning and inference algorithms can be applied. What sets our work apart is that there is still just a single parameter set that is being optimized – the parser parameters. Our method only uses feedback from task specific objectives in order to update the parser parameters, guiding it towards better downstream performance. This is advantageous for two reasons. First, it decouples the tasks, making inference and learning more efficient. Second, it does not force arbitrary paraemter factorizations in order to define a joint search space that can be searched efficiently.

Finally, augmented-loss training can be viewed as multi-task learning (Caruana, 1997) as the model optimizes multiple objectives over multiple data sets with a shared underlying parameter space.

6 Discussion

The empirical results show that incorporating an augmented-loss using the inline-ranker loss framework achieves better performance under metrics associated with the external loss function. For the intrinsic loss, we see that the augmented-loss framework can also result in an improvement in parsing performance; however, in the case of ALS, this is due to the fact that the loss function is very closely related to the standard evaluation metrics of UAS and LAS.

Although our analysis suggests that this algorithm is guaranteed to converge only for the separable case, it makes a further assumption that if there is a better parse under the augmented-loss, then there must be a lower cost parse in the k-best list. The empirical evaluation presented here is based on a very conservative approximation by choosing lists with at most 8 parses. However, in our experiments, we found that increasing the size of the lists did not significantly increase our accuracy under the external metrics. If we do have at least one improvement in our k-best lists, the analysis suggests that this is enough to move in the correct direction for updating the model. The assumption that there will always be an improvement in the k-best list if there is some better parse breaks down as training continues. We suspect that an increasing k, as suggested in Section 2.3, will allow for continued improvements.

Dependency parsing, as presented in this paper, is performed over (k-best) part-of-speech tags and is therefore dependent on the quality of the tagger. The experiments presented in this paper made use of a tagger trained on the source treebank data which severely limits the variation in parses. The augmented-loss perceptron algorithm presented here can be applied to any online learning problem, including part-of-speech tagger training. To build a dependency parser which is better adapted to a downstream task, one would want to perform augmented-loss training on the tagger as well.

7 Conclusion

We introduced the augmented-loss training algorithm and show that the algorithm can incorporate

additional loss functions to adapt the model towards extrinsic evaluation metrics. Analytical results are presented that show that the algorithm can optimize multiple objective functions simultaneously. We present an empirical analysis for training dependency parsers for multiple parsing algorithms and multiple loss functions.

The augmented-loss framework supports both intrinsic and extrinsic losses, allowing for both combinations of objectives as well as multiple sources of data for which the results of a parser can be evaluated. This flexibility makes it possible to tune a model for a downstream task. The only requirement is a metric which can be defined over parses of the downstream data. Our dependency parsing results show that we are not limited to increasing parser performance via more data or external domain adaptation techniques, but that we can incorporate the downstream task into parser training.

Abstract

Linear models have enjoyed great success in structured prediction in NLP. While a lot of progress has been made on efficient training with several loss functions, the problem of endowing learners with a mechanism for feature selection is still unsolved. Common approaches employ ad hoc filtering or L_1-regularization; both ignore the structure of the feature space, preventing practicioners from encoding structural prior knowledge. We fill this gap by adopting regularizers that promote *structured sparsity*, along with efficient algorithms to handle them. Experiments on three tasks (chunking, entity recognition, and dependency parsing) show gains in performance, compactness, and model interpretability.

1 Introduction

Models for structured outputs are in demand across natural language processing, with applications in information extraction, parsing, and machine translation. State-of-the-art models usually involve linear combinations of features and are trained discriminatively; examples are conditional random fields (Lafferty et al., 2001), structured support vector machines (Altun et al., 2003; Taskar et al., 2003; Tsochantaridis et al., 2004), and the structured perceptron (Collins, 2002a). In all these cases, the underlying optimization problems differ only in the choice of loss function; choosing among them has usually a small impact on predictive performance.

In this paper, we are concerned with *model selection*: which features should be used to define the prediction score? The fact that models with few features ("sparse" models) are desirable for several reasons (compactness, interpretability, good generalization) has stimulated much research work which has produced a wide variety of methods (Della Pietra et al., 1997; Guyon and Elisseeff, 2003; McCallum, 2003). Our focus is on methods which embed this selection into the learning problem via the regularization term. We depart from previous approaches in that we seek to make decisions jointly about all candidate features, and we want to promote sparsity patterns that go beyond the mere cardinality of the set of features. For example, we want to be able to select entire *feature templates* (rather than features individually), or to make the inclusion of some features depend on the inclusion of other features.

We achieve the goal stated above by employing regularizers which promote *structured sparsity*. Such regularizers are able to encode prior knowledge and guide the selection of features by modeling the structure of the feature space. Lately, this type of regularizers has received a lot of attention in computer vision, signal processing, and computational biology (Zhao et al., 2009; Kim and Xing, 2010; Jenatton et al., 2009; Obozinski et al., 2010; Jenatton et al., 2010; Bach et al., 2011). Eisenstein et al. (2011) employed structured sparsity in computational sociolinguistics. However, none of these works have addressed structured prediction. Here, we combine these two levels of structure: structure in the output space, and structure in the feature space. The result is a framework that allows building structured predictors with high predictive power, while reducing manual feature engineering. We obtain models that are interpretable, accurate, and often much more compact than L_2-regularized ones. Compared with L_1-regularized models, ours are often more accurate and yield faster runtime.

2 Structured Prediction

We address structured prediction problems, which involve an input set $\mathcal{X}$ (*e.g.*, sentences) and an output set $\mathcal{Y}$, assumed large and structured (*e.g.*, tags or parse trees). We assume that each $x \in \mathcal{X}$ has a set of candidate outputs $\mathcal{Y}(x) \subseteq \mathcal{Y}$. We consider linear models, in which predictions are made according to

$$\widehat{y} = \arg\max_{y \in \mathcal{Y}(x)} \boldsymbol{\theta} \cdot \boldsymbol{\phi}(x, y), \quad (1)$$

where $\boldsymbol{\phi}(x, y) \in \mathbb{R}^D$ is a vector of features, and $\boldsymbol{\theta} \in \mathbb{R}^D$ is the vector of corresponding weights. Let $\mathcal{D} = \{\langle x_i, y_i \rangle\}_{i=1}^N$ be a training sample. We assume a cost function is defined such that $c(\widehat{y}, y)$ is the cost of predicting $\widehat{y}$ when the true output is y; our goal is to learn $\boldsymbol{\theta}$ with small expected cost on unseen data. To achieve this goal, linear models are usually trained by solving a problem of the form

$$\widehat{\boldsymbol{\theta}} = \arg\min_{\boldsymbol{\theta}} \Omega(\boldsymbol{\theta}) + \tfrac{1}{N} \textstyle\sum_{i=1}^N L(\boldsymbol{\theta}, x_i, y_i), \quad (2)$$

where Ω is a *regularizer* and L is a *loss* function. Examples of losses are: the negative conditional log-likelihood used in CRFs (Lafferty et al., 2001),

$$L_{\text{CRF}}(\boldsymbol{\theta}, x, y) = -\log P_{\boldsymbol{\theta}}(y|x), \quad (3)$$

where $P_{\boldsymbol{\theta}}(y|x) \propto \exp(\boldsymbol{\theta} \cdot \boldsymbol{\phi}(x, y))$ is a log-linear model; the margin rescaled loss of structured SVMs (Taskar et al., 2003; Tsochantaridis et al., 2004),

$$L_{\text{SVM}}(\boldsymbol{\theta}, x, y) = \max_{y' \in \mathcal{Y}(x)} \boldsymbol{\theta} \cdot \delta\boldsymbol{\phi}(y') + c(y', y), \quad (4)$$

where $\delta\boldsymbol{\phi}(y') = \boldsymbol{\phi}(x, y') - \boldsymbol{\phi}(x, y)$; and the loss underlying the structured perceptron (Collins, 2002a),

$$L_{\text{SP}}(\boldsymbol{\theta}, x, y) = \max_{y' \in \mathcal{Y}(x)} \boldsymbol{\theta} \cdot \delta\boldsymbol{\phi}(y'). \quad (5)$$

Empirical comparison among these loss functions can be found in the literature (see, *e.g.*, Martins et al., 2010, who also consider interpolations of the losses above). In practice, it has been observed that the choice of loss has far less impact than the model design and choice of features. Hence, in this paper, we focus our attention on the regularization term in Eq. 2. We specifically address ways in which this term can be used to help design the model by promoting *structured sparsity*. While this has been a topic of intense research in signal processing and computational biology (Jenatton et al., 2009; Liu and Ye, 2010; Bach et al., 2011), it has not yet received much attention in the NLP community, where the choice of regularization for supervised learning has essentially been limited to the following:

- L_2-regularization (Chen and Rosenfeld, 2000):

$$\Omega_\lambda^{L_2}(\boldsymbol{\theta}) \triangleq \tfrac{\lambda}{2}\|\boldsymbol{\theta}\|_2^2 = \tfrac{\lambda}{2}\textstyle\sum_{d=1}^D \theta_d^2; \quad (6)$$

- L_1-regularization (Kazama and Tsujii, 2003; Goodman, 2004):

$$\Omega_\tau^{L_1}(\boldsymbol{\theta}) \triangleq \tau\|\boldsymbol{\theta}\|_1 = \tau\textstyle\sum_{d=1}^D |\theta_d|. \quad (7)$$

The latter is known as "Lasso," as popularized by Tibshirani (1996) in the context of sparse regression. In the two cases above, λ and τ are nonnegative coefficients controlling the intensity of the regularization. $\Omega_\lambda^{L_2}$ usually leads to easier optimization and robust performance; $\Omega_\tau^{L_1}$ encourages sparser models, where only a few features receive nonzero weights; see Gao et al. (2007) for an empirical comparison. More recently, Petrov and Klein (2008b) applied L_1 regularization for structure learning in phrase-based parsing; a comparison with L_2 appears in Petrov and Klein (2008a). Elastic nets interpolate between L_1 and L_2, having been proposed by Zou and Hastie (2005) and used by Lavergne et al. (2010) to regularize CRFs.

Neither of the regularizers just described "looks" at the *structure* of the feature space, since they all treat each dimension independently—we call them *unstructured* regularizers, as opposed to the structured ones that we next describe.

3 Structured Sparsity

We are interested in regularizers that share with $\Omega_\tau^{L_1}$ the ability to promote sparsity, so that they can be used for selecting features. In addition, we want to endow the feature space $\mathbb{R}^D$ with additional structure, so that features are not penalized individually (as in the L_1-case) but collectively, encouraging entire *groups* of features to be discarded. The choice of groups will allow encoding prior knowledge regarding the kind of sparsity patterns that are intended in the model. This can be achieved with *group-Lasso regularization*, which we next describe.

3.1 The Group Lasso

To capture the structure of the feature space, we group our D features into M groups $G_1, \ldots, G_M$, where each $G_m \subseteq \{1, \ldots, D\}$. Ahead, we discuss meaningful ways of choosing group decompositions; for now, let us assume a sensible choice is obvious to the model designer. Denote by $\boldsymbol{\theta}_m = \langle \theta_d \rangle_{d \in G_m}$ the subvector of those weights that correspond to the features in the m-th group, and let $d_1, \ldots, d_M$ be nonnegative scalars (one per group). We consider the following *group-Lasso* regularizers:

$$\Omega^{\mathrm{GL}}_{\boldsymbol{d}} = \sum_{m=1}^{M} d_m \|\boldsymbol{\theta}_m\|_2. \quad (8)$$

These regularizers were first proposed by Bakin (1999) and Yuan and Lin (2006) in the context of regression. If $d_1 = \ldots = d_M$, $\Omega^{\mathrm{GL}}_{\boldsymbol{d}}$ becomes the "L_1 norm of the L_2 norms." Interestingly, this is also a norm, called the mixed $L_{2,1}$-norm.[1] These regularizers subsume the L_1 and L_2 cases, which correspond to trivial choices of groups:

- If each group is a singleton, *i.e.*, $M = D$ and $G_d = \{\theta_d\}$, and $d_1 = \ldots = d_M = \tau$, we recover L_1-regularization (cf. Eqs. 7–8).
- If there is a single group spanning all the features, *i.e.*, $M = 1$ and $G_1 = \{1, \ldots, D\}$, then the right hand side of Eq. 8 becomes $d_1 \|\boldsymbol{\theta}\|_2$. This is equivalent to L_2 regularization.[2]

We next present some non-trivial examples concerning different topologies of $\mathcal{G} = \{G_1, \ldots, G_M\}$.

Non-overlapping groups. Let us first consider the case where $\mathcal{G}$ is a *partition* of the feature space: the groups cover all the features ($\bigcup_m G_m = \{1, \ldots, D\}$), and they do not overlap ($G_a \cap G_b = \varnothing$, $\forall a \neq b$). Then, $\Omega^{\mathrm{GL}}_{\boldsymbol{d}}$ is termed a *non-overlapping group-Lasso* regularizer. It encourages sparsity patterns in which entire groups are discarded. A judicious choice of groups can lead to very compact models and pinpoint relevant groups of features. The following examples lie in this category:

- The two cases above (L_1 and L_2 regularization).
- *Label-based groups*. In multi-label classification, where $\mathcal{Y} = \{1, \ldots, L\}$, features are typically designed as conjunctions of input features with label indicators, i.e., they take the form $\boldsymbol{\phi}(x, y) = \boldsymbol{\psi}(x) \otimes \boldsymbol{e}_y$, where $\boldsymbol{\psi}(x) \in \mathbb{R}^{D_X}$, $\boldsymbol{e}_y \in \mathbb{R}^L$ has all entries zero except the y-th entry, which is 1, and $\otimes$ denotes the Kronecker product. Hence $\boldsymbol{\phi}(x, y)$ can be reshaped as a D_X-by-L matrix, and we can let each group correspond to a row. In this case, all groups have the same size and we typically set $d_1 = \ldots = d_M$. A similar design can be made for sequence labeling problems, by considering a similar grouping for the unigram features.[3]
- *Template-based groups*. In NLP, features are commonly designed via *templates*. For example, a template such as $w_0 \wedge p_0 \wedge p_{-1}$ denotes the word in the current position (w_0) conjoined with its part-of-speech (p_0) and that of the previous word (p_{-1}). This template encloses many features corresponding to different instantiantions of w_0, p_0, and p_{-1}. In §5, we learn *feature templates* from the data, by associating each group to a feature template, and letting that group contain all features that are instantiations of this template. Since groups have different sizes, it is a good idea to let d_m increase with the group size, so that larger groups pay a larger penalty for being included.

Tree-structured groups. More generally, we may let the groups in $\mathcal{G}$ overlap but be nested, *i.e.*, we may want them to form a *hierarchy* (two distinct groups either have empty intersection or one is contained in the other). This induces a partial order on $\mathcal{G}$ (the set inclusion relation $\supseteq$), endowing it with the structure of a partially ordered set (*poset*).

A convenient graphical representation of the poset $\langle \mathcal{G}, \supseteq \rangle$ is its *Hasse diagram*. Each group is a node in the diagram, and an arc is drawn from group G_a to group G_b if $G_b \subset G_a$ and there is no b' s.t. $G_b \subset G_{b'} \subset G_a$. When the groups are nested, this diagram is a *forest* (a union of directed trees). The corresponding regularizer enforces sparsity patterns

[1] In the statistics literature, such mixed-norm regularizers, which group features and then apply a separate norm for each group, are called *composite absolute penalties* (Zhao et al., 2009); other norms besides $L_{2,1}$ can be used, such as $L_{\infty,1}$ (Quattoni et al., 2009; Wright et al., 2009; Eisenstein et al., 2011).

[2] Note that Eqs. 8 and 6 do not become *exactly* the same: in Eq. 6, the L_2 norm is squared. However it can be shown that both regularizers lead to identical learning problems (Eq. 2) up to a transformation of the regularization constant.

[3] The same idea is also used in multitask learning, where labels correspond to tasks (Caruana, 1997).

where a group of features is only selected if *all its ancestors are also selected*.[4] Hence, entire subtrees in the diagram can be pruned away. Examples are:

- The *elastic net*. The diagram of $\mathcal{G}$ has a root node for $G_1 = \{1, \ldots, D\}$ and D leaf nodes, one per each singleton group (see Fig. 1).
- The *sparse group-Lasso*. This regularizer was proposed by Friedman et al. (2010):

$$\Omega^{\mathrm{SGL}}_{\boldsymbol{d},\boldsymbol{\tau}}(\boldsymbol{\theta}) = \sum_{m=1}^{M'} \left(d_m \|\boldsymbol{\theta}_m\|_2 + \tau_m \|\boldsymbol{\theta}_m\|_1\right), \tag{9}$$

  where the total number of groups is $M = M' + D$, and the components $\boldsymbol{\theta}_1, \ldots, \boldsymbol{\theta}_{M'}$ are non-overlapping. This regularizer promotes sparsity at both group and feature levels (*i.e.*, it eliminates entire groups and sparsifies within each group).

Graph-structured groups. In general, the groups in $\mathcal{G}$ may overlap without being nested. In this case, the Hasse diagram of $\mathcal{G}$ is a directed acyclic graph (DAG). As in the tree-structured case, a group of features is only selected if all its ancestors are also selected. Based on this property, Jenatton et al. (2009) suggested a way of reverse engineering the groups from the desired sparsity pattern. We next describe a strategy for *coarse-to-fine feature template selection* that directly builds on that idea.

Suppose that we are given M feature templates $\mathcal{T} = \{T_1, \ldots, T_M\}$ which are partially ordered according to some criterion, such that if $T_a \preceq T_b$ we would like to include T_b in our model only if T_a is also included. This criterion could be a measure of coarseness: we may want to let coarser part-of-speech features precede finer lexical features, *e.g.*, $p_0 \wedge p_1 \preceq w_0 \wedge w_1$, or conjoined features come after their elementary parts, *e.g.*, $p_0 \preceq p_0 \wedge p_1$. The order does not need to be total, so some templates may not be comparable (*e.g.*, we may want $p_0 \wedge p_{-1}$ and $p_0 \wedge p_1$ not to be comparable). To achieve the sparsity pattern encoded in $\langle \mathcal{T}, \preceq \rangle$, we choose $\mathcal{G} = \langle G_1, \ldots, G_M \rangle$ as follows: let $I(T_a)$ be the set of features that are instantiations of template T_a; then define $G_a = \bigcup_{b:a \preceq b} I(T_b)$, for $a = 1, \ldots, M$. It is easy to see that $\langle \mathcal{G}, \supseteq \rangle$ and $\langle \mathcal{T}, \preceq \rangle$ are isomorph posets (their Hasse diagrams have the same shape; see Fig. 1). The result is a "coarse-to-fine" regularizer, which prefers to select feature templates that are coarser before zooming into finer features.

[4] We say that a group of features G_m is selected if *some* feature in G_m (but not necessarily all) has a nonzero weight.

3.2 Bayesian Interpretation

The prior knowledge encoded in the group-Lasso regularizer (Eq. 8) comes with a Bayesian interpretation, as we next describe. In a probabilistic model (e.g. in the CRF case, where $L = L_{\mathrm{CRF}}$), the optimization problem in Eq. 2 can be seen as maximum *a posteriori* estimation of $\boldsymbol{\theta}$, where the regularization term $\Omega(\boldsymbol{\theta})$ corresponds to the negative log of a prior distribution (call it $p(\boldsymbol{\theta})$). It is well-known that L_2-regularization corresponds to choosing independent zero-mean Gaussian priors, $\theta_d \sim \mathcal{N}(0, \lambda^{-1})$, and that L_1-regularization results from adopting zero-mean Laplacian priors, $p(\theta_d) \propto \exp(\tau|\theta_d|)$.

Figueiredo (2002) provided an alternative interpretation of L_1-regularization in terms of a two-level hierarchical Bayes model, which happens to generalize to the non-overlapping group-Lasso case, where $\Omega = \Omega^{\mathrm{GL}}_{\boldsymbol{d}}$. As in the L_2-case, we also assume that each parameter receives a zero-mean Gaussian prior, but now with a *group-specific variance* τ_m, *i.e.*, $\boldsymbol{\theta}_m \sim \mathcal{N}(\mathbf{0}, \tau_m \boldsymbol{I})$ for $m = 1, \ldots, M$. This reflects the fact that some groups should have their feature weights shrunk more towards zero than others. The variances $\tau_m \geq 0$ are not pre-specified but rather generated by a one-sided exponential hyperprior $p(\tau_m|d_m) \propto \exp(-d_m^2 \tau_m/2)$. It can be shown that after marginalizing out τ_m, we obtain

$$\begin{aligned} p(\boldsymbol{\theta}_m|d_m) &= \int_0^\infty p(\boldsymbol{\theta}_m|\tau_m) p(\tau_m|d_m) d\tau_m \\ &\propto \exp\left(-d_m \|\boldsymbol{\theta}_m\|\right). \end{aligned} \tag{10}$$

Hence, the non-overlapping group-Lasso corresponds to the following two-level hierachical Bayes model: independently for each $m = 1, \ldots, M$,

$$\tau_m \sim \mathrm{Exp}(d_m^2/2), \qquad \boldsymbol{\theta}_m \sim \mathcal{N}(0, \tau_m \boldsymbol{I}). \tag{11}$$

3.3 Prox-operators

Before introducing our learning algorithm for handling group-Lasso regularization, we need to define the concept of a Ω-*proximity operator*. This is the function $\mathrm{prox}_\Omega : \mathbb{R}^D \to \mathbb{R}^D$ defined as follows:

$$\mathrm{prox}_\Omega(\boldsymbol{\theta}) = \arg\min_{\boldsymbol{\theta}'} \tfrac{1}{2}\|\boldsymbol{\theta}' - \boldsymbol{\theta}\|^2 + \Omega(\boldsymbol{\theta}'). \tag{12}$$

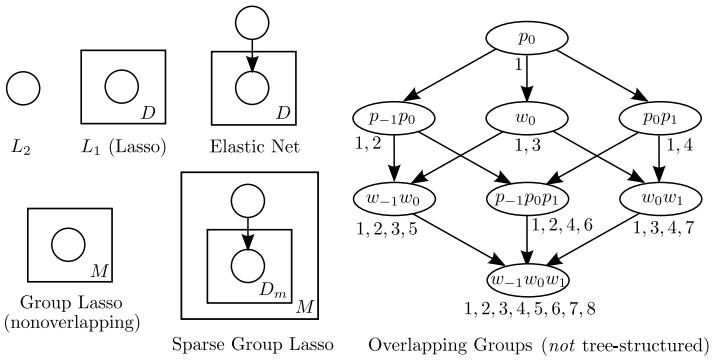

Figure 1: Hasse diagrams of several group-based regularizers. For all tree-structured cases, we use the same plate notation that is traditionally used in probabilistic graphical models. The rightmost diagram represents a coarse-to-fine regularizer: each node is a template involving contiguous sequences of words (w) and POS tags (p); the symbol order $\varnothing \preceq p \preceq w$ induces a template order ($T_a \preceq T_b$ iff at each position i $[T_a]_i \preceq [T_b]_i$). Digits below each node are the group indices where each template belongs.

Proximity operators generalize Euclidean projections and have many interesting properties; see Bach et al. (2011) for an overview. By requiring zero to be a subgradient of the objective function in Eq. 12, we obtain the following closed expression (called *soft-thresholding*) for the $\Omega_\tau^{L_1}$-proximity operator:

$$[\mathrm{prox}_{\Omega_\tau^{L_1}}(\boldsymbol{\theta})]_d = \begin{cases} \theta_d - \tau & \text{if } \theta_d > \tau \\ 0 & \text{if } |\theta_d| \leq \tau \\ \theta_d + \tau & \text{if } \theta_d < -\tau. \end{cases} \quad (13)$$

For the *non-overlapping* group Lasso case, the proximity operator is given by

$$[\mathrm{prox}_{\Omega_{\boldsymbol{d}}^{\mathrm{GL}}}(\boldsymbol{\theta})]_m = \begin{cases} \mathbf{0} & \text{if } \|\boldsymbol{\theta}_m\|_2 \leq d_m \\ \frac{\|\boldsymbol{\theta}_m\|_2 - d_m}{\|\boldsymbol{\theta}_m\|_2}\boldsymbol{\theta}_m & \text{otherwise.} \end{cases} \quad (14)$$

which can be seen as a generalization of Eq. 13: if the L_2-norm of the m-th group is less than d_m, the entire group is discarded; otherwise it is scaled so that its L_2-norm decreases by an amount of d_m.

When groups overlap, the proximity operator lacks a closed form. When $\mathcal{G}$ is tree-structured, it can still be efficiently computed by a recursive procedure (Jenatton et al., 2010). When $\mathcal{G}$ is *not* tree-structured, no specialized procedure is known, and a convex optimizer is necessary to solve Eq. 12.

4 Online Prox-Grad Algorithm

We now turn our attention to efficient ways of handling group-Lasso regularizers. Several fast and scalable algorithms having been proposed for training L_1-regularized CRFs, based on quasi-Newton optimization (Andrew and Gao, 2007), coordinate descent (Sokolovska et al., 2010; Lavergne et al., 2010), and stochastic gradients (Carpenter, 2008; Langford et al., 2009; Tsuruoka et al., 2009). The algorithm that we use in this paper (Alg. 1) extends the stochastic gradient methods for group-Lasso regularization; a similar algorithm was used by Martins et al. (2011) for multiple kernel learning.

Alg. 1 addresses the learning problem in Eq. 2 by alternating between online (sub-)gradient steps with respect to the loss term, and proximal steps with respect to the regularizer. Proximal-gradient methods are very popular in sparse modeling, both in batch (Liu and Ye, 2010; Bach et al., 2011) and online (Duchi and Singer, 2009; Xiao, 2009) settings. The reason we have chosen the algorithm of Martins et al. (2011) is that it effectively handles overlapping groups, without the need of evaluating prox_Ω (which, as seen in §3.3, can be costly if $\mathcal{G}$ is not tree-structured). To do so, it decomposes Ω as

$$\Omega(\boldsymbol{\theta}) = \textstyle\sum_{j=1}^{J} \sigma_j \Omega_j(\boldsymbol{\theta}) \quad (15)$$

for some $J \geq 1$, and nonnegative $\sigma_1, \ldots, \sigma_J$; each Ω_j-proximal operator is assumed easy to compute. Such a decomposition always exists: if $\mathcal{G}$ does not have overlapping groups, take $J = 1$. Otherwise, find $J \leq M$ disjoint sets $\mathcal{G}_1, \ldots, \mathcal{G}_J$ such that $\bigcup_{j=1}^{J} \mathcal{G}_j = \mathcal{G}$ and the groups on each $\mathcal{G}_j$ are non-overlapping. The proximal steps are then applied sequentially, one per each Ω_j. Overall, Alg. 1 satisfies the following important requirements:

- *Computational efficiency.* Each gradient step at round t is *linear* in the number of features that fire for that instance and *independent* of the total number of features D. Each proximal step is *linear* in the number of groups M, and does not need be to performed every round (as we will see later).

Algorithm 1 Online Sparse Prox-Grad Algorithm

input: $\mathcal{D}$, $\langle \Omega_j \rangle_{j=1}^J$, T, gravity sequence $\langle \langle \sigma_{jt} \rangle_{j=1}^J \rangle_{t=1}^T$, stepsize sequence $\langle \eta_t \rangle_{t=1}^T$
initialize $\boldsymbol{\theta} = \mathbf{0}$
for $t = 1$ **to** T **do**
  take training pair $\langle x_t, y_t \rangle \in \mathcal{D}$
  $\boldsymbol{\theta} \leftarrow \boldsymbol{\theta} - \eta_t \nabla L(\boldsymbol{\theta}; x_t, y_t)$ (gradient step)
  for $j = 1$ **to** J **do**
    $\boldsymbol{\theta} = \mathrm{prox}_{\eta_t \sigma_{jt} \Omega_j}(\boldsymbol{\theta})$ (proximal step)
  end for
end for
output: $\boldsymbol{\theta}$

- *Memory efficiency.* Only a small active set of features (those that have nonzero weights) need to be maintained. Entire groups of features can be deleted after each proximal step. Furthermore, only the features which correspond to nonzero entries in the gradient vector need to be inserted in the active set; for some losses (L_{SVM} and L_{SP}) many irrelevant features are never instantianted.
- *Convergence.* With high probability, Alg. 1 produces an ϵ-accurate solution after $T \leq O(1/\epsilon^2)$ rounds, for a suitable choice of stepsizes and holding σ_{jt} constant, $\sigma_{jt} = \sigma_j$ (Martins et al., 2011). This result can be generalized to any sequence $\langle \sigma_{jt} \rangle_{t=1}^T$ such that $\sigma_j = \frac{1}{T} \sum_{t=1}^T \sigma_{jt}$.

We next describe several algorithmic ingredients that make Alg. 1 effective in sparse modeling.

Budget-Driven Shrinkage. Alg. 1 requires the choice of a "gravity sequence." We follow Langford et al. (2009) and set $\langle \sigma_{jt} \rangle_{j=1}^J$ to zero for all t which is not a multiple of some prespecified integer K; this way, proximal steps need only be performed each K rounds, yielding a significant speed-up when the number of groups M is large. A direct adoption of the method of Langford et al. (2009) would set $\sigma_{jt} = K\sigma_j$ for those rounds; however, we have observed that such a strategy makes the number of groups vary substantially in early epochs. We use a different strategy: for each $\mathcal{G}_j$, we specify a *budget* of $B_j \geq 0$ groups (this may take into consideration practical limitations, such as the available memory). If t is a multiple of K, we set σ_{jt} as follows:

1. If $\mathcal{G}_j$ does not have more than B_j nonzero groups, set $\sigma_{jt} = 0$ and do nothing.
2. Otherwise, sort the groups in $\mathcal{G}_j$ by decreasing order of their L_2-norms. Check the L_2-norms of the B_j-th and B_{j+1}-th entries in the list and set σ_{jt} as the mean of these two divided by η_t.
3. Apply a $\eta_t \sigma_{jt} \Omega_j$-proximal step using Eq. 14. At the end of this step, no more than B_j groups will remain nonzero.[5]

If the average of the gravity steps converge, $\lim_{T\to\infty} \frac{1}{T} \sum_{t=1}^T \sigma_{jt} \to \sigma_j$, then the limit points σ_j implicitly define the regularizer, via $\Omega = \sum_{j=1}^J \sigma_j \Omega_j$.[6] Hence, we have shifted the control of the amount of regularization to the budget constants B_j, which unlike the σ_j have a clear meaning and can be chosen under practical considerations.

Space and Time Efficiency. The proximal steps in Alg. 1 have a *scaling* effect on each group, which affects all features belonging to that group (see Eq. 14). We want to avoid explicitly updating each feature in the active set, which could be time consuming. We mention two strategies that can be used for the *non-overlapping* group Lasso case.

- The first strategy is suitable when M is large and only a few groups ($\ll M$) have features that fire in each round; this is the case, *e.g.*, of *label-based groups* (see §3.1). It consists of making *lazy updates* (Carpenter, 2008), *i.e.*, to delay the update of all features in a group until at least one of them fires; then apply a cumulative penalty. The amount of the penalty can be computed if one assigns a timestamp to each group.
- The second strategy is suitable when M is small and some groups are very populated; this is the typical case of *template-based groups* (§3.1). Two operations need to be performed: updating each feature weight (in the gradient steps), and scaling entire groups (in the proximal steps). We adapt a trick due to Shalev-Shwartz et al. (2007): represent the weight vector of the m-th group, $\boldsymbol{\theta}_m$, by a

[5] When overlaps exist (e.g. the coarse-to-fine case), we specify a total pseudo-budget B ignoring the overlaps, which induces budgets $B_1, \ldots, B_J$ which sum to B. The number of actually selected groups may be less than B, however, since in this case some groups can be shrunk more than once. Other heuristics are possible.

[6] The convergence assumption can be sidestepped by freezing the σ_j after a fixed number of iterations.

triple $\langle \boldsymbol{\xi}_m, c_m, \rho_m \rangle \in \mathbb{R}^{|G_m|} \times \mathbb{R}_+ \times \mathbb{R}_+$, such that $\boldsymbol{\theta}_m = c_m \boldsymbol{\xi}_m$ and $\|\boldsymbol{\theta}_m\|^2 = \rho_m$. This representation allows performing the two operations above in constant time, and it keeps track of the group L_2-norms, necessary in the proximal updates.

For sufficient amounts of regularization, our algorithm has a low memory footprint. Only features that, at some point, intervene in the gradient computed in line 5 need to be instantiated; and all features that receive zero weights after some proximal step can be deleted from the model (cf. Fig. 2).

Sparseptron and Debiasing. Although Alg. 1 allows to simultaneously select features and learn the model parameters, it has been observed in the sparse modeling literature that Lasso-like regularizers usually have a strong bias which may harm predictive performance. A post-processing stage is usually taken (called *debiasing*), in which the model is refitted without any regularization and using only the selected features (Wright et al., 2009). If a final debiasing stage is to be performed, Alg. 1 only needs to worry about feature selection, hence it is appealing to choose a loss function that makes this procedure as simple as possible. Examining the input of Alg. 1, we see that both a gravity and a stepsize sequence need to be specified. The former can be taken care of by using budget-driven shrinkage, as described above. The stepsize sequence can be set as $\eta_t = \eta_0 / \sqrt{\lceil t/N \rceil}$, which ensures convergence, however η_0 requires tuning. Fortunately, for the structured perceptron loss L_{SP} (Eq. 5), Alg. 1 is independent of η_0, up to a scaling of $\boldsymbol{\theta}$, which does not affect predictions (see Eq. 1).[7] We call the instantiation of Alg. 1 with a group-Lasso regularizer and the loss L_{SP} the *sparseptron*. Overall, we propose the following two-stage approach:

1. Run the sparsepton for a few epochs and discard the features with zero weights.
2. Refit the model without any regularization and using the loss L which one wants to optimize.

[7] To see why this is the case, note that both gradient and proximal updates come scaled by η_0; and that the gradient of the loss is $\nabla L_{\mathrm{SP}}(\boldsymbol{\theta}, x_t, y_t) = \boldsymbol{\phi}(x_t, \widehat{y}_t) - \boldsymbol{\phi}(x_t, y_t)$, where $\widehat{y}_t$ is the prediction under the current model, which is insensitive to the scaling of $\boldsymbol{\theta}$. This independence on η_0 does not hold when the loss is L_{SVM} or L_{CRF}.

5 Experiments

We present experiments in three structured prediction tasks for several group choices.

Text Chunking. We use the English dataset provided in the CoNLL 2000 shared task (Sang and Buchholz, 2000), which consists of 8,936 training and 2,012 testing sentences (sections 15–18 and 20 of the WSJ.) The input observations are the token words and their POS tags; we want to predict the sequences of `IOB` tags representing phrase chunks. We built 96 contextual feature templates as follows:

- Up to 5-grams of POS tags, in windows of 5 tokens on the left and 5 tokens on the right;
- Up to 3-grams of words, in windows of 3 tokens on the left and 3 tokens on the right;
- Up to 2-grams of word shapes, in windows of 2 tokens on the left and 2 tokens on the right. Each shape replaces characters by their types (case sensitive letters, digits, and punctuation), and deletes repeated types—*e.g.*, `Confidence` and `2,664,098` are respectively mapped to `Aa` and `0,0+,0+` (Collins, 2002b).

We defined unigram features by conjoining these templates with each of the 22 output labels. An additional template was defined to account for label bigrams—features in this template do not look at the input string, but only at consecutive pairs of labels.[8]

We evaluate the ability of group-Lasso regularization to perform *feature template selection*. To do that, we ran 5 epochs of the sparseptron algorithm with template-based groups and budget-driven shrinkage (budgets of 10, 20, 30, 40, and 50 templates were tried). For each group $\mathcal{G}_m$, we set $d_m = \log_2 |G_m|$, which is the average number of bits necessary to encode a feature in that group, if all features were equiprobable. We set $K = 1000$ (the number of instances between consecutive proximal steps). Then, we refit the model with 10 iterations of the max-loss 1-best MIRA algorithm (Crammer et al., 2006).[9] Table 1 compares the F_1 scores and

[8] State-of-the-art models use larger output contexts, such as label trigrams and 4-grams. We resort to bigram labels as we are mostly interested in identifying relevant unigram templates.

[9] This variant optimizes the L_{SVM} loss (Martins et al., 2010). For the refitting, we used unregularized MIRA. For the baseline

Table 2: Results for named entity recognition. Each cell shows F_1 (%) and the number of features.

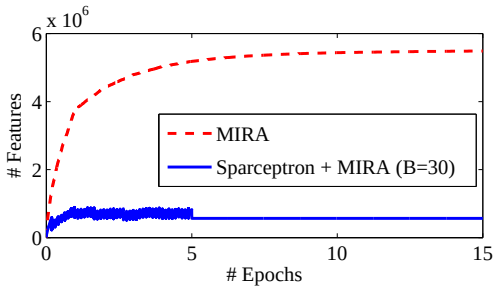

Figure 2: Memory footprints of the MIRA and sparseptron algorithms in text chunking. The oscillation in the first 5 epochs (bottom line) comes from the proximal steps each $K = 1000$ rounds. The features are then frozen and 10 epochs of unregularized MIRA follow. Overall, the sparseptron requires $< 7.5\%$ of the memory as the MIRA baseline.

the model sizes obtained with the several budgets against those obtained by running 15 iterations of MIRA with the original set of features. Note that the total number of iterations is the same; yet, the group-Lasso approach has a much smaller memory footprint (see Fig. 2) and yields much more compact models. The small memory footprint comes from the fact that Alg. 1 may entertain a large number of features without ever instantiating all of them. The predictive power is comparable (although some choices of budget yield slightly better scores for the group-Lasso approach).[10]

Named Entity Recognition. We experiment with the Spanish, Dutch, and English datasets provided in the CoNLL 2002/2003 shared tasks (Sang, 2002; Sang and De Meulder, 2003). For Spanish, we use the POS tags provided by Carreras (`http://www.lsi.upc.es/~nlp/tools/nerc/nerc.html`); for English, we ignore the syntactic chunk tags provided with the dataset. Hence, all datasets have the same sort of input observations (words and POS) and all have 9 output labels. We use the feature templates described above plus some additional ones (yielding a total of 452 templates):

- Up to 3-grams of shapes, in windows of size 3;
- For prefix/suffix sizes of $1, 2, 3$, up to 3-grams of word prefixes/suffixes, in windows of size 3;
- Up to 5-grams of case, punctuation, and digit indicators, in windows of size 5.

As before, an additional feature template was defined to account for label bigrams. We do feature template selection (same setting as before) for budget sizes of 100, 200, and 300. We compare with both MIRA (using all the features) and the sparseptron with a standard Lasso regularizer $\Omega_\tau^{L_1}$, for several values of $C = 1/(\tau N)$. Table 2 shows the results. We observe that template-based group-Lasso wins both in terms of accuracy and compactness. Note also that the ability to discard feature *templates* (rather than individual features) yields faster test runtime than models regularized with the standard Lasso: fewer templates will need to be instantiated, with a speed-up in score computation.

Multilingual Dependency Parsing. We trained non-projective dependency parsers for 6 languages using the CoNLL-X shared task datasets (Buchholz and Marsi, 2006): Arabic, Danish, Dutch, Japanese, Slovene, and Spanish. We chose the languages with the smallest datasets, because regularization is more important when data is scarce. The output to be predicted from each input sentence is the set of dependency links, which jointly define a spanning tree.

(described next), we used L_2-regularized MIRA and tuned the regularization constant with cross-validation.

[10] We also tried label-based group-Lasso and sparse group-Lasso (§3.1), with less impressive results (omitted for space).

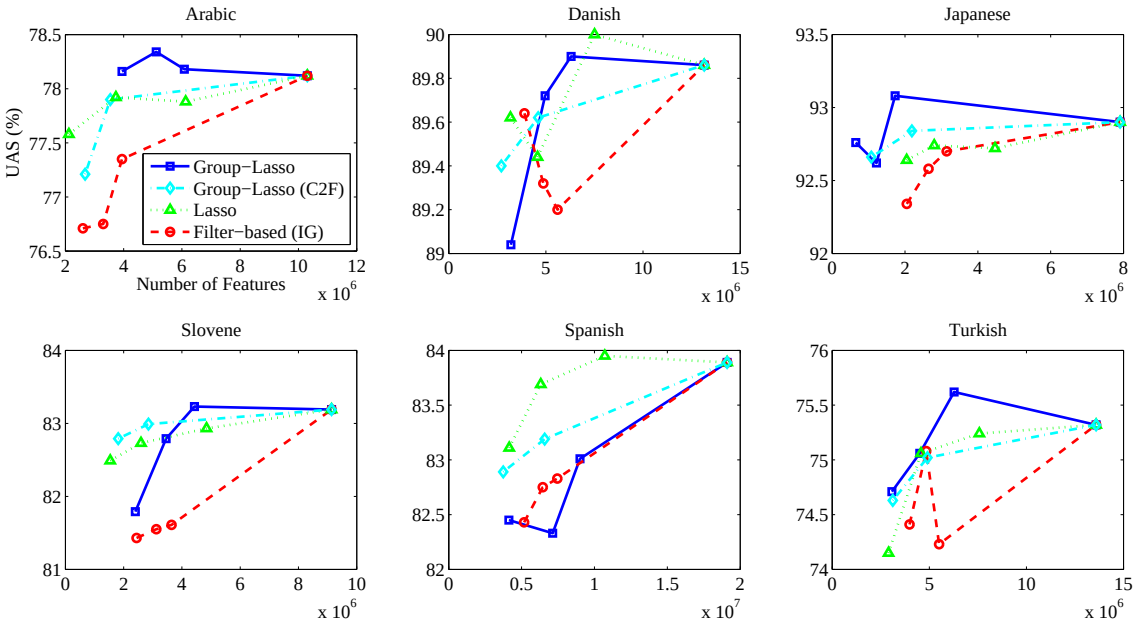

Figure 3: Comparison between non-overlapping group-Lasso, coarse-to-fine group-Lasso (C2F), and a filter-based method based on information gain for selecting feature templates in multilingual dependency parsing. The x-axis is the total number of features at different regularization levels, and the y-axis is the unlabeled attachment score. The plots illustrate how accurate the parsers are as a function of the model sparsity achieved, for each method. The standard Lasso (which does not select templates, but individual features) is also shown for comparison.

We use arc-factored models, for which exact inference is tractable (McDonald et al., 2005). We defined $M = 684$ feature templates for each candidate arc by conjoining the words, shapes, lemmas, and POS of the head and the modifier, as well as the contextual POS, and the distance and direction of attachment. We followed the same two-stage approach as before, and compared with a baseline which selects feature templates by ranking them according to the information gain criterion. This baseline assigns a score to each template T_m which reflects an empirical estimate of the mutual information between T_m and the binary variable A that indicates the presence/absence of a dependency link:

$$IG_m \triangleq \sum_{f \in T_m} \sum_{a \in \{0,1\}} P(f,a) \log_2 \frac{P(f,a)}{P(f)P(a)}, \quad (16)$$

where $P(f,a)$ is the joint probability of feature f firing and an arc being active ($a = 1$) or innactive ($a = 0$), and $P(f)$ and $P(a)$ are the corresponding marginals. All probabilities are estimated from the empirical counts of events observed in the data.

The results are plotted in Fig. 3, for budget sizes of 200, 300, and 400. We observe that for all but one language (Spanish is the exception), non-overlapping group-Lasso regularization is more effective at selecting feature templates than the information gain criterion, and slightly better than coarse-to-fine group-Lasso. For completeness, we also display the results obtained with a standard Lasso regularizer. Table 3 shows what kind of feature templates were most selected for each language. Some interesting patterns can be observed: morphologically-rich languages with small datasets (such as Turkish and Slovene) seem to avoid lexical features, arguably due to potential for overfitting; in Japanese, contextual POS appear to be specially relevant. It should be noted, however, that some of these patterns may be properties of the datasets rather than of the languages themselves.

(2011), along with a theoretical analysis. The focus there, however, was multiple kernel learning, hence overlapping groups were not considered in their experiments. Budget-driven shrinkage and the sparseptron are novel techniques, at the best of our knowledge. Apart from Martins et al. (2011), the only work we are aware of which combines structured sparsity with structured prediction is Schmidt and Murphy (2010); however, their goal is to predict the structure of graphical models, while we are mostly interested in the structure of the feature space. Schmidt and Murphy (2010) used to generative models, while our approach emphasizes discriminative learning.

Mixed norm regularization has been used for a while in statistics as a means to promote structured sparsity. Group Lasso is due to Bakin (1999) and Yuan and Lin (2006), after which a string of variants and algorithms appeared (Bach, 2008; Zhao et al., 2009; Jenatton et al., 2009; Friedman et al., 2010; Obozinski et al., 2010). The flat (non-overlapping) case has tight links with learning formalisms such as multiple kernel learning (Lanckriet et al., 2004) and multi-task learning (Caruana, 1997). The tree-structured case has been addressed by Kim and Xing (2010), Liu and Ye (2010) and Mairal et al. (2010), along with $L_{\infty,1}$ and $L_{2,1}$ regularization. Graph-structured groups are discussed in Jenatton et al. (2010), along with a DAG representation. In NLP, mixed norms have been used recently by Graça et al. (2009) in posterior regularization, and by Eisenstein et al. (2011) in a multi-task regression problem.

7 Conclusions

In this paper, we have explored two levels of structure in NLP problems: structure on the outputs, and structure on the feature space. We have shown how the latter can be useful in model design, through the use of regularizers which promote structured sparsity. We propose an online algorithm with minimal memory requirements for exploring large feature spaces. Our algorithm, which specializes into the *sparseptron*, yields a mechanism for selecting entire groups of features. We apply sparseptron for selecting feature templates in three structured prediction tasks, with advantages over filter-based methods, L_1, and L_2 regularization in terms of performance, compactness, and model interpretability.

