General Chair's Preface

Welcome to EMNLP 2011, Conference on Empirical Methods in Natural Language Processing, a conference organised annually by SIGDAT, the Association for Computational Linguistics' special interest group on linguistic data and corpus-based approaches to NLP. This year the conference is held from July 27th to 29th at the John McIntyre Conference Centre, Edinburgh, UK.

This year EMNLP is, for the first time, not only a stand alone conference, but also an anchor conference to several workshops, that are held on July 30th and July 31st at the Informatics Forum, Edinburgh.

This year's conference continues the successful growing trend of previous years, attracting the largest number of papers to date for EMNLP and requiring a large organisational effort. I would like to thank all the people involved.

Regina Barzilay from MIT and Mark Johnson from Macquarie University chaired a large scientific programme committee and introduced several innovations in the submission, selection and final scheduling of papers.

Marie Candito, of Paris Diderot University, in collaboration with the ACL workshop chairs, selected the workshops, seven of which have been affiliated to EMNLP. They have received a large number of submissions and generated very interesting programmes.

Special thanks go to the publication chair Wanxiang Che, from Harbin Institute of Technology, who had to deal with EMNLP's now famous just-in-time schedule.

We are very grateful to Bonnie Webber and Miles Osborne, from the University of Edinburgh, for accepting the demanding task of organising the largest and most complex EMNLP ever and allowing us to hold this conference in such a remarkable city. Thanks also go to Francesco Figari the webmaster, and to all the student volunteers that make the conference possible.

Miles Osborne is also the contact person for an interesting affiliated event sponsored by Google and the Scottish and Informatics Computer Science Alliance: an Intense Summer School on Hadoop and Natural Language Processing, that will take place in Edinburgh for two days before the conference.

Thanks also to David Yarowsky and Ken Church from SIGDAT who provided much useful information from past conferences and Graeme Hirst and Priscilla Rasmussen from ACL for their help and advice.

This year's EMNLP's sponsors are Google, Yahoo and Textkernel. We thank them for their very welcome contributions, which were obtained by the efforts of the local organisers and of Massimilano Ciaramita (Google) and Stefan Riezler (Heidelberg University), our ACL sponsorship committee members for Europe.

Finally, and foremost, thank to all the authors and conference attendees that have made and will make this conference a success and source of inspiration.

Paola Merlo, University of Geneva
EMNLP 2011 General Chair

Program Chairs' Preface

Welcome to the EMNLP 2011 conference, hosted this year by the the extremely impressive University of Edinburgh.

EMNLP 2011 received 628 submissions, a new record for the conference. The program committee, consisted of 20 area chairs and 545 PC members from Asia, Europe, and North America, was able to accept 149 papers in total (for an acceptance rate of 23.7%). Among them, 94 (i.e., 63%) of the papers were accepted for oral presentations, and 54 (i.e., 36%) for poster presentations. Submissions from PC chairs were handled by the general chair in an off-line procedure that applied considerably stricter acceptance requirements than for ordinary submissions.

First and foremost, we would like to thank the authors who submitted their work to EMNLP 2011. The sheer number of submissions reflects how broad and active our field is. We are deeply indebted to the area chairs and the PC members for their hard work. They enabled us to make a wonderful program and to provide valuable feedback to the authors. We are extremely pleased that our invited speaker David McAllester has agreed to talk at EMNLP. Many thanks to local arrangements chairs, Bonnie Webber and Miles Osborne, who enabled the conference to be held in Edinburgh, one of the great intellectual cities of the world. We'd also like to thank the publications chair, Wanxiang Che, who put this volume together. We greatly benefited from advice from Hang Li and Lluís Màrquez who kindly shared with us their experience from EMNLP 2010. Special thanks to the general chair, Paola Merlo, who provided much valuable advice and assistance in the past months. We are grateful to David Yarowksy for assistance with a variety of aspects of the conference. Rich Gerber and the START team responded to our questions quickly, and helped us manage the large number of submissions smoothly; we would like to thank them as well.

This year's conference is innovative in several ways. The conference contains three additional plenary sessions compared to previous EMNLP conferences; these are used to highlight a diverse set of papers of interest to the entire EMNLP audience. We hope this will help counter the disciplinary fragmentation that some of us feel the standard multi-track conference structure encourages.

For the first time, submitted papers could be optionally accompanied by up to 10MB of supplementary material, which could consist of data, code, and text. Papers can reference the supplementary material in much the same way a paper might refer to software or a tech report available from the authors' web site (albeit without revealing the authors' identities). Reviewers were encouraged but not required to view the supplementary material.

A major challenge this year concerned undisclosed double submissions and plagiarism (especially self-plagiarism) involving papers accepted at other international conferences. We believe this is an issue that must addressed by the broader research community. Our community needs clear, well-publicised, standards on double and overlapping submissions, and also needs procedures for sharing information between relevant conferences to discourage double submission and self-plagiarism.

But we don't want to blow this issue out of proportion. By far the vast majority of EMNLP submissions described creative, innovative work that taken together substantially advances the field. The success of a conference is really a result of the great efforts of everybody involved. We hope that you enjoy this year's conference in the historic city of Edinburgh!

Regina Barzilay and Mark Johnson
EMNLP 2011 Program Co-Chairs

Program Co-chairs

Regina Barzilay, Massachusetts Institute of Technology
Mark Johnson, Macquarie University

Area Chairs

Emily M. Bender, University of Washington
Phil Blunsom, University of Oxford
Eugene Charniak, Brown University
Chris Dyer, Carnegie Mellon University
Jenny Finkel, Columbia University
Radu Florian, IBM Watson Research Center
Amir Globerson, The Hebrew University of Jerusalem
Keith Hall, Google Research
Minlie Huang, Tsinghua University
Katrin Kirchhoff, University of Washington
Mirella Lapata, University of Edinburgh
Chin-Yew Lin, Microsoft Research Asia
Bo Pang, Yahoo! Research
Stefan Riezler, University of Heidelberg
Ellen Riloff, University of Utah
Hinrich Schuetze, University of Stuttgart
Jian Su, Institute for Infocomm Research
Dekai Wu, Hong Kong University of Science and Technology
Luke Zettlemoyer, University of Washington

Local Arrangements Chair

Bonnie Webber, University of Edinburgh
Miles Osborne, University of Edinburgh

Publications Chair

Wanxiang Che, Harbin Institute of Technology

Reviewers

Omri Abend, Rodrigo Agerri, Eneko Agirre, Byung Gyu Ahn, Hua Ai, Enrique Alfonseca, Cecilia Ovesdotter Alm, Vamshi Ambati, Sophia Ananiadou, Shankar Ananthakrishnan, Marianna Apidianaki, Shilpa Arora, Abishek Arun, Nicholas Asher, Giuseppe Attardi, Necip Fazil Ayan, Collin Baker, Tim Baldwin, Carmen Banea, Ken Barker, Marco Baroni, Regina Barzilay, Mary Beckman, Beata Beigman Klebanov, Núria Bel, Anja Belz, Emily M. Table of Contents

Conference Program

Wednesday, July 27, 2011

9:00–10:20 Plenary session: Opening and Invited Talk
Chair: Paola Merlo
Invited Talk: Object Detection Grammars (David McAllester)

10:20–11:00 Coffee break

Session 1: Plenary session
Chair: Jason Eisner

11:00–11:25 *Fast and Robust Joint Models for Biomedical Event Extraction*
Sebastian Riedel and Andrew McCallum

11:25–11:50 *Predicting Thread Discourse Structure over Technical Web Forums*
Li Wang, Marco Lui, Su Nam Kim, Joakim Nivre and Timothy Baldwin

11:50–12:15 *Exact Decoding of Phrase-Based Translation Models through Lagrangian Relaxation*
Yin-Wen Chang and Michael Collins

12:15–12:40 *Optimal Search for Minimum Error Rate Training*
Michel Galley and Chris Quirk

12:40–14:10 Lunch

Session 2A: Syntax and Parsing
Chair: Stephen Clark

14:10–14:35 *Unsupervised Structure Prediction with Non-Parallel Multilingual Guidance*
Shay B. Cohen, Dipanjan Das and Noah A. Smith

14:35–15:00 *Multi-Source Transfer of Delexicalized Dependency Parsers*
Ryan McDonald, Slav Petrov and Keith Hall

15:00–15:25 *SMT Helps Bitext Dependency Parsing*
Wenliang Chen, Jun'ichi Kazama, Min Zhang, Yoshimasa Tsuruoka, Yujie Zhang, Yiou Wang, Kentaro Torisawa and Haizhou Li

15:25–15:50 *Accurate Parsing with Compact Tree-Substitution Grammars: Double-DOP*
Federico Sangati and Willem Zuidema

Wednesday, July 27, 2011 (continued)

Session 2B: Semantics
Chair: Mirella Lapata

14:10–14:35 *A Generate and Rank Approach to Sentence Paraphrasing*
Prodromos Malakasiotis and Ion Androutsopoulos

14:35–15:00 *Correcting Semantic Collocation Errors with L1-induced Paraphrases*
Daniel Dahlmeier and Hwee Tou Ng

15:00–15:25 *Class Label Enhancement via Related Instances*
Zornitsa Kozareva, Konstantin Voevodski and Shanghua Teng

15:25–15:50 *A Joint Model for Extended Semantic Role Labeling*
Vivek Srikumar and Dan Roth

Session 2C: Sentiment Analysis and Opinion Mining
Chair: Bo Pang

14:10–14:35 *Domain-Assisted Product Aspect Hierarchy Generation: Towards Hierarchical Organization of Unstructured Consumer Reviews*
Jianxing Yu, Zheng-Jun Zha, Meng Wang, Kai Wang and Tat-Seng Chua

14:35–15:00 *Semi-Supervised Recursive Autoencoders for Predicting Sentiment Distributions*
Richard Socher, Jeffrey Pennington, Eric H. Huang, Andrew Y. Ng and Christopher D. Manning

15:00–15:25 *Unsupervised Discovery of Discourse Relations for Eliminating Intra-sentence Polarity Ambiguities*
Lanjun Zhou, Binyang Li, Wei Gao, Zhongyu Wei and Kam-Fai Wong

15:25–15:50 *Compositional Matrix-Space Models for Sentiment Analysis*
Ainur Yessenalina and Claire Cardie

Wednesday, July 27, 2011 (continued)

Session 3A: Machine Translation
Chair: Phil Blunsom

16:20–16:45 *Training a Parser for Machine Translation Reordering*
Jason Katz-Brown, Slav Petrov, Ryan McDonald, Franz Och, David Talbot, Hiroshi Ichikawa, Masakazu Seno and Hideto Kazawa

16:45–17:10 *Inducing Sentence Structure from Parallel Corpora for Reordering*
John DeNero and Jakob Uszkoreit

17:10–17:35 *Augmenting String-to-Tree Translation Models with Fuzzy Use of Source-side Syntax*
Jiajun Zhang, Feifei Zhai and Chengqing Zong

17:35–18:00 *A novel dependency-to-string model for statistical machine translation*
Jun Xie, Haitao Mi and Qun Liu

Session 3B: NLP related Machine Learning
Chair: David Smith

16:20–16:45 *Bayesian Checking for Topic Models*
David Mimno and David Blei

16:45–17:10 *Dual Decomposition with Many Overlapping Components*
Andre Martins, Noah Smith, Mario Figueiredo and Pedro Aguiar

17:10–17:35 *Approximate Scalable Bounded Space Sketch for Large Data NLP*
Amit Goyal and Hal Daume III

17:35–18:00 *Optimizing Semantic Coherence in Topic Models*
David Mimno, Hanna Wallach, Edmund Talley, Miriam Leenders and Andrew McCallum

Wednesday, July 27, 2011 (continued)

Session 3C: Discourse Dialogue and Pragmatics
Chair: Oliver Lemon

16:20–16:45 *A Weakly-supervised Approach to Argumentative Zoning of Scientific Documents*
Yufan Guo, Anna Korhonen and Thierry Poibeau

16:45–17:10 *Linear Text Segmentation Using Affinity Propagation*
Anna Kazantseva and Stan Szpakowicz

17:10–17:35 *Minimally Supervised Event Causality Identification*
Quang Do, Yee Seng Chan and Dan Roth

17:35–18:00 *A Model of Discourse Predictions in Human Sentence Processing*
Amit Dubey, Frank Keller and Patrick Sturt

Thursday, July 28, 2011

Session 4: Plenary session
Chair: Michael Collins

9:05–9:30 *Simple Effective Decipherment via Combinatorial Optimization*
Taylor Berg-Kirkpatrick and Dan Klein

9:30–9:55 *Universal Morphological Analysis using Structured Nearest Neighbor Prediction*
Young-Bum Kim, João Graça and Benjamin Snyder

9:55–10:20 *Training a Log-Linear Parser with Loss Functions via Softmax-Margin*
Michael Auli and Adam Lopez

10:20–11:00 Coffee break

Thursday, July 28, 2011 (continued)

Session 5A: Machine Translation
Chair: Philipp Koehn

11:00–11:25 *Large-Scale Cognate Recovery*
David Hall and Dan Klein

11:25–11:50 *Domain Adaptation via Pseudo In-Domain Data Selection*
Amittai Axelrod, Xiaodong He and Jianfeng Gao

11:50–12:15 *Language Models for Machine Translation: Original vs. Translated Texts*
Gennadi Lembersky, Noam Ordan and Shuly Wintner

12:15–12:40 *Better Evaluation Metrics Lead to Better Machine Translation*
Chang Liu, Daniel Dahlmeier and Hwee Tou Ng

Session 5B: Syntax and Parsing
Chair: Ryan McDonald

11:00–11:25 *Evaluating Dependency Parsing: Robust and Heuristics-Free Cross-Annotation Evaluation*
Reut Tsarfaty, Joakim Nivre and Evelina Andersson

11:25–11:50 *Parser Evaluation over Local and Non-Local Deep Dependencies in a Large Corpus*
Emily M. Bender, Dan Flickinger, Stephan Oepen and Yi Zhang

11:50–12:15 *Learning to Simplify Sentences with Quasi-Synchronous Grammar and Integer Programming*
Kristian Woodsend and Mirella Lapata

12:15–12:40 *Bootstrapping Semantic Parsers from Conversations*
Yoav Artzi and Luke Zettlemoyer

Thursday, July 28, 2011 (continued)

Session 5C: Summarization and Generation
Chair: Johanna Moore

11:00–11:25 *Timeline Generation through Evolutionary Trans-Temporal Summarization*
Rui Yan, Liang Kong, Congrui Huang, Xiaojun Wan, Xiaoming Li and Yan Zhang

11:25–11:50 *Corpus-Guided Sentence Generation of Natural Images*
Yezhou Yang, Ching Teo, Hal Daume III and Yiannis Aloimonos

11:50–12:15 *Corroborating Text Evaluation Results with Heterogeneous Measures*
Enrique Amigó, Julio Gonzalo, Jesus Gimenez and Felisa Verdejo

12:15–12:40 *Ranking Human and Machine Summarization Systems*
Peter Rankel, John Conroy, Eric Slud and Dianne O'Leary

12:40–14:10 Lunch

Session 6A: Machine Translation
Chair: Stefan Riezler

14:10–14:35 *Quasi-Synchronous Phrase Dependency Grammars for Machine Translation*
Kevin Gimpel and Noah A. Smith

14:35–15:00 *A Word Reordering Model for Improved Machine Translation*
Karthik Visweswariah, Rajakrishnan Rajkumar, Ankur Gandhe, Ananthakrishnan Ramanathan and Jiri Navratil

15:00–15:25 *Feature-Rich Language-Independent Syntax-Based Alignment for Statistical Machine Translation*
Jason Riesa, Ann Irvine and Daniel Marcu

15:25–15:50 *Efficient retrieval of tree translation examples for Syntax-Based Machine Translation*
Fabien Cromieres and Sadao Kurohashi

Thursday, July 28, 2011 (continued)

Session 6B: Semantics
Chair: Hwee Tou Ng

14:10–14:35 *A generative model for unsupervised discovery of relations and argument classes from clinical texts*
Bryan Rink and Sanda Harabagiu

14:35–15:00 *Random Walk Inference and Learning in A Large Scale Knowledge Base*
Ni Lao, Tom Mitchell and William W. Cohen

15:00–15:25 *Exploring Supervised LDA Models for Assigning Attributes to Adjective-Noun Phrases*
Matthias Hartung and Anette Frank

15:25–15:50 *Semantic Topic Models: Combining Word Distributional Statistics and Dictionary Definitions*
Weiwei Guo and Mona Diab

Session 6C: Sentiment Analysis and Opinion Mining
Chair: Benjamin Snyder

14:10–14:35 *Cooooooooooooooollllllllllll!!!!!!!!!!!!!! Using Word Lengthening to Detect Sentiment in Microblogs*
Samuel Brody and Nicholas Diakopoulos

14:35–15:00 *Personalized Recommendation of User Comments via Factor Models*
Deepak Agarwal, Bee-Chung Chen and Bo Pang

15:00–15:25 *Data-Driven Response Generation in Social Media*
Alan Ritter, Colin Cherry and William B. Dolan

15:25–15:50 *Predicting a Scientific Community's Response to an Article*
Dani Yogatama, Michael Heilman, Brendan O'Connor, Chris Dyer, Bryan R. Routledge and Noah A. Smith

15:50–16:20 Coffee break

Thursday, July 28, 2011 (continued)

Session 7A: Phonology Morphology Tagging Chunking and Segmentation
Chair: Noah Smith

16:20–16:45 *Non-parametric Bayesian Segmentation of Japanese Noun Phrases*
Yugo Murawaki and Sadao Kurohashi

16:45–17:10 *Discovering Morphological Paradigms from Plain Text Using a Dirichlet Process Mixture Model*
Markus Dreyer and Jason Eisner

17:10–17:35 *Multilayer Sequence Labeling*
Ai Azuma and Yuji Matsumoto

17:35–18:00 *A Bayesian Mixture Model for PoS Induction Using Multiple Features*
Christos Christodoulopoulos, Sharon Goldwater and Mark Steedman

Session 7B: Semantics
Chair: Mark Stevenson

16:20–16:45 *Large-Scale Noun Compound Interpretation Using Bootstrapping and the Web as a Corpus*
Su Nam Kim and Preslav Nakov

16:45–17:10 *Linguistic Redundancy in Twitter*
Fabio Massimo Zanzotto, Marco Pennaccchiotti and Kostas Tsioutsiouliklis

17:10–17:35 *Divide and Conquer: Crowdsourcing the Creation of Cross-Lingual Textual Entailment Corpora*
Matteo Negri, Luisa Bentivogli, Yashar Mehdad, Danilo Giampiccolo and Alessandro Marchetti

17:35–18:00 *Literal and Metaphorical Sense Identification through Concrete and Abstract Context*
Peter Turney, Yair Neuman, Dan Assaf and Yohai Cohen

Thursday, July 28, 2011 (continued)

Session 7C: Spoken Language + IR
Chair: Steve Renals

16:20–16:45 *Syntactic Decision Tree LMs: Random Selection or Intelligent Design?*
Denis Filimonov and Mary Harper

16:45–17:10 *The Imagination of Crowds: Conversational AAC Language Modeling using Crowdsourcing and Large Data Sources*
Keith Vertanen and Per Ola Kristensson

17:10–17:35 *Using Syntactic and Semantic Structural Kernels for Classifying Definition Questions in Jeopardy!*
Alessandro Moschitti, Jennifer Chu-carroll, Siddharth Patwardhan, James Fan and Giuseppe Riccardi

17:35–18:00 *Multiword Expression Identification with Tree Substitution Grammars: A Parsing tour de force with French*
Spence Green, Marie-Catherine de Marneffe, John Bauer and Christopher D. Manning

18:30–21:30 Poster session and Reception

Modelling Discourse Relations for Arabic
Amal Al-Saif and Katja Markert

Classifying Sentences as Speech Acts in Message Board Posts
Ashequl Qadir and Ellen Riloff

Learning Local Content Shift Detectors from Document-level Information
Richard Farkas

Collaborative Ranking: A Case Study on Entity Linking
Zheng Chen and Heng Ji

Robust Disambiguation of Named Entities in Text
Johannes Hoffart, Mohamed Amir Yosef, Ilaria Bordino, Hagen Fürstenau, Manfred Pinkal, Marc Spaniol, Bilyana Taneva, Stefan Thater and Gerhard Weikum

A Cascaded Classification Approach to Semantic Head Recognition
Lukas Michelbacher, Alok Kothari, Martin Forst, Christina Lioma and Hinrich Schütze

Linking Entities to a Knowledge Base with Query Expansion
Swapna Gottipati and Jing Jiang

Unsupervised Information Extraction with Distributional Prior Knowledge
Cane Wing-ki Leung, Jing Jiang, Kian Ming A. Chai, Hai Leong Chieu and Loo-Nin Teow

Relation Acquisition using Word Classes and Partial Patterns
Stijn De Saeger, Kentaro Torisawa, Masaaki Tsuchida, Jun'ichi Kazama, Chikara Hashimoto, Ichiro Yamada, Jong Hoon Oh, Istvan Varga and Yulan Yan

Identification of Multi-word Expressions by Combining Multiple Linguistic Information Sources
Yulia Tsvetkov and Shuly Wintner

Analyzing Methods for Improving Precision of Pivot Based Bilingual Dictionaries
Xabier Saralegi, Iker Manterola and Iñaki San Vicente

Fast and Robust Joint Models for Biomedical Event Extraction

Sebastian Riedel **Andrew McCallum**
Department of Computer Science
University of Massachusetts, Amherst
{riedel,mccallum}@cs.umass.edu

Abstract

Extracting biomedical events from literature has attracted much recent attention. The best-performing systems so far have been pipelines of simple subtask-specific local classifiers. A natural drawback of such approaches are cascading errors introduced in early stages of the pipeline. We present three joint models of increasing complexity designed to overcome this problem. The first model performs joint trigger and argument extraction, and lends itself to a simple, efficient and exact inference algorithm. The second model captures correlations between events, while the third model ensures consistency between arguments of the same event. Inference in these models is kept tractable through dual decomposition. The first two models outperform the previous best joint approaches and are very competitive with respect to the current state-of-the-art. The third model yields the best results reported so far on the BioNLP 2009 shared task, the BioNLP 2011 Genia task and the BioNLP 2011 Infectious Diseases task.

1 Introduction

Whenever we advance our scientific understanding of the world, we seek to publish our findings. The result is a vast and ever-expanding body of natural language text that is becoming increasingly difficult to leverage. This is particularly true in the context of life sciences, where large quantities of biomedical articles are published on a daily basis. To support tasks such data mining, search and visualization, there is a clear need for structured representations of the knowledge these articles convey. This is indicated by a large number of public databases with content ranging from simple protein-protein interactions to complex pathways. To increase coverage of such databases, and to keep up with the rate of publishing, we need to *automatically* extract structured representations from biomedical text—a process often referred to as biomedical text mining.

One major focus of biomedical text mining has been the extraction of named entities, such genes or gene products, and of flat binary relations between such entities, such as protein-protein interactions. However, in recent years there has also been an increasing interest in the extraction of biomedical *events* and their causal relations. This gave rise to the BioNLP 2009 and 2011 shared tasks which challenged participants to gather such events from biomedical text (Kim et al., 2009; Kim et al., 2011). Notably, these events can be complex and recursive: they may have several arguments, and some of the arguments may be events themselves.

Current state-of-the-art event extractors follow the same architectural blueprint and divide the extraction process into a pipeline of three stages (Björne et al., 2009; Miwa et al., 2010c). First they predict a set of candidate event trigger words (say, tokens 2, 5 and 6 in figure 1), then argument mentions are attached to these triggers (say, token 4 for trigger 2). The final stage decides how arguments are shared between events—compare how one event subsumes all arguments of trigger 6 in figure 1, while two events share the three arguments of trigger 4 in figure 2. This architecture is prone to cascading errors: If we miss a trigger in the first stage, we will never be able to extract the full event

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 1–12,
Edinburgh, Scotland, UK, July 27–31, 2011.

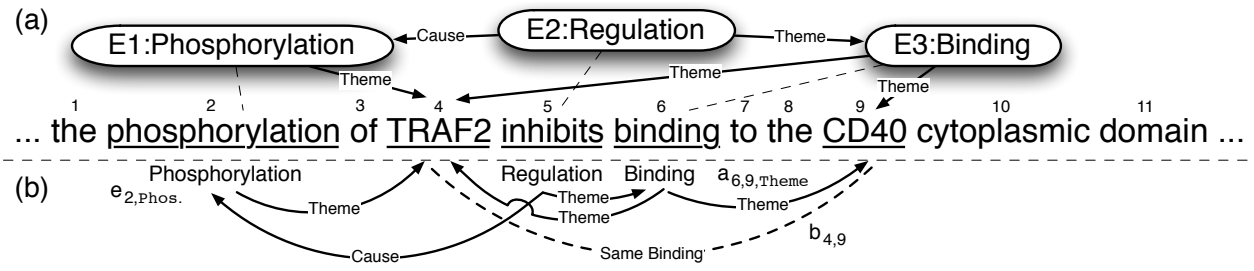

Figure 1: (a) sentence with target event structure to extract; (b) projection to a set of labelled graph over tokens.

it concerns. Current systems attempt to tackle this problem by passing several candidates to the next stage. However, this tends to increase the false positive rate. In fact, Miwa et al. (2010c) observe that 30% of their errors stem from this type of ad-hoc module communication.

Joint models have been proposed to overcome this problem (Poon and Vanderwende, 2010; Riedel et al., 2009). However, besides not being as accurate as their pipelined competitors, mostly because they do not yet exploit the rich set of features used by Miwa et al. (2010b) and Björne et al. (2009), they also suffer from the complexity of inference. For example, to remain tractable, the best joint system so far (Poon and Vanderwende, 2010) works with a simplified representation of the problem in which certain features are harder to capture, employs local search without certificates of optimality, and furthermore requires a 32-core cluster for quick train-test cycles. Existing joint models also rely on heuristics when it comes to deciding which arguments share the same event. Contrast this with the best current pipeline (Miwa et al., 2010c; Miwa et al., 2010b) which uses a classifier for this task.

We present a family of event extraction models that address the aforementioned problems. The first model jointly predicts triggers and arguments. Notably, the highest scoring event structure under this model can be found efficiently in $O(mn)$ time where m is the number of trigger candidates, and n the number of argument candidates. This is only slightly slower than the $O(m'n)$ runtime of a pipeline, where m' is the number of trigger candidates as filtered by the first stage. We achieve these guarantees through a novel algorithm that jointly picks best trigger label and arguments on a per-token basis. Remarkably, it takes roughly as much time to train this model on one core as the model of Poon and Vanderwende (2010) on 32 cores, and leads to better results.

The second model enforces additional constraints that ensure consistency between events in hierarchical regulation structures. While inference in this model is more complicated, we show how dual decomposition (Komodakis et al., 2007; Rush et al., 2010) can be used to efficiently find exact solutions for a large fraction of problems.

Our third model includes the first two, and explicitly captures which arguments are part in the same event—the third stage of existing pipelines. Due to a complex coupling between this model and the first two, inference here requires a *projected* version of the sub-gradient technique demonstrated by Rush et al. (2010).

When evaluated on the BioNLP 2009 shared task, the first two models outperform the previous best joint approaches and are competitive when compared to current state-of-the-art. With 57.4 F1 on the test set, the third model yields the best results reported so far with a 1.1 F1 margin to the results of Miwa et al. (2010b). For the BioNLP 2011 Genia task 1 and the BioNLP 2011 Infectious Diseases task, Model 3 yields the second-best and best results reported so far. The second-best results are achieved with Model 3 as is (Riedel and McCallum, 2011), the best results when using Stanford event predictions as input features (Riedel et al., 2011). The margins between Model 3 and the best runner-ups range from 1.9 F1 to 2.8 F1.

In the following we will first introduce biomedical event extraction and our notation. Then we go on to present our models and their inference routines. We present related work, show our empirical evaluation, and conclude.

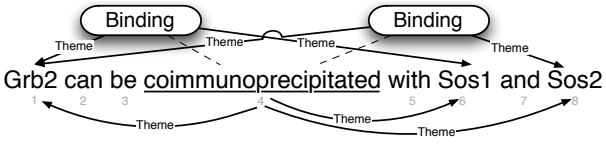

Figure 2: Two binding events with identical trigger. The projection graph does not change even if both events are merged.

2 Biomedical Event Extraction

By bio-molecular event we mean a change of state of one or more bio-molecules. Our task is to extract structured information about such events from natural language text. More concretely, let us consider part (a) of figure 1. We see a snippet of text from a biomedical abstract, and the three events that can be extracted from it. We will use these to characterize the types of events we ought to extract, as defined by the 2009 BioNLP shared task. Note that for the shared task, protein mentions are given by the task organizers and hence do not need to be extracted.

The event E1 in the figure refers to a *Phosphorylation* of the TRAF2 protein. It is an instance of a set of *simple events* that describe changes to a single gene or gene product. Other members of this set are: *Expression*, *Transcription*, *Localization*, and *Catabolism*. Each of these events has to have exactly one *theme*, the protein of which a state change is described. A labelled edge in figure 1a) shows that TRAF2 is the theme of E1.

Event E3 is a *Binding* of TRAF2 and CD40. Binding events are particular in that they may have more than one theme, as there can be several biomolecules associated in a binding structure. This is in fact the case for E3.

In the top-center of figure 1a) we see the *Regulation* event E2. Such events describe regulatory or causal relations between events. Other instances of this type of events are: *Positive Regulation* and *Negative Regulation*. Regulations have to have exactly one theme; this theme can a be protein or, as in our case, another event. Regulations may also have zero or one *cause* arguments that denote events or proteins which trigger the regulation.

In the BioNLP shared task, we are also asked to find a *trigger* (or *clue*) token for each event. This token grounds the event in text and allows users to quickly validate extracted events. For example, the trigger for event E2 is "inhibit", as indicated by a dashed line.

2.1 Event Projection

To formulate the search for event structures of the form shown in figure 1a) as an optimization problem, it will be convenient to represent them through a set of binary variables. We introduce such a representation, inspired by previous work (Riedel et al., 2009; Björne et al., 2009) and based on a projection of events to a graph structure over tokens, as seen figure 1b).

Consider sentence $\mathbf{x}$ and a set of *candidate trigger* tokens, denoted by $\text{Trig}(\mathbf{x})$. We label each candidate i with the event type it is a trigger for, or `None` if it is not a trigger. This decision is represented through a set of binary variables $e_{i,t}$, one for each possible event type t. In our example we have $e_{6,\texttt{Binding}} = 1$. The set of possible event types will be denoted as $\mathcal{T}$, the regulation event types as $\mathcal{T}_{\text{Reg}} \stackrel{\text{def}}{=} \{\texttt{PosReg}, \texttt{NegReg}, \texttt{Reg}\}$ and its complement as $\mathcal{T}_{\neg\text{reg}} \stackrel{\text{def}}{=} \mathcal{T} \setminus \mathcal{T}_{\text{Reg}}$.

For each candidate trigger i we consider the arguments of all events that have i as trigger. Each argument a will either be an event itself, or a protein. For events we add a labelled edge between i and the trigger j of a. For proteins we add an edge between i and the syntactic head j of the protein mention. In both cases we label the edge $i \rightarrow j$ with the role of the argument a. The edge is represented through a binary variable $a_{i,j,r}$, where $r \in \mathcal{R}$ is the argument role and $\mathcal{R} \stackrel{\text{def}}{=} \{\texttt{Theme}, \texttt{Cause}, \texttt{None}\}$. The role `None` is active whenever no `Theme` or `Cause` role is present. In our example we get, among others, $a_{2,4,\texttt{Theme}} = 1$.

So far our representation is equivalent to mappings in previous work (Riedel et al., 2009; Björne et al., 2009) and hence shares their main shortcoming: we cannot differentiate between two (or more) binding events with the same trigger but different arguments, or one binding event with several arguments. Consider, for example, the arguments of trigger 6 in figure 1b) that are all subsumed in a single event. By contrast, the arguments of trigger 4 shown in figure 2 are split between two events.

Previous work has resolved this ambiguity

through ad-hoc rules (Björne et al., 2009) or with a post-processing classifier (Miwa et al., 2010c). We propose to augment the graph representation through edges between pairs of proteins that are themes in the same binding event. For two protein tokens p and q we represent this edge through the binary variable $b_{p,q}$. Hence, in figure 1b) we have $b_{4,9} = 1$, whereas for figure 2 we get $b_{1,6} = b_{1,8} = 1$ but $b_{6,8} = 0$. By explicitly modeling such "sibling" edges we not only minimize the need for post-processing. We can also improve attachment decisions akin to second order models in dependency parsing (McDonald and Pereira, 2006). Note that while merely introducing such variables is easy, enforcing consistency between them and the $e_{i,t}$ and $a_{i,j,r}$ variables is not. We address this in section 3.3.1.

Reconstruction of events from solutions $(\mathbf{e}, \mathbf{a}, \mathbf{b})$ can be done almost exactly as described by Björne et al. (2009). However, while they group binding arguments according to ad-hoc rules based on dependency paths from trigger to argument, we simply query the variables $b_{p,q}$.

To simplify our exposition we introduce additional notation. We denote the set of protein head tokens with $\text{Prot}(\mathbf{x})$; the set of a possible targets for outgoing edges from a trigger is $\text{Cand}(\mathbf{x}) \stackrel{\text{def}}{=} \text{Trig}(\mathbf{x}) \cup \text{Prot}(\mathbf{x})$. We will often omit the domains of indices and instead assign them a fixed domain in advance: $i, l \in \text{Trig}(\mathbf{x})$, $j, k \in \text{Cand}(\mathbf{x})$, $p, q \in \text{Prot}(\mathbf{x})$, $r \in \mathcal{R}$ and $t \in \mathcal{T}$. Bold face letters are used to denote composite vectors $\mathbf{e}$, $\mathbf{a}$ and $\mathbf{b}$ of variables $e_{i,t}$, $a_{i,j,r}$ and $b_{p,q}$. The vector $\mathbf{y}$ is the joint vector of $\mathbf{e}, \mathbf{a}$ and $\mathbf{b}$. The short-form $\mathbf{e}_i \leftarrow t$ will mean $\forall t' : e_{i,t'} \leftarrow \delta_{t,t'}$ where $\delta_{t,t'}$ is the Kronecker Delta. Likewise, $\mathbf{a}_{i,j} \leftarrow r$ means $\forall r' : a_{i,j,r'} \leftarrow \delta_{r,r'}$.

3 Models

In this section we will present three structured prediction models of increasing complexity and expressiveness, as well as their corresponding MAP inference algorithms. Each model m can be represented by a mapping from sentence $\mathbf{x}$ to a set of *legal* structures $\mathcal{Y}_m(\mathbf{x})$, and a linear *scoring function*

$$s_m(\mathbf{y}; \mathbf{x}, \mathbf{w}) = \langle \mathbf{w}, \mathbf{f}(\mathbf{y}, \mathbf{x}) \rangle . \quad (1)$$

Here $\mathbf{f}$ is a feature function on structures $\mathbf{y}$ and input $\mathbf{x}$, and $\mathbf{w}$ is a weight vector for these features.

We can use the scoring function s_m and the set of legal structures $\mathcal{Y}_m(\mathbf{x})$ to predict the event $\mathbf{h}_m(\mathbf{x})$ for a given sentence $\mathbf{x}$ according to

$$\mathbf{h}_m(\mathbf{x}) \stackrel{\text{def}}{=} \arg \max_{\mathbf{y} \in \mathcal{Y}_m(\mathbf{x})} s_m(\mathbf{y}; \mathbf{x}, \mathbf{w}) . \quad (2)$$

For brevity we will from now on omit observations $\mathbf{x}$ and weights $\mathbf{w}$ when they are clear from the context.

3.1 Model 1

Model 1 performs a simple version of joint trigger and argument extraction. It independently scores trigger labels and argument roles:

$$s_1(\mathbf{e}, \mathbf{a}) \stackrel{\text{def}}{=} \sum_{e_{i,t}=1} s_{\text{T}}(i, t) + \sum_{a_{i,j,r}=1} s_{\text{R}}(i, j, r) . \quad (3)$$

Here $s_{\text{T}}(i, t) = \langle \mathbf{w}_{\text{T}}, \mathbf{f}_{\text{T}}(i, t) \rangle$ is a per-trigger scoring function that measures how well the event label t fits to token i. Likewise, $s_{\text{R}}(i, j, r) = \langle \mathbf{w}_{\text{R}}, \mathbf{f}_{\text{R}}(i, j, r) \rangle$ measures the compatibility of role r as label for the edge $i \rightarrow j$.

The jointness of Model 1 stems from enforcing consistency between the trigger label of i and its *outgoing* edges. By consistency we mean that: (a) there is at least one `Theme` whenever there is an event at i; (b) only regulation events are allowed to have `Cause` arguments; (c) all arguments of a `None` trigger must have the `None` role. We will denote the set assignments that fulfill these constraints by O and hence have $\mathcal{Y}_1 \stackrel{\text{def}}{=} \text{O}$.

Enforcing $(\mathbf{e}, \mathbf{a}) \in \text{O}$ guarantees that we never predict triggers i for which no sensible, high-scoring, argument j can be found. It also ensures that when we see an "obvious" argument edge $i \stackrel{r}{\rightarrow} j$ with high score $s_{\text{R}}(i, j, r)$ there is pressure to extract a trigger at i, even if the fact that i is a trigger may not be as obvious.

3.1.1 Inference

As it turns out, the maximizer of equation 2 can be found very efficiently in $O(mn)$ time where $m = |\text{Trig}(\mathbf{x})|$ and $n = |\text{Cand}(\mathbf{x})|$. The corresponding procedure, bestOut$(\cdot)$, is shown in algorithm 1. It takes as input a vector of trigger and edge *penalties* $\mathbf{c}$ that are added to the local scores of the s_{T} and s_{R} functions. For Model 2 and 3 we will use these

penalties to enforce agreement with predictions of other inference subroutines. When using Model 1 by itself we set them to $\mathbf{0}$. We point out that the scoring function s_1 is multiplied with $\frac{1}{2}$ throughout the algorithm. For doing inference in Model 1 and 2 this has no effect, but when we use bestOut$(\cdot)$ for Model 3 inference, it is required.

The bestOut $(\mathbf{c})$ routine exploits the fact that the constraints of Model 1 only act on the label for trigger i and its outgoing edges. In particular, enforcing consistency between $e_{i,t}$ and outgoing edges $a_{i,j,r}$ has no effect on consistency between $e_{l,t}$ and $a_{i',j',r'}$ for any other trigger $i' \neq i$. Moreover, for a given trigger the constraints only differentiate between three cases: (a) regulation event, (b) non-regulation event and (c) no event. This means that we can extract events on a per-trigger basis, and find the best per-trigger structure by comparing cases (a), (b) and (c). Note that bestOut $(\mathbf{c})$ uses the shorthand emptyOut (i) to denote the partial assignment $\mathbf{e}_i \leftarrow \texttt{None}$ and $\forall j : \mathbf{a}_{i,j} \leftarrow \texttt{None}$. The function $s_1^{\mathbf{c}}(i, \mathbf{y}) \stackrel{\text{def}}{=} \sum_t e_{i,t} \left(c_{i,t} + \frac{1}{2} s_{\text{T}}(i,t)\right) + \sum_{j,r} a_{i,j,r} \left(c_{i,j,r} + \frac{1}{2} s_{\text{R}}(i,j,r)\right)$ is a per-trigger frame score with penalties $\mathbf{c}$.

3.2 Model 2

Model 1 may still predict structures that cannot be mapped to events. For example, in figure 1b) we may label token 5 as `Regulation`, add the edge $5 \stackrel{\texttt{Cause}}{\rightarrow} 2$ but fail to label token 2 as an event. While consistent with $(\mathbf{e}, \mathbf{a}) \in \text{O}$, this violates the constraint that every active edge must either end at a protein, or at an active event trigger. This is a requirement on the label of a trigger and the assignment of roles for its *incoming* edges.

Model 2 enforces the above constraint in addition to $(\mathbf{e}, \mathbf{a}) \in \text{O}$, while inheriting the scoring function from Model 1. Hence, using I to denote the set of assignments with consistent trigger labels and incoming edges, we get $\mathcal{Y}_2 \stackrel{\text{def}}{=} \mathcal{Y}_1 \cap \text{I}$ and $s_2(\mathbf{y}) \stackrel{\text{def}}{=} s_1(\mathbf{y})$.

3.2.1 Inference

Inference in Model 2 amounts to optimizing $s_2(\mathbf{e}, \mathbf{a})$ over $\text{O} \cap \text{I}$. This is more involved, as we now have to ensure that when predicting an outgoing edge from trigger i to trigger l there is a high-scoring event at l. We follow Rush et al. (2010) and solve this problem in the framework of dual decomposi-

Algorithm 1 Sub-procedures for inference in Model 1, 2 and 3.

best label and outgoing edges for all triggers under penalties $\mathbf{c}$

bestOut $(\mathbf{c})$:
  $\forall i$ $\mathbf{y}^0 \leftarrow$ emptyOut (i)
    $\mathbf{y}^1 \leftarrow$ out $\left(i, \mathbf{c}, \mathcal{T}_{\text{reg}}, \mathcal{R}\right)$
    $\mathbf{y}^2 \leftarrow$ out $\left(i, \mathbf{c}, \mathcal{T}_{\neg\text{reg}}, \mathcal{R} \setminus \{\texttt{Cause}\}\right)$
    $\mathbf{y}_i \leftarrow \arg\max_{\mathbf{y} \in \{\mathbf{y}^0, \mathbf{y}^1, \mathbf{y}^2\}} s_1^{\mathbf{c}}(i, \mathbf{y})$
  return $(\mathbf{y}_i)_i$

  $\Delta(j) \stackrel{\text{def}}{=} \frac{1}{2} s_{\text{R}}(i,j,\texttt{Theme}) + c_{i,j,\texttt{Theme}} - \text{s}(j)$
  return $\arg\max_j \Delta(j)$

tion. To this end we write our optimization problem as

$$\begin{aligned} \underset{\mathbf{e},\mathbf{a},\bar{\mathbf{e}},\bar{\mathbf{a}}}{\text{maximize}} \quad & \frac{1}{2} s_2(\mathbf{e},\mathbf{a}) + \frac{1}{2} s_2(\bar{\mathbf{e}},\bar{\mathbf{a}}) \\ \text{subject to} \quad & (\mathbf{e},\mathbf{a}) \in \mathrm{O} \wedge (\bar{\mathbf{e}},\bar{\mathbf{a}}) \in \mathrm{I} \wedge \\ & \mathbf{e} = \bar{\mathbf{e}} \wedge \mathbf{a} = \bar{\mathbf{a}} \end{aligned} \tag{M2}$$

and note that this problem could be solved separately for $\mathbf{e}, \mathbf{a}$ and $\bar{\mathbf{e}}, \bar{\mathbf{a}}$ if the coupling constraints $\mathbf{e} = \bar{\mathbf{e}}$ and $\mathbf{a} = \bar{\mathbf{a}}$ were removed.

M2 is an Integer Linear Program, as variables are binary and both objective and constraints can be represented through linear constraints.[1] Dual decomposition solves a Linear Programming (LP) relaxation of M2 (that allows fractional values for all binary variables) through subgradient descent on a particular dual of M2. This dual can be derived by introducing Lagrange multipliers for the coupling constraints. Its attractiveness stems from the fact that calculating the subgradient amounts to solving the decoupled problems in isolation. If, by design, these decoupled problems can be solved efficiently, we can often quickly find the optimal solution to an LP relaxation of our original problem.

Dual decomposition applied to Model 2 is shown in algorithm 2. It maintains the dual variables $\boldsymbol{\lambda}$ that will appear as local penalties in the subproblems to be solved. The algorithm will try to tune these variables such that at convergence the coupling constraints will be fulfilled. This is done by first optimizing $s_2(\mathbf{e},\mathbf{a})$ over O and $s_2(\bar{\mathbf{e}},\bar{\mathbf{a}})$ over I. Now, whenever there is disagreement between two variables to be coupled, the corresponding dual parameter is shifted, increasing the chance that next time both models will agree. For example, if in the first iteration we predict $e_{6,\texttt{Bind}} = 1$ but $\bar{e}_{6,\texttt{Bind}} = 0$, we set $\lambda_{6,\texttt{Bind}} = -\alpha$ where α is some stepsize (chosen according to Koo et al. (2010)). This will decrease the coefficient for $e_{6,\texttt{Bind}}$, and increase the coefficient for $\bar{e}_{6,\texttt{Bind}}$. Hence, we have a higher chance of agreement for this variable in the next iteration.

The algorithm repeats the process described above until all variables agree, or some predefined number R of iterations is reached. In the former case we in fact have the exact solution to the original ILP.

[1]The ILP representation could be taken from the MLNs of Riedel et al. (2009) and the mapping to ILPs of Riedel (2008).

Algorithm 2 Subgradient descent for Model 2, and projected subgradient descent for Model 3.

require:

3	$\mu^{\text{arg2}}_{i,p,q} \leftarrow \left[\mu^{\text{arg2}}_{i,p,q} - \alpha_t (a_{i,q,\texttt{Theme}} - t_{i,p,q})\right]_+$
2,3	$t \leftarrow t + 1$

until no $\boldsymbol{\lambda}$, $\boldsymbol{\mu}$ changed or $t > R$
return $(\mathbf{e},\mathbf{a})$*[model 2]* or $(\mathbf{e},\mathbf{a},\mathbf{b})$ *[model 3]*

In the later case we have no such guarantee, but find that in practice the solutions are still of high quality. Notice that we could still assess the quality of this approximation by measuring the duality gap between primal score and the final dual score.

Algorithm 2 for Model 2 requires us to optimize $s_2(\mathbf{e},\mathbf{a})$ over O and $s_2(\bar{\mathbf{e}},\bar{\mathbf{a}})$ over I. The former, with added penalties, can be done with bestOut($\mathbf{c}$). As the constraint set for I again decomposes on a per-token basis, solving the latter problem requires a very similar procedure, and again $O(mn)$ time. Algorithm 1 shows this procedure under bestIn($\mathbf{c}$). It chooses, for each trigger candidate, the best label and *incoming* set of arguments together with the best outgoing edges to proteins. Adding edges to proteins is not strictly required, but simplifies our exposition. Algorithm bestIn($\mathbf{c}$) requires a per-trigger incoming score: $s^{\mathbf{c}}_2(l,\mathbf{y}_l) \stackrel{\text{def}}{=} \sum_t e_{l,t}\left(c_{l,t} + \frac{1}{2} s_{\mathrm{T}}(l,t)\right) + \sum_{i,r} a_{i,l,r}\left(c_{i,l,r} + \frac{1}{2} s_{\mathrm{R}}(i,l,r)\right) + \sum_{p,r} a_{l,p,r}\left(c_{l,p,r} + \frac{1}{2} s_{\mathrm{R}}(l,p,r)\right)$. Finally, note that emptyIn(i) not only assigns None as trigger label of i and to all incoming edges, but also greedily picks outgoing protein edges (as done within in$(\cdot)$).

3.3 Model 3

Model 2 does not predict the $b_{p,q}$ variables that represent protein pairs p, q in bindings. *Model 3* fixes this by (a) adding binding variables $b_{p,q}$ into the objective, and (b) enforcing that the binding assignment $\mathbf{b}$ is consistent with the trigger and argument assignments $\mathbf{e}$ and $\mathbf{a}$. We will also enforce that the same pair of entities p, q cannot be arguments in more than one event together.

The scoring function for Model 3 is simply

$$s_3(\mathbf{e}, \mathbf{a}, \mathbf{b}) \stackrel{\text{def}}{=} s_2(\mathbf{e}, \mathbf{a}, \mathbf{b}) + \sum_{b_{p,q}=1} s_{\text{B}}(p, q). \quad (4)$$

Here $s_{\text{B}}(p, q) = \langle \mathbf{w}_{\text{B}}, \mathbf{f}_{\text{B}}(p, q) \rangle$ is a per-protein-pair score based on a feature representation of the lexical and syntactic relation between both protein heads.

Our strategy will be based on enforcing consistency partly through linear constraints which we dualize, and partly within our search algorithm. To this end we first introduce a set of auxiliary binary variables $t_{i,p,q}$. When a $t_{i,p,q}$ is active, we enforce that there is a binding trigger at i with proteins p and q as `Theme` arguments. A set of linear constraints can be used for this: $e_{i,\texttt{Bind}} - t_{i,p,q} \geq 0$, $a_{i,p,\texttt{Theme}} - t_{i,p,q} \geq 0$ and $a_{i,q,\texttt{Theme}} - t_{i,p,q} \geq 0$ for all suitable i, p and q. We denote the set of assignments $(\mathbf{e}, \mathbf{a}, \mathbf{t})$ that fulfill these constraints by T.

Consistency between $\mathbf{e}$, $\mathbf{a}$ and $\mathbf{b}$ can now be enforced by making sure that $\mathbf{t}$ is consistent with $\mathbf{e}$ and $\mathbf{a}$, and that $\mathbf{b}$ is consistent with this $\mathbf{t}$. The latter means that an active $b_{p,q}$ requires a trigger i to point to p and q. Or in other words, $t_{i,p,q} = 1$ for exactly one trigger i.

With the set of consistent assignments $(\mathbf{b}, \mathbf{t})$ referred to as B, and a slight abuse of notation, this gives us $\mathcal{Y}_3 \stackrel{\text{def}}{=} \mathcal{Y}_2 \cap \text{T} \cap \text{B}$. Note that it is $(\mathbf{e}, \mathbf{a}, \mathbf{t}) \in \text{T}$ that will be enforced by dualizing constraints, and $(\mathbf{b}, \mathbf{t}) \in \text{B}$ that will be enforced within search.

3.3.1 Inference

We note that inference in Model 3 can be performed by solving the following problem:

$$\begin{aligned} \underset{\mathbf{e},\mathbf{a},\bar{\mathbf{e}},\bar{\mathbf{a}},\mathbf{b},\mathbf{t}}{\text{maximize}} \quad & \frac{1}{2} s_1(\mathbf{e}, \mathbf{a}) + \frac{1}{2} s_2(\bar{\mathbf{e}}, \bar{\mathbf{a}}) + \sum_{b_{p,q}=1} s_{\text{B}}(p, q) \\ \text{subject to} \quad & (\mathbf{e}, \mathbf{a}) \in \text{O} \wedge (\bar{\mathbf{e}}, \bar{\mathbf{a}}) \in \text{I} \wedge (\mathbf{b}, \mathbf{t}) \in \text{B} \wedge \\ & \mathbf{e} = \bar{\mathbf{e}} \wedge \ \mathbf{a} = \bar{\mathbf{a}} \wedge (\mathbf{e}, \mathbf{a}, \mathbf{t}) \in \text{T}. \end{aligned} \quad \text{(M3)}$$

Again, without the final row, M3 would be separable. We exploit this by performing dual decomposition with a dual objective that has multipliers $\boldsymbol{\lambda}$ for the coupling constraints and multipliers $\boldsymbol{\mu}$ for the constraints which enforce $(\mathbf{e}, \mathbf{a}, \mathbf{t}) \in \text{T}$. The resulting subgradient descent method is also shown in algorithm 2. Notably, since the constraints for T are inequalities, we require a *projected* version of the descent algorithm which enforces $\boldsymbol{\mu} \geq 0$. This manifests itself when $\boldsymbol{\mu}$ is updated using the $[\cdot]_+$ projection.

We have already described how to find the best $\mathbf{e}, \mathbf{a}$ and $\bar{\mathbf{e}}, \bar{\mathbf{a}}$ assignments. What changes for Model 3 is the derivation of the penalties for $\mathbf{e}$ and $\mathbf{a}$ that now come from both $\boldsymbol{\lambda}$ and $\boldsymbol{\mu}$. We set $\mathbf{c}^{\text{out}}_{i,t}(\boldsymbol{\lambda}, \boldsymbol{\mu}) \stackrel{\text{def}}{=} \lambda_{i,t} + \delta_{t,\texttt{Bind}} \sum_{p,q} \mu^{\text{trig}}_{i,p,q}$. For $j \notin \text{Prot}(\mathbf{x})$ we set $\mathbf{c}^{\text{out}}_{i,j,r}(\boldsymbol{\lambda}, \boldsymbol{\mu}) \stackrel{\text{def}}{=} \lambda_{i,j,r}$; otherwise we use $\mathbf{c}^{\text{out}}_{i,j,r}(\boldsymbol{\lambda}, \boldsymbol{\mu}) \stackrel{\text{def}}{=} \lambda_{i,j,r} + \sum_p \mu^{\text{arg1}}_{i,j,p} + \sum_q \mu^{\text{arg2}}_{i,q,j}$.

For finding a $(\mathbf{b}, \mathbf{t}) \in \text{B}$ that maximizes $\sum_{b_{p,q}=1} s_{\text{B}}(p, q)$ we use bestBind$(\mathbf{c})$, as shown in algorithm 1. It groups together two proteins p, q if their score plus the penalty of the best possible trigger i exceeds 0. In this case, or if there is at least one trigger with positive penalty $c_{i,p,q} > 0$, we activate the set of triggers $I(p, q)$ with maximal score.

Note that when several triggers i maximize the score, we assign them all the same fractional value $|I(p, q)|^{-1}$. This enforces the constraint that at most one binding event can point to both p and q and also means that we are solving an LP relaxation. We could enforce integer solutions and pick arbitrary triggers at a tie, but this would lower the chances of matching against predictions of other routines.

The penalties for bestBind$(\mathbf{c})$ are derived from the dual $\boldsymbol{\mu}$ by setting $\mathbf{c}^{\text{bind}}_{i,p,q}(\boldsymbol{\mu}) = -\mu^{\text{trig}}_{i,p,q} - \mu^{\text{arg1}}_{i,p,q} - \mu^{\text{arg2}}_{i,,p,q}$.

3.4 Training

We choose prediction-based passive-aggressive (PA) online learning (Crammer and Singer, 2003) with averaging to estimate the weights $\mathbf{w}$ for each of our models. PA is an error-driven learner that shifts weights towards features of the gold solution, and away from features of the current guess, whenever the current model makes a mistake.

PA learning takes into account a user-defined loss function for which we use a weighted sum

of false positives and false negatives: $l(\mathbf{y}, \mathbf{y}') \stackrel{\text{def}}{=} \text{FP}(\mathbf{y}, \mathbf{y}') + \alpha \text{FN}(\mathbf{y}, \mathbf{y}')$. We set $\alpha = 3.8$ by optimizing on the BioNLP 2009 development set.

4 Related Work

Riedel et al. (2009) use Integer Linear Programming and cutting planes (Riedel, 2008) for inference in a model similar to Model 2. By using dual decomposition instead, we can exploit tractable substructure and achieve quadratic (Model 2) and cubic (Model 3) runtime guarantees. An advantage of ILP inference are guaranteed certificates of optimality. However, in practice we also gain certificates of optimality for a large fraction of the instances we process. Poon and Vanderwende (2010) use local search and hence provide no such certificates. Their problem formulation also makes n-gram dependency path features harder to incorporate. McClosky et al. (2011b) cast event extraction as dependency parsing task. Their model assumes that event structures are trees, an assumption that is frequently violated in practice. Finally, all previous joint approaches use heuristics to decide whether binding arguments are part of the same event, while we capture these decisions in the joint model.

We follow a long line of research in NLP that addresses search problems using (Integer) Linear Programs (Germann et al., 2001; Roth and Yih, 2004; Riedel and Clarke, 2006). However, instead of using off-the-shelf solvers, we work in the framework of dual decomposition. Here we extend the approach of Rush et al. (2010) in that in addition to equality constraints we dualize more complex coupling constraints between models. This requires us to work with a projected version of subgradient descent.

While tailored towards (biomedical) event extraction, we believe that our models can also be effective in a more general Semantic Role Labeling (SRL) context. Using variants of Model 1, we can enforce many of the SRL constraints—such as "unique agent" constraints (Punyakanok et al., 2004)—without having to call out to ILP optimizers. Meza-Ruiz and Riedel (2009) showed that inducing pressure on arguments to be attached to at least one predicate is helpful; this is a soft incoming edge constraint. Finally, Model 3 can be used to efficiently capture compatibilities between semantic arguments; such compatibilities have also been shown to be helpful in SRL (Toutanova et al., 2005).

5 Experiments

We evaluate our models on several tracks of the 2009 and 2011 BioNLP shared tasks, using the official "Approximate Span Matching/Approximate Recursive Matching" F1 metric for each. We also investigate the runtime behavior of our algorithms.

5.1 Preprocessing

Each document is first processed by the Stanford CoreNLP[2] tokenizer and sentence splitter. Parse trees come from the Charniak-Johnson parser (Charniak and Johnson, 2005) with a self-trained biomedical parsing model (McClosky and Charniak, 2008), and are converted to dependency structures again using Stanford CoreNLP. Based on trigger words collected from the training set, a set of candidate trigger tokens $\text{Trig}(\mathbf{x})$ is generated for each sentence $\mathbf{x}$.

5.2 Features

The feature function $\mathbf{f}_{\text{T}}(i, t)$ extracts a per-trigger feature vector for trigger i and type $t \in \mathcal{T}$. It creates one active feature for each element in $\{t, t \in \mathcal{T}_{\text{Reg}}\} \times \text{feats}(i)$. Here $\text{feats}(i)$ denotes a collection of representations for the token i: wordform, lemma, POS tag, syntactic heads, syntactic children, and membership in two dictionaries taken from Riedel et al. (2009).

For $\mathbf{f}_{\text{R}}(i, j, r)$ we create active features for each element of $\{r\} \times \text{feats}(i, j)$. Here $\text{feats}(i, j)$ is a collection of representations of the token pair (i, j) taken from Miwa et al. (2010c) and contains: labelled and unlabeled n-gram dependency paths; edge and vertex walk features, argument and trigger modifiers and heads, words in between.

For $\mathbf{f}_{\text{B}}(p, q)$ we re-use the token pair representations from $\mathbf{f}_{\text{R}}$. In particular, we create one active feature for each element in $\text{feats}(p, q)$.

5.3 Shared Task 2009

We first evaluate our models on the Bionlp 2009 task 1. The training, development and test sets for this

Table 2: F1 scores for the test set of Task 1 of the BioNLP 2009 shared task.

task consist of 797, 150 and 250 documents, respectively.

Table 1 shows our results for the development set. We compare our three models (M1, M2 and M3) and previous state-of-the-art systems: *McClosky* (McClosky et al., 2011a), *Poon* (Poon and Vanderwende, 2010), *Bjoerne* (Björne et al., 2009) and *Miwa* (Miwa et al., 2010b; Miwa et al., 2010a). Presented is F1 score for all events (TOT), regulation events (REG), binding events (BIND) and simple events (SVT).

Model 1 is outperforming the previous best joint models of Poon and Vanderwende (2010), as well as the best entry of the 2009 task (Björne et al., 2009). This is achieved without careful tuning of thresholds that control flow of information between trigger and argument extraction. Notably, training Model 1 takes approximately 20 minutes using a single core implementation. Contrast this with 20 minutes on 32 cores reported by Poon and Vanderwende (2010).

Model 2 focuses on regulation structures and results demonstrate this: F1 for regulations goes up by nearly 2 points. While the impact of joint modeling relative to weaker local baselines has been shown shown by Poon and Vanderwende (2010) and Riedel et al. (2009), our findings here provide evidence that it remains effective even when the baseline system is very competitive.

With Model 3 our focus is extended to binding events, improving F1 for such events by at least 5 F1. This also has a positive effect on regulation events, as regulations of binding events can now be more accurately extracted. In total we see a 1.1 F1 increase over the best results reported so far (Miwa et al., 2010b). Crucially, this is achieved using only a single parse tree per sentence, as opposed to three used by Miwa et al. (2010a).

Table 2 shows results for the test set. Here with Model 1 we again already outperform all but the results of Miwa et al. (2010a). Model 2 improves F1 for regulations, while Model 3 again increases F1 for both regulations and binding events. This yields the best binding event results reported so far. Notably, not only are we able to resolve binding ambiguity better. Binding attachments themselves also improve, as we increase attachment F1 from 61.4 to 62.7 when going from Model 2 to Model 3.

Miwa et al. (2010b) use two parsers to generate their input features. For fairer comparison we augment Model 3 with syntactic features based on the *enju* parser (Miyao et al., 2009). With these features (M3+enju) we achieve the best results on this dataset reported so far, and outperform Miwa et al. (2010b) by 1.1 F1 in total, 1.6 F1 on regulation events and 2.0 F1 on binding events.

We also apply Model 3, with slight modifications, to the BioNLP 2009 task 2 which requires cellular locations to be extracted as well. With 53.0 F1 we fall 2 points short of the results of Miwa et al. (2010b) but still substantially outperform any other reported results on the dataset. More parse trees may again substantially improve results, as well as task-specific constraint and feature sets.

5.4 Shared Task 2011

We entered the Shared Task 2011 with Model 3, primarily focusing on Genia track (task 1), and the Infectious Diseases track. The Genia track differs from the 2009 task by including both abstracts and full text articles. In total 908 training, 259 development and 347 test documents are provided.

Genia Task 1		Infectious Diseases	
System	TOT	System	TOT
M3+Stanford	**56.0**	M3+Stanford	**55.6**
M3	55.2	M3	53.4
UTurku	53.3	Stanford	50.6
MSR-NLP	51.5	UTurku	44.2
ConcordU	50.3	PNNL	42.6

Table 3: F1 scores for the test sets of two tracks in the BioNLP 2011 Shared Task.

The top five entries are shown in table 3. Model 3 is the best-performing system that does not use model combination, only outperformed by a version of Model 3 that includes Stanford predictions (McClosky et al., 2011b) as input features (Riedel et al., 2011). Not shown in the table are results for full papers only. Here M3 ranks first with 53.1 F1, while M3+Stanford comes in second with 52.7 F1.

The Infectious Diseases (ID) track of the 2011 task has 152 train, 46 development and 118 test documents. Relative to Genia it provides less data and introduces more types of entities as well as the *biological process* event type. Incorporating these changes into our models is straightforward, and hence we omit details for brevity.

Table 3 shows the top five entries for the Infectious Diseases track. Again Model 3 is the best-performing system that does not use model combination, outperformed only by Model 3 with Stanford predictions as features. We should point out that the feature sets and learning parameters were kept constant when moving from Genia to ID data. The strong results we observe without any tuning to the domain indicate the robustness of joint modeling.

5.5 Runtime Behavior

Table 4 shows the asymptotic complexity of our three models with respect to $m = |\text{Trig}(\mathbf{x})|$, $n = |\text{Cand}(\mathbf{x})|$ and $p = |\text{Prot}(\mathbf{x})|$. We also show the number of iterations needed on average, the average time in milliseconds per sentence,[3] and the fraction of sentences we get certificates of optimality for.

As expected, Model 1 is most efficient, both asymptotically and on average. Given that its accuracy is already good, it can serve as a basis for large-scale extraction tasks. Models 2 and 3 require several iterations and more time, while providing slightly less certificates. However, given the improvement in F1 they deliver, and the fact preprocessing steps such as parsing would still dominate the average time, this seems like a reasonable price to pay.

[3]Measured without preprocessing and feature extraction.

	Complexity	Iter.	Time	Exact
M1	$O(nm)$	1.0	60ms	100%
M2	$O(Rnm)$	10.4	183ms	96%
M3	$O\left(Rnm + Rp^2m\right)$	11.7	297ms	94%

Table 4: Complexity and Runtime Behavior.

6 Conclusion

We presented three joint models for biomedical event extraction. Model 1 reaches near-state-of-the-art results, outperforms all previous joint models and has quadratic runtime guarantees. By explicitly capturing regulation events (Model 2), and binding events (Model 3) we achieve the best results reported so far on several event extraction tasks. The runtime penalty we pay is kept minimal by using dual decomposition. We also show how dual decomposition can be used for constraints that go beyond coupling equalities.

We use joint models, a decomposition technique and supervised online learning. This recipe can be successful in many settings, but requires expensive manual annotation. In the future we want to integrate weak supervision techniques to train extractors with existing biomedical databases, such as KEGG, and only minimal amounts of annotated text.

Abstract

Online discussion forums are a valuable means for users to resolve specific information needs, both interactively for the participants and statically for users who search/browse over historical thread data. However, the complex structure of forum threads can make it difficult for users to extract relevant information. The discourse structure of web forum threads, in the form of labelled dependency relationships between posts, has the potential to greatly improve information access over web forum archives. In this paper, we present the task of parsing user forum threads to determine the labelled dependencies between posts. Three methods, including a dependency parsing approach, are proposed to jointly classify the links (relationships) between posts and the dialogue act (type) of each link. The proposed methods significantly surpass an informed baseline. We also experiment with "in situ" classification of evolving threads, and establish that our best methods are able to perform equivalently well over partial threads as complete threads.