Abstract

We consider the problem of learning factored probabilistic CCG grammars for semantic parsing from data containing sentences paired with logical-form meaning representations. Traditional CCG lexicons list lexical items that pair words and phrases with syntactic and semantic content. Such lexicons can be inefficient when words appear repeatedly with closely related lexical content. In this paper, we introduce factored lexicons, which include both *lexemes* to model word meaning and *templates* to model systematic variation in word usage. We also present an algorithm for learning factored CCG lexicons, along with a probabilistic parse-selection model. Evaluations on benchmark datasets demonstrate that the approach learns highly accurate parsers, whose generalization performance benefits greatly from the lexical factoring.

1 Introduction

Semantic parsers automatically recover representations of meaning from natural language sentences. Recent work has focused on learning such parsers directly from corpora made up of sentences paired with logical meaning representations (Kate et al., 2005; Kate and Mooney, 2006; Wong and Mooney, 2006, 2007; Zettlemoyer and Collins, 2005, 2007; Lu et al., 2008; Kwiatkowski et al., 2010).

For example, in a flight booking domain we might have access to training examples such as:

Sentence: I want flights from Boston
Meaning: $\lambda x.flight(x) \wedge from(x, bos)$

and the goal is to learn a grammar that can map new, unseen, sentences onto their corresponding meanings, or logical forms.

One approach to this problem has developed algorithms for leaning probabilistic CCG grammars (Zettlemoyer and Collins, 2005, 2007; Kwiatkowski et al., 2010). These grammars are well-suited to the task of semantic parsing, as they closely link syntax and semantics. They can be used to model a wide range of complex linguistic phenomena and are strongly lexicalized, storing all language-specific grammatical information directly with the words in the lexicon. For example, a typical learned lexicon might include entries such as:

(1) $flight \vdash N : \lambda x.flight(x)$
(2) $flight \vdash N/(S|NP) : \lambda f \lambda x.flight(x) \wedge f(x)$
(3) $flight \vdash N\backslash N : \lambda f \lambda x.flight(x) \wedge f(x)$
(4) $fare \vdash N : \lambda x.cost(x)$
(5) $fare \vdash N/(S|NP) : \lambda f \lambda x.cost(x) \wedge f(x)$
(6) $fare \vdash N\backslash N : \lambda f \lambda x.cost(x) \wedge f(x)$
(7) $Boston \vdash NP : bos$
(8) $Boston \vdash N\backslash N : \lambda f \lambda x.from(x, bos) \wedge f(x)$
(9) $New\ York \vdash NP : nyc$
(10) $New\ York \vdash N\backslash N : \lambda f \lambda x.from(x, nyc) \wedge f(x)$

Although lexicalization of this kind is useful for learning, as we will see, these grammars can also suffer from sparsity in the training data, since closely related entries must be repeatedly learned for all members of a certain class of words. For example, the list above shows a selection of lexical items that would have to be learned separately.

In this list, the word "flight" is paired with the predicate *flight* in three separate lexical items which are required for different syntactic contexts. Item

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1512–1523,
Edinburgh, Scotland, UK, July 27–31, 2011.

(1) has the standard *N* category for entries of this type, item (2) allows the use of the word "flight" with that-less relative clauses such as "flight departing Boston", and item (3) is useful for phrases with unconventional word order such as "from Boston flight to New York". Representing these three lexical items separately is inefficient, since each word of this class (such as "fare") will require three similarly structured lexical entries differing only in predicate name. There may also be systemtatic semantic variation between entries for a certain class of words. For example, in (6) "Boston" is paired with the constant *bos* that represents its meaning. However, item (7) also adds the predicate *from* to the logical form. This might be used to analyse somewhat elliptical, unedited sentences such as "Show me flights Boston to New York," which can be challenging for semantic parsers (Zettlemoyer and Collins, 2007).

This paper builds upon the insight that a large proportion of the variation between lexical items for a given class of words is systematic. Therefore it should be represented once and applied to a small set of basic lexical units. [1] We develop a *factored lexicon* that captures this insight by distinguishing *lexemes*, which pair words with logical constants, from *lexical templates*, which map lexemes to full lexical items. As we will see, this can lead to a significantly more compact lexicon that can be learned from less data. Each word or phrase will be associated with a few lexemes that can be combined with a shared set of general templates.

We develop an approach to learning factored, probabilistic CCG grammars for semantic parsing. Following previous work (Kwiatkowski et al., 2010), we make use of a higher-order unification learning scheme that defines a space of CCG grammars consistent with the (sentence, logical form) training pairs. However, instead of constructing fully specified lexical items for the learned grammar, we automatically generate sets of lexemes and lexical templates to model each example. This is a difficult learning problem, since the CCG analyses that are required to construct the final meaning representations are not explicitly labeled in the training data. Instead, we model them with hidden variables and develop an online learning approach that simultaneously estimates the parameters of a log-linear parsing model, while inducing the factored lexicon.

We evaluate the approach on the benchmark Atis and GeoQuery domains. This is a challenging setup, since the GeoQuery data has complex meaning representations and sentences in multiple languages, while the Atis data contains spontaneous, unedited text that can be difficult to analyze with a formal grammar representation. Our approach achieves at or near state-of-the-art recall across all conditions, despite having no English or domain-specific information built in. We believe that ours is the only system of sufficient generality to run with this degree of success on all of these datasets.

2 Related work

There has been significant previous work on learning semantic parsers from training sentences labelled with logical form meaning representations.

We extend a line of research that has addressed this problem by developing CCG grammar induction techniques. Zettlemoyer and Collins (2005, 2007) presented approaches that use hand generated, English-language specific rules to generate lexical items from logical forms as well as English specific type-shifting rules and relaxations of the CCG combinators to model spontaneous, unedited sentences. Zettlemoyer and Collins (2009) extends this work to the case of learning in context dependent environments. Kwiatkowski et al. (2010) described an approach for language-independent learning that replaces the hand-specified templates with a higher-order-unification-based lexical induction method, but their approach does not scale well to challenging, unedited sentences. The learning approach we develop for inducing factored lexicons is also language independent, but scales well to these challenging sentences.

There have been a number of other approaches for learning semantic parsers, including ones based on machine translation techniques (Papineni et al., 1997; Ramaswamy and Kleindienst, 2000; Wong and Mooney, 2006), parsing models (Miller et al., 1996; Ge and Mooney, 2006; Lu et al., 2008), in-

[1] A related tactic is commonly used in wide-coverage CCG parsers derived from treebanks, such as work by Hockenmaier and Steedman (2002) and Clark and Curran (2007). These parsers make extensive use of category-changing unary rules, to avoid data sparsity for systematically related categories (such as those related by type-raising). We will automatically learn to represent these types of generalizations in the factored lexicon.

ductive logic programming algorithms (Zelle and Mooney, 1996; Thompson and Mooney, 2002; Tang and Mooney, 2000), probabilistic automata (He and Young, 2005, 2006), and ideas from string kernels and support vector machines (Kate and Mooney, 2006; Nguyen et al., 2006).

More recent work has focused on training semantic parsers without supervision in the form of logical-form annotations. Clarke et al. (2010) and Liang et al. (2011) replace semantic annotations in the training set with target answers which are more easily available. Goldwasser et al. (2011) present work on unsupervised learning of logical form structure. However, all of these systems require significantly more domain and language specific initialization than the approach presented here.

Other work has learnt semantic analyses from text in the context of interactions in computational environments (Branavan et al. (2010), Vogel and Jurafsky (2010)); text grounded in partial observations of a world state (Liang et al., 2009); and from raw text alone (Poon and Domingos, 2009, 2010).

There is also related work that uses the CCG grammar formalism. Clark and Curran (2003) present a method for learning the parameters of a log-linear CCG parsing model from fully annotated normal–form parse trees. Watkinson and Manandhar (1999) describe an unsupervised approach for learning syntactic CCG lexicons. Bos et al. (2004) present an algorithm for building semantic representations from CCG parses but requires fully–specified CCG derivations in the training data.

3 Overview of the Approach

Here we give a formal definition of the problem and an overview of the learning approach.

Problem We will learn a semantic parser that takes a sentences x and returns a logical form z representing its underlying meaning. We assume we have input data $\{(x_i, z_i) | i = 1 \ldots n\}$ containing sentences x_i and logical forms z_i, for example $x_i =$"Show me flights to Boston" and $z_i = \lambda x.flight(x) \wedge to(x, bos)$.

Model We will represent the parser as a factored, probabilistic CCG (PCCG) grammar. A traditional CCG lexical item would fully specify the syntax and semantics for a word (reviewed in Section 4). For example, Boston $\vdash NP : bos$ represents the entry for the word "Boston" with syntactic category NP and meaning represented by the constant bos. Where a lexicon would usually list lexical items such as this, we instead use a factored lexicon (L, T) containing:

- A list of lexemes L. Each lexeme pairs a word or phrase with a list of logical constants that can be used to construct its meaning. For example, one lexeme might be $(\text{Boston}, [bos])$.
- A list of lexical templates T. Each template takes a lexeme and maps it on to a full lexical item. For example, there is a single template that can map the lexeme above to the final lexical entry Boston $\vdash NP : bos$.

We will make central use of this factored representation to provide a more compact representation of the lexicon that can be learned efficiently.

The factored PCCG will also contain a parameter vector, θ, that defines a log-linear distribution over the possible parses y, conditioned on the sentence x.

Learning Our approach for learning factored PCCGs extends the work of Kwiatkowski et al. (2010), as reviewed in Section 7. Specifically, we modify the lexical learning, to produce lexemes and templates, as well as the feature space of the model, but reuse the existing parameter estimation techniques and overall learning cycle, as described in Section 7.

We present the complete approach in three parts by describing the factored representation of the lexicon (Section 5), techniques for proposing potential new lexemes and templates (Section 6), and finally a complete learning algorithm (Section 7). However, the next section first reviews the required background on semantic parsing with CCG.

4 Background

4.1 Lambda Calculus

We represent the meanings of sentences, words and phrases with logical expressions that can contain constants, quantifiers, logical connectors and lambda abstractions. We construct the meanings of sentences from the meanings of words and phrases using lambda-calculus operations. We use a version of the typed lambda calculus (Carpenter, 1997), in which the basic types include e, for entities; t, for truth values; and i for numbers. We also have function types that are assigned to lambda expressions.

The expression $\lambda x.flight(x)$ takes an entity and returns a truth value, and has the function type $\langle e,t \rangle$.

4.2 Combinatory Categorial Grammar

CCG (Steedman, 1996, 2000) is a linguistic formalism that tightly couples syntax and semantics, and can be used to model a wide range of language phenomena. A traditional CCG grammar includes a lexicon Λ with entries like the following:

$$\begin{aligned} &flights \vdash N : \lambda x.flight(x) \\ &\quad to \vdash (N\backslash N)/NP : \lambda y.\lambda f.\lambda x.f(x) \wedge to(x,y) \\ &Boston \vdash NP : bos \end{aligned}$$

where each lexical item w$\vdash X : h$ has words w, a syntactic category X, and a logical form h. For the first example, these are "flights," N, and $\lambda x.flight(x)$. In this paper, we introduce a new way of representing lexical items as (*lexeme*, *template*) pairs, as described in section 5.

CCG syntactic categories may be atomic (such as S or NP) or complex (such as $(N\backslash N)/NP$) where the slash combinators encode word order information. CCG uses a small set of *combinatory rules* to build syntactic parses and semantic representations *concurrently*. Two example combinatory rules are forward ($>$) and backward ($<$) *application*:

$$\begin{array}{llll} X/Y : f & Y : g & \Rightarrow & X : f(g) \qquad (>) \\ Y : g & X\backslash Y : f & \Rightarrow & X : f(g) \qquad (<) \end{array}$$

These rules apply to build syntactic and semantic derivations under the control of the word order information encoded in the slash directions of the lexical entries. For example, given the lexicon above, the phrase "flights to Boston" can be parsed to produce:

$$\dfrac{\dfrac{\text{flights}}{\begin{array}{c}N \\ \lambda x.flight(x)\end{array}} \quad \dfrac{\dfrac{\text{to}}{\begin{array}{c}(N\backslash N)/NP \\ \lambda y\lambda f\lambda x.f(x) \wedge to(x,y)\end{array}} \quad \dfrac{\text{Boston}}{\begin{array}{c}NP \\ bos\end{array}}}{\begin{array}{c}(N\backslash N) \\ \lambda f\lambda x.f(x) \wedge to(x,bos)\end{array}}>}{\begin{array}{c}N \\ \lambda x.flight(x) \wedge to(x,bos)\end{array}}<$$

where each step in the parse is labeled with the combinatory rule ($->$ or $-<$) that was used.

CCG also includes combinatory rules of forward ($>$ **B**) and backward ($<$ **B**) *composition*:

$$\begin{array}{llll} X/Y : f & Y/Z : g & \Rightarrow X/Z : \lambda x.f(g(x)) & (>\mathbf{B}) \\ Y\backslash Z : g & X\backslash Y : f & \Rightarrow X\backslash Z : \lambda x.f(g(x)) & (<\mathbf{B}) \end{array}$$

These rules allow a relaxed notion of constituency which helps limit the number of distinct CCG lexical items required.

To the standard forward and backward slashes of CCG we also add a vertical slash for which the direction of application is underspecified. We shall see examples of this in Section 10.

4.3 Probabilistic CCGs

Due to ambiguity in both the CCG lexicon and the order in which combinators are applied, there will be many parses for each sentence. We discriminate between competing parses using a log-linear model which has a feature vector ϕ and a parameter vector θ. The probability of a parse y that returns logical form z, given a sentence x is defined as:

$$P(y,z|x;\theta,\Lambda) = \frac{e^{\theta \cdot \phi(x,y,z)}}{\sum_{(y',z')} e^{\theta \cdot \phi(x,y',z')}} \qquad (1)$$

Section 8 fully defines the set of features used in the system presented. The most important of these control the generation of lexical items from (lexeme, template) pairs. Each (lexeme, template) pair used in a parse fires three features as we will see in more detail later.

The parsing, or inference, problem done at test time requires us to find the most likely logical form z given a sentence x, assuming the parameters θ and lexicon Λ are known:

$$f(x) = \arg\max_z p(z|x;\theta,\Lambda) \qquad (2)$$

where the probability of the logical form is found by summing over all parses that produce it:

$$p(z|x;\theta,\Lambda) = \sum_y p(y,z|x;\theta,\Lambda) \qquad (3)$$

In this approach the distribution over parse trees y is modeled as a hidden variable. The sum over parses in Eq. 3 can be calculated efficiently using the inside-outside algorithm with a CKY-style parsing algorithm.

To estimate the parameters themselves, we use stochastic gradient updates (LeCun et al., 1998). Given a set of n sentence-meaning pairs $\{(x_i,z_i) : i = 1...n\}$, we update the parameters θ iteratively, for each example i, by following the local gradient of the conditional log-likelihood objective

$O_i = \log P(z_i|x_i;\theta,\Lambda)$. The local gradient of the individual parameter θ_j associated with feature ϕ_j and training instance (x_i, z_i) is given by:

$$\frac{\partial O_i}{\partial \theta_j} = E_{p(y|x_i,z_i;\theta,\Lambda)}[\phi_j(x_i,y,z_i)] - E_{p(y,z|x_i;\theta,\Lambda)}[\phi_j(x_i,y,z)] \quad (4)$$

As with Eq. 3, all of the expectations in Eq. 4 are calculated through the use of the inside-outside algorithm on a pruned parse chart. For a sentence of length m, each parse chart span is pruned using a beam width proportional to $m^{\frac{2}{3}}$, to allow larger beams for shorter sentences.

5 Factored Lexicons

A factored lexicon includes a set L of lexemes and a set T of lexical templates. In this section, we formally define these sets, and describe how they are used to build CCG parses. We will use a set of lexical items from our running example to discuss the details of how the following lexical items:

(1) $flight \vdash N : \lambda x.flight(x)$
(2) $flight \vdash N/(S|NP) : \lambda f \lambda x.flight(x) \wedge f(x)$
...
(6) $Boston \vdash NP : bos$
(7) $Boston \vdash N\backslash N : \lambda f \lambda x.from(x,bos) \wedge f(x)$

are constructed from specific lexemes and templates.

5.1 Lexemes

A lexeme $(\mathrm{w}, \vec{c})$ pairs a word sequence w with an ordered list of logical constants $\vec{c} = [c_1 \ldots c_m]$. For example, item (1) and (2) above would come from a single lexeme $(\text{flight}, [flight])$. Similar lexemes would be represented for other predicates, for example $(\text{fare}, [cost])$. Lexemes also can contain multiple constants, for example $(\text{cheapest}, [argmin, cost])$, which we will see more examples of later.

5.2 Lexical Templates

A lexical template takes a lexeme and produces a lexical item. Templates have the general form

$$\lambda(\omega, \vec{v}).[\omega \vdash X : h_{\vec{v}}]$$

where $h_{\vec{v}}$ is a logical expression that contains variables from the list $\vec{v}$. Applying this template to the input lexeme $(\mathrm{w}, \vec{c})$ gives the full lexical item $\mathrm{w} \vdash X : h$ where the variable ω has been replaced with the wordspan w and the logical form h has been created by replacing each of the variables in $\vec{v}$ with the counterpart constant from $\vec{c}$. For example, the lexical item (6) above would be constructed from the lexeme $(\text{Boston}, [bos])$ using the template $\lambda(\omega, \vec{v}).[\omega \vdash NP : v_1]$. Items (1) and (2) would both be constructed from the single lexeme $(\text{flight}, [flight])$ with the two different templates $\lambda(\omega, \vec{v}).[\omega \vdash N : \lambda x.v_1(x)]$ and $\lambda(\omega, \vec{v}).[\omega \vdash N/(S|NP) : \lambda f \lambda x.v_1(x) \wedge f(x)]$

5.3 Parsing with a Factored Lexicon

In general, there can by many different (lexeme, template) pairs that produce the same lexical item. For example, lexical item (7) in our running example above can be constructed from the lexemes $(\text{Boston}, [bos])$ and $(\text{Boston}, [from, bos])$, given appropriate templates.

To model this ambiguity, we include the selection of a (lexeme, template) pair as a decision to be made while constructing a CCG parse tree. Given the lexical item produced by the chosen lexeme and template, parsing continues with the traditional combinators, as reviewed in Section 4.2. This direct integration allows for features that signal which lexemes and templates have been used while also allowing for well defined marginal probabilities, by summing over all ways of deriving a specific lexical item.

6 Learning Factored Lexicons

To induce factored lexicons, we will make use of two procedures, presented in this section, that factor lexical items into lexemes and templates. Section 7 will describe how this factoring operation is integrated into the complete learning algorithm.

6.1 Maximal Factorings

Given a lexical item l of the form $w \vdash X : h$ with words w, a syntactic category X, and a logical form h, we define the *maximal factoring* to be the unique (lexeme, template) pair that can be used to reconstruct l and includes all of the constants of h in the lexeme (listed in a fixed order based on an ordered traversal of h). For example, the maximal factoring for the lexical item $Boston \vdash NP : bos$ is the pair we saw before: $(\text{Boston}, [bos])$ and $\lambda(\omega, \vec{v}).[\omega \vdash NP : v_1]$. Similarly, the lexical item $Boston \vdash N\backslash N : \lambda f.\lambda x.f(x) \wedge from(x,bos)$ would be factored to produce $(\text{Boston}, [from, bos])$ and $\lambda(\omega, \vec{v}).[\omega \vdash N\backslash N : \lambda f.\lambda x.f(x) \wedge v_1(x, v_2)]$.

As we will see in Section 7, this notion of factor-

ing can be directly incorporated into existing algorithms that learn CCG lexicons. When the original algorithm would have added an entry l to the lexicon, we can instead compute the factoring of l and add the corresponding lexeme and template to the factored lexicon.

6.2 Introducing Templates with Content

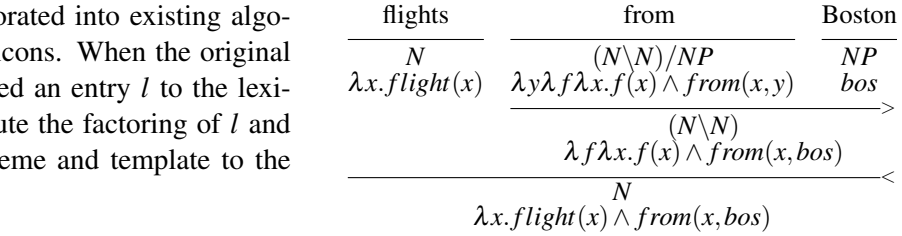
Maximal factorings, as just described, provide for significant lexical generalization but do not handle all of the cases needed to learn effectively. For instance, the maximal split for the item $Boston \vdash N\backslash N : \lambda f.\lambda x.f(x) \wedge from(x,bos)$ would introduce the lexeme $(\text{Boston}, [from, bos])$, which is suboptimal since each possible city would need a lexeme of this type, with the additional *from* constant included. Instead, we would ideally like to learn the lexeme $(\text{Boston}, [bos])$ and have a template that introduces the *from* constant. This would model the desired generalization with a single lexeme per city.

In order to permit the introduction of extra constants into lexical items, we allow the creation of templates that contain logical constants through *partial factorings*. For instance, the template below can introduce the predicate *from*

$$\lambda(\omega, \vec{v}).[\omega \vdash N\backslash N : \lambda f.\lambda x.f(x) \wedge from(x, v_1)]$$

The use of templates to introduce extra semantic constants into a lexical item is similar to, but more general than, the English-specific *type-shifting* rules used in Zettlemoyer and Collins (2007), which were introduced to model spontaneous, unedited text. They are useful, as we will see, in learning to recover semantic content that is implied, but not explicitly stated, such as our original motivating phrase "flights Boston to New York."

To propose templates which introduce semantic content, during learning, we build on the intuition that we need to recover from missing words, such as in the example above. In this scenario, there should also be other sentences that actually include the word, in our example this would be something like "flights from Boston." We will also assume that we have learned a good factored lexicon for the complete example that could produce the parse:



Given analyses of this form, we introduce new templates that will allow us to recover from missing words, for example if "from" was dropped. We identify commonly occurring nodes in the best parse trees found during training, in this case the nonterminal spanning "from Boston," and introduce templates that can produce the nonterminal, even if one of the words is missing. Here, this approach would introduce the desired template $\lambda(\omega, \vec{v}).[\omega \vdash N\backslash N : \lambda f.\lambda x.f(x) \wedge from(x, v_1)]$ for mapping the lexeme $(\text{Boston}, [bos])$ directly to the intermediate structure.

Not all templates introduced this way will model valid generalizations. However, we will incorporate them into a learning algorithm with indicator features that can be weighted to control their use. The next section presents the complete approach.

7 Learning Factored PCCGs

Our Factored Unification Based Learning (FUBL) method extends the UBL algorithm (Kwiatkowski et al., 2010) to induce factored lexicons, while also simultanously estimating the parameters of a log-linear CCG parsing model. In this section, we first review the NEW-LEX lexical induction procedure from UBL, and then present the FUBL algorithm.

7.1 Background: NEW-LEX

NEW-LEX generates lexical items by *splitting* and *merging* nodes in the best parse tree of each training example. Each parse node has a CCG category $X : h$ and a sequence of words w that it spans. We will present an overview of the approach using the running example with the phrase $w =$"in Boston" and the category $X : h = S\backslash NP : \lambda x.loc(x, bos)$, which is of the type commonly seen during learning. The splitting procedure is a two step process that first splits the logical form h, then splits the CCG syntactic category X and finally splits the string w.

The first step enumerates all possible splits of the logical form h into a pair of new expressions

(f, g) that can be used to reconstruct h by either function application ($h = f(g)$) or composition ($h = \lambda x.f(g(x))$). For example, one possible split is:

$$(f = \lambda y.\lambda x.loc(x,y)\ ,\ g = bos)$$

which corresponds to the function application case.

The next two steps enumerate all ways of splitting the syntactic category X and words w to introduce two new lexical items which can be recombined with CCG combinators (application or composition) to recreate the original parse node $X : h$ spanning w. In our example, one possibility would be:

$$(\text{in} \vdash (S\backslash NP)/NP : \lambda y.\lambda x.loc(x,y)\ ,\ \text{Boston} \vdash NP : bos)$$

which could be recombined with the forward application combinator from Section 4.2.

To assign categories while splitting, the grammar used by NEW-LEX only uses two atomic syntactic categories S and NP. This allows NEW-LEX to make use of a direct mapping from semantic type to syntactic category when proposing syntactic categories. In this schema, the standard syntactic category N is replaced by the category $S|NP$ which matches the type $\langle e,t \rangle$ and uses the vertical slash introduced in Section 4.2. We will see categories such as this in the evaluation.

7.2 The FUBL Algorithm

Figure 1 shows the FUBL learning algorithm. We assume training data $\{(x_i, z_i) : i = 1 \ldots n\}$ where each example is a sentence x_i paired with a logical form z_i. The algorithm induces a factored PCCG, including the lexemes L, templates T, and parameters θ.

The algorithm is online, repeatedly performing both lexical expansion (Step 1) and a parameter update (Step 2) for each training example. The overall approach is closely related to the UBL algorithm (Kwiatkowski et al., 2010), but includes extensions for updating the factored lexicon, as motivated in Section 6.

Initialization The model is initialized with a factored lexicon as follows. MAX-FAC is a function that takes a lexical item l and returns the maximal factoring of it, that is the unique, maximal (lexeme, template) pair that can be combined to construct l, as described in Section 6.1. We apply MAX-FAC to each of the training examples (x_i, z_i), creating a single way of producing the desired meaning z_i from a lexeme containing all of the words in x_i. The lexemes and templates created in this way provide the initial factored lexicon.

Inputs: Training set $\{(x_i, z_i) : i = 1 \ldots n\}$ where each example is a sentence x_i paired with a logical form z_i. Set of entity name lexemes L_e. Number of iterations J. Learning rate parameter α_0 and cooling rate parameter c. Empty lexeme set L. Empty template set T.

Definitions: NEW-LEX(y) returns a set of new lexical items from a parse y as described in Section 7.1. MAX-FAC(l) generates a (lexeme, template) pair from a lexical item l. PART-FAC(y) generates a set of templates from parse y. Both of these are described in Section 7.2. The distributions $p(y|x,z;\theta,(L,T))$ and $p(y,z|x;\theta,(L,T))$ are defined by the log-linear model described in Section 4.3.

Initialization:

- For $i = 1 \ldots n$
  - $(\psi, \pi) = \text{MAX-FAC}(x_i \vdash S : z_i)$
  - $L = L \cup \psi\ ,\ T = T \cup \pi$
- Set $L = L \cup L_e$.
- Initialize θ using coocurrence statistics, as described in Section 8.

Algorithm:

For $t = 1 \ldots J, i = 1 \ldots n$:

Step 1: (Add Lexemes and Templates)

- Let $y^* = \arg\max_y p(y|x_i, z_i; \theta, (L,T))$
- For $l \in \text{NEW-LEX}(y^*)$
  - $(\psi, \pi) = \text{MAX-FAC}(l)$
  - $L = L \cup \psi\ ,\ T = T \cup \pi$
- $\Pi = \text{PART-FAC}(y^*)\ ,\ T = T \cup \Pi$

Step 2: (Update Parameters)

- Let $\gamma = \frac{\alpha_0}{1 + c \times k}$ where $k = i + t \times n$.
- Let $\Delta = E_{p(y|x_i,z_i;\theta,(L,T))}[\phi(x_i,y,z_i)] - E_{p(y,z|x_i;\theta,(L,T))}[\phi(x_i,y,z)]$
- Set $\theta = \theta + \gamma\Delta$

Output: Lexemes L, templates T, and parameters θ.

Figure 1: The FUBL learning algorithm.

Step 1 The first step of the learning algorithm in Figure 1 adds lexemes and templates to the factored model given by performing manipulations on the highest scoring correct parse y^* of the current training example (x_i, z_i). First the NEW-LEX procedure is run on y^* as described in Section 6.1 to

generate new lexical items. We then use the function MAX-FAC to create the maximal factorings of each of these new lexical items as described in Section 6 and these are added to the factored representation of the lexicon. New templates can also be introduced through partial factorings of internal parse nodes as described in Section 6.2. These templates are generated by using the function PART-FAC to abstract over the wordspan and a subset of the constants contained in the internal parse nodes of y^*. This step allows for templates that introduce new semantic content to model elliptical language, as described in Section 6.2.

Step 2 The second step does a stochastic gradient descent update on the parameters θ used in the parsing model. This update is described in Section 4.3

Discussion The FUBL algorithm makes use of a direct online approach, where lexemes and templates are introduced in place while analyzing specific sentences. In general, this will overgeneralize; not all ways of combining lexemes and templates will produce high quality lexical items. However, the overall approach includes features, presented in Section 8, that can be used to learn which ones are best in practice. The complete algorithm iterates between adding new lexical content and updating the parameters of the parsing model with each procedure guiding the other.

8 Experimental setup

Data Sets We evaluate on two benchmark semantic parsing datasets: GeoQuery, which is made up of natural language queries to a database of geographical information; and Atis, which contains natural language queries to a flight booking system. The Geo880 dataset has 880 (English-sentence, logical-form) pairs split into a training set of 600 pairs and a test set of 280. The Geo250 data is a subset of the Geo880 sentences that have been translated into Japanese, Spanish and Turkish as well as the original English. We follow the standard evaluation procedure for Geo250, using 10-fold cross validation experiments with the same splits of the data as Wong and Mooney (2007). The Atis dataset contains 5410 (sentence, logical-form) pairs split into a 4480 example training set, a 480 example development set and a 450 example test set.

Evaluation Metrics We report exact match *Recall* (percentage of sentences for which the correct logical-form was returned), *Precision* (percentage of returned logical-forms that are correct) and *F1* (harmonic mean of Precision and Recall). For Atis we also report partial match Recall (percentage of correct literals returned), Precision (percentage of returned literals that are correct) and F1, computed as described by Zettlemoyer and Collins (2007).

Features We introduce two types of features to discriminate between parses: *lexical features* and *logical-form features*.

Lexical features fire on the lexemes and templates used to build the lexical items used in a parse. For each (lexeme,template) pair used to create a lexical item we have indicator features ϕ_l for the lexeme used, ϕ_t for the template used, and $\phi_{(l,t)}$ for the pair that was used. We assign the features on lexical templates a weight of 0.1 to prevent them from swamping the far less frequent but equally informative lexeme features.

Logical-form features are computed on the lambda-calculus expression z returned at the root of the parse. Each time a predicate p in z takes an argument a with type $Ty(a)$ in position i, it triggers two binary indicator features: $\phi_{(p,a,i)}$ for the predicate-argument relation; and $\phi_{(p,Ty(a),i)}$ for the predicate argument-type relation. Boolean operator features look at predicates that occurr together in conjunctions and disjunctions. For each variable v_i that fills argument slot i in two conjoined predicates p_1 and p_2 we introduce a binary indicator feature $\phi_{conj(i,p_1,p_2)}$. We introduce similar features $\phi_{disj(i,p_1,p_2)}$ for variables v_i that are shared by predicates in a disjunction.

Initialization The weights for lexeme features are initialized according to coocurrance statistics between words and logical constants. These are estimated with the Giza++ (Och and Ney, 2003) implementation of IBM Model 1. The initial weights for templates are set by adding -0.1 for each slash in the syntactic category and -2 if the template contains logical constants. Features on lexeme-template pairs and all parse features are initialized to zero.

Systems We compare performance to all recently-published, directly-comparable results. For GeoQuery, this includes the ZC05, ZC07 (Zettlemoyer

and Collins, 2005, 2007), λ-WASP (Wong and Mooney, 2007), UBL (Kwiatkowski et al., 2010) systems and DCS (Liang et al., 2011). For Atis, we report results from HY06 (He and Young, 2006), ZC07, and UBL.

9 Results

Tables 1-4 present the results on the Atis and Geoquery domains. In all cases, FUBL achieves at or near state-of-the-art recall (overall number of correct parses) when compared to directly comparable systems and it significantly outperforms UBL on Atis.

On Geo880 the only higher recall is achieved by DCS with prototypes - which uses significant English-specific resources, including manually specified lexical content, but does not require training sentences annotated with logical-forms. On Geo250, FUBL achieves the highest recall across languages. Each individual result should be interpreted with care, as a single percentage point corresponds to 2-3 sentences, but the overall trend is encouraging.

On the Atis development set, FUBL outperforms ZC07 by 7.5% of recall but on the Atis test set FUBL lags ZC07 by 2%. The reasons for this discrepancy are not clear, however, it is possible that the syntactic constructions found in the Atis test set do not exhibit the same degree of variation as those seen in the development set. This would negate the need for the very general lexicon learnt by FUBL.

Across the evaluations, despite achieving high recall, FUBL achieves significantly lower precision than ZC07 and λ-WASP. This illustrates the trade-off from having a very general model of proposing lexical structure. With the ability to skip unseen words, FUBL returns a parse for all of the Atis test sentences, since the factored lexicons we are learning can produce a very large number of lexical items. These parses are, however, not always correct.

10 Analysis

The Atis results in Tables 1 and 2 highlight the advantages of factored lexicons. FUBL outperforms the UBL baseline by 16 and 11 points respectively in exact-match recall. Without making any modification to the CCG grammars or parsing combinators, we are able to induce a lexicon that is general enough model the natural occurring variations in the data, for example due to sloppy, unedited sentences.

Figure 2 shows a parse returned by FUBL for a sentence on which UBL failed. While the word "cheapest" is seen 208 times in the training data, in only a handful of these instances is it seen in the middle of an utterance. For this reason, UBL never proposes the lexical item, cheapest $\vdash NP\backslash(S|NP)/(S|NP) : \lambda f\lambda g.argmin(\lambda x.f(x) \wedge g(x), \lambda y.cost(y))$, which is used to parse the sentence in Figure 2. In contrast, FUBL uses a lexeme learned from the same word in different contexts, along with a template learnt from similar words in a similar context, to learn to per-

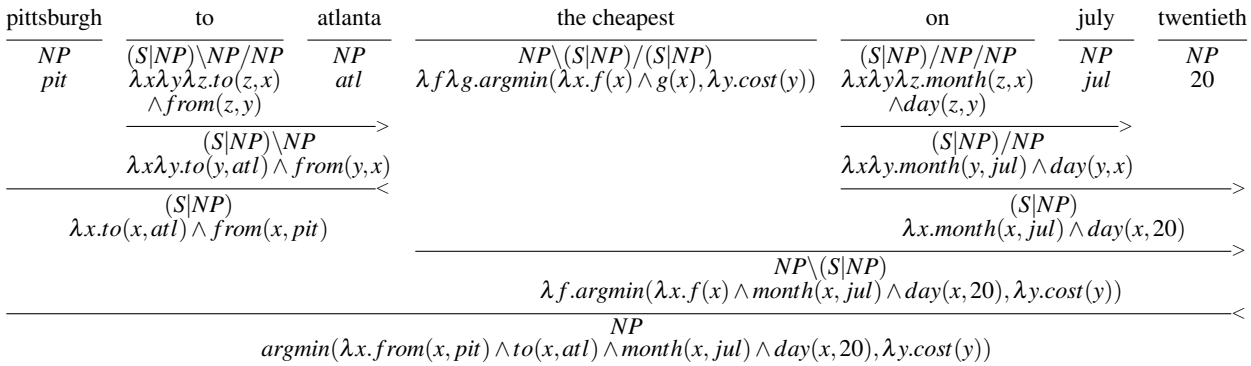

Figure 2: An example learned parse. FUBL can learn this type of analysis with novel combinations of lexemes and templates at test time, even if the individual words, like "cheapest," were never seen in similar syntactic constructions during training, as described in Section 10.

form the desired analysis.

As well as providing a new way to search the lexicon during training, the factored lexicon provides a way of proposing new, unseen, lexical items at test time. We find that new, non-*NP*, lexical items are used in 6% of the development set parses.

Interestingly, the addition of templates that introduce semantic content (as described in Section 6.2) account for only 1.2% of recall on the Atis development set. This is suprising as elliptical constructions are found in a much larger proportion of the sentences than this. In practice, FUBL learns to model many elliptical constructions with lexemes and templates introduced through maximal factorings. For example, the lexeme $(\text{to}, [from, to])$ can be used with the correct lexical template to deal with our motivating example "flights Boston to New York". Templates that introduce content are therefore only used in truly novel elliptical constructions for which an alternative analysis could not be learned.

Table 5 shows a selection of lexemes and templates learned for Atis. Examples 2 and 3 show that morphological variants of the same word must still be stored in separate lexemes. However, as these lexemes now share templates, the total number of lexical variants that must be learned is reduced.

Most common lexemes by type of constants in $\vec{c}$.			
1	e	(Boston, $[bos]$)	(Denver, $[den]$)
2	$\langle e,t \rangle$	(flight, $[flight]$)	(flights, $[flight]$)
3	$\langle e,i \rangle$	(fare, $[cost]$)	(fares, $[cost]$)
4	$\langle e, \langle e,t \rangle \rangle$	(from, $[from]$)	(to, $[to]$)
5	$\langle e,i \rangle, \langle e,t \rangle$	(cheapest, $[argmin, cost]$)	(earliest, $[argmin, dep\_time]$)
6	$\langle i, \langle i,t \rangle \rangle$, $\langle e,i \rangle$	(after, $[>, dep\_time]$)	(before, $[<, dep\_time]$)
Most common templates matching lexemes above.

2	$\lambda(\omega, \vec{v}).\omega \vdash S\|NP : \lambda x.v_1(x)$		
3	$\lambda(\omega, \vec{v}).\omega \vdash NP\|NP : \lambda x.v_1(x)$		
4	$\lambda(\omega, \vec{v}).\omega \vdash S\|NP/NP\backslash(S\|NP) : \lambda x\lambda y.v_1(x,y)$		
5	$\lambda(\omega, \vec{v}).\omega \vdash NP/(S\|NP) : \lambda f.v_1(\lambda x.f(x), \lambda y, v_2(y))$		
6	$\lambda(\omega, \vec{v}).\omega \vdash S\|NP\backslash(S\|NP)/NP : \lambda x\lambda y\lambda z.v_1(v_2(z),x) \wedge y(x)$		

Table 5: Example lexemes and templates learned from the Atis development set.

11 Discussion

We argued that factored CCG lexicons, which include both lexemes and lexical templates, provide a compact representation of lexical knowledge that can have advantages for learning. We also described a complete approach for inducing factored, probabilistic CCGs for semantic parsing, and demonstrated strong performance across a wider range of benchmark datasets that any previous approach.

In the future, it will also be important to explore morphological models, to better model variation within the existing lexemes. The factored lexical representation also has significant potential for lexical transfer learning, where we would need to learn new lexemes for each target application, but much of the information in the templates could, potentially, be ported across domains.

Named Entity Recognition in Tweets: An Experimental Study

Alan Ritter, Sam Clark, Mausam and Oren Etzioni
Computer Science and Engineering

{aritter,ssclark,mausam,etzioni}@cs.washington.edu

Abstract

People tweet more than 100 Million times daily, yielding a noisy, informal, but sometimes informative corpus of 140-character messages that mirrors the zeitgeist in an unprecedented manner. The performance of standard NLP tools is severely degraded on tweets. This paper addresses this issue by re-building the NLP pipeline beginning with part-of-speech tagging, through chunking, to named-entity recognition. Our novel T-NER system doubles F_1 score compared with the Stanford NER system. T-NER leverages the redundancy inherent in tweets to achieve this performance, using LabeledLDA to exploit Freebase dictionaries as a source of distant supervision. LabeledLDA outperforms co-training, increasing F_1 by 25% over ten common entity types.

Our NLP tools are available at: http://github.com/aritter/twitter_nlp

1 Introduction

Status Messages posted on Social Media websites such as Facebook and Twitter present a new and challenging style of text for language technology due to their noisy and informal nature. Like SMS (Kobus et al., 2008), tweets are particularly terse and difficult (See Table 1). Yet tweets provide a unique compilation of information that is more up-to-date and inclusive than news articles, due to the low-barrier to tweeting, and the proliferation of mobile devices.[1] The corpus of tweets already exceeds the size of the Library of Congress (Hachman, 2011) and is growing far more rapidly. Due to the volume of tweets, it is natural to consider named-entity recognition, information extraction, and text mining over tweets. Not surprisingly, the performance of "off the shelf" NLP tools, which were trained on news corpora, is weak on tweet corpora.

In response, we report on a re-trained "NLP pipeline" that leverages previously-tagged out-of-domain text, [2] tagged tweets, and unlabeled tweets to achieve more effective part-of-speech tagging, chunking, and named-entity recognition.

1	The Hobbit has FINALLY started filming! I cannot wait!

Table 1: Examples of noisy text in tweets.

We find that classifying named entities in tweets is a difficult task for two reasons. First, tweets contain a plethora of distinctive named entity types (Companies, Products, Bands, Movies, and more). Almost all these types (except for People and Locations) are relatively infrequent, so even a large sample of manually annotated tweets will contain few training examples. Secondly, due to Twitter's 140 character limit, tweets often lack sufficient context to determine an entity's type without the aid of background

[1] See the "trending topics" displayed on twitter.com

[2] Although tweets can be written on any subject, following convention we use the term "domain" to include text styles or genres such as Twitter, News or IRC Chat.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1524–1534,
Edinburgh, Scotland, UK, July 27–31, 2011.

knowledge.

To address these issues we propose a distantly supervised approach which applies LabeledLDA (Ramage et al., 2009) to leverage large amounts of unlabeled data in addition to large dictionaries of entities gathered from Freebase, and combines information about an entity's context across its mentions.

We make the following contributions:

1. We experimentally evaluate the performance of off-the-shelf news trained NLP tools when applied to Twitter. For example POS tagging accuracy drops from about 0.97 on news to 0.80 on tweets. By utilizing in-domain, out-of-domain, and unlabeled data we are able to substantially boost performance, for example obtaining a 52% increase in F_1 score on segmenting named entities.

2. We introduce a novel approach to *distant supervision* (Mintz et al., 2009) using Topic Models. LabeledLDA is applied, utilizing constraints based on an open-domain database (Freebase) as a source of supervision. This approach increases F_1 score by 25% relative to co-training (Blum and Mitchell, 1998; Yarowsky, 1995) on the task of classifying named entities in Tweets.

The rest of the paper is organized as follows. We successively build the NLP pipeline for Twitter feeds in Sections 2 and 3. We first present our approaches to shallow syntax – part of speech tagging (§2.1), and shallow parsing (§2.2). §2.3 describes a novel classifier that predicts the informativeness of capitalization in a tweet. All tools in §2 are used as features for named entity segmentation in §3.1. Next, we present our algorithms and evaluation for entity classification (§3.2). We describe related work in §4 and conclude in §5.

2 Shallow Syntax in Tweets

We first study two fundamental NLP tasks – POS tagging and noun-phrase chunking. We also discuss a novel capitalization classifier in §2.3. The outputs of all these classifiers are used in feature generation for named entity recognition in the next section.

For all experiments in this section we use a dataset of 800 randomly sampled tweets. All results (Tables 2, 4 and 5) represent 4-fold cross-validation experiments on the respective tasks.[3]

	Accuracy	Error Reduction
Majority Baseline (NN)	0.189	-
Word's Most Frequent Tag	0.760	-
Stanford POS Tagger	0.801	-
T-POS(PTB)	0.813	6%
T-POS(Twitter)	0.853	26%
T-POS(IRC + PTB)	0.869	34%
T-POS(IRC + Twitter)	0.870	35%
T-POS(PTB + Twitter)	0.873	36%
T-POS(PTB + IRC + Twitter)	0.883	41%

Table 2: POS tagging performance on tweets. By training on in-domain labeled data, in addition to annotated IRC chat data, we obtain a 41% reduction in error over the Stanford POS tagger.

2.1 Part of Speech Tagging

Part of speech tagging is applicable to a wide range of NLP tasks including named entity segmentation and information extraction.

Prior experiments have suggested that POS tagging has a very strong baseline: assign each word to its most frequent tag and assign each Out of Vocabulary (OOV) word the most common POS tag. This baseline obtained a 0.9 accuracy on the Brown corpus (Charniak et al., 1993). However, the application of a similar baseline on tweets (see Table 2) obtains a much weaker 0.76, exposing the challenging nature of Twitter data.

A key reason for this drop in accuracy is that Twitter contains far more OOV words than grammatical text. Many of these OOV words come from spelling variation, *e.g.*, the use of the word "n" for "in" in Table 1 example 3. Although NNP is the most frequent tag for OOV words, only about 1/3 are NNPs.

The performance of off-the-shelf news-trained POS taggers also suffers on Twitter data. The state-of-the-art Stanford POS tagger (Toutanova et al., 2003) improves on the baseline, obtaining an accuracy of 0.8. This performance is impressive given that its training data, the Penn Treebank WSJ (PTB), is so different in style from Twitter, however it is a huge drop from the 97% accuracy reported on the

[3]We used Brendan O'Connor's Twitter tokenizer

Gold	Predicted	Stanford Error	T-POS Error	Error Reduction
NN	NNP	0.102	0.072	29%
UH	NN	0.387	0.047	88%
VB	NN	0.071	0.032	55%
NNP	NN	0.130	0.125	4%
UH	NNP	0.200	0.036	82%

Table 3: Most common errors made by the Stanford POS Tagger on tweets. For each case we list the fraction of times the gold tag is misclassified as the predicted for both our system and the Stanford POS tagger. All verbs are collapsed into VB for compactness.

PTB. There are several reasons for this drop in performance. Table 3 lists common errors made by the Stanford tagger. First, due to unreliable capitalization, common nouns are often misclassified as proper nouns, and vice versa. Also, interjections and verbs are frequently misclassified as nouns. In addition to differences in vocabulary, the grammar of tweets is quite different from edited news text. For instance, tweets often start with a verb (where the subject 'I' is implied), as in: "watchng american dad."

To overcome these differences in style and vocabulary, we manually annotated a set of 800 tweets (16K tokens) with tags from the Penn TreeBank tag set for use as in-domain training data for our POS tagging system, T-POS.[4] We add new tags for the Twitter specific phenomena: retweets, @usernames, #hashtags, and urls. Note that words in these categories can be tagged with 100% accuracy using simple regular expressions. To ensure fair comparison in Table 2, we include a postprocessing step which tags these words appropriately for all systems.

To help address the issue of OOV words and lexical variations, we perform clustering to group together words which are distributionally similar (Brown et al., 1992; Turian et al., 2010). In particular, we perform hierarchical clustering using Jcluster (Goodman, 2001) on 52 million tweets; each word is uniquely represented by a bit string based on the path from the root of the resulting hierarchy to the word's leaf. We use the Brown clusters resulting from prefixes of 4, 8, and 12 bits. These clusters are often effective in capturing lexical variations, for example, following are lexical variations on the word "tomorrow" from one cluster after filtering out other words (most of which refer to days):

> '2m', '2ma', '2mar', '2mara', '2maro', '2marrow', '2mor', '2mora', '2moro', '2morow', '2morr', '2morro', '2morrow', '2moz', '2mr', '2mro', '2mrrw', '2mrw', '2mw', 'tmmrw', 'tmo', 'tmoro', 'tmorrow', 'tmoz', 'tmr', 'tmro', 'tmrow', 'tmrrow', 'tmrrw', 'tmrw', 'tmrww', 'tmw', 'tomaro', 'tomarow', 'tomarro', 'tomarrow', 'tomm', 'tommarow', 'tommarrow', 'tommoro', 'tommorow', 'tommorrow', 'tommorw', 'tommrow', 'tomo', 'tomolo', 'tomoro', 'tomorow', 'tomorro', 'tomorrw', 'tomoz', 'tomrw', 'tomz'

T-POS uses Conditional Random Fields[5] (Lafferty et al., 2001), both because of their ability to model strong dependencies between adjacent POS tags, and also to make use of highly correlated features (for example a word's identity in addition to prefixes and suffixes). Besides employing the Brown clusters computed above, we use a fairly standard set of features that include POS dictionaries, spelling and contextual features.

On a 4-fold cross validation over 800 tweets, T-POS outperforms the Stanford tagger, obtaining a 26% reduction in error. In addition we include 40K tokens of annotated IRC chat data (Forsythand and Martell, 2007), which is similar in style. Like Twitter, IRC data contains many misspelled/abbreviated words, and also more pronouns, and interjections, but fewer determiners than news. Finally, we also leverage 50K POS-labeled tokens from the Penn Treebank (Marcus et al., 1994).

Overall T-POS trained on 102K tokens (12K from Twitter, 40K from IRC and 50K from PTB) results in a 41% error reduction over the Stanford tagger, obtaining an accuracy of 0.883. Table 3 lists gains on some of the most common error types, for example, T-POS dramatically reduces error on interjections and verbs that are incorrectly classified as nouns by the Stanford tagger.

2.2 Shallow Parsing

Shallow parsing, or chunking is the task of identifying non-recursive phrases, such as noun phrases,

[4] Using MMAX2 (Müller and Strube, 2006) for annotation.

[5] We use MALLET (McCallum, 2002).

	Accuracy	Error Reduction
Majority Baseline (B-NP)	0.266	-
OpenNLP	0.839	-
T-CHUNK(CoNLL)	0.854	9%
T-CHUNK(Twitter)	0.867	17%
T-CHUNK(CoNLL + Twitter)	0.875	22%

Table 4: Token-Level accuracy at shallow parsing tweets. We compare against the OpenNLP chunker as a baseline.

verb phrases, and prepositional phrases in text. Accurate shallow parsing of tweets could benefit several applications such as Information Extraction and Named Entity Recognition.

Off the shelf shallow parsers perform noticeably worse on tweets, motivating us again to annotate in-domain training data. We annotate the same set of 800 tweets mentioned previously with tags from the CoNLL shared task (Tjong Kim Sang and Buchholz, 2000). We use the set of shallow parsing features described by Sha and Pereira (2003), in addition to the Brown clusters mentioned above. Part-of-speech tag features are extracted based on cross-validation output predicted by T-POS. For inference and learning, again we use Conditional Random Fields. We utilize 16K tokens of in-domain training data (using cross validation), in addition to 210K tokens of newswire text from the CoNLL dataset.

Table 4 reports T-CHUNK's performance at shallow parsing of tweets. We compare against the off-the shelf OpenNLP chunker[6], obtaining a 22% reduction in error.

2.3 Capitalization

A key orthographic feature for recognizing named entities is capitalization (Florian, 2002; Downey et al., 2007). Unfortunately in tweets, capitalization is much less reliable than in edited texts. In addition, there is a wide variety in the styles of capitalization. In some tweets capitalization is informative, whereas in other cases, non-entity words are capitalized simply for emphasis. Some tweets contain all lowercase words (8%), whereas others are in ALL CAPS (0.6%).

To address this issue, it is helpful to incorporate information based on the entire content of the message to determine whether or not its capitalization is informative. To this end, we build a capitalization classifier, T-CAP, which predicts whether or not a tweet is informatively capitalized. Its output is used as a feature for Named Entity Recognition. We manually labeled our 800 tweet corpus as having either "informative" or "uninformative" capitalization. The criteria we use for labeling is as follows: if a tweet contains any non-entity words which are capitalized, but do not begin a sentence, or it contains any entities which are not capitalized, then its capitalization is "uninformative", otherwise it is "informative".

	P	R	F_1
Majority Baseline	0.70	1.00	0.82
T-CAP	0.77	0.98	0.86

Table 5: Performance at predicting reliable capitalization.

For learning , we use Support Vector Machines.[7] The features used include: the fraction of words in the tweet which are capitalized, the fraction which appear in a dictionary of frequently lowercase/capitalized words but are not lowercase/capitalized in the tweet, the number of times the word 'I' appears lowercase and whether or not the first word in the tweet is capitalized. Results comparing against the majority baseline, which predicts capitalization is always informative, are shown in Table 5. Additionally, in §3 we show that features based on our capitalization classifier improve performance at named entity segmentation.

3 Named Entity Recognition

We now discuss our approach to named entity recognition on Twitter data. As with POS tagging and shallow parsing, off the shelf named-entity recognizers perform poorly on tweets. For example, applying the Stanford Named Entity Recognizer to one of the examples from Table 1 results in the following output:

> [Yess]$_{ORG}$! [Yess]$_{ORG}$! Its official [Nintendo]$_{LOC}$ announced today that they Will release the [Nintendo]$_{ORG}$ 3DS in north [America]$_{LOC}$ march 27 for $250

[6] http://incubator.apache.org/opennlp/

[7] http://www.chasen.org/~taku/software/TinySVM/

The OOV word 'Yess' is mistaken as a named entity. In addition, although the first occurrence of 'Nintendo' is correctly segmented, it is misclassified, whereas the second occurrence is improperly segmented – it should be the product "Nintendo 3DS". Finally "north America" should be segmented as a *LOCATION*, rather than just 'America'. In general, news-trained Named Entity Recognizers seem to rely heavily on capitalization, which we know to be unreliable in tweets.

Following Collins and Singer (1999), Downey et al. (2007) and Elsner et al. (2009), we treat classification and segmentation of named entities as separate tasks. This allows us to more easily apply techniques better suited towards each task. For example, we are able to use discriminative methods for named entity segmentation and distantly supervised approaches for classification. While it might be beneficial to jointly model segmentation and (distantly supervised) classification using a joint sequence labeling and topic model similar to that proposed by Sauper et al. (2010), we leave this for potential future work.

Because most words found in tweets are not part of an entity, we need a larger annotated dataset to effectively learn a model of named entities. We therefore use a randomly sampled set of 2,400 tweets for NER. All experiments (Tables 6, 8-10) report results using 4-fold cross validation.

3.1 Segmenting Named Entities

Because capitalization in Twitter is less informative than news, in-domain data is needed to train models which rely less heavily on capitalization, and also are able to utilize features provided by T-CAP.

We exhaustively annotated our set of 2,400 tweets (34K tokens) with named entities.[8] A convention on Twitter is to refer to other users using the @ symbol followed by their unique username. We deliberately choose not to annotate @usernames as entities in our data set because they are both unambiguous, and trivial to identify with 100% accuracy using a simple regular expression, and would only serve to inflate our performance statistics. While there is ambiguity as to the type of @usernames (for example, they can refer to people or companies), we believe they could be more easily classified using features of their associated user's profile than contextual features of the text.

[8]We found that including out-of-domain training data from the MUC competitions lowered performance at this task.

	P	R	F_1	F_1 inc.
Stanford NER	0.62	0.35	0.44	-
T-SEG(None)	0.71	0.57	0.63	43%
T-SEG(T-POS)	0.70	0.60	0.65	48%
T-SEG(T-POS, T-CHUNK)	0.71	0.61	0.66	50%
T-SEG(All Features)	0.73	0.61	0.67	52%

Table 6: Performance at segmenting entities varying the features used. "None" removes POS, Chunk, and capitalization features. Overall we obtain a 52% improvement in F_1 score over the Stanford Named Entity Recognizer.

T-SEG models Named Entity Segmentation as a sequence-labeling task using IOB encoding for representing segmentations (each word either begins, is inside, or is outside of a named entity), and uses Conditional Random Fields for learning and inference. Again we include orthographic, contextual and dictionary features; our dictionaries included a set of type lists gathered from Freebase. In addition, we use the Brown clusters and outputs of T-POS, T-CHUNK and T-CAP in generating features.

We report results at segmenting named entities in Table 6. Compared with the state-of-the-art news-trained Stanford Named Entity Recognizer (Finkel et al., 2005), T-SEG obtains a 52% increase in F_1 score.

3.2 Classifying Named Entities

Because Twitter contains many distinctive, and infrequent entity types, gathering sufficient training data for named entity classification is a difficult task. In any random sample of tweets, many types will only occur a few times. Moreover, due to their terse nature, individual tweets often do not contain enough context to determine the type of the entities they contain. For example, consider following tweet:

KKTNY in 45min.....

without any prior knowledge, there is not enough context to determine what type of entity "KKTNY" refers to, however by exploiting redundancy in the data (Downey et al., 2010), we can determine it is likely a reference to a television show since it of-

ten co-occurs with words such as *watching* and *premieres* in other contexts.[9]

In order to handle the problem of many infrequent types, we leverage large lists of entities and their types gathered from an open-domain ontology (Freebase) as a source of distant supervision, allowing use of large amounts of unlabeled data in learning.

Freebase Baseline: Although Freebase has very broad coverage, simply looking up entities and their types is inadequate for classifying named entities in context (0.38 F-score, §3.2.1). For example, according to Freebase, the mention 'China' could refer to a country, a band, a person, or a film. This problem is very common: 35% of the entities in our data appear in more than one of our (mutually exclusive) Freebase dictionaries. Additionally, 30% of entities mentioned on Twitter do not appear in any Freebase dictionary, as they are either too new (for example a newly released videogame), or are misspelled or abbreviated (for example 'mbp' is often used to refer to the "mac book pro").

Distant Supervision with Topic Models: To model unlabeled entities and their possible types, we apply LabeledLDA (Ramage et al., 2009), constraining each entity's distribution over topics based on its set of possible types according to Freebase. In contrast to previous weakly supervised approaches to Named Entity Classification, for example the Co-Training and Naïve Bayes (EM) models of Collins and Singer (1999), LabeledLDA models each entity string as a mixture of types rather than using a single hidden variable to represent the type of each mention. This allows information about an entity's distribution over types to be shared across mentions, naturally handling ambiguous entity strings whose mentions could refer to different types.

Each entity string in our data is associated with a bag of words found within a context window around all of its mentions, and also within the entity itself. As in standard LDA (Blei et al., 2003), each bag of words is associated with a distribution over topics, Multinomial(θ_e), and each topic is associated with a distribution over words, Multinomial(β_t). In addition, there is a one-to-one mapping between topics and Freebase type dictionaries. These dictionaries constrain θ_e, the distribution over topics for each entity string, based on its set of possible types, $FB[e]$. For example, θ_{Amazon} could correspond to a distribution over two types: *COMPANY*, and *LOCATION*, whereas θ_{Apple} might represent a distribution over *COMPANY*, and *FOOD*. For entities which aren't found in any of the Freebase dictionaries, we leave their topic distributions θ_e unconstrained. Note that in absence of any constraints LabeledLDA reduces to standard LDA, and a fully unsupervised setting similar to that presented by Elsner et. al. (2009).

In detail, the generative process that models our data for Named Entity Classification is as follows:

for each type: $t = 1 \dots T$ **do**
  Generate β_t according to symmetric Dirichlet distribution Dir(η).
end for
for each entity string $e = 1 \dots |E|$ **do**
  Generate θ_e over $FB[e]$ according to Dirichlet distribution Dir($\alpha_{FB[e]}$).
  for each word position $i = 1 \dots N_e$ **do**
    Generate $z_{e,i}$ from Mult(θ_e).
    Generate the word $w_{e,i}$ from Mult($\beta_{z_{e,i}}$).
  end for
end for

To infer values for the hidden variables, we apply Collapsed Gibbs sampling (Griffiths and Steyvers, 2004), where parameters are integrated out, and the $z_{e,i}$s are sampled directly.

In making predictions, we found it beneficial to consider θ_e^{train} as a prior distribution over types for entities which were encountered during training. In practice this sharing of information across contexts is very beneficial as there is often insufficient evidence in an isolated tweet to determine an entity's type. For entities which weren't encountered during training, we instead use a prior based on the distribution of types across all entities. One approach to classifying entities in context is to assume that θ_e^{train} is fixed, and that all of the words inside the entity mention and context, $\mathbf{w}$, are drawn based on a single topic, z, that is they are all drawn from Multinomial(β_z). We can then compute the posterior distribution over types in closed form with a simple application of Bayes rule:

$$P(z|\mathbf{w}) \propto \prod_{w \in \mathbf{w}} P(w|z:\beta) P(z:\theta_e^{\text{train}})$$

During development, however, we found that rather than making these assumptions, using Gibbs Sam-

pling to estimate the posterior distribution over types performs slightly better. In order to make predictions, for each entity we use an informative Dirichlet prior based on θ_e^{train} and perform 100 iterations of Gibbs Sampling holding the hidden topic variables in the training data fixed (Yao et al., 2009). Fewer iterations are needed than in training since the type-word distributions, β have already been inferred.

3.2.1 Classification Experiments

To evaluate T-CLASS's ability to classify entity mentions in context, we annotated the 2,400 tweets with 10 types which are both popular on Twitter, and have good coverage in Freebase: *PERSON*, *GEO-LOCATION*, *COMPANY*, *PRODUCT*, *FACILITY*, *TV-SHOW*, *MOVIE*, *SPORTSTEAM*, *BAND*, and *OTHER*. Note that these type annotations are only used for evaluation purposes, and not used during training T-CLASS, which relies only on distant supervision. In some cases, we combine multiple Freebase types to create a dictionary of entities representing a single type (for example the *COMPANY* dictionary contains Freebase types */business/consumer_company* and */business/brand*). Because our approach does not rely on any manually labeled examples, it is straightforward to extend it for a different sets of types based on the needs of downstream applications.

Training: To gather unlabeled data for inference, we run T-SEG, our entity segmenter (from §3.1), on 60M tweets, and keep the entities which appear 100 or more times. This results in a set of 23,651 distinct entity strings. For each entity string, we collect words occurring in a context window of 3 words from all mentions in our data, and use a vocabulary of the 100K most frequent words. We run Gibbs sampling for 1,000 iterations, using the last sample to estimate entity-type distributions θ_e, in addition to type-word distributions β_t. Table 7 displays the 20 entities (not found in Freebase) whose posterior distribution θ_e assigns highest probability to selected types.

Results: Table 8 presents the classification results of T-CLASS compared against a majority baseline which simply picks the most frequent class (*PERSON*), in addition to the Freebase baseline, which only makes predictions if an entity appears in exactly one dictionary (*i.e.*, appears unambiguous). T-CLASS also outperforms a simple supervised baseline which applies a MaxEnt classifier using 4-fold cross validation over the 1,450 entities which were annotated for testing. Additionally we compare against the co-training algorithm of Collins and Singer (1999) which also leverages unlabeled data and uses our Freebase type lists; for seed rules we use the "unambiguous" Freebase entities. Our results demonstrate that T-CLASS outperforms the baselines and achieves a 25% increase in F_1 score over co-training.

Tables 9 and 10 present a breakdown of F_1 scores by type, both collapsing types into the standard classes used in the MUC competitions (*PERSON*, *LOCATION*, *ORGANIZATION*), and using the 10 popular Twitter types described earlier.

Entity Strings *vs.* Entity Mentions: DL-Cotrain and LabeledLDA use two different representations for the unlabeled data during learning. LabeledLDA groups together words across all mentions of an en-

tity string, and infers a distribution over its possible types, whereas DL-Cotrain considers the entity mentions separately as unlabeled examples and predicts a type independently for each. In order to ensure that the difference in performance between LabeledLDA and DL-Cotrain is not simply due to this difference in representation, we compare both DL-Cotrain and LabeledLDA using both unlabeled datasets (grouping words by all mentions vs. keeping mentions separate) in Table 11. As expected, DL-Cotrain performs poorly when the unlabeled examples group mentions; this makes sense, since Co-Training uses a discriminative learning algorithm, so when trained on entities and tested on individual mentions, the performance decreases. Additionally, LabeledLDA's performance is poorer when considering mentions as "documents". This is likely due to the fact that there isn't enough context to effectively learn topics when the "documents" are very short (typically fewer than 10 words).

End to End System: Finally we present the end to end performance on segmentation and classification (T-NER) in Table 12. We observe that T-NER again outperforms co-training. Moreover, comparing against the Stanford Named Entity Recognizer on the 3 MUC types, T-NER doubles F_1 score.

4 Related Work

There has been relatively little previous work on building NLP tools for Twitter or similar text styles. Locke and Martin (2009) train a classifier to recognize named entities based on annotated Twitter data, handling the types *PERSON*, *LOCATION*, and *ORGANIZATION*. Developed in parallel to our work, Liu et al. (2011) investigate NER on the same 3 types, in addition to *PRODUCT*s and present a semi-

supervised approach using k-nearest neighbor. Also developed in parallel, Gimpell et al. (2011) build a POS tagger for tweets using 20 coarse-grained tags. Benson et. al. (2011) present a system which extracts artists and venues associated with musical performances. Recent work (Han and Baldwin, 2011; Gouws et al., 2011) has proposed lexical normalization of tweets which may be useful as a preprocessing step for the upstream tasks like POS tagging and NER. In addition Finin et. al. (2010) investigate the use of Amazon's Mechanical Turk for annotating Named Entities in Twitter, Minkov et. al. (2005) investigate person name recognizers in email, and Singh et. al. (2010) apply a minimally supervised approach to extracting entities from text advertisements.

In contrast to previous work, we have demonstrated the utility of features based on Twitter-specific POS taggers and Shallow Parsers in segmenting Named Entities. In addition we take a distantly supervised approach to Named Entity Classification which exploits large dictionaries of entities gathered from Freebase, requires no manually annotated data, and as a result is able to handle a larger number of types than previous work. Although we found manually annotated data to be very beneficial for named entity segmentation, we were motivated to explore approaches that don't rely on manual labels for classification due to Twitter's wide range of named entity types. Additionally, unlike previous work on NER in informal text, our approach allows the sharing of information across an entity's mentions which is quite beneficial due to Twitter's terse nature.

Previous work on Semantic Bootstrapping has taken a weakly-supervised approach to classifying named entities based on large amounts of unlabeled text (Etzioni et al., 2005; Carlson et al., 2010; Kozareva and Hovy, 2010; Talukdar and Pereira, 2010; McIntosh, 2010). In contrast, rather than predicting which classes an entity belongs to (e.g. a multi-label classification task), LabeledLDA estimates a *distribution* over its types, which is then useful as a prior when classifying mentions in context.

In addition there has been been work on Skip-Chain CRFs (Sutton, 2004; Finkel et al., 2005) which enforce consistency when classifying multiple occurrences of an entity within a document. Using topic models (e.g. LabeledLDA) for classifying named entities has a similar effect, in that information about an entity's distribution of possible types is shared across its mentions.

5 Conclusions

We have demonstrated that existing tools for POS tagging, Chunking and Named Entity Recognition perform quite poorly when applied to Tweets. To address this challenge we have annotated tweets and built tools trained on unlabeled, in-domain and out-of-domain data, showing substantial improvement over their state-of-the art news-trained counterparts, for example, T-POS outperforms the Stanford POS Tagger, reducing error by 41%. Additionally we have shown the benefits of features generated from T-POS and T-CHUNK in segmenting Named Entities.

We identified named entity classification as a particularly challenging task on Twitter. Due to their terse nature, tweets often lack enough context to identify the types of the entities they contain. In addition, a plethora of distinctive named entity types are present, necessitating large amounts of training data. To address both these issues we have presented and evaluated a distantly supervised approach based on LabeledLDA, which obtains a 25% increase in F_1 score over the co-training approach to Named Entity Classification suggested by Collins and Singer (1999) when applied to Twitter.

Our POS tagger, Chunker Named Entity Recognizer are available for use by the research community: `http://github.com/aritter/twitter_nlp`

Identifying Relations for Open Information Extraction

Anthony Fader, Stephen Soderland, and Oren Etzioni
University of Washington, Seattle
{afader,soderlan,etzioni}@cs.washington.edu

Abstract

Open Information Extraction (IE) is the task of extracting assertions from massive corpora without requiring a pre-specified vocabulary. This paper shows that the output of state-of-the-art Open IE systems is rife with uninformative and incoherent extractions. To overcome these problems, we introduce two simple syntactic and lexical constraints on binary relations expressed by verbs. We implemented the constraints in the REVERB Open IE system, which more than doubles the area under the precision-recall curve relative to previous extractors such as TEXTRUNNER and WOE^{pos}. More than 30% of REVERB's extractions are at precision 0.8 or higher—compared to virtually none for earlier systems. The paper concludes with a detailed analysis of REVERB's errors, suggesting directions for future work.[1]

1 Introduction and Motivation

Typically, Information Extraction (IE) systems learn an extractor for each target relation from labeled training examples (Kim and Moldovan, 1993; Riloff, 1996; Soderland, 1999). This approach to IE does not scale to corpora where the number of target relations is very large, or where the target relations cannot be specified in advance. Open IE solves this problem by identifying *relation phrases*—phrases that denote relations in English sentences (Banko et al., 2007). The automatic identification of relation phrases enables the extraction of *arbitrary* relations from sentences, obviating the restriction to a pre-specified vocabulary.

Open IE systems have achieved a notable measure of success on massive, open-domain corpora drawn from the Web, Wikipedia, and elsewhere. (Banko et al., 2007; Wu and Weld, 2010; Zhu et al., 2009). The output of Open IE systems has been used to support tasks like learning selectional preferences (Ritter et al., 2010), acquiring common sense knowledge (Lin et al., 2010), and recognizing entailment (Schoenmackers et al., 2010; Berant et al., 2011). In addition, Open IE extractions have been mapped onto existing ontologies (Soderland et al., 2010).

We have observed that two types of errors are frequent in the output of Open IE systems such as TEXTRUNNER and WOE: *incoherent extractions* and *uninformative extractions*.

Incoherent extractions are cases where the extracted relation phrase has no meaningful interpretation (see Table 1 for examples). Incoherent extractions arise because the learned extractor makes a sequence of decisions about whether to include each word in the relation phrase, often resulting in incomprehensible predictions. To solve this problem, we introduce a syntactic constraint: every multi-word relation phrase must begin with a verb, end with a preposition, and be a contiguous sequence of words in the sentence. Thus, the identification of a relation phrase is made in one fell swoop instead of on the basis of multiple, word-by-word decisions.

Uninformative extractions are extractions that omit critical information. For example, consider the sentence "Faust made a deal with the devil." Previ-

[1] The source code for REVERB is available at http://reverb.cs.washington.edu/

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1535–1545,
Edinburgh, Scotland, UK, July 27–31, 2011.

ous Open IE systems return the uninformative

(Faust, made, a deal)

instead of

(Faust, made a deal with, the devil).

This type of error is caused by improper handling of relation phrases that are expressed by a combination of a verb with a noun, such as light verb constructions (LVCs). An LVC is a multi-word expression composed of a verb and a noun, with the noun carrying the semantic content of the predicate (Grefenstette and Teufel, 1995; Stevenson et al., 2004; Allerton, 2002). Table 2 illustrates the wide range of relations expressed this way, which are not captured by existing open extractors. Our syntactic constraint leads the extractor to include nouns in the relation phrase, solving this problem.

Although the syntactic constraint significantly reduces incoherent and uninformative extractions, it allows overly-specific relation phrases such as *is offering only modest greenhouse gas reduction targets at*. To avoid overly-specific relation phrases, we introduce an intuitive lexical constraint: a binary relation phrase ought to appear with at least a minimal number of distinct argument pairs in a large corpus.

In summary, this paper articulates two simple but surprisingly powerful constraints on how binary relationships are expressed via verbs in English sentences, and implements them in the REVERB Open IE system. We release REVERB and the data used in our experiments to the research community.

The rest of the paper is organized as follows. Section 2 analyzes previous work. Section 3 defines our constraints precisely. Section 4 describes REVERB, our implementation of the constraints. Section 5 reports on our experimental results. Section 6 concludes with a summary and discussion of future work.

2 Previous Work

Open IE systems like TEXTRUNNER (Banko et al., 2007), WOE^{pos}, and WOE^{parse} (Wu and Weld, 2010) focus on extracting binary relations of the form (arg1, relation phrase, arg2) from text. These systems all use the following three-step method:

1. **Label:** Sentences are automatically labeled with extractions using heuristics or distant supervision.

Sentence	Incoherent Relation
The guide *contains* dead links and *omits* sites.	contains omits
The Mark 14 *was central* to the *torpedo* scandal of the fleet.	was central torpedo
They *recalled* that Nungesser *began* his career as a precinct leader.	recalled began

Table 1: Examples of incoherent extractions. Incoherent extractions make up approximately 13% of TEXTRUNNER's output, 15% of WOE^{pos}'s output, and 30% of WOE^{parse}'s output.

is	is an album by, is the author of, is a city in
has	has a population of, has a Ph.D. in, has a cameo in
made	made a deal with, made a promise to
took	took place in, took control over, took advantage of
gave	gave birth to, gave a talk at, gave new meaning to
got	got tickets to, got a deal on, got funding from

Table 2: Examples of uninformative relations (left) and their completions (right). Uninformative relations occur in approximately 4% of WOE^{parse}'s output, 6% of WOE^{pos}'s output, and 7% of TEXTRUNNER's output.

2. **Learn:** A relation phrase extractor is learned using a sequence-labeling graphical model (*e.g.*, CRF).

3. **Extract:** the system takes a sentence as input, identifies a candidate pair of NP arguments (arg1, arg2) from the sentence, and then uses the learned extractor to label each word between the two arguments as part of the relation phrase or not.

The extractor is applied to the successive sentences in the corpus, and the resulting extractions are collected.

This method faces several challenges. First, the training phase requires a large number of labeled training examples (*e.g.*, 200,000 heuristically-labeled sentences for TEXTRUNNER and 300,000 for WOE). Heuristic labeling of examples obviates hand labeling but results in noisy labels and distorts the distribution of examples. Second, the extraction step is posed as a sequence-labeling problem, where each word is assigned its own label. Because each assignment is uncertain, the likelihood that the extracted relation phrase is flawed increases with the length of the sequence. Finally, the extractor

chooses an extraction's arguments heuristically, and cannot backtrack over this choice. This is problematic when a word that belongs in the relation phrase is chosen as an argument (for example, *deal* from the "made a deal with" sentence).

Because of the feature sets utilized in previous work, the learned extractors ignore both "holistic" aspects of the relation phrase (*e.g.*, is it contiguous?) as well as lexical aspects (*e.g.*, how many instances of this relation are there?). Thus, as we show in Section 5, systems such as TEXTRUNNER are unable to learn the constraints embedded in REVERB. Of course, a learning system, utilizing a different hypothesis space, and an appropriate set of training examples, *could* potentially learn and refine the constraints in REVERB. This is a topic for future work, which we consider in Section 6.

The first Open IE system was TEXTRUNNER (Banko et al., 2007), which used a Naive Bayes model with unlexicalized POS and NP-chunk features, trained using examples heuristically generated from the Penn Treebank. Subsequent work showed that utilizing a linear-chain CRF (Banko and Etzioni, 2008) or Markov Logic Network (Zhu et al., 2009) can lead to improved extraction. The WOE systems introduced by Wu and Weld make use of Wikipedia as a source of training data for their extractors, which leads to further improvements over TEXTRUNNER (Wu and Weld, 2010). Wu and Weld also show that dependency parse features result in a dramatic increase in precision and recall over shallow linguistic features, but at the cost of extraction speed.

Other approaches to large-scale IE have included Preemptive IE (Shinyama and Sekine, 2006), On-Demand IE (Sekine, 2006), and weak supervision for IE (Mintz et al., 2009; Hoffmann et al., 2010). Preemptive IE and On-Demand IE avoid relation-specific extractors, but rely on document and entity clustering, which is too costly for Web-scale IE. Weakly supervised methods use an existing ontology to generate training data for learning relation-specific extractors. While this allows for learning relation-specific extractors at a larger scale than what was previously possible, the extractions are still restricted to a specific ontology.

Many systems have used syntactic patterns based on verbs to extract relation phrases, usually relying on a full dependency parse of the input sentence (Lin and Pantel, 2001; Stevenson, 2004; Specia and Motta, 2006; Kathrin Eichler and Neumann, 2008). Our work differs from these approaches by focusing on relation phrase patterns expressed in terms of POS tags and NP chunks, instead of full parse trees. Banko and Etzioni (Banko and Etzioni, 2008) showed that a small set of POS-tag patterns cover a large fraction of relationships in English, but never incorporated the patterns into an extractor. This paper reports on a substantially improved model of binary relation phrases, which increases the recall of the Banko-Etzioni model (see Section 3.3). Further, while previous work in Open IE has mainly focused on syntactic patterns for relation extraction, we introduce a lexical constraint that boosts precision and recall.

Finally, Open IE is closely related to semantic role labeling (SRL) (Punyakanok et al., 2008; Toutanova et al., 2008) in that both tasks extract relations and arguments from sentences. However, SRL systems traditionally rely on syntactic parsers, which makes them susceptible to parser errors and substantially slower than Open IE systems such as REVERB. This difference is particularly important when operating on the Web corpus due to its size and heterogeneity. Finally, SRL requires hand-constructed semantic resources like Propbank and Framenet (Martha and Palmer, 2002; Baker et al., 1998) as input. In contrast, Open IE systems require no relation-specific training data. ReVerb, in particular, relies on its explicit lexical and syntactic constraints, which have no correlate in SRL systems. For a more detailed comparison of SRL and Open IE, see (Christensen et al., 2010).

3 Constraints on Relation Phrases

In this section we introduce two constraints on relation phrases: a syntactic constraint and a lexical constraint.

3.1 Syntactic Constraint

The syntactic constraint serves two purposes. First, it eliminates incoherent extractions, and second, it reduces uninformative extractions by capturing relation phrases expressed by a verb-noun combination, including light verb constructions.

$$V \mid VP \mid VW^*P$$
V = verb particle? adv?
W = (noun | adj | adv | pron | det)
P = (prep | particle | inf. marker)

Figure 1: A simple part-of-speech-based regular expression reduces the number of incoherent extractions like *was central torpedo* and covers relations expressed via light verb constructions like *gave a talk at*.

The syntactic constraint requires the relation phrase to match the POS tag pattern shown in Figure 1. The pattern limits relation phrases to be either a verb (*e.g.*, *invented*), a verb followed immediately by a preposition (*e.g.*, *located in*), or a verb followed by nouns, adjectives, or adverbs ending in a preposition (*e.g.*, *has atomic weight of*). If there are multiple possible matches in a sentence for a single verb, the longest possible match is chosen. Finally, if the pattern matches multiple adjacent sequences, we merge them into a single relation phrase (*e.g.*, *wants to extend*). This refinement enables the model to readily handle relation phrases containing multiple verbs. A consequence of this pattern is that the relation phrase must be a contiguous span of words in the sentence.

The syntactic constraint eliminates the incoherent relation phrases returned by existing systems. For example, given the sentence

> Extendicare agreed to buy Arbor Health Care for about US $432 million in cash and assumed debt.

TEXTRUNNER returns the extraction

(Arbor Health Care, for assumed, debt).

The phrase *for assumed* is clearly not a valid relation phrase: it begins with a preposition and splices together two distant words in the sentence. The syntactic constraint prevents this type of error by simply restricting relation phrases to match the pattern in Figure 1.

The syntactic constraint reduces uninformative extractions by capturing relation phrases expressed via LVCs. For example, the POS pattern matched against the sentence "Faust made a deal with the Devil," would result in the relation phrase *made a deal with*, instead of the uninformative *made*.

Finally, we require the relation phrase to appear between its two arguments in the sentence. This is a common constraint that has been implicitly enforced in other open extractors.

3.2 Lexical Constraint

While the syntactic constraint greatly reduces uninformative extractions, it can sometimes match relation phrases that are so specific that they have only a few possible instances, even in a Web-scale corpus. Consider the sentence:

> The Obama administration is offering only modest greenhouse gas reduction targets at the conference.

The POS pattern will match the phrase:

is offering only modest greenhouse gas reduction targets at (1)

Thus, there are phrases that satisfy the syntactic constraint, but are not relational.

To overcome this limitation, we introduce a lexical constraint that is used to separate valid relation phrases from overspecified relation phrases, like the example in (1). The constraint is based on the intuition that a valid relation phrase should take many distinct arguments in a large corpus. The phrase in (1) is specific to the argument pair *(Obama administration, conference)*, so it is unlikely to represent a *bona fide* relation. We describe the implementation details of the lexical constraint in Section 4.

3.3 Limitations

Our constraints represent an idealized model of relation phrases in English. This raises the question: How much recall is lost due to the constraints?

To address this question, we analyzed Wu and Weld's set of 300 sentences from a set of random Web pages, manually identifying all verb-based relationships between noun phrase pairs. This resulted in a set of 327 relation phrases. For each relation phrase, we checked whether it satisfies our constraints. We found that 85% of the relation phrases do satisfy the constraints. Of the remaining 15%, we identified some of the common cases where the constraints were violated, summarized in Table 3.

Many of the example relation phrases shown in Table 3 involve long-range dependencies between words in the sentence. These types of dependencies are not easily representable using a pattern over POS tags. A deeper syntactic analysis of the input sentence would provide a much more general language for modeling relation phrases. For example, one could create a model of relations expressed in

	Binary Verbal Relation Phrases
85%	Satisfy Constraints
8%	Non-Contiguous Phrase Structure Coordination: X is produced and maintained by Y Multiple Args: X was founded in 1995 by Y Phrasal Verbs: X turned Y off
4%	Relation Phrase Not Between Arguments Intro. Phrases: Discovered by Y, X ... Relative Clauses: ... the Y that X discovered
3%	Do Not Match POS Pattern Interrupting Modifiers: X has a lot of faith in Y Infinitives: X to attack Y

Table 3: Approximately 85% of the binary verbal relation phrases in a sample of Web sentences satisfy our constraints.

terms of dependency parse features that would capture the non-contiguous relation phrases in Table 3. Previous work has shown that dependency paths do indeed boost the recall of relation extraction systems (Wu and Weld, 2010; Mintz et al., 2009). While using dependency path features allows for a more flexible model of relations, it significantly increases processing time, which is problematic for Web-scale extraction. Further, we have found that this increased recall comes at the cost of lower precision on Web text (see Section 5).

The results in Table 3 are similar to Banko and Etzioni's findings that a set of eight POS patterns cover a large fraction of binary verbal relation phrases. However, their analysis was based on a set of sentences known to contain either a company acquisition or birthplace relationship, while our results are on a random sample of Web sentences. We applied Banko and Etzioni's verbal patterns to our random sample of 300 Web sentences, and found that they cover approximately 69% of the relation phrases in the corpus. The gap in recall between this and the 85% shown in Table 3 is largely due to LVC relation phrases (*made a deal with*) and phrases containing multiple verbs (*refuses to return to*), which their patterns do not cover.

In sum, our model is by no means complete. However, we have empirically shown that the majority of binary verbal relation phrases in a sample of Web sentences are captured by our model. By focusing on this subset of language, our model can be used to perform Open IE at significantly higher precision than before.

4 REVERB

This section introduces REVERB, a novel open extractor based on the constraints defined in the previous section. REVERB first identifies relation phrases that satisfy the syntactic and lexical constraints, and then finds a pair of NP arguments for each identified relation phrase. The resulting extractions are then assigned a confidence score using a logistic regression classifier.

This algorithm differs in three important ways from previous methods (Section 2). First, the relation phrase is identified "holistically" rather than word-by-word. Second, potential phrases are filtered based on statistics over a large corpus (the implementation of our lexical constraint). Finally, REVERB is "relation first" rather than "arguments first", which enables it to avoid a common error made by previous methods—confusing a noun in the relation phrase for an argument, *e.g.* the noun *deal* in *made a deal with*.

4.1 Extraction Algorithm

REVERB takes as input a POS-tagged and NP-chunked sentence and returns a set of (x, r, y) extraction triples.[2] Given an input sentence s, REVERB uses the following extraction algorithm:

1. **Relation Extraction:** For each verb v in s, find the longest sequence of words r_v such that (1) r_v starts at v, (2) r_v satisfies the syntactic constraint, and (3) r_v satisfies the lexical constraint. If any pair of matches are adjacent or overlap in s, merge them into a single match.
2. **Argument Extraction:** For each relation phrase r identified in Step 1, find the nearest noun phrase x to the left of r in s such that x is not a relative pronoun, WHO-adverb, or existential "there". Find the nearest noun phrase y to the right of r in s. If such an (x, y) pair could be found, return (x, r, y) as an extraction.

We check whether a candidate relation phrase r_v satisfies the syntactic constraint by matching it against the regular expression in Figure 1.

[2] REVERB uses OpenNLP for POS tagging and NP chunking: `http://opennlp.sourceforge.net/`

To determine whether r_v satisfies the lexical constraint, we use a large dictionary D of relation phrases that are known to take many distinct arguments. In an offline step, we construct D by finding all matches of the POS pattern in a corpus of 500 million Web sentences. For each matching relation phrase, we heuristically identify its arguments (as in Step 2 above). We set D to be the set of all relation phrases that take at least k distinct argument pairs in the set of extractions. In order to allow for minor variations in relation phrases, we normalize each relation phrase by removing inflection, auxiliary verbs, adjectives, and adverbs. Based on experiments on a held-out set of sentences, we found that a value of $k = 20$ works well for filtering out overspecified relations. This results in a set of approximately 1.7 million distinct normalized relation phrases, which are stored in memory at extraction time.

As an example of the extraction algorithm in action, consider the following input sentence:

> Hudson was born in Hampstead, which is a suburb of London.

Step 1 of the algorithm identifies three relation phrases that satisfy the syntactic and lexical constraints: *was*, *born in*, and *is a suburb of*. The first two phrases are adjacent in the sentence, so they are merged into the single relation phrase *was born in*. Step 2 then finds an argument pair for each relation phrase. For *was born in*, the nearest NPs are *(Hudson, Hampstead)*. For *is a suburb of*, the extractor skips over the NP *which* and chooses the argument pair *(Hampstead, London)*. The final output is

e_1: *(Hudson, was born in, Hampstead)*
e_2: *(Hampstead, is a suburb of, London)*.

4.2 Confidence Function

The extraction algorithm in the previous section has high recall, but low precision. Like with previous open extractors, we want way to trade recall for precision by tuning a confidence threshold. We use a logistic regression classifier to assign a confidence score to each extraction, which uses the features shown in Table 4. All of these features are efficiently computable and relation independent. We trained the confidence function by manually labeling the extractions from a set of $1,000$ sentences from the Web and Wikipedia as correct or incorrect.

Weight	Feature
1.16	(x, r, y) covers all words in s
0.50	The last preposition in r is *for*
0.49	The last preposition in r is *on*
0.46	The last preposition in r is *of*
0.43	$len(s) \leq 10$ words
0.43	There is a WH-word to the left of r
0.42	r matches VW*P from Figure 1
0.39	The last preposition in r is *to*
0.25	The last preposition in r is *in*
0.23	10 words $< len(s) \leq 20$ words
0.21	s begins with x
0.16	y is a proper noun
0.01	x is a proper noun
-0.30	There is an NP to the left of x in s
-0.43	20 words $< len(s)$
-0.61	r matches V from Figure 1
-0.65	There is a preposition to the left of x in s
-0.81	There is an NP to the right of y in s
-0.93	Coord. conjunction to the left of r in s

Table 4: REVERB uses these features to assign a confidence score to an extraction (x, r, y) from a sentence s using a logistic regression classifier.

Previous open extractors require labeled training data to learn a model of relations, which is then used to extract relation phrases from text. In contrast, REVERB uses a specified model of relations for extraction, and requires labeled data only for assigning confidence scores to its extractions. Learning a confidence function is a much simpler task than learning a full model of relations, using two orders of magnitude fewer training examples than TEXTRUNNER or WOE.

4.3 TEXTRUNNER-R

The model of relation phrases used by REVERB is specified, but could a TEXTRUNNER-like system learn this model from training data? While it is difficult to answer such a question for all possible permutations of features sets, training examples, and learning biases, we demonstrate that TEXTRUNNER itself cannot learn REVERB's model even when re-trained using the output of REVERB as labeled training data. The resulting system, TEXTRUNNER-R, uses the same feature representation as TEXTRUNNER, but different parameters, and a different set of training examples.

To generate positive instances, we ran REVERB

on the Penn Treebank, which is the same dataset that TEXTRUNNER is trained on. To generate negative instances from a sentence, we took each noun phrase pair in the sentence that does not appear as arguments in a REVERB extraction. This process resulted in a set of $67,562$ positive instances, and $356,834$ negative instances. We then passed these labeled examples to TEXTRUNNER's training procedure, which learns a linear-chain CRF using closed-class features like POS tags, capitalization, punctuation, *etc.* TEXTRUNNER-R uses the argument-first extraction algorithm described in Section 2.

5 Experiments

We compare REVERB to the following systems:

- REVERB$^{\neg lex}$ - The REVERB system described in the previous section, but without the lexical constraint. REVERB$^{\neg lex}$ uses the same confidence function as REVERB.
- TEXTRUNNER - Banko and Etzioni's 2008 extractor, which uses a second order linear-chain CRF trained on extractions heuristically generated from the Penn Treebank. TEXTRUNNER uses shallow linguistic features in its CRF, which come from the same POS tagger and NP-chunker that REVERB uses.
- TEXTRUNNER-R - Our modification to TEXTRUNNER, which uses the same extraction code, but with a model of relations trained on REVERB extractions.
- WOE^{pos} - Wu and Weld's modification to TEXTRUNNER, which uses a model of relations learned from extractions heuristically generated from Wikipedia.
- WOE^{parse} - Wu and Weld's parser-based extractor, which uses a large dictionary of dependency path patterns learned from heuristic extractions generated from Wikipedia.

Each system is given a set of sentences as input, and returns a set of binary extractions as output. We created a test set of 500 sentences sampled from the Web, using Yahoo's random link service.[3] After running each extractor over the input sentences, two human judges independently evaluated each extraction as correct or incorrect. The judges reached agreement on 86% of the extractions, with an agreement score of $\kappa = 0.68$. We report results on the subset of the data where the two judges concur.

[3] http://random.yahoo.com/bin/ryl

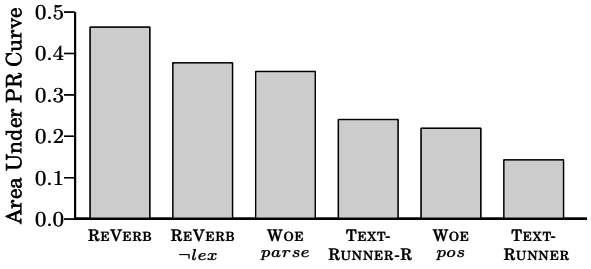

Figure 2: REVERB outperforms state-of-the-art open extractors, with an AUC more than twice that of TEXTRUNNER or WOE^{pos}, and 38% higher than WOE^{parse}.

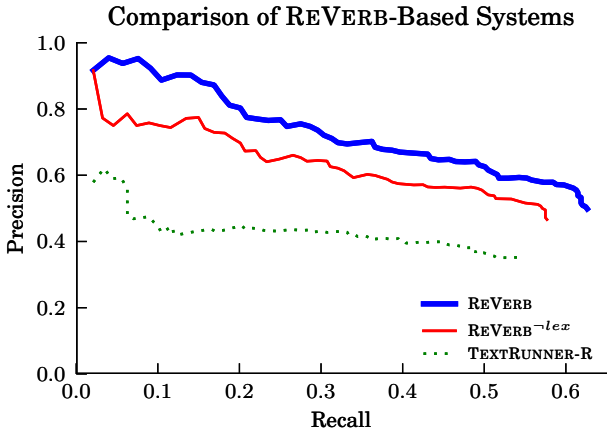

Figure 3: The lexical constraint gives REVERB a boost in precision and recall over REVERB$^{\neg lex}$. TEXTRUNNER-R is unable to learn the model used by REVERB, which results in lower precision and recall.