1 Introduction

Web user forums (or simply "forums") are online platforms for people to discuss information and obtain information via a text-based threaded discourse, generally in a pre-determined domain (e.g. IT support or DSLR cameras). With the advent of Web 2.0, there has been an explosion of web authorship in this area, and forums are now widely used in various areas such as customer support, community development, interactive reporting and online eduction. In addition to providing the means to interactively participate in discussions or obtain/provide answers to questions, the vast volumes of data contained in forums make them a valuable resource for "support sharing", i.e. looking over records of past user interactions to potentially find an immediately applicable solution to a current problem. On the one hand, more and more answers to questions over a wide range of domains are becoming available on forums; on the other hand, it is becoming harder and harder to extract and access relevant information due to the sheer scale and diversity of the data.

This research aims at enhancing information access and support sharing, by mining the discourse structure of troubleshooting-oriented web user forum threads. Previous research has shown that simple thread structure information (e.g. reply-to structure) can enhance tasks such as forum information retrieval (Seo et al., 2009) and post quality assessment (Lui and Baldwin, 2009). We aim to move beyond simple threading, to predict not only the links between posts, but also show the manner of each link, in the form of the discourse structure of the thread. In doing so, we hope to be able to perform richer visualisation of thread structure (e.g. highlighting the key posts which appear to have led to a successful resolution to a problem), and more fine-grained weighting of posts in threads for search purposes.

To illustrate the task, we use an example thread, made up of 5 posts from 4 distinct participants, from the CNET forum dataset of Kim et al. (2010b), as shown in Figure 1. The discourse structure of the thread is modelled as a rooted directed acyclic graph

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 13–25,
Edinburgh, Scotland, UK, July 27–31, 2011.

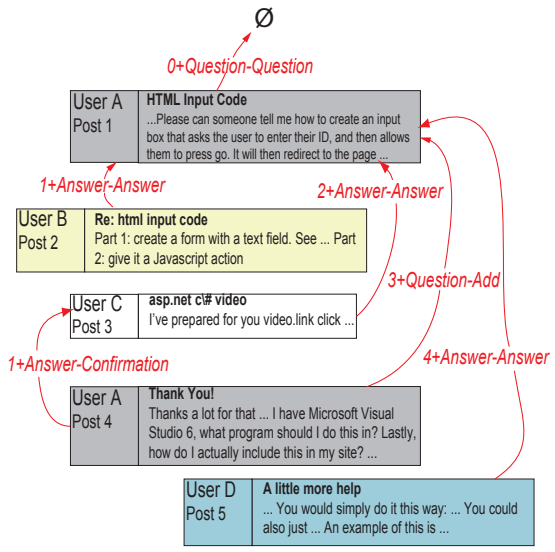

Figure 1: A snippeted and annotated CNET thread

(DAG) with a dialogue act label associated with each edge of the graph. In this example, UserA initiates the thread with a question (dialogue act = Question-Question) in the first post, by asking how to create an interactive input box on a webpage. In response, UserB and UserC provide independent answers (dialogue act = Answer-Answer). UserA responds to UserC to confirm the details of the solution (dialogue act = Answer-Confirmation), and at the same time, adds extra information to his/her original question (dialogue act = Question-Add); i.e., this one post has two distinct dependency links associated with it. Finally, UserD proposes a different solution again to the original question.

To predict thread discourse structure of this type, we jointly classify the links and dialogue acts between posts, experimenting with a variety of supervised classification methods, namely dependency parsing and linear-chain conditional random fields. In this, we build on the earlier work of Kim et al. (2010b) who first proposed the task of thread discourse analysis, but only carried out experiments on post linking and post dialogue act classification as separate tasks. In addition to achieving state-of-the-art accuracy over the task, we carry out in-depth analysis of classification effectiveness at different thread depths, and establish that the accuracy of our method over partial threads is equivalent to that over full threads, indicating that the method is applicable to in-situ thread classification. Finally, we investigate the role of user-level features in discourse structure analysis.

2 Related Work

This work builds directly on earlier work of a subset of the authors (Kim et al., 2010b), whereby a novel post-level dialogue act set was proposed, and used as the basis for annotation of a set of threads taken from CNET. In the original work, we proposed a set of novel features, which we applied to the separate tasks of post link classification and dialogue act classification. We later applied the same basic methodology to dialogue act classification over one-on-one live chat data with provided message dependencies (Kim et al., 2010a), demonstrating the generalisability of the original method. In both cases, however, we tackled only a single task, either link classification (optionally given dialogue act tags) or dialogue act classification, but never the two together. In this paper, we take the obvious step of exploring joint classification of post link and dialogue act tags, to generate full thread discourse structures.

Discourse disentanglement (i.e. link classification) and dialogue act tagging have been studied largely as independent tasks. Discourse disentanglement is the task of dividing a conversation thread (Elsner and Charniak, 2008; Lemon et al., 2002) or document thread (Wolf and Gibson, 2005) into a set of distinct sub-discourses. The disentangled discourse is sometimes assumed to take the form of a tree structure (Grosz and Sidner, 1986; Lemon et al., 2002; Seo et al., 2009), an acyclic graph structure (Rosé et al., 1995; Schuth et al., 2007; Elsner and Charniak, 2008; Wang et al., 2008; Lin et al., 2009), or a more general cyclic chain graph structure (Wolf and Gibson, 2005). Dialogue acts are used to describe the function or role of an utterance in a discourse, and have been applied to the analysis of mediums of communication including conversational speech (Stolcke et al., 2000; Shriberg et al., 2004; Murray et al., 2006), email (Cohen et al., 2004; Carvalho and Cohen, 2005; Lampert et al., 2008), instant messaging (Ivanovic, 2008; Kim et al., 2010a), edited documents (Soricut and Marcu, 2003; Sagae, 2009) and online forums (Xi et al.,

2004; Weinberger and Fischer, 2006; Wang et al., 2007; Fortuna et al., 2007; Kim et al., 2010b). For a more complete review of models for discourse disentanglement and dialogue act tagging, see Kim et al. (2010b).

Joint classification has been applied in a number of different contexts, based on the intuition that it should be possible to harness interactions between different sub-tasks to the mutual benefit of both. Warnke et al. (1997) jointly performed segmentation and dialogue act classification over a German spontaneous speech corpus. In their approach, the predictions of a multi-layer perceptron classifier on dialogue act boundaries were fed into an n-gram language model, which was used for the joint segmentation and classification of dialogue acts. Sutton and McCallum (2005) performed joint parsing and semantic role labelling (SRL), using the results of a probabilistic SRL system to improve the accuracy of a probabilistic parser. Finkel and Manning (2009) built a joint, discriminative model for parsing and named entity recognition (NER), addressing the problem of inconsistent annotations across the two tasks, and demonstrating that NER benefited considerably from the interaction with parsing. Dahlmeier et al. (2009) proposed a joint probabilistic model for word sense disambiguation (WSD) of prepositions and SRL of prepositional phrases (PPs), and achieved state-of-the-art results over both tasks.

There has been a recent growth in user-level research over forums. Lui and Baldwin (2009) explored a range of user-level features, including replies-to and co-participation graph analysis, for post quality classification. Lui and Baldwin (2010) introduced a novel user classification task where each user is classified against four attributes: clarity, proficiency, positivity and effort. User communication roles in web forums have also been studied (Chan and Hayes, 2010; Chan et al., 2010).

Threading information has been shown to enhance retrieval effectiveness for post-level retrieval (Xi et al., 2004; Seo et al., 2009), thread-level retrieval (Seo et al., 2009; Elsas and Carbonell, 2009), sentence-level shallow information extraction (Sondhi et al., 2010), and near-duplicate thread detection (Muthmann et al., 2009). These results suggest that the thread structural representation used in this research, which includes both linking structure and the dialogue act associated with each link, could potentially provide even greater leverage in these retrieval tasks.

Another related research area is post-level classification, such as general post quality classification (Weimer et al., 2007; Weimer and Gurevych, 2007; Wanas et al., 2008; Lui and Baldwin, 2009), and post descriptiveness in particular domains (e.g. medical forums: Leaman et al. (2010)). It has been demonstrated (Wanas et al., 2008; Lui and Baldwin, 2009) that thread discourse structure can significantly improve the classification accuracy for post-level tasks.

Initiation–response pairs (e.g. question–answer, assessment–agreement, and blame–denial) from online forums have the potential to enhance thread summarisation or automatically generate knowledge bases for Community Question Answering (cQA) services such as Yahoo! Answers. While initiation–response pair identification has been explored as a pairwise ranking problem (Wang and Rosé, 2010), question–answer pair identification has been approached via the two separate sub-tasks of question classification and answer detection (Cong et al., 2008; Ding et al., 2008; Cao et al., 2009). Our thread discourse structure prediction task includes joint classification of post roles (i.e. dialogue acts) and links, and could potentially be performed at the sub-post sentence level to extract initiation–response pairs.

3 Task Description and Data Set

The main task performed in this research is joint classification of inter-post links (Link) and dialogue acts (DA) within forum threads. In this, we assume that a post can only link to an earlier post (or a virtual root node), and that dialogue acts are labels on edges. It is possible for there to be multiple edges from a given post, e.g. if a post both confirms the validity of an answer and adds extra information to the original question (as happens in Post4 in Figure 1).

We experiment with two different approaches to joint classification: (1) a linear-chain CRF over combined Link/DA post labels; and (2) a dependency parser. The joint classification task is a natural fit for dependency parsing, in that the task is intrinsically one of inferring labelled dependencies

between posts, but it has a number of special properties that distinguish it from standard dependency parsing:

strict reverse-chronological directionality: the head always precedes the dependent, in terms of the chronological sequencing of posts.

non-projective dependencies: threads can contain non-projective dependencies, e.g. in a 4-post thread, posts 2 and 3 may be dependent on post 1, and post 4 dependent on post 2; around 2% of the threads in our dataset contain non-projective dependencies.

multi-headedness: it is possible for a given post to have multiple heads, including the possibility of multiple dependency links to the same post (e.g. adding extra information to a question [Question-Add] as well as retracting information from the original question [Question-Correction]); around 6% of the threads in our dataset contain multi-headed dependencies.

disconnected sub-graphs: it is possible for there to be disconnected sub-graphs, e.g. in instances where a user hijacks a thread to ask their own unrelated question, or submit an unrelated spam post; around 2% of the threads in our dataset contain disconnected sub-graphs.

The first constraint potentially simplifies dependency parsing, and non-projective dependencies are relatively well understood in the dependency parsing community (Tapanainen and Jarvinen, 1997; McDonald et al., 2005). Multi-headedness and disconnected sub-graphs pose greater challenges to dependency parsing, although there has been research done on both (McDonald and Pereira, 2006; Sagae and Tsujii, 2008; Eisner and Smith, 2005). The combination of non-projectivity, multi-headedness and disconnected sub-graphs in a single dataset, however, poses a challenge for dependency parsing.

In addition to performing evaluation in batch mode over complete threads, we consider the task of "in situ thread classification", whereby we predict the discourse structure of a thread after each post. This is intended to simulate the more realistic setting of incrementally crawling/updating thread data, but needing to predict discourse structure for partial threads. We are interested in determining the relative degradation in accuracy for in situ classification vs. batch classification.

As our dataset, we use the CNET forum dataset of Kim et al. (2010b),[1] which contains 1332 annotated posts spanning 315 threads, collected from the Operating System, Software, Hardware and Web Development sub-forums of cnet.[2] Each post is labelled with one or more links (including the possibility of null-links, where the post doesn't link to any other post), and each link is labelled with a dialogue act. The dialogue act set is made up of 5 super-categories: Question, Answer, Resolution (confirmation of the question being resolved), Reproduction (external confirmation of a proposed solution working) and Other. The Question category contains 4 sub-classes: Question, Add, Confirmation and Correction. Similarly, the Answer category contains 5 sub-classes: Answer, Add, Confirmation, Correction and Objection. For example, the label Question-Add signifies the Question superclass and Add subclass, i.e. addition of extra information to a question. For full details of the dialogue act tagset, see Kim et al. (2010b).

Dependency links are represented by their relative position in the chronologically-sorted list of posts, e.g. 1 indicates a link back to the preceding post, and 2 indicates a link back two posts.

Unless otherwise noted, evaluation is over the combined link and dialogue act tag, including the combination of superclass and subclass for the Question and Answer dialogue acts. For example, 1+Answer-Answer indicates a dependency link back one post, which is an answer to a question. The most common label in the dataset is 1+Answer-answer (28.4%).

4 Learners and Features

4.1 Learners

To predict thread discourse structure, we use a structured classification approach — based on the findings of Kim et al. (2010b) and Kim et al. (2010a) — and a dependency parser. The structured classification approach we experiment with is a linear-

[1] Available from http://www.csse.unimelb.edu.au/research/lt/resources/conll2010-thread/

[2] http://forums.cnet.com/

chain conditional random field learner (CRF: Lafferty et al. (2001)), within which we explore two simple approaches to joint classification, as is explained in Section 5.1. Dependency parsing (Kübler et al., 2009) is the task of automatically predicting the dependency structure of a token sequence, in the form of binary asymmetric dependency relations with dependency types.

Standardly, CRFs have been applied to tasks such as part-of-speech tagging, named entity recognition, semantic role labelling and supertagging, where the individual tokens are single words. Similarly, dependency parsing is conventionally applied to sentences, with single-word tokens. In our case, our tokens are thread posts, with much greater scope for feature engineering than single words, and technical challenges in scaling the underlying implementations to handle potentially much larger feature sets.

As our learners, we deployed CRFSGD (Bottou, 2011) to learn the CRF, and MaltParser (Nivre et al., 2007) as our dependency parser. CRFSGD uses stochastic gradient descent to efficiently solve the convex optimisation problem, and scales well to large feature sets. We used the default parameter settings for CRFSGD, with feature templates including all unigram features of the current token as well as bigram features combining the previous output token with the current token.

MaltParser implements transition-based parsing, where no formal grammar is considered, and a transition system, or state machine, is learned to map a sentence onto its dependency graph. One feature of MaltParser that makes it well suited to our task is that it is possible to define feature models of arbitrary complexity for each token. In presenting the thread data to MaltParser, we represent the null-link from the initial post of each thread, as well as any disconnected posts, as the root.

To the best of our knowledge, there is no past work on using dependency parsing to learn thread discourse structure. Based on extensive experimentation, we determined that the MaltParser configuration that obtains the best results for our task is the Nivre algorithm in arc-standard mode (Nivre, 2003; Nivre, 2004), using LIBSVM (Chang and Lin, 2011) with a linear kernel as the learner, and a feature model with exhaustive combinations of features relating to the features and predictions of the first/top three tokens from both "Input" and "Stack".[3] As such, MaltParser is actually unable to predict any non-projective structures, as experiments with algorithms supporting non-projective structures invariably led to lower results. In our choice of parsing algorithm, we are also unable to detect posts with multiple heads, but can potentially detect disconnected sub-graphs.

4.2 Features

The features used in our classifiers are as follows:

Structural Features:

Initiator a binary feature indicating whether the current post's author is the thread initiator.

Position the relative position of the current post, as a ratio over the total number of posts in the thread.

Semantic Features:

TitSim the relative location of the post which has the most similar title (based on unweighted cosine similarity) to the current post.

PostSim the relative location of the post which has the most similar content (based on unweighted cosine similarity) to the current post.

Punct the number of question marks (QuCount), exclamation marks (ExCount) and URLs (UrlCount) in the current post.

UserProf the class distribution (in the training thread) of the author of the current post.

These features are drawn largely from the work of Kim et al. (2010b), with two major differences: (1) we do not use post context features because our learners (i.e. CRFSGD and MaltParser) inherently capture Markov chains; and (2) our UserProf features are customised to the class set associated with the task at hand, e.g. the UserProf features for the standalone linking task take the form of the link labels (and not dialogue act labels) of the posts by the relevant author in the training data. Table 1 shows the feature representation of the third post in a thread

Feature	Value	Explanation
Initiator	1.0	post from the initiator
ExCount	4.0	4 exclamation marks
QuCount	0.0	0 question marks
UrlCount	0.0	0 URLs
Position	0.25	$\frac{i-1}{n} = \frac{3-1}{8}$
PostSim	2.0	most similar to post 1
TitSim	2.0	most similar to post 1
UserProf	$\vec{x}$	counts for posts of each class from the same author in the training data

Table 1: The feature presentation of the third post in a thread of length 8

of length 8. The values of each feature are scaled to the range $[0, 1]$ before being fed into the learners.

We also experimented with other features, including raw bag-of-words lexical features, dimensionality-reduced lexical features (using principal components analysis), and different post similarity measures such as longest common subsequence (LCS) match. While we were able to obtain gains in isolation, when combined with the other features, these features had no impact, and are thus not included in the results presented in this paper.

5 Classification Methodology

All our experiments were carried out based on stratified 10-fold cross-validation, stratifying at the thread level to ensure that all posts from a given thread occur in a single fold. The results are primarily evaluated using post-level micro-averaged F-score (F_μ: $\beta = 1$), and additionally with thread-level F-score/classification accuracy (i.e. the proportion of threads where all posts have been correctly classified[4]), where space allows. Statistical significance is tested using randomised estimation (Yeh, 2000) with $p < 0.05$. Initial experiments showed it is hard for learners to discover which posts have multiple links, largely due to the sparsity of multi-headed posts (which account for less than 5% of the total posts). Therefore, only the the most recent link for each multi-headed post was included in training, but evaluation still considers all links.

5.1 Joint classification

In our experiments, we test two basic approaches to joint classification for the CRF: (1) classifying the Link and DA separately, and composing the predictions to form the joint classification (Composition); and (2) combining the Link and DA labels into a single class, and applying the learner over the posts with the combined class (Combine). Note that Composition has the potential for mismatches in the number of Link and DA predictions it generates, causing complications in the class composition. Even if the same number of labels is predicted for both Link and DA, if multiple tags are predicted in both cases, we are left with the problem of determining which link label to combine with which dialogue act label. As such, we have our reservations about Composition, but as the CRF performs strict 1-of-n labelling, these are not issues in the experiments reported herein.

MaltParser natively handles the combination of Link and DA in its dependency parsing formulation.

5.2 In Situ Thread Classification

One of the biggest challenges in classifying the discourse structure of a forum thread is that threads evolve over time, as new posts are posted. In order to capture this phenomenon, and compare the accuracy of different models when applied to partial thread data (artificially cutting off a thread at post N) vs. complete threads.[5] This is done in the following way: classification over the first two posts only ($[1, 2]$), the first four posts ($[1, 4]$), the first six posts ($[1, 6]$), the first eight posts ($[1, 8]$), and all posts ($[all]$). In each case, we limit the test data only, meaning that the only variable in play is the extent of thread context used to learn the thread discourse structure for the given set of posts. We break down the results in each case into the indicated subthreads, e.g. we take the predictions for $[all]$, and break them down into the results for $[1, 2]$, $[1, 4]$, $[1, 6]$, $[1, 8]$ and $[all]$, for direct comparison with the predictions over the respective sub-thread data.

[3] `http://maltparser.org/userguide.html#parsingalg`

[4] Classification accuracy = F-score at the thread-level, as each thread is assigned a single label of correct or incorrect.

[5] In practice, completeness is defined at a given point in time, when the crawl was done, and it is highly likely that some of the "complete" threads had extra posts after the crawl.

Method	Link	DA
Kim et al. (2010b)	.863 / .676	.751 / .543
CRFSGD	.891 / .727	.795 / .609

Table 2: Post/thread-level component-wise classification F-scores for Link and DA classes

6 Experiments and Analysis

6.1 Joint classification

As our baseline for the task, we first use a simple majority class classifier in the form of the single joint class of 1+Answer-Answer for all posts, which has a post-level F-score of 0.284. A stronger baseline is to classify all first posts as 0+Question-Question and all subsequent posts as 1+Answer-answer, which achieves a post-level F-score of 0.515 (labelled as Heuristic).

As described in Section 5.1, one approach to joint classification with CRFSGD is to firstly conduct component-wise classification over Link and DA separately, and compose the predictions. The results for the separate Link and DA classification tasks are presented in Table 2, along with the best results for Link and DA classification from Kim et al. (2010b). At the component-wise tasks, our method is superior to Kim et al. (2010b), based on a different learner and slightly different feature set.

Next, we compose the component-wise classifications for the CRF into joint classifications (Composition). We contrast this with the combined class approach for CRFSGD and MaltParser (jointly presented as Joint in Table 3). With the combined class results, we additionally ablate each of the feature types from Section 4.2, and also present results for a dummy model, where no features are provided and the prediction is based simply on sequential priors (Dummy). The results are presented in Table 3, along with the Heuristic baseline result.

Several interesting things can be observed from the post-level F-score results in Table 3. First, with no features (Dummy), while CRFSGD performs slightly worse than the Heuristic baseline, MaltParser significantly surpasses the baseline. This is due to the richer sequential context model of MaltParser. Second, the single feature with the greatest impact on results is UserProf, i.e. user profile features extracted from the training data; CRFSGD in particular benefits from this feature. We return to explore this effect in Section 6.4. Third, although the Initiator feature does not have much effect on CRFSGD, it affects the performance of MaltParser significantly. Further experiments shown that the combination of Initiator and UserProf is sufficient to achieve a competitive result (i.e. 0.731). It therefore seems that MaltParser is more robust than CRFSGD, whose performance relies crucially on user-level features which must be learned from the training data (i.e. UserProf).

Method	CRFSGD	MaltParser
Heuristic	.515*/ .311*	
Dummy	.508*/ .394*	.533*/ .356*
Composition	.728*/ .553*	—
Joint +ALL	.756 / .578	.738 / .578
−Initiator	.745 / .569	.708*/ .534*
−Position	.750 / .565	.736 / .568
−PostSim	.753 / .578	.737 / .568
−TitSim	.760 / .587	.734 / .571
−Punct	.745 / .571	.735 / .578
−UserProf	.672*/ .527*	.701*/ .536*

Table 3: Post/thread-level Link-DA joint classification F-scores ("*" signifies a significantly worse result than that for the same learner with ALL features)

Looking to the thread-level F-scores, we observe some interesting divergences from the post-level F-score results. First, with no features (Dummy), CRFSGD significantly outperforms both the baseline and MaltParser. This appears to be because CRFSGD performs particularly well over short threads (e.g. of length 3 and 4), but worse over longer threads. Second, the best thread-level F-scores from CRFSGD (i.e. 0.587) and MaltParser (i.e. 0.578) are not significantly different, despite the discrepancy in post-level F-score (where CRFSGD is markedly superior in this case). With the extra features, the performance of MaltParser on short threads appears to pick up noticeably, and the difference in post-level predictions is over longer threads.

If we evaluate the two models over DA superclasses only (ignoring mismatches at the subclass level for Question and Answer), the post-level F-scores for joint classification with ALL features for CRFSGD and MaltParser are 0.803 and 0.787, respectively.

Approaches	Link	DA
Component-wise	.891 / .727*	**.795 / .609**
CRFSGD decomp	**.893 / .749**	.785 / .603
MaltParser decomp	.870*/ .730*	.766*/ .571*

Table 4: Post/thread-level Link and DA F-scores from component-wise classification, and from Link-DA classification decomposition ("*" signifies a significantly *worse* result than the **best** result in that column)

Looking at the performance of CRFSGD (in Combine mode) and MaltParser on disconnected sub-graphs, while both models did predict a small number of non-initial posts with null-links (including MaltParser predicting 5 out of 6 posts in a single thread as having null-links), none were correct, and neither model was able to correctly predict any of the 6 actual non-initial instances of null-links in the dataset.

Finally, we took the joint classification results from CRFSGD and MaltParser using ALL features, and decomposed the predictions into Link and DA. The results are presented in Table 4, along with the results for component-wise classification from Table 2. Somewhat surprisingly, the decomposed predictions are mostly slightly worse than the results for the component-wise classification, despite achieving higher F-score for the joint classification task. This is simply due to the combined method tending to get both labels correct or both labels wrong, for a given post.

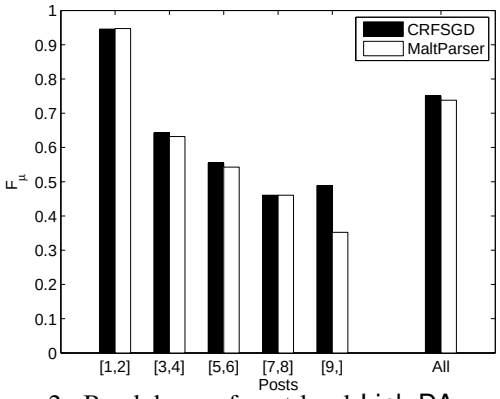

Figure 2: Breakdown of post-level Link-DA results for CRFSGD and MaltParser based on post position

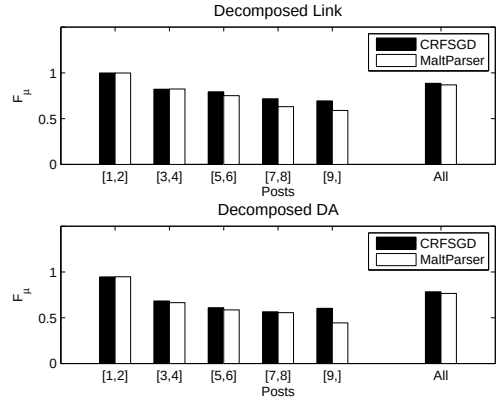

Figure 3: Breakdown of post-level Link and DA F-score based on the decomposition of CRFSGD and MaltParser classifications

6.2 Post Position-based Result Breakdown

One question in thread discourse structure classification is how accurate the predictions are at different depths in a thread (e.g. the first two posts vs. the second two posts). A breakdown of results across posts at different positions is presented in Figure 2.

The overall trend for both CRFSGD and MaltParser is that it becomes increasingly hard to classify posts as we continue through a thread, due to greater variability in discourse structure and greater sparsity in the data. However, it is interesting to note that the results for CRFSGD actually improve from posts 7 and 8 ($[7, 8]$) to posts 9 and onwards ($[9,]$). To further investigate this effect, we performed class decomposition over the joint classification predictions, and performed a similar breakdown of posts for Link and DA; the results are presented in Figure 3. It is clear that the anomaly for CRFSGD comes from the DA component, due to there being greater predictability in the dialogue for final posts in a thread (users tend to confirm a successful resolution of the problem, or report on successful external reproduction of the solution). MaltParser seems less adept at identifying that a post is at the end of a thread, and predicting the dialogue act accordingly. This observation is congruous with the findings of McDonald and Nivre (2007) that errors propagate, due to MaltParser's greedy inference strategy. The higher results for Link are to be expected, as throughout the thread, most posts tend to link locally.

Test \ B/down	$[1,2]$	$[1,4]$	$[1,6]$	$[1,8]$	$[All]$
$[1,2]$	.947/.947	—	—	—	—
$[1,4]$	.946/.947	.836/.841	—	—	
$[1,6]$	.946/.947	.840/.841	.800/.794	—	—
$[1,8]$	.946/.947	.840/.841	.800/.794	.780/.769	—
$[All]$	.946/.946	.840/.838	.800/.791	.776/.767	.756/.738

Table 5: Post-level Link-DA F-score for CRFSGD/MaltParser, based on in situ classification over sub-threads of different lengths (indicated in the rows), broken down over different post extents (indicated in the columns)

6.3 In Situ Structure Prediction

As described in Section 5.2, we simulate in situ thread discourse structure prediction by removing differing numbers of posts from the tail of the thread, and applying the trained model over the resultant sub-threads. The results for in situ classification are presented in Table 5, with the rows indicating the size of the test sub-thread, and the columns being a breakdown of results over different portions of the classified thread. The reason that we do not provide numbers for all cells in the table is that the size of the test sub-thread determines the post extents we can breakdown the results into, e.g. we cannot return results for posts 1–4 ($[1,4]$) when the size of the test thread was only two posts ($[1,2]$).

From the results, we can see that both CRFSGD and MaltParser are very robust when applied to partial threads, to the extent that we actually achieve higher results over shortened versions of the thread than over the complete thread in some instances, although the only difference that is statistically significant is over $[1,8]$ for CRFSGD, where the prediction over the partial thread is actually superior to that over the complete thread. From this, we can conclude that it is possible to apply our method to partial threads without any reduction in effectiveness relative to classification over complete threads. As such, our method is shown to be robust when applied to real-time analysis of dynamically evolving threads.

6.4 User profile feature analysis

In our experiments, we noticed that the user profile feature (UserProf) is the most effective feature for both CRFSGD and MaltParser. To gain a deeper insight into the behaviour of the feature, we binned the posts according to the number of times the author had posted in the training data, evaluated based on a user score ($uscore$) for each user:

$$uscore_i = \frac{\sum_{j=1}^{n_i} s_{p_{i,j}}}{n_i}$$

where n_i is the number of posts by user i, and $s_{p_{i,j}}$ is the number of posts by user i that occur as training instances for other posts by the same author. $uscore$ reflects the average training–test post ratio per user in cross-validation. Note that as we include all posts from a given thread in a single partition during cross-validation, it is possible for an author to have posted 4 times, but have a $uscore$ of 0 due to those posts all occurring in the same thread.

Bin	$uscore$	Posts per user	Total users	Total posts
High	224.6	251	1	251
Medium	1∼41.7	4∼48	45	395
Low	0	2∼4	157	377
Very Low	0	1	309	309

Table 6: Statistics for the 4 groups of users

We ranked the users in the dataset in descending order of $uscore$, sub-ranking on n_i in cases of a tie in $uscore$. The users were binned into 4 groups of roughly equal post size. The detailed statistics are shown in Table 6, noting that the high-frequency bin ("High") contains posts from a single user. We present the post-level micro-averaged F-score for posts in each bin based on CRFSGD, with and without user profile features, in Figure 4.

Contrary to expectation, the UserProf features have the greatest impact for users with fewer posts. In fact, a statistically significant difference was observed only for users with no posts in the training data ($uscore = 0$), where the F-score jumped over 10% in absolute terms for both the Low and Very Low bins. Our explanation for this effect is that the

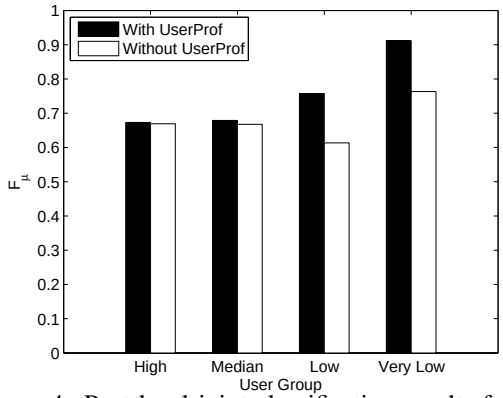

Figure 4: Post-level joint classification results for users binned by $uscore$, based on CRFSGD with and without UserProf features)

lack of user profile information is predictive of the sort of posts we can expect from a user (i.e. they tend to be newbie users, asking questions).

7 Conclusions and Future Work

In this research, we explored the joint classification of web user forum thread discourse structure, in the form of a rooted directed acyclic graph over posts, with edges labelled with dialogue acts. Three classification approaches were proposed: separately predicting Link and DA labels, and composing them into a joint class; predicting a combined Link-DA class using a structured classifier; and applying dependency parsing to the problem. We found the combined approach based on CRFSGD to perform best over the task, closely followed by dependency parsing with MaltParser.

We also examined the task of in situ classification of dialogue structure, in the form of predicting the discourse structure of partial threads, as contrasted with classifying only complete threads. We found that there was no drop in F-score over different subextents of the thread in classifying partial threads, despite the relative lack of thread context.

In future work, we plan to delve further into dependency parsing, looking specifically at the implications of multi-headedness and disconnected subgraphs on dependency parsing. We also intend to carry out meta-classification, combining the predictions of CRFSGD and MaltParser.

Our user profile features were found to be the pick of our features, but counter-intuitively, to benefit users with no posts in the training data, rather than prolific users. We wish to explore this effect further, including incorporating unsupervised user-level features into our classifiers.

Acknowledgements

The authors wish to acknowledge the development efforts of Johan Hall in configuring MaltParser to handle numeric features, and be able to parse thread structures. Abstract

This paper describes an algorithm for exact decoding of phrase-based translation models, based on Lagrangian relaxation. The method recovers exact solutions, with certificates of optimality, on over 99% of test examples. The method is much more efficient than approaches based on linear programming (LP) or integer linear programming (ILP) solvers: these methods are not feasible for anything other than short sentences. We compare our method to MOSES (Koehn et al., 2007), and give precise estimates of the number and magnitude of search errors that MOSES makes.

1 Introduction

Phrase-based models (Och et al., 1999; Koehn et al., 2003; Koehn et al., 2007) are a widely-used approach for statistical machine translation. The decoding problem for phrase-based models is NP-hard[1]; because of this, previous work has generally focused on approximate search methods, for example variants of beam search, for decoding.

This paper describes an algorithm for exact decoding of phrase-based models, based on Lagrangian relaxation (Lemaréchal, 2001). The core of the algorithm is a dynamic program for phrase-based translation which is efficient, but which allows some ill-formed translations. More specifically, the dynamic program searches over the space of translations where exactly N words are translated (N is the number of words in the source-language sentence), but where some source-language words may be translated zero times, or some source-language words may be translated more than once. Lagrangian relaxation is used to enforce the constraint that each source-language word should be translated exactly once. A subgradient algorithm is used to optimize the dual problem arising from the relaxation.

The first technical contribution of this paper is the basic Lagrangian relaxation algorithm. By the usual guarantees for Lagrangian relaxation, if this algorithm converges to a solution where all constraints are satisfied (i.e., where each word is translated exactly once), then the solution is guaranteed to be optimal. For some source-language sentences however, the underlying relaxation is loose, and the algorithm will not converge. The second technical contribution of this paper is a method that incrementally adds constraints to the underlying dynamic program, thereby tightening the relaxation until an exact solution is recovered.

We describe experiments on translation from German to English, using phrase-based models trained by MOSES (Koehn et al., 2007). The method recovers exact solutions, with certificates of optimality, on over 99% of test examples. On over 78% of examples, the method converges with zero added constraints (i.e., using the basic algorithm); 99.67% of all examples converge with 9 or fewer constraints. We compare to a linear programming (LP)/integer linear programming (ILP) based decoder. Our method is much more efficient: LP or ILP decoding is not feasible for anything other than short sentences,[2] whereas the average decoding time for our method (for sentences of length 1-50 words) is 121 seconds per sentence. We also compare our method to MOSES, and give precise estimates of the number and magnitude of search errors that MOSES makes. Even with large beam sizes, MOSES makes a significant number of search errors. As far as we are aware, previous work has not successfully re-

[1] We refer here to the phrase-based models of (Koehn et al., 2003; Koehn et al., 2007), considered in this paper. Other variants of phrase-based models, which allow polynomial time decoding, have been proposed, see the related work section.

[2] For example ILP decoding for sentences of lengths 11-15 words takes on average 2707.8 seconds.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 26–37,
Edinburgh, Scotland, UK, July 27–31, 2011.

covered exact solutions for the type of phrase-based models used in MOSES.

2 Related Work

Lagrangian relaxation is a classical technique for solving combinatorial optimization problems (Korte and Vygen, 2008; Lemaréchal, 2001). Dual decomposition, a special case of Lagrangian relaxation, has been applied to inference problems in NLP (Koo et al., 2010; Rush et al., 2010), and also to Markov random fields (Wainwright et al., 2005; Komodakis et al., 2007; Sontag et al., 2008). Earlier work on belief propagation (Smith and Eisner, 2008) is closely related to dual decomposition. Recently, Rush and Collins (2011) describe a Lagrangian relaxation algorithm for decoding for syntactic translation; the algorithmic construction described in the current paper is, however, very different in nature to this work.

Beam search stack decoders (Koehn et al., 2003) are the most commonly used decoding algorithm for phrase-based models. Dynamic-programming-based beam search algorithms are discussed for both word-based and phrase-based models by Tillmann and Ney (2003) and Tillmann (2006).

Several works attempt exact decoding, but efficiency remains an issue. Exact decoding via integer linear programming (ILP) for IBM model 4 (Brown et al., 1993) has been studied by Germann et al. (2001), with experiments using a bigram language model for sentences up to eight words in length. Riedel and Clarke (2009) have improved the efficiency of this work by using a cutting-plane algorithm, and experimented with sentence lengths up to 30 words (again with a bigram LM). Zaslavskiy et al. (2009) formulate the phrase-based decoding problem as a traveling salesman problem (TSP), and take advantage of existing exact and approximate approaches designed for TSP. Their translation experiment uses a bigram language model and applies an approximate algorithm for TSP. Och et al. (2001) propose an A* search algorithm for IBM model 4, and test on sentence lengths up to 14 words. Other work (Kumar and Byrne, 2005; Blackwood et al., 2009) has considered variants of phrase-based models with restrictions on reordering that allow exact, polynomial time decoding, using finite-state transducers.

The idea of incrementally adding constraints to tighten a relaxation until it is exact is a core idea in combinatorial optimization. Previous work on this topic in NLP or machine learning includes work on inference in Markov random fields (Sontag et al., 2008); work that encodes constraints using finite-state machines (Tromble and Eisner, 2006); and work on non-projective dependency parsing (Riedel and Clarke, 2006).

3 The Phrase-based Translation Model

This section establishes notation for phrase-based translation models, and gives a definition of the decoding problem. The phrase-based model we use is the same as that described by Koehn et al. (2003), as implemented in MOSES (Koehn et al., 2007).

The input to a phrase-based translation system is a source-language sentence with N words, $x_1 x_2 \dots x_N$. A *phrase table* is used to define the set of possible *phrases* for the sentence: each phrase is a tuple $p = (s, t, e)$, where (s, t) are indices representing a contiguous span in the source-language sentence (we have $s \leq t$), and e is a target-language string consisting of a sequence of target-language words. For example, the phrase $p = (2, 5, \textit{the dog})$ would specify that words $x_2 \dots x_5$ have a translation in the phrase table as "the dog". Each phrase p has a score $g(p) = g(s, t, e)$: this score will typically be calculated as a log-linear combination of features (e.g., see Koehn et al. (2003)).

We use $s(p)$, $t(p)$ and $e(p)$ to refer to the three components (s, t, e) of a phrase p.

The output from a phrase-based model is a sequence of phrases $y = \langle p_1 p_2 \dots p_L \rangle$. We will often refer to an output y as a *derivation*. The derivation y defines a target-language translation $e(y)$, which is formed by concatenating the strings $e(p_1), e(p_2), \dots, e(p_L)$. For two consecutive phrases $p_k = (s, t, e)$ and $p_{k+1} = (s', t', e')$, the *distortion distance* is defined as $\delta(t, s') = |t + 1 - s'|$. The score for a translation is then defined as

$$f(y) = h(e(y)) + \sum_{k=1}^{L} g(p_k) + \sum_{k=1}^{L-1} \eta \times \delta(t(p_k), s(p_{k+1}))$$

where $\eta \in \mathbb{R}$ is often referred to as the distortion penalty, and typically takes a negative value. The function $h(e(y))$ is the score of the string $e(y)$ under

a language model.[3]

The decoding problem is to find

$$\arg\max_{y \in \mathcal{Y}} f(y)$$

where $\mathcal{Y}$ is the set of valid derivations. The set $\mathcal{Y}$ can be defined as follows. First, for any derivation $y = \langle p_1 p_2 \ldots p_L \rangle$, define $y(i)$ to be the number of times that the source-language word x_i has been translated in y: that is, $y(i) = \sum_{k=1}^{L} [[s(p_k) \leq i \leq t(p_k)]]$, where $[[\pi]] = 1$ if π is true, and 0 otherwise. Then $\mathcal{Y}$ is defined as the set of finite length sequences $\langle p_1 p_2 \ldots p_L \rangle$ such that:

1. Each word in the input is translated exactly once: that is, $y(i) = 1$ for $i = 1 \ldots N$.
2. For each pair of consecutive phrases p_k, p_{k+1} for $k = 1 \ldots L-1$, we have $\delta(t(p_k), s(p_{k+1})) \leq d$, where d is the *distortion limit*.

An exact dynamic programming algorithm for this problem uses states (w_1, w_2, b, r), where (w_1, w_2) is a target-language bigram that the partial translation ended with, b is a bit-string denoting which source-language words have been translated, and r is the end position of the previous phrase (e.g., see Koehn et al. (2003)). The bigram (w_1, w_2) is needed for calculation of trigram language model scores; r is needed to enforce the distortion limit, and to calculate distortion costs. The bit-string b is needed to ensure that each word is translated exactly once. Since the number of possible bit-strings is exponential in the length of sentence, exhaustive dynamic programming is in general intractable. Instead, people commonly use heuristic search methods such as beam search for decoding. However, these methods have no guarantee of returning the highest scoring translation.

4 A Decoding Algorithm based on Lagrangian Relaxation

We now describe a decoding algorithm for phrase-based translation, based on Lagrangian relaxation. We first describe a dynamic program for decoding which is efficient, but which relaxes the $y(i) = 1$ constraints described in the previous section. We then describe the Lagrangian relaxation algorithm, which introduces Lagrange multipliers for each constraint of the form $y(i) = 1$, and uses a subgradient algorithm to minimize the dual arising from the relaxation. We conclude with theorems describing formal properties of the algorithm, and with an example run of the algorithm.

4.1 An Efficient Dynamic Program

As described in the previous section, our goal is to find the optimal translation $y^* = \arg\max_{y \in \mathcal{Y}} f(y)$. We will approach this problem by defining a set $\mathcal{Y}'$ such that $\mathcal{Y} \subset \mathcal{Y}'$, and such that

$$\arg\max_{y \in \mathcal{Y}'} f(y)$$

can be found efficiently using dynamic programming. The set $\mathcal{Y}'$ omits some constraints—specifically, the constraints that each source-language word is translated once, i.e., that $y(i) = 1$ for $i = 1 \ldots N$—that are enforced for members of $\mathcal{Y}$. In the next section we describe how to reintroduce these constraints using Lagrangian relaxation. The set $\mathcal{Y}'$ does, however, include a looser constraint, namely that $\sum_{i=1}^{N} y(i) = N$, which requires that exactly N words are translated.

We now give the dynamic program that defines $\mathcal{Y}'$. The main idea will be to replace bit-strings (as described in the previous section) by a much smaller number of dynamic programming states. Specifically, the states of the new dynamic program will be tuples (w_1, w_2, n, l, m, r). The pair (w_1, w_2) is again a target-language bigram corresponding to the last two words in the partial translation, and the integer r is again the end position of the previous phrase. The integer n is the number of words that have been translated thus far in the dynamic programming algorithm. The integers l and m specify a contiguous span $x_l \ldots x_m$ in the source-language sentence; this span is the last contiguous span of words that have been translated thus far.

The dynamic program can be viewed as a shortest-path problem in a directed graph, with nodes in the graph corresponding to states (w_1, w_2, n, l, m, r). The transitions in the

[3] The language model score usually includes a word insertion score that controls the length of translations. The relative weights of the $g(p)$ and $h(e(y))$ terms, and the value for η, are typically chosen using MERT training (Och, 2003).

graph are defined as follows. For each state (w_1, w_2, n, l, m, r), we consider any phrase $p = (s, t, e)$ with $e = (e_0 \dots e_{M-1} e_M)$ such that: 1) $\delta(r, s) \leq d$; and 2) $t < l$ or $s > m$. The former condition states that the phrase should satisfy the distortion limit. The latter condition requires that there is no overlap of the new phrase's span (s, t) with the span (l, m). For any such phrase, we create a transition

$$(w_1, w_2, n, l, m, r) \xrightarrow{p=(s,t,e)} (w'_1, w'_2, n', l', m', r')$$

where

- $(w'_1, w'_2) = \begin{cases} (e_{M-1}, e_M) & \text{if } M \geq 2 \\ (w_2, e_1) & \text{if } M = 1 \end{cases}$
- $n' = n + t - s + 1$
- $(l', m') = \begin{cases} (l,\ t\ ) & \text{if } s = m + 1 \\ (s, m) & \text{if } t = l - 1 \\ (s,\ t\ ) & \text{otherwise} \end{cases}$
- $r' = t$

The new target-language bigram (w'_1, w'_2) is the last two words of the partial translation after including phrase p. It comes from either the last two words of e, or, if e consists of a single word, the last word of the previous bigram, w_2, and the first and only word, e_1, in e. (l', m') is expanded from (l, m) if the spans (l, m) and (s, t) are adjacent. Otherwise, (l', m') will be the same as (s, t).

The score of the transition is given by a sum of the phrase translation score $g(p)$, the language model score, and the distortion cost $\eta \times \delta(r, s)$. The trigram language model score is $h(e_1|w_1, w_2) + h(e_2|w_2, e_1) + \sum_{i=1}^{M-2} h(e_{i+2}|e_i, e_{i+1})$, where $h(w_3|w_1, w_2)$ is a trigram score (typically a log probability plus a word insertion score).

We also include start and end states in the directed graph. The start state is (<s>, <s>, 0, 0, 0, 0) where <s> is the start symbol in the language model. For each state (w_1, w_2, n, l, m, r), such that $n = N$, we create a transition to the end state. This transition takes the form

$$(w_1, w_2, N, l, m, r) \xrightarrow{(N, N+1, \text{</s>})} \text{END}$$

For this transition, we define the score as $score = h(\text{</s>}|w_1, w_2)$; thus this transition incorporates the end symbol </s> in the language model.

The states and transitions we have described form a directed graph, where each path from the start state to the end state corresponds to a sequence of phrases $p_1 p_2 \dots p_L$. We define $\mathcal{Y}'$ to be the full set of such sequences. We can use the Viterbi algorithm to solve $\arg\max_{y \in \mathcal{Y}'} f(y)$ by simply searching for the highest scoring path from the start state to the end state.

The set $\mathcal{Y}'$ clearly includes derivations that are ill-formed, in that they may include words that have been translated 0 times, or more than 1 time. The first line of Figure 2 shows one such derivation (corresponding to the translation *the quality and also the and the quality and also .*). For each phrase we show the English string (e.g., *the quality*) together with the span of the phrase (e.g., 3, 6). The values for $y(i)$ are also shown. It can be verified that this derivation is a valid member of $\mathcal{Y}'$. However, $y(i) \neq 1$ for several values of i: for example, words 1 and 2 are translated 0 times, while word 3 is translated twice.

Other dynamic programs, and definitions of $\mathcal{Y}'$, are possible: for example an alternative would be to use a dynamic program with states (w_1, w_2, n, r). However, including the previous contiguous span (l, m) makes the set $\mathcal{Y}'$ a closer approximation to $\mathcal{Y}$. In experiments we have found that including the previous span (l, m) in the dynamic program leads to faster convergence of the subgradient algorithm described in the next section, and in general to more stable results. This is in spite of the dynamic program being larger; it is no doubt due to $\mathcal{Y}'$ being a better approximation of $\mathcal{Y}$.

4.2 The Lagrangian Relaxation Algorithm

We now describe the Lagrangian relaxation decoding algorithm for the phrase-based model. Recall that in the previous section, we defined a set $\mathcal{Y}'$ that allowed efficient dynamic programming, and such that $\mathcal{Y} \subset \mathcal{Y}'$. It is easy to see that $\mathcal{Y} = \{y : y \in \mathcal{Y}', \text{ and } \forall i,\ y(i) = 1\}$. The original decoding problem can therefore be stated as:

$$\arg\max_{y \in \mathcal{Y}'} f(y) \text{ such that } \forall i,\ y(i) = 1$$

We use Lagrangian relaxation (Korte and Vygen, 2008) to deal with the $y(i) = 1$ constraints. We introduce Lagrange multipliers $u(i)$ for each such constraint. The Lagrange multipliers $u(i)$ can take any positive or negative value. The Lagrangian is

$$L(u, y) = f(y) + \sum_i u(i)(y(i) - 1)$$

Initialization: $u^0(i) \leftarrow 0 \quad$ for $i = 1 \ldots N$
for $t = 1 \ldots T$
  $y^t = \arg\max_{y \in \mathcal{Y}'} L(u^{t-1}, y)$
  if $y^t(i) = 1$ for $i = 1 \ldots N$
    return y^t
  else
    for $i = 1 \ldots N$
      $u^t(i) = u^{t-1}(i) - \alpha^t \left(y^t(i) - 1\right)$

Figure 1: The decoding algorithm. $\alpha^t > 0$ is the step size at the t'th iteration.

The dual objective is then

$$L(u) = \max_{y \in \mathcal{Y}'} L(u, y).$$

and the dual problem is to solve

$$\min_u L(u).$$

The next section gives a number of formal results describing how solving the dual problem will be useful in solving the original optimization problem.

We now describe an algorithm that solves the dual problem. By standard results for Lagrangian relaxation (Korte and Vygen, 2008), $L(u)$ is a convex function; it can be minimized by a subgradient method. If we define

$$y_u = \arg\max_{y \in \mathcal{Y}'} L(u, y)$$

and $\gamma_u(i) = y_u(i) - 1$ for $i = 1 \ldots N$, then γ_u is a subgradient of $L(u)$ at u. A subgradient method is an iterative method for minimizing $L(u)$, which perfoms updates $u^t \leftarrow u^{t-1} - \alpha^t \gamma_{u^{t-1}}$ where $\alpha^t > 0$ is the step size for the t'th subgradient step.

Figure 1 depicts the resulting algorithm. At each iteration, we solve

$$\arg\max_{y \in \mathcal{Y}'} \left(f(y) + \sum_i u(i)(y(i) - 1) \right)$$
$$= \arg\max_{y \in \mathcal{Y}'} \left(f(y) + \sum_i u(i) y(i) \right)$$

by the dynamic program described in the previous section. Incorporating the $\sum_i u(i) y(i)$ terms in the dynamic program is straightforward: we simply redefine the phrase scores as

$$g'(s, t, e) = g(s, t, e) + \sum_{i=s}^{t} u(i)$$

Intuitively, each Lagrange multiplier $u(i)$ penalizes or rewards phrases that translate word i; the algorithm attempts to adjust the Lagrange multipliers in such a way that each word is translated exactly once. The updates $u^t(i) = u^{t-1}(i) - \alpha^t(y^t(i) - 1)$ will decrease the value for $u(i)$ if $y^t(i) > 1$, increase the value for $u(i)$ if $y^t(i) = 0$, and leave $u(i)$ unchanged if $y^t(i) = 1$.

4.3 Properties

We now give some theorems stating formal properties of the Lagrangian relaxation algorithm. These results for Lagrangian relaxation are well known: for completeness, we state them here. First, define y^* to be the optimal solution for our original problem:

Definition 1. $y^* = \arg\max_{y \in \mathcal{Y}} f(y)$

Our first theorem states that the dual function provides an upper bound on the score for the optimal translation, $f(y^*)$:

Theorem 1. *For any value of $u \in \mathbb{R}^N$, $L(u) \geq f(y^*)$.*

Proof.

$$\begin{aligned} L(u) &= \max_{y \in \mathcal{Y}'} \; f(y) + \sum_i u(i)(y(i) - 1) \\ &\geq \max_{y \in \mathcal{Y}} \; f(y) + \sum_i u(i)(y(i) - 1) \\ &= \max_{y \in \mathcal{Y}} \; f(y) \end{aligned}$$

The first inequality follows because $\mathcal{Y} \subset \mathcal{Y}'$. The final equality is true since any $y \in \mathcal{Y}$ has $y(i) = 1$ for all i, implying that $\sum_i u(i)(y(i) - 1) = 0$. □

The second theorem states that under an appropriate choice of the step sizes α^t, the method converges to the minimum of $L(u)$. Hence we will successfully find the tightest possible upper bound defined by the dual $L(u)$.

Theorem 2. *For any sequence $\alpha^1, \alpha^2, \ldots$ If 1) $\lim_{t \to \infty} \alpha^t \to 0$; 2) $\sum_{t=1}^{\infty} \alpha^t = \infty$, then $\lim_{t \to \infty} L(u^t) = \min_u L(u)$*

Proof. See Korte and Vygen (2008). □

Figure 2: An example run of the algorithm in Figure 1. For each value of t we show the dual value $L(u^{t-1})$, the derivation y^t, and the number of times each word is translated, $y^t(i)$ for $i = 1 \dots N$. For each phrase in a derivation we show the English string e, together with the span (s, t): for example, the first phrase in the first derivation has English string *the quality and*, and span $(3, 6)$. At iteration 7 we have $y^t(i) = 1$ for $i = 1 \dots N$, and the translation is returned, with a guarantee that it is optimal.

Our final theorem states that if at any iteration the algorithm finds a solution y^t such that $y^t(i) = 1$ for $i = 1 \dots N$, then this is guaranteed to be the optimal solution to our original problem. First, define

Definition 2. $y_u = \arg\max_{y \in \mathcal{Y}'} L(u, y)$.

We then have the theorem

Theorem 3. *If $\exists\ u$, s.t. $y_u(i) = 1$ for $i = 1 \dots N$, then $f(y_u) = f(y^*)$, i.e. y_u is optimal.*

Proof. We have

$$\begin{aligned} L(u) &= \max_{y \in \mathcal{Y}'} \quad f(y) + \sum_i u(i)(y(i) - 1) \\ &= f(y_u) + \sum_i u(i)(y_u(i) - 1) \\ &= f(y_u) \end{aligned}$$

The second equality is true because of the definition of y_u. The third equality follows because by assumption $y_u(i) = 1$ for $i = 1 \dots N$. Because $L(u) = f(y_u)$ and $L(u) \geq f(y^*)$ for all u, we have $f(y_u) \geq f(y^*)$. But $y^* = \arg\max_{y \in \mathcal{Y}} f(y)$, and $y_u \in \mathcal{Y}$, hence we must also have $f(y_u) \leq f(y^*)$. It follows that $f(y_u) = f(y^*)$. □

In some cases, however, the algorithm in Figure 1 may not return a solution y^t such that $y^t(i) = 1$ for all i. There could be two reasons for this. In the first case, we may not have run the algorithm for enough iterations T to see convergence. In the second case, the underlying relaxation may not be tight, in that there may not be *any* settings u for the Lagrange multipliers such that $y_u(i) = 1$ for all i.

Section 5 describes a method for tightening the underlying relaxation by introducing hard constraints (of the form $y(i) = 1$ for selected values of i). We will see that this method is highly effective in tightening the relaxation until the algorithm converges to an optimal solution.

4.4 An Example of the Algorithm

Figure 2 shows an example of how the algorithm works when translating a German sentence into an English sentence. After the first iteration, there are words that have been translated two or three times, and words that have not been translated. At each iteration, the Lagrangian multipliers are updated to encourage each word to be translated once. On this example, the algorithm converges to a solution where all words are translated exactly once, and the solution is guaranteed to be optimal.

5 Tightening the Relaxation

In some cases the algorithm in Figure 1 will not converge to $y(i) = 1$ for $i = 1 \dots N$ because the underlying relaxation is not tight. We now describe a method that incrementally tightens the Lagrangian relaxation algorithm until it provides an exact answer. In cases that do not converge, we introduce hard constraints to force certain words to be translated exactly once in the dynamic programming solver. In experiments we show that typically only a

$Optimize(\mathcal{C}, u)$
while (dual value still improving)
$y^* = \arg\max_{y \in \mathcal{Y}'_{\mathcal{C}}} L(u, y)$
if $y^*(i) = 1$ for $i = 1 \ldots N$ **return** y^*
else for $i = 1 \ldots N$
$u(i) = u(i) - \alpha\,(y^*(i) - 1)$
$count(i) = 0$ for $i = 1 \ldots N$
for $k = 1 \ldots K$
$y^* = \arg\max_{y \in \mathcal{Y}'_{\mathcal{C}}} L(u, y)$
if $y^*(i) = 1$ for $i = 1 \ldots N$ **return** y^*
else for $i = 1 \ldots N$
$u(i) = u(i) - \alpha\,(y^*(i) - 1)$
$count(i) = count(i) + [[y^*(i) \neq 1]]$
Let $\mathcal{C}' =$ set of G i's that have the largest value for $count(i)$, that are not in $\mathcal{C}$, and that are not adjacent to each other
return $Optimize(\mathcal{C} \cup \mathcal{C}', u)$

Figure 3: A decoding algorithm with incremental addition of constraints. The function $Optimize(\mathcal{C}, u)$ is a recursive function, which takes as input a set of constraints $\mathcal{C}$, and a vector of Lagrange multipliers, u. The initial call to the algorithm is with $\mathcal{C} = \emptyset$, and $u = 0$. $\alpha > 0$ is the step size. In our experiments, the step size decreases each time the dual value increases from one iteration to the next; see Appendix A.

few constraints are necessary.

Given a set $\mathcal{C} \subseteq \{1, 2, \ldots, N\}$, we define

$$\mathcal{Y}'_{\mathcal{C}} = \{y : y \in \mathcal{Y}', \text{ and } \forall\, i \in \mathcal{C},\ \ y(i) = 1\}$$

Thus $\mathcal{Y}'_{\mathcal{C}}$ is a subset of $\mathcal{Y}'$, formed by adding hard constraints of the form $y(i) = 1$ to $\mathcal{Y}'$. Note that $\mathcal{Y}'_{\mathcal{C}}$ remains as a superset of $\mathcal{Y}$, which enforces $y(i) = 1$ for all i. Finding $\arg\max_{y \in \mathcal{Y}'_{\mathcal{C}}} f(y)$ can again be achieved using dynamic programming, with the number of dynamic programming states increased by a factor of $2^{|\mathcal{C}|}$: dynamic programming states of the form (w_1, w_2, n, l, m, r) are replaced by states $(w_1, w_2, n, l, m, r, b_{\mathcal{C}})$ where $b_{\mathcal{C}}$ is a bit-string of length $|\mathcal{C}|$, which records which words in the set $\mathcal{C}$ have or haven't been translated in a hypothesis (partial derivation). Note that if $\mathcal{C} = \{1 \ldots N\}$, we have $\mathcal{Y}'_{\mathcal{C}} = \mathcal{Y}$, and the dynamic program will correspond to exhaustive dynamic programming.

We can again run a Lagrangian relaxation algorithm, using the set $\mathcal{Y}'_{\mathcal{C}}$ in place of $\mathcal{Y}'$. We will use Lagrange multipliers $u(i)$ to enforce the constraints $y(i) = 1$ for $i \notin \mathcal{C}$. Our goal will be to find a small set of constraints $\mathcal{C}$, such that Lagrangian relaxation will successfully recover an optimal solution. We will do this by incrementally adding elements to $\mathcal{C}$; that is, by incrementally adding constraints that tighten the relaxation.

The intuition behind our approach is as follows. Say we run the original algorithm, with the set $\mathcal{Y}'$, for several iterations, so that $L(u)$ is close to convergence (i.e., $L(u)$ is close to its minimal value). However, assume that we have not yet generated a solution y^t such that $y^t(i) = 1$ for all i. In this case we have some evidence that the relaxation may not be tight, and that we need to add some constraints. The question is, which constraints to add? To answer this question, we run the subgradient algorithm for K more iterations (e.g., $K = 10$), and at each iteration track which constraints of the form $y(i) = 1$ are violated. We then choose $\mathcal{C}$ to be the G constraints (e.g., $G = 3$) that are violated most often during the K additional iterations, and are not adjacent to each other. We recursively call the algorithm, replacing $\mathcal{Y}'$ by $\mathcal{Y}'_{\mathcal{C}}$; the recursive call may then return an exact solution, or alternatively again add more constraints and make a recursive call.[4]

Figure 3 depicts the resulting algorithm. We initially make a call to the algorithm $Optimize(\mathcal{C}, u)$ with $\mathcal{C}$ equal to the empty set (i.e., no hard constraints), and with $u(i) = 0$ for all i. In an initial phase the algorithm runs subgradient steps, while the dual is still improving. In a second step, if a solution has not been found, the algorithm runs for K more iterations, thereby choosing G additional constraints, then recursing.

If at any stage the algorithm finds a solution y^* such that $y^*(i) = 1$ for all i, then this is the solution to our original problem, $\arg\max_{y \in \mathcal{Y}} f(y)$. This follows because for any $\mathcal{C} \subseteq \{1 \ldots N\}$ we have $\mathcal{Y} \subseteq \mathcal{Y}'_{\mathcal{C}}$; hence the theorems in section 4.3 go through for $\mathcal{Y}'_{\mathcal{C}}$ in place of $\mathcal{Y}'$, with trivial modifications. Note also that the algorithm is guaranteed to eventually find the optimal solution, because eventually $\mathcal{C} = \{1 \ldots N\}$, and $\mathcal{Y} = \mathcal{Y}'_{\mathcal{C}}$.

[4] Formal justification for the method comes from the relationship between Lagrangian relaxation and linear programming relaxations. In cases where the relaxation is not tight, the subgradient method will essentially move between solutions whose convex combination form a fractional solution to an underlying LP relaxation (Nedić and Ozdaglar, 2009). Our method eliminates the fractional solution through the introduction of hard constraints.

# iter.	1-10 words	11-20 words	21-30 words	31-40 words	41-50 words	All sentences

7-9	0 (0.0 %)	0 (0.0 %)	7 (1.2 %)	13 (3.7 %)	12 (7.1 %)	32 (1.8 %)	99.7 %
x	0 (0.0 %)	0 (0.0 %)	0 (0.0 %)	1 (0.3 %)	5 (3.0 %)	6 (0.3 %)	100.0 %

Table 2: Table showing the number of constraints added before convergence of the algorithm in Figure 3, broken down by sentence length. Note that a maximum of 3 constraints are added at each recursive call, but that fewer than 3 constraints are added in cases where fewer than 3 constraints have $count(i) > 0$. x indicates the sentences that fail to converge after 250 iterations. 78.7% of the examples converge without adding any constraints.

The remaining question concerns the "dual still improving" condition; i.e., how to determine that the first phase of the algorithm should terminate. We do this by recording the first and second best dual values $L(u')$ and $L(u'')$ in the sequence of Lagrange multipliers $u^1, u^2, \ldots$ generated by the algorithm. Suppose that $L(u'')$ first occurs at iteration t''. If $\frac{L(u')-L(u'')}{t-t''} < \epsilon$, we say that the dual value does not decrease enough. The value for ϵ is a parameter of the approach: in experiments we used $\epsilon = 0.002$.

See the supplementary material for this submission for an example run of the algorithm.

When $\mathcal{C} \neq \emptyset$, A* search can be used for decoding, with the dynamic program for $\mathcal{Y}'$ providing admissible estimates for the dynamic program for $\mathcal{Y}'_{\mathcal{C}}$. Experiments show that A* gives significant improvements in efficiency. The supplementary material contains a full description of the A* algorithm.

6 Experiments

In this section, we present experimental results to demonstrate the efficiency of the decoding algorithm. We compare to MOSES (Koehn et al., 2007), a phrase-based decoder using beam search, and to a general purpose integer linear programming (ILP) solver, which solves the problem exactly.

The experiments focus on translation from German to English, using the Europarl data (Koehn, 2005). We tested on 1,824 sentences of length at most 50 words. The experiments use the algorithm shown in Figure 3. We limit the algorithm to a maximum of 250 iterations and a maximum of 9 hard constraints. The distortion limit d is set to be four, and we prune the phrase translation table to have 10 English phrases per German phrase.

Our method finds exact solutions on 1,818 out of 1,824 sentences (99.67%). (6 examples do not converge within 250 iterations.) Table 1 shows the number of iterations required for convergence, and Table 2 shows the number of constraints required for convergence, broken down by sentence length. In 1,436/1,818 (78.7%) sentences, the method converges without adding hard constraints to tighten the relaxation. For sentences with 1-10 words, the vast majority (183 out of 185 examples) converge with 0 constraints added. As sentences get longer, more constraints are often required. However most examples converge with 9 or fewer constraints.

Table 3 shows the average times for decoding, broken down by sentence length, and by the number of constraints that are added. As expected, decoding times increase as the length of sentences, and the number of constraints required, increase. The average run time across all sentences is 120.9 seconds. Table 3 also shows the run time of the method without the A* algorithm for decoding. The A* algorithm gives significant reductions in runtime.

Table 3: The average time (in seconds) for decoding using the algorithm in Figure 3, with and without A* algorithm, broken down by sentence length and the number of constraints that are added. A* indicates speeding up using A* search; w/o denotes without using A*.

method		ILP		LP		
set	length	mean	median	mean	median	% frac.
$\mathcal{Y}''$	1-10	275.2	132.9	10.9	4.4	12.4 %
	11-15	2,707.8	1,138.5	177.4	66.1	40.8 %
	16-20	20,583.1	3,692.6	1,374.6	637.0	59.7 %
$\mathcal{Y}'$	1-10	257.2	157.7	18.4	8.9	1.1 %
	11-15	3607.3	1838.7	476.8	161.1	3.0 %

Table 4: Average and median time of the LP/ILP solver (in seconds). % frac. indicates how often the LP gives a fractional answer. $\mathcal{Y}'$ indicates the dynamic program using set $\mathcal{Y}'$ as defined in Section 4.1, and $\mathcal{Y}''$ indicates the dynamic program using states (w_1, w_2, n, r). The statistics for ILP for length 16-20 are based on 50 sentences.