The judges labeled uninformative extractions conservatively. That is, if critical information was dropped from the relation phrase but included in the second argument, it is labeled correct. For example, both the extractions *(Ackerman, is a professor of, biology)* and *(Ackerman, is, a professor of biology)* are considered correct.

Each system returns confidence scores for its extractions. For a given threshold, we can measure the precision and recall of the output. Precision is the fraction of returned extractions that are correct. Recall is the fraction of correct extractions in

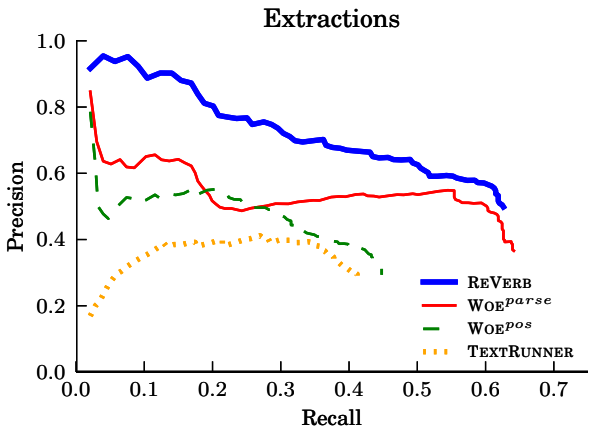

Figure 4: REVERB achieves significantly higher precision than state-of-the-art Open IE systems, and comparable recall to WOE^{parse}.

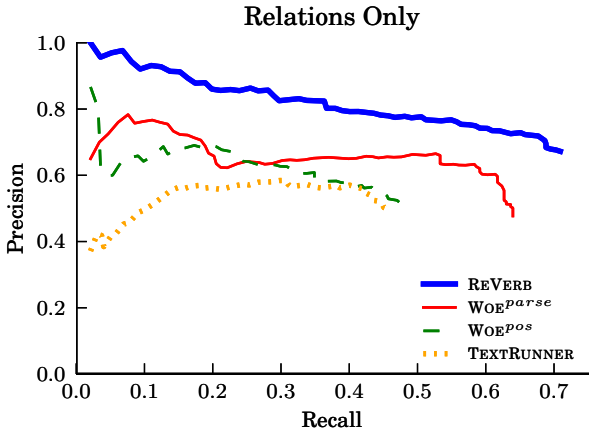

Figure 5: On the subtask of identifying relations phrases, REVERB is able to achieve even higher precision and recall than other systems.

the corpus that are returned. We use the total number of extractions labeled as correct by the judges as our measure of recall for the corpus. In order to avoid double-counting, we treat extractions that differ superficially (*e.g.*, different punctuation or dropping inessential modifiers) as a single extraction. We compute a precision-recall curve by varying the confidence threshold, and then compute the area under the curve (AUC).

5.1 Results

Figure 2 shows the AUC of each system. REVERB achieves an AUC that is 30% higher than WOE^{parse} and is more than double the AUC of WOE^{pos} or TEXTRUNNER. The lexical constraint provides a significant boost in performance, with REVERB achieving an AUC 23% higher than REVERB$^{\neg lex}$. REVERB proves to be a useful source of training data, with TEXTRUNNER-R having an AUC 71% higher than TEXTRUNNER and performing on par with WOE^{pos}. From the training data, TEXTRUNNER-R was able to learn a model that predicts contiguous relation phrases, but still returned incoherent relation phrases (*e.g.*, starting with a preposition) and overspecified relation phrases. These errors are due to TEXTRUNNER-R overfitting the training data and not having access to the lexical constraint.

Figure 3 shows the precision-recall curves of the systems introduced in this paper. TEXTRUNNER-R has much lower precision than REVERB and REVERB$^{\neg lex}$ at all levels of recall. The lexical constraint gives REVERB a boost in precision over REVERB$^{\neg lex}$, reducing overspecified extractions from 20% of REVERB$^{\neg lex}$'s output to 1% of REVERB's. The lexical constraint also boosts recall over REVERB$^{\neg lex}$, since REVERB is able to find a correct relation phrase where REVERB$^{\neg lex}$ finds an overspecified one.

Figure 4 shows the precision-recall curves of REVERB and the external systems. REVERB has much higher precision than the other systems at nearly all levels of recall. In particular, more than 30% of REVERB's extractions are at precision 0.8 or higher, compared to virtually none for the other systems. WOE^{parse} achieves a slightly higher recall than REVERB (0.62 versus 0.64), but at the cost of lower precision.

In order to highlight the role of the relational model of each system, we also evaluate their performance on the subtask of extracting just the relation phrases from the input text. Figure 5 shows the precision-recall curves for each system on the relation phrase-only evaluation. In this case, REVERB has both higher precision and recall than the other systems.

REVERB's biggest improvement came from the elimination of incoherent extractions. Incoherent extractions were a large fraction of the errors made by previous systems, accounting for approximately 13% of TEXTRUNNER's extractions, 15% of WOE^{pos}'s, and 30% of WOE^{parse}'s. Uninformative

REVERB - Incorrect Extractions	
65%	Correct relation phrase, incorrect arguments
16%	N-ary relation
8%	Non-contiguous relation phrase
2%	Imperative verb
2%	Overspecified relation phrase
7%	Other, including POS/chunking errors

Table 5: The majority of the incorrect extractions returned by REVERB are due to errors in argument extraction.

REVERB - Missed Extractions	
52%	Could not identify correct arguments
23%	Relation filtered out by lexical constraint
17%	Identified a more specific relation
8%	POS/chunking error

Table 6: The majority of extractions that were missed by REVERB were cases where the correct relation phrase was found, but the arguments were not correctly identified.

extractions had a smaller effect on other systems' precision, accounting for 4% of WOE^{parse}'s extractions, 5% of WOE^{pos}'s, and 7% of TEXTRUNNER's, while only appearing in 1% of REVERB's extractions. REVERB's reduction in uninformative extractions resulted in a boost in recall, capturing many LVC relation phrases missed by other systems (like those shown in Table 2).

To test the systems' speed, we ran each extractor on a set of 100,000 sentences using a Pentium 4 machine with 4GB of RAM. The processing times were 16 minutes for REVERB, 21 minutes for TEXTRUNNER, 21 minutes for WOE^{pos}, and 11 hours for WOE^{parse}. The times for REVERB, TEXTRUNNER, and WOE^{pos} are all approximately the same, since they all use the same POS-tagging and NP-chunking software. WOE^{parse} processes each sentence with a dependency parser, resulting in much longer processing time.

5.2 REVERB Error Analysis

To better understand the limitations of REVERB, we performed a detailed analysis of its errors in precision (incorrect extractions returned by REVERB) and its errors in recall (correct extractions that REVERB missed).

Table 5 summarizes the types of incorrect extractions that REVERB returns. We found that 65% of the incorrect extractions returned by REVERB were cases where a relation phrase was correctly identified, but the argument-finding heuristics failed. The remaining errors were cases where REVERB extracted an incorrect relation phrase. One common mistake that REVERB made was extracting a relation phrase that expresses an n-ary relationship via a ditransitive verb. For example, given the sentence "I gave him 15 photographs," REVERB extracts *(I, gave, him)*. These errors are due to the fact that REVERB only models binary relations.

Table 6 summarizes the correct extractions that were extracted by other systems and were not extracted by REVERB. As with the false positive extractions, the majority of false negatives (52%) were due to the argument-finding heuristics choosing the wrong arguments, or failing to extract all possible arguments (in the case of coordinating conjunctions). Other sources of failure were due to the lexical constraint either failing to filter out an overspecified relation phrase or filtering out a valid relation phrase. These errors hurt both precision and recall, since each case results in the extractor overlooking a correct relation phrase and choosing another.

5.3 Evaluation At Scale

Section 5.1 shows that REVERB outperforms existing Open IE systems when evaluated on a sample of sentences. Previous work has shown that the frequency of an extraction in a large corpus is useful for assessing the correctness of extractions (Downey et al., 2005). Thus, it is possible *a priori* that REVERB's gains over previous systems will diminish when extraction frequency is taken into account.

In fact, we found that REVERB's advantage over TEXTRUNNER when run at scale is qualitatively similar to its advantage on single sentences. We ran both REVERB and TEXTRUNNER on Banko and Etzioni's corpus of 500 million Web sentences and examined the effect of redundancy on precision.

As Downey's work predicts, precision increased in both systems for extractions found multiple times, compared with extractions found only once. However, REVERB had higher precision than

TEXTRUNNER at all frequency thresholds. In fact, REVERB's frequency 1 extractions had a precision of 0.75, which TEXTRUNNER could not approach even with frequency 10 extractions, which had a precision of 0.34. Thus, REVERB is able to return more correct extractions at a higher precision than TEXTRUNNER, even when redundancy is taken into account.

6 Conclusions and Future Work

The paper's contributions are as follows:

- We have identified and analyzed the problems of incoherent and uninformative extractions for Open IE systems, and shown their prevalence for systems such as TEXTRUNNER and WOE.
- We articulated general, easy-to-enforce constraints on binary, verb-based relation phrases in English that ameliorate these problems and yield richer and more informative relations (see, for example, Table 2).
- Based on these constraints, we designed, implemented, and evaluated the REVERB extractor, which substantially outperforms previous Open IE systems in both recall and precision.
- We make REVERB and the data used in our experiments available to the research community.[4]

In future work, we plan to explore utilizing our constraints to improve the performance of learned CRF models. Roth *et al.* have shown how to incorporate constraints into CRF learners (Roth and Yih, 2005). It is natural, then, to consider whether the combination of heuristically labeled training examples, CRF learning, and our constraints will result in superior performance. The error analysis in Section 5.2 also suggests natural directions for future work. For instance, since many of REVERB's errors are due to incorrect arguments, improved methods for argument extraction are in order.

Acknowledgments

We would like to thank Mausam, Dan Weld, Yoav Artzi, Luke Zettlemoyer, members of the KnowItAll group, and the anonymous reviewers for their helpful comments. This research was supported in part by NSF grant IIS-0803481, ONR grant N00014-08-1-0431, and DARPA contract FA8750-09-C-0179, and carried out at the University of Washington's Turing Center.

Active Learning with Amazon Mechanical Turk

Florian Laws Christian Scheible Hinrich Schütze
Institute for Natural Language Processing
Universität Stuttgart
{lawsfn, scheibcn}@ims.uni-stuttgart.de

Abstract

Supervised classification needs large amounts of annotated training data that is expensive to create. Two approaches that reduce the cost of annotation are *active learning* and *crowdsourcing*. However, these two approaches have not been combined successfully to date. We evaluate the utility of active learning in crowdsourcing on two tasks, named entity recognition and sentiment detection, and show that active learning outperforms random selection of annotation examples in a noisy crowdsourcing scenario.

1 Introduction

Supervised classification is the predominant technique for a large number of natural language processing (NLP) tasks. The large amount of labeled training data that supervised classification relies on is time-consuming and expensive to create, especially when experts perform the data annotation. Recently, crowdsourcing services like Amazon Mechanical Turk (MTurk) have become available as an alternative that offers acquisition of non-expert annotations at low cost. MTurk is a software service that outsources small annotation tasks – called *HITs* – to a large group of freelance workers. The cost of MTurk annotation is low, but a consequence of using non-expert annotators is much lower annotation quality. This requires strategies for quality control of the annotations.

Another promising approach to the data acquisition bottleneck for supervised learning is active learning (AL). AL reduces annotation effort by setting up an annotation loop where, starting from a small seed set, only the maximally informative examples are chosen for annotation. With these annotated examples, the classifier is then retrained to again select more informative examples for further annotation. In general, AL needs a lot fewer annotations to achieve a desired performance level than random sampling.

AL has been successfully applied to a number of NLP tasks such as part-of-speech tagging (Ringger et al., 2007), parsing (Osborne and Baldridge, 2004), text classification (Tong and Koller, 2002), sentiment detection (Brew et al., 2010), and named entity recognition (NER) (Tomanek et al., 2007). Until recently, most AL studies focused on simulating the annotation process by using already available gold standard data. In reality, however, human annotators make mistakes, leading to noise in the annotations. For this reason, some authors have questioned the applicability of AL to noisy annotation scenarios such as MTurk (Baldridge and Palmer, 2009; Rehbein et al., 2010).

AL and crowdsourcing are complementary approaches: AL reduces the number of annotations used while crowdsourcing reduces the cost per annotation. Combined, the two approaches could substantially lower the cost of creating training sets.

Our main contribution in this paper is that we show for the first time that AL is significantly better than randomly selected annotation examples in a real crowdsourcing annotation scenario. Our experiments directly address two tasks, named entity recognition and sentiment detection, but our

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1546–1556,
Edinburgh, Scotland, UK, July 27–31, 2011.

evidence suggests that AL is of general benefit in crowdsourcing. We also show that the effectiveness of MTurk annotation with AL can be further enhanced by using two techniques that increase label quality: *adaptive voting* and *fragment recovery*.

2 Related Work

2.1 Crowdsourcing

Pioneered by Snow et al. (2008), Crowdsourcing, especially using MTurk, has become a widely used service in the NLP community. A number of studies have looked at crowdsourcing for NER. Voyer et al. (2010) use a combination of expert and crowdsourced annotations. Finin et al. (2010) annotate Twitter messages – short sequences of words – and this is reflected in their vertically oriented user interface. Lawson et al. (2010) choose an annotation interface where annotators have to drag the mouse to select entities. Carpenter and Poesio (2010) argue that dragging is less convenient for workers than marking tokens.

These papers do not address AL in crowdsourcing. Another important difference is that previous studies on NER have used data sets for which no "linguistic" gold annotation is available. In contrast, we reannotate the CoNLL-2003 English NER dataset. This allows us to conduct a detailed comparison of MTurk AL to conventional expert annotation.

2.2 Active Learning with Noisy Labels

Hachey et al. (2005) were among the first to investigate the effect of actively sampled instances on agreement of labels and annotation time. They demonstrate applicability of AL when annotators are trained experts. This is an important result. However, AL depends on accurate assessments of uncertainty and informativeness and such an accurate assessment is made more difficult if labels are noisy as is the case in crowdsourcing. For this reason, the problem of AL performance with noisy labels has become a topic of interest in the AL community. Rehbein et al. (2010) investigate AL with human expert annotators for word sense disambiguation, but do not find convincing evidence that AL reduces annotation cost in a realistic (non-simulated) annotation scenario. Brew et al. (2010) carried out experiments on sentiment active learning through crowdsourcing. However, they use a small set of volunteer labelers instead of anonymous paid workers.

Donmez and Carbonell (2008) propose a method to choose annotators from a set of noisy annotators. However, in a crowdsourcing scenario, it is not possible to ask specific annotators for a label, as crowdsourcing workers join and leave the site. Furthermore, they only evaluate their approach in simulations. We use the actual labels of human annotators to avoid the risk of unrealistic assumptions when modeling annotators.

We are not aware of any study that shows that AL is significantly better than a simple baseline of having annotators annotate randomly selected examples in a highly noisy annotation setting like crowdsourcing. While AL generally is superior to this baseline in simulated experiments, it is not clear that this result carries over to crowdsourcing annotation. Crowdsourcing differs in a number of ways from simulated experiments: the difficulty and annotation consistency of examples drawn by AL differs from that drawn by random sampling; crowdsourcing labels are noisy; and because of the noisiness of labels statistical classifiers behave differently in simulated and real annotation experiments.

3 Annotation System

One fundamental design criterion for our annotation system was the ability to select examples *in real time* to support, e.g., the interactive annotation experiments presented in this paper. Thus, we could not use the standard MTurk workflow or services like CrowdFlower.[1]

We therefore designed our own system for annotation experiments. It consists of a two-tiered application architecture. The frontend tier is a web application that serves two purposes. First, the administrator can manage annotation experiments using a web interface and publish annotation tasks associated with an experiment on MTurk. The frontend also provides tools for efficient review of the received answers. Second, the frontend web application presents annotation tasks to MTurk workers. Because we wanted to implement interactive annotation experiments, we used the "external question"

[1] `http://crowdflower.com/`

feature of MTurk. An external question contains an URL to our frontend web application, which is queried when a worker views an annotation task. Our frontend then in turn queries our backend component for an example to be annotated and renders it in HTML.

The backend component is responsible for selection of an example to be annotated in response to a worker's request for an annotation task. The backend implements a diverse choice of random and active selection strategies as well as the multilabeling strategies described in section 3.2. The backend component runs as a standalone server and is queried by the frontend via REST-like HTTP calls.

For the NER task, we present one sentence per HIT, segmented into tokens, with a select box underneath each token containing the classes. The definition of the classes is based on the CoNLL-2003 annotation guidelines (Tjong Kim Sang and De Meulder, 2003). Examples were given for every class. Annotators are forced to make a selection for uppercase tokens. Lowercase tokens are prelabeled with "O" (no named entity), but annotators are encouraged to change this label if the token is in fact part of an entity phrase.

For sentiment annotation, we found in preliminary experiments that using simple radio button selection for the choice of the document label (`positive` or `negative`) leads to a very high amount of spam submissions, taking the overall classification accuracy down to around 55%. We then designed a template that forced annotators to type the label as well as a randomly chosen word from the text. Individual label accuracy was around 75% in this scheme.

3.1 Concurrent example selection

AL works by setting up an interactive annotation loop where at each iteration, the most informative example is selected for annotation. We use a pool-based AL setup where the most informative example is selected from a pool of unlabeled examples. Informativeness is calculated as uncertainty (Lewis and Gale, 1994) using the margin metric (Schein and Ungar, 2007). This metric chooses examples for which the margin of probabilities from the classifier between the two most probable classes is the smallest:

$$M_n = |\hat{P}(c_1|x_n) - \hat{P}(c_2|x_n)|$$

Here, x_n is the instance to be classified, c_1 and c_2 are the two most likely classes, and $\hat{P}$ the classifier's estimate of probability.

For NER, the margins of the tokens are averaged to get an uncertainty assessment of the sentence. For sentiment, whole documents are classified, thus uncertainties can be used directly.

After annotation, the selected example is removed from the unlabeled pool and, together with its label(s), added to the set of labeled examples. The classifier is then retrained on the labeled examples and the informativeness of the remaining examples in the pool is re-evaluated.

Depending on the classifier and the sizes of pool and labeled set, retraining and reevaluation can take some time. To minimize wait times, traditional AL implementations select examples in batches of the n most informative examples. However, batch selection might not give the optimum selection (examples in a batch are likely to be redundant, see Brinker (2003)) and wait times can still occur between one batch and the next.

When performing annotation with MTurk, wait times are unacceptable. Thus, we perform the retraining and uncertainty rescoring concurrently with the annotation user interface. The unlabeled pool is stored in a priority queue that is ordered according to the examples' informativeness. The annotation user interface takes the most informative example from the pool and presents it to the annotator. The labeled example is then inserted into a second queue that feeds and updates retraining and rescoring processes. The pool queue then is resorted according to the new informativeness. In this way, annotation and example selection can run in parallel. This is similar to Haertel et al. (2010).

3.2 Adaptive voting and fragment recovery

MTurk labels often have a high error rate. A common strategy for improving label quality is to acquire *multiple labels* by different workers for each example and then consolidate the annotations into a single label of higher quality. To trade off number of annotated examples against quality of annotations, we adopt *adaptive voting*. It uses majority

			NER						Sentiment

	8	5-v+f	2165	70.5	2.68	79.3	2691	71.2	–	–	–	–	–	–

Table 1: For NER, active learning consistently beats random sampling on MTurk. NER F_1 evaluated on CoNLL test set A. #train = number of sentences in training set, S = single, 3-v = 3-voting, 5/4-voting = 5- and 4-voting for NER and sentiment resp., +f = using fragments; sentiment budget 1130 for run 1, sentiment budget 1756 averaged over 2 runs.

voting and is adaptive in the number of repeated annotations. For NER, a sentence is first annotated by two workers. Then majority voting is performed for each token individually. If there is a majority for every token that is greater than an agreement threshold α, the sentence is accepted with each token labeled with the majority label. Otherwise additional annotations are requested. A sentence is discarded if the number of repeated annotations exceeds a discard threshold d (d-voting).[2] We use the same scheme for sentiment; note that there is just one decision per HIT in this case, not several as in NER.

For NER, we also use *fragment recovery*: we salvage tokens with agreeing labels from discarded sentences. We cut the token sequence of a discarded sentence into several fragments that have agreeing tokens and discard only those parts that disagree. We then include these recovered fragments in the training data just like complete sentences.

Software release. Our active learning framework used can be downloaded at `http://www.ims.uni-stuttgart.de/~lawsfn/active/`.

4 Experiments, Results and Analysis

4.1 Experiments

In our NER experiments, we have workers reannotate the English corpus of the CoNLL-2003 NER shared task. We chose this corpus to be able to compare crowdsourced annotations with gold standard annotations. A HIT is one sentence and is offered for a base payment of $0.01. We filtered out answers that contained unannotated tokens or were obvious spam (e.g., all tokens labeled as MISC). For testing NER performance, we used a system based on conditional random fields with standard named entity features including the token itself, orthographic features like the occurrence of capitalization or special characters and context information about the tokens to the left/right of the current token.

The sentiment detection task was modeled after a well-known document analysis setup for sentiment classification, introduced by Pang et al. (2002). We use their corpus of 1000 positive and 1000 negative movie reviews and the Stanford maximum entropy classifier (Manning and Klein, 2003) to predict the sentiment label of each document d from a unigram representation of d. We randomly split this corpus into a test set of 500 reviews and an active learning pool of 1500 reviews. Each HIT consists of one document, valued at $0.01.

We compare random sampling (RS) and AL in combination with the proposed voting and fragment strategies with different parameters. We want to avoid rerunning experiments on MTurk over and over again, but on the other hand, we believe that using synthetic data for simulations is problematic because it is difficult to generate synthetic data with a realistic model of annotator errors. Thus, we logged a play-by-play record of the annotator interactions and labels. With this recording, we can then rerun strategies with different parameters.

We chose voting with at most $d = 5$ repetitions as

[2] It can take a while in this scheme for annotators to agree on a final annotation for a sentence. We make *tentative* labels of a sentence available to the classifier immediately and replace them with the final labels once voting is completed.

our main reannotation strategy for both random and active sampling for NER annotation. We use simple majority voting ($\alpha = .5$) for NER.

For sentiment, we set $d = 4$ and minimum agreement $\alpha = .75$ because the number of labels is smaller (2 vs. 5) and so random agreement is more likely for sentiment.

To get results for 3-voting NER, we take the recording and discard 5-voting votes not needed in 3-voting. This will result in roughly the same number of annotated sentences, but at a lower cost. This simulation of 3-voting is not exactly what would have happened on MTurk (e.g., the final vote on a sentence might be different, which then influences AL example selection), but we will assume that differences are rare and simulated and actual results are similar. The same considerations apply to single votes and to the sentiment experiments.

We always compare two strategies for the same annotation budget. For example, the *number of training sentences* in Table 1 differ in the two relevant columns, but all strategies compared use exactly *the same annotation budget* (5820, 6931, 1130, and 1756, respectively).

For the single annotation strategy, each interaction record contained only about 40% usable annotations, the rest were repeats. A comparison with the single annotation strategy over approx. 2000 sentences or 450 documents would not have been meaningful; therefore we chose to run an extra experiment with the single annotation strategy to match this up with the budgets of the voting strategies. The results are presented in two separate columns of Table 1 (budgets 6931 and 1756).

4.2 Results

For sentiment detection, *worker accuracy* or *label quality* – the percentage of correctly annotated documents – is 74.8. In contrast, for NER, worker accuracy – the percentage of non-O tokens annotated correctly – is only 51.6 (Table 1, line 1). This demonstrates the challenge of using MTurk for NLP annotation tasks. When we use single annotations of each sentence, NER performance is 59.6 F_1 for random sampling (line 1). When training with gold labels on the same sentences, the performance is 80.0 (not shown). This means we lose more than 20% due to poor worker accuracy. Adaptive voting and fragment recovery manage to recover a small part of the lost performance (lines 2–4); each of the three F_1 scores is significantly better than the one above it as indicated by † (Approximate Randomization Test (Noreen, 1989; Chinchor et al., 1993) as implemented by Padó (2006)).

Using AL turns out to be quite successful for NER performance. For single annotations, NER performance is 67.0 (line 5), an improvement of 7.4% compared to random sampling. Adaptive voting and fragment recovery again increase worker accuracy (lines 6–8) although total improvement of 3.5% (lines 8 vs. 5) is smaller than 4% for random (lines 4 vs. 1). The learning curves of AL vs. random in Figure 1 (top left) confirm this good result for AL. These learning curves are for tokens – not for sentences – to show that the reason for AL's better performance is not that it selects slightly longer sentences than random. In addition, the relative advantage of AL vs random decreases over time, which is typical of pool-based AL experiments.

We carried out two runs of the same experiment for sentiment to validate our first positive result since the difference between the two conditions is not as large as in NER (Figure 1, top right). After about 300 documents, active learning consistently outperforms random sampling. The first AL run performs better because of higher label quality in the beginning. The overall advantage of AL over random is lower than for NER because the set of labels is smaller in sentiment, making the classification task easier. Second, there is a large amount of simple lexical clues for detecting sentiment (cf. Wilson et al. (2005)). It is likely that some of them can be learned well through random sampling at first; however, active learning can gain accuracy over time because it selects examples with more difficult clues.

In Figure 1 (bottom), we compare single annotation with adaptive voting. The graphs show F_1 as a function of cost. Adaptive voting trades quantity of sampled sentences for quality of labels and thus incurs higher net costs per sentence. This results in a smaller dataset for a given budget, but this dataset is still more useful for classifier training. For NER (Figure 1, bottom left), the single annotation strategy has a faster start; so for small budgets, covering a somewhat larger portion of the sample space is beneficial. For larger budgets, however, quality of

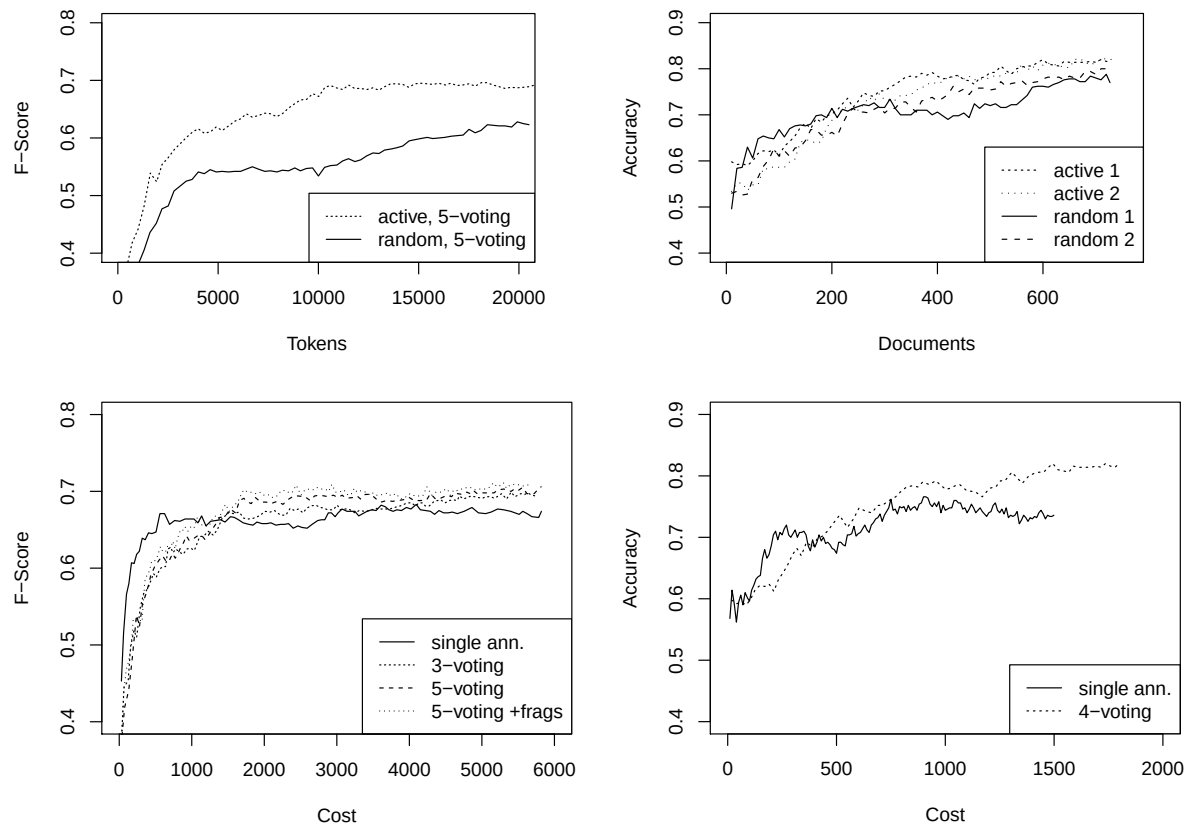

Figure 1: Top: Active learning vs. Random sampling for NER (left) and sentiment (right). Bottom: Active learning: adaptive voting vs. single annotation for NER (left) and sentiment (right).

the voted labels trumps quantity.

For sentiment (Figure 1, bottom right), results are similar: voting has no benefit initially, but as finding maximally informative examples to annotate becomes harder in later stages of learning, adaptive voting gains an advantage over single annotations.

The main result of the experiment is that active learning is better by about 7% F_1 than random sampling for NER and by 2.6% accuracy for sentiment (averaged over two runs at budget 1756). Adaptive voting further improves AL performance for both NER and sentiment.

4.3 Annotation time per token

Most AL work assumes constant cost per annotation unit. This assumption has been questioned because AL often selects hard examples that take longer to annotate (Hachey et al., 2005; Settles et al., 2008).

In annotation with MTurk, cost is not a function of annotation time because workers are paid a fixed amount per HIT. Nevertheless, annotation time plays a part in whether workers are willing to work on a given task for the offered reward. This is particularly problematic for NER since workers have to examine each token individually. We therefore investigate for NER whether the time MTurk workers spend on annotating sentences differs for random vs. AL.

We first compute median and mean annotation times and number of tokens per sentence:

	sec/sentence		tokens/sentence	
strategy	median	mean	all	required
random	17.2	33.1	15.0	3.4
AL	17.8	33.0	17.7	4.0

We see that most sentences are annotated in a very short time; but the mean is much larger than the median because there are outliers of up to eight minutes. AL tends to select slightly longer sentences as

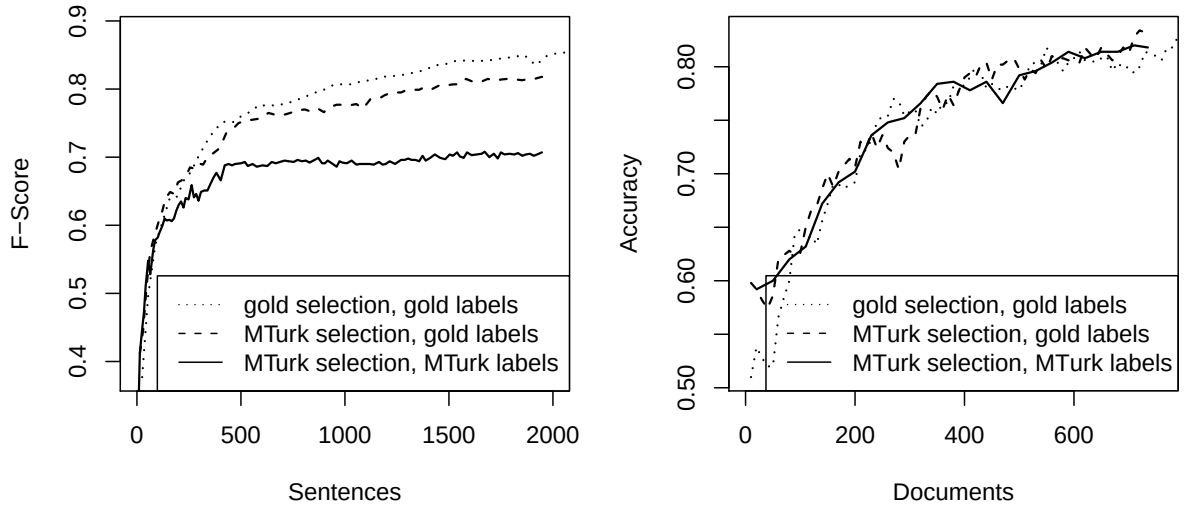

Figure 3: Performance on gold labels. Left: NER. Right: sentiment (run 1).

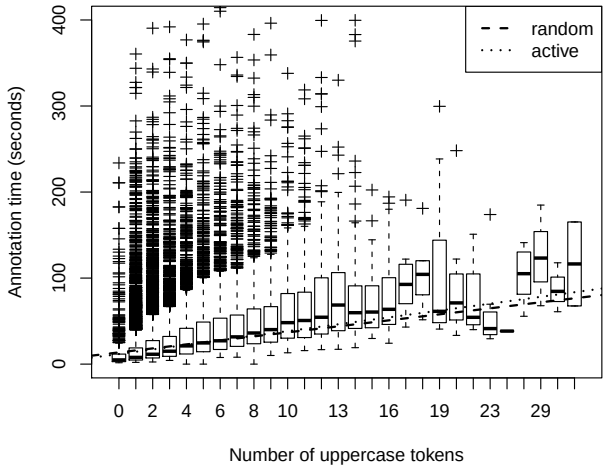

Figure 2: Annotation time vs. # uppercase tokens

well as sentences with slightly more uppercase tokens that require annotation.

In a more detailed analysis, we attempt to distinguish between (i) the effect of more uppercase ("annotation required") tokens vs. (ii) the effect of example difficulty. We fit a linear regression model to annotation time vs. the number of uppercase tokens. For the regression fit, we removed all annotation times > 60 seconds. Such long times indicate distraction of the worker and are not a reliable measure of difficulty.

Figure 2 shows the distribution of annotation times for both cases combined and the fitted models for each. The model estimated an annotation time of 2.3 secs for each required token for random vs. 2.7 secs for AL. We conclude that the difference in difficulty between sentences selected by random sampling vs. AL is small, but noticeable.

4.4 Influence of noise on the selection process

While NER performance for AL is much higher than for random sampling, it is still quite a bit lower than what is possible on gold labels. In the case of AL, there are two reasons why this happens: (i) The noisy labels negatively affect the classifier's ability to learn a good model that is used for classifying the test set. (ii) The noisy labels result in bad intermediate models that then select suboptimal examples to be annotated next. The AL selection process is "misled" by the noisy examples.

We conduct an experiment to determine the contribution of factors (i) and (ii) to the performance loss. First, we preserve the sequence of sentences chosen by our AL experiments on MTurk, with 5-voting for NER and 4-voting for sentiment but replace the noisy worker-provided labels by gold labels. The performance of classifiers trained on this sequence is the dashed line "MTurk selection, gold labels" in Figure 3 for NER (left) and sentiment (right).

Second, we compare with a traditional simulated AL experiment with gold labels. Here, the selection too is controlled by gold labels, so the selection has a noiseless classifier available for scoring and can perform optimal uncertainty selection. These are the

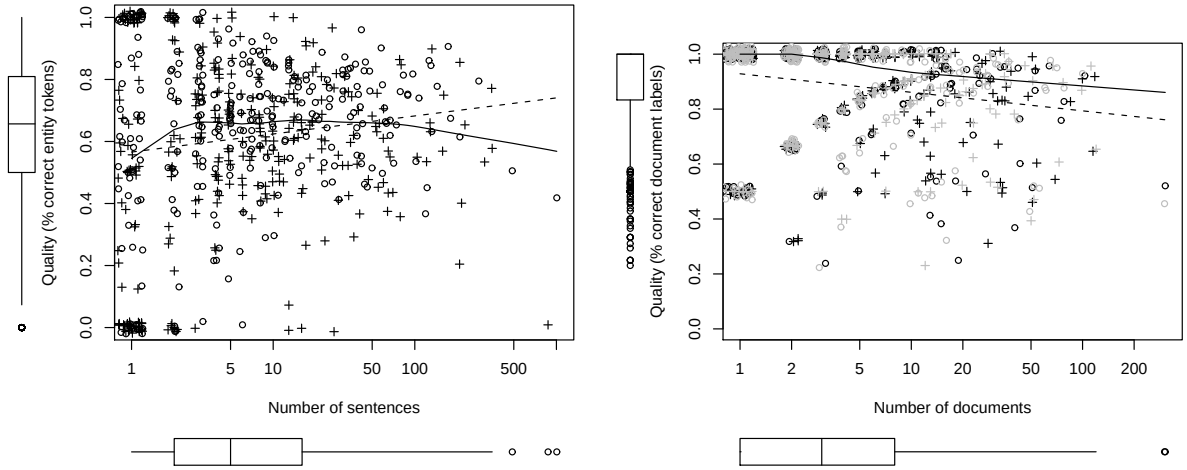

Figure 4: Worker accuracy vs. number of HITs. Each point corresponds to one worker ($\circ$ = active, $+$ =random sampling; black and grey for different runs). Left: NER. Right: Sentiment.

dotted lines "gold selection, gold labels" in Figure 3.

We used a batch-mode AL setup for this comparison experiment. For a fair comparison, we adjust the batchsize to be equal to the average *staleness* of a selected example in concurrent MTurk active learning. The staleness of an example is defined as the number of annotations the system has received, but not yet incorporated in the computation of an example's uncertainty score (Haertel et al., 2010).

For our concurrent NER system, the average staleness of an example was about 12 (min: 1, max: 40), for sentiment it was about 2. The figure for NER is higher than the number cited by Haertel et al. (2010) because there are more annotators accessing our system at the same time via MTurk but not as high for sentiment since documents are longer and retraining the sentiment classifier is faster. The average staleness of an example in a batch-mode system is half the batch size. Thus, we set the batch size of our comparison system to 25 for NER and to 4 for sentiment.

Returning to the two factors introduced above – (i) final effect of noise on test set performance vs. (ii) intermediate effect of noise on example selection – we see in Figure 3 that (i) has a large effect on NER whereas (ii) has a noticeable, but small effect.[3] For example, at 1966 sentences, F_1 scores are 70.6 (MTurk-MTurk), 81.4 (MTurk-gold) and 84.9 (gold-gold). This means that a performance difference of 10 points F_1 has to be attributed to noisy labels resulting in a worse final classifier (effect i), and another 3.5 points are lost due to sub-optimal example selection (effect ii).

For sentiment, the results are different. There is no clear difference between the three runs. We attribute this to the fact that the quality of the labels is higher in sentiment than in NER. Our initial experiments on sentiment were all negative (showing no improvement of AL compared to random) because label quality was too low. Only after we introduced the template described in Section 3 and used 4-voting with $\alpha = .75$ did we get positive results for AL. This leads to an overall label quality of about 90% (over all runs) which is so high that the difference to using gold labels is small if present at all.

5 Worker Quality

So far we have assumed that all workers provide annotations of the same quality. However, this is not the case. Figure 4 shows plots of worker accuracy as a function of worker productivity (number of annotated examples). Some workers submit only one or two HITs just to try out the task. For NER, the majority of workers submit between 5 and 10 sentences, with label qualities between 0.5 and 0.8. The chance level for correctness is around 0.25 (four

[3] Our comparison unit for NER is the sentence. We cannot compare on cost here since we do not know what the per-sentence cost of a "gold" expert annotation is.

different named entity categories for uppercase tokens). For sentiment, most workers submit 1 to 5 documents, with label qualities between 0.5 and 1. Chance level lies at around 0.5 (for two equally distributed labels).

While quality for highly productive workers is mediocre in our experiments, other researchers have found extremely bad quality for their most prolific workers (Callison-Burch, 2009). Some of these workers might be spammers who try to submit answers with automatic scripts. We encountered some spammers that our heuristics did not detect (shown in the bottom-right areas of Figure 4, left), but the voting mechanism was able to mitigate their negative influence.

Given the large variation in Figure 4, using worker quality in crowdsourcing for improved training set creation seems promising. We now test two such strategies for NER in an oracle setup.

5.1 Blocking low-quality workers

A simple approach is to refuse annotations from workers that have been determined to provide low quality answers. We simulated this strategy on NER data using oracle quality ratings. We chose NER because of its lower overall label quality. The results are presented in Figure 5 for random (a) and AL (b). For random, quality filtering with low cutoffs helps by removing bad annotations that likely come from spammers. While the voting strategy prevented a performance decrease with bad annotations, it needed to expend many extra annotations for correction. With filtering, these extra annotations become unnecessary and the system can learn faster. When low-quality workers are less active, as in the AL dataset, we find no meaningful performance increase for low cutoffs up to 0.4. For very high cutoffs (0.7), the beginning of the performance curve shows that further cost reductions can be achieved. However, we did not have enough recorded human annotations available to perform a simulation for the full budget.

5.2 Trusting high-quality workers

The complementary approach is to take annotations from highly rated workers at face value and immediately accept them as the correct label, *bypassing* the voting procedure. Bypassing saves the cost of repeated annotation of the same sentence. Figure 5 shows learning curves for two bypass thresholds on worker quality (measured as proportion of correct non-O tokens) for random (c) and AL (d). Bypassing performs surprisingly well. We find a steeper rise of the learning curve, meaning less cost for the same performance. Not only do we find substantial cost reductions, but also higher overall performance. We believe this is because high-quality annotations can sometimes be voted down by other annotations. If we can identify high-quality workers and directly use their annotations, this can be avoided.

These experiments are oracle experiments using gold data that is normally not available. In future work, we would like to repeat the experiments using methods for worker quality estimation (Ipeirotis et al., 2010; Donmez et al., 2009). For AL, the choice as to which labels are used (as a result of voting, bypassing or other) also has an influence on the selection. However, we had to keep the sequence of the selected sentences fixed in the simulations reported above. While our method of sample selection for AL proved to be quite robust even in the presence of noise, higher quality labels do have an influence on the sample selection (see section 4.4), so the improvement could be even better than indicated here.

5.3 Differences in quality between AL and random

The essence of AL is to select examples that are difficult to classify. As observed in our experiments on annotation time, this difficulty is reflected in the amount of time a human needs to work on examples selected through AL. Another effect to expect from difficulty could be lower annotation accuracy. We therefore examined the accuracies for each worker who contributed to both the AL and the random experiment. We found that in the NER task, the 20 workers in this group had a slightly higher (0.07) average quality for randomly selected examples. This difference is low and does not suggest a significant drop in accuracy for examples selected in AL.

6 Conclusion

We have investigated the use of AL in a real-life annotation experiment with human annotators instead of traditional simulations with gold labels for

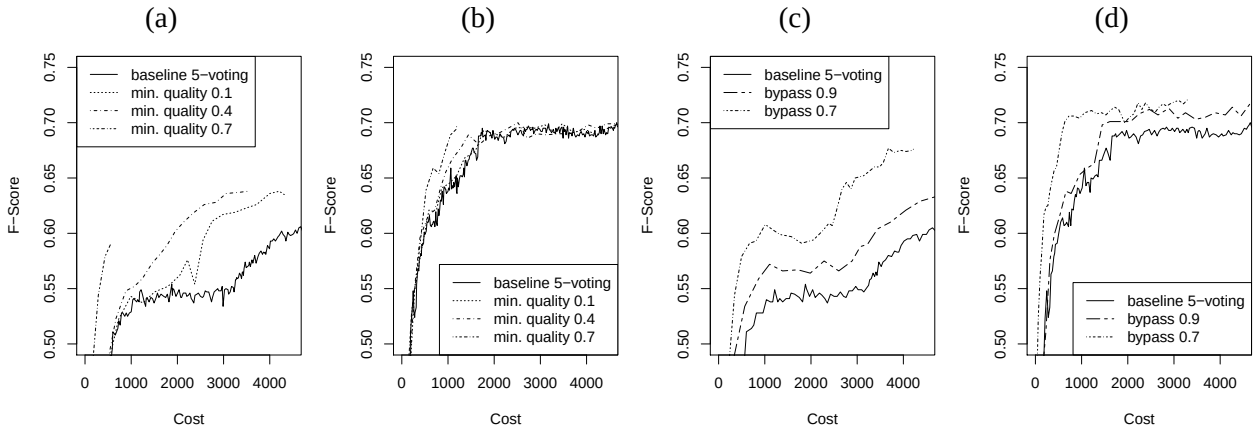

Figure 5: Blocking low-quality workers: (a) random, (b) AL. Bypass voting: (c) random, (d) AL.

named entity recognition and sentiment classification. The annotation was performed using MTurk in an AL framework that features concurrent example selection without wait times. We also evaluated two strategies, adaptive voting and fragment recovery, to improve label quality at low additional cost. We find that even for the relatively high noise levels of annotations gathered with MTurk, AL is successful, improving performance by +6.9 points F_1 compared to random sampling for NER and by +2.6% accuracy for sentiment. Furthermore, this performance level is reached at a smaller MTurk cost compared to random sampling. Thus AL not only reduces annotation costs, but also offers an improvement in absolute performance for these tasks. This is clear evidence that active learning and crowdsourcing are complementary methods for lowering annotation cost and should be used together in training set creation for natural language processing tasks.

We have also conducted oracle experiments that show that further performance gains and cost savings can be achieved by using information about worker quality. We plan to confirm these results by using estimates of quality in the future.