6.1 Comparison to an LP/ILP solver

To compare to a linear programming (LP) or integer linear programming (ILP) solver, we can implement the dynamic program (search over the set $\mathcal{Y}'$) through linear constraints, with a linear objective. The $y(i) = 1$ constraints are also linear. Hence we can encode our relaxation within an LP or ILP. Having done this, we tested the resulting LP or ILP using Gurobi, a high-performance commercial grade solver. We also compare to an LP or ILP where the dynamic program makes use of states (w_1, w_2, n, r)—i.e., the span (l, m) is dropped, making the dynamic program smaller. Table 4 shows the average time taken by the LP/ILP solver. Both the LP and the ILP require very long running times on these shorter sentences, and running times on longer sentences are prohibitive. Our algorithm is more efficient because it leverages the structure of the problem, by directly using a combinatorial algorithm (dynamic programming).

6.2 Comparison to MOSES

We now describe comparisons to the phrase-based decoder implemented in MOSES. MOSES uses beam search to find approximate solutions.

The distortion limit described in section 3 is the same as that in Koehn et al. (2003), and is the same as that described in the user manual for MOSES (Koehn et al., 2007). However, a complicating factor for our comparisons is that MOSES uses an additional distortion constraint, not documented in the manual, which we describe here.[5] We call this constraint the *gap constraint*. We will show in experiments that without the gap constraint, MOSES fails to produce translations on many examples. In our experiments we will compare to MOSES both with and without the gap constraint (in the latter case, we discard examples where MOSES fails).

We now describe the gap constraint. For a sequence of phrases $p_1, \ldots, p_k$ define $\theta(p_1 \ldots p_k)$ to be the index of the left-most source-language word not translated in this sequence. For example, if the bit-string for $p_1 \ldots p_k$ is 111001101000, then $\theta(p_1 \ldots p_k) = 4$. A sequence of phrases $p_1 \ldots p_L$ satisfies the gap constraint if and only if for $k = 2 \ldots L$, $|t(p_k) + 1 - \theta(p_1 \ldots p_k)| \leq d$, where d is the distortion limit. We will call MOSES without this restriction MOSES-nogc, and MOSES with this restriction MOSES-gc.

Results for MOSES-nogc Table 5 shows the number of examples where MOSES-nogc fails to give a translation, and the number of search errors for those cases where it does give a translation, for a range of beam sizes. A search error is defined as a case where our algorithm produces an exact solution that has higher score than the output from MOSES-nogc. The number of search errors is significant, even for large beam sizes.

[5] Personal communication from Philipp Koehn; see also the software for MOSES.

Beam size	Fails	# search errors	percentage
100	650/1,818	214/1,168	18.32 %
200	531/1,818	207/1,287	16.08 %
1000	342/1,818	115/1,476	7.79 %
10000	169/1,818	68/1,649	4.12 %

Table 5: Table showing the number of examples where MOSES-nogc fails to give a translation, and the number/percentage of search errors for cases where it does give a translation.

Diff.	MOSES-gc s =100	MOSES-gc s =200	MOSES-nogc s=1000
0.000 – 0.125	66 (24.26%)	65 (24.07%)	32 (27.83%)
0.125 – 0.250	59 (21.69%)	58 (21.48%)	25 (21.74%)
0.250 – 0.500	65 (23.90%)	65 (24.07%)	25 (21.74%)
0.500 – 1.000	49 (18.01%)	49 (18.15%)	23 (20.00%)
1.000 – 2.000	31 (11.40%)	31 (11.48%)	5 (4.35%)
2.000 – 4.000	2 (0.74%)	2 (0.74%)	3 (2.61%)
4.000 –13.000	0 (0.00%)	0 (0.00%)	2 (1.74%)

Table 6: Table showing statistics for the difference between the translation score from MOSES, and from the optimal derivation, for those sentences where a search error is made. For MOSES-gc we include cases where the translation produced by our system is not reachable by MOSES-gc. The average score of the optimal derivations is -23.4.

Results for MOSES-gc MOSES-gc uses the gap constraint, and thus in some cases our decoder will produce derivations which MOSES-gc cannot reach. Among the 1,818 sentences where we produce a solution, there are 270 such derivations. For the remaining 1,548 sentences, MOSES-gc makes search errors on 2 sentences (0.13%) when the beam size is 100, and no search errors when the beam size is 200, 1,000, or 10,000.

Table 6 shows statistics for the magnitude of the search errors that MOSES-gc and MOSES-nogc make.

BLEU Scores Finally, table 7 gives BLEU scores (Papineni et al., 2002) for decoding using MOSES and our method. The BLEU scores under the two decoders are almost identical; hence while MOSES makes a significant proportion of search errors, these search errors appear to be benign in terms of their impact on BLEU scores, at least for this particular translation model. Future work should investigate why this is the case, and whether this applies to other models and language pairs.

7 Conclusions

We have described an exact decoding algorithm for phrase-based translation models, using Lagrangian relaxation. The algorithmic construction we have described may also be useful in other areas of NLP, for example natural language generation. Possible extensions to the approach include methods that incorporate the Lagrangian relaxation formulation within learning algorithms for statistical MT: we see this as an interesting avenue for future research.

type of Moses	beam size	# sents	Moses	our method
MOSES-gc	100	1,818	24.4773	24.5395
	200	1,818	24.4765	24.5395
	1,000	1,818	24.4765	24.5395
	10,000	1,818	24.4765	24.5395

	200	1,287	27.0591	26.9907
	1,000	1,476	26.5734	26.6128
	10,000	1,649	25.6531	25.6620

Table 7: BLEU score comparisons. We consider only those sentences where both decoders produce a translation.

A Step Size

Similar to Koo et al. (2010), we set the step size at the t'th iteration to be $\alpha^t = 1/(1 + \lambda^t)$, where λ^t is the number of times that $L(u^{(t')}) > L(u^{(t'-1)})$ for all $t' \leq t$. Thus the step size decreases each time the dual value increases from one iteration to the next.

Abstract

Minimum error rate training is a crucial component to many state-of-the-art NLP applications, such as machine translation and speech recognition. However, common evaluation functions such as BLEU or word error rate are generally highly non-convex and thus prone to search errors. In this paper, we present LP-MERT, an exact search algorithm for minimum error rate training that reaches the global optimum using a series of reductions to linear programming. Given a set of N-best lists produced from S input sentences, this algorithm finds a linear model that is globally optimal with respect to this set. We find that this algorithm is polynomial in N and in the size of the model, but exponential in S. We present extensions of this work that let us scale to reasonably large tuning sets (e.g., one thousand sentences), by either searching only promising regions of the parameter space, or by using a variant of LP-MERT that relies on a beam-search approximation. Experimental results show improvements over the standard Och algorithm.

1 Introduction

Minimum error rate training (MERT)—also known as direct loss minimization in machine learning—is a crucial component in many complex natural language applications such as speech recognition (Chou et al., 1993; Stolcke et al., 1997; Juang et al., 1997), statistical machine translation (Och, 2003; Smith and Eisner, 2006; Duh and Kirchhoff, 2008; Chiang et al., 2008), dependency parsing (McDonald et al., 2005), summarization (McDonald, 2006), and phonetic alignment (McAllester et al., 2010). MERT directly optimizes the evaluation metric under which systems are being evaluated, yielding superior performance (Och, 2003) when compared to a likelihood-based discriminative method (Och and Ney, 2002). In complex text generation tasks like SMT, the ability to optimize BLEU (Papineni et al., 2001), TER (Snover et al., 2006), and other evaluation metrics is critical, since these metrics measure qualities (such as fluency and adequacy) that often do not correlate well with task-agnostic loss functions such as log-loss.

While competitive in practice, MERT faces several challenges, the most significant of which is search. The unsmoothed error count is a highly non-convex objective function and therefore difficult to optimize directly; prior work offers no algorithm with a good approximation guarantee. While much of the earlier work in MERT (Chou et al., 1993; Juang et al., 1997) relies on standard convex optimization techniques applied to non-convex problems, the Och algorithm (Och, 2003) represents a significant advance for MERT since it applies a series of special line minimizations that happen to be exhaustive and efficient. Since this algorithm remains inexact in the multidimensional case, much of the recent work on MERT has focused on extending Och's algorithm to find better search directions and starting points (Cer et al., 2008; Moore and Quirk, 2008), and on experimenting with other derivative-free methods such as the Nelder-Mead simplex algorithm (Nelder and Mead, 1965; Zens et al., 2007; Zhao and Chen, 2009).

In this paper, we present LP-MERT, an exact search algorithm for N-best optimization that exploits general assumptions commonly made with MERT, e.g., that the error metric is decomposable by sentence.[1] While there is no known optimal algo-

[1] Note that MERT makes two types of approximations. First, the set of all possible outputs is represented only approximately, by N-best lists, lattices, or hypergraphs. Second, error functions on such representations are non-convex and previous work only offers approximate techniques to optimize them. Our work avoids the second approximation, while the first one is unavoidable when optimization and decoding occur in distinct steps.

rithm to optimize general non-convex functions, the unsmoothed error surface has a special property that enables exact search: the set of translations produced by an SMT system for a given input is finite, so the piecewise-constant error surface contains only a *finite* number of constant regions. As in Och (2003), one could imagine exhaustively enumerating all constant regions and finally return the best scoring one—Och does this efficiently with each one-dimensional search—but the idea doesn't quite scale when searching all dimensions at once. Instead, LP-MERT exploits algorithmic devices such as lazy enumeration, divide-and-conquer, and linear programming to efficiently discard partial solutions that cannot be maximized by any linear model. Our experiments with thousands of searches show that LP-MERT is never worse than the Och algorithm, which provides strong evidence that our algorithm is indeed exact. In the appendix, we formally prove that this search algorithm is optimal. We show that this algorithm is polynomial in N and in the size of the model, but exponential in the number of tuning sentences. To handle reasonably large tuning sets, we present two modifications of LP-MERT that either search only promising regions of the parameter space, or that rely on a beam-search approximation. The latter modification copes with tuning sets of one thousand sentences or more, and outperforms the Och algorithm on a WMT 2010 evaluation task.

This paper makes the following contributions. To our knowledge, it is the first known exact search algorithm for optimizing task loss on N-best lists in general dimensions. We also present an approximate version of LP-MERT that offers a natural means of trading speed for accuracy, as we are guaranteed to eventually find the global optimum as we gradually increase beam size. This trade-off may be beneficial in commercial settings and in large-scale evaluations like the NIST evaluation, i.e., when one has a stable system and is willing to let MERT run for days or weeks to get the best possible accuracy. We think this work would also be useful as we turn to more human involvement in training (Zaidan and Callison-Burch, 2009), as MERT in this case is intrinsically slow.

2 Unidimensional MERT

Let $\mathbf{f}_1^S = \mathbf{f}_1 \dots \mathbf{f}_S$ denote the S input sentences of our tuning set. For each sentence $\mathbf{f}_s$, let $\mathbf{C}_s = \mathbf{e}_{s,1} \dots \mathbf{e}_{s,N}$ denote a set of N candidate translations. For simplicity and without loss of generality, we assume that N is constant for each index s. Each input and output sentence pair $(\mathbf{f}_s, \mathbf{e}_{s,n})$ is weighted by a linear model that combines model parameters $\mathbf{w} = w_1 \dots w_D \in \mathbb{R}^D$ with D feature functions $h_1(\mathbf{f}, \mathbf{e}, \sim) \dots h_D(\mathbf{f}, \mathbf{e}, \sim)$, where $\sim$ is the hidden state associated with the derivation from $\mathbf{f}$ to $\mathbf{e}$, such as phrase segmentation and alignment. Furthermore, let $\mathbf{h}_{s,n} \in \mathbb{R}^D$ denote the feature vector representing the translation pair $(\mathbf{f}_s, \mathbf{e}_{s,n})$.

In MERT, the goal is to minimize an error count $E(\mathbf{r}, \mathbf{e})$ by scoring translation hypotheses against a set of reference translations $\mathbf{r}_1^S = \mathbf{r}_1 \dots \mathbf{r}_S$. Assuming as in Och (2003) that error count is additively decomposable by sentence—i.e., $E(\mathbf{r}_1^S, \mathbf{e}_1^S) = \sum_s E(\mathbf{r}_s, \mathbf{e}_s)$—this results in the following optimization problem:[2]

$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w}} \left\{ \sum_{s=1}^{S} E(\mathbf{r}_s, \hat{\mathbf{e}}(\mathbf{f}_s; \mathbf{w})) \right\}$$
$$= \arg\min_{\mathbf{w}} \left\{ \sum_{s=1}^{S} \sum_{n=1}^{N} E(\mathbf{r}_s, \mathbf{e}_{s,n}) \delta(\mathbf{e}_{s,n}, \hat{\mathbf{e}}(\mathbf{f}_s; \mathbf{w})) \right\} \quad (1)$$

where

$$\hat{\mathbf{e}}(\mathbf{f}_s; \mathbf{w}) = \arg\max_{n \in \{1 \dots N\}} \left\{ \mathbf{w}^\intercal \mathbf{h}_{s,n} \right\}$$

The quality of this approximation is dependent on how accurately the N-best lists represent the search space of the system. Therefore, the hypothesis list is iteratively grown: decoding with an initial parameter vector seeds the N-best lists; next, parameter estimation and N-best list gathering alternate until the search space is deemed representative.

The crucial observation of Och (2003) is that the error count along any line is a piecewise constant function. Furthermore, this function for a single sentence may be computed efficiently by first finding the hypotheses that form the upper envelope of the model score function, then gathering the error count for each hypothesis along the range for which it is optimal. Error counts for the whole corpus are simply the sums of these piecewise constant functions, leading to an

[2] A metric such as TER is decomposable by sentence. BLEU is not, but its sufficient statistics are, and the literature offers several sentence-level approximations of BLEU (Lin and Och, 2004; Liang et al., 2006).

efficient algorithm for finding the global optimum of the error count along any single direction.

Such a hill-climbing algorithm in a non-convex space has no optimality guarantee: without a perfect direction finder, even a globally-exact line search may never encounter the global optimum. Coordinate ascent is often effective, though conjugate direction set finding algorithms, such as Powell's method (Powell, 1964; Press et al., 2007), or even random directions may produce better results (Cer et al., 2008). Random restarts, based on either uniform sampling or a random walk (Moore and Quirk, 2008), increase the likelihood of finding a good solution. Since random restarts and random walks lead to better solutions and faster convergence, we incorporate them into our baseline system, which we refer to as 1D-MERT.

3 Multidimensional MERT

Finding the global optimum of Eq. 1 is a difficult task, so we proceed in steps and first analyze the case where the tuning set contains only one sentence. This gives insight on how to solve the general case. With only one sentence, one of the two summations in Eq. 1 vanishes and one can exhaustively enumerate the N translations $\mathbf{e}_{1,n}$ (or $\mathbf{e}_n$ for short) to find the one that yields the minimal task loss. The only difficulty with $S = 1$ is to know for each translation $\mathbf{e}_n$ whether its feature vector $\mathbf{h}_{1,n}$ (or $\mathbf{h}_n$ for short) can be maximized using any linear model. As we can see in Fig. 1(a), some hypotheses can be maximized (e.g., $\mathbf{h}_1$, $\mathbf{h}_2$, and $\mathbf{h}_4$), while others (e.g., $\mathbf{h}_3$ and $\mathbf{h}_5$) cannot. In geometric terminology, the former points are commonly called *extreme* points, and the latter are *interior* points.[3] The problem of exactly optimizing a single N-best list is closely related to the convex hull problem in computational geometry, for which generic solvers such as the QuickHull algorithm exist (Eddy, 1977; Bykat, 1978; Barber et al., 1996). A first approach would be to construct the convex hull $conv(\mathbf{h}_1 \dots \mathbf{h}_N)$ of the N-best list, then identify the point on the hull with lowest loss ($\mathbf{h}_1$ in Fig. 1) and finally compute an optimal weight vector using hull points that share common facets with the optimal feature vector ($\mathbf{h}_2$ and $\mathbf{h}_4$). Unfortunately, this doesn't quite scale even with a single N-best list, since the best known convex hull algorithm runs in $O(N^{\lfloor D/2 \rfloor + 1})$ time (Barber et al., 1996).[4]

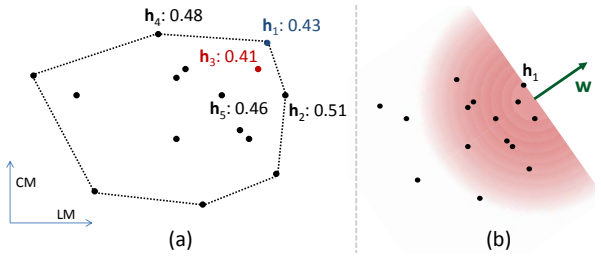

Figure 1: N-best list $(\mathbf{h}_1 \dots \mathbf{h}_N)$ with associated losses (here, TER scores) for a single input sentence, whose convex hull is displayed with dotted lines in (a). For effective visualization, our plots use only two features ($D = 2$). While we can find a weight vector that maximizes $\mathbf{h}_1$ (e.g., the $\mathbf{w}$ in (b)), no linear model can possibly maximize any of the points strictly inside the convex hull.

Algorithms presented in this paper assume that D is unrestricted, therefore we cannot afford to build any convex hull explicitly. Thus, we turn to linear programming (LP), for which we know algorithms (Karmarkar, 1984) that are polynomial in the number of dimensions and linear in the number of points, i.e., $O(NT)$, where $T = D^{3.5}$. To check if point $\mathbf{h}_i$ is extreme, we really only need to know whether we can define a half-space containing all points $\mathbf{h}_1 \dots \mathbf{h}_N$, with $\mathbf{h}_i$ lying on the hyperplane delimiting that half-space, as shown in Fig. 1(b) for $\mathbf{h}_1$. Formally, a vertex $\mathbf{h}_i$ is optimal with respect to $\arg\max_i\{\mathbf{w}^\intercal \mathbf{h}_i\}$ if and only if the following constraints hold:[5]

$$\mathbf{w}^\intercal \mathbf{h}_i = y \quad (2)$$

$$\mathbf{w}^\intercal \mathbf{h}_j \leq y, \text{ for each } j \neq i \quad (3)$$

$\mathbf{w}$ is orthogonal to the hyperplane defining the half-space, and the intercept y defines its position. The

[3] Specifically, a point $\mathbf{h}$ is extreme with respect to a convex set C (e.g., the convex hull shown in Fig. 1(a)) if it does not lie in an open line segment joining any two points of C. In a minor abuse of terminology, we sometimes simply state that a given point $\mathbf{h}$ is extreme when the nature of C is clear from context.

[4] A convex hull algorithm polynomial in D is very unlikely. Indeed, the expected number of facets of high-dimensional convex hulls grows dramatically, and—assuming a uniform distribution of points, $D = 10$, and a sufficiently large N—the expected number of facets is approximately $10^6 N$ (Buchta et al., 1985). In the worst case, the maximum number of facets of a convex hull is $O(N^{\lfloor D/2 \rfloor}/\lfloor D/2 \rfloor!)$ (Klee, 1966).

[5] A similar approach for checking whether a given point is extreme is presented in `http://www.ifor.math.ethz.ch/~fukuda/polyfaq/node22.html`, but our method generates slightly smaller LPs.

above equations represent a linear program (LP), which can be turned into canonical form

$$\begin{aligned} &\text{maximize} && \mathbf{c}^\intercal \mathbf{w} \\ &\text{subject to} && \mathbf{A}\mathbf{w} \leq \mathbf{b} \end{aligned}$$

by substituting y with $\mathbf{w}^\intercal \mathbf{h}_i$ in Eq. 3, by defining $\mathbf{A} = \{a_{n,d}\}_{1 \leq n \leq N; 1 \leq d \leq D}$ with $a_{n,d} = h_{j,d} - h_{i,d}$ (where $h_{j,d}$ is the d-th element of $\mathbf{h}_j$), and by setting $\mathbf{b} = (0, \ldots, 0)^\intercal = \mathbf{0}$. The vertex $\mathbf{h}_i$ is extreme if and only if the LP solver finds a non-zero vector $\mathbf{w}$ satisfying the canonical system. To ensure that $\mathbf{w}$ is zero only when $\mathbf{h}_i$ is interior, we set $\mathbf{c} = \mathbf{h}_i - \mathbf{h}_\mu$, where $\mathbf{h}_\mu$ is a point known to be inside the hull (e.g., the centroid of the N-best list).[6] In the remaining of this section, we use this LP formulation in function LINOPTIMIZER($\mathbf{h}_i; \mathbf{h}_1 \ldots \mathbf{h}_N$), which returns the weight vector $\hat{\mathbf{w}}$ maximizing $\mathbf{h}_i$, or which returns $\mathbf{0}$ if $\mathbf{h}_i$ is interior to $conv(\mathbf{h}_1 \ldots \mathbf{h}_N)$. We also use $conv(\mathbf{h}_i; \mathbf{h}_1 \ldots \mathbf{h}_N)$ to denote whether $\mathbf{h}_i$ is extreme with respect to this hull.

Algorithm 1: LP-MERT (for $S = 1$).

input : sent.-level feature vectors $H = \{\mathbf{h}_1 \ldots \mathbf{h}_N\}$
input : sent.-level task losses $E_1 \ldots E_N$, where $E_n := E(\mathbf{r}_1, \mathbf{e}_{1,n})$
output : optimal weight vector $\hat{\mathbf{w}}$

```
1 begin
    ▷ sort N-best list by increasing losses:
2   (i_1 ... i_N) ← IndexSort(E_1 ... E_N)
3   for n ← 1 to N do
      ▷ find ŵ maximizing i_n-th element:
4     ŵ ← LinOptimizer(h_{i_n}; H)
5     if ŵ ≠ 0 then
6       return ŵ
7   return 0
```

An exact search algorithm for optimizing a single N-best list is shown above. It lazily enumerates feature vectors in increasing order of task loss, keeping only the extreme ones. Such a vertex $\mathbf{h}_j$ is known to be on the convex hull, and the returned vector $\hat{\mathbf{w}}$ maximizes it. In Fig. 1, it would first run LINOPTIMIZER on $\mathbf{h}_3$, discard it since it is interior, and finally accept the extreme point $\mathbf{h}_1$. Each execution of LINOPTIMIZER requires $O(NT)$ time with the interior point method of (Karmarkar, 1984), and since the main loop may run $O(N)$ times in the worst case, time complexity is $O(N^2T)$. Finally, Fig. 2 empirically demonstrates the effectiveness of a linear programming approach, which in practice is seldom affected by D.

[6] We assume that $\mathbf{h}_1 \ldots \mathbf{h}_N$ are not degenerate, i.e., that they collectively span $\mathbb{R}^D$. Otherwise, all points are necessarily on the hull, yet some of them may not be uniquely maximized.

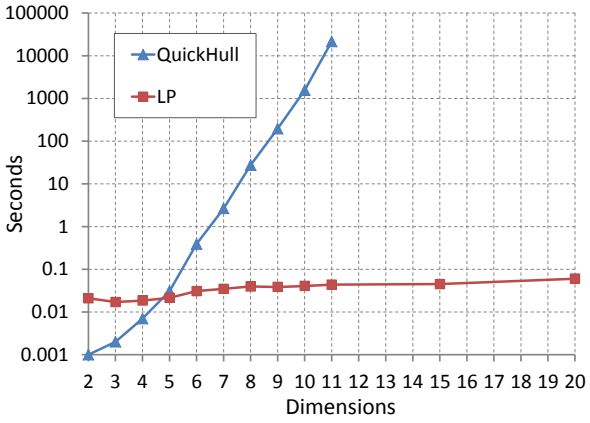

Figure 2: Running times to exactly optimize N-best lists with an increasing number of dimensions. To determine which feature vectors were on the hull, we use either linear programming (Karmarkar, 1984) or one of the most efficient convex hull computation tools (Barber et al., 1996).

3.1 Exact search: general case

We now extend LP-MERT to the general case, in which we are optimizing multiple sentences at once. This creates an intricate optimization problem, since the inner summations over $n = 1 \ldots N$ in Eq. 1 can't be optimized independently. For instance, the optimal weight vector for sentence $s = 1$ may be suboptimal with respect to sentence $s = 2$. So we need some means to determine whether a selection $\mathbf{m} = m(1) \ldots m(S) \in \mathcal{M} = [1, N]^S$ of feature vectors $\mathbf{h}_{1,m(1)} \ldots \mathbf{h}_{S,m(S)}$ is extreme, that is, whether we can find a weight vector that maximizes each $\mathbf{h}_{s,m(s)}$. Here is a reformulation of Eq. 1 that makes this condition on extremity more explicit:

$$\hat{\mathbf{m}} = \underset{\substack{conv(\mathbf{h}[\mathbf{m}]; H) \\ \mathbf{m} \in \mathcal{M}}}{\arg\min} \left\{ \sum_{s=1}^{S} E(\mathbf{r}_s, \mathbf{e}_{s,m(n)}) \right\} \qquad (4)$$

where

$$\mathbf{h}[\mathbf{m}] = \sum_{s=1}^{S} \mathbf{h}_{s,m(s)}$$

$$H = \bigcup_{\mathbf{m}' \in \mathcal{M}} \mathbf{h}[\mathbf{m}']$$

One naïve approach to address this optimization problem is to enumerate all possible combinations among the S distinct N-best lists, determine for each combination $\mathbf{m}$ whether $\mathbf{h}[\mathbf{m}]$ is extreme, and return the extreme combination with lowest total loss. It is evident that this approach is optimal (since it follows directly from Eq. 4), but it is prohibitively slow since it processes $O(N^S)$ vertices to determine whether they are extreme, which thus requires $O(N^S T)$ time per LP optimization and $O(N^{2S} T)$ time in total. We now present several improvements to make this approach more practical.

3.1.1 Sparse hypothesis combination

In the naïve approach presented above, each LP computation to evaluate $conv(\mathbf{h}[\mathbf{m}]; H)$ requires $O(N^S T)$ time since H contains N^S vertices, but we show here how to reduce it to $O(NST)$ time. This improvement exploits the fact that we can eliminate the majority of the N^S points of H, since only $S(N-1)+1$ are really needed to determine whether $\mathbf{h}[\mathbf{m}]$ is extreme. This is best illustrated using an example, as shown in Fig. 3. Both $\mathbf{h}_{1,1}$ and $\mathbf{h}_{2,1}$ in (a) and (b) are extreme with respect to their own N-best list, and we ask whether we can find a weight vector that maximizes both $\mathbf{h}_{1,1}$ and $\mathbf{h}_{2,1}$. The algorithmic trick is to geometrically translate one of the two N-best lists so that $\mathbf{h}_{1,1} = \mathbf{h}'_{2,1}$, where $\mathbf{h}'_{2,1}$ is the translation of $\mathbf{h}'_{2,1}$. Then we use linear programming with the new set of $2N-1$ points, as shown in (c), to determine whether $\mathbf{h}_{1,1}$ is on the hull, in which case the answer to the original question is yes. In the case of the combination of $\mathbf{h}_{1,1}$ and $\mathbf{h}_{2,2}$, we see in (d) that the combined set of points prevents the maximization $\mathbf{h}_{1,1}$, since this point is clearly no longer on the hull. Hence, the combination ($\mathbf{h}_{1,1}$,$\mathbf{h}_{2,2}$) cannot be maximized using any linear model. This trick generalizes to $S \geq 2$. In both (c) and (d), we used $S(N-1)+1$ points instead of N^S to determine whether a given point is extreme. We show in the appendix that this simplification does not sacrifice optimality.

3.1.2 Lazy enumeration, divide-and-conquer

Now that we can determine whether a given combination is extreme, we must next enumerate candidate combinations to find the combination that has lowest task loss among all of those that are extreme. Since the number of feature vector combinations is $O(N^S)$, exhaustive enumeration is not a reasonable

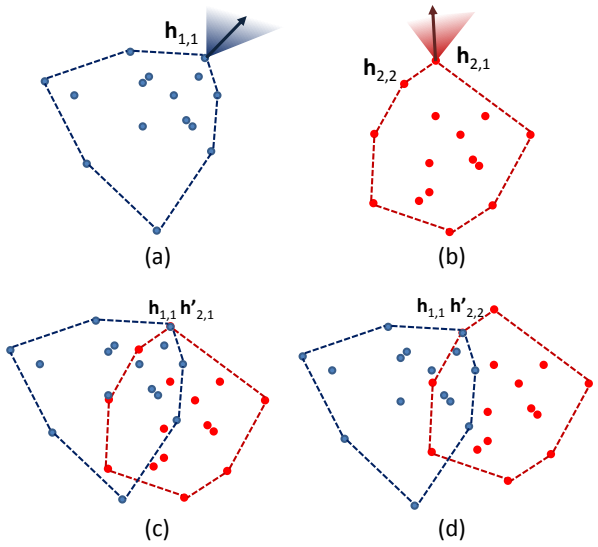

Figure 3: Given two N-best lists, (a) and (b), we use linear programming to determine which hypothesis combinations are extreme. For instance, the combination $\mathbf{h}_{1,1}$ and $\mathbf{h}_{2,1}$ is extreme (c), while $\mathbf{h}_{1,1}$ and $\mathbf{h}_{2,2}$ is not (d).

option. Instead, we use lazy enumeration to process combinations in increasing order of task loss, which ensures that the first extreme combination for $s = 1 \ldots S$ that we encounter is the optimal one. An S-ary lazy enumeration would not be particularly efficient, since the runtime is still $O(N^S)$ in the worst case. LP-MERT instead uses divide-and-conquer and binary lazy enumeration, which enables us to discard early on combinations that are not extreme. For instance, if we find that ($\mathbf{h}_{1,1}$,$\mathbf{h}_{2,2}$) is interior for sentences $s = 1, 2$, the divide-and-conquer branch for $s = 1 \ldots 4$ never actually receives this bad combination from its left child, thus avoiding the cost of enumerating combinations that are known to be interior, e.g., ($\mathbf{h}_{1,1}$,$\mathbf{h}_{2,2}$, $\mathbf{h}_{3,1}$,$\mathbf{h}_{4,1}$).

The LP-MERT algorithm for the general case is shown as Algorithm 2. It basically only calls a recursive divide-and-conquer function (GETNEXTBEST) for sentence range $1 \ldots S$. The latter function uses binary lazy enumeration in a manner similar to (Huang and Chiang, 2005), and relies on two global variables: $\mathcal{I}$ and $\mathcal{L}$. The first of these, $\mathcal{I}$, is used to memoize the results of calls to GETNEXTBEST; given a range of sentences and a rank n, it stores the nth best combination for that range of sentences. The global variable $\mathcal{L}$ stores hypotheses combination matrices, one matrix for each range of sentences (s, t) as shown in

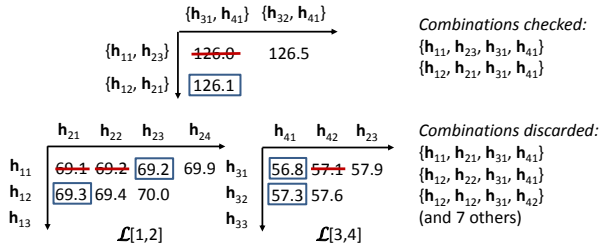

Figure 4: LP-MERT minimizes loss (TER) on four sentences. $O(N^4)$ translation combinations are possible, but the LP-MERT algorithm only tests two full combinations. Without divide-and-conquer—i.e., using 4-ary lazy enumeration—ten full combinations would have been checked unnecessarily.

Algorithm 2: LP-MERT

input : feature vectors $\mathbf{H} = \{\mathbf{h}_{s,n}\}_{1 \le s \le S; 1 \le n \le N}$
input : task losses $\mathbf{E} = \{E_{s,n}\}_{1 \le s \le S; 1 \le n \le N}$, where sent.-level costs $E_{s,n} := E(\mathbf{r}_s, \mathbf{e}_{s,n})$
output : optimal weight vector $\hat{\mathbf{w}}$ and its loss L

1 **begin**
  ▷ *sort N-best lists by increasing losses:*
2 **for** $s \leftarrow 1$ **to** S **do**
3 $(i_{s,1}..i_{s,N}) \leftarrow \text{IndexSort}(E_{s,1}..E_{s,N})$
  ▷ *find best hypothesis combination for* $1 \ldots S$*:*

5 $\hat{\mathbf{w}} \leftarrow \text{LinOptimizer}(\mathbf{h}_*; H_*)$
6 **return** $(\hat{\mathbf{w}}, L)$

Fig. 4, to determine which combination to try next. The function ExpandFrontier returns the indices of unvisited cells that are adjacent (right or down) to visited cells and that might correspond to the next best hypothesis. Once no more cells need to be added to the frontier, LP-MERT identifies the lowest loss combination on the frontier (BestInFrontier), and uses LP to determine whether it is extreme. To do so, it first generates an LP using Combine, a function that implements the method described in Fig. 3. If the LP offers no solution, this combination is ignored. LP-MERT iterates until it finds a cell entry whose combination is extreme. Regarding ranges of length one ($s = t$), lines 3-10 are similar to Algorithm 1 for $S = 1$, but with one difference: GetNextBest may be called multiple times with the same argument s, since the first output of GetNextBest might not be extreme when combined with other feature vectors. Lines 3-10 of GetNextBest handle this case efficiently, since the algorithm resumes at the $(n+1)$-th

Function GetNextBest($\mathbf{H}$,$\mathbf{E}$,s,t)

20 **for** $n' \leftarrow y + 1$ **to** n **do**
21 $\mathcal{I}[v, t, n'] \leftarrow \text{GetNextBest}(\mathbf{H}, \mathbf{E}, v, t)$
22 $\mathbf{L}[m, n] \leftarrow \text{Loss}(\mathcal{I}[s, u, m]) + \text{Loss}(\mathcal{I}[v, t, n])$
23 $(m, n) \leftarrow \text{BestInFrontier}(\mathbf{L})$
24 $(\mathbf{h}_m, H_m, L_m) \leftarrow \mathcal{I}[s, u, m]$
25 $(\mathbf{h}_n, H_n, L_n) \leftarrow \mathcal{I}[v, t, n]$
26 $(\mathbf{h}_*, H_*) \leftarrow \text{Combine}(\mathbf{h}_m, H_m, \mathbf{h}_n, H_n)$
27 $\hat{\mathbf{w}} \leftarrow \text{LinOptimizer}(\mathbf{h}_*; H_*)$
28 **until** $\hat{\mathbf{w}} \neq \mathbf{0}$
29 **return** $(\mathbf{h}_*, H_*, \mathbf{L}[m, n])$

element of the N-best list (where n is the position where the previous execution left off).[7] We can see that a strength of this algorithm is that inconsistent combinations are deleted as soon as possible, which allows us to discard fruitless candidates *en masse*.

3.2 Approximate Search

We will see in Section 5 that our exact algorithm is often too computationally expensive in practice to be used with either a large number of sentences or a large number of features. We now present two

[7] Each N-best list is augmented with a placeholder hypothesis with loss $+\infty$. This ensures n never runs out of bounds at line 7.

Function Combine($\mathbf{h}, H, \mathbf{h}', H'$)

input : H, H': constraint vertices
input : $\mathbf{h}, \mathbf{h}'$: extreme vertices, wrt. H and H'

  $H_i \leftarrow H_i + h'$
for $i \leftarrow 1$ **to** $size(H')$ **do**
  $H'_i \leftarrow H'_i + h$
return $(\mathbf{h} + \mathbf{h}', H \cup H')$

approaches to make LP-MERT more scalable, with the downside that we may allow search errors.

In the first case, we make the assumption that we have an initial weight vector $\mathbf{w}_0$ that is a reasonable approximation of $\hat{\mathbf{w}}$, where $\mathbf{w}_0$ may be obtained either by using a fast MERT algorithm like 1D-MERT, or by reusing the weight vector that is optimal with respect to the previous iteration of MERT. The idea then is to search only the set of weight vectors that satisfy $\cos(\hat{\mathbf{w}}, \mathbf{w}_0) \geq t$, where t is a threshold on cosine similarity provided by the user. The larger the t, the faster the search, but at the expense of more search errors. This is implemented with two simple changes in our algorithm. First, LINOPTIMIZER sets the objective vector $\mathbf{c} = \mathbf{w}_0$. Second, if the output $\hat{\mathbf{w}}$ originally returned by LINOPTIMIZER does not satisfy $\cos(\hat{\mathbf{w}}, \mathbf{w}_0) \geq t$, then it returns $\mathbf{0}$. While this modification of our algorithm may lead to search errors, it nevertheless provides some theoretical guarantee: our algorithm finds the global optimum if it lies within the region defined by $\cos(\hat{\mathbf{w}}, \mathbf{w}_0) \geq t$.

The second method is a beam approximation of LP-MERT, which normally deals with linear programs that are increasingly large in the upper branches of GETNEXTBEST's recursive calls. The main idea is to prune the output of COMBINE (line 26) by model score with respect to $\mathbf{w}_{best}$, where $\mathbf{w}_{best}$ is our current best model on the entire tuning set. Note that beam pruning can discard $\mathbf{h}_*$ (the current best extreme vertex), in which case LINOPTIMIZER returns $\mathbf{0}$. $\mathbf{w}_{best}$ is updated as follows: each time we produce a new non-zero $\hat{\mathbf{w}}$, run $\mathbf{w}_{best} \leftarrow \hat{\mathbf{w}}$ if $\hat{\mathbf{w}}$ has a lower loss than $\mathbf{w}_{best}$ on the entire tuning set. The idea of using a beam here is similar to using cosine similarity (since $\mathbf{w}_{best}$ constrains the search towards a promising region), but beam pruning also helps reduce LP optimization time and thus enables us to explore a wider space. Since $\mathbf{w}_{best}$ often improves during search, it is useful to run multiple iterations of LP-MERT until $\mathbf{w}_{best}$ doesn't change. Two or three iterations suffice in our experience. In our experiments, we use a beam size of 1000.

4 Experimental Setup

Our experiments in this paper focus on only the application of machine translation, though we believe that the current approach is agnostic to the particular system used to generate hypotheses. Both phrase-based systems (e.g., Koehn et al. (2007)) and syntax-based systems (e.g., Li et al. (2009), Quirk et al. (2005)) commonly use MERT to train free parameters. Our experiments use a syntax-directed translation approach (Quirk et al., 2005): it first applies a dependency parser to the source language data at both training and test time. Multi-word translation mappings constrained to be connected subgraphs of the source tree are extracted from the training data; these provide most lexical translations. Partially lexicalized templates capturing reordering and function word insertion and deletion are also extracted. At runtime, these mappings and templates are used to construct transduction rules to convert the source tree into a target string. The best transduction is sought using approximate search techniques (Chiang, 2007).

Each hypothesis is scored by a relatively standard set of features. The mappings contain five features: maximum-likelihood estimates of source given target and vice versa, lexical weighting estimates of source given target and vice versa, and a constant value that, when summed across a whole hypothesis, indicates the number of mappings used. For each template, we include a maximum-likelihood estimate of the target reordering given the source structure. The system may fall back to templates that mimic the source word order; the count of such templates is a feature. Likewise we include a feature to count the number of source words deleted by templates, and a feature to count the number of target words inserted by templates. The log probability of the target string according to a language models is also a feature; we add one such feature for each language model. We include the number of target words as features to balance hypothesis length.

For the present system, we use the training data of WMT 2010 to construct and evaluate an English-to-

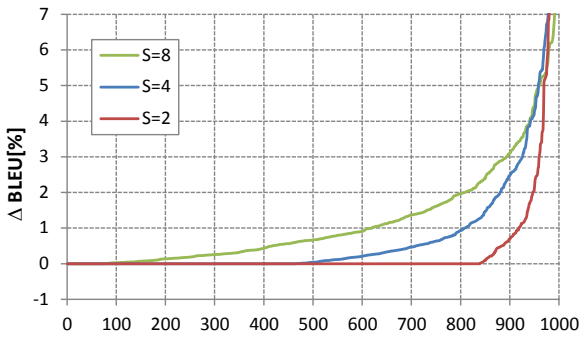

Figure 5: Line graph of sorted differences in BLEUn4r1[%] scores between LP-MERT and 1D-MERT on 1000 tuning sets of size $S = 2, 4, 8$. The highest differences for $S = 2, 4, 8$ are respectively 23.3, 19.7, 13.1.

German translation system. This consists of approximately 1.6 million parallel sentences, along with a much larger monolingual set of monolingual data. We train two language models, one on the target side of the training data (primarily parliamentary data), and the other on the provided monolingual data (primarily news). The 2009 test set is used as development data for MERT, and the 2010 one is used as test data. The resulting system has 13 distinct features.

5 Results

The section evaluates both the exact and beam version of LP-MERT. Unless mentioned otherwise, the number of features is $D = 13$ and the N-best list size is 100. Translation performance is measured with a sentence-level version of BLEU-4 (Lin and Och, 2004), using one reference translation. To enable legitimate comparisons, LP-MERT and 1D-MERT are evaluated on the *same* combined N-best lists, even though running multiple iterations of MERT with either LP-MERT or 1D-MERT would normally produce different combined N-best lists. We use WMT09 as tuning set, and WMT10 as test set. Before turning to large tuning sets, we first evaluate exact LP-MERT on data sizes that it can easily handle. Fig. 5 offers a comparison with 1D-MERT, for which we split the tuning set into 1,000 overlapping subsets for $S = 2, 4, 8$ on a combined N-best after five iterations of MERT with an average of 374 translation per sentence. The figure shows that LP-MERT never underperforms 1D-MERT in any of the 3,000 experiments, and this almost certainly confirms that

length	tested comb.	total comb.	order
8	639,960	1.33×10^{20}	$O(N^8)$
4	134,454	2.31×10^{10}	$O(2N^4)$
2	49,969	430,336	$O(4N^2)$
1	1,059	2,624	$O(8N)$

Table 1: Number of tested combinations for the experiments of Fig. 5. LP-MERT with $S = 8$ checks only 600K full combinations on average, much less than the total number of combinations (which is more than 10^{20}).

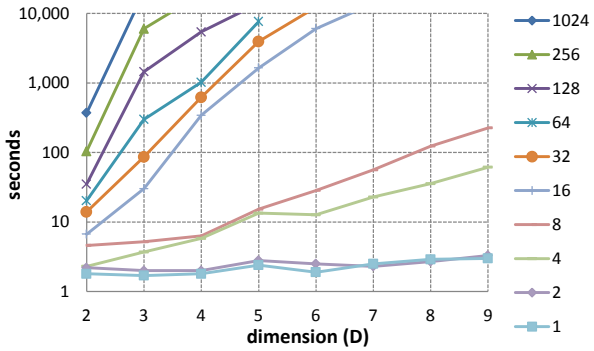

Figure 6: Effect of the number of features (runtime on 1 CPU of a modern computer). Each curve represents a different number of tuning sentences.

LP-MERT systematically finds the global optimum. In the case $S = 1$, Powell rarely makes search errors (about 15%), but the situation gets worse as S increases. For $S = 4$, it makes search errors in 90% of the cases, despite using 20 random starting points.

Some combination statistics for S up to 8 are shown in Tab. 1. The table shows the speedup provided by LP-MERT is very substantial when compared to exhaustive enumeration. Note that this is using $D = 13$, and that pruning is much more effective with less features, a fact that is confirmed in Fig. 6. $D = 13$ makes it hard to use a large tuning set, but the situation improves with $D = 2 \ldots 5$.

Fig. 7 displays execution times when LP-MERT constrains the output $\hat{\mathbf{w}}$ to satisfy $\cos(\mathbf{w_0}, \hat{\mathbf{w}}) \geq t$, where t is on the x-axis of the figure. The figure shows that we can scale to 1000 sentences when (exactly) searching within the region defined by $\cos(\mathbf{w_0}, \hat{\mathbf{w}}) \geq .84$. All these running times would improve using parallel computing, since divide-and-conquer algorithms are generally easy to parallelize.

We also evaluate the beam version of LP-MERT, which allows us to exploit tuning sets of reasonable

size. Results are displayed in Table 2. The gains are fairly substantial, with gains of 0.5 BLEU point or more in all cases where $S \leq 512$.[8] Finally, we perform an end-to-end MERT comparison, where both our algorithm and 1D-MERT are iteratively used to generate weights that in turn yield new N-best lists. Tuning on 1024 sentences of WMT10, LP-MERT converges after seven iterations, with a BLEU score of 16.21%; 1D-MERT converges after nine iterations, with a BLEU score of 15.97%. Test set performance on the full WMT10 test set for LP-MERT and 1D-MERT are respectively 17.08% and 16.91%.

6 Related Work

One-dimensional MERT has been very influential. It is now used in a broad range of systems, and has been improved in a number of ways. For instance, lattices or hypergraphs may be used in place of N-best lists to form a more comprehensive view of the search space with fewer decoding runs (Macherey et al., 2008; Kumar et al., 2009; Chatterjee and Cancedda, 2010). This particular refinement is orthogonal to our approach, though. We expect to extend LP-MERT to hypergraphs in future work. Exact search may be challenging due to the computational complexity of the search space (Leusch et al., 2008), but approximate search should be feasible.

Other research has explored alternate methods of gradient-free optimization, such as the downhill-simplex algorithm (Nelder and Mead, 1965; Zens et al., 2007; Zhao and Chen, 2009). Although the search space is different than that of Och's algorithm, it still relies on one-dimensional line searches to reflect, expand, or contract the simplex. Therefore, it suffers the same problems of one-dimensional MERT: feature sets with complex non-linear interactions are difficult to optimize. LP-MERT improves on these methods by searching over a larger subspace of parameter combinations, not just those on a single line.

We can also change the objective function in a number of ways to make it more amenable to optimization, leveraging knowledge from elsewhere in the machine learning community. Instance reweighting as in boosting may lead to better parameter inference (Duh and Kirchhoff, 2008). Smoothing the objective function may allow differentiation and standard ML learning techniques (Och and Ney, 2002). Smith and Eisner (2006) use a smoothed objective along with deterministic annealing in hopes of finding good directions and climbing past locally optimal points. Other papers use margin methods such as MIRA (Watanabe et al., 2007; Chiang et al., 2008), updated somewhat to match the MT domain, to perform incremental training of potentially large numbers of features. However, in each of these cases the objective function used for training no longer matches the final evaluation metric.

7 Conclusions

Our primary contribution is the first known exact search algorithm for direct loss minimization on N-best lists in multiple dimensions. Additionally, we present approximations that consistently outperform standard one-dimensional MERT on a competitive machine translation system. While Och's method of MERT is generally quite successful, there are cases where it does quite poorly. A more global search such as LP-MERT lowers the expected risk of such poor solutions. This is especially important for current machine translation systems that rely heavily on MERT, but may also be valuable for other textual ap-

[8] One interesting observation is that the performance of 1D-MERT degrades as S grows from 2 to 8 (Fig. 5), which contrasts with the results shown in Tab. 2. This may have to do with the fact that N-best lists with $S = 2$ have much fewer local maxima than with $S = 4, 8$, in which case 20 restarts is generally enough.

plications. Recent speech recognition systems have also explored combinations of more acoustic and language models, with discriminative training of 5-10 features rather than one million (Lööf et al., 2010); LP-MERT could be valuable here as well.

The one-dimensional algorithm of Och (2003) has been subject to study and refinement for nearly a decade, while this is the first study of multi-dimensional approaches. We demonstrate the potential of multi-dimensional approaches, but we believe there is much room for improvement in both scalability and speed. Furthermore, a natural line of research would be to extend LP-MERT to compact representations of the search space, such as hypergraphs.

There are a number of broader implications from this research. For instance, LP-MERT can aid in the evaluation of research on MERT. This approach supplies a truly optimal vector as ground truth, albeit under limited conditions such as a constrained direction set, a reduced number of features, or a smaller set of sentences. Methods can be evaluated based on not only improvements over prior approaches, but also based on progress toward a global optimum.

Appendix A: Proof of optimality

In this appendix, we prove that LP-MERT (Algorithm 2) is exact. As noted before, the naïve approach of solving Eq. 4 is to enumerate all $O(N^S)$ hypotheses combinations in $\mathcal{M}$, discard the ones that are not extreme, and return the best scoring one. LP-MERT relies on algorithmic improvements to speed up this approach, and we now show that none of them affect the optimality of the solution.

Divide-and-conquer. Divide-and-conquer in Algorithm 2 discards any partial hypothesis combination $\mathbf{h}[m(j)\dots m(k)]$ if it is not extreme, even before considering any extension $\mathbf{h}[m(i)\dots m(j)\dots m(k)\dots m(l)]$. This does not sacrifice optimality, since if $conv(\mathbf{h}; H)$ is false, then $conv(\mathbf{h}; H \cup G)$ is false for any set G.

Proof: Assume $conv(\mathbf{h}; H)$ is false, so $\mathbf{h}$ is interior to H. By definition, any interior point $\mathbf{h}$ can be written as a linear combination of other points: $\mathbf{h} = \sum_i \lambda_i \mathbf{h}_i$, with $\forall i(\mathbf{h}_i \in H, \mathbf{h}_i \neq \mathbf{h}, \lambda_i \geq 0)$ and $\sum_i \lambda_i = 1$. This same combination of points also demonstrates that $\mathbf{h}$ is interior to $H \cup G$, thus $conv(\mathbf{h}; H \cup G)$ is false as well.

Sparse hypothesis combination. We show here that the simplification of linear programs in Section 3.1.1 from size $O(N^S)$ to size $O(NS)$ does not change the value of $conv(\mathbf{h}; H)$. More specifically, this means that linear optimization of the output of the COMBINE method at lines 26-27 of function GETNEXTBEST does not introduce any error. Let $(\mathbf{g}_1 \dots \mathbf{g}_U)$ and $(\mathbf{h}_1 \dots \mathbf{h}_V)$ be two N-best lists to be combined, then:

$$conv\Big(\mathbf{g}_u + \mathbf{h}_v; \bigcup_{i=1}^{U}(\mathbf{g}_i + \mathbf{h}_v) \cup \bigcup_{j=1}^{V}(\mathbf{g}_u + \mathbf{h}_j)\Big) = conv\Big(\mathbf{g}_u + \mathbf{h}_v; \bigcup_{i=1}^{U}\bigcup_{j=1}^{V}(\mathbf{g}_i + \mathbf{h}_j)\Big)$$

Proof: To prove this equality, it suffices to show that: (1) if $\mathbf{g}_u + \mathbf{h}_v$ is interior wrt. the first $conv$ binary predicate in the above equation, then it is interior wrt. the second $conv$, and (2) if $\mathbf{g}_u + \mathbf{h}_v$ is interior wrt. the second $conv$, then it is interior wrt. the first $conv$. Claim (1) is evident, since the set of points in the first $conv$ is a subset of the other set of points. Thus, we only need to prove (2). We first geometrically translate all points by $-\mathbf{g}_u - \mathbf{h}_v$. Since $\mathbf{g}_u + \mathbf{h}_v$ is interior wrt. the second $conv$, we can write:

$$\begin{aligned}
\mathbf{0} &= \sum_{i=1}^{U}\sum_{j=1}^{V}\lambda_{i,j}(\mathbf{g}_i + \mathbf{h}_j - \mathbf{g}_u - \mathbf{h}_v) \\
&= \sum_{i=1}^{U}\sum_{j=1}^{V}\lambda_{i,j}(\mathbf{g}_i - \mathbf{g}_u) + \sum_{i=1}^{U}\sum_{j=1}^{V}\lambda_{i,j}(\mathbf{h}_j - \mathbf{h}_v) \\
&= \sum_{i=1}^{U}(\mathbf{g}_i - \mathbf{g}_u)\sum_{j=1}^{V}\lambda_{i,j} + \sum_{j=1}^{V}(\mathbf{h}_j - \mathbf{h}_v)\sum_{i=1}^{U}\lambda_{i,j} \\
&= \sum_{i=1}^{U}\lambda'_i(\mathbf{g}_i - \mathbf{g}_u) + \sum_{j=1}^{V}\lambda'_{U+j}(\mathbf{h}_j - \mathbf{h}_v)
\end{aligned}$$

where $\{\lambda'_i\}_{1\leq i\leq U+V}$ values are computed from $\{\lambda_{i,j}\}_{1\leq i\leq U, 1\leq j\leq V}$ as follows: $\lambda'_i = \sum_j \lambda_{i,j}, i \in [1, U]$ and $\lambda'_{U+j} = \sum_i \lambda_{i,j}, j \in [1, V]$. Since the interior point is $\mathbf{0}$, λ'_i values can be scaled so that they sum to 1 (necessary condition in the definition of interior points), which proves that the following predicate is false:

$$conv\Big(\mathbf{0}; \bigcup_{i=1}^{U}(\mathbf{g}_i - \mathbf{g}_u) \cup \bigcup_{j=1}^{V}(\mathbf{h}_j - \mathbf{h}_v)\Big)$$

which is equivalent to stating that the following is false:

$$conv\Big(\mathbf{g}_u + \mathbf{h}_v; \bigcup_{i=1}^{U}(\mathbf{g}_i + \mathbf{h}_v) \cup \bigcup_{j=1}^{V}(\mathbf{g}_u + \mathbf{h}_j)\Big)$$

Abstract

We describe a method for prediction of linguistic structure in a language for which only unlabeled data is available, using annotated data from a set of one or more helper languages. Our approach is based on a model that locally mixes between supervised models from the helper languages. Parallel data is not used, allowing the technique to be applied even in domains where human-translated texts are unavailable. We obtain state-of-the-art performance for two tasks of structure prediction: unsupervised part-of-speech tagging and unsupervised dependency parsing.

1 Introduction

A major focus of recent NLP research has involved unsupervised learning of structure such as POS tag sequences and parse trees (Klein and Manning, 2004; Johnson et al., 2007; Berg-Kirkpatrick et al., 2010; Cohen and Smith, 2010, *inter alia*). In its purest form, such research has improved our understanding of unsupervised learning practically and formally, and has led to a wide range of new algorithmic ideas. Another strain of research has sought to exploit resources and tools in some languages (especially English) to construct similar resources and tools for other languages, through heuristic "projection" (Yarowsky and Ngai, 2001; Xi and Hwa, 2005) or constraints in learning (Burkett and Klein, 2008; Smith and Eisner, 2009; Das and Petrov, 2011; McDonald et al., 2011) or inference (Smith and Smith, 2004). Joint unsupervised learning (Snyder and Barzilay, 2008; Naseem et al., 2009; Snyder et al., 2009) is yet another research direction that seeks to learn models for many languages at once, exploiting linguistic universals and language similarity. The driving force behind all of this work has been the hope of building NLP tools for languages that lack annotated resources.[1]

In this paper, we present an approach to using annotated data from one or more languages (*helper* languages) to learn models for another language that lacks annotated data (the *target* language). Unlike the previous work mentioned above, our framework does not rely on parallel data in any form. This is advantageous because parallel text exists only in a few text domains (e.g., religious texts, parliamentary proceedings, and news).

We focus on generative probabilistic models parameterized by multinomial distributions. We begin with supervised maximum likelihood estimates for models of the helper languages. In the second stage, we learn a model for the target language using unannotated data, maximizing likelihood over *interpolations* of the helper language models' distributions. The tying is performed at the parameter level, through coarse, nearly-universal syntactic categories (POS tags). The resulting model is then used to *initialize* learning of the target language's model using standard unsupervised parameter estimation.

Some previous multilingual research, such as Bayesian parameter tying across languages (Cohen and Smith, 2009) or models of parameter

[1] Although the stated objective is often to build systems for resource-poor languages and domains, for evaluation purposes, annotated treebank test data figure prominently in this research (including in this paper).

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 50–61,
Edinburgh, Scotland, UK, July 27–31, 2011.

drift down phylogenetic trees (Berg-Kirkpatrick and Klein, 2010) is comparable, but the practical assumption of supervised helper languages is new to this work. Naseem et al. (2010) used universal syntactic categories and rules to improve grammar induction, but their model required expert handwritten rules as constraints.

Herein, we specifically focus on two problems in linguistic structure prediction: unsupervised POS tagging and unsupervised dependency grammar induction. Our experiments demonstrate that the presented method outperforms strong state-of-the-art unsupervised baselines for both tasks. Our approach can be applied to other problems in which a subset of the model parameters can be linked across languages. We also experiment with unsupervised learning of dependency structures from words, by combining our tagger and parser. Our results show that combining our tagger and parser with joint inference outperforms pipeline inference, and, in several cases, even outperforms models built using gold-standard part-of-speech tags.

2 Overview

For each language ℓ, we assume the presence of a set of fine-grained POS tags $\mathcal{F}_\ell$, used to annotate the language's treebank. Furthermore, we assume that there is a set of universal, coarse-grained POS tags $\mathcal{C}$ such that, for every language ℓ, there is a deterministic mapping from fine-grained to coarse-grained tags, $\lambda_\ell : \mathcal{F}_\ell \rightarrow \mathcal{C}$. Our approach can be summarized using the following steps for a given task:

1. Select a set of L helper languages for which there exists annotated data $\langle \mathcal{D}_1, \ldots, \mathcal{D}_L \rangle$. Here, we use treebanks in these languages.
2. For all $\ell \in \{1, \ldots, L\}$, convert the examples in $\mathcal{D}_\ell$ by applying λ_ℓ to every POS tag in the data, resulting in $\tilde{\mathcal{D}}_\ell$. Estimate the parameters of a probabilistic model using $\tilde{\mathcal{D}}_\ell$. In this work, such models are generative probabilistic models based on multinomial distributions,[2] including an HMM and the dependency model with valence (DMV) of Klein and Manning (2004). Denote the subset of parameters that are unlexicalized by $\boldsymbol{\theta}^{(\ell)}$. (Lexicalized parameters will be denoted $\boldsymbol{\eta}^{(\ell)}$.)
3. For the target language, define the set of valid unlexicalized parameters

$$\Theta = \left\{ \boldsymbol{\theta} \;\middle|\; \boldsymbol{\theta}_k = \sum_{\ell=1}^{L} \beta_{\ell,k} \boldsymbol{\theta}_k^{(\ell)}, \sum_{\ell=1}^{L} \beta_{\ell,k} = 1, \boldsymbol{\beta} \geq \mathbf{0} \right\}, \tag{1}$$

   for each group of parameters k, and maximize likelihood over that set, using the target-language unannotated data $\mathcal{U}$. Because the syntactic categories referenced by each $\boldsymbol{\theta}^{(\ell)}$ and all models in Θ are in $\mathcal{C}$, the models will be in the same parametric family. (Figure 1 gives a graphical interpretation of Θ.) Let the resulting model be $\boldsymbol{\theta}$.
4. Transform $\boldsymbol{\theta}$ by expanding the coarse-grained syntactic categories into the target language's fine-grained categories. Use the resulting model to initialize parameter estimation, this time over fine-grained tags, again using the unannotated target-language data $\mathcal{U}$. Initialize lexicalized parameters $\boldsymbol{\eta}$ for the target language using standard methods (e.g., uniform initialization with random symmetry breaking).

The main idea in the approach is to estimate a certain model family for one language, while using supervised models from other languages. The link between the languages is achieved through coarse-grained categories, which are now now commonplace (and arguably central to any theory of natural language syntax). A key novel contribution is the use of helper languages for initialization, and of unsupervised learning to learn the contribution of each helper language to that initialization (step 3). Additional treatment is required in expanding the coarse-grained model to the fine-grained one (step 4).

3 Interpolated Multilingual Probabilistic Context-Free Grammars

Our focus in this paper is on models that consist of multinomial distributions that have relationships between them through a generative process such as a probabilistic context-free grammar (PCFG). More specifically, we assume that we have a model defining a probability distribution over observed surface forms $\boldsymbol{x}$ and derivations $\boldsymbol{y}$ parametrized by $\boldsymbol{\theta}$:

[2] In §4 we also consider a feature-based parametrization.

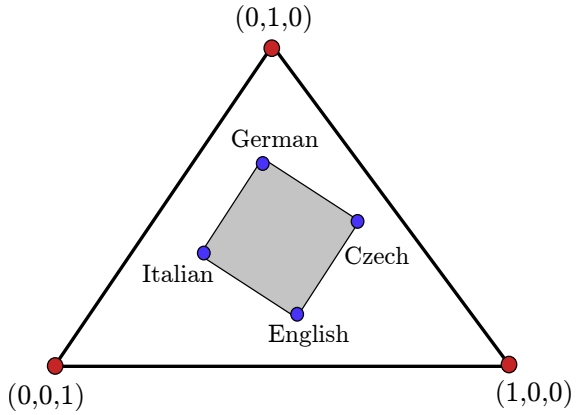

Figure 1: A simple case of interpolation within the 3-event probability simplex. The shaded area corresponds to a convex hull inside the probability simplex, indicating a mixture of the parameters of the four languages shown in the figure.

$$p(\boldsymbol{x}, \boldsymbol{y} \mid \boldsymbol{\theta}) = \prod_{k=1}^{K} \prod_{i=1}^{N_k} \theta_{k,i}^{f_{k,i}(\boldsymbol{x},\boldsymbol{y})} \quad (2)$$

$$= \exp \sum_{k=1}^{K} \sum_{i=1}^{N_k} f_{k,i}(\boldsymbol{x}, \boldsymbol{y}) \log \theta_{k,i} \quad (3)$$

where $f_{k,i}$ is a function that "counts" the number of times the kth distribution's ith event occurs in the derivation. The parameters $\boldsymbol{\theta}$ are a collection of K multinomials $\langle \boldsymbol{\theta}_1, \ldots, \boldsymbol{\theta}_K \rangle$, the kth of which includes N_k events. Letting $\boldsymbol{\theta}_k = \langle \theta_{k,1}, \ldots, \theta_{k,N_k} \rangle$, each $\theta_{k,i}$ is a probability, such that $\forall k, \forall i, \theta_{k,i} \geq 0$ and $\forall k, \sum_{i=1}^{N_k} \theta_{k,i} = 1$.

3.1 Multilingual Interpolation

Our framework places additional, temporary constraints on the parameters $\boldsymbol{\theta}$. More specifically, we assume that we have L existing, parameter estimates for the multinomial families from Eq. 3. Each such estimate $\boldsymbol{\theta}^{(\ell)}$, for $1 \leq \ell \leq L$, corresponds to a the maximum likelihood estimate based on annotated data for the ℓth helper language. Then, to create a model for new language, we define a new set of parameters $\boldsymbol{\theta}$ as:

$$\theta_{k,i} = \sum_{\ell=1}^{L} \beta_{\ell,k} \theta_{k,i}^{(\ell)}, \quad (4)$$

where $\boldsymbol{\beta}$ is the set of coefficients that we will now be interested in estimating (instead of directly estimating $\boldsymbol{\theta}$). Note that for each k, $\sum_{\ell=1}^{L} \beta_{\ell,k} = 1$ and $\beta_{\ell,k} \geq 0$.

3.2 Grammatical Interpretation

We now give an interpretation of our approach relating it to PCFGs. We assume familiarity with PCFGs. For a PCFG $\langle \boldsymbol{G}, \boldsymbol{\theta} \rangle$ we denote the set of nonterminal symbols by $\mathcal{N}$, the set of terminal symbols by Σ, and the set of rewrite rules for each nonterminal $A \in \mathcal{N}$ by $R(A)$. Each $r \in R(A)$ has the form $A \rightarrow \alpha$ where $\alpha \in (\mathcal{N} \cup \Sigma)^*$. In addition, there is a probability attached to each rule $\theta_{A \rightarrow \alpha}$ such that $\forall A \in \mathcal{N}, \sum_{\alpha:(A \rightarrow \alpha) \in R(A)} \theta_{A \rightarrow \alpha} = 1$. A PCFG can be framed as a model using Eq. 3, where $\boldsymbol{\theta}$ correspond to $K = |\mathcal{N}|$ multinomial distributions, where each distribution attaches probabilities to rules with a specific left hand symbol.

We assume that the model we are trying to estimate (over coarse part-of-speech tags) can be framed as a PCFG $\langle \boldsymbol{G}, \boldsymbol{\theta} \rangle$. This is indeed the case for part-of-speech tagging and dependency grammar induction we experiment with in §6. In that case, our approach can be framed for PCFGs as following. We assume that there exists L set of parameters for this PCFG $\boldsymbol{\theta}^{(1)}, \ldots, \boldsymbol{\theta}^{(L)}$, each corresponding to a helper language. We then create a new PCFG $\boldsymbol{G}'$ with parameters $\boldsymbol{\theta}'$ and $\boldsymbol{\beta}$ as follows:

1. $\boldsymbol{G}'$ contains all nonterminal and terminal symbols in $\boldsymbol{G}$, and none of the rules in $\boldsymbol{G}$.
2. For each nonterminal A in $\boldsymbol{G}$, we create a new nonterminal $a_{A,\ell}$ for $\ell \in \{1, \ldots, L\}$.
3. For each nonterminal A in $\boldsymbol{G}$, we create rules $A \rightarrow a_{A,\ell}$ for $\ell \in \{1, \ldots, L\}$ which have probabilities $\beta_{A \rightarrow a_{A,\ell}}$.
4. For each rule $A \rightarrow \alpha$ in $\boldsymbol{G}$, we add to $\boldsymbol{G}'$ the rule $a_{A,\ell} \rightarrow \alpha$ with

$$\theta'_{a_{A,\ell} \rightarrow \alpha} = \theta^{(\ell)}_{A \rightarrow \alpha}. \quad (5)$$

where $\theta^{(\ell)}_{A \rightarrow \alpha}$ is the probability associated with rule $A \rightarrow \alpha$ in the ℓth helper language.

At each point, the derivational process of this PCFG uses the nonterminal's specific $\boldsymbol{\beta}$ coefficients

to choose one of the helper languages. It then selects a rule according to the multinomial from that language. This step is repeated until a whole derivation is generated.

This PCFG representation of the approach in §3 points to a possible generalization. Instead of using an identical CFG backbone for each language, we can use a set of PCFGs, $\langle \boldsymbol{G}^{(\ell)}, \boldsymbol{\theta}^{(\ell)} \rangle$ with an identical nonterminal set and alphabet, and repeat the same construction as above, replacing step 4 with the addition of rules of the form $a_{A,\ell} \rightarrow \alpha$ for each rule $A \rightarrow \alpha$ in $\boldsymbol{G}^{(\ell)}$. Such a construction allows more syntactic variability in the language we are trying to estimate, originating in the syntax of the various helper languages. In this paper, we do not use this generalization, and always use the same PCFG backbone for all languages.

Note that the interpolated model can still be understood in terms of the exponential model of Eq. 3. For a given collection of multinomials and base models of the form of Eq. 3, we can analogously define a new log-linear model over a set of extended derivations. These derivations will now include $L \times K$ features of the form $g_{\ell,k}(\boldsymbol{x}, \boldsymbol{y})$, corresponding to a count of the event of choosing the ℓth mixture component for multinomial k. In addition, the feature set $f_{k,i}(\boldsymbol{x}, \boldsymbol{y})$ will be extended to a feature set of the form $f_{\ell,k,i}(\boldsymbol{x}, \boldsymbol{y})$, analogous to step 4 in constructed PCFG above. The model parameterized according to Eq. 4 can be recovered by marginalizing out the "g" features. We will refer to the model with these new set of features as "the extended model."

4 Inference and Parameter Estimation

The main building block commonly required for unsupervised learning in NLP is that of computing feature expectations for a given model. These feature expectations can be used with an algorithm such as expectation-maximization (where the expectations are normalized to obtain a new set of multinomial weights) or with other gradient based log-likelihood optimization algorithms such as L-BFGS (Liu and Nocedal, 1989) for feature-rich models.

Estimating Multinomial Distributions Given a surface form $\boldsymbol{x}$, a multinomial k and an event i in the multinomial, "feature expectation" refers to the calculation of the following quantities (in the extended model):

$$\mathbb{E}[f_{\ell,k,i}(\boldsymbol{x}, \boldsymbol{y})] = \sum_{\boldsymbol{y}} p(\boldsymbol{x}, \boldsymbol{y} \mid \boldsymbol{\theta}) f_{\ell,k,i}(\boldsymbol{x}, \boldsymbol{y}) \quad (6)$$

$$\mathbb{E}[g_{\ell,k}(\boldsymbol{x}, \boldsymbol{y})] = \sum_{\boldsymbol{y}} p(\boldsymbol{x}, \boldsymbol{y} \mid \boldsymbol{\theta}) g_{\ell,k}(\boldsymbol{x}, \boldsymbol{y}) \quad (7)$$

These feature expectations can usually be computed using algorithms such as the forward-backward algorithm for hidden Markov models, or more generally, the inside-outside algorithm for PCFGs. In this paper, however, the task of estimation is different than the traditional task. As mentioned in §2, we are interested in estimating $\boldsymbol{\beta}$ from Eq. 4, while fixing $\boldsymbol{\theta}^{(\ell)}$. Therefore, we are only interested in computing expectations of the form of Eq. 7.

As explained in §3.2, any model interpolating with the $\boldsymbol{\beta}$ parameters can be reduced to a new log-linear model with additional features representing the mixture coefficients of $\boldsymbol{\beta}$. We can then use the inside-outside algorithm to obtain the necessary feature expectations for features of the form $g_{\ell,k}(\boldsymbol{x}, \boldsymbol{y})$, expectations which assist in the estimation of the $\boldsymbol{\beta}$ parameters.

These feature expectations can readily be used in estimation algorithms such as expectation-maximization (EM). With EM, the update at iteration t would be:

$$\beta_{\ell,k}^{(t)} = \frac{\mathbb{E}[g_{\ell,k}(\boldsymbol{x}, \boldsymbol{y})]}{\sum_{\ell} \mathbb{E}[g_{\ell,k}(\boldsymbol{x}, \boldsymbol{y})]}, \quad (8)$$

where the expectations are taken with respect to $\boldsymbol{\beta}^{(t-1)}$ and the fixed $\boldsymbol{\theta}^{(l)}$ for $\ell = 1, \ldots, L$.

Estimating Feature-Rich Directed Models Recently Berg-Kirkpatrick et al. (2010) found that replacing traditional multinomial parameterizations with locally normalized, feature-based log-linear models was advantageous. This can be understood as parameterizing $\boldsymbol{\theta}$:

$$\theta_{k,i} = \frac{\exp \boldsymbol{\psi}^{\top} \mathbf{h}(k, i)}{\sum_{i'} \exp \boldsymbol{\psi}^{\top} \mathbf{h}(k, i')} \quad (9)$$

where $\mathbf{h}(k, i)$ are a set of features looking at event i in context k. For such a feature-rich model, our multilingual modeling framework still substitutes $\boldsymbol{\theta}$ with a mixture of supervised multinomials for L helper languages as in Eq. 4. However, for computational

convenience, we also reparametrize the mixture coefficients $\boldsymbol{\beta}$:

$$\beta_{\ell,k} = \frac{\exp \gamma_{\ell,k}}{\sum_{\ell'=1}^{L} \exp \gamma_{\ell',k}} \quad (10)$$

Here, each $\gamma_{\ell,k}$ is an unconstrained parameter, and the above "softmax" transformation ensures that $\boldsymbol{\beta}$ lies within the probability simplex for context k. This is done so that a gradient-based optimization method like L-BFGS (Liu and Nocedal, 1989) can be used to estimate $\boldsymbol{\gamma}$ without having to worry about additional simplex constraints. For optimization, derivatives of the data log-likelihood with respect to $\boldsymbol{\gamma}$ need to be computed. We calculate the derivatives following Berg-Kirkpatrick et al. (2010, §3.1), making use of feature expectations, calculated exactly as before.

In addition to these estimation techniques, which are based on the optimization of the log-likelihood, we also consider a trivially simple technique for estimating $\boldsymbol{\beta}$: setting $\beta_{l,k}$ to the uniform weight L^{-1}, where L is the number of helper languages.

5 Coarse-to-Fine Multinomial Expansion

To expand these multinomials involving coarse-grained categories into multinomials over fine-grained categories specific to the target language t, we do the following:

- Whenever a multinomial *conditions* on a coarse category $c \in \mathcal{C}$, we make copies of it for each fine-grained category in $\lambda_t^{-1}(c) \subset \mathcal{F}_t$.[3] If the multinomial does not condition on coarse categories, it is simply copied.
- Whenever a probability θ_i within a multinomial distribution involves a coarse-grained category c as an event (i.e., it is on the left side of the conditional bar), we expand the event into $|\lambda_t^{-1}(c)|$ new events, one per corresponding fine-grained category, each assigned the value $\frac{\theta_i}{|\lambda_t^{-1}(c)|}$.[4]

[3] We note that in the models we experiment with, we always condition on at most one fine-grained category.

[4] During this expansion process for a coarse event, we tried adding random noise to $\frac{\theta_i}{|\lambda_t^{-1}(c)|}$ and renormalizing, to break symmetry between the fine events, but that was found to be harmful in preliminary experiments.

The result of this expansion is a model in the desired family; we use it to initialize conventional unsupervised parameter estimation. Lexical parameters, if any, do not undergo this expansion process, and they are estimated anew in the fine grained model during unsupervised learning, and are initialized using standard methods.

6 Experiments and Results

In this section, we describe the experiments undertaken and the results achieved. We first note the characteristics of the datasets and the universal POS tags used in multilingual modeling.

6.1 Data

For our experiments, we fixed a set of four helper languages with relatively large amounts of data, displaying nontrivial linguistic diversity: Czech (Slavic), English (West-Germanic), German (West-Germanic), and Italian (Romance). The datasets are the CoNLL-X shared task data for Czech and German (Buchholz and Marsi, 2006),[5] the Penn Treebank for English (Marcus et al., 1993), and the CoNLL 2007 shared task data for Italian (Montemagni et al., 2003). This was the only set of helper languages we tested; improvements are likely possible. We leave an exploration of helper language choice (a subset selection problem) to future research, instead demonstrating that the concept has merit.

We considered ten target languages: Bulgarian (Bg), Danish (Da), Dutch (Nl), Greek (El), Japanese (Jp), Portuguese (Pt), Slovene (Sl), Spanish (Es), Swedish (Sv), and Turkish (Tr). The data come from the CoNLL-X and CoNLL 2007 shared tasks (Buchholz and Marsi, 2006; Nivre et al., 2007). For all the experiments conducted, we trained models on the training section of a language's treebank and tested on the test set. Table 1 shows the number of sentences in the treebanks and the size of fine POS tagsets for each language.

Following standard practice, in unsupervised grammar induction experiments we remove punctuation and then eliminate sentences from the data of length greater than 10.

[5] These are based on the Prague Dependency Treebank (Hajič, 1998) and the Tiger treebank (Brants et al., 2002) respectively.

	Pt	Tr	Bg	Jp	El	Sv	Es	Sl	Nl	Da
Training sentences	9,071	4,997	12,823	17,044	2,705	11,042	3,306	1,534	13,349	5,190
Test sentences	288	623	398	709	197	389	206	402	386	322
Size of POS tagset	22	31	54	80	38	41	47	29	12	25

Table 1: The first two rows show the sizes of the training and test datasets for each language. The third row shows the number of fine POS tags in each language including punctuations.

6.2 Universal POS Tags

Our coarse-grained, universal POS tag set consists of the following 12 tags: NOUN, VERB, ADJ (adjective), ADV (adverb), PRON (pronoun), DET (determiner), ADP (preposition or postposition), NUM (numeral), CONJ (conjunction), PRT (particle), PUNC (punctuation mark) and X (a catch-all for other categories such as abbreviations or foreign words). These follow recent work by Das and Petrov (2011) on unsupervised POS tagging in a multilingual setting with parallel data, and have been described in detail by Petrov et al. (2011).

While there might be some controversy about what an appropriate universal tag set should include, these 12 categories (or a subset) cover the most frequent parts of speech and exist in one form or another in all of the languages that we studied. For each language in our data, a mapping from the fine-grained treebank POS tags to these universal POS tags was constructed manually by Petrov et al. (2011).

6.3 Part-of-Speech Tagging

Our first experimental task is POS tagging, and here we describe the specific details of the model, training and inference and the results attained.

6.3.1 Model

The model is a hidden Markov model (HMM), which has been popular for unsupervised tagging tasks (Merialdo, 1994; Elworthy, 1994; Smith and Eisner, 2005; Berg-Kirkpatrick et al., 2010).[6] We use a bigram model and a locally normalized log-linear parameterization, like Berg-Kirkpatrick et al. (2010). These locally normalized log-linear models can look at various aspects of the observation x given a tag y, or the pair of tags in a transition, incorporating overlapping features. In basic monolingual experiments, we used the same set of features as Berg-Kirkpatrick et al. (2010). For the transition log-linear model, Berg-Kirkpatrick et al. (2010) used only a single indicator feature of a tag pair, essentially equating to a traditional multinomial distribution. For the emission log-linear model, several features were used: an indicator feature conjoining the state y and the word x, a feature checking whether x contains a digit conjoined with the state y, another feature indicating whether x contains a hyphen conjoined with y, whether the first letter of x is upper case along with the state y, and finally indicator features corresponding to suffixes up to length 3 present in x conjoined with the state y.

Since only the unlexicalized transition distributions are common across multiple languages, assuming that they all use a set of universal POS tags, akin to Eq. 4, we can have a multilingual version of the transition distributions, by incorporating supervised helper transition probabilities. Thus, we can write:

$$\theta_{y \to y'} = \sum_{\ell=1}^{L} \beta_{\ell,y} \theta^{(\ell)}_{y \to y'} \tag{11}$$

We use the above expression to replace the transition distributions, obtaining a multilingual mixture version of the model. Here, the transition probabilities $\theta^{(\ell)}_{y \to y'}$ for the ℓth helper language are fixed after being estimated using maximum likelihood estimation on the helper language's treebank.

6.3.2 Training and Inference

We trained both the basic feature-based HMM model as well as the multilingual mixture model by optimizing the following objective function:[7]

$$\mathcal{L}(\boldsymbol{\psi}) \quad = \sum_{i=1}^{N} \log \sum_{\boldsymbol{y}} p(\boldsymbol{x}^{(i)}, \boldsymbol{y} \mid \boldsymbol{\psi}) - C\|\boldsymbol{\psi}\|_2^2$$

[6] HMMs can be understood as a special case of PCFGs.

[7] Note that in the objective function, for brevity, we abuse notation by using $\boldsymbol{\psi}$ for both models – monolingual and multilingual; the latter model is also parameterized by $\boldsymbol{\gamma}$.

Method	Pt	Tr	Bg	Jp	El	Sv	Es	Sl	Nl	Da	Avg

(b)

Table 2: Results for unsupervised POS induction (a) without a tagging dictionary and (b) with a tag dictionary constructed from the training section of the corresponding treebank. DG (at the bottom) stands for the direct gradient method of Berg-Kirkpatrick et al. (2010) using a monolingual feature-based HMM. "Mixture+DG" is the model where multilingual mixture coefficients $\boldsymbol{\beta}$ of helper languages are estimated using coarse tags (§4), followed by expansion (§5), and then initializing DG with the expanded transition parameters. "Uniform+DG" is the case where $\boldsymbol{\beta}$ are set to 1/4, transitions of helper languages are mixed, expanded, and then DG is initialized with the result. For (a), evaluation is performed using one-to-one mapping accuracy. In case of (b), the tag dictionary solves the problem of tag identification and performance is measured using per word POS accuracy. "Avg" denotes macro-average across the ten languages.

Note that this involves marginalizing out all possible state configurations $\boldsymbol{y}$ for a sentence $\boldsymbol{x}$, resulting in a non-convex objective. As described in §4, we optimized this function using L-BFGS. For the monolingual model, derivatives of the feature weights took the exact same form as Berg-Kirkpatrick et al. (2010), while for the mixture case, we computed gradients with respect to $\boldsymbol{\gamma}$, the unconstrained parameters used to express the mixture coefficients $\boldsymbol{\beta}$ (see Eq. 10). The regularization constant C was set to 1.0 for all experiments, and L-BFGS was run till convergence.

During training, for the basic monolingual feature-based HMM model, we initialized all parameters using small random real values, sampled from $\mathcal{N}(0, 0.01)$. For estimation of the mixture parameters $\boldsymbol{\gamma}$ for our multilingual model (step 3 in §2), we similarly sampled real values from $\mathcal{N}(0, 0.01)$ as an initialization point. Moreover, during this stage, the emission parameters also go through parameter estimation, but they are *monolingual*, and are initialized with real values sampled from $\mathcal{N}(0, 0.01)$; as explained in §2, coarse universal tags are used both in the transitions and emissions during multilingual estimation.

After the mixture parameters $\boldsymbol{\gamma}$ are estimated, we compute the mixture probabilities $\boldsymbol{\beta}$ using Eq. 10. Next, for each tag pair y, y', we compute $\theta_{y \to y'}$, which are the coarse transition probabilities interpolated using $\boldsymbol{\beta}$, given the helper languages. We then expand these transition probabilities (see §5) to result in transition probabilities based on fine tags. Finally, we train a feature-HMM by initializing its transition parameters with natural logarithms of the expanded $\boldsymbol{\theta}$ parameters, and the emission parameters using small random real values sampled from $\mathcal{N}(0, 0.01)$. This implies that the lexicalized emission parameters $\boldsymbol{\eta}$ that were previously estimated in the coarse multilingual model are thrown away and not used for initialization; instead standard initialization is used.

For inference at the testing stage, we use minimum Bayes-risk decoding (or "posterior decoding"), by choosing the most probable tag for each word position, given the entire observation $\boldsymbol{x}$. We chose this strategy because it usually performs slightly better than Viterbi decoding (Cohen and Smith, 2009; Ganchev et al., 2010).

6.3.3 Experimental Setup

For experiments, we considered three configurations, and for each, we implemented two variants of POS induction, one without any kind of supervision, and the other with a tag dictionary. Our baseline is

the direct gradient approach of Berg-Kirkpatrick et al. (2010), which is the current state of the art for this task, outperforming classical HMMs. Because this model achieves strong performance using straightforward MLE, it also serves as the core model within our approach. This model has also been applied in a multilingual setting with parallel data (Das and Petrov, 2011). In this baseline, we set the number of HMM states to the number of fine-grained treebank tags for the given language.

We test two versions of our model. The first initializes training of the target language's POS model using a uniform mixture of the helper language models (i.e., each $\beta_{\ell,y} = \frac{1}{L} = \frac{1}{4}$), and expansion from coarse-grained to fine-grained POS tags as described in §5. We call this model "Uniform+DG."

The second version estimates the mixture coefficients to maximize likelihood, then expands the POS tags (§5), using the result to initialize training of the final model. We call this model "Mixture+DG."

No Tag Dictionary For each of the above configurations, we ran purely unsupervised training without a tag dictionary, and evaluated using *one-to-one mapping* accuracy constraining at most one HMM state to map to a unique treebank tag in the test data, using maximum bipartite matching. This is a variant of the greedy one-to-one mapping scheme of Haghighi and Klein (2006).[8]

With a Tag Dictionary We also ran a second version of each experimental configuration, where we used a tag dictionary to restrict the possible path sequences of the HMM during both learning and inference. This tag dictionary was constructed only from the training section of a given language's treebank. It is widely known that such knowledge improves the quality of the model, though it is an open debate whether such knowledge is realistic to assume. For this experiment we removed punctuation from the training and test data, enabling direct use within the dependency grammar induction experiments.

[8]We also evaluated our approach using the greedy version of this evaluation metric, and results followed the same trends with only minor differences. We did not choose the other variant, *many-to-one mapping* accuracy, because quite often the metric mapped several HMM states to one treebank tag, leaving many treebank tags unaccounted for.

6.3.4 Results

All results for POS induction are shown in Table 2. Without a tag dictionary, in eight out of ten cases, either Uniform+DG or Mixture+DG outperforms the monolingual baseline (Table 2a). For six of these eight languages, the latter model where the mixture coefficients are learned automatically fares better than uniform weighting. *With* a tag dictionary, the multilingual variants outperform the baseline in seven out of ten cases, and the learned mixture outperforms or matches the uniform mixture in five of those seven (Table 2b).

6.4 Dependency Grammar Induction

We next describe experiments for dependency grammar induction. As the basic grammatical model, we adopt the dependency model with valence (Klein and Manning, 2004), which forms the basis for state-of-the-art results for dependency grammar induction in various settings (Cohen and Smith, 2009; Spitkovsky et al., 2010; Gillenwater et al., 2010; Berg-Kirkpatrick and Klein, 2010). As shown in Table 3, DMV obtains much higher accuracy in the supervised setting than the unsupervised setting, suggesting that more can be achieved with this model family.[9] For this reason, and because DMV is easily interpreted as a PCFG, it is our starting point and baseline.

We consider four conditions. The independent variables are (1) whether we use uniform $\boldsymbol{\beta}$ (all set to $\frac{1}{4}$) or estimate them using EM (as described in §4), and (2) whether we simply use the mixture model to decode the test data, or to initialize EM for the DMV. The four settings are denoted "Uniform," "Mixture," "Uniform+EM," and "Mixture+EM."

The results are given in Table 3. In general, the use of data from other languages improves performance considerably; all of our methods outperform the Klein and Manning (2004) initializer, and we achieve state-of-the-art performance for eight out of ten languages. Uniform and Mixture behave similarly, with a slight advantage to the trained mixture setting. Using EM to train the mixture coefficients more often hurts than helps (six languages out of ten). It is well known that likelihood does not cor-

[9]Its supervised performance is still far from the supervised state of the art in dependency parsing.

Table 3: Results for dependency grammar induction given gold-standard POS tags, reported as attachment accuracy (fraction of parents which are correct). The three existing methods are: our replication of EM with the initializer from Klein and Manning (2004), denoted "EM"; reported results from Gillenwater et al. (2010) for posterior regularization ("PR"); and reported results from Berg-Kirkpatrick and Klein (2010), denoted "Phylo." "Supervised (MLE)" are oracle results of estimating parameters from gold-standard annotated data using maximum likelihood estimation. "Avg" denotes macro-average across the ten languages.

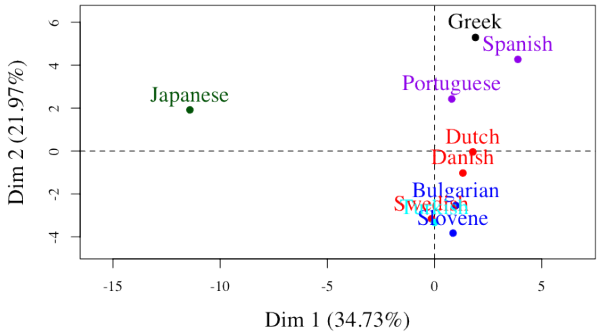

Figure 2: Projection of the learned mixture coefficients through PCA. In green, Japanese. In red, Dutch, Danish and Swedish. In blue, Bulgarian and Slovene. In magenta, Portuguese and Spanish. In black, Greek. In cyan, Turkish.

relate with the true accuracy measurement, and so it is unsurprising that this holds in the constrained mixture family as well. In future work, a different parametrization of the mixture coefficients, through features, or perhaps a Bayesian prior on the weights, might lead to an objective that better simulates accuracy.

Table 3 shows that even uniform mixture coefficients are sufficient to obtain accuracy which supercedes most unsupervised baselines. We were interested in testing whether the coefficients which are learned actually reflect similarities between the languages. To do that, we projected the learned vectors β for each tested language using principal component analysis and plotted the result in Figure 2. It is interesting to note that languages which are closer phylogenetically tend to appear closer to each other in the plot.

Our experiments also show that multilingual learning performs better for dependency grammar induction than part-of-speech tagging. We believe that this happens because of the nature of the models and data we use. The transition matrix in part-of-speech tagging largely depends on word order in the various helper languages, which differs greatly. This means that a mixture of transition matrices will not necessarily yield a meaningful transition matrix. However, for dependency grammar, there are certain universal dependencies which appear in all helper languages, and therefore, a mixture between multinomials for these dependencies still yields a useful multinomial.

6.5 Inducing Dependencies from Words

Finally, we combine the models for POS tagging and grammar induction to perform grammar induction directly from words, instead of gold-standard POS tags. Our approach is as follows:

1. *With* a tag dictionary, learn a fine-grained POS tagging model unsupervised, using either DG or Mixture+DG as described in §6.3 and shown in Table 2b.

Method	Tags	Pt	Tr	Bg	Jp	El	Sv	Es	Sl	Nl	Da	Avg
Joint	DG	**68.4**	**52.4**	62.4	61.4	63.5	**58.2**	67.7	**47.2**	48.3	**50.4**	**57.9**
Joint	Mixture+DG	62.2	47.4	**67.0**	**69.5**	52.2	49.1	**69.3**	36.8	**52.2**	50.1	55.6
Pipeline	DG	60.0	50.8	57.7	64.2	**68.2**	57.9	65.8	45.8	49.9	48.9	56.9
Pipeline	Mixture+DG	59.8	47.1	62.9	68.6	50.0	47.6	68.1	36.4	51.2	48.3	54.0
Gold-standard tags		*79.8*	*45.3*	*75.6*	*63.9*	*73.0*	*74.0*	*76.7*	*46.1*	*50.7*	*59.9*	*64.5*

Table 4: Results for dependency grammar induction over words. "Joint"/"Pipeline" refers to joint/pipeline decoding of tags and dependencies as described in the text. See §6.3 for a description of DG and Mixture+DG. For the induction of dependencies we use the Mixture+EM setting as described in §6.4. All tag induction uses a dictionary as specified in §6.3. The last row in this table indicates the best results using multilingual guidance taken from our methods in Table 3. "Avg" denotes macro-average across the ten languages.

2. Apply the fine-grained tagger to the words in the training data for the dependency parser. We consider two variants: the most probable assignment of tags to words (denoted "Pipeline"), and the posterior distribution over tags for each word, represented as a weighted "sausage" lattice (denoted "Joint"). This idea was explored for joint inference by Cohen and Smith (2007).
3. We apply the Mixture+EM unsupervised parser learning method from §6.4 to the automatically tagged sentences, or the lattices.
4. Given the two models, we infer POS tags on the test data using DG or Mixture+DG to get a lattice (Joint) or a sequence (Pipeline) and then parse using the model from the previous step.[10] The resulting dependency trees are evaluated against the gold standard.

Results are reported in Table 4. In almost all cases, joint decoding of tags and trees performs better than the pipeline. Even though our part-of-speech tagger with multilingual guidance outperforms the completely unsupervised baseline, there is not always an advantage of using this multilingually guided part-of-speech tagger for dependency grammar induction. For Turkish, Japanese, Slovene and Dutch, our unsupervised learner from words outperforms unsupervised parsing using gold-standard part-of-speech tags.

We note that some recent work gives a treatment to unsupervised parsing (but not of dependencies) directly from words (Seginer, 2007). Earlier work that induced part-of-speech tags and then performed unsupervised parsing in a pipeline includes Klein and Manning (2004) and Smith (2006). Headden et al. (2009) described the use of a lexicalized variant of the DMV model, with the use of gold part-of-speech tags.

[10]The decoding method on test data (Joint or Pipeline) was matched to the training method, though they are orthogonal in principle.

7 Conclusion

We presented an approach to exploiting annotated data in helper languages to infer part-of-speech tagging and dependency parsing models in a different, target language, without parallel data. Our approach performs well in many cases. We also described a way to do joint decoding of part-of-speech tags and dependencies which performs better than a pipeline. Future work might consider exploiting a larger number of treebanks, and more powerful techniques for combining models than simple local mixtures.

Abstract

We present a simple method for transferring dependency parsers from source languages with labeled training data to target languages without labeled training data. We first demonstrate that delexicalized parsers can be directly transferred between languages, producing significantly higher accuracies than unsupervised parsers. We then use a constraint driven learning algorithm where constraints are drawn from parallel corpora to project the final parser. Unlike previous work on projecting syntactic resources, we show that simple methods for introducing multiple source languages can significantly improve the overall quality of the resulting parsers. The projected parsers from our system result in state-of-the-art performance when compared to previously studied unsupervised and projected parsing systems across eight different languages.

1 Introduction

Statistical parsing has been one of the most active areas of research in the computational linguistics community since the construction of the Penn Treebank (Marcus et al., 1993). This includes work on phrase-structure parsing (Collins, 1997; Charniak, 2000; Petrov et al., 2006), dependency parsing (McDonald et al., 2005; Nivre et al., 2006) as well as a number of other formalisms (Clark and Curran, 2004; Wang and Harper, 2004; Shen and Joshi, 2008). As underlying modeling techniques have improved, these parsers have begun to converge to high levels of accuracy for English newswire text. Subsequently, researchers have begun to look at both porting these parsers to new domains (Gildea, 2001; McClosky et al., 2006; Petrov et al., 2010) and constructing parsers for new languages (Collins et al., 1999; Buchholz and Marsi, 2006; Nivre et al., 2007).

One major obstacle in building statistical parsers for new languages is that they often lack the manually annotated resources available for English. This observation has led to a vast amount of research on unsupervised grammar induction (Carroll and Charniak, 1992; Klein and Manning, 2004; Smith and Eisner, 2005; Cohen and Smith, 2009; Berg-Kirkpatrick and Klein, 2010; Naseem et al., 2010; Spitkovsky et al., 2010; Blunsom and Cohn, 2010). Grammar induction systems have seen large advances in quality, but parsing accuracies still significantly lag behind those of supervised systems. Furthermore, they are often trained and evaluated under idealized conditions, e.g., only on short sentences or assuming the existence of gold-standard part-of-speech (POS) tags.[1] The reason for these assumptions is clear. Unsupervised grammar induction is difficult given the complexity of the analysis space. These assumptions help to give the model traction.

The study of unsupervised grammar induction has many merits. Most notably, it increases our understanding of how computers (and possibly humans) learn in the absence of any explicit feedback. However, the gold POS tag assumption weakens any conclusions that can be drawn, as part-of-speech are also a form of syntactic analysis, only shallower. Furthermore, from a practical standpoint, it is rarely the case that we are completely devoid of resources for most languages. This point has been made by

[1] A notable exception is the work of Seginer (2007).

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 62–72,
Edinburgh, Scotland, UK, July 27–31, 2011.

studies that transfer parsers to new languages by projecting syntax across word alignments extracted from parallel corpora (Hwa et al., 2005; Ganchev et al., 2009; Smith and Eisner, 2009). Although again, most of these studies also assume the existence of POS tags.

In this work we present a method for creating dependency parsers for languages for which no labeled training data is available. First, we train a source side English parser that, crucially, is delexicalized so that its predictions rely soley on the part-of-speech tags of the input sentence, in the same vein as Zeman and Resnik (2008). We empirically show that directly transferring delexicalized models (i.e. parsing a foreign language POS sequence with an English parser) already outperforms state-of-the-art unsupervised parsers by a significant margin. This result holds in the presence of both gold POS tags as well as automatic tags projected from English. This emphasizes that even for languages with no syntactic resources – or possibly even parallel data – simple transfer methods can already be more powerful than grammar induction systems.

Next, we use this delexicalized English parser to seed a perceptron learner for the target language. The model is trained to update towards parses that are in high agreement with a source side English parse based on constraints drawn from alignments in the parallel data. We use the augmented-loss learning procedure (Hall et al., 2011) which is closely related to constraint driven learning (Chang et al., 2007; Chang et al., 2010). The resulting parser consistently improves on the directly transferred delexicalized parser, reducing relative errors by 8% on average, and as much as 18% on some languages. Finally, we show that by transferring parsers from multiple source languages we can further reduce errors by 16% over the directly transferred English baseline. This is consistent with previous work on multilingual part-of-speech (Snyder et al., 2009) and grammar (Berg-Kirkpatrick and Klein, 2010; Cohen and Smith, 2009) induction, that shows that adding languages leads to improvements.

We present a comprehensive set of experiments on eight Indo-European languages for which a significant amount of parallel data exists. We make no language specific enhancements in our experiments. We report results for sentences of *all* lengths, as well as with gold and automatically induced part-of-speech tags. We also report results on sentences of length 10 or less with gold part-of-speech tags to compare with previous work. Our results consistently outperform the previous state-of-the-art across all languages and training configurations.

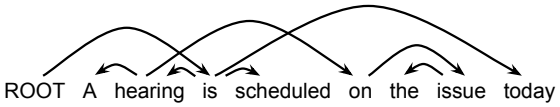

Figure 1: An example (unlabeled) dependency tree.

2 Preliminaries

In this paper we focus on transferring dependency parsers between languages. A dependency parser takes a tokenized input sentence (optionally part-of-speech tagged) and produces a connected tree where directed arcs represent a syntactic head-modifier relationship. An example of such a tree is given in Figure 1. Dependency tree arcs are often labeled with the role of the syntactic relationship, e.g., *is* to *hearing* might be labeled as SUBJECT. However, we focus on unlabeled parsing in order to reduce problems that arise due to different treebank annotation schemes. Of course, even for unlabeled dependencies, significant variations in the annotation schemes remain. For example, in the Danish treebank determiners govern adjectives and nouns in noun phrases, while in most other treebanks the noun is the head of the noun phrase. Unlike previous work (Zeman and Resnik, 2008; Smith and Eisner, 2009), we do not apply any transformations to the treebanks, which makes our results easier to reproduce, but systematically underestimates accuracy.

2.1 Data Sets

The treebank data in our experiments are from the CoNLL shared-tasks on dependency parsing (Buchholz and Marsi, 2006; Nivre et al., 2007). We use English (en) only as a source language throughout the paper. Additionally, we use the following eight languages as both source and target languages: Danish (da), Dutch (nl), German (de), Greek (el), Italian (it), Portuguese (pt), Spanish (es) and Swedish (sv). For languages that were included in both the 2006 and 2007 tasks, we used the treebank from the lat-

ter. We focused on this subset of languages because they are Indo-European and a significant amount of parallel data exists for each language. By presenting results on eight languages our study is already more comprehensive than most previous work in this area. However, the restriction to Indo-European languages does make the results less conclusive when one wishes to transfer a parser from English to Chinese, for example. To account for this, we report additional results in the discussion for non-Indo-European languages. For all data sets we used the predefined training and testing splits.

Our approach relies on a consistent set of part-of-speech tags across languages and treebanks. For this we used the universal tagset from Petrov et al. (2011), which includes: NOUN (nouns), VERB (verbs), ADJ (adjectives), ADV (adverbs), PRON (pronouns), DET (determiners), ADP (prepositions or postpositions), NUM (numerals), CONJ (conjunctions), PRT (particles), PUNC (punctuation marks) and X (a catch-all tag). Similar tagsets are used by other studies on grammar induction and projection (Naseem et al., 2010; Zeman and Resnik, 2008). For all our experiments we replaced the language specific part-of-speech tags in the treebanks with these universal tags.

Like all treebank projection studies we require a corpus of parallel text for each pair of languages we study. For this we used the Europarl corpus version 5 (Koehn, 2005). The corpus was preprocessed in standard ways and word aligned by running six iterations of IBM Model 1 (Brown et al., 1993), followed by six iterations of the HMM model (Vogel et al., 1996) in both directions. We then intersect word alignments to generate one-to-one alignments.

2.2 Parsing Model

All of our parsing models are based on the transition-based dependency parsing paradigm (Nivre, 2008). Specifically, all models use an arc-eager transition strategy and are trained using the averaged perceptron algorithm as in Zhang and Clark (2008) with a beam size of 8. The features used by all models are: the part-of-speech tags of the first four words on the buffer and of the top two words on the stack; the word identities of the first two words on the buffer and of the top word on the stack; the word identity of the syntactic head of the top word on the stack (if available). All feature conjunctions are included. For treebanks with non-projective trees we use the pseudo-projective parsing technique to transform the treebank into projective structures (Nivre and Nilsson, 2005). We focus on using this parsing system for two reasons. First, the parser is near state-of-the-art on English parsing benchmarks and second, and more importantly, the parser is extremely fast to train and run, making it easy to run a large number of experiments. Preliminary experiments using a different dependency parser – MSTParser (McDonald et al., 2005) – resulted in similar empirical observations.

2.3 Evaluation

All systems are evaluated using unlabeled attachment score (UAS), which is the percentage of words (ignoring punctuation tokens) in a corpus that modify the correct head (Buchholz and Marsi, 2006). Furthermore, we evaluate with both gold-standard part-of-speech tags, as well as predicted part-of-speech tags from the projected part-of-speech tagger of Das and Petrov (2011).[2] This tagger relies only on labeled training data for English, and achieves accuracies around 85% on the languages that we consider. We evaluate in the former setting to compare to previous studies that make this assumption. We evaluate in the latter setting to measure performance in a more realistic scenario – when no target language resources are available.

3 Transferring from English

To simplify discussion, we first focus on the most common instantiation of parser transfer in the literature: transferring from English to other languages. In the next section we expand our system to allow for the inclusion of multiple source languages.

3.1 Direct Transfer

We start with the observation that discriminatively trained dependency parsers rely heavily on part-of-speech tagging features. For example, when training and testing a parser on our English data, a parser with all features obtains an UAS of 89.3%[3] whereas

[2] Available at http://code.google.com/p/pos-projection/

[3] The best system at CoNLL 2007 achieved 90.1% and used a richer part-of-speech tagset (Nivre et al., 2007).

a *delexicalized* parser – a parser that only has non-lexical features – obtains an UAS of 82.5%. The key observation is that part-of-speech tags contain a significant amount of information for unlabeled dependency parsing.

This observation combined with our universal part-of-speech tagset, leads to the idea of *direct transfer*, i.e., directly parsing the target language with the source language parser without relying on parallel corpora. This idea has been previously explored by Zeman and Resnik (2008) and recently by Søgaard (2011). Because we use a mapping of the treebank specific part-of-speech tags to a common tagset, the performance of a such a system is easy to measure – simply parse the target language data set with a delexicalized parser trained on the source language data. We conducted two experiments. In the first, we assumed that the test set for each target language had gold part-of-speech tags, and in the second we used predicted part-of-speech tags from the projection tagger of Das and Petrov (2011), which also uses English as the source language.

UAS for all sentence lengths without punctuation are given in Table 1. We report results for both the English direct transfer parser (en-dir.) as well as a baseline unsupervised grammar induction system – the dependency model with valence (DMV) of Klein and Manning (2004), as obtained by the implementation of Ganchev et al. (2010). We trained on sentences of length 10 or less and evaluated on all sentences from the test set.[4] For DMV, we reversed the direction of all dependencies if this led to higher performance. From this table we can see that direct transfer is a very strong baseline and is over 20% absolute better than the DMV model for both gold and predicted POS tags. Table 4, which we will discuss in more detail later, further shows that the direct transfer parser also significantly outperforms state-of-the-art unsupervised grammar induction models, but in a more limited setting of sentences of length less than 10.

Direct transfer works for a couple of reasons. First, part-of-speech tags contain a significant amount of information for parsing unlabeled dependencies. Second, this information can be transferred, to some degree, across languages and treebank standards. This is because, at least for Indo-European languages, there is some regularity in how syntax is expressed, e.g., primarily SVO, prepositional, etc. Even though there are some differences with respect to relative location of certain word classes, strong head-modifier POS tag preferences can still help resolve these, especially when no other viable alternatives are available. Consider for example an artificial sentence with a tag sequence: 'VERB NOUN ADJ DET PUNC'. The English parser still predicts that the NOUN and PUNC modify the VERB and the ADJ and DET modify the NOUN, even though in the English data such noun phrases are unlikely.[5]

3.2 Projected Transfer

Unlike most language transfer systems for parsers, the direct transfer approach does not rely on projecting syntax across aligned parallel corpora (modulo the fact that non-gold tags come from a system that uses parallel corpora). In this section we describe a simple mechanism for projecting from the direct transfer system using large amounts of parallel data in a similar vein to Hwa et al. (2005), Ganchev et al. (2009), Smith and Eisner (2009) inter alia. The algorithm is based on the work of Hall et al. (2011) for training extrinsic parser objective functions and borrows heavily from ideas in learning with weak supervision including work on learning with constraints (Chang et al., 2007) and posterior regularization (Ganchev et al., 2010). In our case, the weak signals come from aligned source and target sentences, and the agreement in their corresponding parses, which is similar to posterior regularization or the bilingual view of Smith and Smith (2004) and Burkett et al. (2010).

The algorithm is given in Figure 2. It starts by labeling a set of target language sentences with a parser, which in our case is the direct transfer parser from the previous section (line 1). Next, it uses these parsed target sentences to 'seed' a new parser by training a parameter vector using the predicted parses as a gold standard via standard perceptron updates for J rounds (lines 3-6). This generates a parser that emulates the direct transfer parser, but

[4] Training on all sentences results in slightly lower accuracies on average.

[5] This requires a transition-based parser with a beam greater than 1 to allow for ambiguity to be resolved at later stages.

Notation:

x:	input sentence
y:	dependency tree
a:	alignment
w:	parameter vector
$\phi(x, y)$:	feature vector
DP:	dependency parser, i.e., $DP : x \rightarrow y$

Input:

$\mathcal{X} = \{x_i\}_{i=1}^{n}$:	target language sentences
$\mathcal{P} = \{(x_i^s, x_i^t, a_i)\}_{i=1}^{m}$:	aligned source-target sentences
DP_{delex}:	delexicalized source parser
DP_{lex}:	lexicalized source parser

Algorithm:

1. Let $\mathcal{X}' = \{(x_i, y_i)\}_{i=1}^{n}$ where $y_i = DP_{\text{delex}}(x_i)$
2. $w = 0$

seed-stage

3. for $j : 1 \ldots J$
4. for $x_i : x_1 \ldots x_n$
5. Let $y = \text{argmax}_y \, w \cdot \phi(x_i, y)$
6. $w = w + \phi(x_t, y_i) - \phi(x_i, y)$

projection-stage

7. for $(x_i^s, x_i^t, a_i) : (x_1^s, x_1^t, a_1) \ldots (x_m^s, x_m^s, a_m)$
8. Let $y_s = DP_{\text{lex}}(x_i^s)$
9. Let $\mathcal{Y}_t = \{y_i^1, \ldots, y_i^k\}$, where:
   $y_i^k = \text{argmax}_{y \notin \{y_i^1, \ldots, y_i^{k-1}\}} \, w \cdot \phi(x_i^t, y)$
10. Let $y_t = \text{argmax}_{y_t \in \mathcal{Y}_t} \text{ALIGN}(y_s, y_t, a_i)$
11. $w = w + \phi(x_i, y_t) - \phi(x_i, y_i^1)$

return DP^* such that $DP^*(x) = \text{argmax}_y \, w \cdot \phi(x, y)$

Figure 2: Perceptron-based learning algorithm for training a parser by seeding the model with a direct transfer parser and projecting constraints across parallel corpora.

has now been lexicalized and is working in the space of target language sentences. Next, the algorithm iterates over the sentences in the parallel corpus. It parses the English sentence with an English parser (line 8, again a lexicalized parser). It then uses the current target language parameter vector to create a k-best parse list for the target sentence (line 9). From this list, it selects the parse whose dependencies align most closely with the English parse via the pre-specified alignment (line 10, also see below for the definition of the ALIGN function). It then uses this selected parse as a proxy to the gold standard parse to update the parameters (line 11).

The intuition is simple. The parser starts with non-random accuracies by emulating the direct transfer model and slowly tries to induce better parameters by selecting parses from its k-best list that are considered 'good' by some external metric. The algorithm then updates towards that output. In this case 'goodness' is determined through the pre-specified sentence alignment and how well the target language parse aligns with the English parse. As a result, the model will, ideally, converge to a state where it predicts target parses that align as closely as possible with the corresponding English parses. However, since we seed the learner with the direct transfer parser, we bias the parameters to select parses that both align well and also have high scores under the direct transfer model. This helps to not only constrain the search space at the start of learning, but also helps to bias dependencies between words that are not part of the alignment.

So far we have not defined the ALIGN function that is used to score potential parses. Let $a = \{(s_{(1)}, t_{(1)}), \ldots, (s_{(n)}, t_{(n)})\}$ be an alignment where $s_{(i)}$ is a word in the source sentence x_s (not necessarily the i^{th} word) and $t_{(i)}$ is similarly a word in the target sentence x_t (again, not necessarily the i^{th} word). The notation $(s_{(i)}, t_{(i)}) \in a$ indicates two words are the i^{th} aligned pair in a. We define the ALIGN function to encode the Direct Correspondence Assumption (DCA) from Hwa et al. (2005):

$$\text{ALIGN}(y_s, y_t, a) = \sum_{\substack{(s_{(i)}, t_{(i)}) \in a \\ (s_{(j)}, t_{(j)}) \in a}} \text{SCORE}(y_s, y_t, (s_{(i)}, s_{(j)}), (t_{(i)}, t_{(j)}))$$

$$\text{SCORE}(y_s, y_t, (s_{(i)}, s_{(j)}), (t_{(i)}, t_{(j)})) = \begin{cases} +1 & \text{if } (s_{(i)}, s_{(j)}) \in y_s \text{ and } (t_{(i)}, t_{(j)}) \in y_t \\ -1 & \text{if } (s_{(i)}, s_{(j)}) \in y_s \text{ and } (t_{(i)}, t_{(j)}) \notin y_t \\ -1 & \text{if } (s_{(i)}, s_{(j)}) \notin y_s \text{ and } (t_{(i)}, t_{(j)}) \in y_t \\ 0 & \text{otherwise} \end{cases}$$

The notation $(i, j) \in y$ indicates that a dependency from head i to modifier j is in tree y. The ALIGN function rewards aligned head-modifier pairs and penalizes unaligned pairs when a possible alignment exists. For all other cases it is agnostic, i.e., when one or both of the modifier or head are not aligned.

Figure 3 shows an example of aligned English-Greek sentences, the English parse and a potential Greek parse. In this case the ALIGN function returns a value of 2. This is because there are three aligned dependencies: *took*→*book*, *book*→*the* and

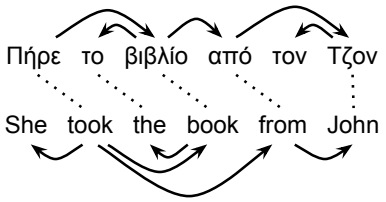

Figure 3: A Greek and English sentence pair. Word alignments are shown as dashed lines, dependency arcs as solid lines.

from→John. These add 3 to the score. There is one incorrectly aligned dependency: the preposition mistakenly modifies the noun on the Greek side. This subtracts 1. Finally, there are two dependencies that do not align: the subject on the English side and a determiner to a proper noun on the Greek side. These do not effect the result.

The learning algorithm in Figure 2 is an instance of augmented-loss training (Hall et al., 2011) which is closely related to the constraint driven learning algorithms of Chang et al. (2007). In that work, external constraints on output structures are used to help guide the learner to good parameter regions. In our model, we use constraints drawn from parallel data exactly in the same manner. Since posterior regularization is closely related to constraint driven learning, this makes our algorithm also similar to the parser projection approach of Ganchev et al. (2009). There are a couple of differences. First, we bias our model towards the direct transfer model, which is already quite powerful. Second, our alignment constraints are used to select parses from a k-best list, whereas in posterior regularization they are used as soft constraints on full model expectations during training. The latter is beneficial as the use of k-best lists does not limit the class of parsers to those whose parameters and search space decompose neatly with the DCA loss function. An empirical comparison to Ganchev et al. (2009) is given in Section 5.

Results are given in Table 1 under the column *en-proj*. For all experiments we train the seed-stage perceptron for 5 iterations ($J = 5$) and we use one hundred times as much parallel data as seed stage non-parallel data ($m = 100n$). The seed-stage non-parallel data is the training portion of each treebank, stripped of all dependency annotations. After training the projected parser we average the parameters

Table 1: UAS for the unsupervised DMV model (DMV), a delexicalized English direct transfer parser (en-dir.) and a English projected parser (en-proj.). Measured on all sentence lengths for both gold and predicted part-of-speech tags as input.

of the model (Collins, 2002). The parsers evaluated using predicted part-of-speech tags use the predicted tags at both training and testing time and are thus free of any target language specific resources.

When compared with the direct transfer model (en-dir. in Table 1), we can see that there is an improvement for every single language, reducing relative error by 8% on average (57.0% to 60.4%) and up to 18% for Dutch (60.8 to 67.8%). One could wonder whether the true power of the projection model comes from the re-lexicalization step – lines 3-6 of the algorithm. However, if just this step is run, then the average UAS only increases from 57.0% to 57.4%, showing that most of the improvement comes from the projection stage. Note that the results in Table 1 indicate that parsers using predicted part-of-speech tags are only slightly worse than the parsers using gold tags (about 2-3% absolute), showing that these methods are robust to tagging errors.

4 Multi-Source Transfer

The previous section focused on transferring an English parser to a new target language. However, there are over 20 treebanks available for a variety of language groups including Indo-European, Altaic (including Japanese), Semitic, and Sino-Tibetan. Many of these are even in standardized formats (Buchholz and Marsi, 2006; Nivre et al., 2007). Past studies have shown that for both part-of-speech tagging and grammar induction, learning with multiple comparable languages leads to improvements (Cohen and Smith, 2009; Snyder et al., 2009; Berg-Kirkpatrick and Klein, 2010). In this section we ex-

Table 2: UAS for all source-target language pairs. Each column represents which source language was used to train a delexicalized parser and each row represents which target language test data was used. Bold numbers are when source equals target and underlined numbers are the single best UAS for a target language. Results are for all sentence lengths without punctuation.

amine whether this is also true for parser transfer.

Table 2 shows the matrix of source-target language UAS for all nine languages we consider (the original eight target languages plus English). We can see that there is a wide range from 33.3% to 74.7%. There is also a wide range of values depending on the source training data and/or target testing data, e.g., Portuguese as a source tends to parse target languages much better than Danish, and is also more amenable as a target testing language. Some of these variations are expected, e.g., the Romance languages (Spanish, Italian and Portuguese) tend to transfer well to one another. However, some are unexpected, e.g., Greek being the best source language for Dutch, as well as German being one of the worst. This is almost certainly due to different annotation schemes across treebanks. Overall, Table 2 does indicate that there are possible gains in accuracy through the inclusion of additional languages.

In order to take advantage of treebanks in multiple languages, our multi-source system simply concatenates the training data from all non-target languages. In other words, the multi-source direct transfer parser for Danish will be trained by first concatenating the training corpora of the remaining eight languages, training a delexicalized parser on this data and then directly using this parser to analyze the Danish test data. For the multi-source projected parser, the procedure is identical to that in Section 3.2 except that we use the multi-source direct transfer model to seed the algorithm instead of the English-only direct transfer model. For these experiments we still only use English-target parallel data because that is the format of the readily available data in the Europarl corpus.

Table 3 presents four sets of results. The first (best-source) is the direct transfer results for the oracle single-best source language per target language. The second (avg-source) is the mean UAS over all source languages per target language. The third (multi-dir.) is the multi-source direct transfer system. The fourth and final result set (multi-proj.) is the multi-source projected system. The resulting parsers are typically much more accurate than the English direct transfer system (Table 1). On average, the multi-source direct transfer system reduces errors by 10% relative over the English-only direct transfer system. These improvements are not consistent. For Greek and Dutch we see significant losses relative to the English-only system. An inspection of Table 2 shows that for these two languages English is a particularly good source training language.

For the multi-source projected system the results are mixed. Some languages see basically no change relative the multi-source direct transfer model, while some languages see modest to significant increases. But again, there is an overall trend to better models. In particular, starting with an English-only direct transfer parser with 57.0% UAS on average, by adding parallel corpora and multiple source languages we finish with parser having 63.8% UAS on average, which is a relative reduction in error of roughly 16% and more than doubles the performance of a DMV model (Table 1).

Interestingly, the multi-source systems provide, on average, accuracies near that of the single-best source language and significantly better than the average source UAS. Thus, even this simple method of

multi-source transfer already provides strong performance gains. We expect that more principled techniques will lead to further improvements. For example, recent work by Søgaard (2011) explores data set sub-sampling methods. Unlike our work, Søgaard found that simply concatenating all the data led to degradation in performance. Cohen et al. (2011) explores the idea learning language specific mixture coefficients for models trained independently on the target language treebanks. However, their results show that this method often did not significantly outperform uniform mixing.

5 Comparison

Comparing unsupervised and parser projection systems is difficult as many publications use non-overlapping sets of languages or different evaluation criteria. We compare to the following three systems that do not augment the treebanks and report results for some of the languages that we considered:

- **USR**: The weakly supervised system of Naseem et al. (2010), in which manually defined universal syntactic rules (USR) are used to constrain a probabilistic Bayesian model. In addition to their original results, we also report results using the same part-of-speech tagset as the systems described in this paper (**USR**†). This is useful for two reasons. First, it makes the comparison more direct. Second, we can generate USR results for all eight languages and not just for the languages that they report.

- **PGI**: The phylogenetic grammar induction (PGI) model of Berg-Kirkpatrick and Klein (2010), in which the parameters of completely unsupervised DMV models for multiple languages are coupled via a phylogenetic prior.

- **PR**: The posterior regularization (PR) approach of Ganchev et al. (2009), in which a supervised English parser is used to generate constraints that are projected using a parallel corpus and used to regularize a target language parser. We report results without treebank specific rules.

Table 4 gives results comparing the models presented in this work to those three systems. For this comparison we use sentences of length 10 or less after punctuation has been removed in order to be consistent with reported results. The overall trends carry over from the full treebank setting to this reduced sentence length setup: the projected models outperform the direct transfer models and multi-source transfer gives higher accuracy than transferring only from English. Most previous work has assumed gold part-of-speech tags, but as the code for USR is publicly available we were able to train it using the same projected part-of-speech tags used in our models. These results are also given in Table 4 under USR†. Again, we can see that the multi-source systems (both direct and projected) significantly outperform the unsupervised models.

It is not surprising that a parser transferred from annotated resources does significantly better than unsupervised systems since it has much more information from which to learn. The PR system of Ganchev et al. (2009) is similar to ours as it also projects syntax across parallel corpora. For Spanish we can see that the multi-source direct transfer parser is better (75.1% versus 70.6%), and this is also true for the multi-source projected parser

Table 4: UAS on sentences of length 10 or less without punctuation, comparing the systems presented in this work to three representative systems from related work. en-dir./en-proj. are the direct/projected English parsers and multi-dir./multi-proj. are the multi-source direct/projected parsers. Section 5 contains a description of the baseline systems.

(73.2%). Ganchev et al. also report results for Bulgarian. We trained a multi-source direct transfer parser for Bulgarian which obtained a score of 72.8% versus 67.8% for the PR system. If we only use English as a source language, as in Ganchev et al., the English direct transfer model achieves 66.1% on Bulgarian and 69.3% on Spanish versus 67.8% and 70.6% for PR. In this setting the English projected model gets 72.0% on Spanish. Thus, under identical conditions the direct transfer model obtains accuracies comparable to PR.[6]

Another projection based system is that of Smith and Eisner (2009), who report results for German (68.5%) and Spanish (64.8%) on sentences of length 15 and less inclusive of punctuation. Smith and Eisner use custom splits of the data and modify a subset of the dependencies. The multi-source projected parser obtains 71.9% for German and 67.8% for Spanish on this setup.[7] If we cherry-pick the source language the results can improve, e.g., for Spanish we can obtain 71.7% and 70.8% by directly transferring parsers form Italian or Portuguese respectively.

6 Discussion

One fundamental point the above experiments illustrate is that even for languages for which no resources exist, simple methods for transferring parsers work remarkably well. In particular, if one can transfer part-of-speech tags, then a large part of transferring unlabeled dependencies has been solved. This observation should lead to a new baseline in unsupervised and projected grammar induction – the UAS of a delexicalized English parser. Of course, our experiments focus strictly on Indo-European languages. Preliminary experiments for Arabic (ar), Chinese (zh), and Japanese (ja) suggest similar direct transfer methods are applicable. For example, on the CoNLL test sets, a DMV model obtains UAS of 28.7/41.8/34.6% for ar/zh/ja respectively, whereas an English direct transfer parser obtains 32.1/53.8/32.2% and a multi-source direct transfer parser obtains 39.9/41.7/43.3%. In this setting only Indo-European languages are used as source data. Thus, even across language groups direct transfer is a reasonable baseline. However, this is not necessary as treebanks are available for a number of language groups, e.g., Indo-European, Altaic, Semitic, and Sino-Tibetan.

The second fundamental observation is that when available, multiple sources should be used. Even through naive multi-source methods (concatenating data), it is possible to build a system that has comparable accuracy to the single-best source for all languages. This advantage does not come simply from having more data. In fact, if we randomly sampled from the multi-source data until the training set size was equivalent to the size of the English data, then the results still hold (and in fact go up slightly for some languages). This suggests that even better transfer models can be produced by separately weighting each of the sources depending on the target language – either weighting by hand, if we know the language group of the target language, or auto-

[6] Note that the last set of results was obtained by using the same English training data as Ganchev et al. Using the CoNLL 2007 English data set for training, the English direct transfer model is 63.2% for Bulgarian and 58.0% for Spanish versus 67.8% and 70.6% for PR, highlighting the large impact that difference treebank annotation standards can have.

[7] Data sets and evaluation criteria obtained via communications with David Smith and Jason Eisner.

matically, if we do not. As previously mentioned, the latter has been explored in both Søgaard (2011) and Cohen et al. (2011).

7 Conclusions

We presented a simple, yet effective approach for projecting parsers from languages with labeled training data to languages without any labeled training data. Central to our approach is the idea of delexicalizing the models, which combined with a standardized part-of-speech tagset allows us to directly transfer models between languages. We then use a constraint driven learning algorithm to adapt the transferred parsers to the respective target language, obtaining an additional 16% error reduction on average in a multi-source setting. Our final parsers achieve state-of-the-art accuracies on eight Indo-European languages, significantly outperforming previous unsupervised and projected systems.

Abstract

We propose a method to improve the accuracy of parsing bilingual texts (bitexts) with the help of statistical machine translation (SMT) systems. Previous bitext parsing methods use human-annotated bilingual treebanks that are hard to obtain. Instead, our approach uses an auto-generated bilingual treebank to produce bilingual constraints. However, because the auto-generated bilingual treebank contains errors, the bilingual constraints are noisy. To overcome this problem, we use large-scale unannotated data to verify the constraints and design a set of effective bilingual features for parsing models based on the verified results. The experimental results show that our new parsers significantly outperform state-of-the-art baselines. Moreover, our approach is still able to provide improvement when we use a larger monolingual treebank that results in a much stronger baseline. Especially notable is that our approach can be used in a purely monolingual setting with the help of SMT.

1 Introduction

Recently there have been several studies aiming to improve the performance of parsing bilingual texts (bitexts) (Smith and Smith, 2004; Burkett and Klein, 2008; Huang et al., 2009; Zhao et al., 2009; Chen et al., 2010). In bitext parsing, we can use the information based on "bilingual constraints" (Burkett and Klein, 2008), which do not exist in monolingual sentences. More accurate bitext parsing results can be effectively used in the training of syntax-based machine translation systems (Liu and Huang, 2010).

Most previous studies rely on bilingual treebanks to provide bilingual constraints for bitext parsing. Burkett and Klein (2008) proposed joint models on bitexts to improve the performance on either or both sides. Their method uses bilingual treebanks that have human-annotated tree structures on both sides. Huang et al. (2009) presented a method to train a source-language parser by using the reordering information on words between the sentences on two sides. It uses another type of bilingual treebanks that have tree structures on the source sentences and their human-translated sentences. Chen et al. (2010) also used bilingual treebanks and made use of tree structures on the target side. However, the bilingual treebanks are hard to obtain, partly because of the high cost of human translation. Thus, in their experiments, they applied their methods to a small data set, the manually translated portion of the Chinese Treebank (CTB) which contains only about 3,000 sentences. On the other hand, many large-scale monolingual treebanks exist, such as the Penn English Treebank (PTB) (Marcus et al., 1993) (about 40,000 sentences in Version 3) and the latest version of CTB (over 50,000 sentences in Version 7).

In this paper, we propose a bitext parsing approach in which we produce the bilingual constraints on existing monolingual treebanks with the help of SMT systems. In other words, we aim to improve source-language parsing with the help of automatic translations.

In our approach, we first use an SMT system to translate the sentences of a source monolingual treebank into the target language. Then, the target sentences are parsed by a parser trained on a target monolingual treebank. We then obtain a bilingual treebank that has human annotated trees on the source side and auto-generated trees on the target side. Although the sentences and parse trees on the

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 73–83,
Edinburgh, Scotland, UK, July 27–31, 2011.

target side are not perfect, we expect that we can improve bitext parsing performance by using this newly auto-generated bilingual treebank. We build word alignment links automatically using a word alignment tool. Then we can produce a set of bilingual constraints between the two sides.

Because the translation, parsing, and word alignment are done automatically, the constraints are not reliable. To overcome this problem, we verify the constraints by using large-scale unannotated monolingual sentences and bilingual sentence pairs. Finally, we design a set of bilingual features based on the verified results for parsing models.

Our approach uses existing resources including monolingual treebanks to train monolingual parsers on both sides, bilingual unannotated data to train SMT systems and to extract bilingual subtrees, and target monolingual unannotated data to extract monolingual subtrees. In summary, we make the following contributions:

- We propose an approach that uses an auto-generated bilingual treebank rather than human-annotated bilingual treebanks used in previous studies (Burkett and Klein, 2008; Huang et al., 2009; Chen et al., 2010). The auto-generated bilingual treebank is built with the help of SMT systems.
- We verify the unreliable constraints by using the existing large-scale unannotated data and design a set of effective bilingual features over the verified results. Compared to Chen et al. (2010) that also used tree structures on the target side, our approach defines the features on the auto-translated sentences and auto-parsed trees, while theirs generates the features by some rules on the human-translated sentences.
- Our parser significantly outperforms state-of-the-art baseline systems on the standard test data of CTB containing about 3,000 sentences. Moreover, our approach continues to achieve improvement when we build our system using the latest version of CTB (over 50,000 sentences) that results in a much stronger baseline.
- We show the possibility that we can improve the performance even if the test set has no human translation. This means that our proposed approach can be used in a purely monolingual setting with the help of SMT. To our knowledge, this paper is the first one that demonstrates this widened applicability, unlike the previous studies that assumed that the parser is applied only on the bitexts made by humans.

Throughout this paper, we use Chinese as the source language and English as the target language. The rest of this paper is organized as follows. Section 2 introduces the motivation of this work. Section 3 briefly introduces the parsing model used in the experiments. Section 4 describes a set of bilingual features based on the bilingual constraints and Section 5 describes how to use large-scale unannotated data to verify the bilingual constraints and define another set of bilingual features based on the verified results. Section 6 explains the experimental results. Finally, in Section 7 we draw conclusions.

2 Motivation

Here, bitext parsing is the task of parsing source sentences with the help of their corresponding translations. Figure 1-(a) shows an example of the input of bitext parsing, where ROOT is an artificial root token inserted at the beginning and does not depend on any other token in the sentence, the dashed undirected links are word alignment links, and the directed links between words indicate that they have a dependency relation. Given such inputs, we build dependency trees for the source sentences. Figure 1-(b) shows the output of bitext parsing for the example in 1-(a).

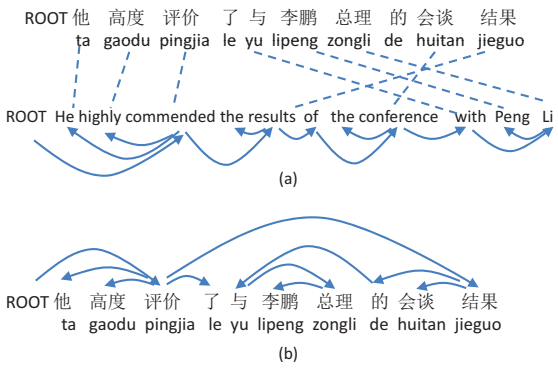

Figure 1: Input and output of our approach

In bitext parsing, some ambiguities exist on the source side, but they may be unambiguous on the

target side. These differences are expected to help improve source-side parsing.

Suppose we have a Chinese sentence shown in Figure 2-(a). In this sentence, there is a nominalization case (Li and Thompson, 1997) in which the particle "的(de)/nominalizer" is placed after the verb compound "培育(peiyu)起来(qilai)/cultivate" to modify "技巧(jiqiao)/skill". This nominalization is a relative clause, but does not have a clue about its boundary. That is, it is very hard to determine which word is the head of "技巧(jiqiao)/skill". The head may be "发挥(fahui)/demonstrate" or "培育(peiyu)/cultivate", as shown in Figure 2-(b) and -(c), where (b) is correct.

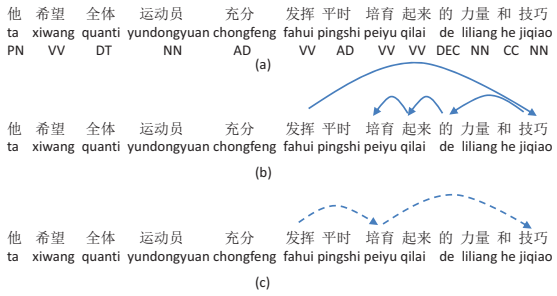

Figure 2: Example of an ambiguity on the Chinese side

In its English translation (Figure 3), word "that" is a clue indicating the relative clause which shows the relation between "skill" and "cultivate", as shown in Figure 3. The figure shows that the translation can provide useful bilingual constraints. From the dependency tree on the target side, we find that the word "skill" corresponding to "技巧(jiqiao)/skill" depends on the word "demonstrate" corresponding to "发挥(fahui)/demonstrate", while the word "cultivate" corresponding to "培育(peiyu)/cultivate" is a grandchild of "skill". This is a positive evidence for supporting "发挥(fahui)/demonstrate" as being the head of "技巧(jiqiao)/skill".