Abstract

We present a named entity recognition (NER) system for extracting product attributes and values from listing titles. Information extraction from short listing titles present a unique challenge, with the lack of informative context and grammatical structure. In this work, we combine supervised NER with bootstrapping to expand the seed list, and output normalized results. Focusing on listings from eBay's clothing and shoes categories, our bootstrapped NER system is able to identify new brands corresponding to spelling variants and typographical errors of the known brands, as well as identifying novel brands. Among the top 300 new brands predicted, our system achieves 90.33% precision. To output normalized attribute values, we explore several string comparison algorithms and found n-gram substring matching to work well in practice.

1 Introduction

Traditional named entity recognition (NER) task has expanded beyond identifying people, location, and organization to book titles, email addresses, phone numbers, and protein names (Nadeau and Sekine 2007). Recently there has been a surge of interest in extracting product attributes from online data due to the rapid growth of E-Commerce. Current work in this domain focuses on mining product reviews and descriptions from retailer websites. Such text data tend to be long and generate enough context for the target task (Brody and Elhadad 2010; Liu et al. 2005; Popescu and Etzioni 2005). In this paper, we focus on mining short product listing titles, which poses unique challenges.

Short listings are typical in classified ads where each seller is given limited space (in terms of words) to describe the product. On eBay, product listing titles cannot exceed 55 characters in length. Similarly, on Craigslist and newspaper ads, the length of a listing title is restricted. Extracting product attributes from such short titles faces the following challenges:

- Loss of grammatical structure in short listings where many nouns are piled together.
- Typographical errors, abbreviations, and acronyms that must be normalized to the standardized values.
- Lack of contextual information to infer product attribute value.

It can be argued that the use of short listings simplifies the problem of attribute extraction, since short listings can be easily annotated and one can apply supervised learning approach to extract product attributes. However, as the size of the data grows, obtaining labeled training set on the scale of millions of listings becomes very expensive. In such a scenario, incorporating unlabeled examples in a semi-supervised fashion to scale up the solution becomes a necessity rather than a luxury.

We formulate the product attribute extraction problem as a named entity recognition (NER) task and investigate supervised and semi-supervised approaches to this problem. In addition, we have investigated attribute discovery, and normalization to standardized values. We use listings from eBay's clothing and shoes categories and develop an attribute extraction system for 4 attribute types. We have $105,335$ listings from men's clothing category and $72,628$ listings from women's clothing category

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1557–1567,
Edinburgh, Scotland, UK, July 27–31, 2011.

on eBay, constituting a dataset of $1,380,337$ word tokens.

In the first part of this work, we outline a supervised learning approach to attribute value extraction where we train a sequential classifier and evaluate the extraction performance on a set of hand-labeled listings. Using maximum entropy and SVM as the base classifier (for classifying the individual word tokens), a hidden Markov model (HMM) is trained on the the probabilistic output of the base classifier, and a sequential label prediction is obtained using a Viterbi decoding. We show a performance comparison of supervised HMM, MaxEnt, SVM, and CRF for this task.

In the second part of our work, to grow our seed list of attributes, we present a bootstrapped algorithm for attribute value discovery and normalization, honing in on one particular attribute (brand). The goal is given an initial list of unambiguous brands, we grow the seed dictionary by discovering context patterns that are often associated with such attribute type. First, we automatically partition data into a training/test set by labeling word tokens in each listing using exact matching to entries in the dictionary. Brand phrases that can be confused with other attributes, e.g. the word *camel* — both a brand and a color — will not be a part of this initial seed list to create the training set. A classifier is then trained to learn context patterns surrounding the known brands from the training set, and is used to discover new brands from the test set.

Finally, for known attribute values, we normalize the results to match to words in our dictionary. Normalizing the variants of a known brand to a single normalized output value is an important aspect of a successful information extraction system. To this end, we investigate several string similarity/distance measures for this task and found that n-gram substring similarity (Kondrak 2005) yields accurate normalization results.

The main contribution of this work is a product attribute extraction system that addresses the unique problems of information extraction from short listing titles. We combine supervised NER with bootstrapping to expand the seed list, and investigate several methods to normalize the extracted results. Our system has been tested on large-scale eBay listing datasets to demonstrate its effectiveness.

2 Related Work

Recent work on product attribute extraction by (Brody and Elhadad 2010) applies a Latent Dirichlet Allocation (LDA) model to identify different aspects of products from user reviews. Similar work is presented in (Liu et al. 2005). Topic models such as LDA groups similar words together by identifying topics (product aspects) from patterns of word-occurrences. Such grouping can discover new aspects of a product such as "portability" (for netbook computers), but it may generate aspects that are vague and not easily interpretable. Indeed, how to refine discovered aspects and clean up words in each aspect remains an open question. The LDA approach also treats documents as bags of words, where important information in word sequences is not taken into account in learning the model.

Our work is most closely related to (Ghani 2006), where a set of product attributes of interests are predefined and a supervised learning method is applied to extract the correct attribute values for each class. Starting out from a small set of training examples, a bootstrapping technique is used to generate more training data from unlabeled data. The main difference to our method lies in how bootstrapping is used. (Ghani 2006) used EM to add more training data from unlabeled data, while in our approach bootstrapping is used to expand the seed list. First, we automatically generate labeled data by matching seed list to unlabeled data. Then, these auto-labeled training set is used to train a classifier to identify new attribute values from a separate set of unlabeled data. Thirdly, newly discovered product attribute values are added back to our seed list. Thus our original classifier for product attribute extraction can be improved through an expanded seed list.

In (Ghani and Jones 2002; Jones 2005), several bootstrapping methods are compared. These methods include self-training, co-EM and EM. All of these approaches are different from ours, as described in detail earlier. In (Probst et al. 2006), a Naive Bayes learner is combined with Co-EM to generate more training data from unlabeled data, and attribute-value pairs are extracted on adjacent words.

The automatic bootstrapping in this paper was inspired by (Pakhomov 2002)—an acronym expansion algorithm for medical text documents. The underlying assumption is that abbreviated forms and their

corresponding expansions occur in similar contexts; consequently, the surrounding context patterns can be used in associating the correct expansion to its acronym.

Our seed list expansion algorithm indeed bears some similarity to the work of (Nadeau el al 2006) and (Nadeau 2007). In (Nadeau el al 2006), automobile brands are learned automatically from web page context. First, a small set of 196 seed brands are extracted together with their associated web page contexts from popular news feed. The web context is subsequently used to extract additional automobile brands, which result in a total of 5701 brands. However, the reported results in (Nadeau el al 2006) have low precision, in some case less than 50%. Eventually their approach needs to rely on rule-based ambiguity resolver to increase the precision. Our system does not rely on manually created rules.

A more NLP-oriented approach is proposed in (Popescu and Etzioni 2005), where noun phrases are extracted from online user reviews. Their system tries to identify product features and user opinions from such noun phrases. A PMI (pointwise mutual information) score is evaluated between each noun phrase and discriminators associated with the product class. The noun-phrase approach does not work well in informal texts. In our case, user-generated short product listings may have many nouns concatenated together without forming a phrase or obeying correct grammatical rules.

Finally, another similar bootstrapping method is presented in (Mintz et al. 2009), where instances of known entity relations (or seed list in our paper) are matched to sentences in a set of Wikipedia articles, and a learning algorithm is trained from the surrounding features of the entities. The trained model is then applied to a test set of Wikipedia articles, and has been reported to be able to discover new instances. In our case, we apply our learned model to a new test set, and discover new brand names from the listings.

The nature of non-grammatical text we face makes our work similar to the NER work on informal texts. (Minkov et al. 2005) proposes an NER system that extracts personal names from emails. The work in (Gruhl et al 2009) identifies song titles from online forums on popular music, where song titles can be very ambiguous. By using real-world constraints such as known song titles, (Gruhl et al 2009) restricts the set of possible entities and are able to obtain reasonable recognition performance.

3 Corpus

The data used in all analysis in this paper is obtained from eBay's clothing and shoes category. Clothing and shoes have been important revenue-generating categories on the eBay site, and a successful attribute extraction system will serve as an invaluable tool for gathering important business and marketing intelligence. For these categories, the attributes that we are interested in are *brand (B)*, *garment type/style (G)*, *size (S)*, and *color (C)*. We gather $105,335$ listings from men's clothing category and $72,628$ listings from women's clothing category, constituting a dataset of $1,380,337$ word tokens. On average, each listing title contains 7.76 words.

A few examples of listings from eBay's clothing and shoes categories are shown in Fig 1. When designing an attribute extraction system to distinguish between the 4 attribute types, we must take into account the fact that individual words alone — without considering context — are ambiguous, as each word can belong to multiple attribute types. To give concrete examples, *inc* is a brand name of women's apparel but many sellers use it as an acronym for inch (brand vs. size). The word *blazer* can be a brand entity or it can be a garment type (brand vs. garment type). In addition, like other real-world user-generated texts, eBay listings are littered with site-specific acronyms, e.g. *BNWT* (brand new with tag), *NIB* (new in box), and abbreviations introduced by individual sellers, e.g. *immac* (immaculate), *trs* (trousers). In designing an information extraction system for our dataset, we need to account for the general as well as specific properties of our dataset.

4 Supervised Named Entity Recognition

In the first part of this work, we adopt a supervised named entity recognition (NER) framework for the attribute extraction problem from eBay listing titles. The goal is to correctly extract attribute values corresponding to the 4 attribute types, from each listing. One key assumption of the supervised learning paradigm is the availability of a labeled training data for training a classifier to distinguish between different classes. We generate our training data in

Figure 1: Example listings and their corresponding labels from the clothing and shoes category.

the following manner. For each listing, we remove extraneous punctuation symbols (*,(,),!,:,;) and tokenize each listing into a sequence of tokens. Given 4 dictionaries of seed values for the 4 attribute types, we match n-gram tokens to the seed values in the dictionaries, and create an initial round of labeled training set, which must then be manually inspected for correctness. In this work, we tagged and manually verified $1,000$ listings randomly sampled from the $105,335$ listings from the men's clothing category, resulting in a total of $7,921$ labeled tokens with $1,521$-word vocabulary. Fig. 1 shows examples of labeled listings, with tags *B* corresponding to brand, *C* for color, *S* for size, *G* for garment type/style, and *NA* for none of the above.

4.1 Classifiers

One of the most popular generative model based classifiers for named entity recognition tasks is Hidden Markov Model (HMM), which explicitly captures temporal statistics in the data by modeling state (label/tag) transitions over time. Discriminative classifiers, which directly model the posterior distribution of class label given features, i.e. SVM (Isozaki and Kazawa 2002) and Maximum Entropy model for NER (Chieu and Ng 2003), have been shown to outperform generative model based classifiers. More recently, Conditional Random Fields (CRF) (Feng and McCallum 2004; McCallum 2003) has been proposed for a sequence labeling problem and has been established by many as the state-of-the-art model for supervised named entity recognition task. In this section, we briefly summarize the pros and cons of each approach.

4.1.1 Hidden Markov Models

A hidden Markov model (HMM) is a probabilistic generative model for sequential data. HMM is characterized by 2 sets of model parameters — emission probabilities which produce the observation variable given the hidden state, and the state transition probability matrix which captures the temporal correlation in the hidden state sequences. Given a set of labeled training sequences as shown in Figure 1, one can train an HMM to model temporal statistics in the observation sequences. In our task, a sequence of word tokens from listing titles are our observations. One simple approach to use HMM is to set a hidden state to correspond to a tag class. In the training phase, since all the tags are given, the hidden states indeed become visible and inference in this model becomes much more simplified. The multinomial parameter for the emission probabilities $p(w|s)$ can be learned with a closed-form update (maximum likelihood estimate). During testing, however, an efficient forward-backward algorithm must be used to infer the most likely tag sequence that accounts for the observation.

One main drawback of HMM is the type of features that it can handle. Like other probabilistic generative models, in order to account for rich, overlapping feature sets, e.g. text formatting features, the correlation structures in the overlapping features must be explicitly modeled. Indeed, in the classic HMM based NER, the simple feature used is the word identity itself, which might not be sufficiently discriminative in distinguishing between different classes. In addition, because of data sparsity (out-of-vocabulary) problem due to the long-tailed distribution of words in natural language, sophisticated unknown word models are generally needed for good performance (Klein et al. 2003).

4.1.2 Maximum Entropy models

The principle of maximum entropy states that among all the distributions that satisfy feature constraints, we should pick the distribution with the highest entropy, since it makes the least assumption about the data and will have better generalization capability to unseen data. Maximum entropy classifier, therefore, is the highest entropy conditional distribution of the class label given features, which has been shown to conveniently take an exponential form. Maximum entropy classifier is thus closely related to logistic regression model.

Position Features:
- Position from the beginning of listing
- Position to the end of listing
Orthographic Features:
- Identity of the current word
- Current word contains a digit
- Current word contains only digits
- Current word is capitalized
- Current word begins with a capitalized letter followed by all non-cap letters.
- Current word is &
- Current word is £
- N-gram substring features of current word ($N = 4, 5, 6$)
Context Features:
- Identity of 2 words before the current word
- Identity of 2 words after the current word
- Previous word is *from*
- Previous word is *by*
- Previous word is *and*
- N-gram substring features of neighboring words ($N = 4, 5, 6$)
Dictionary Features:
- Membership to the 4 dictionaries of attributes
- Exclusive membership to dictionary of brand names
- Exclusive membership to dictionary of garment types
- Exclusive membership to dictionary of sizes
- Exclusive membership to dictionary of colors

Table 1: Feature set used in discriminative classifiers.

MaxEnt classifiers (Ratnaparkhi 1996; Ratnaparkhi 1998) have been applied to various NLP applications. The attraction of the framework lies in the ease with which different information sources used in the modeling process are combined and the good results that are reported with the use of these models. The set of redundant features used for the MaxEnt classifier is the same as those used for the SVM classifier, which we outline in the next section.

4.1.3 Support Vector Machines

Support Vector Machine (SVM) is yet another popular classifier for a supervised NER task. In a binary classification case, SVM finds parameters of a linearly separating hyperplane that best separates data from the 2 classes, in a sense that the margin of separation is maximized. Since only the samples closest to the decision boundary (the so-called support vectors) determine the location of the separating hyperplane, SVM can be trained on very few training examples even for data in a high-dimensional space. For our supervised NER system, we use the following features, as described in detail in Table 1, as input to the discriminative classifiers.

The use of char N-gram (N-gram substring) features was inspired by the work of (Klein et al. 2003), where the introduction of such features has been shown to improve the overall F1 score by over 20%. In (Kanaris et al. 2006), char N-gram features consistently outperform word features in learning effective spam classifiers. Indeed the use of character N-gram features as an input to the classifier subsumes the use of prefix, suffix, and the entire word features. Generally speaking, char N-gram features provide a more robust representation against misspelling since string $s1$ and its spelling variant $s2$ may share many char N-gram substrings in common.

POS and punctuation features are not used in our NER system. This is mainly due to the fact that eBay listing titles are not complete sentences and the output from running a POS tagger through such data can indeed be unreliable. For punctuation features, eBay sellers are known to abuse punctuation marks excessively to draw attention of the potential buyers to click on their listings. In addition, we find that morphological features are less predictive of entity names in eBay listing titles than they are in formal documents. To give a concrete example, capitalization is a good predictor of entity names in traditional NER systems, but on the eBay site, many sellers use all-cap or all-lowercase letters for every word in their titles, bringing into question the discriminative power of widely used features in traditional NER systems.

4.1.4 Viterbi Smoothing

The Viterbi algorithm can be used to smooth the prediction output from SVM or MaxEnt. More specifically, the Viterbi decoder enforces the temporal consistency on the individual label prediction as inferred by the base classifier — MaxEnt or SVM, independently based on the feature representation of each word token. The probabilistic ouput of the base classifier is the observation or evidence, while the temporal consistency is encoded in the empirical state transition probability matrix inferred from the training data. This scenario is analogous to comparing MAP (maximum a priori) estimate with that of ML (maximum likelihood) in that the former incorporates a prior belief when making a final estimate of the parameter values (most likely label sequence predicted by the Viterbi algorithm), while the latter uses only the observation to infer the most likely parameter estimate (independently inferred predicted labels of each word token from the base classifier).

We adopt the approach from the work of (Chieu and Ng 2003), which uses Viterbi to improve the classification results from MaxEnt classifier for NER tasks. Instead of computing the transition probability matrix by recording the frequency of how many times state i at time T transitions to state j at time $T+1$, we simply record that this state i to j transition is admissible. This approach, indeed, divides a set of all label sequences into ones that are admissible and inadmissible, and assign equal probabilities to all the admissible sequences. Such an approach therefore eliminates all the inadmissible sequences of labels (i.e. prohibit the scenario where *-in* sub-tag is followed by *-begin* sub-tag), while allowing the Viterbi algorithm to give more weight to the classification outputs from SVM or MaxEnt.

4.1.5 Conditional Random Field (CRF)

Conditional Random Field, since its conception in the seminal work of (Lafferty et al. 2002), is a discriminative classifier for sequential data that combines the best of both worlds. Like SVM and MaxEnt, CRF is a discriminative classifier that directly models the conditional distribution of the target variable given the observed variable, i.e. no modeling resource is wasted in modeling complex correlation structures in the observation sequences. Like HMM, CRF makes prediction on the label sequence by incorporating the temporal smoothness. Indeed CRF has been established by many as the state-of-the-art supervised named entity recognition system for traditional NER tasks (Feng and McCallum 2004; McCallum 2003), for NER in biomedical texts (Settles 2004), and in various languages besides English, such as Bengali (Ekbal et al. 2008) and Chinese (Mao et al 2008). Various modifications to CRF have recently been introduced to take into account of non-local dependencies (Krishnan and Manning 2006) or broader context beyond training data (Du et al. 2010).

4.2 Experimental Results

In this section, we compare the generative model based and discriminative model classifiers for supervised NER tasks. Given $1,000$ manually tagged listings from the clothing and shoes category in eBay, we adopt a 90-10 split and use 90% of the data for training and 10% for testing. Each listing title is tokenized into a sequence of word tokens, each manually assigned to one of the 5 tags: brand (*B*), size (*S*), color (*C*), garment type (*G*), and none of the above (*NA*). In order to more accurately capture the boundary of multi-token attribute values, we further sub-divide each tag into 2 classes using *-beg* and *-in* sub-tags. This step increases the number of classes that our classifier needs to handle from 5 to 9 classes given as follows: {*B-beg*, *B-in*, *C-beg*, *C-in*, *S-beg*, *S-in*, *G-beg*, *G-in*, and *NA*}.

	SVM	**MaxEnt**	**HMM**	**CRF**
w/o Viterbi	89.05%	87.64%	-	-
w/ Viterbi	**89.47%**	**88.13%**	**83.82**	**93.35%**

Table 2: Classification accuracy (%) on 9-class NER on men's clothing dataset, comparing SVM, MaxEnt, supervised HMM, and CRF.

Table 2 shows a comparison of classification accuracy from 4 classifiers — SVM, MaxEnt, HMM, and CRF. Supervised HMM, with the most simplistic feature, yields the baseline result at 83.82% accuracy. All the discriminative classifiers — CRF, MaxEnt, and SVM — outperform the baseline by HMM, with CRF improving on the baseline performance by the largest margin, concurring to other reports of its state-of-the-art results. Indeed, when using exactly the same set of features as SVM and MaxEnt, the performance of CRF indeed drops to 89.11%, which is on par with that of SVM and MaxEnt. However, when restricting to using dictionary and word identity features, the performance of CRF improves, indicating the importance of feature selection to such model. SVM and MaxEnt yield similar performance with SVM slightly outperforming MaxEnt classifier by 1.6%. The incorporation of temporal smoothness constraint enforced by the Viterbi algorithm slightly improves the label sequence prediction (comparing row 1 and row 2 in Table 2).

The HMM implementation used in our experiments is the Hunpos tagger in (Halacsy et al. 2007), which captures the state transitional probabilities using second-order Markov model. For SVM, we use the popular libSVM package (Chang and Lin 2001) which produces probabilistic output from fitting a sigmoid function to the distances between samples and the separating hyperplane. We use linear kernel in our experiments, although RBF kernel with grid search for optimal parameters yield slightly superior

performance, with a significantly higher computational cost. The MaxEnt implementation used in our experiment is the version available from the NLTK toolkit, with BFGS optimizer. For CRF, we use the linear-chain CRF model available from the Mallet package[1].

5 Bootstrapping for Dictionary Expansion

The supervised learning approach assumes the existence of an annotated set of training data. Often times, training data must be painstakingly marked up and collecting large-scale labeled training examples can be very costly. In recent years, more and more research effort has been focused on how to leverage a vast amount of unlabeled data in a semi-supervised or entirely unsupervised fashion for NER as well as for other similar NLP tasks, e.g. POS tagging, sentence boundary detection, and word sense disambiguation (Riloff 1999; Ghani and Jones 2002; Probst et al. 2006; Brody and Elhadad 2010; Haghighi 2010).

One way to incorporate a vast amount of unlabeled data is to learn a clustering of words that assigns syntactically similar words to the same clusters. Popular clustering algorithms used prevalently in many NER systems are, for example, the combination of distributional and morphological similarity work of (Clark 2003) or the classic N-gram language model based clustering algorithm of (Brown et al. 1992). In such a system, when training an NER classifier, we introduce a word cluster id as an additional feature in the input, with the hope that the model will pick out clusters that are highly indicative of each class. When encountering words that are out-of-vocabulary (OOV) in the test set, if those words are assigned the same cluster membership as some other words in the training set, the cluster feature will fire, allowing for correct classification results to be obtained (Lin and Wu 2009; Faruqui and Pado 2010).

5.1 Growing Seed Dictionary

In this work, we focus on the problem of how to grow the seed dictionary and discovering new brand names from eBay listing data. While the performances of supervised NER classifiers as described in sections 4.1.1-4.1.5 are satisfactory, in practice, however, especially with a small training set size, we often find that the trained model puts too much weight on the dictionary membership feature and new attribute values are not properly detected. In this section, instead of using the seed list of known attribute values as a feature into a classifier, we use the seed values to automatically generate labeled training data. For the specific case of brand discovery, this initial list used to generate training data must contain only names that are unambiguously brands. We hence remove ambiguous names or phrases that belong to multiple attribute types from the list, such as *jumpers*(both a brand name and a garment type), or (ii) *camel* is a short name of brand *Camel active* as well as a color, or (iii) *lrg* is an acronym for a brand as well as an acronym for large which specifies size.

The training/test data is generated by matching N-gram tokens in listing titles to all the entries in the initial brand seed dictionary. Following the convention in (Minkov et al. 2005), we use the following set of 5 tags, (1) one-token entity (B1 tag) (2) first token of a multi-token entity (Bo tag for Brand-open) (3) last token of a multi-token entity (Bc tag for Brand-close) (4) middle token of a multi-token entity (Bi tag for Brand-inside) (5) token that is not part of a brand entity (NA tag). The listings with at least one non-NA tags are put in the training set, and listings that contain only NA tags are in the test set. Similar to the acronym expansion algorithm of (Pakhomov 2002) which learns contexts that associate acronyms to their correct expansions, the intuition behind our work in this section is that the classifier, trained on a labeled training set of known brands, learns context patterns that can discriminate the current word as being a brand (more precisely as part of a brand) from the other attribute types, which are now lumped together as *NA*.

5.2 Experiments

In the first experiment, a set of $72,628$ listings from the women's clothing category is partitioned into a training set of $39,448$ listings and test set of $33,180$ listings based on an initial seed list of known $6,312$ women's apparel brands manually prepared by our fashion experts. The partitioning is done, as described in great detail above, in such a way that known brands in the seed list do not exist in the

Table 3: Discovered attribute values, ranked order by their confidence scores. (Left) Discovered brands from Women's clothing category. We use 6,312 brands as seed values. (Middle) Discovered brands from Men's clothing category, with 3,499 seed values used. (Right) Discovered garment types (styles) from Men's clothing category, learned from 203 seed values.

test data (using exact string matching criterion). We train a 5-class MaxEnt classifier and adopt the same feature sets as described in Section 4.1.3. During the test phase, the classifier predicts the most likely brand attribute from each listing, where we are only interested in the predictions with confidence scores exceeding a set threshold. We ranked order the predicted brands by their confidence scores (probabilities) and the top 300 unique brands are selected. We manually verify the 300 predicted brands and found that 90.33% of the predicted brands are indeed names of designers or women's apparel stores (true positive), resulting a precision score of 90.33%.

Indeed, the precision score presented above is obtained using an exact matching criterion where partial extraction of a brand is regarded as a miss, i.e. our extractor extracts only *Calvin* when *Calvin Klein* is present in the listing (false positive). The left column of Table 3 shows examples of newly discovered brands from Women's clothing category. Many of these newly discovered brands are indeed misspelled versions of the known brands in the seed dictionary.

The middle column of Table 3 shows a set of Men's clothing brands learned automatically from a similar experiment conducted on a set of $105,335$ listings from Men's clothing category. Using an initial set of $3,499$ known brand seeds, we partition the dataset into a training set of $67,307$ listings and a test set of $38,028$ listings (for later reference we refer to this test set as set A). Based on the top 200 predicted brands, 179 of which are verified as being true positive samples, resulting in 89.5% precision. We carry out a similar experiment to grow the seed dictionary for garment type, and are able to identify the top 60 new garment types. 54 out of 60 are true positive samples, resulting in precision score = 90%. Examples of the newly discovered garment types are shown in Table 3 (right column), where abbreviated forms of garment types such as *jkt* (short for jacket) and *pjs* (short for pajamas) are also discovered through our algorithm.

Seed list	Test set 1	Test set 2
Orig. seeds	83.56%	90.02%
Orig. seed + 200 new brands	92.75%	93.66%

Table 4: NER Accuracy on 2 test sets as the seed dictionary for brands grows. Results shown here are obtained the same Men's clothing category dataset, as used to show the supervised NER results in Table 2.

By adding these newly discovered attributes back to the dictionary, we can now re-evaluate our supervised NER system from section 4 with the grown seed list. To this end, we construct 2 test sets from the same $105,335$ listings of Men's clothing category as used in Section 4. Test set 1 is a set of 500 listings randomly sampled from the $38,028$-listing subset known not to contain any brands in the original brand seed dictionary (set A). As seen in Table 4, an improvement of 9% in accuracy results from the use of the grown seed list. Since this dataset is known to not contain any brands from the original brand seed dictionary, the addition of 200 new brands solely accounts for all the accuracy boost. Test set 2 is constructed slightly differently by randomly sampling 500 listings from the entire $105,335$ listings of Men's clothing category. As seen in Table 4, a smaller improvement of 3.7% is observed.

6 Normalization

With the above described brand discovery algorithm, the newly discovered brands from the test set can be grouped into 2 categories — (i) misspelling, spelling

invariants, abbreviated forms of known brands in the seed list or (ii) novel brands or clothing/shoes designers, which are not members of the original seed list. Normalizing the variants of a known brand to a single normalized output value is an important aspect of our attribute extraction algorithm, as these variants account for over 20% of listings in the eBay clothing and shoes category. When gathering business/marketing intelligence, missing out on 20% of the data could skew the calculation of supply, demand, and pricing metrics, and eventually lead to the wrong policy decision made.

The problem of alternate spellings of names has been addressed in the database community successfully using fuzzy string matching algorithms e.g. Soundex or string edit distance. In this work, since the attribute values are often partially extracted, i.e. a word in a multi-word phrase is extracted, in order to match to the correct normalized value, we must investigate robust substring matching algorithms suitable for partial matching. To this end, we explore 2 string similarity/distance measures for normalizing the extracted attributes. First, we investigate n-gram similarity measures defined as the number of shared character n-grams, i.e. substrings of length n (Kondrak 2005). More specifically, a string similarity measure between $s1$ and $s2$ is defined as the percentage of common substrings of length n (out of all substrings of length n). This similarity measure is quite robust to partial matching, as a two-word phrase can appear out of order while most of the character n-grams, where n = 3, remain virtually unchanged. Certainly, finding the right value of n will greatly impact the matching performance of the algorithm. In our experiment, we find the optimal n for brands to be 3 and 4. Table 5 shows a few examples of normalized outputs as a result of finding the best match for the extracted brand names from among a set of predefined normalized values. When the best matching score falls below a threshold, we declare no match is found and classify the extracted brand as a new brand.

Another distance measure that we explore is the Jaro-Winkler distance. Designed to be more suitable for matching short strings such as people's names, Jaro-Winkler distance is defined based on the number of character transpositions and the number of matching characters. In addition, a prefix scale p parameter is used and can be tuned to weigh more favorably on strings that match from the beginning for a set prefix length. In our experiments with brand normalization, over 50% of the matches from the Jaro-Winkler distance are, however, identified as being incorrect.

7 Conclusion

In this work, we have described an information extraction system for applications in the domain of inventory/business Intelligence. The goal is given an eBay listing title, our system correctly extracts the defining attributes in order to associate each item to a specific product. We investigate and compare several supervised NER systems — supervised HMM, SVM, MaxEnt, and CRF — and found SVM and MaxEnt with Viterbi decoding to yield the best performance. Focusing on the clothing and shoes categories on eBay's site, we presented a bootstrapped algorithm that can identify new brand names corresponding to (1) spelling invariants or typographical errors of the known brands in the seed list and (2) novel brands or designers. Our attribute extractor correctly discovers new brands with over 90% precision on multiple corpora of listings. To output normalized attribute values, we explore several fuzzy string comparison algorithms and found n-gram substring matching to work well in practice.

8 Acknowledgment

The authors would like to thank Nalini Johnas and Padmanaban Ramasamy for their help in gathering listing data used in all of our experiments.

Abstract

With the recent rise in popularity and scale of social media, a growing need exists for systems that can extract useful information from huge amounts of data. We address the issue of detecting influenza epidemics. First, the proposed system extracts influenza related tweets using Twitter API. Then, only tweets that mention actual influenza patients are extracted by the support vector machine (SVM) based classifier. The experiment results demonstrate the feasibility of the proposed approach (0.89 correlation to the gold standard). Especially at the outbreak and early spread (early epidemic stage), the proposed method shows high correlation (0.97 correlation), which outperforms the state-of-the-art methods. This paper describes that Twitter texts reflect the real world, and that NLP techniques can be applied to extract only tweets that contain useful information.

1 Introduction

Twitter[1], a popular micro-blogging service, has received much attention recently. It is an online network used by millions of people around the world to stay connected to their friends, family members, and co-workers through their computers and mobile telephones (Milstein et al., 2010).

Nowadays, Twitter users have increased rapidly. Its community estimated as 120 million worldwide, posts more than 5.5 million messages (*tweets*) every day (reported by Twitter.com in March 2011). Twitter can potentially serve as a valuable information resource for various applications. Huberman et al. (2009) analyzed the relations among friends. Boyd et al. (2010) investigated commutation activity. Sakaki et al. (2010) addressed the detection of earthquakes. Among the numerous potential applications, this study addresses the issue of detecting influenza epidemics, which presents two outstanding advantages over current methods.

- **Large Scale**: More than a thousand messages include the word "*influenza*" each day (Nov. 2008 – Oct. 2009). Such a huge data volume dwarfs traditional surveillance resources.

- **Real-time**: Twitter enables real-time and direct surveillance. This characteristic is extremely suitable for influenza epidemic detection because early stage detection is important for influenza warnings.

Although Twitter based influenza warnings potentially offer the advantages noted above, it might also expose inaccurate or biased information from tweets like the following (brackets **[]** indicate the comments):

- *Headache? You might have **flu.*** **[Suspicions]**
- *The World Health Organization reports the avian influenza, or bird **flu**, epidemic has spread to nine Asian countries in the past few weeks.* **[General News]**

[1] http://twitter.com/

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1568–1576,
Edinburgh, Scotland, UK, July 27–31, 2011.

- *Are you coming down with **influenza**?* **[Question]**

Although these tweets include mention of "*influenza*" or "*flu*", they do not indicate that an influenza patient is present nearby. We regard such messages (merely suspicions/questions, general news, etc.) as **negative influenza tweets**. We call others **positive influenza tweets**. In our experiments, 42% of all tweets that include "*influenza*" are negative influenza tweets. The huge volume of such negative tweets biases the results.

This paper presents a proposal of a machine-learning based classifier to filter out negative influenza tweets. First, we build an annotated corpus of pairs of a tweet and positive/negative labels. Then, a support vector machine (SVM) (Cortes and Vapnik, 1995) based sentence classifier extracts only positive influenza tweets from tweets. In the experiments, the results demonstrated the high correlation (0.89 of the correlation), which is equal performance to that of the state-of-the-art method.

The specified research point of this study is two-fold:

(1) This report describes that an SVM-based classifier can filter out the negative influenza tweets (*f*-measure=0.76).
(2) Experiments empirically demonstrate that the proposed method detects the influenza epidemics with high accuracy (correlation ratio=0.89): it outperforms the state-of-the-art method.

2 Influenza Epidemic Detection

The detection of influenza epidemics is a national mission in every country for two reasons.

(1) Anti-influenza drugs, which differ among influenza types, must be prepared before the epidemics.
(2) We can only slightly predict what type of influenza will spread in any given season.

This situation naturally demands the early detection of influenza epidemics. This section presents a description of previous methods of influenza epidemic detection.

2.1 Traditional Approaches

Most countries have their own influenza surveillance organization/center: the U.S. has the Centers for Disease Control and Prevention (CDC)[2], the E.U. has its European Influenza Surveillance Scheme (EISS), and Japan has its Infection Disease Surveillance Center (IDSC). Their surveillance systems fundamentally rely on both virology and clinical data. For example, the IDSC gathers influenza patient data from 5,000 clinics and releases summary reports. Such manual systems typically have a 1–2 week reporting lag. This time lag is sometimes pointed out as a major flaw.

2.2 Recent Approaches

In an attempt to provide earlier influenza detection, various new approaches are proposed each year.

Espino et al. (2003) described a telephone triage service, a public service, to give advice to users via telephone. They investigated the number of telephone calls and reported a significant correlation with influenza epidemics.

Magruder (2003) used the amount of over-the-counter drug sales. Because an influenza patient usually requires anti-influenza drugs, this approach is reasonable. However, in most countries, anti-influenza drugs are not available at the drug store (only hospitals provide such drugs).

The state-of-the-art approach is that proposed by Ginsberg et al. (2009). They used Google web search queries that correlate with an influenza epidemic. Their approach demonstrated high accuracy (average correlation ratio of 0.97; min=0.92; max=0.99)[3]. Several research groups have used similar approaches. Polgreen et al. (2008) used a Yahoo! query log. Hulth et al. (2009) used a query log of a Switzerland web search engine.

Although the above approaches use different information, they share the same approach, which is to observe patient actions directly. This approach was sufficient to obtain more numerous data than traditional services. Nevertheless, such information is unfortunately limited only to the service provider. For example, web search queries are available only for several companies: Google, Yahoo!, and Microsoft.

This paper examines Twitter data, which are widely available. Note that Paul and Dredze (2011) also propose a similar Twitter based approach. While they focus on a word distribution, this paper

[2] http://www.cdc.gov/flu/weekly/
[3] Their service is available at http://www.google.org/flutrends/ (Google Flu Trend).

employs a sentence classification (discrimination of negative influenza tweets).

3 Influenza Corpus

As described in Section 1, it is necessary to filter out **negative influenza tweets** to infer precise amounts of influenza epidemics. To do so, we constructed the influenza corpus (Section 3). Then, we trained the SVM-based classifier using the corpus (Section 4).

The corpus comprises pairs of sentences and a label (positive or negative). Several examples are presented in Table 1. This corpus was built using the following procedure.

3.1 Influenza Tweet

First, we collected 300 million tweets, starting from 2008 November to 2010 June, via Twitter API. Crawling results are presented in Figure 1. We extracted only influenza-related tweets using a simple word look-up of "*influenza*". This operation gave us 0.4 million tweets. We separated the data into two data groups.

Training Data are 5,000 tweets sent in November 2008. These were annotated by human annotators, and were then used for training.

Test Data are the other data. They were used in experiments of influenza epidemics detection. Because of the three dropout periods (Figure 1), the test data were separated into four periods (winter 2008, summer 2009, winter 2009, and summer 2010).

3.2 Positive–negative Annotation

To each tweet in the training dataset, a human annotator assigned one of two labels: positive or negative. In this labeling procedure, we regarded a tweet that meets the following two conditions as positive data.

Condition 1 (A Tweet person or Surrounding persons have Flu): one or more people who have influenza should exist *around* the tweet person. Here, we regard "*around*" as a distance in the same city. In cases in which the distance is unknown, we regard it as negative. Because of this annotation policy, the re-tweet type message is negative.

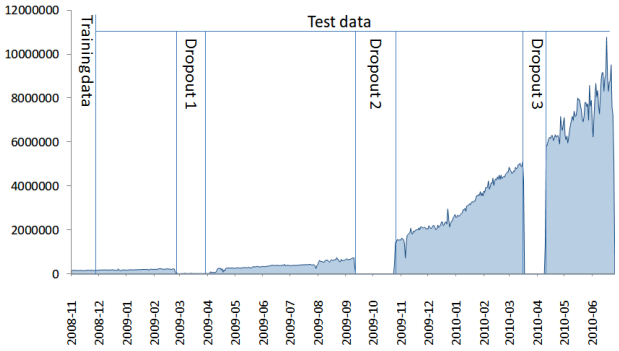

Figure 1: Twitter Data used in this Study.
The data include three dropout periods because the Twitter API specifications changed in those periods. The dropout periods were removed from evaluation in the experiments (Section 5).

Table 1: Corpus (Tweets with a Positive or Negative Label)

Positive(+1)/ Negative(-1)	Tweet
+1	A bad influenza is going around in our lab.
+1	I caught the flu. I was burning up.
+1	I think I'm coming down with the flu.
+1	It's the flu season. I had it and now he do es.
+1	Don't give me the flu. (Nearby people have the flu)
+1	My flu is worse than it was yesterday.
-1	In the normal flu season, 80 percent of deaths occur in people over 65 (Simply a fact)
-1	Influenza is now raging throughout Japan. (Too general.)
-1	His wife also contracted the bird flu, but has recovered. (Where is his wife?)
-1	You might have the flu. Has anyone around you had it? (Where are you?)
-1	Bird flu damage is spreading in Japan. (Too general.)

"+1" indicates a positive influenza tweet. "-1" indicates a negative influenza tweet. The case arc "()" indicates the reason for the positive or negative annotation.

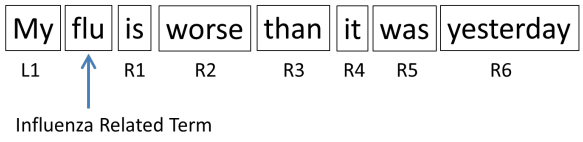

Figure 2: Feature Representation.
The word boundary is detected by a morph analyzer JUMAN[4].

[4] http://nlp.kuee.kyoto-u.ac.jp/nl-resource/juman.html

Condition 2 (Tense/Modality): The tense should be the present tense (current) or *recent past*. Here, we define the "*recent past*" as the prior 24 hour period (such as "*yesterday*"). The sentence should be affirmative (not interrogative and not subjunctive).

4 Influenza Positive–negative Classifier

Using the corpus (Section 3), we built a classifier that judges whether a given tweet is positive or negative. This task setting is similar to a sentence classification (such as spam e-mail filtering, sentiment analysis, and so on). We used a popular means for sentence classification, which is based on a machine learning classifier under the bag-of-words (BOW) representation (Figure 2). The parameters were investigated in preliminary experiments in terms of feature window size (Section 4.1) and machine-learning methods (Section 4.2). These preliminary experiments were conducted under the ten-fold cross variation manner using the training set.

4.1 Feature (window size)

Performance was dependent on the window size (the number of left/right side words). Figure 3 depicts the performance obtained using various window sizes. The best performance was scored at the BOTH=6 setting. Therefore, this window size was used for the following experiments. These results also indicated that entire sentences (BOTH=∞) are unsuitable for this task.

4.2 Machine Learning Method

We compared various machine-learning methods from two points of view: accuracy and time. The result, presented in Table 2, shows that SVM with a polynomial kernel showed feasibility from both viewpoints of accuracy and the training time.

5 Experiments

We assessed the detection performance using actual influenza reports provided by the Japanese IDSC.

5.1 Comparable Methods

We compared the various methods as follows:

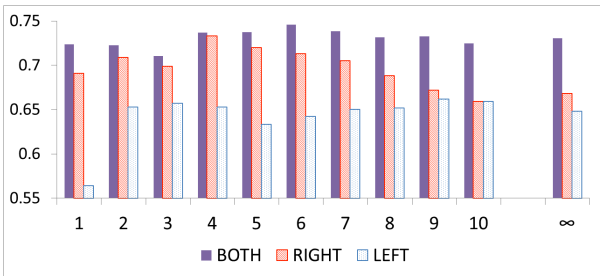

Figure 3: Window size and Accuracy (*F*-measure). RIGHT shows a method used only the right context. LEFT shows a method used only the left context. BOTH represents a method using both the right and left context. The number shows the window size. ∞ uses all words in each context direction.

Classifier	F-Measure	Training Time (sec)
AdaBoost (Freund 1996)	0.592	40.192
Bagging (Breiman 1996)	0.739	30.310
Decision Tree (Quinlan1993)	0.698	239.446
Logistic Regression	0.729	696.704
Naive Bayes	0. 741	**7.383**
Nearest Neighbor	0.695	22.441
Random Forest (Breiman 2001)	0.729	38.683
SVM (RBF kernel) (Cortes and Vapnik 1995)	0.738	92.723
SVM (polynomial kernel; d=2)	**0.756**	13.256

Table 2: Machine Learning Methods and Performance (*F*-measure and Training Time)

- **`TWEET-SVM`**: The proposed SVM-based method (window size = 6).
- **`TWEET-RAW`**: A simple frequency-based method. This approach outputs the relative frequency of word "*influenza*" appearing in Twitter.
- **`DRUG`**: The amounts of drug sales (sales of cold medicines). Statistics are provided by the Japanese Ministry of Health, Labor and Welfare.
- **`GOOGLE`**: Google flu trend detection (Japanese version). This method uses a query log of the Google search engine (Ginsberg et al., 2009)[5].

[5] http://www.google.org/flutrends/

5.2 Gold Standard and Test-Set

For gold standard data, we used data that are described in Section 2, as reported from IDSC. The report is released once a week. Therefore, the evaluation is done on a weekly basis.

We split the data into four seasons as follows:

- Season I: winter 2008,
- Season II: summer 2009,
- Season III: winter 2009,
- Season IV: summer 2010.

To investigate further detailed evaluations, we split the winters into two sub-seasons: **before the peak** and **after the peak**. We regard the peak point as the day with the highest number in that season. The statistics derived from the data are presented in Table 3.

Excessive News Period: In our experimental data, Season II and the earlier peak of Season III are special periods because news related to swine flu (H1N1 flu) is extremely hot in those seasons (Fig. 4). This paper calls them **Excessive News Periods**. We also investigated the results with and without the excessive news period.

Figure 4: A CNN news on "swine flu" in June 2009 (Season II in our experiment).

Experimental data include such excessive news periods.

5.3 Evaluation Metric

The evaluation metric is based on correlation (Pearson correlation) between the gold standard value and the estimated value.

5.4 Result

The results are presented in Table 4. In the non-excessive news period, the proposed method achieved the highest performance (0.890 correlation). This correlation is considerably higher than the query-based approach (**GOOGLE**), demonstrating the basic feasibility of the proposed approach. However, during the excessive news periods, the proposed method suffers from an avalanche of news, generating a news bias. This phenomenon is a remaining problem to be resolved in future studies.

6 Discussion

6.1 SVM-based Negative Filtering contributes to Performance

In most seasons, the proposed SVM approach (**TWEET-SVM**) shows higher correlation than the simple word lookup method (**TWEET-RAW**). The average improvement is 0.196 (max 0.56; min-0.009), which significantly boosts the correlation. This result demonstrates the basic feasibility of the proposed approach. In the future, more advantages attributable to the proposed approach can be obtained if the classification performance improves.

6.2 All Methods Suffer from News Bias in Excessive News Period

All methods expose the poor performance that prevails during the excessive news period (from Season II to Season III before the peak). Especially, tweet-based methods show dramatically reduced correlation, which indicates that Twitter is vulnerable to newswire bias.

One reason for that vulnerability is that Twitter is a kind of communication tool by which a tweet affects other people. Consequently, the possibility exists that a few tweets related to "flu" might spread widely, generating an explosive burst of influenza-related tweets. Future studies must address this burst phenomenon.

	After peak	**0.960**	**0.944**	0.364	**0.936**
Season IV		0.391	**0.957**	0.130	**0.976**

Table 4: Results (Correlation Ratio).
The number in bold indicates the significance correlation (p=0.05). The number with underline indicates the highest value in each season.

6.3 Tweets have Advantages in Early Stage Detection

From practical viewpoints, the most important task is to detect influenza epidemics before the peak (early stage detection). Consequently, the correlation of the two seasons, Season I before the peak and Season III before the peak, presents the practical performance. Figure 5 portrays detailed results of all methods.

In Season I before the peak (Figure 5 Left), the proposed method (TWEET-SVM) shows the best performance among all methods.

In Season II before the peak (Figure 5 Right), all methods including the proposed method showed poor correlation because they are included in the excessive news periods. During that season, the newswires heavily reported the swine flu twice (April 2009 and May 2009). Because of this news, we can see two peaks in Twitter-based methods (TWEET-SVM and TWEET-RAW), which indicates that Twitter is more sensitive to the newswires.