The above case uses the human translation on the target side. However, there are few human-annotated bilingual treebanks and the existing bilingual treebanks are usually small. In contrast, there are large-scale monolingual treebanks, e.g., the PTB and the latest version of CTB. So we want to use existing resources to generate a bilingual treebank with the help of SMT systems. We hope to improve source side parsing by using this newly built bilingual treebank.

Figure 3: Example of human translation

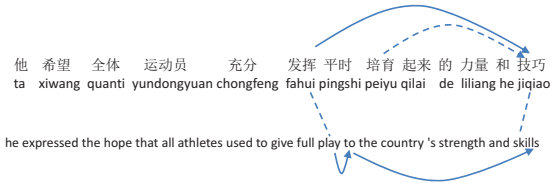

Figure 4: Example of Moses translation

Figure 4 shows an example of a translation using a Moses-based system, where the target sentence is parsed by a monolingual target parser. The translation contains some errors, but it does contain some correct parts that can be used for disambiguation. In the figure, the word "skills" corresponding to "技巧(jiqiao)/skill" is a grandchild of the word "play" corresponding to "发挥(fahui)/demonstrate". This is a positive evidence for supporting "发挥(fahui)/demonstrate" as being the head of "技巧(jiqiao)/skill".

From this example, although the sentences and parse trees on the target side are not perfect, we still can explore useful information to improve bitext parsing. In this paper, we focus on how to design a method to verify such unreliable bilingual constraints.

3 Parsing model

In this paper, we implement our approach based on graph-based parsing models (McDonald and Pereira, 2006; Carreras, 2007). Note that our approach can also be applied to transition-based parsing models (Nivre, 2003; Yamada and Matsumoto, 2003).

The graph-based parsing model is to search for the maximum spanning tree (MST) in a graph (McDonald and Pereira, 2006). The formulation defines the score of a dependency tree to be the sum of edge scores,

$$s(x, y) = \sum_{g \in y} score(w, x, g) = \sum_{g \in y} w \cdot f(x, g) \quad (1)$$

where x is an input sentence, y is a dependency tree for x, and g is a spanning subgraph of y. $f(x, g)$ can be based on arbitrary features of the subgraph and the input sequence x and the feature weight vector w are the parameters to be learned by using MIRA (Crammer and Singer, 2003) during training.

In our approach, we use two types of features for the parsing model. One is monolingual features based on the source sentences. The monolingual features include the first- and second- order features presented in McDonald and Pereira (2006) and the parent-child-grandchild features used in Carreras (2007). The other one is bilingual features (described in Sections 4 and 5) that consider the bilingual constraints.

We call the parser with the monolingual features on the source side Parser^s, and the parser with the monolingual features on the target side Parser^t.

4 Original bilingual features

In this paper, we generate two types of bilingual features, original and verified bilingual features. The original bilingual features (described in this section) are based on the bilingual constraints without being verified by large-scale unannotated data. And the verified bilingual features (described in Section 5) are based on the bilingual constraints verified by using large-scale unannotated data.

4.1 Auto-generated bilingual treebank

Assuming that we have monolingual treebanks on the source side, an SMT system that can translate the source sentences into the target language, and a Parser^t trained on the target monolingual treebank.

We first translate the sentences of the source monolingual treebank into the target language using the SMT system. Usually, SMT systems can output the word alignment links directly. If they can not, we perform word alignment using some publicly available tools, such as Giza++ (Och and Ney, 2003) or Berkeley Aligner (Liang et al., 2006; DeNero and Klein, 2007). The translated sentences are parsed by the Parser^t. Then, we have a newly auto-generated bilingual treebank.

4.2 Bilingual constraint functions

In this paper, we focus on the first- and second-order graph models (McDonald and Pereira, 2006; Carreras, 2007). Thus we produce the constraints for bigram (a single edge) and trigram (adjacent edges) dependencies in the graph model. For the trigram dependencies, we consider the parent-sibling and parent-child-grandchild structures described in McDonald and Pereira (2006) and Carreras (2007). We leave the third-order models (Koo and Collins, 2010) for a future study.

Suppose that we have a (candidate) dependency relation r_s that can be a bigram or trigram dependency. We examine whether the corresponding words of the source words of r_s have a dependency relation r_t in the target trees. We also consider the direction of the dependency relation. The corresponding word of the head should also be the head in r_t. We define a binary function for this bilingual constraint: $F_{bn}(r_{sn} : r_{tk})$, where n and k refers to the types of the dependencies (2 for bigram and 3 for trigram). For example, in $r_{s2} : r_{t3}$, r_{s2} is a bigram dependency on the source side and r_{t3} is a trigram dependency on the target side.

4.2.1 Bigram constraint function: F_{b2}

For r_{s2}, we consider two types of bilingual constraints. The first constraint function, denoted as $F_{b2}(r_{s2} : r_{t2})$, checks if the corresponding words also have a direct dependency relation r_{t2}. Figure 5 shows an example, where the source word "全体(quanti)" depends on "运动员(yundongyuan)" and word "all" corresponding to "全体(quanti)" depends on word "athletes" corresponding to "运动员(yundongyuan)". In this case, $F_{b2}(r_{s2} : r_{t2}) = +$. However, when the source words are "他(ta)" and "希望(xiwang)", this time their corresponding words "He" and "hope" do not have a direct dependency relation. In this case, $F_{b2}(r_{s2} : r_{t2}) = -$.

The second constraint function, denoted as $F_{b2}(r_{s2} : r_{t3})$, checks if the corresponding words form a parent-child-grandchild relation that often occurs in translation (Koehn et al., 2003). Figure 6 shows an example. The source word "技巧(jiqiao)" depends on "发挥(fahui)" while its corresponding word "skills" indirectly depends on "play" which corresponds to "发挥(fahui)" via "to". In this case, $F_{b2}(r_{s2} : r_{t3}) = +$.

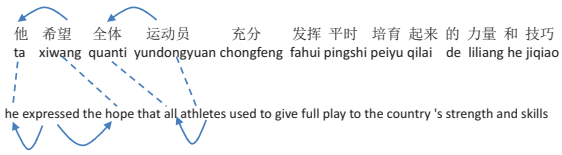

Figure 5: Example of bilingual constraints (2to2)

Figure 6: Example of bilingual constraints (2to3)

4.2.2 Trigram constraint function: F_{b3}

For a second-order relation on the source side, we consider one type of constraint. We have three source words that form a second-order relation and all of them have the corresponding words. We define function $F_{b3}(r_{s3} : r_{t3})$ for this constraint. The function checks if the corresponding words form a trigram dependencies structure. An example is shown in Figure 7. The source words "力量(liliang)", "和(he)", and "技巧(jiqiao)" form a parent-sibling structure, while their corresponding words "strength", "and", and "skills" also form a parent-sibling structure on the target side. In this case, function $F_{b3}(r_{s3} : r_{t3}) = +$.

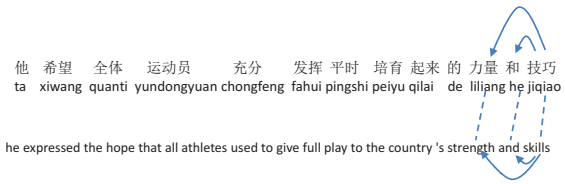

Figure 7: Example of bilingual constraints (3to3)

4.3 Bilingual reordering function: F_{ro}

Huang et al. (2009) proposed features based on reordering between languages for a shift-reduce parser. They define the features based on word-alignment information to verify whether the corresponding words form a contiguous span to resolve shift-reduce conflicts. We also implement similar features in our system. For example, in Figure 1-(a) the source span is [会谈(huitan), 结果(jieguo)], which maps onto [results, conference]. Because no word within this target span is aligned to a source word outside of the source span, this span is a contiguous span. In this case, function $F_{ro} = +$, otherwise $F_{ro} = -$.

4.4 Original bilingual features

We define original bilingual features based on the bilingual constraint functions and the bilingual reordering function.

Table 1 lists the original features, where Dir refers to the directions[1] of the source-side dependencies, F_{b2} can be $F_{b2}(r_{s2} : r_{t2})$ and $F_{b2}(r_{s2} : r_{t3})$, and F_{b3} is $F_{b3}(r_{s3} : r_{t3})$. Each line of the table defines a feature template that is a combination of functions.

First-order features	Second-order features
$\langle F_{ro} \rangle$	
$\langle F_{b2}, Dir \rangle$	$\langle F_{b3}, Dir \rangle$
$\langle F_{b2}, Dir, F_{ro} \rangle$	$\langle F_{b3}, Dir, F_{ro} \rangle$

Table 1: Original bilingual features

We use an example to show how to generate the original bilingual features in practice. In Figure 4, we want to define the bilingual features for the bigram dependency (r_{s2}) between "发挥(fahui)" and "技巧(jiqiao)". The corresponding words form a trigram relation r_{t3} in the target dependency tree. The direction of the bigram dependency is right. Then we have feature "$\langle F_{b2}(r_{s2} : r_{t3}) = +, RIGHT \rangle$" for the second first-order feature template in Table 1.

5 Verified bilingual features

However, because the bilingual treebank is generated automatically, using the bilingual constraints alone is not reliable. Therefore, in this section we verify the constraints by using large-scale unannotated data to overcome this problem. More specifically, r_{tk} of the constraint is verified by checking a list of target monolingual subtrees and $r_{sn} : r_{tk}$ is verified by checking a list of bilingual subtrees. The subtrees are extracted from the large-scale unannotated data. The basic idea is as follows: if the dependency structures of a bilingual constraint can be found in the list of the target monolingual subtrees

[1]For the second order features, Dir is the combination of the directions of two dependencies.

or bilingual subtrees, this constraint will probably be reliable.

We first parse the large-scale unannotated monolingual and bilingual data. Subsequently, we extract the monolingual and bilingual subtrees from the parsed data. We then verify the bilingual constraints using the extracted subtrees. Finally, we generate the bilingual features based on the verified results for the parsing models.

5.1 Verified constraint functions

5.1.1 Monolingual target subtrees

Chen et al. (2009) proposed a simple method to extract subtrees from large-scale monolingual data and used them as features to improve monolingual parsing. Following their method, we parse large unannotated data with the Parser^t and obtain the subtree list (ST_t) on the target side. We extract two types of subtrees: bigram (two words) subtree and trigram (three words) subtree.

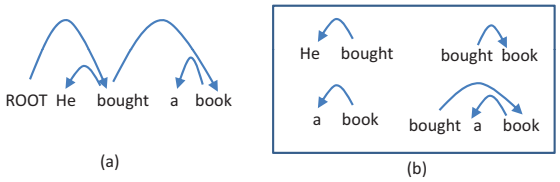

Figure 8: Example of monolingual subtree extraction

From the dependency tree in Figure 8-(a), we obtain the subtrees shown in Figure 8-(b) where the first three are bigram subtrees and the last one is a trigram subtree. After extraction, we obtain the subtree list ST_t that includes two sets, one for bigram subtrees, and the other one for trigram subtrees. We remove the subtrees occurring only once in the data. For each set, we assign labels to the extracted subtrees according to their frequencies by using the same method as that of Chen et al. (2009). If the frequency of a subtree is in the top 10% in the corresponding set, it is labeled HF. If the frequency is between the top 20% and 30%, it is labeled MF. We assign the label LF to the remaining subtrees. We use $Type(st_t)$ to refer to the label of a subtree, st_t.

5.1.2 Verified target constraint function: $F_{vt}(r_{tk})$

We use the extracted target subtrees to verify the r_{tk} of the bilingual constraints. In fact, r_{tk} is a candidate subtree. If the r_{tk} is included in ST_t, function $F_{vt}(r_{tk}) = Type(r_{tk})$, otherwise $F_{vt}(r_{tk}) = ZERO$. For example, in Figure 5 the bigram structure of "all" and "athletes" can form a bigram subtree that is included ST_t and its label is HF. In this case, $F_{vt}(r_{t2}) = HF$.

5.1.3 Bilingual subtrees

We extract bilingual subtrees from a bilingual corpus, which is parsed by the Parser^s and Parser^t on both sides. We extract three types of bilingual subtrees: bigram-bigram (st_{bi22}), bigram-trigram (st_{bi23}), and trigram-trigram (st_{bi33}) subtrees. For example, st_{bi22} consists of a bigram subtree on the source side and a bigram subtree on the target side.

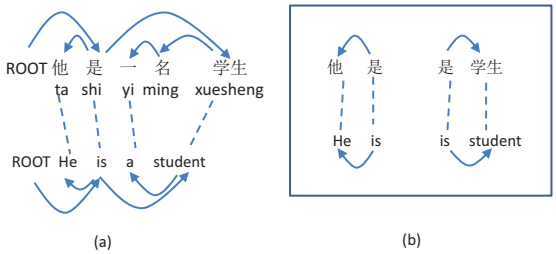

Figure 9: Example of bilingual subtree extraction

From the dependency tree in Figure 9-(a), we obtain the bilingual subtrees shown in Figure 9-(b). Figure 9-(b) shows the extracted bigram-bigram bilingual subtrees. After extraction, we obtain the bilingual subtrees ST_{bi}. We remove the subtrees occurring only once in the data.

5.1.4 Verified bilingual constraint function: $F_{vb}(r_{bink})$

We use the extracted bilingual subtrees to verify the r_{sn} : r_{tk} (r_{bink} in short) of the bilingual constraints. r_{sn} and r_{tk} form a candidate bilingual subtree st_{bink}. If the st_{bink} is included in ST_{bi}, function $F_{vb}(r_{bink}) = +$, otherwise $F_{vb}(r_{bink}) = -$.

5.2 Verified bilingual features

Then, we define another set of bilingual features by combining the verified constraint functions. We call these bilingual features 'verified bilingual features'.

Table 2 lists the verified bilingual features used in our experiments, where each line defines a feature template that is a combination of functions.

We use an example to show how to generate the verified bilingual features in practice. In Figure 4, we want to define the verified features for the bigram dependency (r_{s2}) between "发挥(fahui)" and "技巧(jiqiao)". The corresponding words form a trigram relation r_{t3}. The direction of the bigram dependency is right. Suppose we can find r_{t3} in ST_t with label MF and can not find the candidate bilingual subtree in ST_{bi}. Then we have feature "$\langle F_{b2}(r_{s2} : r_{t3}) = +, F_{vt}(r_{t3}) = MF, RIGHT\rangle$" for the third first-order feature template and feature "$\langle F_{b2}(r_{s2} : r_{t3}) = +, F_{vb}(r_{bi23}) = -, RIGHT\rangle$" for the fifth in Table 2.

First-order features	Second-order features
$\langle F_{ro}\rangle$	
$\langle F_{b2}, F_{vt}(r_{tk})\rangle$	$\langle F_{b3}, F_{vt}(r_{tk})\rangle$
$\langle F_{b2}, F_{vt}(r_{tk}), Dir\rangle$	$\langle F_{b3}, F_{vt}(r_{tk}), Dir\rangle$
$\langle F_{b2}, F_{vb}(r_{bink})\rangle$	$\langle F_{b3}, F_{vb}(r_{bink})\rangle$
$\langle F_{b2}, F_{vb}(r_{bink}), Dir\rangle$	$\langle F_{b3}, F_{vb}(r_{bink}), Dir\rangle$
$\langle F_{b2}, F_{ro}, F_{vb}(r_{bink})\rangle$	

Table 2: Verified bilingual features

6 Experiments

We evaluated the proposed method on the translated portion of the Chinese Treebank V2 (referred to as CTB2$_{tp}$) (Bies et al., 2007), articles 1-325 of CTB, which have English translations with gold-standard parse trees. The tool "Penn2Malt"[2] was used to convert the data into dependency structures. Following the studies of Burkett and Klein (2008), Huang et al. (2009) and Chen et al. (2010), we used the exact same data split: 1-270 for training, 301-325 for development, and 271-300 for testing. Note that we did not use human translation on the English side of this bilingual treebank to train our new parsers. For testing, we used two settings: a test with human translation and another with auto-translation. To process unannotated data, we trained a first-order Parser^s on the training data.

To prove that the proposed method can work on larger monolingual treebanks, we also tested our methods on the CTB7 (LDC2010T07) that includes much more sentences than CTB2$_{tp}$. We used articles 301-325 for development, 271-300 for testing, and the other articles for training. That is, we evaluated the systems on the same test data as CTB2$_{tp}$. Table 3 shows the statistical information on the data sets.

	Train	Dev	Test
CTB2$_{tp}$	2,745	273	290
CTB7	50,747	273	290

Table 3: Number of sentences of data sets used

We built Chinese-to-English SMT systems based on Moses[3]. Minimum error rate training (MERT) with respect to BLEU score was used to tune the decoder's parameters. The translation model was created from the FBIS corpus (LDC2003E14). We used SRILM[4] to train a 5-gram language model. The language model was trained on the target side of the FBIS corpus and the Xinhua news in English Gigaword corpus (LDC2009T13). The development and test sets were from NIST MT08 evaluation campaign[5]. We then used the SMT systems to translate the training data of CTB2$_{tp}$ and CTB7.

To directly compare with the results of Huang et al. (2009) and Chen et al. (2010), we also used the same word alignment tool, Berkeley Aligner (Liang et al., 2006; DeNero and Klein, 2007), to perform word alignment for CTB2$_{tp}$ and CTB7. We trained a Berkeley Aligner on the FBIS corpus (LDC2003E14). We removed notoriously bad links in {a, an, the}×{的(de), 了(le)} following the work of Huang et al. (2009).

To train an English parser, we used the PTB (Marcus et al., 1993) in our experiments and the tool "Penn2Malt" to convert the data. We split the data into a training set (sections 2-21), a development set (section 22), and a test set (section 23). We trained first-order and second-order Parser^t on the training data. The unlabeled attachment score (UAS) of the second-order Parser^t was 91.92, indicating state-of-the-art accuracy on the test data. We used the second-order Parser^t to parse the auto-translated/human-made target sentences in the CTB

[5] http://www.itl.nist.gov/iad/mig//tests/mt/2008/

data.

To extract English subtrees, we used the BLLIP corpus (Charniak et al., 2000) that contains about 43 million words of WSJ texts. We used the MX-POST tagger (Ratnaparkhi, 1996) trained on training data to assign POS tags and used the first-order Parser^t to process the sentences of the BLLIP corpus. To extract bilingual subtrees, we used the FBIS corpus and an additional bilingual corpus containing 800,000 sentence pairs from the training data of NIST MT08 evaluation campaign. On the Chinese side, we used the morphological analyzer described in (Kruengkrai et al., 2009) trained on the training data of CTB$_{tp}$ to perform word segmentation and POS tagging and used the first-order Parser^s to parse all the sentences in the data. On the English side, we used the same procedure as we did for the BLLIP corpus. Word alignment was performed using the Berkeley Aligner.

We reported the parser quality by the UAS, i.e., the percentage of tokens (excluding all punctuation tokens) with correct HEADs.

6.1 Experimental settings

For baseline systems, we used the monolingual features mentioned in Section 3. We called these features basic features. To compare the results of (Burkett and Klein, 2008; Huang et al., 2009; Chen et al., 2010), we used the test data with human translation in the following three experiments. The target sentences were parsed by using the second-order Parser^t. We used PAG to refer to our parsers trained on the auto-generated bilingual treebank.

6.2 Training with CTB2$_{tp}$

	Order-1	Order-2
Baseline	84.35	87.20
PAG$_o$	84.71(+0.36)	87.85(+0.65)
PAG	85.37(+1.02)	88.49(+1.29)
ORACLE	85.79(+1.44)	88.87(+1.67)

Table 4: Results of training with CTB2$_{tp}$

First, we conducted the experiments on the standard data set of CTB2$_{tp}$, which was also used in other studies (Burkett and Klein, 2008; Huang et al., 2009; Chen et al., 2010). The results are given in Table 4, where Baseline refers to the system with the basic features, PAG$_o$ refers to that after adding the original bilingual features of Table 1 to Baseline, PAG refers to that after adding the verified bilingual features of Table 2 to Baseline, and ORACLE[6] refers to using human-translation for training data with adding the features of Table 1. We obtained an absolute improvement of 1.02 points for the first-order model and 1.29 points for the second-order model by adding the verified bilingual features. The improvements of the final systems (PAG) over the Baselines were significant in McNemar's Test ($p < 0.001$ for the first-order model and $p < 0.0001$ for the second-order model). If we used the original bilingual features (PAG$_o$), the system dropped 0.66 points for the first-order and 0.64 points for the second-order compared with system PAG. This indicated that the verified bilingual constraints did provide useful information for the parsing models.

We also found that PAG was about 0.3 points lower than ORACLE. The reason is mainly due to the imperfect translations, although we used the large-scale subtree lists to help verify the constraints. We tried adding the features of Table 2 to the ORACLE system, but the results were worse. These facts indicated that our approach obtained the benefits from the verified constraints, while using the bilingual constraints alone was enough for ORACLE.

6.3 Training with CTB7

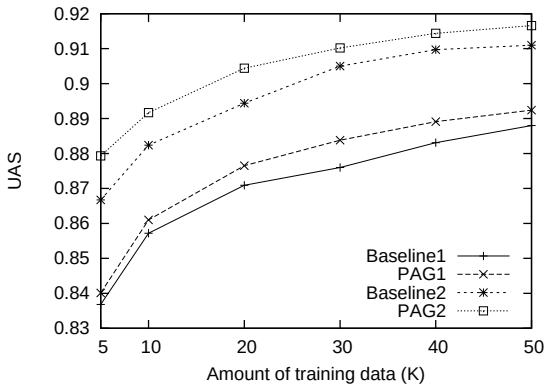

Figure 10: Results of using different sizes of training data

Here, we demonstrate that our approach is still able to provide improvement, even if we use larger

[6]Note that we also used the tool to perform the word alignment automatically.

	Baseline	D10	D20	D50	D100	GTran
BLEU	n/a	14.71	15.84	16.92	17.95	n/a
UAS	87.20	87.63	87.67	88.20	88.49	88.58

Table 5: Results of using different translations

training data that result in strong baseline systems. We incrementally increased the training sentences from the CTB7. Figure 10 shows the results of using different sizes of CTB7 training data, where the numbers of the x-axis refer to the sentence numbers of training data used, Baseline1 and Baseline2 refer to the first- and second-order baseline systems, and PAG1 and PAG2 refer to our first- and second-order systems. The figure indicated that our system always outperformed the baseline systems. For small data sizes, our system performed much better than the baselines. For example, when using 5,000 sentences, our second-order system provided a 1.26 points improvement over the second-order baseline. Finally, when we used all of the CTB7 training data, our system achieved 91.66 for the second-order model, while the baseline achieved 91.10.

6.4 With different settings of SMT systems

We investigated the effects of different settings of SMT systems. We randomly selected 10%, 20%, and 50% of FBIS to train the Moses systems and used them to translate CTB2$_{tp}$. The results are in Table 5, where D10, D20, D50, and D100 refer to the system with 10%, 20%, 50%, and 100% data respectively. For reference, we also used the Google-translate online system[7], indicated as GTran in the table, to translate the CTB2$_{tp}$.

From the table, we found that our system outperformed the Baseline even if we used only 10% of the FBIS corpus. The BLEU and UAS scores became higher, when we used more data of the FBIS corpus. And the gaps among the results of D50, D100, and GTran were small. This indicated that our approach was very robust to the noise produced by the SMT systems.

6.5 Testing with auto-translation

We also translated the test data into English using the Moses system and tested the parsers on the new test data. Table 6 shows the results. The results showed that PAG outperformed the baseline systems for both the first- and second-order models. This indicated that our approach can provide improvement in a purely monolingual setting with the help of SMT.

	Order-1	Order-2
Baseline	84.35	87.20
PAG	84.88(+0.53)	87.89(+0.69)

Table 6: Results of testing with auto-translation (training with CTB2$_{tp}$)

6.6 Comparison results

	With CTB2$_{tp}$		With CTB7	
Type	System	UAS	System	UAS
M	Baseline	87.20	Baseline	91.10
HA	Huang2009	86.3	n/a	
	Chen2010$_{BI}$	88.56		
	Chen2010$_{ALL}$	90.13		
AG	PAG	88.49	PAG	91.66
	PAG+ST$_s$	89.75		

Table 7: Comparison of our results with other previous reported systems. Type M denotes training on monolingual treebank. Types HA and AG denote training on human-annotated and auto-generated bilingual treebanks respectively.

We compared our results with the results reported previously for the same data. Table 7 lists the results, where Huang2009 refers to the result of Huang et al. (2009), Chen2010$_{BI}$ refers to the result of using bilingual features in Chen et al. (2010), and Chen2010$_{ALL}$ refers to the result of using all of the features in Chen et al. (2010). The results showed that our new parser achieved better accuracy than Huang2009 and comparable to Chen2010$_{BI}$. To achieve higher performance, we also added the source subtree features (Chen et al., 2009) to our system: PAG+ST$_s$. The new result is close to Chen2010$_{ALL}$. Compared with the approaches of

[7] http://translate.google.com/

Huang et al. (2009) and Chen et al. (2010), our approach used an auto-generated bilingual treebank while theirs used a human-annotated bilingual treebank. By using all of the training data of CTB7, we obtained a more powerful baseline that performed much better than the previous reported results. Our parser achieved 91.66, much higher accuracy than the others.

7 Conclusion

We have presented a simple yet effective approach to improve bitext parsing with the help of SMT systems. Although we trained our parser on an auto-generated bilingual treebank, we achieved an accuracy comparable to the systems trained on human-annotated bilingual treebanks on the standard test data. Moreover, our approach continued to provide improvement over the baseline systems when we used a much larger monolingual treebank (over 50,000 sentences) where target human translations are not available and very hard to construct. We also demonstrated that the proposed approach can be effective in a purely monolingual setting with the help of SMT.

Abstract

We present a novel approach to Data-Oriented Parsing (DOP). Like other DOP models, our parser utilizes syntactic fragments of arbitrary size from a treebank to analyze new sentences, but, crucially, it uses only those which are encountered at least twice. This criterion allows us to work with a relatively small but representative set of fragments, which can be employed as the symbolic backbone of several probabilistic generative models. For parsing we define a transform-backtransform approach that allows us to use standard PCFG technology, making our results easily replicable. According to standard Parseval metrics, our best model is on par with many state-of-the-art parsers, while offering some complementary benefits: a simple generative probability model, and an explicit representation of the larger units of grammar.

1 Introduction

Data-oriented Parsing (DOP) is an approach to wide-coverage parsing based on assigning structures to new sentences using fragments of variable size extracted from a treebank. It was first proposed by Scha in 1990 and formalized by Bod (1992), and preceded many developments in statistical parsing (e.g., the "treebank grammars" of Charniak 1997) and linguistic theory (e.g., the current popularity of "constructions", Jackendoff 2002). A rich literature on DOP has emerged since, yielding state-of-the-art results on the Penn treebank benchmark test (Bod, 2001; Bansal and Klein, 2010) and inspiring developments in related frameworks including tree kernels (Collins and Duffy, 2002), reranking (Charniak and Johnson, 2005) and Bayesian adaptor and fragment grammars (e.g., Johnson et al., 2007; O'Donnell et al., 2009; Cohn et al., 2010). By formalizing the idea of using large fragments of earlier language experience to analyze new sentences, DOP captures an important property of language cognition that has shaped natural language. It therefore complements approaches that have focused on properties like lexicalization or incrementality, and might bring supplementary strengths in other NLP tasks.

Early versions of DOP (e.g., Bod et al., 2003) aimed at extracting all subtrees of all trees in the treebank. The total number of constructions, however, is prohibitively large for non-trivial treebanks: it grows exponentially with the length of the sentences, yielding the astronomically large number of approximately 10^{48} for section 2-21 of the Penn WSJ corpus. These models thus rely on a big sample of fragments, which inevitably includes a substantial portion of overspecialized constructions. Later DOP models have used the Goodman transformation (Goodman, 1996, 2003) to obtain a compact representation of all fragments in the treebank (Bod, 2003; Bansal and Klein, 2010). In this case the grammatical constructions are no longer explicitly represented, and substantial engineering effort is needed to optimally tune the models and make them efficient.

In this paper we present a novel DOP model (Double-DOP) in which we extract a restricted yet representative subset of fragments: those recurring at least twice in the treebank. The explicit representation of the fragments allows us to derive simple

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 84–95,
Edinburgh, Scotland, UK, July 27–31, 2011.

ways of estimating probabilistic models on top of the symbolic grammar. This and other implementation choices aim at making the methodology transparent and easily replicable. The accuracy of Double-DOP is well within the range of state-of-the-art parsers currently used in other NLP-tasks, while offering the additional benefits of a simple generative probability model and an explicit representation of grammatical constructions.

The contributions of this paper are summarized as follows: (i) we describe an efficient tree-kernel algorithm which allows us to extract all recurring fragments, reducing the set of potential elementary units from the astronomical 10^{48} to around 10^6. (ii) We implement and compare different DOP estimation techniques to induce a probability model (PTSG) on top of the extracted symbolic grammar. (iii) We present a simple transformation of the extracted fragments into CFG-rules that allows us to use off-the-shelf PCFG parsing and inference. (iv) We integrate Double-DOP with recent state-splitting approaches (Petrov et al., 2006), yielding an even more accurate parser and a better understanding of the relation between DOP and state-splitting.

The rest of the paper is structured as follows. In section 2 we describe the symbolic backbone of the grammar formalism that we will use for parsing. In section 3 we illustrate the probabilistic extension of the grammar, including our transformation of PTSGs to PCFGs that allows us to use a standard PCFG parser, and a different transform that allows us to use a standard implementation of the inside-outside algorithm. In section 4 we present the experimental setup and the results.

2 The symbolic backbone

The basic idea behind DOP is to allow arbitrarily large fragments from a treebank to be the elementary units of production of the grammar. Fragments can be combined through *substitution* to obtain the phrase-structure tree of a new sentence. Figure 1 shows an example of a complete syntactic tree obtained by combining three elementary fragments. As in previous work, two fragments f_i and f_j can be combined ($f_i \circ f_j$) only if the leftmost substitution site $X\downarrow$ in f_i has the same label as the root node of f_j; in this case the resulting tree will correspond to f_i with f_j replacing X. The DOP formalism is discussed in detail in e.g., Bod et al. (2003).

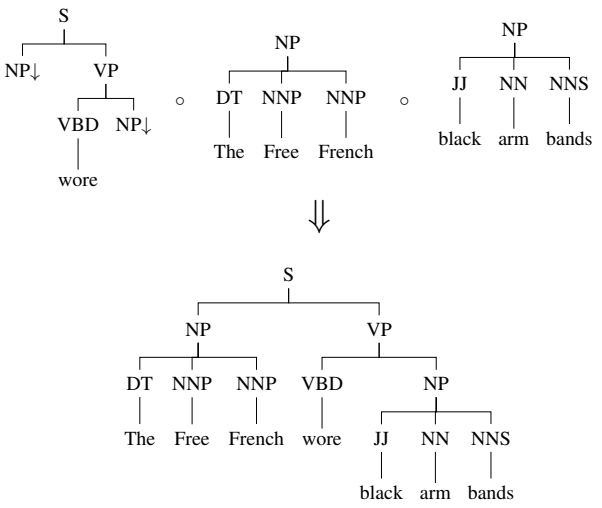

Figure 1: An example of a derivation of a complete syntactic structure (below) obtained combining three elementary fragments (above) by means of the substitution operation ∘. Substitution sites are marked with ↓.

2.1 Finding Recurring Fragments

The first step to build a DOP model is to define its symbolic grammar, i.e. the set of elementary fragments in the model. In the current work we explicitly extract a subset of fragments from the training treebank. To limit the fragment set size, we use a simple but heretofore unexplored constraint: we extract only those fragments that occur two or more times in the treebank[1]. Extracting this particular set of fragments is not trivial, though: a naive approach that filters a complete table of fragments together with their frequencies fails because that set, in a reasonably sized treebank, is astronomically large. Instead, we use a dynamic programming algorithm based on tree-kernel techniques (Collins and Duffy, 2001; Moschitti, 2006; Sangati et al., 2010).

The algorithm iterates over every pair of trees in

[1]More precisely we extract only the largest shared fragments for all pairs of trees in the treebank. All subtrees of these extracted fragments necessarily also occur at least twice, but they are only explicitly represented in our extracted set if they happen to form a largest shared fragment from another pair of trees. Hence, if a large tree occurs twice in the treebank the algorithm will extract from this pair only the full tree as a fragment and not all its (exponentially many) subtrees.

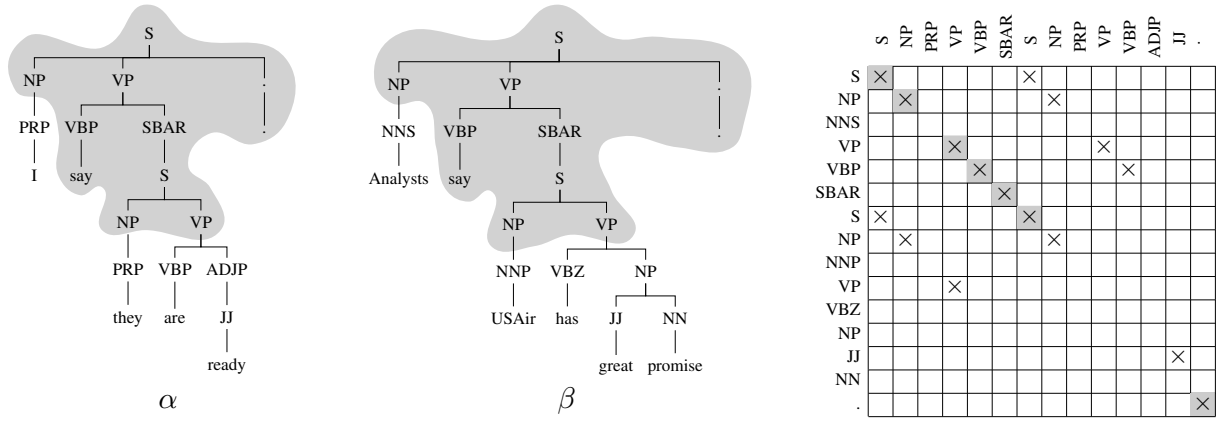

Figure 2: Left: example of two trees sharing a single maximum fragment, circled in the two trees. Right: the chart $\mathcal{M}$ which is used in the dynamic algorithm to extract all maximum fragments shared between the two trees. The highlighted cells in the chart are the ones which contribute to extract the shared fragment. The marked cells are those for which the corresponding nodes in the two tree have equivalent labels but differ in their lists of child nodes.

the treebank to look for common fragments. Figure 2 shows an example of a pair of trees $\langle \alpha, \beta \rangle$ being compared. The algorithm builds a chart $\mathcal{M}$ with one column for every indexed non-terminal node α_i in α, and one row for every indexed non-terminal node β_j in β. Each cell $\mathcal{M}\langle i, j \rangle$ identifies a set of indices corresponding to the largest fragment in common between the two trees starting from α_i and β_j. This set is empty if α_i and β_j differ in their labels, or they don't have the same list of child nodes. Otherwise (if both the labels and the lists of children match) the set is computed recursively as follows:

$$\mathcal{M}\langle i, j \rangle = \{\alpha_i\} \cup \left(\bigcup_{c=\{1,2,\ldots,|ch(\alpha)|\}} \mathcal{M}\langle ch(\alpha_i, c), ch(\beta_j, c) \rangle \right) \quad (1)$$

where $ch(\alpha)$ returns the indices of α's children, and $ch(\alpha, c)$ the index of its c^{th} child.

After filling the chart, the algorithm extracts the set of recurring fragments, and stores them in a table to keep track of their counts. This is done by converting back each fragment implicitly defined in every cell-set[2], and filtering out those that are properly contained in others.

In a second pass over the treebank, exact counts are obtained for each fragment in the extracted set. Parse trees in the training corpus are not necessarily covered entirely by recurring fragments; to ensure coverage, we also include in the symbolic backbone of our Double-DOP model all PCFG-productions not included in the set of extracted fragments.

2.2 Comparison with previous DOP work

Explicit grammars The number of recurring fragments in our symbolic grammar, extracted from the training sections of the Penn WSJ treebank[3], is around 1 million, and thus is significantly lower than previous work extracting explicit fragments (e.g., Bod, 2001, used more than 5 million fragments up to depth 14).

When looking at the extracted fragments we ask if we could have predicted which fragments occur twice or more. Figure 3 attempts to tackle this question by reporting some statistics on the extracted fragments. The majority of fragments are rather small with a limited number of words or substitution sites in the frontier. Yet, there is a significant portion of fragments, in the tail of the distribution, with more than 10 words or substitution sites. Since the space of all fragments with such characteristics is enormously large, selecting big recurring fragments using random sampling technique is like finding a needle in a haystack. Hence, random sampling processes (like Bod, 2001), will tend to represent fre-

[2] A cell-set containing a single index corresponds to the fragment including the node with that index together with all its children.

[3] This is after the treebank has been preprocessed. See also section 4.

quent recurring constructions such as *from NP to NP* or *whether S or not*, together with infrequent overspecialized fragments like *from Houston to NP*, while missing large generic constructions such as *everything you always wanted to know about NP but were afraid to ask*. These large constructions are excluded completely by models that only allow elementary trees up to a certain depth (typically 4 or 5) into the symbolic grammar (Zollmann and Sima'an, 2005; Zuidema, 2007; Borensztajn et al., 2009), or only elementary trees with exactly one lexical anchor (Sangati and Zuidema, 2009).

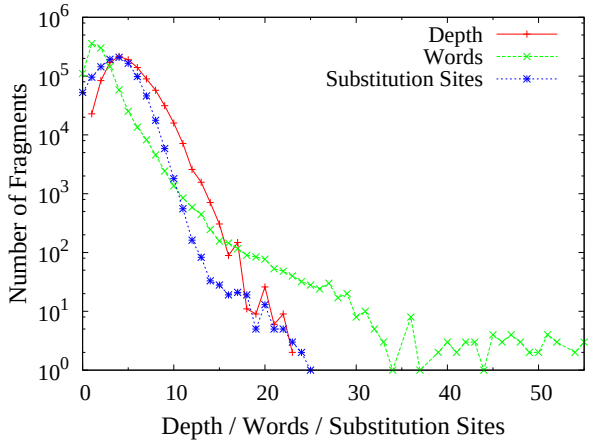

Figure 3: Distribution of the recurring fragments types according to several features: depth, number of words, and number of substitution sites. Their corresponding curves peak at 4 (depth), 1 (words), and 4 (substitution sites).

Implicit grammars Goodman (1996, 2003) defined a transformation for some versions of DOP to an equivalent PCFG-based model, with the number of rules extracted from each parse tree linear in the size of the trees. This transform, representing larger fragments only *implicitly*, is used in most recent DOP parsers (e.g., Bod, 2003; Bansal and Klein, 2010). Bod has promoted the Goodman transform as the solution to the computational challenges of DOP (e.g., Bod, 2003); it's important to realize, however, that the resulting grammars are still very large: WSJ sections 2-21 yield about 2.5 million rules in the basic version of Goodman's transform. Moreover, the transformed grammars differ from untransformed DOP grammars in that larger fragments are no longer explicitly represented. Rather, information about their frequency is distributed over many CFG-rules: if a construction occurs n times and contains m context-free productions, Goodman's transform uses the weights of $7nm + m$ rules to encode this fact. Thus, the information that the idiomatic fragment *(PP (IN "out") (PP (IN "of") (NP (NN "town")))))* occurs 3 times in WSJ sections 2-21, is distributed over 132 rules. This way, an attractive feature of DOP, viz. the explicit representation of the 'productive units' of language, is lost[4].

In addition, grammars that implicitly encode all fragments found in a treebank are strongly biased to over-represent big constructions: the great majority of the entire set of fragments belongs in fact to the largest tree in the treebank[5]. DOP models relying on Goodman's transform, need therefore to counteract this tendency. Bansal and Klein (2010), for instance, rely on a sophisticated tuning technique to correctly adjust the weights of the rules in the grammar. In our Double-DOP approach, instead, the number of fragments extracted from each tree varies much less (it ranges between 4 and 1,759). This comparison is shown in figure 4.

3 The probabilistic model

Like CFG grammars, our symbolic model produces extremely many parse trees for a given test sentence. We therefore need to disambiguate between the possible parses by means of a probability model that assigns probabilities to fragments, and defines a proper distribution over the set of possible full parse trees. For every nonterminal X in the treebank we have:

$$\sum_{f \in F_X} p(f) = 1 \qquad (2)$$

where F_X is the set of fragments in our symbolic grammar rooted in X. A derivation $d = f_1, f_2, \ldots, f_n$ of t is a sequence of the fragments that through left-most substitution produces t. The probability of a derivation is computed as the product of

[4]Bansal and Klein (2010) address this issue for contiguous constructions by extending the Goodman transform with a 'Packed Graph Encoding' for fragments that "bottom out in terminals". However, constructions with variable slots, such as *whether S or not*, are left unchanged.

[5]In fact, the number of extracted fragments increase exponentially with the size of the tree.

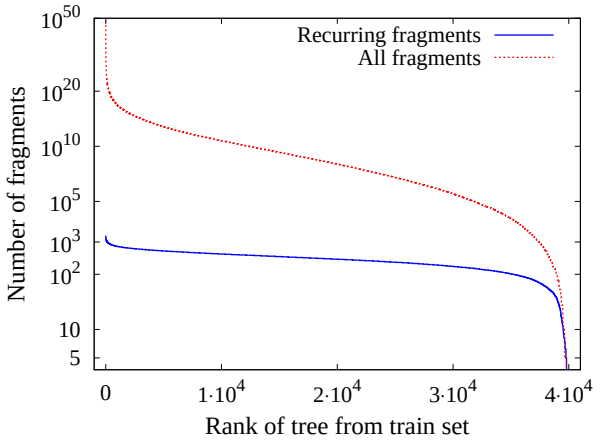

Figure 4: Number of fragments extracted from each tree in sections 2-21 of the WSJ treebank, when considering all-fragments (dotted line) and recurring-fragments (solid line). Trees on the x-axis are ranked according to the number of fragments. Note the double logarithmic scale on the y-axis.

the probability of each of its fragments.

$$P(d) = \prod_{f \in d} p(f) \quad (3)$$

In section 3.2 we describe ways of obtaining different probability distributions over the fragments in our grammar. In the following section we assume a given probabilistic model, and illustrate how to use standard PCFG parsing.

3.1 Parsing

It is possible to define a simple transform of our probabilistic fragment grammar, such that off-the-shelf parsers can be used. In order to perform the PTSG/PCFG conversion, every fragment in our grammar must be mapped to a CFG rule which will keep the same probability as the original fragment. The corresponding rule will have as the left hand side the root of the fragment and as the right hand side its yield, i.e., a sequence of terminals and non-terminals (substitution sites).

It might occur that several fragments are mapped to the same CFG rule[6]. These are interesting cases of syntactic ambiguity as shown in figure 5. In order to resolve this problem we need to map each ambiguous fragment to two unique CFG rules chained by a unique artificial node, as shown at the bottom of the same figure. To the first CFG rule in the chain we assign the probability of the fragment, while the second will receive probability 1, so the product gives back the original probability. The ambiguous and unambiguous PTSG/PCFG mappings need to be stored in a table, in order to convert back the compressed CFG derivations to the original PTSG model after parsing.

Such a transformed PCFG will generate the same derivations as the original PTSG grammar with identical probabilities. In our experiment we use a standard PCFG parser to produce a list of k-best Viterbi derivations. These, in turn, will be used to maximize possible objectives as described in section 3.3.

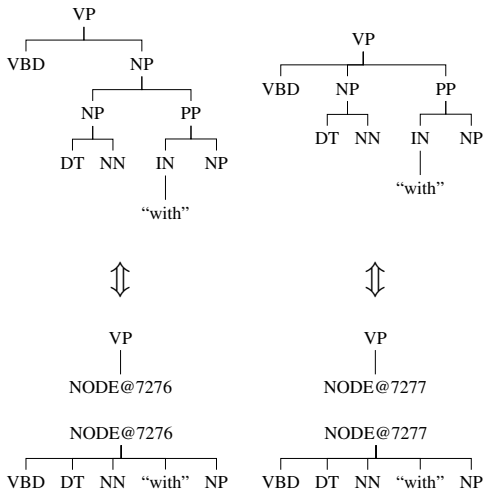

Figure 5: Above: example of 2 ambiguous fragments mapping to the same CFG rule VP → VBD DT NN "with" NP. The first fragment occurs 5 times in the training treebank, (e.g. in the sentence *was an executive with a manufacturing concern*) while the second fragment occurs 4 times (e.g. in the sentence *began this campaign with such high hopes*). Below: the two pairs of CFG rules that are used to map the two fragments to separate CFG derivations.

3.2 Inducing probability distributions

Relative Frequency Estimate (RFE) The simplest way to assign probabilities to fragments is to make them proportional to their counts[7] in the training set. When enforcing equation 2, that gives the

[6] In our binarized treebank we have 31,465 fragments types that are ambiguous in this sense.

[7] We refer to the counts of each fragment as returned by our extraction algorithm in section 2.1.

Relative Frequency Estimate (RFE):

$$p_{\text{RFE}}(f) = \frac{count(f)}{\sum_{f' \in F_{root(f)}} count(f')} \quad (4)$$

Unlike RFE for PCFGs, however, the RFE for PTSGs has no clear probabilistic interpretation. In particular, it does not yield the maximum likelihood solution, and when used as an estimator for an all-fragments grammar, it is strongly biased since it assigns the great majority of the probability mass to big fragments (Johnson, 2002). As illustrated in figure 4 this bias is much weaker when restricting the set of fragments with our approach. Although this does not solve all theoretical issues, it makes RFE a reasonable first choice again.

Equal Weights Estimate (EWE) Various other ways of choosing the weights of a DOP grammar have been worked out. The best empirical results have been reported by Bod (2003) with the EWE proposed by Goodman (2003). Goodman defined it for grammars in the Goodman transform, but for explicit grammars it becomes:

$$w_{\text{EWE}}(f) = \sum_{t \in TB} \frac{count(f,t)}{|\{f' \in t\}|} \quad (5)$$

$$p_{\text{EWE}}(f) = \frac{w_{\text{EWE}}(f)}{\sum_{f' \in F_{root(f)}} w_{\text{EWE}}(f')} \quad (6)$$

where the first sum is over all parse trees t in the treebank (TB), $count(f,t)$ gives the number of times fragment f occurs in t, and $|\{f' \in t\}|$ is the total number of subtrees of t that were included in the symbolic grammar.

Maximum Likelihood (ML) For reestimation, we can aim at maximizing the likelihood (ML) of the treebank. For this, it turns out that we can define another transformation of our PTSG, such that we can apply standard Inside-Outside algorithm for PCFGs (Lari and Young, 1990). The original version of IO is defined over *string rewriting* PCFGs, and maximizes the likelihood of the training set consisting of plain sentences. Reestimation shifts probability mass between alternative parse trees for a sentence. In contrast, our grammars consist of fragments of various size, and our training set consists of parse trees. Reestimation here shifts probability mass between alternative derivations for a parse tree.

Our transformation approach is illustrated with an example in figure 6. In step (b) the fragments in the grammar as well as the original parse trees in the treebank are "flattened" into bracket notation. In step (c) each fragment is transformed into a CFG rule in the transformed meta-grammar, whose right-hand side is constituted by the bracket notation of the fragment. Each substitution site $X\!\downarrow$ is raised to a meta-nonterminal X', and all other symbols, including parentheses, become meta-terminals. The left-hand side of the rule is constituted by the original root symbol R of the fragment raised to a meta-nonterminal R'.

The resulting PCFG generates trees in bracket notation, and we can run an of-the-shelf inside-outside algorithm by presenting it parse trees from the train corpus in bracket notation[8]. In the experiments that we report below we used the RFE from section 3, to generate the initial weights for the grammar.

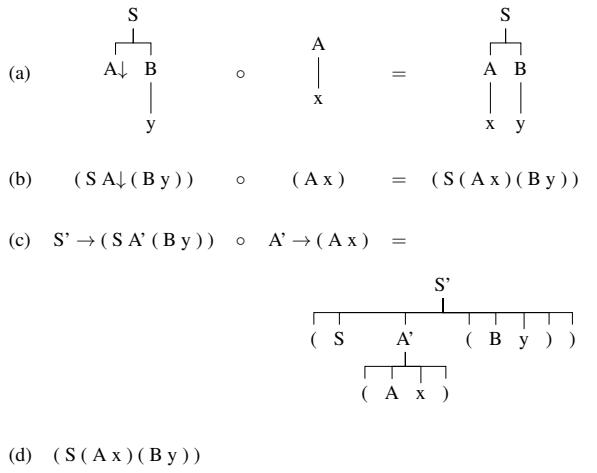

Figure 6: Rule and tree transforms that turn PTSG reestimation into PCFG reestimation; (a) a derivation of the sentence $x\,y$ through successive substitutions of elementary trees from a PTSG; (b) the same elementary trees and resulting parse tree in bracket notation; (c) an equivalent derivation with the meta-grammar, where the original substitution sites reappear as meta-nonterminals (marked with a prime) and all other symbols as meta-terminals; (d) the yield of the derivation in c.

[8] However, the results with inside-outside reported in this paper were obtained with an earlier version of our code that uses an equivalent but special-purpose implementation.

3.3 Maximizing Objectives

MPD The easiest objective in parsing, is to select the most probable derivation (MPD), obtained by maximizing equation 3.

MPP A DOP grammar can often generate the same parse tree t through different derivations $D(t) = d_1, d_2, \ldots d_m$. The probability of t is therefore obtained by summing the probabilities of all its possible derivations.

$$P(t) = \sum_{d \in D(t)} p(d) = \sum_{d \in D(t)} \prod_{f \in d} p(f) \quad (7)$$

An intuitive objective for a parser is to select, for a given sentence, the parse tree with highest probability according to equation 7, i.e., the most probable parse (MPP): unfortunately, identifying the MPP is computationally intractable (Sima'an, 1996). However, we can approximate the MPP by deriving a list of k-best derivations, summing up the probabilities of those resulting in the same parse tree, and select the tree with maximum probability.

MCP, MRS Following Goodman (1998), Sima'an (1999, 2003), and others, we also consider other objectives, in particular, the max constituent parse (MCP), and the max rule sum (MRS).

MCP maximizes a weighted average of the expected labeled recall L/N_C and (approximated) labeled precision L/N_G under the given posterior distribution, where L is the number of correctly labeled constituents, N_C the number of constituents in the correct tree, and N_G the number of constituents in the guessed tree. Recall is easy to maximize since the estimated N_C is constant. L/N_C can be in fact maximized in:

$$\hat{t} = \arg\max_t \sum_{lc \in t} P(lc) \quad (8)$$

where lc ranges over all labeled constituents in t and $P(lc)$ is the marginalized probability of all the derivation trees in the grammar yielding the sentence under consideration which contains lc.

Precision, instead, is harder because the denominator N_G depends on the chosen guessed tree. Goodman (1998) proposes to look at another metric which is strongly correlated with precision, which is the mistake rate $(N_G - L)/N_C$ that we want to minimize. We combine recall with mistake rate through linear interpolation:

$$\hat{t} = \arg\max_t \mathcal{E}(\frac{L}{N_C} - \lambda \frac{N_G - L}{N_C}) \quad (9)$$

$$= \arg\max_t \sum_{lc \in t} P(lc) - \lambda(1 - P(lc)) \quad (10)$$

where 10 is obtained from 9 assuming N_C constant, and the optimal level for λ has to be evaluated empirically.

Unlike MPP, the MCP can be calculated efficiently using dynamic programming techniques over the parse forest. However, in line with the aims of this paper to produce an easily reproducible implementation of DOP, we developed an accurate approximation of the MCP using a list of k-best derivations, such as those that can be obtained with an off-the-shelf PCFG parser.

We do so by building a standard CYK chart, where every cell corresponds to a specific span in the test sentence. We store in each cell the probability of seeing every label in the grammar yielding the corresponding span, by marginalizing the probabilities of all the parse trees in the obtained k-best derivations that contains that label covering the same span. We then compute the Viterbi-best parse maximizing equation 10.

We implement max rule sum (MRS) in a similar way, but do not only keep track of labels in every cell, but of each CFG rule that span the specific yield (see also Sima'an, 1999, 2003). We haven't implemented the max rule product (MRP) where posteriors are multiplied instead of added (Petrov and Klein, 2007; Bansal and Klein, 2010).

4 Experimental Setup

In order to build and test our Double-DOP model[9], we employ the Penn WSJ Treebank (Marcus et al., 1993). We use sections 2-21 for training, section 24 for development and section 23 for testing.

Treebank binarization We start with some preprocessing of the treebank, following standard prac-

[9]The software produced for running our model is publicly available and included in the supplementary material to this paper. To the best of our knowledge this is the first DOP software released that can be used to parse the WSJ PTB.

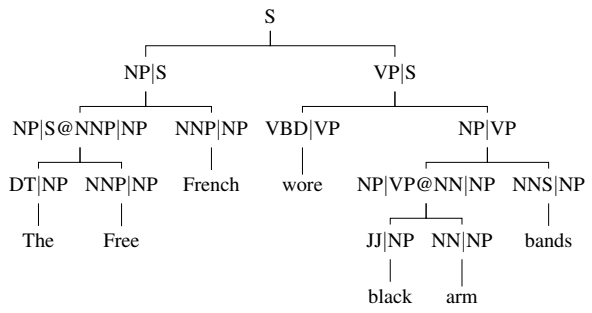

Figure 7: The binarized version of the tree in figure 1, with H=1 and P=1.

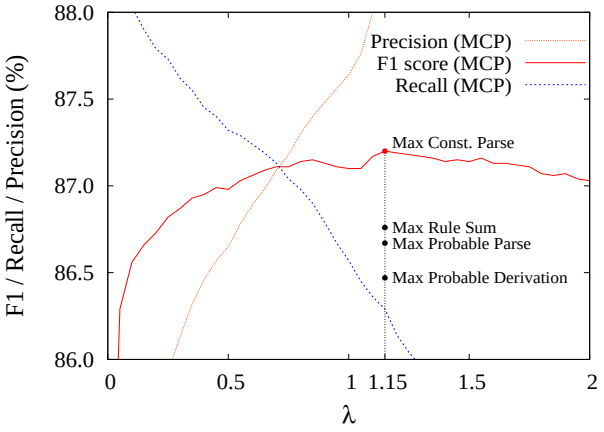

Figure 8: Double-DOP results on the development section (≤ 40) with different maximizing objectives.

tice in WSJ parsing. We remove traces and functional tags. We apply a left binarization of the training treebank as in Matsuzaki et al. (2005) and Klein and Manning (2003), setting the horizontal history H=1 and the parent labeling P=1. This means that when a node has more than 2 children, the i^{th} child (for $i \geq 3$) is conditioned on child $i-1$. Moreover the labels of all non-lexical nodes are enriched with the labels of their parent node. Figure 7 shows the binarized version of the tree structure in figure 1.

Unknown words We replace words appearing less than 5 times in the training data by one of 50 unknown word categories based on the presence of lexical features as implemented in Petrov (2009). In some of the experiments we also perform a smoothing over the lexical elements assigning low counts ($\epsilon = 0.01$) to open-class $\langle$words, PoS-tags$\rangle$ pairs not encountered in the training corpus[10].

Fragment extraction We extract the symbolic grammar and fragment frequencies from this preprocessed treebank as explained in section 2. This is the the most time-consuming step (around 160 CPU hours[11]).

In the extracted grammar we have in total 1,029,342 recurring fragments and 17,768 unseen CFG rules. We test several probability distributions over the fragments (section 3.2) and various maximization objectives (section 3.3).

[10] A PoS-tag is an open class if it rewrites to at least 50 different words in the training corpus. A word is an open class word if it has been seen only with open-class PoS-tags.

[11] Although our code could still be optimized further, it does already allow for running the job on M CPUs in parallel, reducing the time required by a factor M (10 hours with 16-CPUs).

Parsing We convert our PTSG into a PCFG (section 3.1) and use `Bitpar`[12] for parsing. For approximating MPP and other objectives we marginalize probabilities from the 1,000 best derivations.

4.1 Results

We start by presenting in figure 8 the results we obtain on the development set (section 24). Here we compare the *maximizing objectives* presented in section 3.3, using RFE to obtain the probability distribution over the fragments. We conclude that, empirically, MCP for $\lambda = 1.15$, is the best choice to maximize F1, followed by MRS, MPP, and MPD.

We also compare the various *estimators* presented in section 3.2, on the same development set, keeping MCP with $\lambda = 1.15$ as the maximizing objective. We find that RFE is the best estimator (87.2 F1[13]) followed by EWE (86.8) and ML (86.6). Our best results with ML are obtained when removing fragments occurring less than 6 times (apart from CFG-rules) and when stopping at the second iteration. This filtering is done in order to limit the number of big fragments in the grammar. It is well known that IO for DOP tends to assign most of the probability mass to big fragments, quickly overfitting the training data. It is surprising that EWE and ML perform worse than RFE, in contrast to earlier findings (Bod, 2003).

[12] `http://www.ims.uni-stuttgart.de/tcl/SOFTWARE/BitPar.html`

[13] We computed F1 scores with EvalB (`http://nlp.cs.nyu.edu/evalb/`) using parameter file *new.prm*.

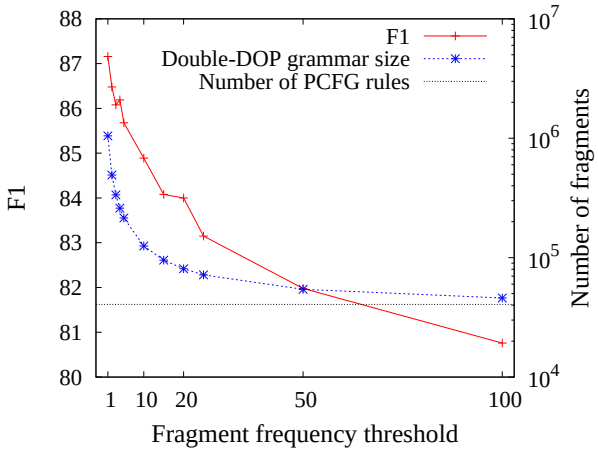

Figure 9: Performance (on the development set) and size of Double-DOP when considering only fragments whose occurring frequency in the training treebank is above a specific threshold (x-axis). In all cases, all PCFG-rules are included in the grammars. For instance, at the right-hand side of the plot a grammar is evaluated which included only 6754 fragments with a frequency > 100 as well as 39227 PCFG rules.

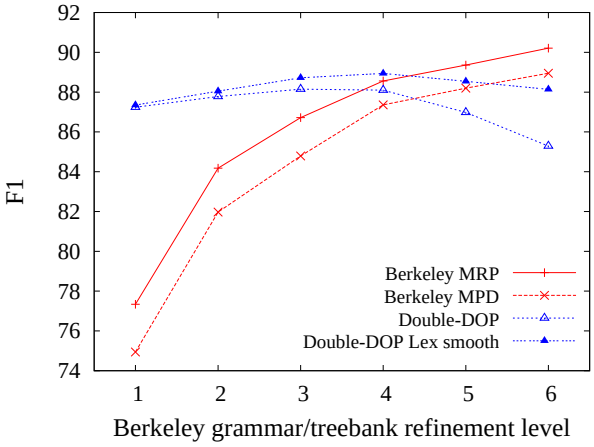

Figure 10: Comparison on section 24 between the performance of Double-DOP (using RFE and MCP with $\lambda = 1.15$, H=0, P=0) and Berkeley parser on different stages of refinement of the treebank/grammar.

We also investigate how a further restriction on the set of extracted fragments influences the performance of our model. In figure 9 we illustrate the performance of Double-DOP when restricting the grammar to fragments having frequencies greater than $1, 2, \ldots, 100$. We can notice a rather sharp decrease in performance as the grammar becomes more and more compact.

Next, we present some results on various Double-DOP grammars extracted from the same training treebank after refining it using the Berkeley state-splitting model[14] (Petrov et al., 2006; Petrov and Klein, 2007). In total we have 6 increasingly refined versions of the treebank, corresponding to the 6 cycles of the Berkeley model. We observe in figure 10 that our grammar is able to benefit from the state splits for the first four levels of refinement, reaching the maximum score at cycle 4, where we improve over our base model. For the last two data points, the treebank gets too refined, and using Double-DOP model on top of it, no longer improves accuracy.

We have also compared our best Double-DOP base model and the Berkeley parser on per-category performance. Here we observe an interesting trend: the Berkeley parser outperforms Double-DOP on very frequent categories, while Double-DOP performs better on infrequent ones. A detailed comparison is included in table 1.

Finally, in table 2 we present our results on the test set (section 23). Our best model (according to the best settings on the development set) performs slightly worse than the one by Bansal and Klein (2010) when trained on the original corpus, but outperforms it (and the version of their model with additional refinements) when trained on the refined version, in particular for the exact match score.

5 Conclusions

We have described Double-DOP, a novel DOP approach for parsing, which uses all constructions recurring at least twice in a treebank. This methodology is driven by the linguistic intuition that constructions included in the grammar should prove to be reusable in a representative corpus.

The extracted set of fragments is significantly smaller than in previous approaches. Moreover constructions are explicitly represented, which makes them potentially good candidates as semantic or translation units to be used in other applications.

Despite earlier reported excellent results with DOP parsers, they are almost never used in other

[14] We use the Berkeley grammar labeler following the base settings for the WSJ: trees are right-binarized, H=0, and P=0. Berkeley parser package is available at `http://code.google.com/p/berkeleyparser/`

Table 2: Summary of the results of different parsers on the test set (sec 23). Double-DOP experiments use RFE, MCP with $\lambda = 1.15$, H=1, P=1; those on state-splitting (Double-DOP-Sp) use Berkeley cycle 4, H=0, P=0. Results from Petrov and Klein (2007) already include smoothing which is performed similarly to our smoothing technique (see section 4). (* Results on a development set, with sentences up to length 20.)

NLP tasks: where other successful parsers often feature as components of machine translation, semantic role labeling, question-answering or speech recognition systems, DOP is conspicuously absent in these neighboring fields (but for a possible application of closely related formalisms see, e.g., Yamangil and Shieber, 2010). The reasons for this are many, but most important are probably the computational inefficiency of many instances of the approach, the lack of downloadable software and the difficulties with replicating some of the key results.

In this paper we have addressed all three obstacles: our efficient algorithm for identifying the recurrent fragments in a treebank runs in polynomial time. The transformation to PCFGs that we define allows us to use a standard PCFG parser, while retaining the benefit of explicitly representing larger fragments. A different transform also allows us to run the popular inside-outside algorithm. Although IO results are slightly worse than with the naive relative frequency estimate, it is important to establish that the standard method for dealing with latent information (i.e., the derivations of a given parse) is not the best choice in this case. We expect that other re-estimation methods, for instance Variational Bayesian techniques, could be formulated in the same manner.

Finally, the availability of our programs, as well as the third party software that we use, also addresses the replicability issue. Where some researchers in the field have been skeptical of the DOP approach to parsing, we believe that our independent development of a DOP parser adds credibility to the idea that an approach that uses very many large subtrees, can lead to very accurate parsers.

A Generate and Rank Approach to Sentence Paraphrasing

Prodromos Malakasiotis[*] and **Ion Androutsopoulos**[*+]
[*]Department of Informatics, Athens University of Economics and Business, Greece
[+]Digital Curation Unit – IMIS, Research Centre "Athena", Greece

Abstract

We present a method that paraphrases a given sentence by first generating candidate paraphrases and then ranking (or classifying) them. The candidates are generated by applying existing paraphrasing rules extracted from parallel corpora. The ranking component considers not only the overall quality of the rules that produced each candidate, but also the extent to which they preserve grammaticality and meaning in the particular context of the input sentence, as well as the degree to which the candidate differs from the input. We experimented with both a Maximum Entropy classifier and an SVR ranker. Experimental results show that incorporating features from an existing paraphrase recognizer in the ranking component improves performance, and that our overall method compares well against a state of the art paraphrase generator, when paraphrasing rules apply to the input sentences. We also propose a new methodology to evaluate the ranking components of generate-and-rank paraphrase generators, which evaluates them across different combinations of weights for grammaticality, meaning preservation, and diversity. The paper is accompanied by a paraphrasing dataset we constructed for evaluations of this kind.

1 Introduction

In recent years, significant effort has been devoted to research on paraphrasing (Androutsopoulos and Malakasiotis, 2010; Madnani and Dorr, 2010). The methods that have been proposed can be roughly classified into three categories: (i) *recognition* methods, i.e., methods that detect whether or not two input sentences or other texts are paraphrases; (ii) *generation* methods, where the aim is to produce paraphrases of a given input sentence; and (iii) *extraction* methods, which aim to extract paraphrasing rules (e.g., "X wrote Y" "$\leftrightarrow$ Y was authored by X") or similar patterns from corpora. Most of the methods that have been proposed belong in the first category, possibly because of the thrust provided by related research on textual entailment recognition (Dagan et al., 2009), where the goal is to decide whether or not the information of a given text is entailed by that of another. Significant progress has also been made in paraphrase extraction, where most recent methods produce large numbers of paraphrasing rules from multilingual parallel corpora (Bannard and Callison-Burch, 2005; Callison-Burch, 2008; Zhao et al., 2008; Zhao et al., 2009a; Zhao et al., 2009b; Kok and Brockett, 2010). In this paper, we are concerned with paraphrase generation, which has received less attention than the other two categories.

There are currently two main approaches to paraphrase generation. The first one treats paraphrase generation as a machine translation problem, with the peculiarity that the target language is the same as the source one. To bypass the lack of large *monolingual* parallel corpora, which are needed to train statistical machine translation (SMT) systems for paraphrasing, monolingual clusters of news articles referring to the same event (Quirk et al., 2004) or other similar monolingual comparable corpora can be used, though sentence alignment methods for parallel corpora may perform poorly on comparable corpora (Nelken and Shieber, 2006); alternatively, large collections of paraphrasing rules obtained via paraphrase extraction from multilingual parallel corpora can be used as monolingual phrase tables in a

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 96–106,
Edinburgh, Scotland, UK, July 27–31, 2011.

phrase-based SMT systems (Zhao et al., 2008; Zhao et al., 2009a); in both cases, paraphrases can then be generated by invoking an SMT system's decoder (Koehn, 2009). A second paraphrase generation approach is to treat existing machine translation engines as black boxes, and translate each input sentence to a pivot language and then back to the original language (Duboue and Chu-Carroll, 2006). An extension of this approach uses multiple translation engines and pivot languages (Zhao et al., 2010).

In this paper, we investigate a different paraphrase generation approach, which does not produce paraphrases by invoking machine translation system(s). We use an existing collection of monolingual paraphrasing rules extracted from multilingual parallel corpora (Zhao et al., 2009b); each rule is accompanied by one or more scores, intended to indicate the rule's *overall* quality without considering particular contexts where the rule may be applied. Instead of using the rules as a monolingual phrase table and invoking an SMT system's decoder, we follow a generate and rank approach, which is increasingly common in several language processing tasks.[1] Given an input sentence, we use the paraphrasing rules to generate a large number of candidate paraphrases. The candidates are then represented as feature vectors, and a ranker (or classifier) selects the best ones; we experimented with a Maximum Entropy classifier and a Support Vector Regression (SVR) ranker.

The vector of each candidate paraphrase includes features indicating the overall quality of the rules that produced the candidate, the extent to which the rules preserve grammaticality and meaning in the particular context of the input sentence, and the degree to which the candidate's surface form differs from that of the input; we call the latter factor *diversity*. The intuition is that a good paraphrase is grammatical, preserves the meaning of the original sentence, while also being as different as possible.

Experimental results show that including in the ranking (or classification) component features from an existing paraphrase recognizer leads to improved results. We also propose a new methodology to evaluate the ranking components of generate-and-rank paraphrase generators, which evaluates them across different combinations of weights for grammaticality, meaning preservation, and diversity. The paper is accompanied by a new publicly available paraphrasing dataset we constructed for evaluations of this kind. Further experiments indicate that when paraphrasing rules apply to the input sentences, our paraphrasing method is competitive to a state of the art paraphrase generator that uses multiple translation engines and pivot languages (Zhao et al., 2010).

We note that paraphrase generation is useful in several language processing tasks. In question answering, for example, paraphrase generators can be used to paraphrase the user's queries (Duboue and Chu-Carroll, 2006; Riezler and Liu, 2010); and in machine translation, paraphrase generation can help improve the translations (Callison-Burch et al., 2006; Marton et al., 2009; Mirkin et al., 2009; Madnani et al., 2007), or it can be used when evaluating machine translation systems (Lepage and Denoual, 2005; Zhou et al., 2006; Kauchak and Barzilay, 2006; Padó et al., 2009).

The remainder of this paper is structured as follows: Section 2 explains how our method generates candidate paraphrases; Section 3 introduces the dataset we constructed, which is also used in subsequent sections; Section 4 discusses how candidate paraphrases are ranked; Section 5 compares our overall method to a state of the art paraphrase generator; and Section 6 concludes.

2 Generating candidate paraphrases

We use the approximately one million English paraphrasing rules of Zhao et al. (2009b). Roughly speaking, the rules were extracted from a parallel English-Chinese corpus, based on the assumption that two English phrases e_1 and e_2 that are often aligned to the same Chinese phrase c are likely to be paraphrases and, hence, they can be treated as a paraphrasing rule $e_1 \leftrightarrow e_2$.[2] Zhao et al.'s method actually operates on slotted English phrases, obtained from parse trees, where slots correspond to part of speech (POS) tags. Hence, rules like the following three may be obtained, where NN_i indicates a noun slot and NNP_i a proper name slot.

[1] See, for example, Collins and Koo (2005).

[2] This pivot-based paraphrase extraction approach was first proposed by Bannard and Callison-Burch (2005). It underlies several other paraphrase extraction methods (Riezler et al., 2007; Callison-Burch, 2008; Kok and Brockett, 2010).

(1) a lot of NN_1 ↔ plenty of NN_1
(2) NNP_1 area ↔ NNP_1 region
(3) NNP_1 wrote NNP_2 ↔ NNP_2 was written by NNP_1

In the basic form of their method, called Model 1, Zhao et al. (2009b) use a log-linear ranker to assign scores to candidate English paraphrase pairs $\langle e_1, e_2 \rangle$; the ranker uses the alignment probabilities $P(c|e_1)$ and $P(e_2|c)$ as features, along with features that assess the quality of the corresponding alignments. In an extension of their method, Model 2, Zhao et al. consider two English phrases e_1 and e_2 as paraphrases, if they are often aligned to two Chinese phrases c_1 and c_2, which are themselves paraphrases according to Model 1 (with English used as the pivot language). Again, a log-linear ranker assigns a score to each $\langle e_1, e_2 \rangle$ pair, now with $P(c_1|e_1)$, $P(c_2|c_1)$, and $P(e_2|c_1)$ as features, along with similar features for alignment quality. In a further extension, Model 3, all the candidate phrase pairs $\langle e_1, e_2 \rangle$ are collectively treated as a monolingual parallel corpus. The phrases of the corpus are aligned, as when aligning a bilingual parallel corpus, and additional features, based on the alignment, are added to the log-linear ranker, which again assigns a score to each $\langle e_1, e_2 \rangle$.

The resulting paraphrasing rules $e_1 \leftrightarrow e_2$ typically contain short phrases (up to four or five words excluding slots) on each side; hence, they can be used to rewrite only parts of longer sentences. Given an input (source) sentence S, we generate candidate paraphrases by applying rules whose left or right hand side matches any part of S. For example, rule (1) matches the source sentence (4); hence, (4) can be rewritten as the candidate paraphrase (5).[3]

(4) S: He had a lot of [$_{NN_1}$admiration] for his job.
(5) C: He had plenty of [$_{NN_1}$admiration] for his job.

Several rules may apply to S; for example, they may rewrite different parts of S, or they may replace the same parts of S by different phrases. We allow all possible combinations of applicable rules to apply to S, excluding combinations that include rules rewriting overlapping parts of S.[4] To avoid generating too many candidates (C), we use only the 20 rules (that apply to S) with the highest scores. Zhao et al. actually associate each rule with three scores. The first one, hereafter called r_1, is the Model 1 score, and the other two, r_2 and r_3, are the forward and backward alignment probabilities of Model 3; see Zhao et al. (2009b) for details. We use the average of the three scores, hereafter r_4, when generating candidates.

Unfortunately, Zhao et al.'s scores reflect the overall quality of each rule, without considering the context of the particular S where the rule is applied. Szpektor et al. (2008) point out that, for example, a rule like "X acquire Y" ↔ "X buy Y" may work well in many contexts, but not in "Children acquire language quickly". Similarly, "X charged Y with" ↔ "X accused Y of" should not be applied to sentences about charging batteries. Szpektor et al. propose, roughly speaking, to associate each rule with a model of the contexts where the rule is applicable, as well as models of the expressions that typically fill its slots, in order to be able to assess the applicability of each rule in specific contexts. The rules that we use do not have associated models of this kind, but we follow Szpektor et al.'s idea of assessing the applicability of each rule in each particular context, when ranking candidates, as discussed below.

3 A dataset of candidate paraphrases

Our generate and rank method relies on existing large collections of paraphrasing rules to generate candidate paraphrases. Our main contribution is in the ranking of the candidates. To be able to evaluate the performance of different rankers in the task we are concerned with, we first constructed an evaluation dataset that contains pairs $\langle S, C \rangle$ of source (input) sentences and candidate paraphrases, and we asked human judges to assess the degree to which the C of each pair was a good paraphrase of S.

We selected randomly 75 source (S) sentences from the AQUAINT corpus, such that at least one of the paraphrasing rules applied to each S.[5] For each S, we generated candidate Cs using Zhao et al.'s rules, as discussed in Section 2. This led to 1,935 $\langle S, C \rangle$ pairs, approx. 26 pairs for each S. The pairs were given to 13 judges other than the authors.[6] Each judge evaluated approx. 148 (different) $\langle S, C \rangle$

[3] We use Stanford's POS tagger, MaxEnt classifier, and dependency parser; see `http://nlp.stanford.edu/`.

[4] A possible extension, which we have not explored, would be to recursively apply the same process to the resulting Cs.

[5] The corpus is available from the LDC (LDC2002T31).

[6] The judges were fluent, but not native English speakers.

Figure 1: Distribution of overall quality scores in the evaluation dataset (1 = totally unacceptable, 4 = perfect).

pairs; each of the 1,935 pairs was evaluated by one judge. The judges were asked to provide grammaticality, meaning preservation, and overall paraphrase quality scores for each $\langle S, C \rangle$ pair, each score on a 1–4 scale (1 for totally unacceptable, 4 for perfect); guidelines and examples were also provided.

Figure 1 shows the distribution of the overall quality scores in the 1,935 $\langle S, C \rangle$ pairs of the evaluation dataset; the distributions of the grammaticality and meaning preservation scores are similar. Notice that although we used only the 20 applicable paraphrasing rules with the highest scores to generate the $\langle S, C \rangle$ pairs, less than half of the candidate paraphrases (C) were considered good, and approximately only 20% perfect. In other words, applying paraphrasing rules (even only those with the 20 best scores) to each input sentence S and randomly picking one of the resulting candidate paraphrases C, without any further filtering (or ranking) of the candidates, would on average produce unacceptable paraphrases more frequently than acceptable ones. Hence, the role of the ranking component is crucial.

We also measured inter-annotator agreement by constructing, in the same way, 100 additional $\langle S, C \rangle$ pairs (other than the 1,935) and asking 3 of the 13 judges to evaluate all of them. We measured the mean absolute error, i.e., the mean absolute difference in the judges' scores (averaged over all pairs of judges) and the mean (over all pairs of judges) K statistic (Carletta, 1996). In the overall scores, K was 0.64, which is in the range often taken to indicate substantial agreement (0.61–0.80).[7] Agreement was higher for grammaticality ($K = 0.81$), and lower ($K = 0.59$) for meaning preservation. Table 1 shows that the mean absolute difference in the annotators' scores was $\frac{1}{5}$ to $\frac{1}{4}$ of a point.

	mean abs. diff.	K-statistic
grammaticality	0.20	0.81
meaning preserv.	0.26	0.59
overall quality	0.22	0.64

Table 1: Inter-annotator agreement when manually evaluating candidate paraphrases.

Several judges commented that they had trouble deciding to what extent the overall quality score should reflect grammaticality or meaning preservation. They also wondered if it was fair to consider as perfect candidate paraphrases that differed in only one or two words from the source sentences, i.e., candidates with low diversity. These comments led us to ignore the judges' overall quality scores in some experiments, and to use a weighted average of grammaticality, meaning preservation, and (automatically measured) diversity instead, with different weight combinations corresponding to different application requirements, as discussed further below.

In the same way, 1,500 more $\langle S, C \rangle$ pairs (other than the 1,935 and the 100, not involving previously seen Ss) were constructed, and they were evaluated by the first author. The 1,500 pairs were used as a training dataset in experiments discussed below. Both the 1,500 training and the 1,935 evaluation (test) pairs are publicly available.[8] We occasionally refer to the training and evaluation datasets as a single dataset, but they are clearly separated.

4 Ranking candidate paraphrases

We now discuss the ranking component of our method, which assesses the candidate paraphrases.

4.1 Features of the ranking component

Each $\langle S, C \rangle$ pair is represented as a feature vector. To allow the ranking component to assess the degree to which a candidate C is grammatical, or at least as grammatical as the source S, we include in the feature vectors the language model scores of S, C, and the difference between the two scores. We use a 3-gram language model trained on approximately

[7] It is also close to 0.67, which is sometimes taken to be a cutoff for substantial agreement in computational linguistics.

[8] See the paper's supplementary material.

6.5 million sentences of the AQUAINT corpus.[9] To allow the ranker to consider the (context-insensitive) quality scores of the rules that generated C from S, we also include as features the highest, lowest, and average r_1, r_2, r_3, and r_4 scores (Section 2) of these rules, 12 features in total.

The features discussed so far are similar to those employed by Zhao et al. (2009a) in the only comparable paraphrase generation method we are aware of that uses paraphrasing rules. That method, hereafter called ZHAO-RUL, uses the language model score of C and scores similar to r_1, r_2, r_3 in a log-linear model.[10] The log-linear model of ZHAO-RUL is used by an SMT-like decoder to identify the transformations (applications of rules) that produce the (hopefully) best paraphrase. By contrast, we first generate a large number of candidates using the paraphrasing rules, and we then rank them. Unfortunately, we did not have access to an implementation of ZHAO-RUL to compare against, but below we compare against another paraphraser proposed by Zhao et al. (2010), hereafter called ZHAO-ENG, which uses multiple machine translation engines and pivot languages, instead of paraphrasing rules, and which Zhao et al. found to outperform ZHAO-RUL.

To further help the ranking component assess the degree to which C preserves the meaning of S, we also optionally include in the vectors of the $\langle S, C\rangle$ pairs the features of an existing paraphrase recognizer (Malakasiotis, 2009) that obtained the best published results (Androutsopoulos and Malakasiotis, 2010) on the widely used MSR paraphrasing corpus.[11] Most of the recognizer's features are computed by using nine similarity measures: Levenshtein, Jaro-Winkler, Manhattan, Euclidean, and n-gram ($n = 3$) distance, cosine similarity, Dice, Jaccard, and matching coefficients, all computed on tokens; consult Malakasiotis (2009) for details. For each $\langle S, C\rangle$ pair, the nine similarity measures are applied to ten different forms $\langle s_1, c_1\rangle, \ldots, \langle s_{10}, c_{10}\rangle$ of $\langle S, C\rangle$, described below, leading to 90 features.

$\langle s_1, c_1\rangle$: The original forms of S and C.

$\langle s_2, c_2\rangle$: S and C with tokens replaced by stems.

$\langle s_3, c_3\rangle$: S and C, with tokens replaced by POS tags.

$\langle s_4, c_4\rangle$: S and C, tokens replaced by soundex codes.[12]

$\langle s_5, c_5\rangle$: S and C, but having removed non-nouns.

$\langle s_6, c_6\rangle$: As previously, but nouns replaced by stems.

$\langle s_7, c_7\rangle$: As previously, nouns replaced by soundex.

$\langle s_8, c_8\rangle$: S and C, but having removed non-verbs.

$\langle s_9, c_9\rangle$: As previously, but verbs replaced by stems.

$\langle s_{10}, c_{10}\rangle$: As previously, verbs replaced by soundex.

When constructing all ten forms $\langle s_i, c_i\rangle$ of $\langle S, C\rangle$, synonyms (in any WordNet synset) are treated as identical words. Additional variants of some of the 90 features compare a sliding window of some of the s_i forms to the corresponding c_i forms (or vice versa), adding 40 more features; see Malakasiotis (2009). Two more Boolean features indicate the existence or absence of negation in S or C, respectively; and another feature computes the ratio of the lengths of S and C, measured in tokens. Finally, three additional features compare the dependency trees of S and C:

$$R_S = \frac{|\text{common dependencies of } S, C|}{|\text{dependencies of } S|}$$

$$R_C = \frac{|\text{common dependencies of } S, C|}{|\text{dependencies of } C|}$$

$$F_{\beta=1} = \frac{2 \cdot R_S \cdot R_C}{R_S + R_C}$$

The recognizer's features are 136 in total.[13] Hence, the full feature set of our paraphraser's ranking component comprises 151 features.

[9] We use SRILM; see `http://www-speech.sri.com/`.

[10] Application-specific features are also included, which can be used, for example, to favor paraphrases that are shorter than the input in sentence compression (Knight and Marcu, 2002; Clarke and Lapata, 2008). Similar features could also be added to application-specific versions of our method.

[11] The MSR corpus contains pairs that are paraphrases or not. It is a benchmark for paraphrase recognizers, not generators. It provides only one paraphrase (true or false) of each source, and few of the true paraphrases can be obtained by the rules we use.

[12] The Soundex algorithm maps English words to alphanumeric codes, so that words with the same pronunciations receive the same codes, despite spelling differences; see `http://en.wikipedia.org/wiki/Soundex`.

[13] Malakasiotis (2009) shows that although there is a lot of redundancy in the recognizer's feature set, the full feature set still leads to better paraphrase recognition results, compared to subsets constructed via feature selection with hill-climbing or beam search. The same paper reports that the recognizer performs almost as well without the last three features, which may not be available in languages with no reliable dependency parsers. Notice, also, that the recognizer does not use paraphrasing rules.

4.2 Learning rate with a MaxEnt classifier

To obtain a first indication of whether or not a ranking component equipped with the features discussed above could learn to distinguish good from bad candidate paraphrases, and to investigate if our training dataset is sufficiently large, we initially experimented with a Maximum Entropy classifier (with the 151 features) as the ranking component. This initial version of the ranking component, called ME-REC, was trained on increasingly larger parts of the training dataset of Section 3, and it was always evaluated on the entire test dataset of that section. For simplicity, we used only the judges' overall quality scores in these experiments, and we treated the problem as one of binary classification; overall quality scores of 1 and 2 where conflated to a negative category, and scores of 3 and 4 to a positive category.

Figure 2 plots the error rate of ME-REC, computed both on the test set and the encountered training subset. The error rate on the training instances a learner has encountered is typically lower than the error rate on the test set (unseen instances); hence, the former error rate can be seen as a lower bound of the latter. ME-REC shows signs of having reached its lower bound when the entire training dataset is used, suggesting that the training dataset is sufficiently large. The baseline (BASE) of Figure 2 uses only a threshold on the average r_4 (Section 2) of the rules that turned S into C. If the average r_4 is higher than the threshold, the $\langle S, C \rangle$ pair is classified in the positive class, otherwise in the negative one. The threshold was tuned by experimenting on a separate tuning dataset. Clearly, ME-REC outperforms the baseline, which uses only the average (context-insensitive) scores of the applied paraphrasing rules.

4.3 Experiments with an SVR ranker

As already noted, when our dataset were constructed the judges felt it was not always clear to what extent the overall quality scores should reflect meaning preservation or grammaticality; and they also wondered if the overall quality scores should have also taken into consideration diversity. To address these concerns, in the experiments described in this section (and the remainder of the paper) we ignored the judges' overall scores, and we used a weighted average of the grammaticality, meaning preservation,

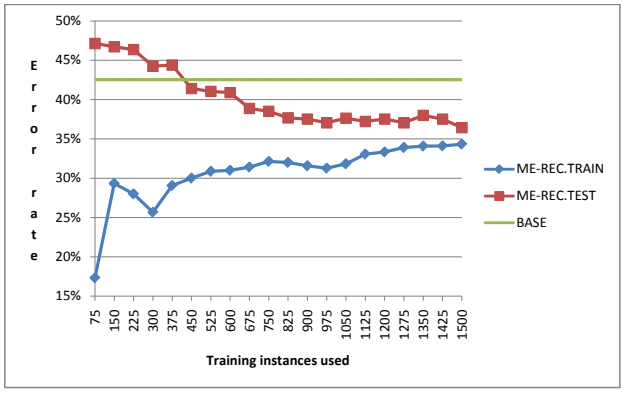

Figure 2: Learning curves of a Maximum Entropy classifier used as the ranking component of our method.

and diversity scores instead; the grammaticality and meaning preservation scores were those provided by the judges, while diversity was automatically computed as the edit distance (Levenshtein, computed on tokens) between S and C. Stated otherwise, the correct score $y(x_i)$ of each training or test instance x_i (i.e., of each feature vector of an $\langle S, C \rangle$ pair) was taken to be a linear combination of the grammaticality score $g(x_i)$, the meaning preservation score $m(x_i)$, and the diversity $d(x_i)$, as in Equation (6), where $\lambda_3 = 1 - \lambda_1 - \lambda_2$.

$$y(x_i) = \lambda_1 \cdot g(x_i) + \lambda_2 \cdot m(x_i) + \lambda_3 \cdot d(x_i) \quad (6)$$

We believe that the λ_i weights should in practice be application-dependent. For example, when paraphrasing user queries to a search engine that turns them into bags of words, diversity and meaning preservation may be more important than grammaticality; by contrast, when paraphrasing the sentences of a generated text to avoid repeating the same expressions, grammaticality is very important. Hence, generic paraphrase generators, like ours, intended to be useful in many different applications, should be evaluated for many different combinations of the λ_i weights. Consequently, in the experiments of this section we trained and evaluated the ranking component of our method (on the training and evaluation part, respectively, of the dataset of Section 3) several times, each time with a different combination of $\lambda_1, \lambda_2, \lambda_3$ values, with the values of each λ_i ranging from 0 to 1 with a step of 0.2.

We employed a Support Vector Regression (SVR) model in the experiments of this section, instead of

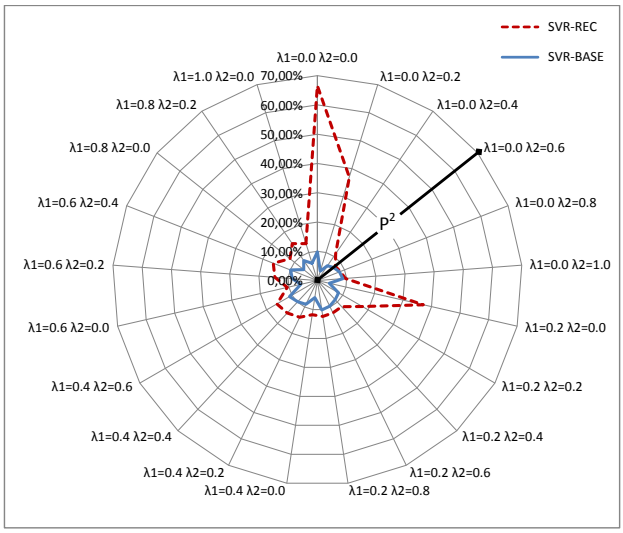

Figure 3: Performance of our method's SVR ranking component with (SVR-REC) and without (SVR-BASE) the additional features of the paraphrase recognizer.

a classifier, given that the $y(x_i)$ scores that we want to predict are real values.[14] An SVR is very similar to a Support Vector Machine (Vapnik, 1998; Cristianini and Shawe-Taylor, 2000; Joachims, 2002), but it is trained on examples of the form $\langle x_i, y(x_i)\rangle$, where $x_i \in \mathbb{R}^n$ and $y(x_i) \in \mathbb{R}$, and it learns a ranking function $f : \mathbb{R}^n \rightarrow \mathbb{R}$ that is intended to return $f(x_i)$ values as close as possible to the correct ones $y(x_i)$, given feature vectors x_i. In our case, the correct $y(x_i)$ values were those of Equation (6). We call SVR-REC the SVR ranker with all the 151 features of Section 4.2, and SVR-BASE the SVR ranker without the 136 features of the paraphrase recognizer.

We used the squared correlation coefficient ρ^2 to evaluate SVR-REC against SVR-BASE.[15] The ρ^2 coefficient shows how well the scores returned by the SVR are correlated with the desired scores $y(x_i)$; the higher the ρ^2 the higher the agreement. Figure 3 shows the experimental results. Each line from the diagram's center represents a different experimental setting, i.e., a different combination of λ_1 and λ_2; recall that $\lambda_3 = 1 - \lambda_1 - \lambda_2$. The distance of a method's curve from the center is the method's ρ^2 for that setting. The farther a point is from the center the higher ρ^2 is; hence, methods whose curves are closer to the diagram's outmost perimeter are better. Clearly, SVR-REC (which includes the recognizer's features) outperforms SVR-BASE (which relies only on the language model and the scores of the rules).

The two peaks of SVR-REC's curve are when λ_3 is very high (1 or 0.8), i.e., when $y(x_i)$ is dominated by the diversity score; in these cases, SVR-REC is at a clear advantage, since it includes features for surface string similarity (e.g., Levenshtein distance measured on $\langle s_1, c_1\rangle$), which in effect measure diversity, unlike SVR-BASE. Even when λ_1 is very high (1 or 0.8), i.e., when all or most of the weight is placed on grammaticality, SVR-REC outperforms SVR-BASE, indicating that the extra features in SVR-REC also contribute towards assessing grammaticality; by contrast SVR-BASE relies exclusively on the language model for grammaticality. Unfortunately, when λ_2 is very high (1 or 0.8), i.e., when all or most of the weight is placed on meaning preservation, there is no or very small difference between SVR-REC and SVR-BASE, suggesting that the extra features of the paraphrase recognizer are not as useful to the SVR, when assessing meaning preservation, as we would have hoped. Nevertheless, SVR-REC is overall better than SVR-BASE.

We believe that the dataset of Section 3 and the evaluation methodology summarized by Figure 3 will prove useful to other researchers, who may wish to evaluate other ranking components of generate-and-rank paraphrasing methods against ours, for example with different ranking algorithms or features. Similar datasets of candidate paraphrases can also be created using different collections of paraphrasing rules.[16] The same methodology can then be used to evaluate ranking components on those datasets.

5 Comparison to the state of the art

Having established that SVR-REC is a better configuration of our method's ranker than SVR-BASE, we

[14] Additional experiments confirmed that the SVR performs better than ME-REC as the ranking component. We use the SVR implementation of LIBSVM, available from `http://www.csie.ntu.edu.tw/~cjlin/libsvm/`, with an RBF kernel and default settings. All the features are normalized in $[-1, 1]$, when using SVR or ME-REC.

[15] If n is the number of test pairs, $f(x_i)$ the score returned by the SVR for the i-th pair, and $y(x_i)$ the correct score, then ρ^2 is:

$$\frac{(n\sum_{i=1}^{n} f(x_i)y_i - \sum_{i=1}^{n} f(x_i)\sum_{i=1}^{n} y(x_i))^2}{(n\sum_{i=1}^{n} f(x_i)^2 - (\sum_{i=1}^{n} f(x_i))^2)(n\sum_{i=1}^{n} y_i^2 - (\sum_{i=1}^{n} y(x_i))^2)}$$

[16] See Androutsopoulos and Malakasiotis (2010) for pointers.

proceed to investigate how well our overall generate-and-rank method (with SVR-REC) compares against a state of the art paraphrase generator.

As already mentioned, Zhao et al. (2010) recently presented a method (we call it ZHAO-ENG) that outperforms their previous method (Zhao et al., 2009a), which used paraphrasing rules and an SMT-like decoder (we call that previous method ZHAO-RUL). Given an input sentence S, ZHAO-ENG produces candidate paraphrases by translating S to 6 pivot languages via 3 different commercial machine translation engines (treated as black boxes) and then back to the original language, again via 3 machine translation engines (54 combinations). Roughly speaking, ZHAO-ENG then ranks the candidate paraphrases by their average distance from all the other candidates, selecting the candidate(s) with the smallest distance; distance is measured as BLEU score (Papineni et al., 2002).[17] Hence, ZHAO-ENG is also, in effect, a generate-and-rank paraphraser, but the candidates are generated by invoking multiple machine translation engines instead of applying paraphrasing rules, and they are ranked by the average distance measure rather than using an SVR.

An obvious practical advantage of ZHAO-ENG is that it exploits the vast resources of existing commercial machine translation engines when generating candidate paraphrases, which allows it to always obtain large numbers of candidate paraphrases. By contrast, the collection of paraphrasing rules that we currently use does not manage to produce any candidate paraphrases in 40% of the sentences of the New York Times part of AQUAINT, because no rule applies. Hence, in terms of ability to always paraphrase the input, ZHAO-ENG is clearly better, though it should be possible to improve our methods's performance in that respect by using larger collections of paraphrasing rules.[18] A further interesting question, however, is how good the paraphrases of the two methods are, when both methods manage to paraphrase the input, i.e., when at least one paraphrasing rule applies to S. This scenario can be seen as an emulation of the case where the collection of paraphrasing rules is sufficiently large to guarantee that at least one rule applies to any source sentence.

To answer the latter question, we re-implemented ZHAO-ENG, with the same machine translation engines and languages used by Zhao et al. (2010). We also trained our paraphraser (with SVR-REC) on the training part of the dataset of Section 3. We then selected 300 random source sentences S from AQUAINT that matched at least one of the paraphrasing rules, excluding sentences that had been used before. Then, for each one of the 300 S sentences, we kept the single best candidate paraphrase C_1 and C_2, respectively, returned by our paraphraser and ZHAO-ENG. The resulting $\langle S, C_1 \rangle$ and $\langle S, C_2 \rangle$ pairs were given to 10 human judges. This time the judges assigned only grammaticality and meaning preservation scores (on a 1–4 scale); diversity was again computed as edit distance. Each pair was evaluated by one judge, who was given an equal number of pairs from the two methods, without knowing which method each pair came from. The same judge never rated two pairs with the same S. Since we had no way to make ZHAO-ENG sensitive to $\lambda_1, \lambda_2, \lambda_3$, we trained SVR-REC with $\lambda_1 = \lambda_2 = 1/3$, as the most neutral combination of weights.

Table 2 lists the average grammaticality, meaning preservation, and diversity scores of the two methods. All scores were normalized in $[0, 1]$, but the reader should keep in mind that diversity was computed as edit distance, whereas the other two scores were provided by human judges on a 1–4 scale. The grammaticality score of our method was better than ZHAO-ENG's, and the difference was statistically significant.[19] In meaning preservation, ZHAO-ENG was slightly better, but the difference was not statistically significant. The difference in diversity was larger and statistically significant, with the diversity scores indicating that it takes approximately twice as many edit operations (insert, delete, replace) to turn each source sentence to ZHAO-ENG's paraphrase, compared to the paraphrase of our method.

We note that our method can be tuned, by adjusting the λ_i weights, to produce paraphrases with

[17] We use the version of ZHAO-ENG that Zhao et al. (2010) call "selection-based", since they reported it performs overall better than an alternative decoding-based version.

[18] Recall that the paraphrasing rules we use were extracted from an English-Chinese parallel corpus. Additional rules could be extracted from other parallel corpora, like Europarl (`http://www.statmt.org/europarl/`).

[19] We used Analysis of Variance (ANOVA) (Fisher, 1925), followed by post-hoc Tukey tests to check whether the scores of the two methods differ significantly ($p < 0.05$).

score (%)	our method	ZHAO-ENG
grammaticality	**90.89**	85.33
meaning preserv.	76.67	78.56
diversity	6.50	**14.58**

Table 2: Evaluation of our paraphrasing method (with SVR-REC) against ZHAO-ENG, using human judges. Results in bold indicate statistically significant differences.

higher grammaticality, meaning preservation, or diversity scores; for example, we could increase λ_3 and decrease λ_1 to obtain higher diversity at the cost of lower grammaticality in the results of Table 2.[20] It is unclear how ZHAO-ENG could be tuned that way.

Overall, our method seems to perform well against ZHAO-ENG, despite the vastly larger resources of ZHAO-ENG, provided of course that we limit ourselves to source sentences to which paraphrasing rules apply. It would be interesting to investigate in future work if our method's coverage (sentences it can paraphrase) can increase to ZHAO-ENG's level by using larger collections of paraphrasing rules. It would also be interesting to combine the two methods, perhaps by using SVR-REC (without features for the quality scores of the rules) to rank candidate paraphrases generated by ZHAO-ENG.

6 Conclusions and future work

We presented a generate-and-rank method to paraphrase sentences. The method first produces candidate paraphrases by applying existing paraphrasing rules extracted from parallel corpora, and it then ranks (or classifies) the candidates to keep the best ones. The ranking component considers not only the context-insensitive quality scores of the paraphrasing rules that produced each candidate, but also features intended to measure the extent to which the rule applications preserve grammaticality and meaning in the particular context of the input sentence, as well as the degree to which the resulting candidate differs from the input sentence (diversity).

Initial experiments with a Maximum Entropy classifier confirmed that the features we use can help a ranking component select better candidate paraphrases than a baseline ranker that considers only the average context-insensitive quality scores of the applied rules. Further experiments with an SVR ranker indicated that our full feature set, which includes features from an existing paraphrase recognizer, leads to improved performance, compared to a smaller feature set that includes only the context-insensitive scores of the rules and language modeling scores. We also propose a new methodology to evaluate the ranking components of generate-and-rank paraphrase generators, which evaluates them across different combinations of weights for grammaticality, meaning preservation, and diversity. The paper is accompanied by a paraphrasing dataset we constructed for evaluations of this kind.

Finally, we evaluated our overall method against a state of the art sentence paraphraser, which generates candidates by using several commercial machine translation systems and pivot languages. Overall, our method performed well, despite the vast resources of the machine translation systems employed by the system we compared against. Our method performed better in terms of grammaticality, equally well in meaning preservation, and worse in diversity, but it could be tuned to obtain higher diversity at the cost of lower grammaticality, whereas it is unclear how the system we compare against could be tuned this way. On the other hand, an advantage of the paraphraser we compared against is that it always produces paraphrases; by contast, our system does not produce paraphrases when no paraphrasing rule applies to the source sentence. Larger collections of paraphrasing rules would be needed to improve our method in that respect.

Apart from obtaining and experimenting with larger collections of paraphrasing rules, it would be interesting to evaluate our method in vivo, for example by embedding it in question answering systems (to paraphrase the questions), in information extraction systems (to paraphrase extraction templates), or in natural language generators (to paraphrase template-like sentence plans). We also plan to investigate the possibility of embedding our SVR ranker in the sentence paraphraser we compared against, i.e., to rank candidates produced by using several machine translation systems and pivot languages, as in ZHAO-ENG.

[20] Additional application-specific experiments confirm that this tuning is possible (Malakasiotis, 2011).

Abstract

We present a novel approach for automatic collocation error correction in learner English which is based on paraphrases extracted from parallel corpora. Our key assumption is that collocation errors are often caused by semantic similarity in the first language (L1-language) of the writer. An analysis of a large corpus of annotated learner English confirms this assumption. We evaluate our approach on real-world learner data and show that L1-induced paraphrases outperform traditional approaches based on edit distance, homophones, and WordNet synonyms.

1 Introduction

Grammatical error correction (GEC) is emerging as a commercially attractive application of natural language processing (NLP) for the booming market of English as foreign or second language (EFL/ESL[1]).

The de facto standard approach to GEC is to build a statistical model that can choose the most likely correction from a *confusion set* of possible correction choices. The way the confusion set is defined depends on the type of error. Work in context-sensitive spelling error correction (Golding and Roth, 1999) has traditionally focused on confusion sets with similar spelling (e.g., {*dessert*, *desert*}) or similar pronunciation (e.g., {*there*, *their*}). In other words, the words in a confusion set are deemed confusable because of orthographic or phonetic similarity. Other work in GEC has defined the confusion sets based on syntactic similarity, for example all English articles or the most frequent English prepositions form a confusion set (see for example (Tetreault et al., 2010; Rozovskaya and Roth, 2010; Gamon, 2010; Dahlmeier and Ng, 2011) among others).

In contrast, we investigate in this paper a class of grammatical errors where the source of confusion is the similar *semantics* of the words, rather than orthography, phonetics, or syntax. In particular, we focus on *collocation errors* in EFL writing. The term *collocation* (Firth, 1957) describes a sequence of words that is conventionally used together in a particular way by native speakers and appears more often together than one would expect by chance. The correct use of collocations is a major difficulty for EFL students (Farghal and Obiedat, 1995).

In this work, we present a novel approach for automatic correction of collocation errors in EFL writing. Our key observation is that words are potentially confusable for an EFL student if they have similar translations in the writer's first language (L1-language), or in other words if they have the same semantics in the L1-language of the writer. The Chinese word 看 (*kàn*), for example, has over a dozen translations in English, including the words *see*, *look*, *read*, and *watch*. A Chinese speaker who still "thinks" in Chinese has to choose from all these possible translations when he wants to express a sentence like *I like to **watch** movies* and might instead produce a sentence like **I like to **look** movies*. Although the meanings of *watch* and *look* are similar, the former is clearly the more fluent choice in this context. While these types of *L1-transfer er-*

[1]For simplicity, we will collectively refer to both terms as *English as a foreign language (EFL)*

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 107–117,
Edinburgh, Scotland, UK, July 27–31, 2011.

rors have been known in the EFL teaching literature (Swan and Smith, 2001; Meng, 2008), research in GEC has mostly ignored this fact.

We first analyze collocation errors in the NUS Corpus of Learner English (NUCLE), a fully annotated one-million-word corpus of learner English which we will make available to the community for research purposes (see Section 3 for details about the corpus). Our analysis confirms that many collocation errors can be traced to similar translations in the writer's L1-language. Based on this result, we propose a novel approach for automatic collocation error correction. The key component in our approach generates *L1-induced paraphrases* which we automatically extract from an L1-English parallel corpus. Our proposed approach outperforms traditional approaches based on edit distance, homophones, and WordNet synonyms on a test set of real-world learner data in an automatic and a human evaluation. Finally, we present a detailed analysis of unsolved instances in our data set to highlight directions for future work.

Our work adds to a growing body of research that leverages parallel corpora for semantic NLP tasks, for example in word sense disambiguation (Ng et al., 2003; Chan and Ng, 2005; Ng and Chan, 2007; Zhong and Ng, 2009), paraphrasing (Bannard and Callison-Burch, 2005; Liu et al., 2010a), and machine translation evaluation (Snover et al., 2009; Liu et al., 2010b).

The remainder of this paper is organized as follows. The next section reviews related work. Section 3 presents our analysis of collocation errors. Section 4 describes our approach for automatic collocation error correction. The experimental setup and the results are described in Sections 5 and 6, respectively. Section 7 provides further analysis. Section 8 concludes the paper.

2 Related Work

In this section, we give an overview of related work on collocation error correction. We also highlight differences between collocation error correction and related NLP tasks like context-sensitive spelling error correction, synonym extraction, lexical substitution, and paraphrasing.

Most work in collocation error correction has relied on dictionaries or manually created databases to generate collocation candidates (Shei and Pain, 2000; Wible et al., 2003; Futagi et al., 2008). Other work has focused on finding candidates that collocate with similar words, e.g., verbs that appear with the same noun objects form a confusion set (Liu et al., 2009; Wu et al., 2010). The work most similar to ours is probably the one presented by Chang *et al.* (2008), as they also use translation information to generate collocation candidates. However, they do not use automatically derived paraphrases from parallel corpora but bilingual dictionaries. Dictionaries usually have lower coverage, do not contain longer phrases or inflected forms, and do not provide any translation probability estimates. Also, their work focuses solely on verb-noun collocations, while we target collocations of arbitrary syntactic type.

Context-sensitive spelling error correction is the task of correcting spelling mistakes that result in another valid word, see for example (Golding and Roth, 1999). It has traditionally focused on a small number of pre-defined confusion sets, like homophones or frequent spelling errors. Even when the confusion sets are formed automatically, the similarity of words in a confusion set has been based on edit distance or phonetic similarity (Carlson et al., 2001). In contrast, we focus on words that are confusable due to their similar semantics instead of similar spelling or pronunciation. Also, we do not assume that the set of confusion sets is already given to us. Instead, we automatically extract confusable candidates from a parallel corpus.

Synonym extraction (Wu and Zhou, 2003), lexical substitution (McCarthy and Navigli, 2007) and paraphrasing (Madnani and Dorr, 2010) are related to collocation correction in the sense that they try to find semantically equivalent words or phrases. However, there is a subtle but important difference between these tasks and collocation correction. In the former, the main criterion is whether the original phrase and the synonym/paraphrase candidate are substitutable, i.e., both form a grammatical sentence when substituted for each other in a particular context. In contrast, in collocation correction, we are primarily interested in finding candidates which are *not substitutable* in their English context but *appear to be substitutable* in the L1-language of the writer, i.e., one forms a grammatical English sentence but the other does not.

Sentences	52,149

Table 1: Statistics of the NUS Corpus of Learner English (NUCLE)

3 Analysis of EFL collocation errors

While the fact that collocation errors can be caused by L1-transfer has been ascertained by EFL researchers (Meng, 2008), we need to quantify how frequent collocation errors can be traced to these types of transfer errors in order to estimate how many errors in EFL writing we can potentially hope to correct with information about the writer's L1-language.

We base our analysis on the NUS Corpus of Learner English (NUCLE). The corpus consists of about 1,400 essays written by EFL university students on a wide range of topics, like environmental pollution or healthcare. Most of the students are native Chinese speakers. The corpus contains over one million words which are completely annotated with error tags and corrections. All annotations have been performed by professional English instructors. The statistics of the corpus are summarized in Table 1. The annotation is stored in a stand-off fashion. Each error tag consists of the start and end offset of the annotation, the type of the error, and the appropriate gold correction as deemed by the annotator. The annotators were asked to provide a correction that would result in a grammatical sentence if the selected word or phrase would be replaced by the correction.

In this work, we focus on errors which have been marked with the error tag *wrong collocation/idiom/preposition*. As preposition errors are not the focus of this work, we automatically filter out all instances which represent simple substitutions of prepositions, using a fixed list of frequent English prepositions. In a similar way, we filter out a small number of article errors which were marked as collocation errors. Finally, we filter out instances where the annotated phrase or the suggested correction is longer than 3 words, as we observe that they contain highly context-specific corrections and are unlikely to generalize well (e.g., *"for the simple reasons that these can help them"* $\rightarrow$ *"simply to"*).

After filtering, we end up with 2,747 collocation errors and their respective corrections, which account for about 6% of all errors in NUCLE. This makes collocation errors the 7th largest class of errors in the corpus after article errors, redundancies, prepositions, noun number, verb tense, and mechanics. Not counting duplicates, there are 2,412 distinct collocation errors and corrections. Although there are other error types which are more frequent, collocation errors represent a particular challenge as the possible corrections are not restricted to a closed set of choices and they are directly related to *semantics* rather than syntax. We analyzed the collocation errors and found that they can be attributed to the following sources of confusion:

Spelling: We suspect that an error is caused by similar orthography if the edit distance between the erroneous phrase and its correction is less than a certain threshold.

Homophones: We suspect that an error is caused by similar pronunciation if the erroneous word and its correction have the same pronunciation. We use the CuVPlus English dictionary (Mitton, 1992) to map words to their phonetic representations.

Synonyms: We suspect that an error is caused by synonymy if the erroneous word and its correction are synonyms in WordNet (Fellbaum, 1998). We use WordNet 3.0.

L1-transfer: We suspect that an error is caused by L1-transfer if the erroneous phrase and its correction share a common translation in a Chinese-English phrase table. The details of the phrase table construction are described in Section 4. We note that although we focus on Chinese-English translation, our method is applicable to any language pair where parallel corpora are available.

As CuVPlus and WordNet are defined for individual words, we extend the matching process to phrases in the following way: two phrases A and B are deemed homophones/synonyms if they have the same length and the i-th word in phrase A is a homophone/synonym of the corresponding i-th word in phrase B.

Spelling	... it received *critics (criticism)* as much as complaints ...
	... budget for the aged to *improvise (improve)* other areas.
Homophones	... diverse spending can *aide (aid)* our country.
	... *insure (ensure)* the safety of civilians ...
Synonyms	... rapid *increment (increase)* of the seniors ...
	... energy that we can *apply (use)* in the future ...
L1-transfer	... and *give (provide,* 给予 *)* reasonable fares to the public ...
	... and *concerns (attention,* 关注 *)* that the nation put on technology and engineering ...

Table 3: Examples of collocation errors with different sources of confusion. The correction is shown in parenthesis. For L1-transfer, we also show the shared Chinese translation. The L1-transfer examples shown here do not belong to any of the other categories.

Suspected Error Source	Tokens	Types
Spelling	154	131
Homophones	2	2
Synonyms	74	60
L1-transfer	1016	782
L1-transfer w/o spelling	954	727
L1-transfer w/o homophones	1015	781
L1-transfer w/o synonyms	958	737
L1-transfer w/o spelling, homophones, synonyms	906	692

Table 2: Analysis of collocation errors. The threshold for spelling errors is one for phrases of up to six characters and two for the remaining phrases.

The results of the analysis are shown in Table 2. Tokens refer to running erroneous phrase-correction pairs including duplicates, and types refer to distinct erroneous phrase-correction pairs. As a collocation error can be part of more than one category, the rows in the table do not sum up to the total number of errors. The number of errors that can be traced to L1-transfer greatly outnumbers all other categories. The table also shows the number of collocation errors that can be traced to L1-transfer but not the other sources. 906 collocation errors with 692 distinct collocation error types can be attributed only to L1-transfer but not to spelling, homophones, or synonyms. Table 3 shows some examples of collocation errors for each category from our corpus. We note that there are also collocation error types that cannot be traced to any of the above sources. We will return to these errors in Section 7.

4 Correcting Collocation Errors

In this section, we propose a novel approach for correcting collocation errors in EFL writing.

4.1 L1-induced Paraphrases

We use the popular technique of paraphrasing with parallel corpora (Bannard and Callison-Burch, 2005) to automatically find collocation candidates from a sentence-aligned L1-English parallel corpus. As most of the essays in our corpus are written by native Chinese speakers, we use the FBIS Chinese-English corpus, which consists of about 230,000 Chinese sentences (8.5 million words) from news articles, each with a single English translation. We tokenize and lowercase the English half of the corpus in the standard way. We segment the Chinese half of the corpus using the maximum entropy segmenter from (Ng and Low, 2004; Low et al., 2005). Subsequently, we automatically align the texts at the word level using the Berkeley aligner (Liang et al., 2006; Haghighi et al., 2009). We extract English-L1 and L1-English phrases of up to three words from the aligned texts using the widely used phrase extraction heuristic in (Koehn et al., 2003). The paraphrase probability of an English phrase e_1 given an English phrase e_2 is defined as

$$p(e_1|e_2) = \sum_f p(e_1|f)p(f|e_2) \qquad (1)$$

where f denotes a foreign phrase in the L1 language. The phrase translation probabilities $p(e_1|f)$ and $p(f|e_2)$ are estimated by maximum likelihood estimation and smoothed using Good-Turing smoothing (Foster et al., 2006). Finally, we only keep para-

phrases with a probability above a certain threshold (set to 0.001 in our work).

4.2 Collocation Correction with Phrase-based SMT

We implement our approach in the framework of phrase-based statistical machine translation (SMT) (Koehn et al., 2003). Phrase-based SMT tries to find the highest scoring translation $\mathbf{e}$ given an input sentence $\mathbf{f}$. The *decoding* process of finding the highest scoring translation is guided by a log-linear model which scores translation candidates using a set of feature functions $h_i,\ i = 1, \ldots, n$

$$score(\mathbf{e}|\mathbf{f}) = \exp\left(\sum_{i=1}^{n} \lambda_i h_i(\mathbf{e}, \mathbf{f})\right) . \quad (2)$$

Typical features include a phrase translation probability $p(e|f)$, an inverse phrase translation probability $p(f|e)$, a language model score $p(\mathbf{e})$, and a constant phrase penalty. The optimization of the feature weights $\lambda_i,\ i = 1, \ldots, n$ can be done using minimum error rate training (MERT) (Och, 2003) on a development set of input sentences and their reference translations.

Because of the great flexibility of the log-linear model, researchers have used the framework for other tasks outside SMT, including grammatical error correction (Brockett et al., 2006). We adopt a similar approach in this work. We modify the phrase table of the popular phrase-based SMT decoder MOSES (Koehn et al., 2007) to include collocation corrections with features derived from spelling, homophones, synonyms, and L1-induced paraphrases.

- **Spelling:** For each English word, the phrase table contains entries consisting of the word itself and each word that is within a certain edit distance from the original word. Each entry has a constant feature of 1.0.

- **Homophones:** For each English word, the phrase table contains entries consisting of the word itself and each of the word's homophones. We determine homophones using the CuVPlus dictionary. Each entry has a constant feature of 1.0.

- **Synonyms:** For each English word, the phrase table contains entries consisting of the word itself and each of its synonyms in WordNet. If a word has more than one sense, we consider all its senses. Each entry has a constant feature of 1.0.

- **L1-paraphrases:** For each English phrase, the phrase table contains entries consisting of the phrase and each of its L1-derived paraphrases as described in Section 4.1. Each entry has two real-valued features: a paraphrase probability according to Equation 1 and an inverse paraphrase probability.

- **Baseline** We combine the phrase tables built for spelling, homophones, and synonyms. The combined phrase table contains three binary features for spelling, homophones, and synonyms, respectively.

- **All** We combine the phrase tables from spelling, homophones, synonyms, and L1-paraphrases. The combined phrase table contains five features: three binary features for spelling, homophones, and synonyms, and two real-valued features for the L1-paraphrase probability and inverse L1-paraphrase probability.

Additionally, each phrase table contains the standard constant phrase penalty feature. The first four tables only contain collocation candidates for individual words. We leave it to the decoder to construct corrections for longer phrases during the decoding process if necessary.

5 Experiments

In this section, we empirically evaluate our approach on real collocation errors in learner English.

5.1 Data Set

We randomly sample a development set of 770 sentences and a test set of 856 sentences from our corpus. Each sentence contains exactly one collocation error. The sampling is performed in a way that sentences from the same document cannot end up in both the development and the test set. In order to

keep conditions as realistic as possible, we make no attempt to filter the test set in any way.

We build phrase tables as described in Section 4.2. For the purpose of the experiments reported in this paper, we only need to generate phrase table entries for words and phrases which actually appear in the development or test set.

5.2 Evaluation Metrics

We conduct an automatic and a human evaluation. Our main evaluation metric is *mean reciprocal rank (MRR)* which is the arithmetic mean of the inverse ranks of the first correct answer returned by the system

$$\text{MRR} = \frac{1}{N}\sum_{i=1}^{N}\frac{1}{rank(i)} \quad (3)$$

where N is the size of the test set. If the system did not return a correct answer for a test instance, we set $\frac{1}{rank(i)}$ to zero.

In the human evaluation, we additionally report precision at rank k, $k = 1, 2, 3$, which we calculate as follows:

$$\text{P@k} = \frac{\sum_{a \in A} score(a)}{|A|} \quad (4)$$

where A is the set of returned answers of rank k or less and $score(\cdot)$ is a real-valued scoring function between zero and one.

5.3 Collocation Error Experiments

Automatic correction of collocation errors can conceptually be divided into two steps: *i) identification* of wrong collocations in the input, and *ii) correction* of the identified collocations. In this work, we focus on the second step and assume that the erroneous collocation has already been identified. While this might seem like a simplification, it has been the common evaluation setup in collocation error correction (see for example (Wu et al., 2010)). It also has a practical application where the user first selects a word or phrase and the system displays possible corrections.

In our experiments, we use the start and end offset of the collocation error provided by the human annotator to identify the location of the collocation error. We fix the translation of the rest of the sentence to its identity. We remove phrase table entries where the phrase and the candidate correction are identical, thus practically forcing the system to change the identified phrase. We set the distortion limit of the decoder to zero to achieve monotone decoding. We previously observed that word order errors are virtually absent in our collocation errors. For the language model, we use a 5-gram language model trained on the English Gigaword corpus with modified Kneser-Ney smoothing. All experiments use the same language model to allow a fair comparison.

We perform MERT training with the popular BLEU metric (Papineni et al., 2002) on the development set of erroneous sentences and their corrections. As the search space is restricted to changing a single phrase per sentence, training converges relatively quickly after two or three iterations. After convergence, the model can be used to automatically correct new collocation errors.

6 Results

We evaluate the performance of the proposed method on our test set of 856 sentences, each with one collocation error. We conduct both an automatic and a human evaluation. In the automatic evaluation, the system's performance is measured by computing the rank of the gold answer provided by the human annotator in the n-best list of the system. We limit the size of the n-best list to the top 100 outputs. If the gold answer is not found in the top 100 outputs, the rank is considered to be infinity, or in other words, the inverse of the rank is zero. We also report the number of test instances for which the gold answer was ranked among the top k answers, $k = 1, 2, 3, 10, 100$. The results of the automatic evaluation are shown in Table 4

For collocation errors, there are usually more than one possible correct answer. Therefore, automatic evaluation underestimates the actual performance of the system by only considering the single gold answer as correct and all other answers as wrong. As such, we carried out a human evaluation for the systems BASELINE and ALL. We recruited two English speakers to judge a subset of 500 test sentences. For each sentence, a judge was shown the original sentence and the 3-best candidates of each of the two systems. We restricted human evaluation to the 3-best candidates, as we believe that answers at a rank

Model	Rank = 1	Rank ≤ 2	Rank ≤ 3	Rank ≤ 10	Rank ≤ 100	MRR
Spelling	35	41	42	44	44	4.51
Homophones	1	1	1	1	1	0.11
Synonyms	32	47	52	60	61	4.98
Baseline	49	68	80	93	96	7.61
L1-paraphrases	93	133	154	**216**	**243**	15.43
All	**112**	**150**	**166**	**216**	241	**17.21**

Table 4: Results of automatic evaluation. Columns two to six show the number of gold answers that are ranked within the top k answers. The last column shows the mean reciprocal rank in percentage. Bigger values are better.

P(A)	0.8076
Kappa	0.6152

Table 5: Inter-annotator agreement. $P(E) = 0.5$.

larger than three will not be very useful in a practical application. The candidates are displayed together in alphabetical order without any information about their rank or which system produced them or the gold answer by the annotator. The difference between the candidates and the original sentence is highlighted. The judges were asked to make a binary judgment for each of the candidates on whether the proposed candidate is a valid correction of the original or not. We represent valid corrections with a score of 1.0 and invalid corrections with a score of 0.0. Inter-annotator agreement is reported in Table 5. The chance of agreement $P(A)$ is the percentage of times that the annotators agree, and $P(E)$ is the expected agreement by chance, which is 0.5 in our case. The Kappa coefficient is defined as

$$\text{Kappa} = \frac{\text{P(A)} - \text{P(E)}}{1 - \text{P(E)}}$$

We obtain a Kappa coefficient of 0.6152. A Kappa coefficient between 0.6 and 0.8 is considered as showing *substantial* agreement according to Landis and Koch (1977). To compute precision at rank k, we average the judgments. Thus, a system can receive a score of 0.0 (both judgments negative), 0.5 (judges disagree), or 1.0 (both judgments positive) for each returned answer. To compute MRR, we cannot simply average the judgments as MRR requires binary judgments on whether an item is correct or not. Instead, we report MRR on the union and the intersection of the judgments. In the first case, the rank of the first correct item is the minimum rank of any item judged correct by *either* judge. In the second case, the rank of the first correct item is the minimum rank of any item judged correct by *both* judges. The results for the human evaluation are shown in Table 6. Our best system ALL outperforms the BASELINE approach on all measures. It receives a precision at rank 1 of 38.20% and a MRR of 33.16% (intersection) and 57.26% (union). Table 7 shows some examples from our test set.

Unfortunately, comparison of our results with previous work is complicated by the fact that there currently exists no standard data set for collocation error correction. We will make our corpus available for research purposes in the hope that it will allow researchers to more directly compare their results in future.

7 Analysis

In this section, we analyze and categorize those test instances for which the ALL system could not produce an acceptable correction in the top 3 candidates. We manually analyze 100 test sentences for which neither judge had deemed any candidate answer to be a valid correction. Based on our findings, we categorize the 100 sentences into eight categories which are shown below. Table 8 shows examples from each category.

Out-of-vocabulary (21/100) The most frequent reason why the system does not produce a good correction is that the erroneous collocation is out of vocabulary. These collocations often involve compound words, like *man-hours* or *carefully-nurturing*, or infrequent expressions, like *copy phenomena*, which do not appear in the FBIS parallel corpus. We expect that this problem can be reduced by using larger parallel corpora for paraphrase extraction.

Near miss (18/100) The second largest category

Model	Rank = 1	Rank $\leq$ 2	Rank $\leq$ 3	P@1	P@2	P@3	MRR
Baseline	43 ǀ 141	69 ǀ 201	83 ǀ 237	18.40	16.68	15.36	12.13 ǀ 36.60
All	**137 ǀ 245**	**176 ǀ 303**	**204 ǀ 340**	**38.20**	**32.87**	**29.30**	**33.16 ǀ 57.26**

Table 6: Results of human evaluation. Rank and MRR results are shown for the intersection (first value) and union (second value) of human judgments.

Original	it must be clear, concise and unambiguous to *prevent* any off-track
Gold	it must be clear, concise and unambiguous to *avoid* any off-track
All	it must be clear, concise and unambiguous to *avoid* any off-track
	it must be clear, concise and unambiguous to *stop* any off-track
	it must be clear, concise and unambiguous to *block* any off-track
Baseline	*it must be clear, concise and unambiguous to *present* any off-track
	it must be clear, concise and unambiguous to *forestall* any off-track
	*it must be clear, concise and unambiguous to *lock* any off-track

Original	although many may *agree* that public spending on the elderly should be limited . . .
Gold	although many may *argue* that public spending on the elderly should be limited . . .
All	although many may *believe* that public spending on the elderly should be limited . . .
	although many may *think* that public spending on the elderly should be limited . . .
	although many may *accept* that public spending on the elderly should be limited . . .
Baseline	*although many may *agreed* that public spending on the elderly should be limited . . .
	*although many may *hold* that public spending on the elderly should be limited . . .
	*although many may *agrees* that public spending on the elderly should be limited . . .

Table 7: Examples of test sentences with the top 3 answers of the ALL and BASELINE system. An answer judged incorrect by at least one judge is marked with an asterisk (*).

Out of vocabulary	. . . many illegal *copy phenomena (copy phenomena, **copies**)* in china.
	. . . lead to reduced *man-hours (man-hours, **productivity**)* as people fall sick . . .
Near miss	. . . smaller groups of people, sometimes *even (more, **only**)* individual .
	. . . take pre-emptive *actions (activities, **measures**)* . . .
Function/auxiliary words	. . . entertainment an elderly person can *have (be, **enjoy**)* .
	. . . and the security issue is solved *also (and, **too**)*
Discourse specific	. . . make other countries respect and fear *you (<question mark>, **a country**)*
	. . . will contribute nothing to the *accident (explosion, **problem**)* .
Spelling errors	this *incidence (rate, **incident**)* had also resulted in 4 fatalities . . .
	refrigerator did not *compromise (yield, **comprise**)* of any moving parts . . .
Word sense	. . . refers to the desire or shortage of a *good (better, **commodity**)* and . . .
	. . . members are always from different *majors (major league, **specialties**)*
Preposition constructions	. . . can be an area worth *investing (investing, **investing in**)*
	. . . in spending their *resources (resources, **resources on**)*
Others	this might *redirect (make sound, **reduce**)* foreign investments . . .
	. . . a trading hub since *british 's (british 's, **british**)* rule.

Table 8: Examples of sentences without valid corrections by the ALL model. The top-1 suggestion of the system and the gold answer (in bold) are shown in parenthesis.

consists of instances where the system barely misses the gold standard answer. This includes cases where the extracted L1-paraphrases do not contain the exact phrase required, e.g., the paraphrase table contains *even|||only get* when the gold correction was *even* → *only*, or the phrase table actually contains the gold answer but fails to rank it among the top 3 answers. The first problem could be addressed by modifying the phrase extraction heuristic to produce more fine-grained phrase pairs. The second problem requires a better language model. Although our language model is trained on the large English Gigaword corpus, it is not always successful in promoting the correct candidate to the top. The domain mismatch between the newswire domain of Gigaword and student essays could be one reason for this.

Function/auxiliary words (14/100) We observe that collocation errors that involve function words or auxiliary words are not handled very well by our model. Function words and auxiliary words in English lack direct counterparts in Chinese, which is why the word alignments and therefore the extracted phrases for these words contain a high amount of noise. As function words and auxiliaries are essentially a closed set, it might be more promising to build separate models with fixed confusion sets for them.

Discourse specific (14/100) Some of the gold answers are highly specific to the particular discourse that they appear in. As our model corrects collocation errors at the sentence level, such gold answers will be very difficult or impossible to determine correctly. Including more context beyond the sentence level might help to overcome this problem, although it is not easy to integrate this larger context information.

Spelling errors (9/100) Some of the collocation errors are caused by spelling mistakes, e.g., *incidence* instead of *incident*. Although the ALL model includes candidates which are created through edit distance, paraphrase candidates created from the misspelled word can dominate the top 3 ranks, e.g., *rate* and *frequently* are paraphrases of *incidence*. A possible solution would be to perform spell-checking as a separate pre-processing step prior to collocation correction.

Word sense (7/100) Some of the failures of the model can be attributed to ambiguous senses of the collocation phrase. As we do not perform word sense disambiguation in our current work, candidates from other word senses can end up as the top candidates. Including word sense disambiguation into the model might help, although accurate word sense disambiguation on noisy learner text may not be easy.

Preposition constructions (6/100) Some of the collocation errors involve preposition constructions, e.g., the student wrote *attend* instead of *attend to*. Because prepositions do not have a direct counterpart in Chinese, the L1-paraphrases do not model their semantics very well. This category is closely related to the function/auxiliary word category. Again, since prepositions are a closed set, it might be more promising to build a separate model for them.

Others (11/100) Other mistakes include collocation errors where the gold answer slightly changed the semantics of the target word, e.g., *redirect potential foreign investments* → *reduce potential foreign investments*, active-passive alternation (*enhanced economics* → *was economical*), and noun possessive errors (*british 's rule* → *british rule*).

8 Conclusion and Future Work

We have presented a novel approach for correcting collocation errors in written learner text. Our approach exploits the semantic similarity of words in the writer's L1-language based on paraphrases extracted from an L1-English parallel corpus. Our experiments on real-world learner data show that our approach outperforms traditional approaches based on edit distance, homophones, and synonyms by a large margin.

In future work, we plan to extend our system to fully automatic collocation correction that involves both identification and correction of collocation errors.

Abstract

Class-instance label propagation algorithms have been successfully used to fuse information from multiple sources in order to enrich a set of unlabeled instances with class labels. Yet, nobody has explored the relationships between the instances themselves to enhance an initial set of class-instance pairs. We propose two graph-theoretic methods (centrality and regularization), which start with a small set of labeled class-instance pairs and use the instance-instance network to extend the class labels to all instances in the network. We carry out a comparative study with state-of-the-art knowledge harvesting algorithm and show that our approach can learn additional class labels while maintaining high accuracy. We conduct a comparative study between class-instance and instance-instance graphs used to propagate the class labels and show that the latter one achieves higher accuracy.

1 Introduction

Many natural language processing applications use and rely on semantic knowledge resources. Since manually built lexical repositories such as WordNet (Fellbaum, 1998) cover a limited amount of knowledge and are tedious to maintain over time, researchers have developed algorithms for automatic knowledge extraction from structured and unstructured texts. There is a substantial body of work on extracting is-a relations (Etzioni et al., 2005; Kozareva et al., 2008), part-of relations (Girju et al., 2003; Pantel and Pennacchiotti, 2006) and general facts (Lin and Pantel, 2001; Davidov and Rappoport, 2009; Jain and Pantel, 2010). The usefulness of the generated resources has been shown to be valuable to information extraction (Riloff and Jones, 1999), question answering (Katz et al., 2003) and textual entailment (Zanzotto et al., 2006) systems.

Among the most common knowledge acquisition approaches are those based on lexical patterns (Hearst, 1992; Etzioni et al., 2005; Kozareva et al., 2008) and clustering (Lin and Pantel, 2002; Davidov and Rappoport, 2008). While clustering can find instances and classes that are not explicitly expressed in text, they often may not generate the granularity needed by the users. In contrast, pattern-based approaches generate highly accurate lists, but they are constraint to the information matched by the pattern and often suffer from recall. (Paşca, 2004; Snow et al., 2006; Kozareva and Hovy, 2010) have shown that complete lists of semantic classes and instances are valuable for the enrichment of existing resources like WordNet and for taxonomy induction. Therefore, researchers have focused on the development of methods that can automatically augment the initially extracted class-instance pairs.