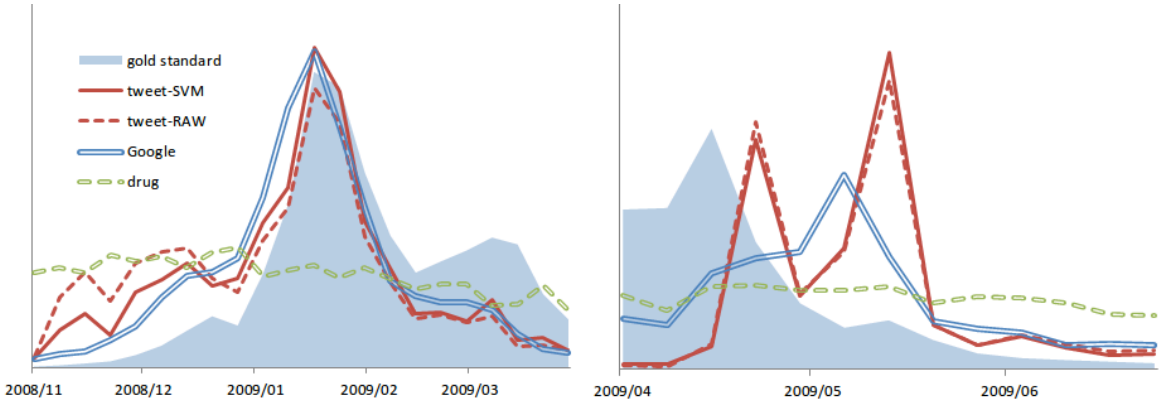

Figure 5: Predicted Values in Season I (Left) and Season II (Right):
the X-axis shows the date; the Y-axis shows the relative predicted value using each method.

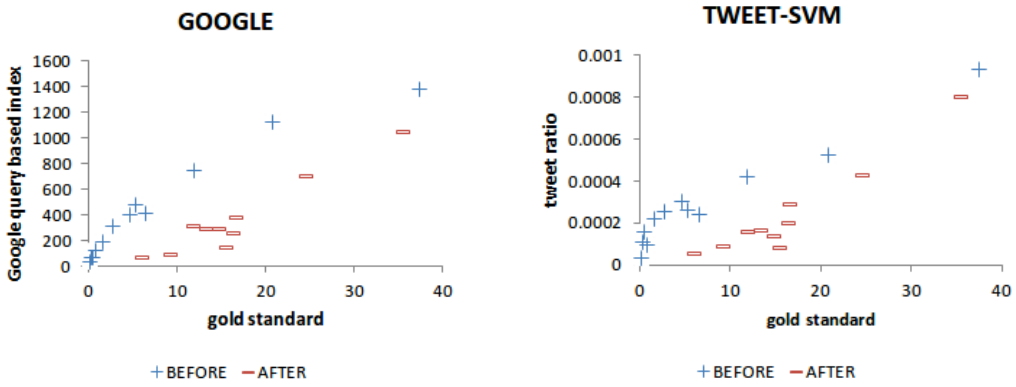

Figure 6: Patient Actions (Web Search Query and Tweet) is Sensitive before the Epidemic Peaks.
Distribution between the gold standard and Detected Values (Search Engine Query (Left) and Tweet (Right)): "+" denotes the distribution before the peak; "-" denotes the distribution after the peak.

6.4 Human Action is Sensitive before Epidemics

Figure 6 presents the distribution between the detected values (using **GOOGLE** and using **TWEET-SVM**) and the gold standard value (before the peak is shown by "+"; that after the peak is shown as "-"). Although the detected values fundamentally correlate with the gold standard, we can see different sensitivity before and after peak (The distribution before peak "+" is a higher value than after peak "-".).

Results show that human action, a web search (**GOOGLE**) and a tweet (**TWEET-SVM**), highly corresponds to the real influenza before the epidemic peaks, and vice versa. More acute detection is possible if we incorporate a model considering this aspect of human nature.

7 Related Works

The core technology of the proposed method is to classify whether the event is positive or negative. This task is similar to negation identification, which is a traditional topic, especially in medical fields. Therefore, we can find many previous studies of the topic in the relevant literature. An algorithm based approach, *NegEx* (Chapman et al., 2001), *Negfinder* (Mutalik et al., 2001), and *ConText* (Chapman et al., 2007), a machine learning based approach (Elkin et al., 2005; Huang and H.J. Lowe, 2007).

	Previous Negation (Syntactic)	This study: Negative Influenza (Semantic)
I caught a flu.	Positive sentence	Positive Influenza
I don't have the flu!	Negative sentence	Negative Influenza
I have enough flu drugs.	Positive sentence	Negative Influenza
I have not recovered from the flu.	Negative sentence	Positive Influenza

Table 5: Our target influenza negation (semantic) and previous negation (syntactic)

Although these approaches specifically examine the syntactic negation, this study detects the negative influenza, which is a specified semantic negation. Table 5 presents the difference between both negations. In general, the semantic operation is difficult in general. However, this paper revealed that the domain (influenza domain) specific semantic operation provides reasonable results.

Another aspect of this study is the target material, Twitter data, which have drawn much attention. Twitter can provide suitable material for many applications such as named entity recognition (NER) (Finin et al., 2010) and sentiment analysis (Barbosa and Feng, 2010). Although these studies specifically examine the fundamental NLP techniques, this study directly targets an NLP application that can contribute to our daily life.

8 Conclusion

This paper proposed a new Twitter-based influenza epidemics detection method, which relies on the Natural Language Processing (NLP). Our proposed method could successfully filter out the negative influenza tweets (*f*-measure=0.76), which are posted by the ones who did not actually catch the influenza. The experiments with the test data empirically demonstrate that the proposed method detects influenza epidemics with high correlation (correlation ratio=0.89), which outperforms the state-of-the-art Google method. This result shows that Twitter texts precisely reflect the real world, and that the NLP technique can extract the useful information from Twitter streams.

A Simple Word Trigger Method for Social Tag Suggestion

Zhiyuan Liu, Xinxiong Chen and **Maosong Sun**

Abstract

It is popular for users in Web 2.0 era to freely annotate online resources with tags. To ease the annotation process, it has been great interest in automatic tag suggestion. We propose a method to suggest tags according to the text description of a resource. By considering both the description and tags of a given resource as summaries to the resource written in two languages, we adopt word alignment models in statistical machine translation to bridge their *vocabulary gap*. Based on the translation probabilities between the words in descriptions and the tags estimated on a large set of description-tags pairs, we build a word trigger method (WTM) to suggest tags according to the words in a resource description. Experiments on real world datasets show that WTM is effective and robust compared with other methods. Moreover, WTM is relatively simple and efficient, which is practical for Web applications.

1 Introduction

In Web 2.0, Web users often use tags to collect and share online resources such as Web pages, photos, videos, movies and books. Table 1 shows a book entry annotated with multiple tags by users[1]. On the top of Table 1 we list the title and a short introduction of the novel "The Count of Monte Cristo". The bottom half of Table 1 shows the annotated tags, each of which is followed by a number in bracket, the total number of users who use the tag to annotate this book. Since the tags of a resource are annotated collaboratively by multiple users, we also name these tags as *social* tags. For a resource, we refer to the additional information, such as the title and introduction of a book, as *description*, and the user-annotated social tags as *annotation*.

Description
`Title:` The Count of Monte Cristo
`Intro:` *The Count of Monte Cristo* is one of the most popular fictions by Alexandre Dumas. The writing of the work was completed in 1844. ...
Annotation
Dumas (2748), Count of Monte Cristo (2716), foreign literature (1813), novel (1345), France (1096), classic (1062), revenge (913), famous book (759), ...

Table 1: An example of social tagging. The number in the bracket after each tag is the total count of users that annotate the tag on this book.

Social tags concisely indicate the main content of the given resource, and potentially reflect user interests. Social tagging has thus been widely studied and successfully applied in recommender systems (Eck et al., 2007; Yanbe et al., 2007; Zhou et al., 2010), trend detection and tracking (Hotho et al., 2006), personalization (Wetzker et al., 2010), advertising (Mirizzi et al., 2010), etc.

The task of automatic social tag suggestion is to automatically recommend tags for a user when he/she wants to annotate a resource. Social tag suggestion, as a crucial component for social tagging systems, can help users annotate resources. Moreover, social tag suggestion is usually considered as an equivalent problem to modeling social

[1]The original record is obtained from the book review website Douban (`www.douban.com`) in Chinese. Here we translate it to English for comprehension.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1577–1588,
Edinburgh, Scotland, UK, July 27–31, 2011.

tagging behaviors, which is playing a more and more important role in social computing and information retrieval (Wang et al., 2007).

Most online resources contain descriptions, which usually contain much resource information. For example, on a book review website, each book entry contains a title, the author(s) and an introduction of the book. Some researchers thus propose to automatically suggest tags based on resource descriptions, which are collectively known as the *content-based approach*.

One may think to suggest tags by selecting important words from descriptions. This is far from enough because descriptions and annotations are using diverse vocabularies, usually referred to as a *vocabulary gap* problem. Take the book entry in Table 1 for instance, the word "popular" used in the description contrasts the tags "classic" and "famous book" in the annotation; the word "novel" is used in the description, while most users annotate with the tag "fiction". The vocabulary gap usually reflects in two main issues:

- Some tags in the annotation do appear in the corresponding description, but they may not be statistically significant.

- Some tags may even not appear in the description.

It is not trivial to reduce the vocabulary gap and find the semantic correspondence between descriptions and annotations. By regarding both the description and the annotation as *parallel* summaries of a resource, we use word alignment models in statistical machine translation (SMT) (Brown et al., 1993) to estimate the translation probabilities between the words in descriptions and annotations. SMT has been successfully applied in many applications to bridge vocabulary gap. For detailed descriptions of related work, readers can refer to Section 2.2. In this paper, besides employing word alignment models to social tagging, we also propose a method to efficiently build description-annotation pairs for sufficient learning translation probabilities by word alignment models.

Based on the learned translation probabilities between words in descriptions and annotations, we regard the tagging behavior as a word trigger process:

1. A user reads the resource description to realize its substance by seeing some important words in the description.

2. Triggered by these important words, the user translates them into the corresponding tags, and annotates the resource with these tags.

Based on this perspective, we build a simple word trigger method (WTM) for social tag suggestion. In Fig. 1, we use a simple example to show the basic idea of using word trigger for social tag suggestion. In this figure, some words in the first sentence of the book description in Table 1 are triggered to the tags in annotation.

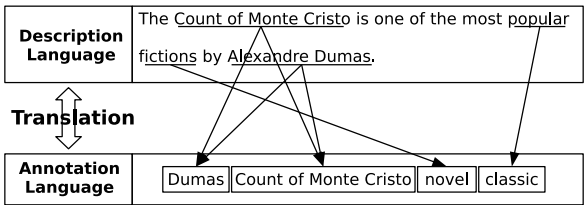

Figure 1: An example of the word trigger method for suggesting tags given a description.

2 Related Work

2.1 Social Tag Suggestion

Previous work has been proposed to automatic social tag suggestion.

Many researchers built tag suggestion systems based on *collaborative filtering* (CF) (Herlocker et al., 1999; Herlocker et al., 2004), a widely used technique in recommender systems (Resnick and Varian, 1997). These collaboration-based methods typically base their suggestions on the tagging history of the given resource and user, without considering resource descriptions. FolkRank (Jaschke et al., 2008) and Matrix Factorization (Rendle et al., 2009) are representative CF methods for social tag suggestion. Most of these methods suffer from the *cold-start problem*, i.e., they are not able to perform effective suggestions for resources that no one has annotated yet.

The content-based approach for social tag suggestion remedies the cold-start problem of the

collaboration-based approach by suggesting tags according to resource descriptions. Therefore, the content-based approach plays an important role in social tag suggestion.

Some researchers regarded social tag suggestion as a classification problem by considering each tag as a category label (Ohkura et al., 2006; Mishne, 2006; Lee and Chun, 2007; Katakis et al., 2008; Fujimura et al., 2008; Heymann et al., 2008). Various classifiers such as Naive Bayes, kNN, SVM and neural networks have been explored to solve the social tag suggestion problem.

There are two issues emerging from the classification-based methods:

- The annotations provided by users are noisy, and the classification-based methods can not handle the issue well.
- The training cost and classification cost of many classification-based methods are usually in proportion to the number of classification labels. These methods may thus be inefficient for a real-world social tagging system, where hundreds of thousands of unique tags should be considered as classification labels.

Inspired by the popularity of latent topic models such as Latent Dirichlet Allocation (LDA) (Blei et al., 2003), various methods have been proposed to model tags using generative latent topic models. One intuitive approach is assuming that both tags and words are generated from the same set of latent topics. By representing both tags and descriptions as the distributions of latent topics, this approach suggests tags according to their likelihood given the description (Krestel et al., 2009; Si and Sun, 2009). Bundschus et al. (2009) proposed a joint latent topic model of users, words and tags. Iwata et al. (2009) proposed an LDA-based topic model, Content Relevance Model (CRM), which aimed at finding the content-related tags for suggestion. Empirical experiments showed that CRM outperformed both classification methods and Corr-LDA (Blei and Jordan, 2003), a generative topic model for contents and annotations.

Most latent topic models have to pre-specify the number of topics before training. We can either use cross validation to determine the optimal number of topics or employ the infinite topic models, such as Hierarchical Dirichlet Process (HDP) (Teh et al., 2006) and nested Chinese Restaurant Process (Blei et al., 2010), to automatically adjust the number of topics during training. Both solutions are usually computationally complicated. What is more important, topic-based methods suggest tags by measuring the topical relevance of tags and resource descriptions. The latent topics are of concept-level which are usually too general to precisely suggest those specific tags such as named entities, e.g., the tags "Dumas" and "Count of Monte Cristo" in Table 1. To remedy the problem, Si et al. (2010) proposed a generative model, Tag Allocation Model (TAM), which considers the words in descriptions as the possible topics to generate tags. However, TAM assumes each tag can only have at most one word as its reason. This is against the fact that a tag may be annotated triggered by multiple words in the description.

It should also be noted that social tag suggestion is different from automatic keyphrase extraction (Turney, 2000; Frank et al., 1999; Liu et al., 2009a; Liu et al., 2010b; Liu et al., 2011). Keyphrase extraction aims at selecting terms from the given document to represent the main topics of the document. On the contrary, in social tag suggestion, the suggested tags do not necessarily appear in the given resource description. We can thus regard social tag suggestion as a task of selecting appropriate tags from a controlled tag vocabulary for the given resource description.

2.2 Applications of SMT

SMT techniques have been successfully used in many tasks of information retrieval and natural language processing to bridge the vocabulary gap between two types of objects. Some typical tasks are document information retrieval (Berger and Lafferty, 1999; Murdock and Croft, 2004; Karimzadehgan and Zhai, 2010), question answering (Berger et al., 2000; Echihabi and Marcu, 2003; Soricut and Brill, 2006; Riezler et al., 2007; Surdeanu et al., 2008; Xue et al., 2008), query expansions (Riezler et al., 2007; Riezler et al., 2008; Riezler and Liu, 2010), paraphrasing (Quirk et al., 2004; Zhao et al., 2010a; Zhao et al., 2010b), summarization (Banko et al., 2000), collocation extraction (Liu et al., 2009b;

Liu et al., 2010c), keyphrase extraction (Liu et al., 2011), sentiment analysis (Dalvi et al., 2009), computational advertising (Ravi et al., 2010), and image/video annotation and retrieval (Duygulu et al., 2002; Jeon et al., 2003).

3 Word Trigger Method for Social Tag Suggestion

3.1 Method Framework

We describe the word trigger method (WTM) for social tag suggestion as a 3-stage process:

1. Preparing description-annotation pairs. Given a collection of annotated resources, we first prepare description-annotation pairs for learning translation probabilities using word alignment models.

2. Learning a translation model. Given a collection of description-annotation pairs, we adopt IBM Model-1, a widely used word alignment model, to learn the translation probabilities between words in descriptions and tags in annotations.

3. Suggesting tags given a resource description. After building translation probabilities between words and tags, given a resource description, we first compute the trigger power of each word in the description and then suggest tags according to their translation probabilities from the triggered words.

Before introducing the method in details, we introduce the notations. In a social tagging system, a resource is denoted as $r \in R$, where R is the set of all resources. Each resource contains a description and an annotation containing a set of tags. The description d_r of resource r can be regarded as a bag of words $\mathbf{w}_r = \{(w_i, e_i)\}_{i=1}^{N_r}$, where e_i is the count of word w_i and N_r is the number of unique words in r. The annotation a_r of resource r is represented as $\mathbf{t}_r = \{(t_i, e_i)\}_{i=1}^{M_r}$, where e_i is the count of tag t_i and M_r is the number of unique tags for r.

3.2 Preparing Description-Annotation Pairs

Learning translation probabilities requires a parallel training dataset consisting of a number of aligned sentence pairs. We assume the description and the annotation of a resource as being written in two distinct languages. We thus prepare our parallel training dataset by pairing descriptions with annotations.

The annotation of a resource is a bag of tags with no position information. We thus select IBM Model-1 (Brown et al., 1993) for training, which does not take word position information into account on both sides for each aligned pair.

In a social tagging system, the length of a resource description is usually limited to hundreds of words. Meanwhile, it is common that some popular resources are annotated by multiple users with thousands of tags. For example, the tag *Dumas* is annotated by $2,748$ users for the book in Table 1. We have to deal with the length-unbalance between a resource description and its corresponding annotation for two reasons.

- It is impossible to list all annotated tags on the annotation side of a description-annotation pair. The performance of word alignment models will also suffer from the unbalanced length of sentence pairs in the parallel training data set (Och and Ney, 2003).

- Moreover, the annotated tags may have different importance for the resource. It would be unfair to treat these tags without distinction.

Here we propose a sampling method to prepare length-balanced description-annotation pairs for word alignment. The basic idea is to sample a bag of tags from the annotation according to tag weights and make the generated bag of tags with comparable length with the description.

We consider two parameters when sampling tags. First, we have to select a **tag weighting type** for sampling. In this paper, we investigate two straightforward sampling types, including tag frequency (TF_t) within the annotation and tag-frequency inverse-resource-frequency (TF-IRF_t). Given resource r, TF_t and TF-IRF_t of tag t are defined as $\text{TF}_t = e_t / \sum_t e_t$ and $\text{TF-IRF}_t = e_t / \sum_t e_t \times \log\left(|R| / |\sum_{r \in R} I_{e_t > 0}|\right)$, where $|\sum_{r \in R} I_{e_t > 0}|$ indicates the number of resources that have been annotated with tag t.

Another parameter is the **length ratio** between the description and the sampled annotation. We denote the ratio as $\delta = |\mathbf{w}_r| / |\mathbf{t}_r|$, where $|\mathbf{w}_r|$ is the number of words in the description and $|\mathbf{t}_r|$ is the number of tags in the annotation.

3.3 Learning Translation Probabilities Using Word Alignment Models

Suppose the source language is resource description and the target language is resource annotation. In IBM Model-1, the relationship of the source language $\mathbf{w} = w_1^J$ and the target language $\mathbf{t} = t_1^I$ is connected via a hidden variable describing an alignment mapping from source position j to target position a_j:

$$\Pr(w_1^J|t_1^I) = \sum_{a_1^J} \Pr(w_1^J, a_1^J|t_1^I). \quad (1)$$

The alignment a_1^J also contains empty-word alignments $a_j = 0$ which align source words to the an empty word. IBM Model-1 can be trained using Expectation-Maximization (EM) algorithm in an unsupervised fashion, and obtains the translation probabilities of two vocabularies, i.e., $\Pr(w|t)$, where t is a tag and w is a word.

IBM Model-1 only produces one-to-many alignments from source language to target language. The learned model is thus asymmetric. We will learn translation models on two directions: one is regarding descriptions as the source language and annotations as the target language, and the other is in reverse direction of the pairs. We denote the first model as $\Pr_{d2a}$ and the latter as $\Pr_{a2d}$. We further define $\Pr(t|w)$ as the harmonic mean of the two models:

$$\Pr(t|w) \propto \Big(\lambda/\Pr{}_{d2a}(t|w)+(1-\lambda)/\Pr{}_{a2d}(t|w)\Big)^{-1}, \quad (2)$$

where λ is the harmonic factor to combine the two models. When $\lambda = 1$ or $\lambda = 0$, it simply uses model $\Pr_{d2a}$ or $\Pr_{a2d}$ correspondingly.

3.4 Tag Suggestion Using Triggered Words and Translation Probabilities

When given the description of a resource, we can rank tags by computing the scores:

$$\Pr(t|d = \mathbf{w}_d) = \sum_{w \in \mathbf{w}_d} \Pr(t|w) \Pr(w|d), \quad (3)$$

in which $\Pr(w|d)$ is the trigger power of the word w in the description, which indicates the importance of the word. According to the ranking scores, we can suggest the top-ranked tags to users.

Here we explore three methods to compute the trigger power of a word in a resource description: TF-IRF$_w$, TextRank and their product. TF-IRF$_w$ and TextRank are two most widely adopted methods for keyword extraction.

Similar to TF-IRF$_t$ mentioned in Section 3.2, TF-IRF$_w$ considers both the local importance (TF$_w$) and global specification (IRF$_w$).

TextRank (Mihalcea and Tarau, 2004) is a graph-based method to compute term importance. Given a resource description, TextRank first builds a term graph by connecting the terms in the description according to their semantic relations, and then run PageRank algorithm (Page et al., 1998) to measure the importance of each term in the graph. Readers can refer to (Mihalcea and Tarau, 2004) for detailed information.

We also use the product of TF-IRF$_w$ and TextRank to weight terms, which potentially takes both global information and term relations into account.

Emphasize Tags Appearing In Description for WTM (EWTM) In some social tagging systems, the tags that appear in the resource description are more likely to be selected by users for annotation. Therefore, we propose to emphasize the tags in the description by ranking tags as follows

$$\Pr(t|d) = \sum_{w \in \mathbf{w}_d} \big(\gamma I_t(w) + (1-\gamma) \Pr(t|w)\big) \Pr(w|d), \quad (4)$$

where $I_t(w)$ is an indicator function which gets value 1 when $t = w$ and 0 when $t \neq w$; and γ is the smooth factor with range $\gamma \in [0.0, 1.0]$. When $\gamma = 1.0$, it suggests tags simply according to their trigger powers within the description, while when $\gamma = 0.0$, it does not emphasize the tags appearing in the description and just suggests according to their translation probabilities. In Section 4.4, we will show the performance of EWTM.

4 Experiments

4.1 Datasets and Evaluation Metrics

Datasets In our experiments, we select two real world datasets which are of diverse properties to evaluate our methods. In Table 2 we show the detailed statistical information of the two datasets.

Data	R	W	T	$\bar{N}_w$	$\bar{N}_t$
BOOK	70,000	174,748	46,150	211.6	3.5
BIBTEX	158,924	91,277	50,847	5.8	2.7

Table 2: Statistical information of two datasets. R, W, T, $\bar{N}_w$ and $\bar{N}_t$ are the number of resources, the vocabulary of descriptions, the vocabulary of tags, the average number of words in each description and the average number of tags in each resource, respectively.

The first dataset, denoted as BOOK, is obtained from a popular Chinese book review website `www.douban.com`, which contains the descriptions of books and the tags collaboratively annotated by users. The second dataset, denoted as BIBTEX, is obtained from an English online bibliography website `www.bibsonomy.org`[2]. The dataset contains the descriptions for academic papers (including the title and note for each paper) and the tags annotated by users. As shown in Table 2, the average length of descriptions in the BIBTEX dataset is much shorter than the BOOK dataset. Moreover, the BIBTEX dataset does not provide how many times each tag is annotated to a resource.

Evaluation Metrics We use precision, recall and F-measure to evaluate the performance of tag suggestion methods. For a resource, we denote the original tags (gold standard) as T_a, the suggested tags as T_s, and the correctly suggested tags as $T_s \cap T_a$. Precision, recall and F-measure are defined as

$$p = \frac{|T_s \cap T_a|}{|T_s|}, \quad r = \frac{|T_s \cap T_a|}{|T_a|}, \quad F = \frac{2pr}{(p+r)}. \tag{5}$$

The final evaluation scores are computed by micro-averaging (i.e., averaging on resources of test set). We perform 5-fold cross validation for each method on all two datasets. In experiments, the number of suggested tags M ranges from 1 to 10.

4.2 Comparing Results

Baseline Methods We select four content-based algorithms as the baselines for comparison: Naive Bayes (NB) (Manning et al., 2008), k nearest neighbor algorithm (kNN) (Manning et al., 2008), Content Relevance (CRM) model (Iwata et al., 2009) and Tag Allocation Model (TAM) (Si et al., 2010).

NB and kNN are two representative classification methods. NB is a simple generative model, which models the probability of each tag t given description d as

$$\Pr(t|d) \propto \Pr(t) \prod_{w \in d} \Pr(w|t). \tag{6}$$

$\Pr(t)$ is estimated by the frequency of the resources annotated with the tag t. $\Pr(w|t)$ is estimated by the frequency of the word w in the resource descriptions annotated with the tag t. kNN is a widely used classification method for tag suggestion, which recommends tags to a resource according to the annotated tags of similar resources measured using vector space models (Manning et al., 2008).

CRM and TAM are selected to represent topic-based methods for tag suggestion. CRM is an LDA-based generative model. The number of latent topics K is the key parameter for CRM. In experiments, we evaluated the performance of CRM with different K values, and here we only show the best one obtained by setting $K = 1,024$. TAM is also a generative model which considers the words in descriptions as the topics to further generate tags for the resource. We set parameters for TAM as in (Si et al., 2010). For comparison, we denote our method as WTM.

Complexity Analysis We compare the complexity of these methods. We denote the number of training iterations in CRM, TAM and WTM as I [3], and the number of topics in CRM as K. For the training phase, the complexity of NB is $O(R\bar{N}_w\bar{N}_t)$, kNN is $O(1)$, TAM is $O(IR\bar{N}_w\bar{N}_t)$, CRM is $O(IKR\bar{N}_w\bar{N}_t)$, and WTM is $O(IR\bar{N}_w\bar{N}_t)$[4]. When suggesting for a given resource description with length N_w, the complexity of NB is $O(N_wT)$, kNN is $O(R\bar{N}_w\bar{N}_t)$, CRM is $O(IKN_wT)$, TAM

[2]The dataset can be obtained from `http://www.kde.cs.uni-kassel.de/bibsonomy/dumps`

[3]In fact, the numbers of iterations of the three methods are different from each other. For simplicity, here we denote them using the same notation.

[4]In more detail, the training phase of WTM contains preparing parallel training dataset with $O(R\bar{N}_t)$ and learning translation probabilities using word alignment models with $O(IR\bar{N}_w\bar{N}_t)$, where I is the number of iterations for learning translation probabilities, and $\bar{N}_t$ is the average number of tags for each resource after sampling.

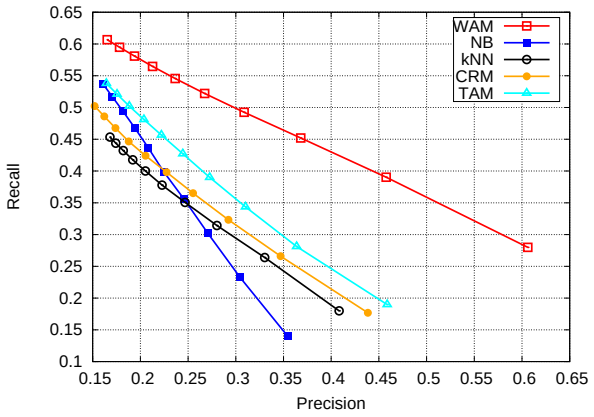
is $O(IN_wT)$ and WTM is $O(N_wT)$. From the analysis, we can see that WTM is a relatively simple method for both training and suggestion. This is especially valuable because WTM also shows good effectiveness for tag suggestion compared with other methods as we will shown later.

Parameter Settings We use GIZA++ (Och and Ney, 2003)[5] as IBM Model-1 to learn translation probabilities using description-annotation pairs for WTM. The experimental results of WTM are obtained by setting parameters as follows: tag weighting type as TF-IRF$_t$, length ratio $\delta = 1$, harmonic factor $\lambda = 0.5$ and the type of word trigger strength as TF-IRF$_w$. The influence of parameters to WTM can be found in Section 4.3.

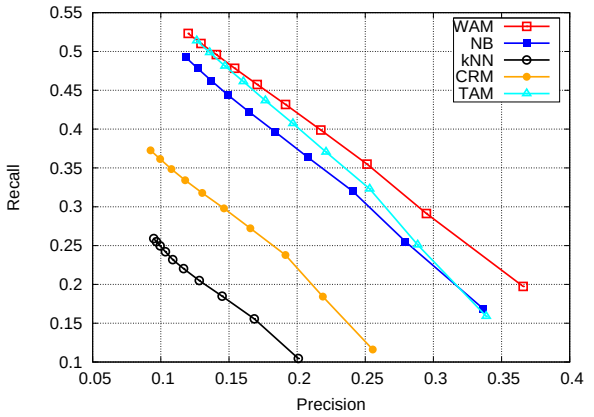
Experiment Results and Analysis In Fig. 2 we show the precision-recall curves of NB, kNN, CRM and WTM on two datasets. Each point of a precision-recall curve represents different numbers of suggested tags from $M = 1$ (bottom right, with higher precision and lower recall) to $M = 10$ (upper left, with higher recall but lower precision) respectively. The closer the curve to the upper right, the better the overall performance of the method. From Fig. 2, we observe that:

- WTM consistently performs the best on both datasets. This indicates that WTM is robust and effective for tag suggestion.
- The advantage of WTM is more significant on the BOOK dataset. The reason is that WTM can take a good advantage of annotation count information of tags compared to other methods.
- The average length of resource descriptions is short in the BIBTEX dataset, which makes it difficult to determine the trigger powers of words. But even on the BIBTEX dataset with no count information of tags, WTM still outperforms other methods especially when recommending first several tags.

To further demonstrate the performance of WTM and other baseline methods, in Table 3 we show the



(a) BOOK



(b) BIBTEX

Figure 2: Performance comparison between NB, kNN, CRM, TAM and WTM on two datasets.

precision, recall and F-measure of NB, kNN, CRM, TAM and WTM on BOOK dataset when suggesting $M = 3$ tags[6]. Due to the limit of space, we only show the variance of F-measure. In fact, WTM achieves its best performance when $M = 2$, where the F-measure of WTM is 0.370, outperforming both CRM ($F = 0.263$) and TAM ($F = 0.277$) by about 10%.

An Example In Table 4 we show top 10 tags suggested by NB, CRM, TAM and WTM for the book in Table 1. The number in bracket after the name of each method is the count of correctly suggested tags. The correctly suggested tags are marked in bold face. We select not to show

[5]GIZA++ is freely available on `code.google.com/p/giza-pp`. The toolkit is widely used for word alignment in SMT. In this paper, we use the default setting of parameters for training.

[6]We select to show this number because it is near the average number of tags for BOOK dataset

Method	Precision	Recall	F-measure
NB	0.271	0.302	0.247 ± 0.004
kNN	0.280	0.314	0.258 ± 0.002
CRM	0.292	0.323	0.266 ± 0.004
TAM	0.310	0.344	0.283 ± 0.001
WTM	**0.368**	**0.452**	$\mathbf{0.355 \pm 0.002}$

Table 3: Comparing results of NB, kNN, CRM, TAM and WTM on BOOK dataset when suggesting $M = 3$ tags.

the results of kNN because the tags suggested by kNN are totally unrelated to the book due to the insufficient finding of nearest neighbors.

From Table 4, we observe that NB, CRM and TAM, as generative models, tend to suggest general tags such as "novel", "literature", "classic" and "France", and fail in suggesting specific tags such as "Alexandre Dumas" and "Count of Monte Cristo". On the contrary, WTM succeeds in suggesting both general and specific tags related to the book.

NB (+6): **novel**, **foreign literature**, **literature**, **history**, Japan, **classic**, **France**, philosophy, America, biography
CRM (+5): **novel**, **foreign literature**, **literature**, biography, philosophy, culture, **France**, British, comic, **history**
TAM (+5): **novel**, sociology, finance, **foreign literature**, **France**, **literature**, biography, **France literature**, comic, China
WTM (+7): **novel**, **Alexandre Dumas**, **history**, **Count of Monte Cristo**, **foreign literature**, biography, **suspense**, comic, America, **France**

Table 4: Top 10 tags suggested by NB, CRM, TAM and WTM for the book in Table 1.

In Table 5, we list four important words (using TF-IRF$_w$ as weighting metric) of the description and their corresponding tags with the highest translation probabilities. The values in brackets are the probability of tag t given word w, $\Pr(t|w)$. For each word, we eliminated the tags with the probability less than 0.1. We can see that the translation probabilities can map the words in descriptions to their semantically corresponding tags in annotations.

Count of Monte Cristo: Count of Monte Cristo (0.728), Alexandre Dumas (0.270), . . .
Alexandre Dumas: Alexandre Dumas (0.966), . . .
revenge: foreign literature (0.168), classic (0.130), martial arts (0.123), Alexandre Dumas (0.122), . . .
France: France (0.99), . . .

Table 5: Four important words (in bold face) in the book description in Table 1 and their corresponding tags with the highest translation probabilities.

4.3 Parameter Influences

We explore the parameter influences to WTM for social tag suggestion. The parameters include harmonic factor, length ratio, tag weighting types, and types of word trigger strength. When investigating one parameter, we set other parameters to be the values inducing the best performance as mentioned in Section 4.2. Finally, we also investigate the influence of training data size for suggestion performance. In experiments we find that WTM reveals similar trends on both the BOOK dataset and the BIBTEX dataset. We thus only show the experimental results on the BOOK dataset for analysis.

Harmonic Factor In Fig. 3 we investigate the influence of harmonic factor via the curves of F-measure of WTM versus the number of suggested tags on the BOOK dataset when harmonic factor λ ranges from 0.0 to 1.0. As shown in Section 3.3, harmonic factor λ controls the proportion between model $\Pr_{d2a}$ and $\Pr_{a2d}$.

From Fig. 3, we observe that neither single model $\Pr_{d2a}$ ($\lambda = 1.0$) nor $\Pr_{a2d}$ ($\lambda = 0.0$) achieves the best performance. When the two models are combined by harmonic mean, the performance is consistently better, especially when λ ranges from 0.2 to 0.6. This is reasonable because IBM Model-1 constrains that only the term in source language can be aligned to multiple terms in target language, which makes the translation probability learned by a single model be asymmetric.

Length Ratio Fig. 4 shows the influence of length ratios on the BOOK dataset. From the figure, we observe that the performance for tag suggestion is robust as the length ratio varies, except when the ratio breaks the default restriction of GIZA++ (i.e.,

$\delta = 10$)[7].

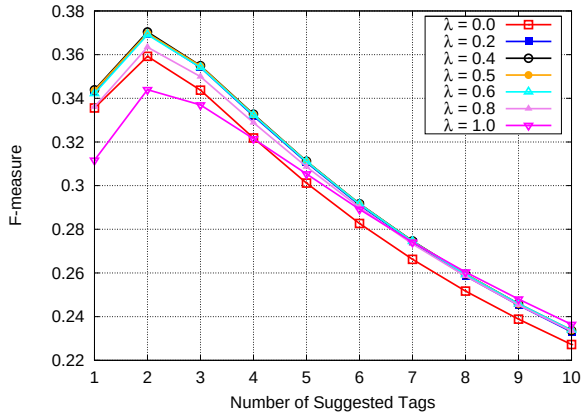


Figure 3: F-measure of WTM versus the number of suggested tags on the BOOK dataset when harmonic factor λ ranges from 0.0 to 1.0.

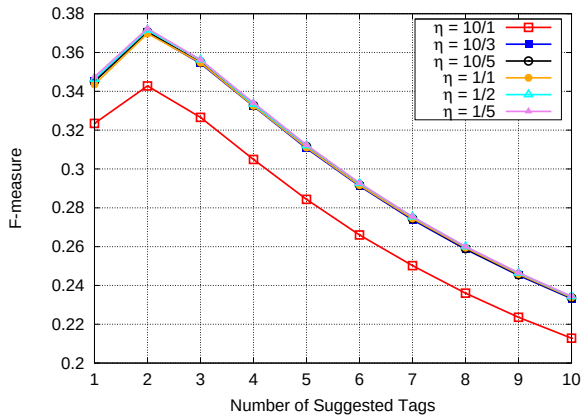

Figure 4: F-measure of WTM versus the number of suggested tags on the BOOK dataset when length ratio δ ranges from $10/1$ to $1/5$.

Tag Weighting Types The influence of two weighting types, TF_t and TF-IRF_t, on social tag suggestion when $M = 3$ on the BOOK dataset is shown in Table 6. TF-IRF_t tends to select the tags more specific to the resource while TF_t tends to select the most popular tags, because the latter does not consider global information (the IRF_t part).

[7]GIZA++ restricts the values of length ratio within $[\frac{1}{9}, 9]$ by setting parameter `maxfertility=10`. From Fig. 4, we can see when $\delta = 10$, the performance becomes much worse since GIZA++ will cut off the sentences out of range.

Table 6 verifies the analysis, where TF-IRF_t is slightly better than TF_t.

Weighting	Precision	Recall	F-measure
TF_t	0.356	0.437	0.342 ± 0.002
TF-IRF_t	0.368	0.452	0.355 ± 0.002

Table 6: Evaluation results for different tag weighting types when $M = 3$ on the BOOK dataset.

Methods for Computing Word Trigger Power In Table 7, we show the performance of social tag suggestions on the BOOK dataset with different methods for computing word trigger power. From the table, we can see that there is not significant difference between TF-IRF_w and the product of TF-IRF_w and TextRank, while TextRank itself performs the worst. This indicates that TextRank is less competitive to measure word trigger power since it does not take global information into consideration.

Weighting	Precision	Recall	F-measure
TF-IRF_w	0.368	0.452	0.355 ± 0.002
TextRank	0.345	0.424	0.332 ± 0.002
Product	0.368	0.451	0.354 ± 0.002

Table 7: Evaluation results for different methods for computing word trigger powers when $M = 3$ on the BOOK dataset.

Training Data Size We investigate the influence of training data size for social tag suggestion. As shown in Fig. 5, we increased the training data size from $8,000$ to $56,000$ step by $8,000$, and carried out evaluation on $4,000$ resources. The figure shows that:

- When the training data size is small (e.g., $8,000$), WTM can still achieve good suggestion performance.
- As the training data size increases, the performance of WTM improves, while the improvement speed declines.

The observation indicates that WTM does not require huge-size dataset to achieve good performance.

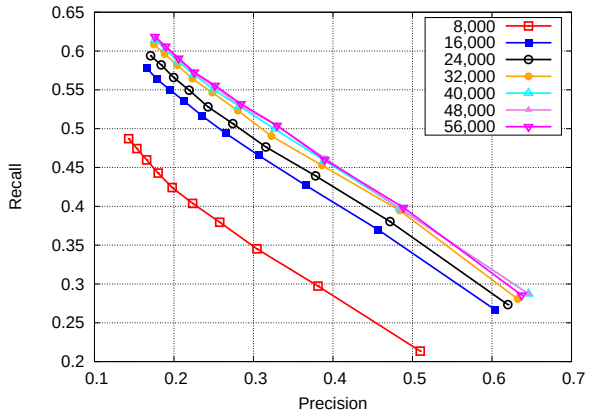

Figure 5: Precision-recall curves when the training data size increases from $8,000$ thousand to $56,000$ thousand on the BOOK dataset.

Conclusion By analyzing the influences of parameters on WTM, we find that WTM is robust to parameter variations.

4.4 Performance of EWTM

At the end of this section, we investigate the performance of EWTM for social tag suggestion. Here we simply set the smooth factor $\gamma = 0.5$.

As shown in Table 8, EWTM improves the performance of WTM (in Table 7) on the BOOK dataset when using TF-IRF$_w$ and the product as the methods for computing the word trigger powers, but decays when using TextRank. This verifies that TF-IRF$_w$ is the best method to measure word trigger powers for WTM. Table 8 indicates that emphasizing the tags appearing in the descriptions may enhance the suggestion power of the word trigger method.

Weighting	Precision	Recall	F-measure
TF-IRF$_w$	0.385	0.472	0.371 ± 0.001
TextRank	0.344	0.423	0.332 ± 0.002
Product	0.374	0.457	0.360 ± 0.001

Table 8: The evaluation results of EWTM with different methods for computing word trigger powers when $M = 3$ on the BOOK dataset.

However, the performance of EWTM on the BIBTEX dataset decays much compared to WTM. The F-measure of EWTM is only $F = 0.229$ compared with WTM $F = 0.267$. The main reason of the decay is that: the resource descriptions in the BIBTEX dataset are usually too short to provide sufficient information to precisely emphasize tags. In this case, EWTM may emphasize wrong tags and drop correct tags.

The experimental results on EWTM suggest that, the performance of EWTM is heavily influenced by the length of resource descriptions. Therefore, we have to analyze the characteristics of social tagging systems to decide whether to emphasize the tags that appear in the corresponding resource descriptions.

As future work, we will investigate the influence of the smooth factor γ to EWTM. It is also worth to investigate the problem when combining with collaboration-based methods for social tag suggestion.

5 Conclusion and Future Work

In this paper, we present a new perspective to social tagging and propose the word trigger method for social tag suggestion based on word alignment in statistical machine translation. Experiments show that our method is effective and efficient for social tag suggestion compared to other baselines.

There are still several open problems that should be further investigated:

1. We can exploit other word alignment methods like log-linear models (Liu et al., 2010a) for social tag suggestion.

2. We will ensemble WTM with other content-based and collaboration-based methods to build a practical social tag suggestion system.

3. WTM and EWTM can only suggest the tags that have appeared in translation models. In future, we plan to incorporate keyphrase extraction in social tag suggestion to make it suggest more appropriate tags not only from translation models but also from the resource descriptions.

Rumor has it: Identifying Misinformation in Microblogs

Vahed Qazvinian Emily Rosengren Dragomir R. Radev Qiaozhu Mei
University of Michigan

{vahed,emirose,radev,qmei}@umich.edu

Abstract

A rumor is commonly defined as a statement whose true value is unverifiable. Rumors may spread misinformation (false information) or disinformation (deliberately false information) on a network of people. Identifying rumors is crucial in online social media where large amounts of information are easily spread across a large network by sources with unverified authority. In this paper, we address the problem of rumor detection in microblogs and explore the effectiveness of 3 categories of features: content-based, network-based, and microblog-specific memes for correctly identifying rumors. Moreover, we show how these features are also effective in identifying disinformers, users who endorse a rumor and further help it to spread. We perform our experiments on more than 10,000 manually annotated tweets collected from Twitter and show how our retrieval model achieves more than 0.95 in Mean Average Precision (MAP). Finally, we believe that our dataset is the first large-scale dataset on rumor detection. It can open new dimensions in analyzing online misinformation and other aspects of microblog conversations.

1 Introduction

A rumor is an unverified and instrumentally relevant statement of information spread among people (DiFonzo and Bordia, 2007). Social psychologists argue that rumors arise in contexts of ambiguity, when the meaning of a situation is not readily apparent, or potential threat, when people feel an acute need for security. For instance rumors about 'office renovation in a company' is an example of an ambiguous context, and the rumor that 'underarm deodorants cause breast cancer' is an example of a context in which one's well-being is at risk (DiFonzo et al., 1994).

The rapid growth of online social media has made it possible for rumors to spread more quickly. Online social media enable unreliable sources to spread large amounts of unverified information among people (Herman and Chomsky, 2002). Therefore, it is crucial to design systems that automatically detect misinformation and disinformation (the former often seen as simply false and the latter as deliberately false information).

Our definition of a rumor is established based on social psychology, where a rumor is defined as a statement whose truth-value is unverifiable or deliberately false. In-depth rumor analysis such as determining the intent and impact behind the spread of a rumor is a very challenging task and is not possible without first retrieving the complete set of social conversations (e.g., tweets) that are actually about the rumor. In our work, we take this first step to retrieve a complete set of tweets that discuss a specific rumor. In our approach, we address two basic problems. The first problem concerns retrieving online microblogs that are rumor-related. In the second problem, we try to identify tweets in which the rumor is endorsed (the posters show that they believe the rumor).

2 Related Work

We review related work on 3 main areas: Analyzing rumors, mining microblogs, and sentiment analysis and subjectivity detection.

2.1 Rumor Identification and Analysis

Though understanding rumors has been the subject of research in psychology for some time (Allport and Lepkin, 1945), (Allport and Postman, 1947), (DiFonzo and Bordia, 2007), research has

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1589–1599,
Edinburgh, Scotland, UK, July 27–31, 2011.

only recently begun to investigate how rumors are manifested and spread differently online. Microblogging services, like Twitter, allow small pieces of information to spread quickly to large audiences, allowing rumors to be created and spread in new ways (Ratkiewicz et al., 2010).

Related research has used different methods to study the spread of memes and false information on the web. Leskovec et al. use the evolution of quotes reproduced online to identify memes and track their spread overtime (Leskovec et al., 2009). Ratkiewicz et al. (Ratkiewicz et al., 2010) created the "Truthy" system, identifying misleading political memes on Twitter using tweet features, including hashtags, links, and mentions. Other projects focus on highlighting disputed claims on the Internet using pattern matching techniques (Ennals et al., 2010). Though our project builds on previous work, our work differs in its general focus on identifying rumors from a corpus of relevant phrases and our attempts to further discriminate between phrases that confirm, refute, question, and simply talk about rumors of interest.

Mendoza et al. explore Twitter data to analyze the behavior of Twitter users under the emergency situation of 2010 earthquake in Chile (Mendoza et al.,). They analyze the re-tweet network topology and find that the patterns of propagation in rumors differ from news because rumors tend to be questioned more than news by the Twitter community.