(Pennacchiotti and Pantel, 2009) fused information from pattern-based and distributional systems using an ensemble method and a rich set of features derived from query logs, web-crawl and Wikipedia. (Talukdar et al., 2008) improved class-instance extractions exploring the relationships between the classes and the instances to propagate the initial class-labels to the remaining unlabeled instances. Later on (Talukdar and Pereira, 2010) showed that class-instance extraction with label propagation can be further improved by adding semantic information

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 118–128,
Edinburgh, Scotland, UK, July 27–31, 2011.

in the form of instance-attribute edges derived from independently developed knowledge base. Similarly to (Talukdar et al., 2008) and (Talukdar and Pereira, 2010), we are interested in enriching class-instance extractions with label propagation. However, unlike the previous work, we model the relationships between the instances themselves to propagate the initial set of class labels to the remaining unlabeled instances. To our knowledge, this is the first work to explore the connections between instances for the task of class-label propagation.

Our work addresses the following question: *Is it possible to effectively explore the structure of the text-mined instance-instance networks to enhance an incomplete set of class labels?* Our intuition is that if an instance like *bear* belongs to a semantic class *carnivore*, and the instance *bear* is connected to the instance *fox*, then it is more likely that the unlabeled instance *fox* is also of class *carnivore*. To solve this problem, we propose two graph-based approaches that use the structure of the *instance-instance* graph to propagate the class labels. Our methods are agnostic to the sources of semantic instances and classes. In this work, we carried out experiments with a state-of-the-art instance extraction system and conducted a comparative study between the original and the enhanced class-instance pairs. The results show that this labeling procedure can begin to bridge the gap between the extraction power of the pattern-based approaches and the desired recall by finding class-instance pairs that are not explicitly mentioned in text. The contributions of the paper are as follows:

- We use only the relationships between the instances themselves to propagate class labels.
- We observe how often labels are propagated along the edges of our semantic network, and propose two ways to extend an initial set of class labels to all the instance nodes in the network. The first approach uses a linear system to compute the network centrality relative to the initially labeled instances. The second approach uses a regularization framework with respect to a random walk on the network.
- We evaluate the proposed approaches and show that they discover many new class-instance pairs compared to state-of-the-art knowledge harvesting algorithm, while still maintaining high accuracy.
- We conduct a comparative study between class-instance and instance-instance graphs used to propagate class labels. The experiments show that considering relationships between instances achieves higher accuracy.

The rest of the paper is organized as follows. In Section 2, we review related work. Section 3 describes the Web-based knowledge harvesting algorithm used to extract the instance network and the class-instance pairs necessary for our experimental evaluation. Section 4 describes the two graph-theoretic methods for class label propagation using an instance-instance network. Section 5 shows a comparative study between the proposed graph algorithms and different baselines. We also show a comparison between class-instance and instance-instance graphs used in the label propagation. Finally, we conclude in Section 6.

2 Related Work

In the past decade, we have reached a good understanding on the knowledge harvesting technology from structured (Suchanek et al., 2007) and unstructured text. Researchers have harvested with varying success semantic lexicons (Riloff and Shepherd, 1997) and concept lists (Katz et al., 2003). Many efforts have also focused on the extraction of is-a relations (Hearst, 1992; Paşca, 2004; Etzioni et al., 2005; Paşca, 2007; Kozareva et al., 2008), part-of relations (Girju et al., 2003; Pantel and Pennacchiotti, 2006) and general facts (Etzioni et al., 2005; Davidov and Rappoport, 2009; Jain and Pantel, 2010). Various approaches have been proposed following the patterns of (Hearst, 1992) and clustering (Lin and Pantel, 2002; Davidov and Rappoport, 2008). A substantial body of work has explored issues such as reranking the harvested knowledge using mutual information (Etzioni et al., 2005) and graph algorithms (Hovy et al., 2009), estimating the goodness of text-mining seeds (Vyas et al., 2009), organizing the extracted information (Cafarella et al., 2007a; Cafarella et al., 2007b) and inducing term taxonomies with WordNet (Snow et al., 2006) or starting from scratch (Kozareva and Hovy, 2010).

Since pattern-based approaches tend to be high-precision and low-recall in nature, recently of great interest to the research community is the development of approaches that can increment the recall of the harvested class-instance pairs. (Pennacchiotti and Pantel, 2009) proposed an ensemble semantic framework that mixes distributional and pattern-based systems with a large set of features from a web-crawl, query logs, and Wikipedia. (Talukdar et al., 2008) combined extractions from free text and structured sources using graph-based label propagation algorithm. (Talukdar and Pereira, 2010) conducted a comparative study of graph algorithms and showed that class-instance extraction can be improved using additional information that can be modeled as instance-attribute edges.

Closest to our work is that of (Talukdar et al., 2008; Talukdar and Pereira, 2010) who model class-instance relations to propagate class-labels. Although these algorithms can be applied to other relations (Alfonseca et al., 2010), to our knowledge yet nobody has modeled the connections between the instances themselves for the task of class-label propagation. We propose regularization and centrality graph-theoretic methods, which exploit the instance-instance network and a small set of class-instance pairs to propagate the class-labels to the remaining unlabeled instances. While objectives similar to regularization have been used for class-label propagation, the application of node centrality for this task is also novel. The proposed solutions are intuitive and almost parameter-free (both methods have a single parameter, which is easy to interpret and does not require careful tuning).

3 Knowledge Harvesting from the Web

Our proposed class-label enhancement approaches are agnostic to the sources of semantic instances and classes. Several methods have been developed to harvest instances from the Web (Paşca, 2004; Etzioni et al., 2005; Paşca, 2007; Kozareva et al., 2008) and potentially we can use any of them. In our experiments, we use the doubly-anchored (DAP) method of (Kozareva et al., 2008), because it achieves higher precision than (Etzioni et al., 2005; Paşca, 2007), it is easy to implement and requires minimum supervision (only one seed instance and a lexico-syntactic pattern).

For a given semantic class of interest say *animals*, the algorithm starts with a *seed* example of the class, say *whales*. The *seed* instance is fed into a doubly-anchored pattern "<*semantic-class*> such as <*seed*> and *", which extracts on the position of the * new instances of the semantic class. Then, the newly acquired instances are individually placed on the position of the *seed* in the DAP pattern. The bootstrapping procedure is repeated until no new instances are found. We use the harvested instances to build the instance-instance graph in which the nodes are the learned instances and directed edges like (*whales*,*dolphins*) indicate that the instance *whales* extracted the instance *dolphins*. The edges between the instances are weighted based on the number of times the DAP pattern extracted the instances together.

Different strategies can be employed to acquire semantic classes for each instance. We follow the fully automated approach of (Hovy et al., 2009), which takes the learned instance pairs from DAP and feeds them into the pattern "* such as <*instance*$_1$> and <*instance*$_2$>". The algorithm extracts on the position of the * new semantic classes related to *instance*$_1$. According to (Hovy et al., 2009), the usage of two instances acts as a disambiguator and leads to much more accurate semantic class extraction compared to (Ritter et al., 2009).

4 Methods

We model the output of the instance harvesting algorithm as a directed weighted graph that is given by a set of vertices V and a set of edges E. We use n to denote the number of vertices. A node u corresponds to a learned instance, and an edge $(u, v) \in E$ indicates that the instance v was learned from the instance u using the *DAP* pattern. The weight of the edge $w(u, v)$ specifies the number of times the pair of instances were found by the *DAP* pattern. We define the adjacency matrix of the graph as:

$$A(u,v) = \begin{cases} w(u,v) & \text{if } (u,v) \in E \\ 0 & \text{otherwise.} \end{cases}$$

We use $d_{\text{out}}(u)$ to specify the out-degree of u: $d_{\text{out}}(u) = \sum_{(u,v)\in E} w(u,v)$, and $d_{\text{in}}(v)$ to specify the in-degree of v: $d_{\text{in}}(v) = \sum_{(u,v)\in E} w(u,v)$.

We represent the initial set of instances L that are believed to belong to class C (the set of *labeled* instances) by a row vector $l \in \{0,1\}^n$, where $l(u) = 1$ if $u \in L$. Our objective is to compute a vector $\hat{l}$ where $\hat{l}(u)$ is proportional to how likely it is that u belongs to C. We write all vectors as row vectors, and use $\vec{c}$ to denote a 1 by n *constant* vector such that $\vec{c}(u) = c$ for all $u \in V$.

4.1 Personalized Centrality

Our first approach is based on the intuition that if $u \in C$ and $(u,v) \in E$, then it is more likely that $v \in C$. Moreover, the larger the weight of the edge $w(u,v)$, the more likely it is that $v \in C$. When we extend this intuition to all the in-neighbors, we say that the score of each node is proportional to the sum of the scores of its in-neighbors scaled by the edge weights: $\hat{l}(v) = \alpha \sum_{(u,v)\in E} \hat{l}(u) w(u,v)$. We can verify that the vector $\hat{l}$ must then satisfy $\hat{l} = \alpha \hat{l} A$, so it is an eigenvector of the adjacency matrix of the graph with an eigenvalue of α.

However, this formulation is insufficient because even though it captures our intuition that the nodes get their scores from their in-neighbors, we are still ignoring the initial scores of the nodes. A way to take the initial scores into consideration is to compute the following steady-state equation:

$$\hat{l} = l + \alpha \cdot \hat{l} A. \tag{1}$$

Equation 1 specifies that the score $\hat{l}(u)$ of each node u is the sum of its initial score $l(u)$ and the weighted sum of the scores of its neighbors, which is scaled by α. This equation is known as α-centrality, which was first introduced by (Bonacich and Lloyd, 2001). The α parameter controls how much the score of each node depends on the scores of its neighbors. When $\alpha = 0$ the score of each node is equivalent to its initial score, and does not depend on the scores of its neighbors at all.

Alternately, we can think of the vector $\hat{l}$ as the fixed-point of the process in which in each iteration some node v updates its score $\tilde{l}(v)$ by setting $\tilde{l}(v) = l(v) + \alpha \sum_{(u,v)\in E} w(u,v) \tilde{l}(u)$.

Solving Equation 1 we can see that $\hat{l} = l(I - \alpha A)^{-1}$, where I is the identity matrix of size n. The solution is also closely related to the following expression, which is known as a Katz score (Katz, 1953):

$$s \sum_{t=1}^{\infty} \alpha^t A^t.$$

We can verify that $A^t(u,v)$ gives the number of paths of length t between u and v. Katz proposed using the above expression with the starting vector $s = \vec{1}$ to measure centrality in a network. Therefore, the score of node v is given by the number of paths from u to v for all $u \in V$, with longer paths given less weight based on the value of α. The method proposed here measures a similar quantity with a non-uniform starting vector. To show the relationship between the two measures we use the identity that $\sum_{t=1}^{\infty} \alpha^t A^t = (I - \alpha A)^{-1} - I$. It is easy to see that

$$\begin{aligned} \hat{l} &= l(I - \alpha A)^{-1} \\ &= l(\textstyle\sum_{t=1}^{\infty} \alpha^t A^t + I) \\ &= l \textstyle\sum_{t=1}^{\infty} \alpha^t A^t + l \\ &= l \textstyle\sum_{t=0}^{\infty} \alpha^t A^t. \end{aligned} \tag{2}$$

Equation 2 shows that $\hat{l}(v)$ is given by the number of paths from u to v for all $u \in L$ (the initial labeled set). Using a larger value of α corresponds to giving more weight to paths of longer length. The summation $\sum_{t=0}^{\infty} \alpha^t A^t$ converges as long as $|\alpha| < 1/\lambda_{\max}$, where $\lambda_{\max}$ is the largest eigenvalue of A. Therefore, we can only consider values of α in this range.

4.2 Regularization Using Random Walks

Our second approach constrains $\hat{l}$ to be as consistent or *smooth* as possible with respect to the structure of the graph. The simplest way to express this is to require that for each edge $(u,v) \in E$, the scores of the endpoints $\hat{l}(u)$ and $\hat{l}(v)$ must be as similar as possible. Moreover, the greater the weight of the edge $w(u,v)$ the more important it is for the scores to match. Using this intuition we can define the following optimization problem:

$$\text{argmin}_{\hat{l}\in\{0,1\}^n} \sum_{(u,v)\in E} (\hat{l}(u) - \hat{l}(v))^2.$$

Setting $\hat{l} = \vec{0}$ or $\hat{l} = \vec{1}$ clearly optimizes this function, but does not give a meaningful solution. However, we can additionally constrain $\hat{l}$ by requiring that the initial labels cannot be modified, or more generally penalizing the discrepancy between $\hat{l}(u)$ and $l(u)$ for $u \in L$. The methods of (Talukdar and Pereira, 2010) optimize objective functions of this type.

Unlike the work of (Talukdar and Pereira, 2010), here we use an objective function that considers smoothness with respect to a *random walk* on the graph. Performing a random walk allows us to take more of the graph structure into account. For example, if nodes u and v are part of the same cluster then it is likely that the edge (u, v) is heavily traversed during the random walk, and should have a lot of probability in the stationary distribution of the walk. Simply considering the weight of the edge $w(u, v)$ gives us no such information. Therefore if our objective function requires the scores to be consistent with respect to the stationary probability of the edges in the random walk, we can compute scores that are consistent with the *clustering structure* of the graph.

Our semantic network is not strongly connected, so we must make some modifications to the random walk to ensure that it has a stationary distribution. Section 4.2.1 describes our random walk and how we compute the transition probability matrix P and its stationary probability distribution π. The definition of our objective function and the description of how it is optimized is given in Section 4.2.2.

4.2.1 Teleporting Random Walk

Formally, a random walk is a process where at each step we move from some node to one of its neighbors. The transition probabilities are given by edge weights, therefore the transition probability matrix W is the normalized adjacency matrix where each row sums to one:

$$W = D^{-1}A.$$

Here the D matrix is the degree matrix, which is a diagonal matrix given by

$$D(u, v) = \begin{cases} d_{\text{out}}(u) & \text{if } u = v \\ 0 & \text{otherwise.} \end{cases}$$

In our semantic network some nodes have no out-neighbors, so in order to compute W we first add a self-loop to any such node. In addition, we modify the random walk to *reset* at each step with nonzero probability β to ensure that it has a steady-state probability distribution. When the walk resets it jumps or *teleports* to any node in the graph with equal probability. The transition probability matrix of this process is given by

$$P = \beta K + (1 - \beta)W,$$

where K is an n by n matrix given by $K(u, v) = \frac{1}{n}$ for all $u, v \in V$. The stationary distribution π must satisfy $\pi = \pi P$. Equivalently π can be viewed as a solution to the following PageRank equation:

$$\pi = \beta s + (1 - \beta)\pi W.$$

Here the *starting* vector $s = \frac{1}{n}\vec{1}$ gives the probability distribution for where the walk transitions when it resets. In our computations we use a jump probability $\beta = 0.15$, which is standard for computations of PageRank. The stationary distribution π can be computed by either solving the PageRank equation or computing the eigenvector of P corresponding to the eigenvalue of 1.

4.2.2 Regularization

(Zhou et al., 2005) propose the following function to measure the smoothness of $\hat{l}$ with respect to the stationary distribution of the random walk:

$$\Omega(\hat{l}) = \frac{1}{2} \sum_{(u,v)\in E} \pi(u)P(u, v)\left(\frac{\hat{l}(u)}{\sqrt{\pi(u)}} - \frac{\hat{l}(v)}{\sqrt{\pi(v)}}\right)^2.$$

Here $\pi(u)P(u, v)$ gives the steady-state probability of traversing the edge (u, v), and $\pi(u)$ and $\pi(v)$ specify how much probability u and v have in the stationary distribution π. Zhou et al. point out that using this function gives better results than smoothness with respect to the edge weights, which can be formulated by replacing $\pi(u)p(u, v)$ with $w(u, v)$, and replacing $\pi(u)$ and $\pi(v)$ with $d_{\text{out}}(u)$ and $d_{\text{in}}(v)$, respectively. This observation is consistent with our intuition that considering a random walk takes more of the graph structure into account.

In addition to minimizing $\Omega(\hat{l})$, we also want $\hat{l}$ to be as close as possible to l, which gives the following optimization problem:

$$\text{argmin}_{\hat{l}\in\mathbb{R}^n}\{\Omega(\hat{y}) + \mu||\hat{l} - l||^2\}. \quad (3)$$

Here the $\mu > 0$ parameter specifies the tradeoff between the two terms: using a larger μ corresponds to placing more emphasis on agreement with the initial labels. (Zhou et al., 2005) show that this objective is optimized by computing

$$\hat{l} = (I - \gamma\Theta)^{-1}l, \quad (4)$$

where $\Theta = (\Pi^{1/2}P\Pi^{-1/2} + \Pi^{-1/2}P\Pi^{1/2})/2$, and $\gamma = 1/(1 + \mu)$. Π is a diagonal matrix given by

$$\Pi(u,v) = \begin{cases} \pi(u) & \text{if } u = v \\ 0 & \text{otherwise.} \end{cases}$$

Zhou et al. propose this approach for semi-supervised learning of labels on the graph, given an initial vector l such that $l(u) = 1$ if vertex u has the label, $l(u) = -1$ if u does not have the label, and $l(u) = 0$ if the vertex is unlabeled. They propose taking the sign of $\hat{l}(u)$ to classify u as positive or negative. Using our labeling procedure we do not have any negative examples, so our initial vector l is non-negative, resulting in a non-negative vector $\hat{l}$. This is not a problem because we can still interpret $\hat{l}(u)$ to be proportional to how likely it is that u has the label. Rather than trying different settings of μ, we directly vary γ, with a smaller γ placing more emphasis on agreement with initial labels.

5 Experimental Evaluation

5.1 Data Collection

For our experimental study, we select three widely used domains in the harvesting community (Etzioni et al., 2005; Paşca, 2007; Hovy et al., 2009; Kozareva and Hovy, 2010): *animals* and *vehicles*. For each domain we randomly selected different semantic classes, which resulted in 20 classes altogether. To generate the instance-instance semantic network, we use the harvesting procedure described in Section 3. For example, to learn instances associated with animals, we instantiate the bootstrapping algorithm with the semantic class *animals*, the seed instance *bears* and the pattern "*animals* such as *bears* and *"". We submitted the pattern as queries to Yahoo!Boss and collected new instances. We ranked the instances following (Kozareva et al., 2008) which resulted in 397 animal, 4471 plant and 1425 vehicle instances. Table 1 shows the number of nodes (instances) and directed edges for the constructed semantic networks.

class	#instances	#directed-edges
animals	397	2812
vehicles	1425	3191

Table 1: *Nodes & Edges in the Instance Network.*

Next, we use the harvested instances to automatically learn the semantic classes associated with them. For example, *bears* and *wolves* are *animals* but also *mammals*, *predators*, *vertebrates* among others. The obtained class harvesting results are shown in Table 2. We indicate with *Inst(Hovy et al., 2009)* the number of instances in the semantic network that discovered the class during the pattern-based harvesting, and with *InstInWordNet* the number of instances in the semantic network belonging to the class according to WordNet.

ClassName	*Inst(Hovy et al., 2009)*	*InstInWordNet*
arthropods	12	50
carnivores	24	57
chordates	2	313
eutherians	3	193
insects	5	29
invertebrates	53	84
mammals	114	205
reptile	5	22
ruminants	14	34
ungulates	16	66
crafts	24	68
motor vehicles	27	127
self-propelled vehicles	36	145
vessels	11	36
wheeled vehicles	54	190

Table 2: *Learned & Gold Standard Class-Instances.*

We can see that the pattern-based approach of (Hovy et al., 2009) does not recover a lot of the class-instance relations present in WordNet. Because of this gap between the actual and the harvested class-instance pairs arises the objective of our work, which is to explore the relationships between the instances to propagate the initially learned class labels to the remaining unlabeled instances. To evaluate the performance of our approach, we use as a gold standard the WordNet class-instance mappings.

5.2 Testing Our Approach

Our approach is based on the intuition that given a labeled instance u of class C, and an instance v in our network, if there is an edge (u, v) then it is more likely that v has the label C as well. For example, if the instance *bears* is of class *vertebrates* and there is an edge between the instances *bears* and *wolves*, then it is likely that *wolves* are also *vertebrates*. Before proceeding with the instance-instance class-label propagation algorithms, first we study whether this intuition is correct.

Individually for each class label C, we construct a set T_C that contains all instances in the network belonging to C according to WordNet. Then we compute the probability that v belongs to C in WordNet

given that (u, v) is an edge in the instance network and u belongs to C in WordNet: $Pr_h = \Pr[v \in T_C \mid (u, v) \in E \text{ and } u \in T_C]$. We compare this to the background probability $Pr_b = \Pr[v \in T_C \mid u, v \in V \text{ and } u \in T_C]$, which gives the probability that v belongs to C in WordNet if it is chosen at random. In other words, if $Pr_h = 1$, this means that whenever u has the label C and (u, v) is an edge, then v is always labeled with C. If indeed this is the case, then a good classifier can simply take the initial set L and extend the labels to all nodes reachable from L in the semantic network. The larger the difference between Pr_h and Pr_b, the more information the links of the instance network carry for the task of label propagation. Table 3 shows the Pr_h and Pr_b values for each class.

CLASS	Pr_h	Pr_b
arthropods	.46	.12
carnivores	.49	.14
chordates	.95	.80
eutherians	.80	.49
insects	.31	.07
invertebrates	.74	.21
mammals	.82	.52
reptile	.27	.05
ruminants	.39	.08
ungulates	.60	.16
crafts	.07	.05
motor vehicles	.10	.09
self-propelled vehicles	.11	.10
vessels	.08	.02
wheeled vehicles	.13	.13

Table 3: *Learned & Gold Standard Class-Instances.*

This study verifies our intuition that using the relationships between the instances to extend a class label to the remaining unlabeled nodes is an effective approach to enhancing an incomplete set of initial labels.

5.3 Comparative Study

The objective of our work is given a set of initially labeled nodes L, to assign to each node a score that indicates how likely it is to belong to L. The simplest way to do this using the edges of the instance network is to say that a node that has more in-neighbors that have a certain label is more likely to have this label. We define the *in-neighbor* score $i(v)$ of a node v as $i(v) = |\{u \in V | (u, v) \in E \text{ and } u \in L\}|$. We expect that the higher the *in-neighbor* score of v, the more likely it is that v has the label L. The *personalized centrality* method that we proposed generalizes this intuition to indirect neighbors (see Methods). Our *regularization using random walks* technique further explores the link structure of the instance network by considering a random walk on it (see Methods). We compare our approaches with a method that labels nodes at *random*. The expected accuracy for class C is given by $\frac{|T_C|}{n}$, where n is the number of nodes in the network, and T_C is the set containing all nodes that belong to C according to WordNet. In other words, given that there are 84 nodes in the network that are classified as *invertebrate* according to WordNet, and there are 397 nodes in total, if we choose any number of nodes at random our expected accuracy is 21%.

We evaluate the performance of our approaches against the WordNet gold standard and show the obtained results in Tables 4 and 5.

Invertebrates				
rank	centrality	regularization	in-neighbor	random
5	1.0	1.0	.80	.21
10	1.0	1.0	.70	.21
20	.95	1.0	.75	.21
50	.96	.98	.76	.21
100	.69	.73	.67	.21
Mammals				
rank	centrality	regularization	in-neighbor	random
5	.80	1.0	.80	.52
10	.90	1.0	.90	.52
20	.95	.95	.85	.52
50	.86	.96	.80	.52
100	.92	.92	.76	.52
Carnivores				
rank	centrality	regularization	in-neighbor	random
5	1.0	1.0	.80	.14
10	.80	.80	.60	.14
20	.80	.85	.55	.14
50	.50	.68	.48	.14
100	.41	.44	.41	.14

Table 4: *Accuracy @ Different Ranks.*

Table 4 shows the accuracy at rank R calculated as the number of correctly labeled instances with class C at rank R divided by the total number of instances with class C at rank R. Due to space limitation, we show detailed ranking only for three of the classes. We can see that using the semantic network significantly enhances our ability to learn class labels. Even the simple *in-neighbor* method produces results that are very significant compared to chance. Our *centrality* and *regularization* techniques further explore the structure of the semantic network to give

better predictions.

Table 5 shows the accuracy of the class label propagation algorithms for each class. For each class we consider the top k ranked nodes, where k is the number of instances that belong to this class according to WordNet. For example, the accuracy of centrality for *carnivores* is 80% showing that from the top 57 ranked animal instances, 80% belong to *carnivores*. In the final column we also report the performance of a label propagation algorithm that uses class-instance graph instead of an instance-instance graph. To build the graph we remove the edges between the instances and keep the class-instance mappings discovered by the harvesting algorithm of (Hovy et al., 2009). We use the modified adsorption algorithm (MAD) of (Talukdar et al., 2008), which is freely available from the Junto toolkit[1]. To rank the instances for each class label produced by Junto, we use the computed label scores as a ranking criteria and measure accuracy similarly to centrality and regularization.

class	Centrality	Regular.	Rand	MAD
arthropods	.50	.60	.12	.56
carnivores	.80	.85	.14	.44
chordates	.81	.83	.80	.79
eutherians	.54	.60	.49	.60
insects	.38	.52	.07	.17
invertebrates	.94	.96	.21	.64
mammals	.82	.90	.52	.63
reptile	.45	.55	.05	.14
ruminants	.41	.44	.08	.41
ungulates	.44	.61	.16	.32
crafts	.47	.56	.05	.35
motor vehicle	.45	.48	.09	.24
self-propelled vehicle	.49	.47	.10	.27
vessel	.33	.39	.02	.31
wheeled vehicle	.51	.52	.13	.33

Table 5: *Comparative Study.*

The obtained results show that for almost all cases the methods that use the structure of the instance network significantly outperform predictions that use the class-instance graph. This indicates that we can indeed learn a lot form the instance-instance relationships by exploring the structure of the instance network. Among all approaches *regularization* achieves the best results. We believe that regularization works well because it considers a random walk on the semantic graph, and within-cluster edges are traversed more often in a random walk. The regularization technique computes scores that are consistent with the clustering structure of the graph by requiring that the endpoints of highly traversed edges, which are likely in the same cluster, have similar scores (see Methods). Overall, *regularization* enhanced the original output generated by the pattern-based knowledge harvesting approach of (Hovy et al., 2009) with 1219 new class-instance pairs (75% additional information) while maintaining 61.87% accuracy.

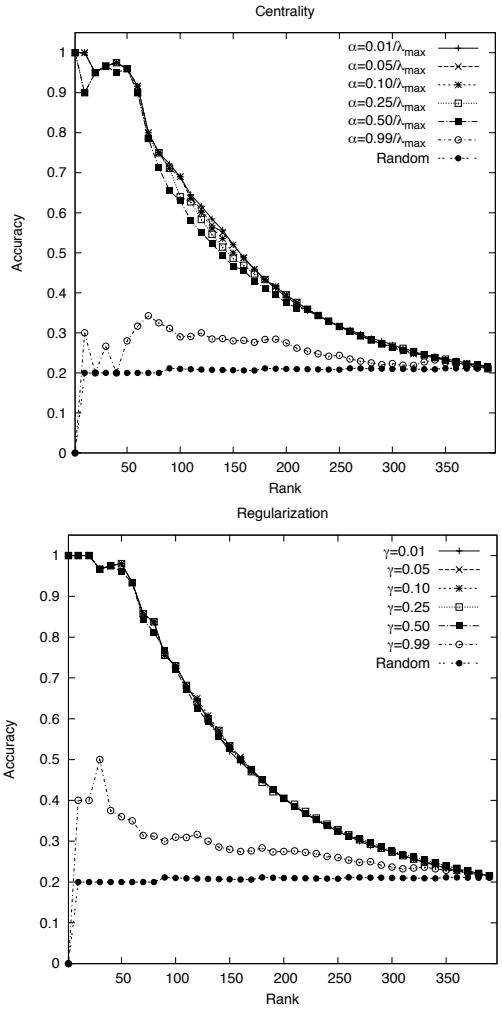

Figure 1: Parameter Tuning For **Invertebrates**.

5.4 Parameter Tuning

Both of our *centrality* and *regularization* methods have a single tunable parameter. For *centrality* the parameter α controls how much the label of each node depends on the labels of its neighbors in the

[1] http://code.google.com/p/junto/

graph. The values range from 0 to $1/\lambda_{\max}$, where $\lambda_{\max}$ is the largest eigenvalue of the adjacency matrix of the semantic network. When $\alpha = 0$ the label of each node is equivalent to its initial label, while higher values of α give more weight to the labels of nodes that are further away.

For *regularization* the parameter γ controls how much emphasis is placed on the agreement between the initial and learned labels. The values of γ are between 0 and 1. Smaller values require that the learned labels be more consistent with the original labels. When $\gamma = 0$ the learned labels will exactly match the original labels.

For each method we try several parameter settings and show the results in Figure 1 for the propagation of the class label *invertebrate*. We can see that both methods are quite insensitive to the parameter settings, unless we choose very extreme values that ignore the original labels.

5.5 Effect of number of labeled class-instances

We also study how the quality of the results is affected by the number of initial class-instance pairs used by our propagation methods. We conduct experiments using only 25%, 50%, 75% and 100% of the initial class-instance pairs learned by (Hovy et al., 2009). Figure 2 shows the results for the label propagation of the class *invertebrate*.

The performance of our methods significantly improves when we incorporate more labels. Still, if we are less concerned with recall and want to find small sets of nodes with very high accuracy, the number of initial labels is less important. For example, starting with only 13 labeled nodes we can still achieve 100% accuracy for the top 30 nodes using *regularization*, and 96% accuracy for the top 25 nodes using *centrality*.

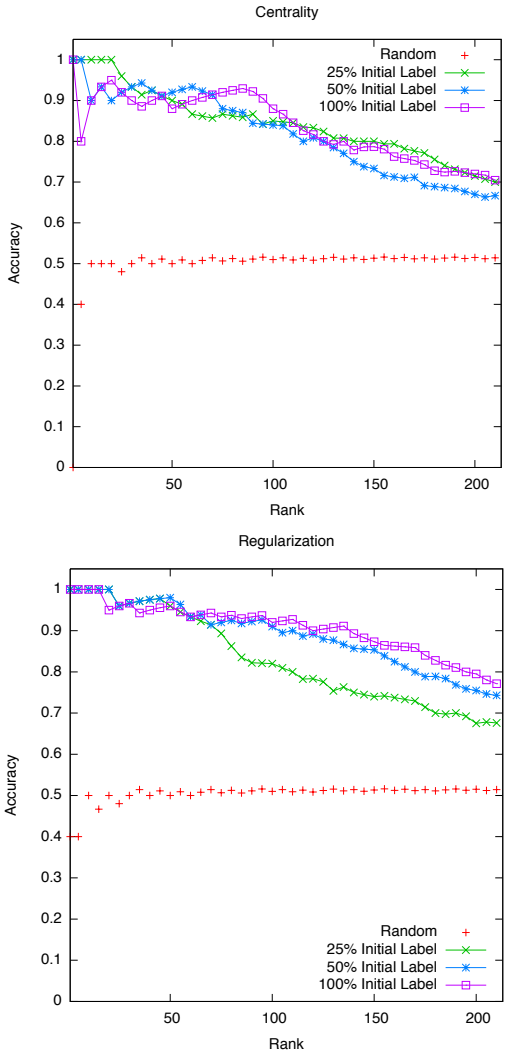

Figure 2: Effect of Number of Initial Class-Instance Pairs for **Invertebrates**.

6 Conclusions

In this paper we proposed a centrality and regularization graph-theoretic methods that explore the relationships between the instances themselves to effectively extend a small set of class-instance labels to all instances in a semantic network. The proposed approaches are intuitive and almost parameter-free. We conducted a series of experiments in which we compared the effectiveness of the centrality and regularization methods to learn new labels for the unlabeled instances. We showed that the enhanced class labels improve the original output generated by the pattern-based knowledge harvesting approach of (Hovy et al., 2009). Finally, we have studied the impact of the class-instance and instance-instance graphs for the class-label propagation task. The latter approach has shown to produce much more accurate results. In the future, we want to apply our approach to Web-based taxonomy induction, which according to (Kozareva and Hovy, 2010) is stifled due to the lacking relations between the instances and the classes, and the classes themselves. The proposed methods can be also applied to enhance fact

farms (Jain and Pantel, 2010).

A Joint Model for Extended Semantic Role Labeling

Vivek Srikumar and Dan Roth
University of Illinois, Urbana-Champaign
Urbana, IL 61801
{vsrikum2, danr}@illinois.edu

Abstract

This paper presents a model that extends semantic role labeling. Existing approaches independently analyze relations expressed by verb predicates or those expressed as nominalizations. However, sentences express relations via other linguistic phenomena as well. Furthermore, these phenomena interact with each other, thus restricting the structures they articulate. In this paper, we use this intuition to define a joint inference model that captures the inter-dependencies between verb semantic role labeling and relations expressed using prepositions. The scarcity of jointly labeled data presents a crucial technical challenge for learning a joint model. The key strength of our model is that we use existing structure predictors as black boxes. By enforcing consistency constraints between their predictions, we show improvements in the performance of both tasks without retraining the individual models.

1 Introduction

The identification of semantic relations between sentence constituents has been an important task in NLP research. It finds applications in various natural language understanding tasks that require complex inference going beyond the surface representation. In the literature, semantic role extraction has been studied mostly in the context of verb predicates, using the Propbank annotation of Palmer et al. (2005), and also for nominal predicates, using the Nombank corpus of Meyers et al. (2004).

However, sentences express semantic relations through other linguistic phenomena. For example, consider the following sentence:

(1) The field goal by Brien changed the game in the fourth quarter.

Verb centered semantic role labeling would identify the arguments of the predicate *change* as (a) *The field goal by Brien* (A0, the causer of the change), (b) *the game* (A1, the thing changing), and (c) *in the fourth quarter* (temporal modifier). However, this does not tell us that the scorer of the field goal was Brien, which is expressed by the preposition *by*. Also, note that the *in* indicates a temporal relation, which overlaps with the verb's analysis.

In this paper, we propose an extension of the standard semantic role labeling task to include relations expressed by lexical items other than verbs and nominalizations. Further, we argue that there are interactions between the different phenomena which suggest that there is a benefit in studying them together. However, one key challenge is that large jointly labeled corpora do not exist. This motivates the need for novel learning and inference schemes that address the data problem and can still benefit from the interactions among the phenomena.

This paper has two main contributions.

1. From the machine learning standpoint, we propose a joint inference scheme to combine *existing* structure predictors for multiple linguistic phenomena. We do so using hard constraints that involve only the labels of the phenomena. The strength of our model is that it is easily

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 129–139,
Edinburgh, Scotland, UK, July 27–31, 2011.

extensible, since adding new phenomena does not require fully retraining the joint model from scratch. Furthermore, our approach minimizes the need for extensive jointly labeled corpora and, instead, uses existing predictors as black boxes.

2. From an NLP perspective, we motivate the extension of semantic role labeling beyond verbs and nominalizations. We instantiate our joint model for the case of extracting preposition and verb relations together. Our model uses existing systems that identify verb semantic roles and preposition object roles and jointly predicts the output of the two systems in the presence of linguistic constraints that enforce coherence between the predictions. We show that using constraints to combine models improves the performance on both tasks. Furthermore, since the constraints depend only on the labels of the two tasks and not on any specific dataset, our experiments also demonstrate that enforcing them allows for better domain adaptation.

The rest of the paper is organized as follows: We motivate the need for extending semantic role labeling and the necessity for joint inference in Section 2. In Section 3, we describe the component verb SRL and preposition role systems. The global model is defined in Section 4. Section 5 provides details on the coherence constraints we use and demonstrates the effectiveness of the joint model through experiments. Section 6 discusses our approach in comparison to existing work and Section 7 provides concluding remarks.

2 Problem Definition and Motivation

Semantic Role Labeling has been extensively studied in the context of verbs and nominalizations. While this analysis is crucial to understanding a sentence, it is clear that in many natural language sentences, information is conveyed via other lexical items. Consider, for example, the following sentences:

(2) Einstein's theory of relativity changed physics.

(3) The plays of Shakespeare are widely read.

(4) The bus, which was heading for Nairobi in Kenya, crashed in the Kabale district of Uganda.

The examples contain information that cannot be captured by analyzing the verbs and the nominalizations. In sentence (2), the possessive form tells us that the *theory of relativity* was discovered by *Einstein*. Furthermore, the *theory* is on the subject of *relativity*. The usage of the preposition *of* is different in sentence (3), where it indicates a creator-creation relationship. In the last sentence, the same preposition tells us that the Kabale district is located in Uganda. Prepositions, compound nouns, possessives, adjectival forms and punctuation marks often express relations, the identification of which is crucial for text understanding tasks like recognizing textual entailment, paraphrasing and question answering.

The relations expressed by different linguistic phenomena often overlap. For example, consider the following sentence:

(5) Construction of the library began in 1968.

The relation expressed by the nominalization *construction* recognizes *the library* as the argument of the predicate *construct*. However, the same analysis can also be obtained by identifying the sense of the preposition *of*, which tells us that the subject of the preposition is a nominalization of the underlying verb. A similar redundancy can be observed with analyses of the verb *began* and the preposition *in*. The above example motivates the following key intuition: *The correct interpretation of a sentence is the one that gives a consistent analysis across all the linguistic phenomena expressed in it.*

An inference mechanism that simultaneously predicts the structure for different phenomena should account for consistency between the phenomena. A model designed to address this has the following desiderata:

1. It should account for the dependencies between phenomena.

2. It should be extensible to allow easy addition of new linguistic phenomena.

3. It should be able to leverage existing state-of-the-art models with minimal use of jointly labeled data, which is expensive to obtain.

Systems that are trained on each task independently do not account for the interplay between them. One approach for tackling this is to define pipelines, where the predictions for one of the tasks acts as the input for another. However, a pipeline does not capture the two-way dependency between the tasks. Training a fully joint model from scratch is also unrealistic because it requires text that is annotated with all the tasks, thus making joint training implausible from a learning theoretic perspective (See Punyakanok et al. (2005) for a discussion about the learning theoretic requirements of joint training.)

3 Tasks and Individual Systems

Before defining our proposed model that captures the requirements listed in the previous section, we introduce the tasks we consider and their independently trained systems that we improve using the joint system. Though the model proposed here is general and can be extended to several linguistic phenomena, in this paper, we focus on relations expressed by verbs and prepositions. This section describes the tasks, the data sets we used for our experiments and the current state-of-the-art systems for these tasks.

We use the following sentence as our running example to illustrate the phenomena: *The company calculated the price trends on the major stock markets on Monday.*

3.1 Preposition Relations

Prepositions indicate a relation between the attachment point of the preposition and its object. As we have seen, the same preposition can indicate different types of relations. In the literature, the polysemy of prepositions is addressed by The Preposition Project[1] of Litkowski and Hargraves (2005), which is a large lexical resource for English that labels prepositions with their sense. This sense inventory formed the basis of the SemEval-2007 task of preposition word sense disambiguation of Litkowski and Hargraves (2007). In our example, the first *on* would be labeled with the sense **8(3)** which identifies the object of the preposition as the topic, while the second instance would be labeled as **17(8)**, which indicates that argument is the day of the occurrence.

The preposition sense inventory, while useful to identify the fine grained distinctions between preposition usage, defines a unique sense label for each preposition by indexing the definitions of the prepositions in the Oxford Dictionary of English. For example, in the phrase *at noon*, the at would be labeled with the sense **2(2)**, while the preposition in *I will see you in an hour* will be labeled **4(3)**. Note that both these (and also the second *on* in our running example) indicate a temporal relation, but are assigned different labels based on the preposition. To counter this problem we collapsed preposition senses that are semantically similar to define a new label space, which we refer to as *Preposition Roles*.

We retrained classifiers for preposition sense for the new label space. Before describing the preposition role dataset, we briefly describe the datasets and the features for the sense problem. The best performing system at the SemEval-2007 shared task of preposition sense disambiguation (Ye and Baldwin (2007)) achieves a mean precision of 69.3% for predicting the fine grained senses. Tratz and Hovy (2009) and Hovy et al. (2010) attained significant improvements in performance using features derived from the preposition's neighbors in the parse tree. We extended the feature set defined in the former for our independent system. Table 1 summarizes the rules for identifying the syntactically related words for each preposition. We used dependencies from the easy-first dependency parser of Goldberg and Elhadad (2010).

For each word extracted from these rules, the features include the word itself, its lemma, the POS tag, synonyms and hypernyms of the first WordNet sense and an indicator for capitalization. These features improved the accuracy of sense identification to 75.1% on the SemEval test set. In addition, we also added the following new features for each word:

1. Indicators for gerunds and nominalizations of verbs.

2. The named entity tag (Person, Location or Organization) associated with a word, if any. We

[1] http://www.clres.com/prepositions.html

Id.	Feature
1.	Head noun/verb that dominates the preposition along with its modifiers
2.	Head noun/verb that is dominated by the preposition along with its modifiers
3.	Subject, negator and object(s) of the immediately dominating verb
4.	Heads of sibling prepositions
5.	Words withing a window of 5 centered at the preposition

used the state-of-the-art named entity tagger of Ratinov and Roth (2009) to label the text.

3. Gazetteer features, which are active if a word is a part of a phrase that belongs to a gazetteer list. We used the gazetteer lists which were used by the NER system. We also used the CBC word clusters of Pantel and Lin (2002) as additional gazetteers and Brown cluster features as used by Ratinov and Roth (2009) and Koo et al. (2008).

Dahlmeier et al. (2009) annotated senses for the prepositions *at, for, in, of, on, to* and *with* in the sections 2-4 and 23 of the Wall Street Journal portion of the Penn Treebank[2]. We trained sense classifiers on both datasets using the Averaged Perceptron algorithm with the one-vs-all scheme using the Learning Based Java framework of Rizzolo and Roth (2010)[3]. Table 2 reports the performance of our sense disambiguation systems for the Treebank prepositions.

As mentioned earlier, we collapsed the sense labels onto the newly defined preposition role labels. Table 3 shows this label set along with frequencies of the labels in the Treebank dataset. According to this labeling scheme, the first *on* in our running example will be labeled TOPIC and the second one will be labeled TEMPORAL[4]. We re-trained the sense disambiguation system to predict preposition roles. When trained on the Treebank data, our system attains an accuracy of 67.82% on Section 23 of the Treebank. We use this system as our independent baseline for preposition role identification.

3.2 Verb SRL

The goal of verb Semantic Role Labeling (SRL) is to identify the predicate-argument structure defined by verbs in sentences. The CoNLL Shared Tasks of 2004 and 2005 (See Carreras and Màrquez

[2]This dataset does not annotate all prepositions and restricts itself mainly to prepositions that start a Propbank argument. The data is available at `http://nlp.comp.nus.edu.sg/corpora`

[3]Learning Based Java can be downloaded from `http://cogcomp.cs.illinois.edu`.

[4]The mapping from the preposition senses to the roles defines a new dataset and is available for download at `http://cogcomp.cs.illinois.edu/`.

(2004), Carreras and Màrquez (2005)) studied the identification of the predicate-argument structure of verbs using the PropBank corpus of Palmer et al. (2005). Punyakanok et al. (2008) and Toutanova et al. (2008) used global inference to ensure that the predictions across all arguments of the same predicate are coherent. We re-implemented the system of Punyakanok et al. (2008), which we briefly describe here, to serve as our baseline verb semantic role labeler [5]. We refer the reader to the original paper for further details.

The verb SRL system of Punyakanok et al. (2008) consists of four stages – candidate generation, argument identification, argument classification and inference. The candidate generation stage involves using the heuristic of Xue and Palmer (2004) to generate an over-complete set of argument candidates for each predicate. The identification stage uses a classifier to prune the candidates. In the argument classification step, the candidates that remain after the identification step are assigned scores for the SRL arguments using a multiclass classifier. One of the labels of the classifier is $\emptyset$, which indicates that the candidate is, in fact, not an argument. The inference step produces a combined prediction for all argument candidates of a verb proposition by enforcing global constraints.

The inference enforces the following structural and linguistic constraints: (1) Each candidate can have at most one label. (2) No duplicate core arguments. (3) No overlapping or embedding arguments. (4) Given the predicate, some argument classes are illegal. (5) If a candidate is labeled as an R-arg, then there should be one labeled as arg. (6) If a candidate is labeled as a C-arg, there should be one labeled arg that occurs *before* the C-arg.

Instead of using the identifier to filter candidates for the classifier, in our SRL system, we added the identifier to the global inference and enforced consistency constraints between the identifier and the argument classifier predictions – the identifier should predict that a candidate is an argument if, and only if, the argument classifier does not predict the label $\emptyset$. This change is in keeping with the idea of using joint inference to combine independently learned systems, in this case, the argument identifier and the role classifier. Furthermore, we do not need to explicitly tune the identifier for high recall.

We phrase the inference task as an integer linear program (ILP) following the approach developed in Roth and Yih (2004). Integer linear programs were used by Roth and Yih (2005) to add general constraints for inference with conditional random fields. ILPs have since been used successfully in many NLP applications involving complex structures – Punyakanok et al. (2008) for semantic role labeling, Riedel and Clarke (2006) and Martins et al. (2009) for dependency parsing and several others[6].

Let $v^C_{i,a}$ be the Boolean indicator variable that denotes that the i^{th} argument candidate for a predicate is assigned a label a and let $\Theta^C_{i,a}$ represent the score assigned by the argument classifier for this decision. Similarly, let v^I_i denote the identifier decision for the i^{th} argument candidate of the predicate and Θ^I_i denote its identifier score. Then, the objective of inference is to maximize the total score of the assignment

$$\max_{\mathbf{v}^C,\mathbf{v}^I} \sum_{i,a} \Theta^C_{i,a} v^C_{i,a} + \sum_i \Theta^I_i v^I_i \qquad (1)$$

Here, $\mathbf{v}^C$ and $\mathbf{v}^I$ denote all the argument classifier and identifier variables respectively. This maximization is subject to the constraints described above, which can be transformed to linear (in)equalities. We denote these constraints as $\mathcal{C}^{SRL}$. In addition to $\mathcal{C}^{SRL}$ which were defined by Punyakanok et al. (2008), we also have the constraints linking the predictions of the identifier and classifier:

$$v^C_{v,i,\emptyset} + v^I_{v,i} = 1; \;\; \forall v, i. \qquad (2)$$

Inference in our baseline SRL system is, thus, the maximization of the objective defined in (1) subject to constraints $\mathcal{C}^{SRL}$, the identifier-classifier constraints defined in (2) and the restriction of the variables to take values in $\{0, 1\}$.

To train the classifiers, we used parse trees from the Charniak and Johnson (2005) parser with the

[5]The verb SRL system be downloaded from `http://cogcomp.cs.illinois.edu/page/software`

[6]The primary advantage of using ILP for inference is that this representation enables us to add arbitrary coherence constraints between the phenomena. If the underlying optimization problem itself is tractable, then so is the corresponding integer program. However, other approaches to solve the constrained maximization problem can also be used for inference.

same feature representation as in the original system. We trained the classifiers on the standard Propbank training set using the one-vs-all extension of the average Perceptron algorithm. As with the preposition roles, we implemented our system using Learning Based Java of Rizzolo and Roth (2010). We normalized all classifier scores using the softmax function. Compared to the 76.29% F1 score reported by Punyakanok et al. (2008) using single parse tree predictions from the parser, our system obtained 76.22% F1 score on section 23 of the Penn Treebank.

4 A Joint Model for Verbs and Prepositions

We now introduce our model that captures the needs identified in Section 2. The approach we develop in this paper follows the one proposed by Roth and Yih (2004) of training individual models and combining them at inference time. Our joint model is a Constrained Conditional Model (See Chang et al. (2011)), which allows us to build upon existing learned models using declarative constraints.

We represent our component inference problems as integer linear program instances. As we saw in Section 3.2, the inference for SRL is instantiated as an ILP problem. The problem of predicting preposition roles can be easily transformed into an ILP instance. Let $v^R_{p,r}$ denote the decision variable that encodes the prediction that the preposition p is assigned a role r and let $\Theta^R_{p,r}$ denote its score. Let $\mathbf{v}^R$ denote all the role variables for a sentence. Then role prediction is equivalent to the following maximization problem:

$$\max_{\mathbf{v}^R} \quad \sum_{p,r} \Theta^R_{p,r} \cdot v^R_{p,r} \tag{3}$$

$$\text{subj. to} \quad \sum_{r} v^R_{p,r} = 1, \quad \forall p \tag{4}$$

$$v^R_{p,r} \in \{0,1\}, \quad \forall p, r. \tag{5}$$

In general, let p denote a linguistic structure prediction task of interest and let $\mathcal{P}$ denote all such tasks. Let Z^p denote the set of labels that the parts of the structure associated with phenomenon p can take. For example, for the SRL argument classification component, the parts of the structure are all the candidates that need to be labeled for a given sentence and the set Z^p is the set of all argument labels. For each phenomenon $p \in \mathcal{P}$, we use $\mathbf{v}^p$ to denote its set of inference variables for a given sentence. Each inference variable $v^p_{Z,y} \in \mathbf{v}^p$ corresponds to the prediction that the part y has the label Z in the final structure. Each variable is associated with a score $\Theta^p_{Z,y}$ that is obtained from a learned score predictor. Let $\mathcal{C}^p$ denote the structural constraints that are "local" to the phenomenon. Thus, for verb SRL, these would be the constraints defined in the previous section, and for preposition role, the only local constraint would be the constraint (4) defined above.

The independent inference problem for the phenomenon p is the following integer program:

$$\max_{\mathbf{v}^p} \quad \sum_{Z \in Z^p} \sum_{v^p} v^p_{Z,y} \cdot \Theta^p_{Z,y}, \tag{6}$$

$$\text{subj. to} \quad \mathcal{C}^p(\mathbf{v}^p), \tag{7}$$

$$v^p_{Z,y} \in \{0,1\}, \qquad \forall v^p_{Z,y}. \tag{8}$$

As a technical point, this defines one inference problem per sentence, rather than per predicate as in the verb SRL system of Punyakanok et al. (2008). This simple extension enabled Surdeanu et al. (2007) to study the impact of incorporating cross-predicate constraints for verb SRL. In this work, this extension allows us to incorporate cross-phenomena inference.

4.1 Joint inference

We consider the problem of jointly predicting several phenomena incorporating linguistic knowledge that enforce consistency between the output labels. Suppose p_1 and p_2 are two phenomena. If $z^{p_1}_1$ is a label associated with the former and $z^{p_2}_1, z^{p_2}_2, \cdots$ are labels associated with the latter, we consider constraints of the form

$$z^{p_1}_1 \rightarrow z^{p_2}_1 \vee z^{p_2}_2 \vee \cdots \vee z^{p_2}_n \tag{9}$$

We expand this language of constraints by allowing the specification of pre-conditions for a constraint to apply. This allows us to enforce constraints of the form *"If an argument that starts with the preposition 'at' is labeled* AM-TMP*, then the preposition can be labeled either* NUMERIC/LEVEL *or* TEMPORAL*."* This constraint is universally quantified for

all arguments that satisfy the precondition of starting with the preposition *at*.

Given a first-order constraint in this form and an input sentence, suppose the inference variable $v_1^{p_1}$ is a grounding of $z_1^{p_1}$ and $v_1^{p_2}, v_2^{p_2}, \cdots$ are groundings of the right hand labels such that the preconditions are satisfied, then the constraint can be phrased as the following linear inequality.

$$-v_1^{p_1} + \sum_i v_i^{p_2} \geq 0$$

In the context of the preposition role and verb SRL, we consider constraints between labels for a preposition and SRL argument candidates that begin with that preposition. This restriction forms the precondition for all the joint constraints considered in this paper. Since the joint constraints involve only the labels, they can be derived either manually from the definition of the tasks or using statistical relation learning techniques. In addition to mining constraints of the form (9), we also use manually specified joint constraints. The constraints used in our experiments are described further in Section 5.

In general, let J denote a set of pairwise joint constraints. The joint inference problem can be phrased as that of maximizing the score of the assignment subject to the structural constraints of each phenomenon ($\mathcal{C}^p$) *and* the joint linguistic constraints (J). However, since, the individual tasks were not trained on the same datasets, the scoring functions need not be in the same numeric scale. In our model, each label Z for a phenomenon p is associated with a scoring function $\Theta^p_{Z,y}$ for a part y. To scale the scoring functions, we associate each label with a parameter λ^p_Z. This gives us the following integer linear program for joint inference:

$$\max_{\mathbf{v}} \quad \sum_{p \in \mathcal{P}} \sum_{Z \in Z^p} \lambda^p_Z \left(\sum_{y^p} v^p_{Z,y} \cdot \Theta^p_{Z,y} \right), \quad (10)$$

$$\text{subj. to} \quad \mathcal{C}^p(\mathbf{v}^p), \quad \forall p \in \mathcal{P} \quad (11)$$

$$J(\mathbf{v}), \quad (12)$$

$$v^p_{Z,y} \in \{0, 1\}, \quad \forall v^p_{Z,y}. \quad (13)$$

Here, $\mathbf{v}$ is the vector of inference variables which is obtained by stacking all the inference variables of each phenomena.

For our experiments, we use a cutting plane solver to solve the integer linear program as in Riedel (2009). This allows us to solve the inference problem without explicitly having to instantiate all the joint constraints.

4.2 Learning to rescale the individual systems

Given the individual models and the constraints, we only need to learn the scaling parameters λ^p_Z. Note that the number of scaling parameters is the total number of labels. When we jointly predict verb SRL and preposition role, we have 22 preposition roles (from table 3), one SRL identifier label and 54 SRL argument classifier labels. Thus we learn only 77 parameters for our joint model. This means that we only need a very small dataset that is jointly annotated with all the phenomena.

We use the Structure Perceptron of Collins (2002) to learn the scaling weights. Note that for learning the scaling weights, we need each label to be associated with a real-valued feature. Given an assignment of the inference variables $\mathbf{v}$, the value of the feature corresponding to the label Z of task p is given by the sum of scores of all parts in the structure for p that have been assigned this label, i.e. $\sum_{y^p} v^p_{Z,y} \cdot \Theta^p_{Z,y}$. This feature is computed for the gold and the predicted structures and is used for updating the weights.

5 Experiments

In this section, we describe our experimental setup and evaluate the performance of our approach. The research question addressed by the experiments is the following: *Given independently trained systems for verb SRL and preposition roles, can their performance be improved using joint inference between the two tasks?* To address this, we report the results of the following two experiments:

1. First, we compare the joint system against the baseline systems and with pipelines in both directions. In this setting, both base systems are trained on the Penn Treebank data.

2. Second, we show that using joint inference can provide strong a performance gain even when the underlying systems are trained on different domains.

In all experiments, we report the F1 measure for the verb SRL performance using the CoNLL 2005

evaluation metric and the accuracy for the preposition role labeling task.

5.1 Data and Constraints

For both the verb SRL and preposition roles, we used the first 500 sentences of section 2 of the Penn Treebank corpus to train our scaling parameters. For the first set of experiments, we trained our underlying systems on the rest of the available Penn Treebank training data for each task. For the adaptation experiment, we train the role classifier on the SemEval data (restricted to the same Treebank prepositions). In both cases, we report performance on section 23 of the Treebank.

We mined consistency constraints from the sections 2, 3 and 4 of the Treebank data. As mentioned in Section 4.1, we considered joint constraints relating preposition roles to verb argument candidates that start with the preposition. We identified the following types of constraints: (1) For each preposition, the set of invalid verb arguments and preposition roles. (2) For each preposition role, the set of allowed verb argument labels if the role occurred more than ten times in the data, and (3) For each verb argument, the set of allowed preposition roles, similarly with a support of ten. Note that, while the constraints were obtained from jointly labeled data, the constraints could be written down because they encode linguistic intuition about the labels.

The following is a constraint extracted from the data, which applies to the preposition *with*:

$$
\begin{aligned}
\text{srlarg(A2)} \quad &\rightarrow \quad \text{prep-role(ATTRIBUTE)} \\
&\vee \quad \text{prep-role(CAUSE)} \\
&\vee \quad \text{prep-role(INSTRUMENT)} \\
&\vee \quad \text{prep-role(OBJECTOFVERB)} \\
&\vee \quad \text{prep-role(PARTWHOLE)} \\
&\vee \quad \text{prep-role(PARTICIPANT/ACCOMPAINER)} \\
&\vee \quad \text{prep-role(PROFESSIONALASPECT).}
\end{aligned}
$$

This constraint says that if any candidate that starts with *with* is labeled as an A2, then the preposition can be labeled only with one of the roles on the right hand side.

Some of the mined constraints have negated variables to enforce that a role or an argument label should not be allowed. These can be similarly converted to linear inequalities. See Rizzolo and Roth (2010) for a further discussion about converting logical expressions into linear constraints.

In addition to these constraints that were mined from data, we also enforce the following handwritten constraints: (1) If the role of a verb attached preposition is labeled TEMPORAL, then there should be a verb predicate for which this prepositional phrase is labeled AM-TMP. (2) For verb attached prepositions, if the preposition is labeled with one of ACTIVITY, ENDCONDITION, INSTRUMENT or PROFESSIONALASPECT, there should be at least one predicate for which the corresponding prepositional phrase is not labeled $\emptyset$.

The conversion of the first constraint to a linear inequality is similar to the earlier cases. For each of the roles in the second constraint, let r denote a role variable that assigns the label to some preposition. Suppose there are n SRL candidates across all verb predicates begin with that preposition, and let $s_1, s_2, \cdots, s_n$ denote the SRL variables that assign these candidates to the label $\emptyset$. Then the second constraint corresponds to the following inequality:

$$r + \sum_{i=1}^{n} s_i \leq n$$

5.2 Results of joint learning

First, we compare our approach to the performance of the baseline independent systems and to pipelines in both directions in Table 4. For one pipeline, we added the prediction of the baseline preposition role system as an additional feature to both the identifier and the argument classifier for argument candidates that start with a preposition. Similarly, for the second pipeline, we added the SRL predictions as features for prepositions that were the first word of an SRL argument. In all cases, we performed five-fold cross validation to train the classifiers.

The results show that both pipelines improve performance. This justifies the need for a joint system because the pipeline can improve only one of the tasks. The last line of the table shows that the joint inference system improves upon both the baselines. We achieve this improvement without retraining the underlying models, as done in the case of the pipelines.

On analyzing the output of the systems, we found that the SRL precision improved by 2.75% but the

Setting	SRL (F1)	Preposition Role (Accuracy)
Baseline SRL	76.22	–
Baseline Prep.	–	67.82
Prep. → SRL	**76.84**	–
SRL → Prep.	–	**68.55**
Joint inference	**77.07**	**68.39**

Table 4: Performance of the joint system, compared to the individual systems and the pipelines. All performance measures are reported on Section 23 of the Penn Treebank. The verb SRL systems were trained on sections 2-21, while the preposition role classifiers were trained on sections 2-4. For the joint inference system, the scaling parameters were trained on the first 500 sentences of section 2, which were held out. All the improvements in this table are statistically significant at the 0.05 level.

recall decreased by 0.98%, contributing to the overall F1 improvement. The decrease in recall is due to the joint hard constraints that prohibit certain assignments to the variables which would have otherwise been possible. Note that, for a given sentence, even if the joint constraints affect only a few argument candidates directly, they can alter the labels of the other candidates via the "local" SRL constraints.

Consider the following example of the system output which highlights the effect of the constraints.

(6) Weatherford said market conditions led to the cancellation of the planned exchange.

The independent preposition role system incorrectly identifies the *to* as a LOCATION. The semantic role labeling component identifies the phrase *to the cancellation of the planned exchange* as the A2 of the verb *led*. One of the constraints mined from the data prohibits the label LOCATION for the preposition *to* if the argument it starts is labeled A2. This forces the system to change the preposition label to the correct one, namely ENDCONDITION. Both the independent and the joint systems also label the preposition *of* as OBJECTOFVERB, which indicates that the phrase *the planned exchange* is the object of the deverbal noun *cancellation*.

5.3 Effect of constraints on adaptation

Our second experiment compares the performance of the preposition role classifier that has been trained on the SemEval dataset with and without joint constraints. Note that Table 2 in Section 3, shows the drop in performance when applying the preposition sense classifier. We see that the SemEval-trained preposition role classifier (baseline in the table) achieves an accuracy of 53.29% when tested on the Treebank dataset. Using this classifier jointly with the verb SRL classifier via joint constraints gets an improvement of almost 3 percent in accuracy.

Setting	Preposition Role (Accuracy)
Baseline	53.29
Joint inference	**56.22**

Table 5: Performance of the SemEval-trained preposition role classifier, when tested on the Treebank dataset with and without joint inference with the verb SRL system. The improvement, in this case is statistically significant at the 0.01 level using the sign test.

The primary reason for this improvement, even without re-training the classifier, is that the constraints are defined using only the labels of the systems. This avoids the standard adaptation problems of differing vocabularies and unseen features.

6 Discussion and Related work

Roth and Yih (2004) formulated the problem of extracting entities and relations as an integer linear program, allowing them to use global structural constraints at inference time even though the component classifiers were trained independently. In this paper, we use this idea to combine classifiers that were trained for two different tasks on different datasets using constraints to encode linguistic knowledge.

In the recent years, we have seen several joint models that combine two or more NLP tasks . Andrew et al. (2004) studied verb subcategorization and sense disambiguation of verbs by treating it as a problem of learning with partially labeled structures and proposed to use EM to train the joint model. Finkel and Manning (2009) modeled the task of named entity recognition together with parsing. Meza-Ruiz and Riedel (2009) modeled verb SRL, predicate identification and predicate sense recognition jointly using Markov Logic. Henderson et al. (2008) was designed for jointly learning to predict syntactic and semantic dependencies. Dahlmeier et

al. (2009) addressed the problem of jointly learning verb SRL and preposition sense using the Penn Treebank annotation that was introduced in that work. The key difference between these and the model presented in this paper lies in the simplicity of our model and its easy extensibility because it leverages existing trained systems. Moreover, our model has the advantage that the complexity of the joint parameters is small, hence does not require a large jointly labeled dataset to train the scaling parameters.

Our approach is conceptually similar to that of Rush et al. (2010), which combined separately trained models by enforcing agreement using global inference and solving its linear programming relaxation. They applied this idea to jointly predict dependency and phrase structure parse trees and on the task of predicting full parses together with part-of-speech tags. The main difference in our approach is that we treat the scaling problem as a separate learning problem in itself and train a joint model specifically for re-scaling the output of the trained systems.

The SRL combination system of Surdeanu et al. (2007) studied the combination of three different SRL systems using constraints and also by training secondary scoring functions over the individual systems. Their approach is similar to the one presented in this paper in that, unlike standard reranking, as in Collins (2000), we entertain all possible solutions during inference, while reranking approaches train a discriminative scorer for the top-K solutions of an underlying system. Unlike the SRL combination system, however, our approach spans multiple phenomena. Moreover, in contrast to their re-scoring approaches, we do not define joint features drawn from the predictions of the underlying components to define our global model.

We consider the tasks verb SRL and preposition roles and combine their predictions to provide a richer semantic annotation of text. This approach can be easily extended to include systems that predict structures for other linguistic phenomena because we do not retrain the underlying systems. The semantic relations can be enriched by incorporating more linguistic phenomena such as nominal SRL, defined by the Nombank annotation scheme of Meyers et al. (2004), the preposition function analysis of O'Hara and Wiebe (2009) and noun compound analysis as defined by Girju (2007) and Girju et al. (2009) and others. This presents an exciting direction for future work.

7 Conclusion

This paper presents a strategy for extending semantic role labeling without the need for extensive retraining or data annotation. While standard semantic role labeling focuses on verb and nominal relations, sentences can express relations using other lexical items also. Moreover, the different relations interact with each other and constrain the possible structures that they can take. We use this intuition to define a joint model for inference. We instantiate our model using verb semantic role labeling and preposition role labeling and show that, using linguistic constraints between the tasks and minimal joint learning, we can improve the performance of both tasks. The main advantage of our approach is that we can use existing trained models without re-training them, thus making it easy to extend this work to include other linguistic phenomena.

Domain-Assisted Product Aspect Hierarchy Generation: Towards Hierarchical Organization of Unstructured Consumer Reviews

Abstract

This paper presents a domain-assisted approach to organize various aspects of a product into a hierarchy by integrating domain knowledge (e.g., the product specifications), as well as consumer reviews. Based on the derived hierarchy, we generate a hierarchical organization of consumer reviews on various product aspects and aggregate consumer opinions on these aspects. With such organization, user can easily grasp the overview of consumer reviews. Furthermore, we apply the hierarchy to the task of implicit aspect identification which aims to infer implicit aspects of the reviews that do not explicitly express those aspects but actually comment on them. The experimental results on 11 popular products in four domains demonstrate the effectiveness of our approach.