2.2 Sentiment Analysis

The automated detection of rumors is similar to traditional NLP sentiment analysis tasks. Previous work has used machine learning techniques to identify positive and negative movie reviews (Pang et al., 2002). Hassan et al. use a supervised Markov model, part of speech, and dependency patterns to identify attitudinal polarities in threads posted to Usenet discussion posts (Hassan et al., 2010). Others have designated sentiment scores for news stories and blog posts based on algorithmically generated lexicons of positive and negative words (Godbole et al., 2007). Pang and Lee provide a detailed overview of current techniques and practices in sentiment analysis and opinion mining (Pang and Lee, 2008; Pang and Lee, 2004).

Though rumor classification is closely related to opinion mining and sentiment analysis, it presents a different class of problem because we are concerned not just with the opinion of the person posting a tweet, but with whether the statements they post appear controversial. The automatic identification of rumors from a corpus is most closely related to the identification of memes done in (Leskovec et al., 2009), but presents new challenges since we seek to highlight a certain type of recurring phrases. Our work presents one of the first attempts at automatic rumor analysis.

2.3 Mining Twitter Data

With its nearly constant update of new posts and public API, Twitter can be a useful source for collecting data to be used in exploring a number of problems related to natural language processing and information diffusion (Bifet and Frank, 2010). Pak and Paroubek demonstrated experimentally that despite frequent occurrences of irregular speech patterns in tweets, Twitter can provide a useful corpus for sentiment analysis (Pak and Paroubek, 2010). The diversity of Twitter users make this corpus especially valuable. Ratkiewicz et al also use Twitter to detect and track misleading political memes (Ratkiewicz et al., 2010).

Along with many advantages, using Twitter as a corpus for sentiment analysis does present unusual challenges. Because posts are limited to 140 characters, tweets often contain information in an unusually compressed form and, as a result, grammar used may be unconventional. Instances of sarcasm and humor are also prevalent (Bifet and Frank, 2010). The procedures we used for the collection and analysis of tweets are similar to those described in previous work. However, our goal of developing computational methods to identify rumors being transmitted through tweets differentiates our project.

3 Problem Definition

Assume we have a set of tweets that are about the same topic that has some controversial aspects. Our objective in this work is two-fold: (1) Extract tweets that are about the controversial aspects of the story and spread misinformation (**Rumor retrieval**). (2) Identify users who believe that misinformation versus users who refute or question the rumor (**Belief**

Name	Rumor	Regular Expression Query	Status	#tweets
obama	Is Barack Obama muslim?	`Obama & (muslim|islam)`	false	4975
airfrance	Air France mid-air crash photos?	`(air.france|air france) & (photo|pic|pix)`	false	505
cellphone	Cell phone numbers going public?	`(cell|cellphone|cell phone)`	mostly false	215
michelle	Michelle Obama hired too many staff?	`staff & (michelle obama|first lady|1st lady)`	partly true	299
palin	Sarah Palin getting divorced?	`palin & divorce`	false	4423

Table 1: List of rumor examples and their corresponding queries used to collect data from Twitter

classification).

The following two tweets are two instances of the tweets written about president Obama and the Muslim world. The first tweet below is about president Obama and Muslim world, where the second tweet spread misinformation that president Obama is Muslim.

(non-rumor) "As Obama bows to Muslim leaders Americans are less safe not only at home but also overseas. Note: The terror alert in Europe... "

(rumor) "RT @johnnyA99 Ann Coulter Tells Larry King Why People Think Obama Is A Muslim http://bit.ly/9rs6pa #Hussein via @NewsBusters #tcot .."

The goal of the retrieval task is to discriminate between such tweets. In the second task, we use the tweets that are flagged as rumorous, and identify users that endorse (believe) the rumor versus users who deny or question it. The following three tweets are about the same story. The first user is a believer and the second and third are not.

(confirm) "RT @moronwatch: Obama's a Muslim. Or if he's not, he sure looks like one #whyimvotingrepublican."

(deny) "Barack Obama is a Christian man who had a Christian wedding with 2 kids baptised in Jesus name. Tea Party clowns call that muslim #p2 #gop"

(doubtful) "President Barack Obama's Religion: Christian, Muslim, or Agnostic? - The News of Today (Google): Share With Friend... http://bit.ly/bk42ZQ"

The first task is substantially more challenging than a standard IR task because of the requirement of both high precision (every result should be actually discussing the rumor) and high recall (the set should be complete). To do this, we submit a handcrafted regexp (extracted from about.com) to Twitter and retrieve a large primitive set of tweets that is supposed to have a high recall. This set however, contains a lot of false positives, tweets that match the regexp but are not about the rumor (e.g., "Obama meets muslim leaders"). Moreover, a rumor is usually stated using various instances (e.g., "Barack HUSSEIN Obama" versus "Obama is muslim"). Our goal is then to design a learning framework that filters all such false positives and retrieves various instances of the same rumor

Although our second task, belief classification, can be viewed as an opinion mining task, it is substantially different from opinion mining in nature. The difference from a standard opinion mining task is that here we are looking for attitudes about a subtle statement (e.g., "Palin is getting divorce") instead of the overall sentiment of the text or the opinion towards an explicit object or person (e.g., "Sarah Palin").

4 Data

As September 2010, Twitter reports that its users publish nearly 95 million tweets per day[1]. This makes Twitter an excellent case to analyze misinformation in social media.

Our goal in this work was to collect and annotate a large dataset that includes all the tweets that are written about a rumor in a certain period of time. To collect such a complete and self-contained dataset about a rumor, we used the Twitter search API, and retrieved all the tweets that matched a given regular expression. This API is the only API that returns results from the entire public Twitter stream and not a small randomly selected sample. To overcome the rate limit enforced by Twitter, we collected matching tweets once per hour, and remove any duplicates.

To use the search API, we carefully designed regular expression queries to be broad enough to match

[1] http://twitter.com/about

all the tweets that are about a rumor. Each query represents a popular rumor that is listed as "false" or only "partly true" on About.com's Urban Legends reference site[2] between 2009 and 2010. Table 1 lists the rumor examples that we used to collect our dataset along with their corresponding regular expression queries and the number of tweets collected.

4.1 Annotation

We asked two annotators to go over all the tweets in the dataset and mark each tweet with a "1" if it is about any of the rumors from Table 1, and with a "0" otherwise. This annotation scheme will be used in our first task to detect false positives, tweets that match the broad regular expressions and are retrieved, but are not about the rumor. For instance, both of the following tweets match the regular expression for the `palin` example, but only the second one is rumorous.

(0) "McCain Divorces Palin over her 'untruths and out right lies' in the book written for her. McCain's team says Palin is a petty liar and phony"

(1) "Sarah and Todd Palin to divorce, according to local Alaska paper. http://ow.ly/iNxF"

We also asked the annotators to mark each previously annotated rumorous tweet with "11" if the tweet poster endorses the rumor and with "12" if the user refutes the rumor, questions its credibility, or is neutral.

(12) "Sarah Palin Divorce Rumor Debunked on Facebook http://ff.im/62Evd"

(11) "Todd and Sarah Palin to divorce http://bit.ly/15StNc"

Our annotation of more than 10,400 tweets shows that $\%35$ of all the instances that matched the regular expressions are false positives, tweets that are not rumor-related but match the initial queries. Moreover, among tweets that are about particular rumors, nearly $\%43$ show the poster believe the rumor, demonstrating the importance of identifying misinformation and those who are misinformed. Table 2 shows the basic statistics extracted from the annotations for each story.

[2]http://urbanlegends.about.com

Rumor	non-rumor (0)	believe (11)	deny/ (12) doubtful/neutral	total
obama	3,036	926	1,013	4975
airfrance	306	71	128	505
cellphone	132	74	9	215
michelle	83	191	25	299
palin	86	1,709	2,628	4,423
total	3,643	2,971	3,803	10,417

Table 2: Number of instances in each class from the annotated data

task	κ
rumor retrieval	0.954
belief classification	0.853

Table 3: Inter-judge agreement in two annotation tasks in terms of κ-statistic

4.2 Inter-Judge Agreement

To calculate the annotation accuracy, we annotated 500 instances twice. These annotations were compared with each other, and the Kappa coefficient (κ) was calculated. The κ statistic is formulated as

$$\kappa = \frac{\Pr(a) - \Pr(e)}{1 - \Pr(e)}$$

where $Pr(a)$ is the relative observed agreement among raters, and $Pr(e)$ is the probability that annotators agree by chance if each annotator is randomly assigning categories (Krippendorff, 1980; Carletta, 1996). Table 3 shows that annotators can reach a high agreement in both extracting rumors ($\kappa = 0.95$) and identifying believers ($\kappa = 0.85$).

5 Approach

In this section, we describe a general framework, which given a tweet, predicts (1) whether it is a rumor-related statement, and if so (2) whether the user believes the rumor or not. We describe 3 sets of features, and explain why these are intuitive to use for identification of rumors.

We process the tweets as they appear in the user timeline, and do not perform any pre-processing. Specially, we think that capitalization might be an important property. So, we do not lower-case the tweet texts either.

Our approach is based on building different Bayes classifiers as high level features and then learning a linear function of these classifiers for retrieval in the first task and classification in the second. Each

Bayes classifier, which corresponds to a feature f_i, calculates the likelihood ratio for a given tweet t, as shown in Equation 1.

$$\frac{P(\theta_i^+|t)}{P(\theta_i^-|t)} = \frac{P(\theta_i^+)}{P(\theta_i^-)} \frac{P(t|\theta_i^+)}{P(t|\theta_i^-)} \quad (1)$$

Here θ_i^+ and θ_i^- are two probabilistic models built based on feature f_i using a set of positive (+) and negative (−) training data. The likelihood ratio expresses how many times more likely the tweet t is under the positive model than the negative model with respect to f_i.

For computational reasons and to avoid dealing with very small numbers we use the log of the likelihood ratio to build each classifier.

$$LL_i = \log \frac{P(\theta_i^+|t)}{P(\theta_i^-|t)} = \log \frac{P(\theta_i^+)}{P(\theta_i^-)} + \log \frac{P(t|\theta_i^+)}{P(t|\theta_i^-)} \quad (2)$$

The first term $\frac{P(\theta_i^+)}{P(\theta_i^-)}$ can be easily calculated using the maximum likelihood estimates of the probabilities (i.e., the estimate of each probability is the corresponding relative frequency). The second term is calculated using various features that we explain below.

5.1 Content-based Features

The first set of features are extracted from the text of the tweets. We propose 4 content based features. We follow (Hassan et al., 2010) and present the tweet with 2 different patterns:

- Lexical patterns: All the words and segments in the tweet are represented as they appear and are tokenized using the space character.

- Part-of-speech patterns: All words are replaced with their part-of-speech tags. To find the part-of-speech of a hashtag we treat it as a word (since they could have semantic roles in the sentence), by omitting the tag sign, and then precede the tag with the label `TAG/`. We also introduce a new tag, `URL`, for URLs that appear in a tweet.

From each tweet we extract 4 (2×2) features, corresponding to unigrams and bigrams of each representation. Each feature is the log-likelihood ratio calculated using Equation 2. More formally, we represent each tweet t, of length n, lexically as $(w_1 w_2 \cdots w_n)$ and with part-of-speech tags as $(p_1 p_2 \cdots p_n)$. After building the positive and negative models (θ^+, θ^-) for each feature using the training data, we calculate the likelihood ratio as defined in Equation 2 where

$$\frac{P(t|\theta^+)}{P(t|\theta^-)} = \sum_{j=1}^{n} \log \frac{P(w_j|\theta^+)}{P(w_j|\theta^-)} \quad (3)$$

for unigram-lexical features (**`TXT1`**) and

$$\frac{P(t|\theta^+)}{P(t|\theta^-)} = \sum_{j=1}^{n-1} \log \frac{P(w_j w_{j+1}|\theta^+)}{P(w_j w_{j+1}|\theta^-)} \quad (4)$$

for bigram-based lexical features (**`TXT2`**). Similarly, we define the unigram and bigram-based part-of-speech features (**`POS1`** and **`POS2`**) as the log-likelihood ratio with respect to the positive and negative part-of-speech models.

5.2 Network-based Features

The features that we have proposed so far are all based on the content of individual tweets. In the second set of features we focus on user behavior on Twitter. We observe 4 types of network-based properties, and build 2 features that capture them.

Twitter enables users to re-tweet messages from other people. This interaction is usually easy to detect because the re-tweeted messages generally start with the specific pattern: '`RT @user`'. We use this property to infer about the re-tweeted message.

Let's suppose a user u_i re-tweets a message t from the user u_j (u_i: "`RT` @u_j t"). Intuitively, t is more likely to be a rumor if (1) u_j has a history of posting or re-tweeting rumors, or (2) u_i has posted or re-tweeted rumors in the past.

Given a set of training instances, we build a positive (θ^+) and a negative (θ^-) user models. The first model is a probability distribution over all users that have posted a positive instance or have been re-tweeted in a positive instance. Similarly, the second model is a probability distribution over users

that have posted (or been re-tweeted in) a negative instance. After building the models, for a given tweet we calculate two log-likelihood ratios as two network-based features.

The first feature is the log-likelihood ratio that u_i is under a positive user model (**USR1**) and the second feature is the log-likelihood ratio that the tweet is re-tweeted from a user (u_j) who is under a positive user model than a negative user model (**USR2**).

The distinction between the posting user and the re-tweeted user is important, since some times the users modify the re-tweeted message in a way that changes its meaning and intent. In the following example, the original user is quoting president Obama. The second user is re-tweeting the first user, but has added more content to the tweet and made it sound rumorous.

original message (non-rumor) "Obama says he's doing 'Christ's work'."

re-tweeted (rumor) "Obama says he's doing 'Christ's work.' Oh my God, CHRIST IS A MUSLIM."

5.3 Twitter Specific Memes

Our final set of features are extracted from memes that are specific to Twitter: hashtags and URLs. Previous work has shown the usefulness of these memes (Ratkiewicz et al., 2010).

5.3.1 Hashtags

One emergent phenomenon in the Twitter ecosystem is the use of hashtags: words or phrases prefixed with a hash symbol (#). These hashtags are created by users, and are widely used for a few days, then disappear when the topic is outdated (Huang et al., 2010).

In our approach, we investigate whether hashtags used in rumor-related tweets are different from other tweets. Moreover, we examine whether people who believe and spread rumors use hashtags that are different from those seen in tweets that deny or question a rumor.

Given a set of training tweets of positive and negative examples, we build two statistical models (θ^+, θ^-), each showing the usage probability distribution of various hashtags. For a given tweet, t, with a set of m hashtags ($\#h_1 \cdots \#h_m$), we calculate the log-likelihood ratio using Equation 2 where

	Feature	LL-ratio	model
Content	**TXT1**	content unigram	content unigram
	TXT2	content bigram	content unigram
	POS1	content pos	content pos unigram
	POS2	content pos	content pos bigram
Twitter	**URL1**	content unigram	target URL unigram
	URL2	content bigram	target URL bigram
	TAG	hashtag	hashtag
Network	**USR1**	tweeting user	all users in the data
	USR2	re-tweeted user	all users in the data

Table 4: List of features used in our optimization framework. Each feature is a log-likelihood ratio calculated against a a positive (+) and negative (−) training models.

$$\frac{P(t|\theta^+)}{P(t|\theta^-)} = \sum_{j=1}^{m} \log \frac{P(\#h_j|\theta^+)}{P(\#h_j|\theta^-)} \quad (5)$$

5.3.2 URLs

Previous work has discussed the role of URLs in information diffusion on Twitter (Honeycutt and Herring, 2009). Twitter users share URLs in their tweets to refer to external sources or overcome the length limit forced by Twitter. Intuitively, if a tweet is a positive instance, then it is likely to be similar to the content of URLs shared by other positive tweets. Using the same reasoning, if a tweet is a negative instance, then it should be more similar to the web pages shared by other negative instances.

Given a set of training tweets, we fetch all the URLs in these tweets and build θ^+ and θ^- once for unigrams and once for bigrams. These models are merely built on the content of the URLs and ignore the tweet content. Similar to previous features, we calculate the log-likelihood ratio of the content of each tweet with respect to θ^+ and θ^- for unigrams (**URL1**) and bigrams **URL2**).

Table 4 summarizes the set of features used in our proposed framework, where each feature is a log-likelihood ratio calculated against a positive (+) and negative (−) training models. To build these language models, we use the CMU Language Modeling toolkit (Clarkson and Rosenfeld, 1997).

5.4 Optimization

We build an L_1-regularized log-linear model (Andrew and Gao, 2007) on various features discussed before to predict each tweet. Suppose, a procedure generates a set of candidates for an input x. Also,

let's suppose $\Phi : X \times Y \rightarrow \mathbb{R}^D$ is a function that maps each (x, y) to a vector of feature values. Here, the feature vector is the vector of coefficients corresponding to different network, content, and twitter-based properties, and the parameter vector $\theta \in \mathbb{R}^D$ ($D \leq 9$ in our experiments) assigns a real-valued weight to each feature. This estimator chooses θ to minimize the sum of least squares and a regularization term R.

$$\hat{\theta} = arg\min_{\theta}\{\frac{1}{2}\sum_{i}||\langle\theta, x_i\rangle - y_i||_2^2 + R(\theta)\} \quad (6)$$

where the regularizer term $R(\theta)$ is the weighted L_1 norm of the parameters.

$$R(\theta) = \alpha\sum_{j}|\theta_j| \quad (7)$$

Here, α is a parameter that controls the amount of regularization (set to 0.1 in our experiments).

Gao et. al (Gao et al., 2007) argue that optimizing L_1-regularized objective function is challenging since its gradient is discontinuous whenever some parameters equal zero. In this work, we use the *orthant-wise limited-memory quasi-Newton* algorithm (OWL-QN), which is a modification of L-BFGS that allows it to effectively handle the discontinuity of the gradient (Andrew and Gao, 2007). OWL-QN is based on the fact that when restricted to a single orthant, the L_1 regularizer is differentiable, and is in fact a linear function of θ. Thus, as long as each coordinate of any two consecutive search points does not pass through zero $R(\theta)$ does not contribute at all to the curvature of the function on the segment joining them. Therefore, we can use L-BFGS to approximate the Hessian of $L(\theta)$ alone and use it to build an approximation to the full regularized objective that is valid on a given orthant. This algorithm works quite well in practice, and typically reaches convergence in even fewer iterations than standard L-BFGS (Gao et al., 2007).

6 Experiments

We design 2 sets of experiments to evaluate our approach. In the first experiment we assess the effectiveness of the proposed method when employed in an Information Retrieval (IR) framework for rumor retrieval and in the second experiment we employ various features to detect users' beliefs in rumors.

6.1 Rumor Retrieval

In this experiment, we view different stories as queries, and build a relevance set for each query. Each relevance set is an annotation of the entire 10,417 tweets, where each tweet is marked as *relevant* if it matches the regular expression query and is marked as a rumor-related tweet by the annotators. For instance, according to Table 2 the `cellphone` dataset has only 83 relevant documents out of the entire 10,417 documents.

For each query we use 5-fold cross-validation, and predict the relevance of tweets as a function of their features. We use these predictions and rank all the tweets with respect to the query. To evaluate the performance of our ranking model for a single query (Q) with the set of relevant documents $\{d_1, \cdots, d_m\}$, we calculate Average Precision as

$$AP(Q) = \frac{1}{m}\sum_{k=1}^{m}\text{Precision}(R_k) \quad (8)$$

where R_k is the set of ranked retrieval results from the top result to the k^{th} relevant document, d_k (Manning et al., 2008).

6.1.1 Baselines

We compare our proposed ranking model with a number of other retrieval models. The first two simple baselines that indicate a difficulty lower-bound for the problem are **Random** and **Uniform** methods. In the Random baseline, documents are ranked based on a random number assignment to them. In the Uniform model, we use a 5-fold cross validation, and in each fold the label of the test documents is determined by the majority vote from the training set.

The main baseline that we use in this work, is the regular expression that was submitted to Twitter to collect data (**regexp**). Using the same regular expression to mark the relevance of the documents will cause a recall value of 1.00 (since it will retrieve all the relevant documents), but will also retrieve false positives, tweets that match the regular expression but are not rumor-related. We would like to investigate whether using training data will help us decrease the rate of false positives in retrieval.

Finally, using the Lemur Toolkit software[3], we employ a KL divergence retrieval model with

[3]http://www.lemurproject.org/

Dirichlet smoothing (**KL**). In this model, documents are ranked according to the negation of the divergence of query and document language models. More formally, given the query language model θ_Q, and the document language model θ_D, the documents are ranked by $-D(\theta_Q||\theta_D)$, where D is the KL-divergence between the two models.

$$D(\theta_Q||\theta_D) = \sum_w p(w|\theta_Q) \log \frac{p(w|\theta_Q)}{p(w|\theta_D)} \quad (9)$$

To estimate $p(w|\theta_D)$, we use Bayesian smoothing with Dirichlet priors (Berger, 1985).

$$p_s(w|\theta_D) = \frac{C(w,D) + \mu.p(w|\theta_S)}{\mu + \sum_w C(w,D)} \quad (10)$$

where, μ is a parameter, C is the count function, and $theta_S$ is the collection language model. Higher values of μ put more emphasis on the collection model. Here, we try two variants of the model, one using the default parameter value in Lemur ($\mu = 2000$), and one in which μ is tuned based on the the data ($\mu = 10$). Using the test data to tune the parameter value, μ, will help us find an upper-bound estimate of the effectiveness of this method.

Table 5 shows the Mean Average Precision (MAP) and $F_{\beta=1}$ for each method in the rumor retrieval task. This table shows that a method that employs training data to re-rank documents with respect to rumors makes significant improvements over the baselines and outperforms other strong retrieval systems.

6.1.2 Feature Analysis

To investigate the effectiveness of using individual features in retrieving rumors, we perform 5-fold cross validations for each query, using different feature sets each time. Figure 1 shows the average precision and recall for our proposed optimization system when content-based (**TXT1**+**TXT2**+**POS1**+**POS2**), network-based (**USR1**+**USR2**), and twitter specific memes (**TAG**+**URL1**+**URL2**) are employed individually.

Figure 1 shows that features that are calculated using the content language models are very effective in achieving high precision and recall. Twitter specific features, especially hashtags, can result in high precisions but lead to a low recall value because many tweets do not share hashtags or are not written based on the contents of external URLs.

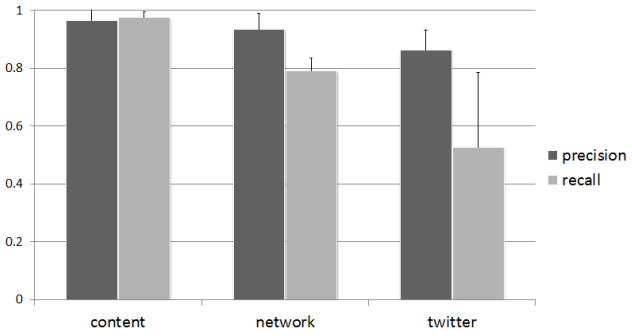

Figure 1: Average precision and recall of the proposed method employing each set of features: content-based, network-based, and twitter specific.

Finally, we find that user history can be a good indicator of rumors. However, we believe that this feature could be more helpful with a complete user set and a more comprehensive history of their activities.

6.1.3 Domain Training Data

As our last experiment with rumor retrieval we investigate how much new labeled data from an emergent rumor is required to effectively retrieve instances of that particular rumor. This experiment helps us understand how our proposed framework could be generalized to other stories.

To do this experiment, we use the `obama` story, which is a large dataset with a significant number of false positive instances. We extract 400 randomly selected tweets from this dataset and keep them for testing. We also build an initial training dataset of the other 4 rumors, and label them as *not relevant*. We assess the performance of the retrieval model as we gradually add the rest of the `obama` tweets. Figure 2 shows both Average Precision and labeling accuracy versus the size of the labeled data used from the `obama` dataset. This plot shows that both measures exhibit a fast growth and reach 80% when the number of labeled data reaches 2000.

6.2 Belief Classification

In previous experiments we showed that maximizing a linear function of log-likelihood ratios is an effective method in retrieving rumors. Here, we in-

Method	MAP	95% C.I.	$F_{\beta=1}$	95% C.I.
Random	0.129	[-0.065, 0.323]	0.164	[-0.051, 0.379]
Uniform	0.129	[-0.066, 0.324]	0.198	[-0.080, 0.476]
regexp	0.587	[0.305, 0.869]	0.702	[0.479, 0.925]
KL ($\mu = 2000$)	0.678	[0.458, 0.898]	0.538	[0.248, 0.828]
KL ($\mu = 10$)	0.803	[0.641, 0.965]	0.681	[0.614, 0.748]
LL (all 9 features)	**0.965**	[0.936, 0.994]	**0.897**	[0.828, 0.966]

Table 5: Mean Average Precision (MAP) and $F_{\beta=1}$ of each method in the rumor retrieval task. (C.I.: Confidence Interval)

Method	Accuracy	Precision	Recall	$F_{\beta=1}$	Win/Loss Ratio
random	0.501	0.441	0.513	0.474	1.004
uniform	0.439	0.439	1.000	0.610	0.781
TXT	0.934	0.925	0.924	0.924	14.087
POS	0.742	0.706	0.706	0.706	2.873
content (**TXT+POS**)	**0.941**	0.934	0.930	**0.932**	15.892
network (**USR**)	0.848	0.873	0.765	0.815	5.583
TAG	0.589	0.734	0.099	0.175	1.434
URL	0.664	0.630	0.570	0.598	1.978
twitter (**TAG+URL**)	0.683	0.658	0.579	0.616	2.155
all	0.935	**0.944**	0.906	0.925	14.395

Table 6: Accuracy, precision, recall, $F_{\beta=1}$, and win/loss ratio of belief classification using different features.

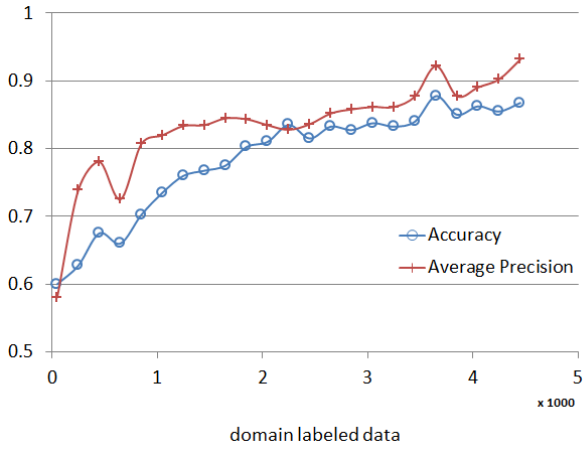

Figure 2: Average Precision and Accuracy learning curve for the proposed method employing all 9 features.

vestigate whether this method, and in particular, the proposed features are useful in detecting users' beliefs in a rumor that they post about. Unlike retrieval, detecting whether a user endorses a rumor or refutes it may be possible using similar methods regardless of the rumor. Intuitively, linguistic features such as negation (e.g., "obama is not a muslim"), or capitalization (e.g., "barack HUSSEIN obama ..."), user history (e.g., liberal tweeter vs. conservative tweeter), hashtags (e.g., #tcot vs. #tdot), and URLs (e.g., links to fake airfrance crash photos) should help to identify endorsements.

We perform this experiment by making a pool of all the tweets that are marked as "rumorous" in the annotation task. Table 2 shows that there are 6,774 such tweets, from which 2,971 show belief and 3,803 tweets show that the user is doubtful, denies, or questions it.

Using various feature settings, we perform 5-fold cross-validation on these 6,774 rumorous tweets. Table 6 shows the results of this experiment in terms of F-score, classification accuracy, and win/loss ratio, the ratio of correct classification to an incorrect

classification.

7 Conclusion

In this paper we tackle the fairly unaddressed problem of identifying misinformation and disinformers in Microblogs. Our contributions in this paper are two-fold: (1) We propose a general framework that employs statistical models and maximizes a linear function of log-likelihood ratios to retrieve rumorous tweets that match a more general query. (2) We show the effectiveness of the proposed feature in capturing tweets that show user endorsement. This will help us identify disinformers or users that spread false information in online social media.

Our work has resulted in a manually annotated dataset of 10,000 tweets from 5 different controversial topics. To the knowledge of authors this is the first large-scale publicly available rumor dataset, and can open many new dimensions in studying the effects of misinformation or other aspects of information diffusion in online social media.

In this paper we effectively retrieve instances of rumors that are already identified and evaluated by an external source such as About.com's Urban Legends reference. Identifying new emergent rumors directly from the Twitter data is a more challenging task. As our future work, we aim to build a system that employs our findings in this paper and the emergent patterns in the re-tweet network topology to identify whether a new trending topic is a rumor or not.

Abstract

Attempts to profile authors according to their characteristics extracted from textual data, including native language, have drawn attention in recent years, via various machine learning approaches utilising mostly lexical features. Drawing on the idea of contrastive analysis, which postulates that syntactic errors in a text are to some extent influenced by the native language of an author, this paper explores the usefulness of syntactic features for native language identification. We take two types of parse substructure as features—horizontal slices of trees, and the more general feature schemas from discriminative parse reranking—and show that using this kind of syntactic feature results in an accuracy score in classification of seven native languages of around 80%, an error reduction of more than 30%.

1 Introduction

Inferring characteristics of authors from their textual data, often termed *authorship profiling*, has seen a number of computational approaches proposed in recent years. The problem is typically treated as a classification task, where an author is classified with respect to characteristics such as gender, age, native language, and so on. This profile information is often of interest to marketing organisations for product promotional reasons as well as governments or law enforcements for crime investigation purposes. The particular application that motivates the present study is detection of phishing (Myers, 2007), the attempt to defraud through texts that are designed to deceive Internet users into giving away confidential details. One class of countermeasures to phishing consists of technical methods such as email authentication; another looks at profiling of the text's author(s) (Fette et al., 2007; Zheng et al., 2003), to find any indications of the source of the text.

In this paper we investigate classification of a text with respect to an author's native language, where this is not the language that that text is written in (which is often the case in phishing); we refer to this as *native language identification*. Initial work by Koppel et al. (2005) was followed by Tsur and Rappoport (2007), Estival et al. (2007), van Halteren (2008), and Wong and Dras (2009). By and large, the problem was tackled using various supervised machine learning approaches, with mostly lexical features over characters, words, and parts of speech, as well as some document structure.

Syntactic features, in contrast, in particular those that capture grammatical errors, which might potentially be useful for this task, have received little attention. Koppel et al. (2005) did suggest using syntactic errors in their work but did not investigate them in any detail. Wong and Dras (2009) noted the relevance of the concept of *contrastive analysis* (Lado, 1957), which postulates that native language constructions lead to characteristic errors in a second language. In their experimental work, however, they used only three manual syntactic constructions drawn from the literature; an ANOVA analysis showed a detectable effect, but they did not improve classification accuracy over purely lexical features.

In this paper, we investigate syntactic features for native language identification that are more general

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1600–1610,
Edinburgh, Scotland, UK, July 27–31, 2011.

than, and that do not require the manual construction of, the above approach. Taking the trees produced by statistical parsers, we use tree cross-sections as features in a machine learning approach to determine which ones characterise non-native speaker errors. Specifically, we look at two types of parse tree substructure to use as features: horizontal slices of the trees—that is, characterising parse trees as sets of context-free grammar production rules—and the features schemas used in discriminative parse reranking. The goal of the present study is therefore to investigate the influence to which syntactic features represented by parse structures would have on the classification task of identifying an author's native language relative to, and in combination with, lexical features.

The remainder of this paper is structured as follows. In Section 2, we discuss some related work on the two key topics of this paper: primarily on comparable work in native language identification, and then on how the notion of contrastive analysis can be applicable here. We then describe the models examined in Section 3, followed by experimental setup in Section 4. Section 5 presents results, and Section 6 discussion of those results.

2 Related Work

2.1 Native Language Identification

The earliest work on native language identification in this classification paradigm is that of Koppel et al. (2005), in which they deployed a machine learning approach to the task, using as features function words, character n-grams, and part-of-speech (PoS) bi-grams, as well as some spelling mistakes. With five different groups of English authors (of native languages Bulgarian, Czech, French, Russian, and Spanish) selected from the first version of *International Corpus of Learner English* (ICLE), they gained a relatively high classification accuracy of 80%. Koppel et al. (2005) also suggested that syntactic features (syntactic errors) might be useful features, but only investigated this idea at a shallow level by treating rare PoS bigrams as ungrammatical structures.

Tsur and Rappoport (2007) replicated the work of Koppel et al. (2005) to investigate the hypothesis that the choice of words in second language writing is highly influenced by the frequency of native language syllables — the *phonology* of the native language. Approximating this by character bi-grams alone, they managed to achieve a classification accuracy of 66%.

Native language is also amongst the characteristics investigated in the task of authorship profiling by Estival et al. (2007), as well as other demographic and personality characteristics. This study used a variety of lexical and document structure features. For the native language identification classification task, their model yielded a reasonably high accuracy of 84%, but this was over a set of only three languages (Arabic, English and Spanish) and against a most frequent baseline of 62.9%.

Another related work is that of van Halteren (2008), who used the Europarl corpus of parliamentary speeches. In Europarl, one original language is transcribed, and the others translated from it; the task was to identify the original language. On the basis of frequency counts of word-based n-grams, surprisingly high classification accuracies within the range of 87-97% were achieved across six languages (English, German, French, Dutch, Spanish, and Italian). This turns out, however, to be significantly influenced by the use of particular phrases used by speakers of different languages in the parliamentary context (e.g. the way Germans typically address the chamber).

To our knowledge, Wong and Dras (2009) is the only work that has investigated the usefulness of syntactic features for the task of native language identification. They first replicated the work of Koppel et al. (2005) with the three types of lexical feature, namely function words, character n-grams, and PoS bi-grams. They then examined the literature on contrastive analysis (see Section 2.2), from the field of second language acquisition, and selected three syntactic errors commonly observed in non-native English users—subject-verb disagreement, noun-number disagreement and misuse of determiners—that had been identified as being influenced by the native language. An ANOVA analysis showed that the native language identification constructions were identifiable; however, the overall classification was not improved over the lexical features by using just the three manually detected syntactic errors. The best overall accuracy re-

ported was 73.71%; this was on the second version of ICLE, across seven languages (those of Koppel et al. (2005), plus the two Asian languages Chinese and Japanese).

As a possible approach that would improve the classification accuracy over just the three manually detected syntactic errors, Wong and Dras (2009) suggested deploying (but did not carry out) an idea put forward by Gamon (2004) (citing Baayen et al. (1996)) for the related task of identifying the author of a text: to use CFG production rules to characterise syntactic structures used by authors.[1] We note that similar ideas have been used in the task of sentence grammaticality judgement, which utilise parser outputs (both trees and by-products) as classification features (Mutton et al., 2007; Sun et al., 2007; Foster et al., 2008; Wagner et al., 2009; Tetreault et al., 2010; Wong and Dras, 2010). We combine this idea with one we introduce in this paper, of using discriminative reranking features as a broader characterisation of the parse tree.

2.2 Contrastive analysis

Contrastive analysis (Lado, 1957) was an early attempt in the field of second language acquisition to explain the kinds and source of errors that non-native speakers make. It arose out of behaviourist psychology, and saw language learning as an issue of habit formation that could be inhibited by previous habits inculcated in learning the native language. The theory was also tied to structural linguistics: it compared the syntactic structures of the native and second languages to find differences that might cause learning difficulties. The Lado work postulated the Contrastive Analysis Hypothesis (CAH), claiming that "those elements which are similar to [the learner's] native language will be simple for him, and those elements that are different will be difficult"; the consequence is that there will be more errors made in those difficult elements.

While contrastive analysis was influential at first, it was increasingly noticed that many errors were common across all language learners regardless of native language, which could not be explained under contrastive analysis. Corder (1967) then described an alternative, *error analysis*, where contrastive analysis-style errors were seen as only one type of error, 'interlanguage' or 'interference' errors; other types were 'intralingual' and 'developmental' errors, which are not specific to the native language (Richards, 1971).

In an overview of contrastive analysis after the emergence of error analysis, Wardhaugh (1970) noted that there were two interpretations of the CAH, termed the strong and weak forms. Under the strong form, all errors were attributed to the native language, and clearly that was not tenable in light of error analysis evidence. In the weak form, these differences have an influence but are not the sole determinant of language learning difficulty. Wardhaugh noted claims at the time that the hypothesis was no longer useful in either the strong or the weak version: "Such a claim is perhaps unwarranted, but a period of quiescence is probable for CA itself". This appears to be the case, with the then-dominant error analysis giving way to newer, more specialised theories of second language acquisition, such as the *competition model* of MacWhinney and Bates (1989) or the *processability theory* of Pienemann (1998). Nevertheless, smaller studies specifically of interlanguage errors have continued to be carried out, generally restricted in their scope to a specific grammatical aspect of English in which the native language of the learners might have an influence. To give some examples, Granger and Tyson (1996) examined the usage of connectors in English by a number of different native speakers – French, German, Dutch, and Chinese; Vassileva (1998) investigated the employment of first person singular and plural by another different set of native speakers – German, French, Russian, and Bulgarian; Slabakova (2000) explored the acquisition of telicity marking in English by Spanish and Bulgarian learners; Yang and Huang (2004) studied the impact of the absence of grammatical tense in Chinese on the acquisition of English tense-aspect system (i.e. telicity marking); Franck et al. (2002) and Vigliocco et al. (1996) specifically examined the usage of subject-verb agreement in English by French and Spanish, respectively. There are also a few teaching resources

[1] It is not entirely clear how this might work for authorship identification: would the Brontë sisters, the corpus Gamon worked with, have used a significant number of different syntactic constructions from each other? In the context of native language identification, however, constrastive analysis postulates that this is exactly the case for the different classes.

for English language teachers that collate such phenomena, such as that of Swan and Smith (2001).

NLP techniques and a probabilistic view of native language identification now let us revisit and make use of the weak form of the CAH. Interlanguage errors, as represented by differences in parse trees, may be characteristic of the native language of a learner; we can use the occurrence of these to come up with a revised likelihood of the native language. In this paper, we use machine learning in a prediction task as our approach to this.

3 Models

This section describes the three basic models investigated: the lexical model, based on Koppel et al. (2005), as the baseline; and then the two models that exploit syntactic information. In Section 5 we look at the performance of each model independently and also in combination: to combine, we just concatenate feature vectors.

Lexical As Wong and Dras (2009), we replicate the features of Koppel et al. (2005) to produce our LEXICAL model. These are of three types: function words,[2] character n-grams, and PoS n-grams. We follow Wong and Dras (2009) in resolving some unclear issues from Koppel et al. (2005). Specifically, we use the same list of function words, left unspecified in Koppel et al. (2005), that were empirically determined by Wong and Dras (2009) to be the best of three candidates; we used character bi-grams, as the best performing n-grams, although this also had been left unspecified by Koppel et al. (2005); and we used the most frequently occurring PoS bi-grams and tri-grams, obtained by using the Brill tagger provided in NLTK (Bird et al., 2009) being trained on the Brown corpus. In total, there are 798 features of this class with 398 function words, 200 most frequently occurring character bi-grams, and 200 most frequently occurring PoS bi-grams. Both function words and PoS bi-grams have feature values of binary type; while for character bi-grams, the feature value is the relative frequency. (These types of feature value are the best performing one for each lexical feature.)

We omitted the 250 rare bi-grams used by Koppel et al. (2005), as an ablative analysis showed that they contributed nothing to classification accuracy.

Production Rules Under this model (PRODRULE), we take as features horizontal slices of parse trees, in effect treating them as sets of CFG production rules. Feature values are binary. We look at all possible rules as features, but also present results for subsets of features chosen using feature selection. For each language in our dataset, we identify the n rules most characteristic of the language using Information Gain (IG). For m classes, we use the formulation of Yang and Pedersen (1997):

$$\begin{aligned} IG(r) = & -\sum_{i=1}^{m} \Pr(c_i) \log \Pr(c_i) \\ & + \Pr(r) \sum_{i=1}^{m} \Pr(c_i|r) \log \Pr(c_i|r) \\ & + \Pr(\bar{r}) \sum_{i=1}^{m} \Pr(c_i|\bar{r}) \log \Pr(c_i|\bar{r}) \end{aligned} \quad (1)$$

We also investigated simple frequencies, frequency ratios, and pointwise mutual information; as in much other work, IG performed best, so we do not present results for the others. Bi-normal separation (Forman, 2003), often competitive with IG, is only suitable for binary classification.

It is worth noting that the production rules being used here are all non-lexicalised ones, except those lexicalised with function words and punctuation, to avoid topic-related clues.

Reranking Features As opposed to the horizontal parse production rules, features used for discriminative reranking are cross-sections of parse trees that might capture other aspects of ungrammatical structures. For these we use the 13 feature schemas described in Charniak and Johnson (2005), which were inspired by earlier work in discriminative estimation techniques, such as Johnson et al. (1999) and Collins (2000). Examples of these feature schemas include tuples covering head-to-head dependencies, preterminals together with their closest maximal projection ancestors, and subtrees rooted in the least common ancestor.

These feature schemas are not the only possible ones—they were empirically selected for the specific purpose of augmenting the Charniak parser. However, much subsequent work has tended to use

[2] As with most work in authorship profiling, only function words are used, so that the result is not tied to a particular domain, and no clues are obtained from different topics that different authors might write about.

these same features, albeit sometimes with extensions for specific purposes (e.g. Johnson and Ural (2010) for the Berkeley parser (Petrov et al., 2006), Ng et al. (2010) for the C&C parser (Clark and Curran, 2007)). We also use this standard set, specifically the set of instantiated feature schemas from the parser from Charniak and Johnson (2005) as trained on the Wall Street Journal (WSJ), which gives 1,333,837 potential features.

4 Experimental Setup

4.1 Data

We use the *International Corpus of Learner English* (ICLE) compiled by Granger et al. (2009) for the precise purpose of studying the English writings of non-native English learners from diverse countries. All the contributors to the corpus are claimed to possess similar English proficiency levels (ranging from intermediate to advanced learners) and are in the same age group (all in their twenties at the time of corpus collection.) This was also the data used by Koppel et al. (2005) and Tsur and Rappoport (2007), although where they used the first version of the corpus, we use version 2.

Briefly, the first version contains 11 sub-corpora of English essays contributed by second-year and third-year university students of different native language backgrounds (mostly European and Slavic languages) — Bulgarian, Czech, Dutch, Finnish, French, German, Italian, Polish, Russian, Spanish, and Swedish; the second version has been extended to additional 5 other native languages (including Asian languages) — Chinese, Japanese, Norwegian, Turkish, and Tswana.

As per Wong and Dras (2009), we examine seven languages, namely Bulgarian, Czech, French, Russian, Spanish, Chinese, and Japanese. For each native language, we randomly select from amongst essays with length of 500-1000 words. For the purpose of the present study, we have 95 essays per native language. For the same reason as highlighted by Wong and Dras (2009), we intentionally use fewer essays as compared to Koppel et al. (2005)[3] with a view to reserving more data for future work. We divide these into training sets of 70 essays per language, with a held-out test set of 25 essays per language. There are 17,718 training sentences and 6,791 testing sentences.

4.2 Parsers

We use two parsers: the Stanford parser (Klein and Manning, 2003) and the Charniak and Johnson (henceforth C&J) parser (Charniak and Johnson, 2005). Both are widely used, and produce relatively accurate parses: the Stanford parser gets a labelled f-score of 85.61 on the WSJ, and the C&J 91.09.

With the Stanford parser, there are 26,284 unique parse production rules extractable from our ICLE training set of 490 texts, while the C&J parser produces 27,705. For reranking, we use only the C&J parser—since the parser stores these features during parsing, we can use them directly as classification features. On the ICLE training data, there are 6,230 features with frequency >10, and 19,659 with frequency >5.

4.3 Classifiers

For our experiments we used a maximum entropy (MaxEnt) machine learner, MegaM[4] (fifth release) by Hal Daumé III. (We also used an SVM for comparison, but the results were uniformly worse, and degraded more quickly as number of features increased, so we only report the MaxEnt results here). The classifier is tuned to obtain an optimal classification model.

4.4 Evaluation Methodology

Given our relatively small amount of data, we use k-fold cross-validation, choosing $k = 5$. While testing for statistical significance of classification results is often not carried out in NLP, we do so here because the quantity of data could raise questions about the certainty of any effect. In an encyclopedic survey of cross-validation in machine learning contexts, Refaeilzadeh et al. (2009) note that there is as yet no universal standard for testing of statistical significance; and that while more sophisticated techniques have been proposed, none is more widely accepted than a paired t-test over folds. We therefore use this paired t-test over folds, as formulated of Alpaydin

[3] Koppel et al. (2005) took all 258 texts per language from ICLE Version 1 and evaluated using 10-fold cross valiadation.

[4] MegaM is available on `http://www.cs.utah.edu/~hal/megam/`.

(2004). Under this cross-validation, 5 separate training feature sets are constructed, excluding the test fold; 3 folds are used for training, 1 fold for tuning and 1 fold for testing.

We also use a held-out test set for comparison, as it is well-known that cross-validation can overestimate prediction error (Hastie et al., 2009). We do not carry out significance testing here—with this held-out test set size ($n = 125$), two models would have to differ by a great deal to be significant. We only use it as a check on the effect of applying to completely new data.

5 Results

Table 1 presents the results for the three models individually under cross-validation. The first point to note is that PROD-RULE, under both parsers, is a substantial improvement over LEXICAL when (non-lexicalised) parse rules together with rules lexicalised with function words are used (rows marked with * in Table 1), with the largest difference as much as 77.75% for PROD-RULE[both]* ($n = all$) versus 64.29% for LEXICAL; these differences with respect to LEXICAL are statistically significant. (To give an idea, the paired t-test standard error for this largest difference is 2.52%.) In terms of error reduction, this is over 30%.

There appears to be no difference according to the parser used, regardless of their differing accuracy on the WSJ. Using the selection metric for PROD-RULE without rules lexicalised with function words produces results all around those for LEXICAL; using fewer reranking features is worse as the quality of RERANKING declines as feature cut-offs are raised.

Another, somewhat surprising point is that the RERANKING results are also generally around those of LEXICAL even though like PROD-RULE they are also using cross-sections of the parse tree. We consider there might be two possible reasons for this. The first is that the feature schemas used were originally chosen for the specific purpose of augmenting the performance of the Charniak parser; perhaps others might be more appropriate here. The second is that we selected only those instantiated feature schemas that occurred in the WSJ, and then applied them to ICLE. As the WSJ is filled with predominantly grammatical text, perhaps those that were not seen on the WSJ are precisely those that might indicate ungrammaticality. In contrast, the production rules of PROD-RULE were selected only from the ICLE training data.

Features	MaxEnt
LEXICAL ($n = 798$)	64.29
PROD-RULE[Stanford] ($n = 1000$)	65.72
PROD-RULE[Stanford]* ($n = 1000$)	74.08
PROD-RULE[Stanford]* ($n = all$)	74.49
PROD-RULE[C&J] ($n = 1000$)	62.25
PROD-RULE[C&J]* ($n = 1000$)	71.84
PROD-RULE[C&J]* ($n = all$)	71.63
PROD-RULE[both] ($n = 2000$)	67.96
PROD-RULE[both]* ($n = 2000$)	74.69
PROD-RULE[both]* ($n = all$)	77.75
RERANKING (all features)	67.96
RERANKING (>5 counts)	66.33
RERANKING (>10 counts)	64.90

Table 1: Classification results based on 5-fold cross validation with parse rules as syntactic features (accuracy %)

Features	MaxEnt
Lexical features ($n = 798$)	75.43
PROD-RULE[Stanford] ($n = 1000$)	74.29
PROD-RULE[Stanford]* ($n = 1000$)	79.43

PROD-RULE[C&J] ($n = 1000$)*	79.43
PROD-RULE[C&J] ($n = all$)*	80.00
PROD-RULE[both] ($n = 2000$)	77.71
PROD-RULE[both] ($n = 2000$)*	78.85
PROD-RULE[both] ($n = all$)*	80.00
RERANKING (all features)	77.14
RERANKING (>5 counts)	76.57
RERANKING (>10 counts)	75.43

Table 2: Classification results based on hold-out validation with parse rules as syntactic features (accuracy %)

Table 2 presents the results for the individual models on the held-out test set. The results are generally higher than for cross-validation—this is not surprising, as the texts are of the same type, but all the training data is used (rather than the $1-1/k$ proportion for cross-validation). Overall, the pattern is still the same, with PROD-RULE best, then RERANKING and LEXICAL broadly similar; as expected, no differences are significant with this smaller dataset. The gap has narrowed, but without significance test-

Features	MaxEnt
LEXICAL ($n = 798$)	64.29
LEXICAL + PROD-RULE[both] ($n = 2000$)	63.06
LEXICAL + PROD-RULE[both]* ($n = 2000$)	72.45
LEXICAL + PROD-RULE[both]* ($n = all$)	70.82
LEXICAL + RERANKING ($n = all$)	68.17

Table 3: Classification results based on 5-fold cross validation for combined models (accuracy %)

Features	MaxEnt
LEXICAL ($n = 798$)	75.43
LEXICAL + PROD-RULE[both] ($n = 2000$)	80.57
LEXICAL + PROD-RULE[both]* ($n = 2000$)	81.14
LEXICAL + PROD-RULE[both]* ($n = all$)	81.71
LEXICAL + RERANKING ($n = all$)	76.00

Table 4: Classification results based on hold-out validation for combined models (accuracy %)

ing it is difficult to say whether this is a genuine phenomenon. The accuracy rate for LEXICAL here is in line with Wong and Dras (2009); and given the smaller dataset and larger set of languages, also broadly in line with Koppel et al. (2005).

Tables 3 and 4 present results for model combinations. It can be seen that the model combinations do not produce results better than PROD-RULE alone. Combining all features (results not presented here) seems to degrade the overall performance even of the MegaM: perhaps we need to derive feature vectors more compactly than by feature concatenation.

6 Discussion

As illustrated in the confusion matrices (Table 5 for the PROD-RULE model, and Table 6 for the LEXICAL model), misclassifications occur largely in Spanish and Slavic languages, Bulgarian and Russian in particular. Unsurprisingly, Chinese is almost completely identified since it comes from a entirely different language family, Sino-Tibetan, as compared to the rest of the languages which are from the branches of the Indo-European family (with Japanese as the exception). Japanese and French also appear to be easily distinguished, which could probably be attributed to their word order or sentence structure which are, to some extent, quite different from English. Japanese is a 'subject-object-verb' language; and French, although having the same word order as English, heads of phrases in

Table 6: Confusion matrix based on lexical features on the held-out set (BL:Bulgarian, CZ:Czech, FR:French, RU:Russian, SP:Spanish, CN:Chinese, JP:Japanese)

French typically come before modifiers as opposed to English. Overall, the PROD-RULE model results in fewer misclassifications compared to the LEXICAL model; there are mostly only incremental improvements for each language, with perhaps the exception of the reduction in confusion in the Slavic languages.

We looked at some of the data, to see what kind of syntactic substructure is useful in classifying native language. Although using feature selection with only 1000 features did not improve performance, the information gain ranking does identify particular constructions as characteristic of one of the languages, and so are useful for inspection.

A phenomenon that the literature has noted as occurring with Chinese speakers is that of the missing determiner.[5] This corresponds to a higher frequency of NP rules without determiners. These rules may be valid in other contexts, but are also used to describe ungrammatical constituents. One example is

[5]This does happen with native speakers of some other languages, such as Slavic ones, but not generally (from our knowledge of the literature) with native speakers of others, such as Romance ones.

Figure 2: Parse from Chinese-speaking authors, illustrating *according to*

NP → NN NN. In Figure 1 we give the parse (from the Stanford parser) of the sentence *The development of* ***country park*** *can directly elp to alleviate overcrowdedness and overpopulation in urban area*. The phrase *country park* should either have a determiner or be plural (in which case the appropriate rule would be NP → NN NNS). There is a similar phenomenon with *in urban area*, although this is an instance of the rule NP → JJ NN.

Another production rule that occurs typically—in fact, almost exclusively—in the texts of native Chinese speakers is PP → VBG PP (by the Stanford parser), which almost always corresponds to the phrase *according to*. In Figure 2 we give the parse of a short sentence (*According to <R>, burning of*

```

Figure 3: Parse illustrating parser correction

plastic waste generates toxic by-products—<R>is an in-text citation that was removed in the preparation of ICLE) that illustrates this particular construction. It appears that speakers of Chinese frequently use this phrase as a translation of *gēn jù*. So in this case, what is identified is not the sort of error that is of interest to contrastive analysis, but just a particular construction that is characteristic of a certain native speaker's language, one that is perfectly grammatical but which is used relatively infrequently by others and has a slightly unusual analysis by the parser.

We had expected to see more rules that displayed obvious ungrammaticality, such as VP → DT IN. However, both parsers appear to be good at 'ignoring' errors, and producing relatively grammatical structures (albeit ones with different frequencies for different native languages). Figure 3 gives the C&J parse for *Overall, cyber **cafeis** a good place as recreational centre with a bundle of **up-to-dated** information*. The correction of *up-to-dated* rather than *up-to-date* is straightforward, but the simple typographical error of running together *cafe* and *is* leads to more complex problems for the parser. Nevertheless, the parser produces a solid grammatical tree, specifically assigning the category VBD to the compound *cafeis*. This appears to be because both the Stanford and C&J parsers have implicit linguistic constraints such as assumptions about heads; these are imposed even when the text does not provide evidence for them.

We also present in Table 7 the top 10 rules chosen under the IG feature selection for the Stanford parser on the held-out set. A number of these, and those ranked lower, are concerned with punctuation: these seem unlikely to be related to native language, but perhaps rather to how students of a particular language background are taught. Others are more typical of the sorts of example we illustrated above: PP → VBG PP, for example, is typically connected to the *according to* construction discussed in connection with Figure 2, and it can be seen that the dominant frequency count there is for native Chinese speakers (column 6 of the counts).

7 Conclusion

In this paper we have shown that, using cross-sections of parse trees, we can improve above an already good baseline in the task of native language identification. While we do not make any strong claims for the Contrastive Analysis Hypothesis, the usefulness of syntax in the context of this problem does provide some support.

The best features arising from the classification have been horizontal cross-sections of trees, rather than the more general discriminative parse reranking features that might have been expected to perform at least as well. This relatively poorer performance by the reranking features may be due to a number of factors, all of which could be investigated in future work. One is the use of feature schema instances that did not appear in the largely grammatical WSJ; another is the extension of feature schemas; and a third is the use of a parser that does not enforce linguistic constraints such as the Berkeley parser (Petrov et al., 2006).

Examining some of the substructures showed some errors that were expected; other constructions that were grammatical, but were just characteristic translations of constructions that were common in the native language; and a large number where grammatical errors were glossed over by the parser's linguistic constraints, suggesting another purpose for further work with the Berkeley parser. Overall, the use of these led to an error reduction in over 30%

in the cross-validation evaluation with significance testing.

Acknowledgments

The authors would like to acknowledge the support of ARC Linkage Grant LP0776267 and ARC Discovery Grant DP1095443, and thank the reviewers for useful feedback. Much gratitude is due to Mark Johnson for his guidance on the extraction of reranking features.

A Probabilistic Forest-to-String Model for Language Generation from Typed Lambda Calculus Expressions

Wei Lu and **Hwee Tou Ng**

{luwei,nght}@comp.nus.edu.sg

Abstract

This paper describes a novel probabilistic approach for generating natural language sentences from their underlying semantics in the form of typed lambda calculus. The approach is built on top of a novel reduction-based weighted synchronous context free grammar formalism, which facilitates the transformation process from typed lambda calculus into natural language sentences. Sentences can then be generated based on such grammar rules with a log-linear model. To acquire such grammar rules automatically in an unsupervised manner, we also propose a novel approach with a generative model, which maps from sub-expressions of logical forms to word sequences in natural language sentences. Experiments on benchmark datasets for both English and Chinese generation tasks yield significant improvements over results obtained by two state-of-the-art machine translation models, in terms of both automatic metrics and human evaluation.

1 Introduction

This work focuses on the task of generating natural language sentences from their underlying meaning representations in the form of formal logical expressions (typed lambda calculus). Many early approaches to generation from logical forms make use of rule-based methods (Wang, 1980; Shieber et al., 1990), which concern surface realization (ordering and inflecting of words) but largely ignore lexical acquisition. Recent approaches start to employ corpus-based probabilistic methods, but many of them assume the underlying meaning representations are of specific forms such as variable-free tree-structured representations (Wong and Mooney, 2007a; Lu et al., 2009) or database entries (Angeli et al., 2010).

While these algorithms usually work well on specific semantic formalisms, it is unclear how well they could be applied to a different semantic formalism. In this work, we propose a general probabilistic model that performs generation from underlying formal semantics in the form of typed lambda calculus expressions (we refer to them as λ-*expressions* throughout this paper), where both lexical acquisition and surface realization are integrated in a single framework.

One natural proposal is to adopt a state-of-the-art statistical machine translation approach. However, unlike text to text translation, which has been extensively studied in the machine translation community, translating from logical forms into text presents additional challenges. Specifically, logical forms such as λ-expressions may have complex internal structures and variable dependencies across sub-expressions. Problems arise when performing automatic acquisition of a translation lexicon, as well as performing lexical selection and surface realization during generation.

In this work, we tackle these challenges by making the following contributions:

- *A novel forest-to-string generation algorithm*: Inspired by the work of Chiang (2007), we introduce a novel reduction-based weighted binary synchronous context-free grammar formalism for generation from logical forms (λ-expressions), which can then be integrated with a probabilistic forest-to-string generation algo-

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1611–1622,
Edinburgh, Scotland, UK, July 27–31, 2011.

rithm.

- *A novel grammar induction algorithm*: To automatically induce such synchronous grammar rules, we propose a novel generative model that establishes phrasal correspondences between logical sub-expressions and natural language word sequences, by extending a previous model proposed for parsing natural language into meaning representations (Lu et al., 2008).

To our best knowledge, this is the first probabilistic model for generating sentences from the lambda calculus encodings of their underlying formal meaning representations, that concerns both surface realization and lexical acquisition. We demonstrate the effectiveness of our model in Section 5.

2 Related Work

The task of language generation from logical forms has a long history. Many early works do not rely on probabilistic approaches. Wang (1980) presented an approach for generation from an extended predicate logic formalism using hand-written rules. Shieber et al. (1990) presented a semantic head-driven approach for generation from logical forms based on rules written in Prolog. Shemtov (1996) presented a system for generation of multiple paraphrases from ambiguous logical forms. Langkilde (2000) presented a probabilistic model for generation from a packed forest meaning representation, without concerning lexical acquisition. Specifically, we are not aware of any prior work that handles both automatic unsupervised lexical acquisition and surface realization for generation from logical forms in a single framework.

Another line of research efforts focused on the task of language generation from other meaning representation formalisms. Wong and Mooney (2007a) as well as Chen and Mooney (2008) made use of synchronous grammars to transform a variable-free tree-structured meaning representation into sentences. Lu et al. (2009) presented a language generation model using the same meaning representation based on tree conditional random fields. Angeli et al. (2010) presented a domain-independent probabilistic approach for generation from database entries. All these models are probabilistic models.

Recently there are also substantial research efforts on the task of mapping natural language to meaning representations in various formalisms – the inverse task of language generation called *semantic parsing*. Examples include Zettlemoyer and Collins (2005; 2007; 2009), Kate and Mooney (2006), Wong and Mooney (2007b), Lu et al. (2008), Ge and Mooney (2009), as well as Kwiatkowski et al. (2010).

Of particular interest is our prior work Lu et al. (2008), in which we presented a joint generative process that produces a hybrid tree structure containing words, syntactic structures, and meaning representations, where the meaning representations are in a variable-free tree-structured form. One important property of the model in our prior work is that it induces a hybrid tree structure automatically in an unsupervised manner, which reveals the correspondences between natural language word sequences and semantic elements. We extend our prior model in the next section, so as to support λ-expressions. The model in turn serves as the basis for inducing the synchronous grammar rules later.

3 λ-Hybrid Tree

In Lu et al. (2008), a generative model was presented to model the process that jointly generates both natural language sentences and their underlying meaning representations of a variable-free tree-structured form. The model was defined over a *hybrid tree*, which consists of meaning representation tokens as internal nodes and natural language words as leaves. One limitation of the hybrid tree model is that it assumes a single fixed tree structure for the meaning representation. However, λ-expressions exhibit complex structures and variable dependencies, and thus it is not obvious how to represent them in a single tree structure.

In this section, we present a novel *λ-hybrid tree* model that provides the following extensions over the model of Lu et al. (2008):

1. The internal nodes of a meaning representation tree involve λ-expressions which are not necessarily of variable-free form;
2. The meaning representation has a packed forest representation, rather than a single deterministic tree structure.

3.1 Packed λ-Meaning Forest

We represent a λ-expression with a packed forest of meaning representation trees (called *λ-meaning for-*

est). Multiple different meaning representation trees (called λ-*meaning trees*) can be extracted from the same λ-meaning forest, but they all convey equivalent semantics via reductions, as discussed next.

Constructing a λ-meaning forest for a given λ-expression requires decomposition of a complete λ-expression into semantically complete and syntactically correct sub-expressions in a principled manner. This can be achieved with a process called higher order unification (Huet, 1975). The process was known to be very complex and was shown to be undecidable in unrestricted form (Huet, 1973). Recently a restricted form of higher order unification was applied to a semantic parsing task (Kwiatkowski et al., 2010). In this work, we employ a similar technique for building the λ-meaning forest.

For a given λ-expression e, our algorithm finds either two expressions h and f such that $(h\ f) \equiv e$, or three expressions h, f, and g such that $((h\ f)\ g) \equiv e$, where the symbol $\equiv$ is interpreted as α-*equivalent* after *reductions*[1] (Barendregt, 1985). We then build the λ-meaning forest based on the expressions h, f, and g. In practice, we develop a BUILDFOREST(e) procedure which recursively builds λ-forests by applying restricted higher-order unification rules on top of the λ-expression e. Each node of the λ-forest is called a λ-production, to which we will give more details in Section 3.2. For example, once a candidate triple (h, f, g) as in $((h\ f)\ g) \equiv e$ has been identified, the procedure creates a λ-forest with the root node being a λ-production involving h, and two sets of child λ-forests given by BUILDFOREST(f) and BUILDFOREST(g) respectively. For restricted higher-order unification, besides the similar assumptions made by Kwiatkowski et al. (2010), we also impose one additional assumption: limited free variable, which states that the expression h must contain no more than one free variable. Note that this process provides a semantically equivalent packed forest representation of the original λ-expression, without altering its semantics in any way.

For better readability, we introduce the symbol $\lhd$ as an alternative notation for functional application. In other words, $h \lhd f$ refers to $(h\ f)$ or $h(f)$, and $h \lhd f \lhd g$ refers to $((h\ f)\ g)$. For example, the expression $\lambda x.state(x) \wedge loc(boston, x)$ can be represented as the functional application form of $[\lambda f.\lambda x.f(x) \wedge loc(boston, x)] \lhd \lambda x.state(x)$.[2]

Such a packed forest representation contains exponentially many tree structures which all convey the same semantics. We believe such a semantic representation is more advantageous than the single fixed tree-structured representation. In fact, one could intuitively regard a different decomposition path as a different way of interpreting the same semantics. Thus, such a representation could potentially accommodate a wider range of natural language expressions, which all share the same semantics but with very different word choices, phrase orderings, and syntactic structures (like paraphrases). It may also alleviate the non-isomorphism issue that was commonly faced by researchers when mapping meaning representations and sentences (Wong and Mooney, 2007b). We will validate our belief later through experiments.

3.2 The Joint Generative Process

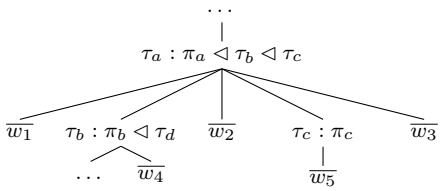

Figure 1: The joint generative process of both λ-meaning tree and its corresponding natural language sentence, which results in a λ-hybrid tree.

The generative process for a sentence together with its corresponding λ-meaning tree is illustrated in Figure 1, which results in a λ-*hybrid tree*. Internal nodes of a λ-hybrid tree are called λ-*productions*, which are building blocks of a λ-forest. Each λ-production in turn has at most two child λ-productions. A λ-production has the form $\tau_a : \pi_a \lhd \overline{\tau_b}$, where τ_a is the expected *type*[3] after type evaluation of the terms to its right, π_a is a λ-expression (serves as the functor), and $\overline{\tau_b}$ are types of the child λ-productions (as the arguments). The leave nodes

[1] In this work, for reductions, we consider α-conversions (changing bound variables) and β-conversions (applying functors to their arguments).

[2] Throughout this paper, we abuse this notation a bit by allowing the arguments to be types rather than actual expressions, such as $\lambda y.\lambda x.loc(y, x)) \lhd e$, which indicates that the functor $\lambda y.\lambda x.loc(y, x)$ expects an expression of type e to serve as its argument.

[3] This work considers basic types: e (entities) and t (truth values). It also allows function types, e.g., $\langle e, t\rangle$ is the type assigned to functions that map from entities to truth values.

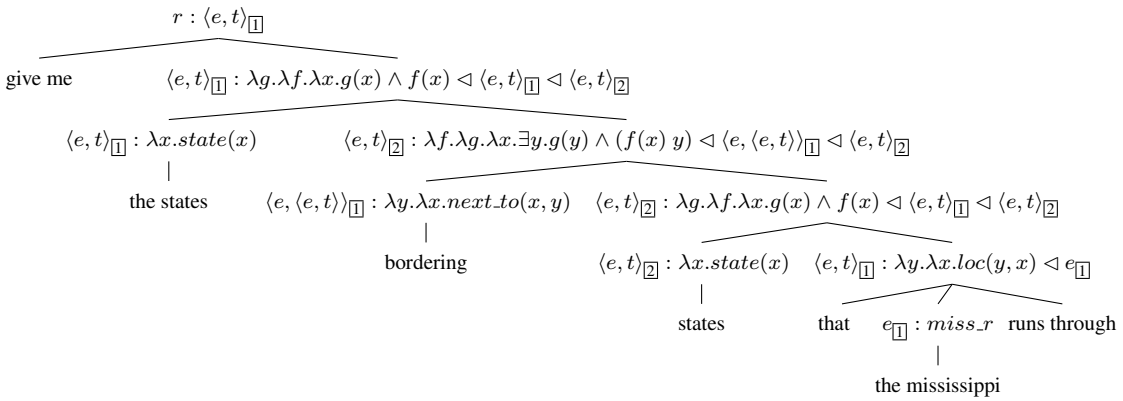

Figure 2: One example λ-hybrid tree for the sentence "give me the states bordering states that the mississippi runs through" together with its logical form "$\lambda x_0.state(x_0) \wedge \exists x_1.[loc(miss\_r, x_1) \wedge state(x_1) \wedge next\_to(x_1, x_0)]$".

$\overline{w}$ are contiguous word sequences. The model repeatedly generates λ-*hybrid sequences*, which consist of words intermixed with λ-productions, from each λ-production at different levels.

Consider part of the example λ-hybrid tree in Figure 2. The probability associated with generation of the subtree that spans the sub-sentence "that the mississippi runs through" can be written as:

$$P\Big(\lambda x.loc(miss\_r, x), \text{that the mississippi runs through}\Big)$$
$$= \phi(m \rightarrow \overline{\mathbf{w}\mathcal{Y}\mathbf{w}}|p_1) \times \psi(\text{that } e_{\boxed{1}} \text{ runs through}|p_1)$$
$$\times \rho(p_2|p_1, \arg_1) \times \phi(m \rightarrow \overline{\mathbf{w}}|p_2) \times \psi(\text{the mississippi}|p_2)$$

where $p_1 = \langle e,t\rangle : \lambda y.\lambda x.loc(y,x) \lhd e_{\boxed{1}}$, and $p_2 = e : miss\_r$.

Following the work of Lu et al. (2008), the generative process involves three types of parameters $\overline{\theta} = \{\phi, \psi, \rho\}$: 1) pattern parameters ϕ, which model in what way the words and child λ-productions are intermixed; 2) emission parameters ψ, which model the generation process of words from λ-productions, where either a unigram or a bigram assumption can be made (Lu et al., 2008); and 3) meaning representation (MR) model parameters ρ, which model the generation process from one λ-production to its child λ-productions. An analogous inside-outside algorithm (Baker, 1979) used there is employed here. Since we allow a packed λ-meaning forest representation rather than a fixed tree structure, the MR model parameters ρ in this work should be estimated with the inside-outside algorithm as well, rather than being estimated directly from the training data by simple counting, as was done in Lu et al. (2008).

4 The Language Generation Algorithm

Now we present the algorithm for language generation. We introduce the grammar first, followed by the features we use. Next, we present the method for grammar induction, and then discuss the decoder.

4.1 The Grammar

We use a weighted synchronous context free grammar (SCFG) (Aho and Ullman, 1969), which was previously used in Chiang (2007) for hierarchical phrase-based machine translation. The grammar is defined as follows:

$$\tau \rightarrow \quad \langle p_\lambda\ , h_w, \sim \rangle \qquad (1)$$

where τ is the type associated with the λ-production p_λ[4], and h_w is a sequence consisting of natural language words intermixed with types. The symbol $\sim$ denotes the one-to-one correspondence between nonterminal occurrences (i.e., in this case types of λ-expressions) in both p_λ and h_w.

We allow a maximum of two nonterminal symbols in each synchronous rule, as was also assumed in Chiang (2007), which makes the grammar a binary SCFG. Two example rules are:

$$\langle e,t\rangle \rightarrow \Big\langle \lambda y.\lambda x.loc(y,x) \lhd e_{\boxed{1}}\ ,\ \text{that } e_{\boxed{1}} \text{ runs through} \Big\rangle$$
$$e \rightarrow \Big\langle miss\_r,\ \text{the mississippi} \Big\rangle$$

where the boxed indices give the correspondences between nonterminals.

A derivation with the above two synchronous rules results in the following λ-expression paired with its natural language counterpart:

[4]Since type is already indicated by τ, we avoid redundancy by omitting it when writing p_λ, without loss of information.

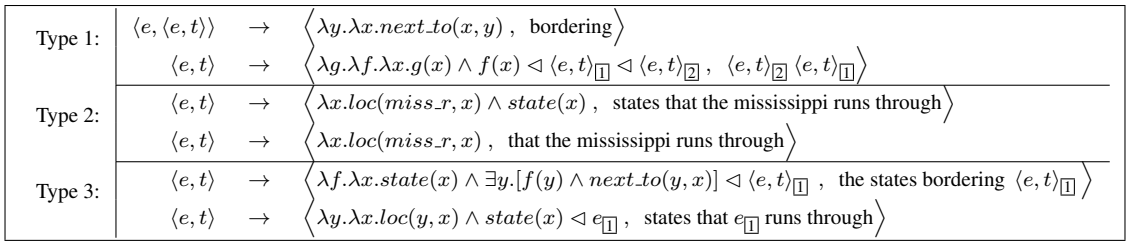

Figure 3: Example synchronous rules that can be extracted from the λ-hybrid tree of Figure 2.

$$\langle e, t\rangle \rightarrow \left\langle \lambda x.loc(miss\_r, x)\ ,\ \text{that the mississippi runs through} \right\rangle$$

where the source side λ-expression is constructed from the application $\lambda y.\lambda x.loc(y, x) \lhd miss\_r$ followed by a reduction (β-conversion). Assuming the λ-expression to be translated is $\lambda x.loc(miss\_r, x)$, the above rule in fact gives one candidate translation "that the mississippi runs through".

4.2 Features

Following the work of Chiang (2007), we assign scores to derivations with a log-linear model, which are essentially weighted products of feature values.

For generality, we only consider the following four simple features in this work:

1. $\tilde{p}(h_w|p_\lambda)$: the relative frequency estimate of a hybrid sequence h_w given the λ-production p_λ;
2. $\tilde{p}(p_\lambda|h_w, \tau)$: the relative frequency estimate of a λ-production p_λ given the phrase h_w and the type τ;
3. $\exp(-wc(h_w))$: the number of words generated, where $wc(h_w)$ refers to the number of words in h_w (i.e., word penalty); and
4. $p_{LM}(\hat{s})$: the language model score of the generated sentence $\hat{s}$.

The first three features, which are also widely used in state-of-the-art machine translation models (Koehn et al., 2003; Chiang, 2007), are rule-specific and thus can be computed before decoding. The last feature is computed during the decoding phase in combination with the sibling rules used.

We score a derivation D with a log-linear model:

$$\mathbf{w}(D) = \left(\prod_{r \in D} \prod_i f_i(r)^{w_i} \right) \times p_{LM}(\hat{s})^{w_{LM}} \qquad (2)$$

where $r \in D$ refers to a rule r that appears in the derivation D, $\hat{s}$ is the target side (sentence) associated with the derivation D, and f_i is a rule-specific feature (one of features 1–3 above) which is weighted with w_i. The language model feature is weighted with w_{LM}.

Once the feature values are computed, our goal is to find the optimal weight vector $\bar{w}^*$ that maximizes a certain evaluation metric when used for decoding, as we will discuss in Section 4.4.

Following popular approaches to learning feature weights in the machine translation community (Och and Ney, 2004; Chiang, 2005), we use the minimum error rate training (MERT) (Och, 2003) algorithm to learn the feature weights that directly optimize certain automatic evaluation metric. Specifically, the Z-MERT (Zaidan, 2009) implementation of the algorithm is used in this work.

4.3 Grammar Induction

Automatic induction of the grammar rules as described above from training data (which consists of pairs of λ-expressions and natural language sentences) is a challenging task. Current state-of-the-art string-based translation systems (Koehn et al., 2003; Chiang, 2005; Galley and Manning, 2010) typically begin with a word-aligned corpus to construct phrasal correspondences. Word-alignment information can be estimated from alignment models, such as the IBM alignment models (Brown et al., 1993) and HMM-based alignment models (Vogel et al., 1996; Liang et al., 2006). However, unlike texts, logical forms have complex internal structures and variable dependencies across sub-expressions. It is not obvious how to establish alignments between logical terms and texts with such alignment models.

Fortunately, the generative model for λ-hybrid tree introduced in Section 3 explicitly models the mappings from λ-sub-expressions to (possibly discontiguous) word sequences with a joint generative process. This motivates us to extract grammar rules from the λ-hybrid trees. Thus, we first find the Viterbi λ-hybrid trees for all training instances,

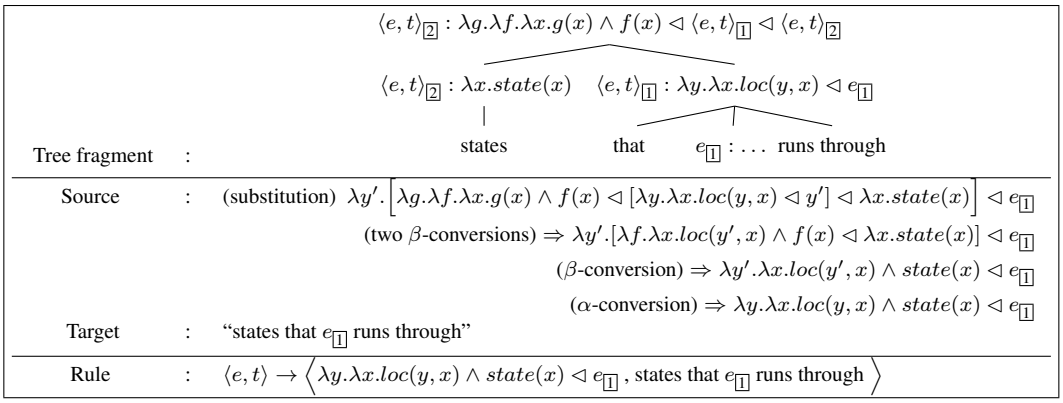

Figure 4: Construction of a two-level λ-hybrid sequence rule via substitution and reductions from a tree fragment. Note that the subtree rooted by $e_{\boxed{1}} : miss\_r$ gets "abstracted" by its type e. The auxiliary variable y' of type e is thus introduced to facilitate the construction process.

based on the learned parameters of the generative λ-hybrid tree model.

Next, we extract grammar rules on top of these λ-hybrid trees. Specifically, we extract the following three types of synchronous grammar rules, with examples given in Figure 3:

1. λ-hybrid sequence rules: They are the conventional rules constructed from one λ-production and its corresponding λ-hybrid sequence.
2. Subtree rules: These rules are constructed from a complete subtree of the λ-hybrid tree. Each rule provides a mapping between a complete sub-expression and a contiguous sub-sentence.
3. Two-level λ-hybrid sequence rules: These rules are constructed from a tree fragment with one of its grandchild subtrees (the subtree rooted by one of its grandchild nodes) being abstracted with its type only. These rules are constructed via substitution and reductions.
   Figure 4 gives an example based on a tree fragment of the λ-hybrid tree in Figure 2. Note that the first step makes use of the auxiliary variable y' of type e to represent the grandchild subtree. $\lambda y'$ is introduced so as to allow any λ-expression of type e serving as this expression's argument to replace y'. In fact, if the semantics conveyed by the grandchild subtree serves as its argument, we will obtain the exact complete semantics of the current subtree. As we can see, the resulting rule is more general, and is able to capture longer structural dependencies. Such rules are thus potentially more useful.

The overall algorithm for learning the grammar rules is sketched in Figure 5.

4.4 Decoding

Our goal in decoding is to find the most probable sentence $\hat{s}$ for a given λ-expression e:

$$\hat{s} = s\left(\arg\max_{D \text{ s.t. } e(D) \equiv e} \mathbf{w}(D)\right) \quad (3)$$

where $e(D)$ refers to the source side (λ-expression) of the derivation D, and $s(D)$ refers to the target side (natural language sentence) of D.

A conventional CKY-style decoder as used by Chiang (2007) is not applicable to this work since the source side does not exhibit a linear structure. As discussed in Section 3.1, λ-expressions are represented as packed λ-meaning forests. Thus, in this work, we make use of a bottom-up dynamic programming chart-parsing algorithm that works directly on translating forest nodes into target natural language words. The algorithm is similar to that of Langkilde (2000) for generation from an underlying packed semantic forest. Language models are incorporated when scoring the n-best candidates at each forest node, where the cube-pruning algorithm of Chiang (2007) is used. In order to accommodate type 2 and type 3 rules as discussed in Section 4.3, whose source side λ-productions are not present in the nodes of the original λ-meaning forest, new λ-productions are created (via substitution and reductions) and attached to the original λ-meaning forest.

Procedures

- $f \leftarrow \text{BUILDFOREST}(e)$
  It takes in a λ-expression e and outputs its λ-meaning forest f. (Sec. 3.1)
- $\bar{\theta} \leftarrow \text{TRAINGENMODEL}(\mathbf{f}, \mathbf{s})$
  It takes in λ-meaning forest-sentence pairs $(\mathbf{f}, \mathbf{s})$, performs EM training of the generative model, and outputs the parameters $\bar{\theta}$. (Sec. 3.2)
- $h \leftarrow \text{FINDHYBRIDTREE}(f, s, \bar{\theta})$
  It finds the most probable λ-hybrid tree h containing the given f-s pair, under the generative model parameters $\bar{\theta}$. (Sec. 4.3)
- $\Gamma_h \leftarrow \text{EXTRACTRULES}(h)$
  It takes in a λ-hybrid tree h, and extracts a set of grammar rules Γ_h out of it. (Sec. 4.3)

Algorithm

1. Inputs and initializations:
   - A training set $(\mathbf{e}, \mathbf{s})$, an empty rule set $\Gamma = \emptyset$
2. Learn the grammar:
   - For each $e_i \in \mathbf{e}$, find its λ-meaning forest: $f_i = \text{BUILDFOREST}(e_i)$. This gives the set $(\mathbf{f}, \mathbf{s})$.
   - Learn the generative model parameter : $\bar{\theta}^* = \text{TRAINGENMODEL}(\mathbf{f}, \mathbf{s})$.
   - For each $(f_i, s_i) \in (\mathbf{f}, \mathbf{s})$, find the most probable λ-hybrid tree h_i, and then extract the grammar rules from it:
     $h_i = \text{FINDHYBRIDTREE}(f_i, s_i, \bar{\theta}^*)$
     $\Gamma = \Gamma \cup \text{EXTRACTRULES}(h_i)$
3. Output the learned grammar rule set Γ.

Figure 5: The algorithm for learning the grammar rules

5 Experiments

For experiments, we evaluated on the GEOQUERY dataset, which consists of 880 queries on U.S. geography. The dataset was manually labeled with λ-expressions as their semantics in Zettlemoyer and Collins (2005). It was used in many previous research efforts on semantic parsing (Zettlemoyer and Collins, 2005; Wong and Mooney, 2006; Zettlemoyer and Collins, 2007; Kwiatkowski et al., 2010). The original dataset was annotated with English sentences only. In order to assess the generation performance across different languages, in our work the entire dataset was also manually annotated with Chinese by a native Chinese speaker with linguistics background[5].

For all the experiments we present in this section, we use the same split as that of Kwiatkowski et al. (2010), where 280 instances are used for testing, and the remaining instances are used for learning. We further split the learning set into two portions, where 500 instances are used for training the models, which includes induction of grammar rules, training a language model, and computing feature values, and the remaining 100 instances are used for tuning the feature weights.

As we have mentioned earlier, we are not aware of any previous work that performs generation from formal logical forms that concerns both lexical acquisition and surface realization. The recent work by Angeli et al. (2010) presented a generation system from database records with an additional focus on content selection (selection of records and their subfields for generation). It is not obvious how to adopt their algorithm in our context where content selection is not required but the more complex logical semantic representation is used as input. Other earlier approaches such as the work of Wang (1980) and Shieber et al. (1990) made use of rule-based approaches without automatic lexical acquisition.

We thus compare our system against two state-of-the-art machine translation systems: a phrase-based translation system, implemented in the Moses toolkit (Koehn et al., 2007)[6], and a hierarchical phrase-based translation system, implemented in the Joshua toolkit (Li et al., 2009), which is a reimplementation of the original Hiero system (Chiang, 2005; Chiang, 2007). The state-of-the-art unsupervised Berkeley aligner (Liang et al., 2006) with default setting is used to construct word alignments. We train a trigram language model with modified Kneser-Ney smoothing (Chen and Goodman, 1996) from the training dataset using the SRILM toolkit (Stolcke, 2002), and use the same language model for all three systems. We use an n-best list of size 100 for all three systems when performing MERT.

5.1 Automatic Evaluation

For automatic evaluation, we measure the original IBM BLEU score (Papineni et al., 2002) (4-gram precision with brevity penalty) and the TER score (Snover et al., 2006) (the amount of edits required to change a system output into the reference)[7]. Note that TER measures the translation error rate, thus a

[5]The annotator created annotations with both λ-expressions and corresponding English sentences available as references.

[6]We used the default settings, and enabled the default lexicalized reordering model, which yielded better performance.

[7]We used tercom version 0.7.25 with the default settings.

smaller score indicates a better result. For clarity, we report 1−TER scores. Following the tuning procedure as conducted in Galley and Manning (2010), we perform MERT using BLEU as the metric.

We compare our model against state-of-the-art statistical machine translation systems. As a baseline, we first conduct an experiment with the following naive approach: we treat the λ-expressions as plain texts. All the bound variables (e.g., x in $\lambda x.state(x)$) which do not convey semantics are removed, but free variables (e.g., $state$ in $\lambda x.state(x)$) which might convey semantics are left intact. Quantifiers and logical connectives are also left intact. While this naive approach might not appear very sensible, we merely want to treat it as our simplest baseline.

Alternatively, analogous to the work of Wong and Mooney (2007a), we could first parse the λ-expressions into binary tree structures with a deterministic procedure, and then linearize the tree structure as a sequence. Since there exists different ways to linearize a binary tree, we consider preorder, inorder, and postorder traversal of the trees, and linearize them in these three different ways.

As for our system, during the grammar learning phase, we initialize the generative model parameters with output from the IBM alignment model 1 (Brown et al., 1993)[8], and run the λ-hybrid tree generative model with the unigram emission assumption for 10 iterations, followed by another 10 iterations with the bigram assumption. Grammar rules are then extracted based on the λ-hybrid trees obtained from such learned generative model parameters.

Since MERT is prone to search errors, we run each experiment 5 times with randomly initialized feature weights, and report the averaged scores. Experimental results for both English and Chinese are presented in Table 1. As we can observe, the way that a meaning representation tree is linearized has a significant impact on the translation performance. Interestingly, for both Moses and Joshua, the preorder setting yields the best performance for English, whereas it is inorder that yields the best performance for Chinese. This is perhaps due to the fact that Chinese presents a very different syntactic structure and word ordering from English.

[8]We assume word unigrams are generated from free variables, quantifiers, and logical connectives in IBM model 1.

Our system, on the other hand, employs a packed forest representation for λ-expressions. Therefore, it eliminates the ordering constraint by encompassing exponentially many possible tree structures during both the alignment and decoding stage. As a result, our system obtains significant improvements in both BLEU and 1−TER using the significance test under the paired bootstrap resampling method of Koehn (2004). We obtain $p < 0.01$ for all cases, except when comparing against Joshua-preorder for English, where we obtain $p < 0.05$ for both metrics.

		English		Chinese

Table 1: Performance on generating English and Chinese from λ-expressions with automatic evaluation metrics (we report percentage scores).

5.2 Human Evaluation

We also conducted human evaluation with 5 evaluators each on English and Chinese. We randomly selected about 50% (139) test instances and obtained output sentences from the three systems. Moses and Joshua were run with the top-performing settings in terms of automatic metrics (i.e., preorder for English and inorder for Chinese). Following Angeli et al. (2010), evaluators are instructed to give scores based on language fluency and semantic correctness, on the following scale:

Score	Language Fluency	Semantic Correctness
5	Flawless	Perfect
4	Good	Near Perfect
3	Non-native	Minor Errors
2	Disfluent	Major Errors
1	Gibberish	Completely Wrong

For each test instance, we first randomly shuffled the output sentences of the three systems, and presented them together with the correct reference to the evaluators. The evaluators were then asked to score all the output sentences at once. This evaluation process not only ensures that the annotators have no access to which system generated the out-

English	Judge E1		Judge E2		Judge E3		Judge E4		Judge E5		Average

put, but also minimizes bias associated with scoring different outputs for the same input. The detailed and averaged results (with one standard deviation) for human evaluation are presented in Table 2 for English and Chinese respectively. For both languages, our system achieves a significant improvement over Moses and Joshua ($p < 0.01$ with paired t-tests), in terms of both language fluency and semantic correctness. This set of results is important, as it demonstrates that our system produces more fluent texts with more accurate semantics when perceived by real humans.

5.3 Additional Experiments

We also performed the following additional experiments. First, we attempted to increase the number of EM iterations (to 100) when training the model with the bigram assumption, so as to assess the effect of the number of EM iterations on the final generation performance. We observed similar performance. Second, in order to assess the importance of the two types of novel rules – subtree rules (type 2) and two-level λ-hybrid sequence rules (type 3), we also conducted experiments without these rules for generation. Experiments show that these two types of rules are important. Specifically, type 3 rules, which are able to capture longer structural dependencies, are of particular importance for generating Chinese. Detailed results for these additional experiments are presented in Table 1.

5.4 Experiments on Variable-free Meaning Representations

Finally, we also assess the effectiveness of our model on an alternative meaning representation formalism in the form of variable-free tree structures. Specifically, we tested on the ROBOCUP dataset (Kuhlmann et al., 2004), which consists of 300 English instructions for coaching robots for soccer games, and a variable-free version of the GEOQUERY dataset. These are the standard datasets used in the generation tasks of Wong and Mooney (2007a) and Lu et al. (2009). Similar to the technique introduced in Kwiatkowski et al. (2010), our proposed algorithm could still be applied to such datasets by writing the tree-structured representations as function-arguments forms. The higher order unification-based decomposition algorithm could be applied on top of such forms accordingly. For example, $midfield(opp) \equiv \lambda x.midfield(x) \lhd opp$. See Kwiatkowski et al. (2010) for more details. However, since such forms present monotonous structures, and thus give less alternative options in the higher-order unification-based decomposition process, it prevents the algorithm from creating many disjunctive nodes in the packed forest. It is thus hypothesized that the advantages of the packed forest representation could not be fully exploited with such a meaning representation formalism.

Following previous works, we performed 4 runs of 10-fold cross validation based on the same split as that of Wong and Mooney (2007a) and Lu et al. (2009), and measured standard BLEU percentage and NIST (Doddington, 2002) scores. For experimentation on each fold, we trained a trigram language model on the training data of that fold, and randomly selected 70% of the training data for grammar induction, with the remaining 30% for learning of the feature weights using MERT. Next, we performed grammar induction with the complete training data of that fold, and used the learned feature weights for decoding of the test instances. The averaged results are shown in Table 3. Our approach outperforms the previous system WASP^{-1}++ (Wong and Mooney, 2007a) significantly, and achieves comparable or slightly better performance as compared to Lu et al. (2009). This set of results is particularly striking. We note

Variable-present dataset	
λ-expression :	$argmax(x, river(x) \wedge \exists y.[state(y) \wedge next\_to(y, india\_s) \wedge loc(x, y)], len(x))$
Reference :	what is the longest river that flows through a state that borders indiana

that the algorithm of Lu et al. (2009) is capable of modeling dependencies over phrases, which gives global optimization over the sentence generated, and works by building conditional random fields (Lafferty et al., 2001) over trees. But the algorithm of Lu et al. (2009) is also limited to handling tree-structured meaning representation, and is therefore unable to accept inputs such as the variable version of λ-expressions. Our algorithm works well by introducing additional new types of synchronous rules that are able to capture longer range dependencies. WASP^{-1}++, on the other hand, also makes use of a synchronous parsing-based statistical machine translation approach. Their system, however, requires linearization of the tree structure for both alignment and translation. In contrast, our model directly performs alignment and translation from a packed forest representation to a sentence. As a result, though WASP^{-1}++ made use of additional features (lexical weights), our system yielded better performance. Sample English output sentences are given in Figure 6.

	Robocup		Geoquery

6 Conclusions and Future Work

In this work, we presented a novel algorithm for generating natural language sentences from their underlying semantics in the form of typed lambda calculus. We tackled the problem by introducing a novel reduction-based weighted synchronous context-free grammar formalism, which allows sentence generation with a log-linear model. In addition, we proposed a novel generative model that jointly generates lambda calculus expressions and natural language sentences. The model is then used for automatic grammar induction. Empirical results show that our model outperforms state-of-the-art machine translation models, for both English and Chinese, in terms of both automatic and human evaluation. Furthermore, we have demonstrated that the model can also effectively handle inputs with a variable-free version of meaning representation.

We believe the algorithm used for inducing the reduction-based synchronous grammar rules may find applications in other research problems, such as statistical machine translation and phrasal synchronous grammar induction. We are interested in exploring further along such directions in the future.

Acknowledgments

This research was done for CSIDM Project No. CSIDM-200804 partially funded by a grant from the National Research Foundation (NRF) administered by the Media Development Authority (MDA) of Singapore. We would like to thank Tom Kwiatkowski and Luke Zettlemoyer for sharing their dataset, and Omar F. Zaidan for his help with Z-MERT.