1 Introduction

With the rapidly expanding e-commerce, most retail Web sites encourage consumers to write reviews to express their opinions on various aspects of products. Huge collections of consumer reviews are now available on the Web. These reviews have become an important resource for both consumers and firms. Consumers commonly seek quality information from online consumer reviews prior to purchasing a product, while many firms use online reviews as an important resource in their product development, marketing, and consumer relationship management. However, the reviews are disorganized, leading to the difficulty in information navigation and knowledge acquisition. It is impractical for user to grasp the overview of consumer reviews and opinions on various aspects of a product from such enormous reviews. Among hundreds of product aspects, it is also inefficient for user to browse consumer reviews and opinions on a specific aspect. Thus, there is a compelling need to organize consumer reviews, so as to transform the reviews into a useful knowledge structure. Since the hierarchy can improve information representation and accessibility (Cimiano, 2006), we propose to organize the aspects of a product into a hierarchy and generate a hierarchical organization of consumer reviews accordingly.

Towards automatically deriving an aspect hierarchy from the reviews, we could refer to traditional hierarchy generation methods in ontology learning, which first identify concepts from the text, then determine the parent-child relations between these concepts using either pattern-based or clustering-based methods (Murthy et al., 2010). However, pattern-based methods usually suffer from inconsistency of parent-child relationships among the concepts, while clustering-based methods often result in low accuracy. Thus, by directly utilizing these methods to generate an aspect hierarchy from consumer reviews, the resulting hierarchy is usually inaccurate, leading to unsatisfactory review organization. On the other hand, domain knowledge of products is now available on the Web. For example, there are more than 248,474 product specifications in the product selling Web site CNet.com (Beckham, 2005). These product specifications cover some product aspects and provide coarse-grained parent-child relations among these aspects. Such domain knowledge is useful to help organize the product as-

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 140–150,
Edinburgh, Scotland, UK, July 27–31, 2011.

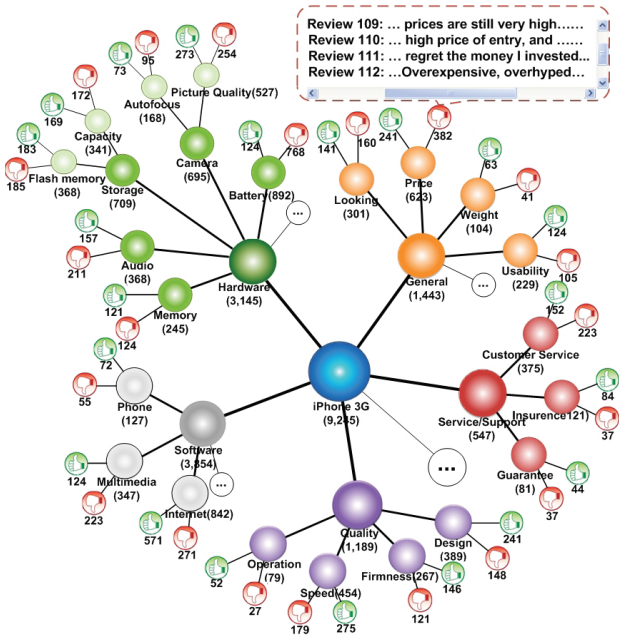

Figure 1: Sample hierarchical organization for iPhone 3G

pects into a hierarchy. However, the initial hierarchy obtained from domain knowledge usually cannot fit the review data well. For example, the initial hierarchy is usually too coarse and may not cover the specific aspects commented in the reviews, while some aspects in the hierarchy may not be of interests to users in the reviews.

Motivated by the above observations, we propose in this paper to organize the product aspects into a hierarchy by simultaneously exploiting the domain knowledge (e.g., the product specification) and consumer reviews. With derived aspect hierarchy, we generate a hierarchical organization of consumer reviews on various aspects and aggregate consumer opinions on these aspects. Figure 1 illustrates a sample of hierarchical review organization for the product "*iPhone 3G*". With such organization, users can easily grasp the overview of product aspects as well as conveniently navigate the consumer reviews and opinions on any aspect. For example, users can find that 623 reviews, out of 9,245 reviews, are about the aspect "*price*", with 241 positive and 382 negative reviews.

Given a collection of consumer reviews on a specific product, we first automatically acquire an initial aspect hierarchy from domain knowledge and identify the aspects from the reviews. Based on the initial hierarchy, we develop a multi-criteria optimization approach to construct an aspect hierarchy to contain all the identified aspects. Our approach incrementally inserts the aspects into the initial hierarchy based on inter-aspect semantic distance, a metric used to measure the semantic relation among aspects. In order to derive reliable semantic distance, we propose to leverage external hierarchies, sampled from WordNet and Open Directory Project, to assist semantic distance learning. With resultant aspect hierarchy, the consumer reviews are then organized to their corresponding aspect nodes in the hierarchy. We then perform sentiment classification to determine consumer opinions on these aspects. Furthermore, we apply the hierarchy to the task of implicit aspect identification. This task aims to infer implicit aspects of the reviews that do not explicitly express those aspects but actually comment on them. For example, the implicit aspect of the review "It is so expensive" is "price." Most existing aspect identification approaches rely on the appearance of aspect terms, and thus are not able to handle implicit aspect problem. Based on our aspect hierarchy, we can infer the implicit aspects by clustering the reviews into their corresponding aspect nodes in the hierarchy. We conduct experiments on 11 popular products in four domains. More details of the corpus are discussed in Section 4. The experimental results demonstrate the effectiveness of our approach.

The main contributions of this work can be summarized as follows:

1) We propose to hierarchically organize consumer reviews according to an aspect hierarchy, so as to transfer the reviews into a useful knowledge structure.

2) We develop a domain-assisted approach to generate an aspect hierarchy by integrating domain knowledge and consumer reviews. In order to derive reliable semantic distance between aspects, we propose to leverage external hierarchies to assist semantic distance learning.

3) We apply the aspect hierarchy to the task of implicit aspect identification, and achieve satisfactory performance.

The rest of this paper is organized as follows. Our approach is elaborated in Section 2 and applied to implicit aspect identification in Section 3. Section 4 presents the evaluations, while Section 5 reviews

related work. Finally, Section 6 concludes this paper with future works.

2 Approach

Our approach consists of four components, including initial hierarchy acquisition, aspect identification, semantic distance learning, and aspect hierarchy generation. Next, we first define some preliminary and notations and then elaborate these components.

2.1 Preliminary and Notations

Preliminary 1. An aspect hierarchy is defined as a tree that consists of a set of unique aspects $\mathcal{A}$ and a set of parent-child relations $\mathcal{R}$ between these aspects.

Given the consumer reviews of a product, let $\mathcal{A} = \{a_1, \cdots, a_k\}$ denotes the product aspects commented in the reviews. $\mathcal{H}^0(\mathcal{A}^0, \mathcal{R}^0)$ denotes the initial hierarchy derived from domain knowledge. It contains a set of aspects $\mathcal{A}^0$ and relations $\mathcal{R}^0$. Our task is to construct an aspect hierarchy $\mathcal{H}(\mathcal{A}, \mathcal{R})$, to cover all the aspects in $\mathcal{A}$ and their parent-child relations $\mathcal{R}$, so that the consumer reviews are hierarchically organized. Note that $\mathcal{H}^0$ can be empty.

2.2 Initial Hierarchy Acquisition

As aforementioned, product specifications on product selling websites cover some product aspects and coarse-grained parent-child relations among these aspects. Such domain knowledge is useful to help organize aspects into a hierarchy. We here employ the approach proposed by Ye and Chua (2006) to automatically acquire an initial aspect hierarchy from the product specifications. The method first identifies the Web page region covering product descriptions and removes the irrelevant contents from the Web page. It then parses the region containing the product information to identify the aspects as well as their structure. Based on the aspects and their structure, it generates an aspect hierarchy.

2.3 Aspect Identification

To identify aspects in consumer reviews, we first parse each review using the Stanford parser [1]. Since the aspects in consumer reviews are usually noun or noun phrases (Liu, 2009), we extract the noun phrases (*NP*) from the parse tree as aspect candidates. While these candidates may contain much noise, we leverage *Pros* and *Cons* reviews (see Figure 2), which are prevalent in forum Web sites, to assist identify aspects from the candidates. It has been shown that simply extracting the frequent noun terms from the *Pros* and *Cons* reviews can get high accurate aspect terms (Liu el al., 2005). Thus, we extract the frequent noun terms from *Pros* and *Cons* reviews as features, then train a one-class *SVM* (Manevitz et al., 2002) to identify aspects from the candidates. While the obtained aspects may contain some synonym terms, such as "earphone" and "headphone", we further perform synonym clustering to get unique aspects. Specifically, we first expand each aspect term with its synonym terms obtained from the synonym terms Web site [2], then cluster them to obtain unique aspects based on unigram feature.

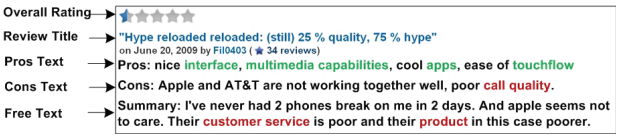

Figure 2: Sample Pros and Cons reviews

2.4 Semantic Distance Learning

Our aspect hierarchy generation approach is essentially based on the semantic relations among aspects. We here define a metric, *Semantic Distance*, $d(a_x, a_y)$, to quantitatively measure the semantic relation between aspects a_x and a_y. We formulate $d(a_x, a_y)$ as the weighted sum of some underlying features,

$$d(a_x, a_y) = \sum\nolimits_j w_j f_j(a_x, a_y), \qquad (1)$$

where w_j is the weight for j-th feature function $f_j(\cdot)$.

Next, we first introduce the linguistic features used in our work and then present the semantic distance learning algorithm that aims to find the optimal weights in Eq.(1).

[1] http://nlp.stanford.edu/software/lex-parser.shtml

[2] http://thesaurus.com

2.4.1 Linguistic Features

Given two aspects a_x and a_y, a feature is defined as a function generating a numeric score $f(a_x, a_y)$ or a vector of scores. The features include *Contextual*, *Co-occurrence*, *Syntactic*, *Pattern* and *Lexical* features (Yang and Callan, 2009). These features are generated based on auxiliary documents collected from Web.

Specifically, we issue each aspect term and aspect term pair as queries to Google and Wikipedia, respectively, and collect the top 100 returned documents of each query. We then split the documents into sentences. Based on these documents and sentences, the features are generated as follows.

Contextual features. For each aspect, we collect the documents containing the aspect as context to build a unigram language model without smoothing. Given two aspects, the KL-divergence between their language models is computed as the *Global-Context* feature between them. Similarly, we collect the left two and right two words surrounding each aspect as context and build a unigram language model. The KL-divergence between the language models of two aspects is defined as the *Local-Context* feature.

Co-occurrence features. We measure the co-occurrence of two aspects by Pointwise Mutual Information (PMI): *PMI*(a_x,a_y)=log(*Count*(a_x,a_y)/ *Count*(a_x) *Count*(a_y)), where *Count*($\cdot$) stands for the number of documents or sentences containing the aspect(s), or the number of Google document hits for the aspect(s). Based on different definitions of *Count*($\cdot$), we define the features of *Document PMI*, *Sentence PMI*, and *Google PMI*, respectively.

Syntactic features. We parse the sentences that contain each aspect pair into syntactic trees via the Stanford Parser. The *Syntactic-path* feature is defined as the average length of the shortest syntactic path between the aspect pair in the tree. In addition, for each aspect, we collect a set of sentences containing it, and label the semantic role of the sentences via ASSERT parser [3]. Given two aspects, the number of the Subject terms overlaps between their sentence sets is computed as the *Subject Overlap* feature. Similarly, for other semantic roles, such as objects, modifiers, and verbs, we define the features of *Object Overlap*, *Modifier Overlap*, and *Verb Overlap*, respectively.

Pattern features. 46 patterns are used in our work, including 6 patterns indicating the hypernym relations of two aspects (Hearst, 1992), and 40 patterns measuring the part-of relations of two aspects (Girju et al., 2006). These pattern features are asymmetric, and they take the parent-child relations among the aspects into consideration. All the patterns are listed in Appendix A (submitted as supplementary material). Based on these patterns, a 46-dimensional score vector is obtained for each aspect pair. A score is 1 if two aspects match a pattern, and 0 otherwise.

Lexical features. We take the word length difference between two aspects, as *Length Difference* feature. In addition, we issue the query "define:aspect" to Google, and collect the definition of each aspect. We then count the word overlaps between the definitions of two aspects, as *Definition Overlap* feature.

2.4.2 Semantic Distance Learning

This section elaborates the learning algorithm that optimizes the semantic distance metric, i.e., the weighting parameters in Eq.(1). Typically, we can utilize the initial hierarchy as training data. The ground-truth distance between two aspects $d^{\mathcal{G}}(a_x, a_y)$ is generated by summing up all the edge distances along the shortest path between a_x and a_y, where every edge weight is assumed as 1. The distance metric is then obtained by solving the following optimization problem,

$$\arg\min_{w_j|_{j=1}^m} \sum_{\substack{a_x,a_y\in\mathcal{A}^0 \\ x<y}} (d^{\mathcal{G}}(a_x,a_y) - \sum_{j=1}^{m} w_j f_j(a_x,a_y))^2 + \eta \cdot \sum_{j=1}^{m} w_j^2, \tag{2}$$

where m is the dimension of linguistic feature, η is a tradeoff parameter. Eq.(2) can be rewrote to its matrix form as,

$$\arg\min_{\mathbf{w}} \left\|\mathbf{d} - \mathbf{f}^T\mathbf{w}\right\|^2 + \eta \cdot \|\mathbf{w}\|^2, \tag{3}$$

where vector $\mathbf{d}$ contains the ground-truth distance of all the aspect pairs. Each element corresponds to the distance of certain aspect pair, and $\mathbf{f}$ is the corresponding feature vector. The optimal solution of $\mathbf{w}$ is given as

$$\mathbf{w}^* = (\mathbf{f}^T\mathbf{f} + \eta \cdot \mathbf{I})^{-1}(\mathbf{f}^T\mathbf{d}) \tag{4}$$

[3] http://cemantix.org/assert.html

where $\mathbf{I}$ is the identity metric.

The above learning algorithm can perform well when sufficient training data (i.e., aspect (term) pairs) is available. However, the initial hierarchy is usually too coarse and thus cannot provide sufficient information. On the other hand, abundant handcrafted hierarchies are available on the Web, such as WordNet and Open Directory Project (ODP). We here propose to leverage these external hierarchies to assist semantic distance learning. A distance metric $\mathbf{w}_0$ is learned from the external hierarchies using the above algorithm. Since $\mathbf{w}_0$ might be biased to the characteristics of the external hierarchies, directly using $\mathbf{w}_0$ in our task may not perform well. Alternatively, we use $\mathbf{w}_0$ as prior knowledge to assist learning the optimal distance metric $\mathbf{w}$ from the initial hierarchy. The learning problem is formulated as follows,

$$\arg\min_{\mathbf{w}} \left\|\mathbf{d} - \mathbf{f}^T\mathbf{w}\right\|^2 + \eta \cdot \|\mathbf{w}\|^2 + \gamma \cdot \|\mathbf{w} - \mathbf{w}_0\|^2, \tag{5}$$

where η and γ are tradeoff parameters.

The optimal solution of $\mathbf{w}$ can be obtained as

$$\mathbf{w}^* = (\mathbf{f}^T\mathbf{f} + (\eta+\gamma)\cdot\mathbf{I})^{-1}(\mathbf{f}^T\mathbf{d} + \gamma\cdot\mathbf{w}_0). \tag{6}$$

As a result, we can compute the semantic distance between each two aspects according to Eq.(1).

2.5 Aspect Hierarchy Generation

Given the aspects $\mathcal{A} = \{a_1, \cdots, a_k\}$ identified from reviews and the initial hierarchy $\mathcal{H}^0(\mathcal{A}^0, \mathcal{R}^0)$ obtained from domain knowledge, our task is to construct an aspect hierarchy to contain all the aspects in $\mathcal{A}$. Inspired by Yang and Callan (2009), we adopt a multi-criteria optimization approach to incrementally insert the aspects into appropriate positions in the hierarchy based on multiple criteria.

Before going to the details, we first introduce an information function to measure the amount of information carried in a hierarchy. An information function $Info(\mathcal{H})$ is defined as the sum of the semantic distances of all the aspect pairs in the hierarchy (Yang and Callan, 2009).

$$Info(\mathcal{H}(\mathcal{A},\mathcal{R})) = \sum_{x<y;a_x,a_y\in\mathcal{A}} d(a_x,a_y). \tag{7}$$

Based on this information function, we then introduce the following three criteria for aspect insertion: *minimum Hierarchy Evolution*, *minimum Hierarchy Discrepancy* and *minimum Semantic Inconsistency*.

Hierarchy Evolution is designed to monitor the structure evolution of a hierarchy. The hierarchy is incrementally hosting more aspects until all the aspects are allocated. The insertion of a new aspect a into different positions in the current hierarchy $\mathcal{H}^{(i)}$ leads to different new hierarchies. Among these new hierarchies, we here assume that the optimal one $\mathcal{H}^{(i+1)}$ should introduce the least changes of information to $\mathcal{H}^{(i)}$.

$$\hat{\mathcal{H}}^{(i+1)} = \arg\min_{\mathcal{H}^{(i+1)}} \Delta Info(\mathcal{H}^{(i+1)} - \mathcal{H}^{(i)}). \tag{8}$$

By plugging in Eq.(7) and using *least square* to measure the information changes, we have,

$$obj_1 = \arg\min_{\mathcal{H}^{(i+1)}} (\textstyle\sum_{x<y;a_x,a_y\in\mathcal{A}_i\cup\{a\}} d(a_x,a_y) - \sum_{x<y;a_x,a_y\in\mathcal{A}_i} d(a_x,a_y))^2, \tag{9}$$

Hierarchy Discrepancy is used to measure the global changes of the structure. We assume a good hierarchy should bring the least changes to the initial hierarchy,

$$\hat{\mathcal{H}}^{(i+1)} = \arg\min_{\mathcal{H}^{(i+1)}} \frac{\Delta Info(\mathcal{H}^{(i+1)} - \mathcal{H}^{(0)})}{i+1}. \tag{10}$$

We then get,

$$obj_2 = \arg\min_{\mathcal{H}^{(i+1)}} \tfrac{1}{i+1}(\textstyle\sum_{x<y;a_x,a_y\in\mathcal{A}_i\cup\{a\}} d(a_x,a_y) - \sum_{x<y;a_x,a_y\in\mathcal{A}_0} d(a_x,a_y))^2. \tag{11}$$

Semantic Inconsistency is introduced to quantify the inconsistency between the semantic distance estimated via the hierarchy and that computed from the feature functions. We assume that a good hierarchy should precisely reflect the semantic distance between aspects. For two aspects, their semantic distance reflected by the hierarchy is computed as the sum of adjacent distances along the shortest path between them,

$$d^{\mathcal{H}}(a_x,a_y) = \sum\nolimits_{p<q;(a_p,a_q)\in SP(a_x,a_y)} d(a_p,a_q), \tag{12}$$

where $SP(a_x,a_y)$ is the shortest path between the aspects (a_x,a_y), (a_p,a_q) are the adjacent nodes along the path.

We then define the following criteria to find the hierarchy with minimum semantic inconsistency,

$$obj_3 = \arg\min_{\mathcal{H}^{(i+1)}} \sum_{x<y; a_x, a_y \in \mathcal{A}_i \cup \{a\};} (d^{\mathcal{H}}(a_x, a_y) - d(a_x, a_y))^2, \tag{13}$$

where $d(a_x, a_y)$ is the distance computed based on the feature functions in Section 2.4.

Through integrating the above criteria, the multi-criteria optimization framework is formulated as,

$$obj = \arg\min_{\mathcal{H}^{(i+1)}} (\lambda_1 \cdot obj_1 + \lambda_2 \cdot obj_2 + \lambda_3 \cdot obj_3)$$
$$\lambda_1 + \lambda_2 + \lambda_3 = 1; \;\; 0 \leq \lambda_1, \lambda_2, \lambda_3 \leq 1. \tag{14}$$

where λ_1, λ_2, λ_3 are the tradeoff parameters.

To summarize, our aspect hierarchy generation process starts from an initial hierarchy and inserts the aspects into it one-by-one until all the aspects are allocated. Each aspect is inserted to the optimal position found by Eq.(14). It is worth noting that the insertion order may influence the result. To avoid such influence, we select the aspect with the least objective function value in Eq.(14) to insert. Based on resultant hierarchy, the consumer reviews are then organized to their corresponding aspect nodes in the hierarchy. We further prune out the nodes without reviews from the hierarchy.

Moreover, we perform sentiment classification to determine consumer opinions on various aspects. In particular, we train a *SVM* sentiment classifier based on the *Pros* and *Cons* reviews described in Section 2.3. We collect sentiment terms in the reviews as features and represent reviews as feature vectors using Boolean weighting. Note that we define sentiment terms as those appear in the sentiment lexicon provided by *MPQA* project (Wilson et al., 2005).

3 Implicit Aspect Identification

In this section, we apply the aspect hierarchy to the task of implicit aspect identification. This task aims to infer the aspects of reviews that do not explicitly express those aspects but actually comment on them (Liu et al. 2005). Take the review "The phone is too large" as an example, the task is to infer its implicit aspect "size." It has been observed that the reviews commenting on a same aspect usually use some same sentiment terms (Su et al., 2008). Therefore, sentiment term is an effective feature for identifying implicit aspects. We here collect the sentiment terms as features to represent each review into a feature vector. For each aspect node in the hierarchy, we define its centroid as the average of its feature vectors, i.e., the feature vectors of all the reviews that are allocated at this node. We then calculate the cosine similarity of each implicit-aspect review to the centriods of all the aspect nodes, and allocate the review into the node with maximum similarity. As a result, the implicit aspect reviews are grouped to their related aspect nodes. In other word, their aspects are identified as the corresponding aspect nodes.

4 Evaluations

In this section, we evaluate the effectiveness of our approach on aspect identification, aspect hierarchy generation, and implicit aspect identification.

4.1 Data and Experimental Setting

The details of our product review corpus are given in Table 1. This corpus contains consumer reviews on 11 popular products in four domains. These reviews were crawled from several prevalent forum Web sites, including cnet.com, viewpoints.com, reevoo.com and gsmarena.com. All of the reviews were posted between June, 2009 and Sep 2010. The aspects of the reviews, as well as the opinions on the aspects were manually annotated. We also invited five annotators to construct the gold-standard hierarchies for the products by providing them the initial hierarchies and the aspects in reviews. The conflicts between annotators were resolved through their discussions. For semantic distance learning, we collected 50 hierarchies from WordNet and ODP, respectively. The details are shown in Table 2. We listed the topics of the hierarchies in Appendix B (submitted as supplementary material).

Product Name	*Domain*	*Review#*	*Sentence#*
Canon EOS 450D (Canon EOS)	camera	440	628
Fujifilm Finepix AX245W (Fujifilm)	camera	541	839
Panasonic Lumix DMC-TZ7 (Panasonic)	camera	650	1,546
Apple MacBook Pro (MacBook)	laptop	552	4,221
Samsung NC10 (Samsung)	laptop	2,712	4,946
Apple iPod Touch 2nd (iPod Touch)	MP3	4,567	10,846
Sony NWZ-S639 16GB (Sony NWZ)	MP3	341	773
BlackBerry Bold 9700 (BlackBerry)	phone	4,070	11,008
iPhone 3GS 16GB (iPhone 3GS)	phone	12,418	43,527
Nokia 5800 XpressMusic (Nokia 5800)	phone	28,129	75,001
Nokia N95	phone	15,939	44,379

Table 1: Statistics of the reviews corpus, # denotes the size of the reviews/sentences

Average # depth	5.5	5.9
Total # related topics	12	16

Table 2: Statistics of the External Hierarchies

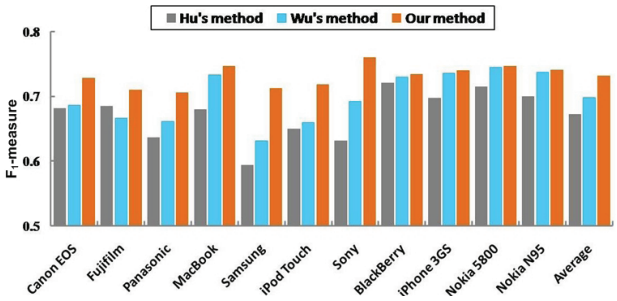

Figure 3: Evaluations on Aspect Identification. t-test, p-values$<$0.05

We employed F_1-measure, which is the combination of *precision* and *recall*, as the evaluation metric for all the evaluations. For the evaluation on aspect hierarchy, we defined *precision* as the percentage of correctly returned parent-child pairs out of the total returned pairs, and *recall* as the percentage of correctly returned parent-child pairs out of the total pairs in the gold standard. Throughout the experiments, we empirically set $\lambda_1 = 0.4$, $\lambda_2 = 0.3$, $\lambda_3 = 0.3$, $\eta = 0.4$ and $\gamma = 0.6$.

4.2 Evaluations on Aspect Identification

We compared our approach against two state-of-the-art methods: a) the method proposed by Hu and Liu (2004), which is based on the association rule mining, and b) the method proposed by Wu et al. (2009), which is based on the dependency parser. The results are presented in Figure 3. On average, our approach significantly outperforms Hu's and Wu's method in terms of F_1-measure by over 5.87% and 3.27%, respectively.

4.3 Evaluations on Aspect Hierarchy

4.3.1 Comparisons with the State-of-the-Arts

We compared our approach against four traditional hierarchy generation methods in the researches on ontology learning, including a) pattern-based method (Hearst, 1992) and b) clustering-based method by Shi et al. (2008), c) the method proposed by Snow et al. (2006) which was based on a probabilistic model, and d) the method proposed by Yang and Callan (2009). Since our approach and Yang's method can utilize initial hierarchy to assist hierarchy generation, we evaluated their performance with or without initial hierarchy, respectively. For the sake of fair comparison, Snow's, Yang's and our methods used the same linguistic features in Section 2.4.1.

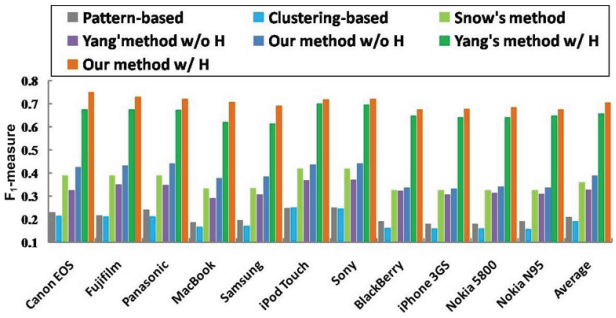

Figure 4: Evaluations on Aspect Hierarchy Generation. t-test, p-values$<$0.05. w/ H denotes the methods with initial hierarchy, accordingly, w/o H refers to the methods without initial hierarchy.

Figure 4 shows the performance comparisons of these five methods. We can see that our approach without using initial hierarchy outperforms the pattern-based, clustering-based, Snow's, and Yang's methods by over 17.9%, 19.8%, 2.9% and 6.1% respectively in terms of average F_1-measure. By exploiting initial hierarchy, our approach improves the performance significantly. As compared to the pattern-based, clustering-based and Snow's methods, it improves the average performance by over 49.4%, 51.2% and 34.3% respectively. Compared to Yang's method with initial hierarchy, it achieves 4.7% improvements on the average performance.

The results show that pattern-based and clustering-based methods perform poor. Pattern-based method may suffer from the problem of low coverage of patterns, especially when the patterns are manually pre-defined, while the clustering-based method (Shi et al., 2008) may sustain to the bisection clustering mechanism which can only generate a binary-tree. The results also illustrate that our approach outperforms Snow's and Yang's methods. By exploiting external hierarchies, our

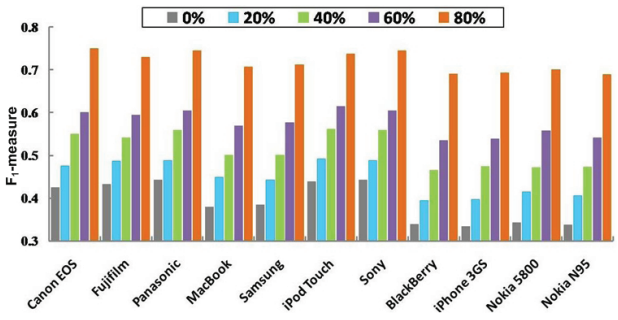

Figure 5: Evaluations on the Impact of Initial Hierarchy. t-test, p-values$<$0.05.

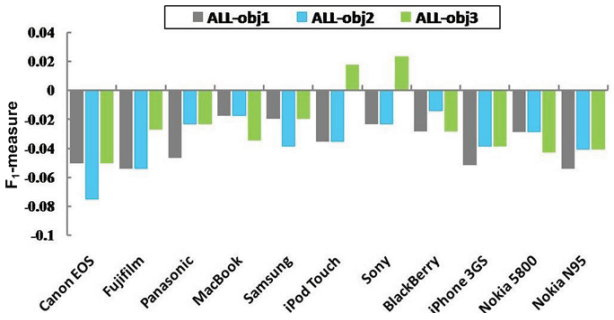

Figure 6: Evaluations of the Optimization Criteria. % of change in F_1-measure when a single criterion is removed. t-test, p-values$<$0.05.

approach is able to derive reliable semantic distance between aspects and thus improve the performance.

4.3.2 Evaluations on Effectiveness of Initial Hierarchy

In this section, we show that even based on a small part of the initial hierarchy, our approach can still generate a satisfactory hierarchy. We explored different proportion of initial hierarchy, including 0%, 20%, 40%, 60% and 80% of the aspect pairs which are collected top-down from the initial hierarchy. As shown in Figure 5, the performance increases when larger proportion of the initial hierarchy is used. Thus, we can speculate that domain knowledge is valuable in aspect hierarchy generation.

4.3.3 Evaluations on Effectiveness of Optimization Criteria

We conducted a leave-one-out study to evaluate the effectiveness of each optimization criterion. In particular, we set one of the tradeoff parameters (λ_1, λ_2, λ_3) in Eq.(14) to zero, and distributed its weight to the rest parameters averagely. From Figure 6, we find that removing any optimization criterion would degrade the performance on most products. It is interesting to note that removing the third optimization criterion, i.e., minimum semantic inconsistency, slightly increases the performance on two products (ipad touch and sony MP3). The reason might be that the values of the three tradeoff parameters (empirically set in Section 4.1) are not suitable for these two products.

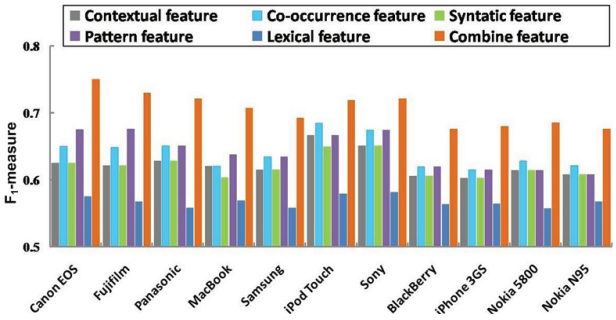

Figure 7: Evaluations on the Impact of Linguistic Features. t-test, p-values$<$0.05.

4.3.4 Evaluations on Semantic Distance Learning

In this section, we evaluated the impact of the features and external hierarchies in semantic distance learning. We investigated five sets of features as described in Section 2.4.1, including contextual, co-occurrence, syntactic, pattern and lexical features. From Figure 7, we observe that the co-occurrence and pattern features perform much better than contextual and syntactic features. A possible reason is that co-occurrence and pattern features are more likely to indicate parent-child aspect relationships, while contextual and syntactic features are probable to measure sibling aspect relationships. Among these features, the lexical features perform the worst. The combination of all the features achieves the best performance.

Next, we evaluated the effectiveness of external hierarchies in semantic distance learning. We compared the performance of our approach with or without the external hierarchies. From Figure 8, we find that by exploiting the external hierarchies, our ap-

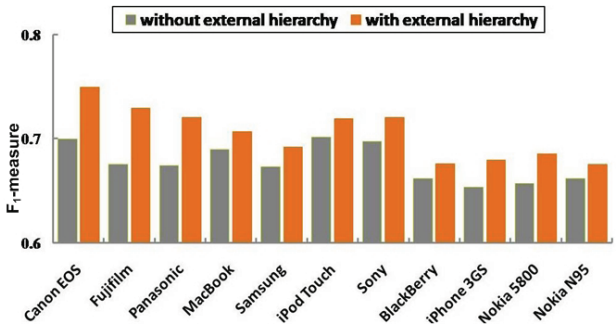

Figure 8: Evaluations on the Impact of External Hierarchy. t-test, p-values$<$0.05.

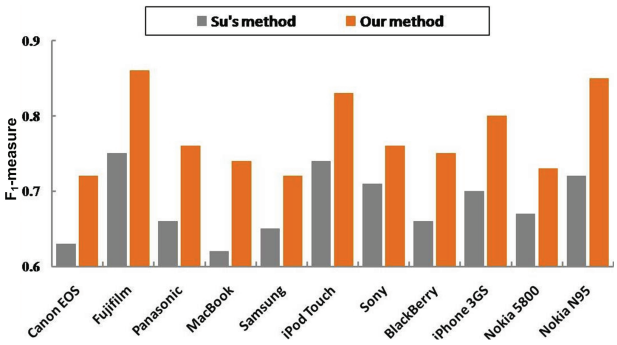

Figure 9: Evaluations on Implicit Aspects Identification. t-test, p-values$<$0.05

proach improves the performance significantly. The improvement is over 2.81% in terms of average F_1-measure. This implies that by using external hierarchies, our approach can obtain effective semantic distance, and thus improve the performance of aspect hierarchy generation.

Additionally, for sentiment classification, our *SVM* classifier achieves an average F_1-measure of 0.787 in the 11 products.

4.4 Evaluations on Implicit Aspect Identification

To evaluate the performance of our approach on implicit aspect identification, we collected 29,657 implicit aspect review sentences on the 11 products from the four forum Web sites introduced in Section 4.1. While most existing approaches for implicit aspect identification rely on hand-crafted rules (Liu, 2009), the method proposed in Su et al. (2008) can identify implicit aspects without hand-crafted rules based on mutual clustering. Therefore, we adopt Su's method as the baseline here. Figure 9 illustrates the performance comparison between Su's and our approach. We can see that our approach outperforms Su's method by over 9.18% in terms of average F_1-measure. This shows that our approach can identify the implicit aspects accurately by exploiting the underlying associations among the sentiment terms and each aspect in the hierarchy.

5 Related Work

Some researches treated review organization as a multi-document summarization problem, and generated a summary by selecting and ordering sentences taken from multiple reviews (Nishikawa et al., 2010). These works did not drill down to the fine-grained level to explore the opinions on the product aspects. Other researchers proposed to produce a summary covering consumer opinions on each aspect. For example, Hu and Liu (2004) focused on extracting the aspects and determining opinions on the aspects. However, their generated summary was unstructured, where the possible relationships between aspects were not recognized (Cadilhac et al., 2010). Subsequently, Carenini et al. (2006) proposed to map the aspect to a user-defined taxonomy, but the taxonomy was hand-crafted which was not scalable.

Different from the previous works, we focus on automatically generating an aspect hierarchy to hierarchically organize consumer reviews. There are some related works on ontology learning, which first identify concepts from text, and then determine parent-child relations between these concepts using either pattern-based or clustering-based methods (Murthy et al., 2010). Pattern-based methods usually defined some lexical syntactic patterns to extract the relations, while clustering-based methods mostly utilized the hierarchical clustering methods to build a hierarchy (Roy et al., 2006). Some works proposed to integrate the pattern-based and clustering-based methods in a general model, such as the probabilistic model (Snow et al., 2006) and metric-based model (Yang and Callan, 2009).

The researches on aspect identification are also related to our work. Various aspect identification methods have been proposed (Popescu et al., 2005), including supervised methods (Liu el al., 2005), and unsupervised methods (Mei et al., 2007). Different

features have been investigated for this task. For example, Wu et al. (2009) identified aspects based on the features explored by dependency parser. For implicit aspect identification, some works proposed to define rules for identification (Liu el al., 2005), while others suggested to automatically generate rules via mutual clustering (Su et al., 2008). On the other hand, there are some related works on sentiment classification (Pang and Lee, 2008). These works can be categorized into four granularities: document-level, sentence-level, aspect-level and word-level sentiment classification (Liu, 2009). Existing researches have been studied unsupervised (Kim et al., 2004), supervised (Pang et al., 2002; Pang et al., 2005) and semi-supervised classification approaches (Goldberg et al., 2006; Li et al., 2009) on these four levels.

6 Conclusions and Future Works

In this paper, we have developed a domain-assisted approach to generate product aspect hierarchy by integrating domain knowledge and consumer reviews. Based on the derived hierarchy, we can generate a hierarchical organization of consumer reviews as well as consumer opinions on the aspects. With such organization, user can easily grasp the overview of consumer reviews, as well as seek consumer reviews and opinions on any specific aspect by navigating through the hierarchy. We have further applied the hierarchy to the task of implicit aspect identification. We have conducted evaluations on 11 different products in four domains. The experimental results have demonstrated the effectiveness of our approach. In the future, we will explore other linguistic features to learn the semantic distance between aspects, as well as apply our approach to other applications.

Abstract

We introduce a novel machine learning framework based on recursive autoencoders for sentence-level prediction of sentiment label distributions. Our method learns vector space representations for multi-word phrases. In sentiment prediction tasks these representations outperform other state-of-the-art approaches on commonly used datasets, such as movie reviews, without using any pre-defined sentiment lexica or polarity shifting rules. We also evaluate the model's ability to predict sentiment distributions on a new dataset based on confessions from the experience project. The dataset consists of personal user stories annotated with multiple labels which, when aggregated, form a multinomial distribution that captures emotional reactions. Our algorithm can more accurately predict distributions over such labels compared to several competitive baselines.

1 Introduction

The ability to identify sentiments about personal experiences, products, movies etc. is crucial to understand user generated content in social networks, blogs or product reviews. Detecting sentiment in these data is a challenging task which has recently spawned a lot of interest (Pang and Lee, 2008).

Current baseline methods often use bag-of-words representations which cannot properly capture more complex linguistic phenomena in sentiment analysis (Pang et al., 2002). For instance, while the two phrases "white blood cells destroying an infection" and "an infection destroying white blood cells" have the same bag-of-words representation, the former is a positive reaction while the later is very negative. More advanced methods such as (Nakagawa et al., 2010) that can capture such phenomena use many manually constructed resources (sentiment lexica, parsers, polarity-shifting rules). This limits the applicability of these methods to a broader range of tasks and languages. Lastly, almost all previous work is based on single, positive/negative categories or scales such as star ratings. Examples are movie reviews (Pang and Lee, 2005), opinions (Wiebe et al., 2005), customer reviews (Ding et al., 2008) or multiple aspects of restaurants (Snyder and Barzilay, 2007). Such a one-dimensional scale does not accurately reflect the complexity of human emotions and sentiments.

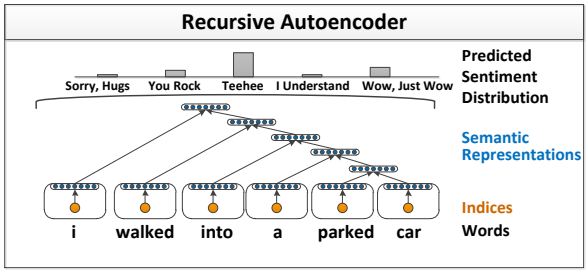

Figure 1: Illustration of our recursive autoencoder architecture which learns semantic vector representations of phrases. Word indices (orange) are first mapped into a semantic vector space (blue). Then they are recursively merged by the same autoencoder network into a fixed length sentence representation. The vectors at each node are used as features to predict a distribution over sentiment labels.

In this work, we seek to address three issues. (i) Instead of using a bag-of-words representation, our model exploits hierarchical structure and uses compositional semantics to understand sentiment. (ii) Our system can be trained both on unlabeled domain data and on supervised sentiment data and does not require any language-specific sentiment lexica,

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 151–161,
Edinburgh, Scotland, UK, July 27–31, 2011.

parsers, etc. (iii) Rather than limiting sentiment to a positive/negative scale, we predict a multidimensional distribution over several complex, interconnected sentiments.

We introduce an approach based on semi-supervised, recursive autoencoders (RAE) which use as input continuous word vectors. Fig. 1 shows an illustration of the model which learns vector representations of phrases and full sentences as well as their hierarchical structure from unsupervised text. We extend our model to also learn a distribution over sentiment labels at each node of the hierarchy.

We evaluate our approach on several standard datasets where we achieve state-of-the art performance. Furthermore, we show results on the recently introduced experience project (EP) dataset (Potts, 2010) that captures a broader spectrum of human sentiments and emotions. The dataset consists of very personal confessions anonymously made by people on the experience project website *www.experienceproject.com*. Confessions are labeled with a set of five reactions by other users. Reaction labels are *you rock* (expressing approvement), *tehee* (amusement), *I understand*, *Sorry, hugs* and *Wow, just wow* (displaying shock). For evaluation on this dataset we predict both the label with the most votes as well as the full distribution over the sentiment categories. On both tasks our model outperforms competitive baselines. A set of over 31,000 confessions as well as the code of our model are available at *www.socher.org*.

After describing the model in detail, we evaluate it qualitatively by analyzing the learned n-gram vector representations and compare quantitatively against other methods on standard datasets and the EP dataset.

2 Semi-Supervised Recursive Autoencoders

Our model aims to find vector representations for variable-sized phrases in either unsupervised or semi-supervised training regimes. These representations can then be used for subsequent tasks. We first describe neural word representations and then proceed to review a related recursive model based on autoencoders, introduce our recursive autoencoder (RAE) and describe how it can be modified to jointly learn phrase representations, phrase structure and sentiment distributions.

2.1 Neural Word Representations

We represent words as continuous vectors of parameters. We explore two settings. In the first setting we simply initialize each word vector $x \in \mathbb{R}^n$ by sampling it from a zero mean Gaussian distribution: $x \sim \mathcal{N}(0, \sigma^2)$. These word vectors are then stacked into a word embedding matrix $L \in \mathbb{R}^{n \times |V|}$, where $|V|$ is the size of the vocabulary. This initialization works well in supervised settings where a network can subsequently modify these vectors to capture certain label distributions.

In the second setting, we pre-train the word vectors with an unsupervised neural language model (Bengio et al., 2003; Collobert and Weston, 2008). These models jointly learn an embedding of words into a vector space and use these vectors to predict how likely a word occurs given its context. After learning via gradient ascent the word vectors capture syntactic and semantic information from their co-occurrence statistics.

In both cases we can use the resulting matrix of word vectors L for subsequent tasks as follows. Assume we are given a sentence as an ordered list of m words. Each word has an associated vocabulary index k into the embedding matrix which we use to retrieve the word's vector representation. Mathematically, this look-up operation can be seen as a simple projection layer where we use a binary vector b which is zero in all positions except at the kth index,

$$x_i = Lb_k \in \mathbb{R}^n. \quad (1)$$

In the remainder of this paper, we represent a sentence (or any n-gram) as an ordered list of these vectors $(x_1, \ldots, x_m)$. This word representation is better suited to autoencoders than the binary number representations used in previous related autoencoder models such as the recursive autoassociative memory (RAAM) model (Pollack, 1990; Voegtlin and Dominey, 2005) or recurrent neural networks (Elman, 1991) since sigmoid units are inherently continuous. Pollack circumvented this problem by having vocabularies with only a handful of words and by manually defining a threshold to binarize the resulting vectors.

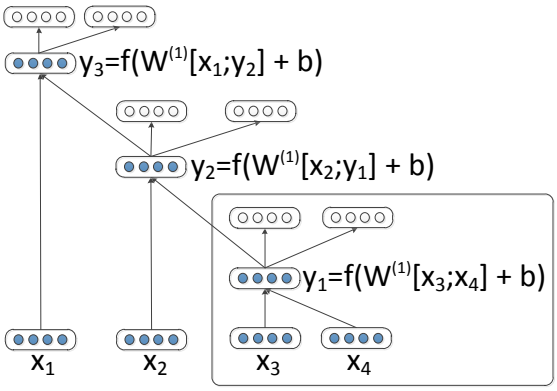

Figure 2: Illustration of an application of a recursive autoencoder to a binary tree. The nodes which are not filled are only used to compute reconstruction errors. A standard autoencoder (in box) is re-used at each node of the tree.

2.2 Traditional Recursive Autoencoders

The goal of autoencoders is to learn a representation of their inputs. In this section we describe how to obtain a reduced dimensional vector representation for sentences.

In the past autoencoders have only been used in setting where the tree structure was given a-priori. We review this setting before continuing with our model which does not require a given tree structure. Fig. 2 shows an instance of a recursive autoencoder (RAE) applied to a given tree. Assume we are given a list of word vectors $x = (x_1, \ldots, x_m)$ as described in the previous section as well as a binary tree structure for this input in the form of branching triplets of parents with children: $(p \rightarrow c_1 c_2)$. Each child can be either an input word vector x_i or a nonterminal node in the tree. For the example in Fig. 2, we have the following triplets: $((y_1 \rightarrow x_3 x_4), (y_2 \rightarrow x_2 y_1), (y_1 \rightarrow x_1 y_2))$. In order to be able to apply the same neural network to each pair of children, the hidden representations y_i have to have the same dimensionality as the x_i's.

Given this tree structure, we can now compute the parent representations. The first parent vector y_1 is computed from the children $(c_1, c_2) = (x_3, x_4)$:

$$p \quad = \quad f(W^{(1)}[c_1; c_2] + b^{(1)}), \tag{2}$$

where we multiplied a matrix of parameters $W^{(1)} \in \mathbb{R}^{n \times 2n}$ by the concatenation of the two children. After adding a bias term we applied an element-wise activation function such as $\tanh$ to the resulting vector. One way of assessing how well this n-dimensional vector represents its children is to try to reconstruct the children in a reconstruction layer:

$$\left[c_1'; c_2'\right] \quad = \quad W^{(2)} p + b^{(2)}. \tag{3}$$

During training, the goal is to minimize the reconstruction errors of this input pair. For each pair, we compute the Euclidean distance between the original input and its reconstruction:

$$E_{rec}([c_1; c_2]) = \frac{1}{2} \left|\left|[c_1; c_2] - \left[c_1'; c_2'\right]\right|\right|^2. \tag{4}$$

This model of a standard autoencoder is boxed in Fig. 2. Now that we have defined how an autoencoder can be used to compute an n-dimensional vector representation (p) of two n-dimensional children (c_1, c_2), we can describe how such a network can be used for the rest of the tree.

Essentially, the same steps repeat. Now that y_1 is given, we can use Eq. 2 to compute y_2 by setting the children to be $(c_1, c_2) = (x_2, y_1)$. Again, after computing the intermediate parent vector y_2, we can assess how well this vector capture the content of the children by computing the reconstruction error as in Eq. 4. The process repeat until the full tree is constructed and we have a reconstruction error at each nonterminal node. This model is similar to the RAAM model (Pollack, 1990) which also requires a fixed tree structure.

2.3 Unsupervised Recursive Autoencoder for Structure Prediction

Now, assume there is no tree structure given for the input vectors in x. The goal of our structure-prediction RAE is to minimize the reconstruction error of all vector pairs of children in a tree. We define $A(x)$ as the set of all possible trees that can be built from an input sentence x. Further, let $T(y)$ be a function that returns the triplets of a tree indexed by s of all the non-terminal nodes in a tree. Using the reconstruction error of Eq. 4, we compute

$$RAE_\theta(x) = \underset{y \in A(x)}{\arg\min} \sum_{s \in T(y)} E_{rec}([c_1; c_2]_s) \tag{5}$$

We now describe a greedy approximation that constructs such a tree.

Greedy Unsupervised RAE. For a sentence with m words, we apply the autoencoder recursively. It takes the first pair of neighboring vectors, defines them as potential children of a phrase $(c_1; c_2) = (x_1; x_2)$, concatenates them and gives them as input to the autoencoder. For each word pair, we save the potential parent node p and the resulting reconstruction error.

After computing the score for the first pair, the network is shifted by one position and takes as input vectors $(c_1, c_2) = (x_2, x_3)$ and again computes a potential parent node and a score. This process repeats until it hits the last pair of words in the sentence: $(c_1, c_2) = (x_{m-1}, x_m)$. Next, it selects the pair which had the lowest reconstruction error (E_{rec}) and its parent representation p will represent this phrase and replace both children in the sentence word list. For instance, consider the sequence (x_1, x_2, x_3, x_4) and assume the lowest E_{rec} was obtained by the pair (x_3, x_4). After the first pass, the new sequence then consists of $(x_1, x_2, p_{(3,4)})$. The process repeats and treats the new vector $p_{(3,4)}$ like any other input vector. For instance, subsequent states could be either: $(x_1, p_{(2,(3,4))})$ or $(p_{(1,2)}, p_{(3,4)})$. Both states would then finish with a deterministic choice of collapsing the remaining two states into one parent to obtain $(p_{(1,(2,(3,4)))})$ or $(p_{((1,2),(3,4))})$ respectively. The tree is then recovered by unfolding the collapsing decisions.

The resulting tree structure captures as much of the single-word information as possible (in order to allow reconstructing the word vectors) but does not necessarily follow standard syntactic constraints. We also experimented with a method that finds better solutions to Eq. 5 based on CKY-like beam search algorithms (Socher et al., 2010; Socher et al., 2011) but the performance is similar and the greedy version is much faster.

Weighted Reconstruction. One problem with simply using the reconstruction error of both children equally as describe in Eq. 4 is that each child could represent a different number of previously collapsed words and is hence of bigger importance for the overall meaning reconstruction of the sentence. For instance in the case of $(x_1, p_{(2,(3,4))})$ one would like to give more importance to reconstructing p than x_1. We capture this desideratum by adjusting the reconstruction error. Let n_1, n_2 be the number of words underneath a current potential child, we re-define the reconstruction error to be $E_{rec}([c_1; c_2]; \theta) =$

$$\frac{n_1}{n_1+n_2}\left|\left|c_1 - c_1'\right|\right|^2 + \frac{n_2}{n_1+n_2}\left|\left|c_2 - c_2'\right|\right|^2 \quad (6)$$

Length Normalization. One of the goals of RAEs is to induce semantic vector representations that allow us to compare n-grams of different lengths. The RAE tries to lower reconstruction error of not only the bigrams but also of nodes higher in the tree. Unfortunately, since the RAE computes the hidden representations it then tries to reconstruct, it can just lower reconstruction error by making the hidden layer very small in magnitude. To prevent such undesirable behavior, we modify the hidden layer such that the resulting parent representation always has length one, after computing p as in Eq. 2, we simply set: $p = \frac{p}{||p||}$.

2.4 Semi-Supervised Recursive Autoencoders

So far, the RAE was completely unsupervised and induced general representations that capture the semantics of multi-word phrases.In this section, we extend RAEs to a semi-supervised setting in order to predict a sentence- or phrase-level target distribution t.[1]

One of the main advantages of the RAE is that each node of the tree built by the RAE has associated with it a distributed vector representation (the parent vector p) which could also be seen as features describing that phrase. We can leverage this representation by adding on top of each parent node a simple $\mathrm{softmax}$ layer to predict class distributions:

$$d(p; \theta) = \mathrm{softmax}(W^{label} p). \quad (7)$$

Assuming there are K labels, $d \in \mathbb{R}^K$ is a K-dimensional multinomial distribution and $\sum_{k=1} d_k = 1$. Fig. 3 shows such a semi-supervised RAE unit. Let t_k be the kth element of the multinomial target label distribution t for one entry. The $\mathrm{softmax}$ layer's outputs are interpreted as conditional probabilities $d_k = p(k|[c_1; c_2])$, hence the cross-entropy error is

$$E_{cE}(p, t; \theta) = -\sum_{k=1}^{K} t_k \log d_k(p; \theta). \quad (8)$$

[1]For the binary label classification case, the distribution is of the form $[1, 0]$ for class 1 and $[0, 1]$ for class 2.

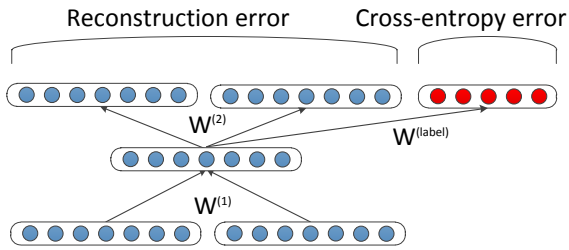

Figure 3: Illustration of an RAE unit at a nonterminal tree node. Red nodes show the supervised *softmax* layer for label distribution prediction.

Using this cross-entropy error for the label and the reconstruction error from Eq. 6, the final semi-supervised RAE objective over (sentences,label) pairs (x, t) in a corpus becomes

$$J = \frac{1}{N}\sum_{(x,t)} E(x,t;\theta) + \frac{\lambda}{2}||\theta||^2, \qquad (9)$$

where we have an error for each entry in the training set that is the sum over the error at the nodes of the tree that is constructed by the greedy RAE:

$$E(x,t;\theta) = \sum_{s \in T(RAE_\theta(x))} E([c_1;c_2]_s, p_s, t, \theta).$$

The error at each nonterminal node is the weighted sum of reconstruction and cross-entropy errors, $E([c_1;c_2]_s, p_s, t, \theta) =$

$$\alpha E_{rec}([c_1;c_2]_s;\theta) + (1-\alpha)E_{cE}(p_s, t;\theta).$$

The hyperparameter α weighs reconstruction and cross-entropy error. When minimizing the cross-entropy error of this softmax layer, the error will backpropagate and influence both the RAE parameters and the word representations. Initially, words such as *good* and *bad* have very similar representations. This is also the case for Brown clusters and other methods that use only cooccurrence statistics in a small window around each word. When learning with positive/negative sentiment, the word embeddings get modified and capture less syntactic and more sentiment information.

In order to predict the sentiment distribution of a sentence with this model, we use the learned vector representation of the top tree node and train a simple logistic regression classifier.

3 Learning

Let $\theta = (W^{(1)}, b^{(1)}, W^{(2)}, b^{(1)}, W^{label}, L)$ be the set of our model parameters, then the gradient becomes:

$$\frac{\partial J}{\partial \theta} = \frac{1}{N}\sum_{(x,t)} \frac{\partial E(x,t;\theta)}{\partial \theta} + \lambda\theta. \qquad (10)$$

To compute this gradient, we first greedily construct all trees and then derivatives for these trees are computed efficiently via backpropagation through structure (Goller and Küchler, 1996). Because the algorithm is greedy and the derivatives of the supervised cross-entropy error also modify the matrix $W^{(1)}$, this objective is not necessarily continuous and a step in the gradient descent direction may not necessarily decrease the objective. However, we found that L-BFGS run over the complete training data (batch mode) to minimize the objective works well in practice, and that convergence is smooth, with the algorithm typically finding a good solution quickly.

4 Experiments

We first describe the new experience project (EP) dataset, results of standard classification tasks on this dataset and how to predict its sentiment label distributions. We then show results on other commonly used datasets and conclude with an analysis of the important parameters of the model.

In all experiments involving our model, we represent words using 100-dimensional word vectors. We explore the two settings mentioned in Sec. 2.1. We compare performance on standard datasets when using randomly initialized word vectors (random word init.) or word vectors trained by the model of Collobert and Weston (2008) and provided by Turian et al. (2010).[2] These vectors were trained on an unlabeled corpus of the English Wikipedia. Note that alternatives such as Brown clusters are not suitable since they do not capture sentiment information (*good* and *bad* are usually in the same cluster) and cannot be modified via backpropagation.

[2] http://metaoptimize.com/projects/wordreprs/

Corpus	K	Instances	Distr.(+/-)	Avg$\|W\|$
MPQA	2	10,624	0.31/0.69	3
MR	2	10,662	0.5/0.5	22
EP	5	31,675	.2/.2/.1/.4/.1	113
EP≥ 4	5	6,129	.2/.2/.1/.4/.1	129

Table 1: Statistics on the different datasets. K is the number of classes. Distr. is the distribution of the different classes (in the case of 2, the positive/negative classes, for EP the rounded distribution of total votes in each class). $|W|$ is the average number of words per instance. We use EP≥ 4, a subset of entries with at least 4 votes.

4.1 EP Dataset: The Experience Project

The confessions section of the experience project website[3] lets people anonymously write short personal stories or "confessions". Once a story is on the site, each user can give a single vote to one of five label categories (with our interpretation):

1 Sorry, Hugs: User offers condolences to author.
2. You Rock: Indicating approval, congratulations.
3. Teehee: User found the anecdote amusing.
4. I Understand: Show of empathy.
5. Wow, Just Wow: Expression of surprise,shock.

The EP dataset has 31,676 confession entries, a total number of 74,859 votes for the 5 labels above, the average number of votes per entry is 2.4 (with a variance of 33). For the five categories, the numbers of votes are $[14,816; 13,325; 10,073; 30,844; 5,801]$. Since an entry with less than 4 votes is not very well identified, we train and test only on entries with at least 4 total votes. There are 6,129 total such entries. The distribution over total votes in the 5 classes is similar: $[0.22; 0.2; 0.11; 0.37; 0.1]$. The average length of entries is 129 words. Some entries contain multiple sentences. In these cases, we average the predicted label distributions from the sentences. Table 1 shows statistics of this and other commonly used sentiment datasets (which we compare on in later experiments). Table 2 shows example entries as well as gold and predicted label distributions as described in the next sections.

Compared to other datasets, the EP dataset contains a wider range of human emotions that goes far beyond positive/negative product or movie reviews. Each item is labeled with a multinomial distribution over interconnected response categories. This is in contrast to most other datasets (including multi-aspect rating) where several distinct aspects are rated independently but on the same scale. The topics range from generic happy statements, daily clumsiness reports, love, loneliness, to relationship abuse and suicidal notes. As is evident from the total number of label votes, the most common user reaction is one of empathy and an ability to relate to the authors experience. However, some stories describe horrible scenarios that are not common and hence receive more offers of condolence. In the following sections we show some examples of stories with predicted and true distributions but refrain from listing the most horrible experiences.

For all experiments on the EP dataset, we split the data into train (49%), development (21%) and test data (30%).

4.2 EP: Predicting the Label with Most Votes

The first task for our evaluation on the EP dataset is to simply predict the single class that receives the most votes. In order to compare our novel joint phrase representation and classifier learning framework to traditional methods, we use the following baselines:

Random Since there are five classes, this gives 20% accuracy.

Most Frequent Selecting the class which most frequently has the most votes (the class *I understand*).

Baseline 1: Binary BoW This baseline uses logistic regression on binary bag-of-word representations that are 1 if a word is present and 0 otherwise.

Baseline 2: Features This model is similar to traditional approaches to sentiment classification in that it uses many hand-engineered resources. We first used a spell-checker and Wordnet to map words and their misspellings to synsets to reduce the total number of words. We then replaced sentiment words with a sentiment category identifier using the sentiment lexica of the Harvard Inquirer (Stone, 1966) and LIWC (Pennebaker et al., 2007). Lastly, we used tf-idf weighting on the bag-of-word representations and trained an SVM.

.92		4	My paper is due in less than 24 hours and I'm still dancing round my room!

Table 2: Example EP confessions from the test data with KL divergence between our predicted distribution (light blue, left bar on each of the 5 classes) and ground truth distribution (red bar and numbers underneath), number of votes. The 5 classes are [Sorry, Hugs ;You Rock; Teehee;I Understand;Wow, Just Wow]. Even when the KL divergence is higher, our model makes reasonable alternative label choices. Some entries are shortened.

Baseline 3: Word Vectors We can ignore the RAE tree structure and only train softmax layers directly on the pre-trained words in order to influence the word vectors. This is followed by an SVM trained on the average of the word vectors.

We also experimented with latent Dirichlet allocation (Blei et al., 2003) but performance was very low.

Table 3 shows the results for predicting the class with the most votes. Even the approach that is based on sentiment lexica and other resources is outperformed by our model by almost 3%, showing that for tasks involving complex broad-range human sentiment, the often used sentiment lexica lack in coverage and traditional bag-of-words representations are not powerful enough.

Method	Accuracy
Random	20.0
Most Frequent	38.1
Baseline 1: Binary BoW	46.4
Baseline 2: Features	47.0
Baseline 3: Word Vectors	45.5
RAE (our method)	**50.1**

Table 3: Accuracy of predicting the class with most votes.

4.3 EP: Predicting Sentiment Distributions

We now turn to evaluating our distribution-prediction approach. In both this and the previous maximum label task, we backprop using the gold multinomial distribution as a target. Since we maximize likelihood and because we want to predict a distribution that is closest to the distribution of labels that people would assign to a story, we evaluate using KL divergence: $KL(g||p) = \sum_i g_i \log(g_i/p_i)$, where g is the gold distribution and p is the predicted one. We report the average KL divergence, where a smaller value indicates better predictive power. To get an idea of the values of KL divergence, predict-

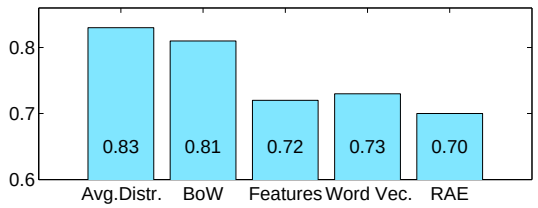

Figure 4: Average KL-divergence between gold and predicted sentiment distributions (lower is better).

ing random distributions gives a an average of 1.2 in KL divergence, predicting simply the average distribution in the training data give 0.83. Fig. 4 shows that our RAE-based model outperforms the other baselines. Table 2 shows EP example entries with predicted and gold distributions, as well as numbers of votes.

4.4 Binary Polarity Classification

In order to compare our approach to other methods we also show results on commonly used sentiment datasets: movie reviews[4] (MR) (Pang and Lee, 2005) and opinions[5] (MPQA) (Wiebe et al., 2005).We give statistical information on these and the EP corpus in Table 1.

We compare to the state-of-the-art system of (Nakagawa et al., 2010), a dependency tree based classification method that uses CRFs with hidden variables. We use the same training and testing regimen (10-fold cross validation) as well as their baselines: majority phrase voting using sentiment and reversal lexica; rule-based reversal using a dependency tree; Bag-of-Features and their full Tree-CRF model. As shown in Table 4, our algorithm outperforms their approach on both datasets. For the movie review (MR) data set, we do not use any hand-designed lexica. An error analysis on the MPQA dataset showed several cases of single words which never occurred in the training set. Correctly classifying these instances can only be the result of having them in the original sentiment lexicon. Hence, for the experiment on MPQA we added the same sentiment lexicon that (Nakagawa et al., 2010) used in their system to our training set. This improved accuracy from 86.0 to 86.4.Using the pre-trained word vectors boosts performance by less than 1% compared to randomly initialized word vectors (setting: random word init). This shows that our method can work well even in settings with little training data. We visualize the semantic vectors that the recursive autoencoder learns by listing n-grams that give the highest probability for each polarity. Table 5 shows such n-grams for different lengths when the RAE is trained on the movie review polarity dataset.

On a 4-core machine, training time for the smaller corpora such as the movie reviews takes around 3 hours and for the larger EP corpus around 12 hours until convergence. Testing of hundreds of movie reviews takes only a few seconds.

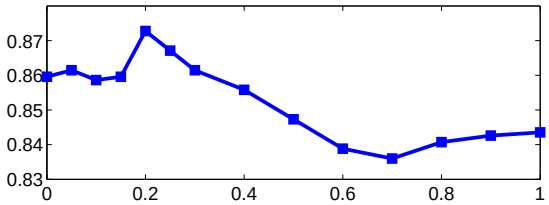

Figure 5: Accuracy on the development split of the MR polarity dataset for different weightings of reconstruction error and supervised cross-entropy error: $err = \alpha E_{rec} + (1-\alpha)E_{cE}$.

4.5 Reconstruction vs. Classification Error

In this experiment, we show how the hyperparameter α influences accuracy on the development set of one of the cross-validation splits of the MR dataset. This parameter essentially trade-off the supervised and unsupervised parts of the objective. Fig. 5 shows that a larger focus on the supervised objective is important but that a weight of $\alpha = 0.2$ for the reconstruction error prevents overfitting and achieves the highest performance.

5 Related Work

5.1 Autoencoders and Deep Learning

Autoencoders are neural networks that learn a reduced dimensional representation of fixed-size inputs such as image patches or bag-of-word representations of text documents. They can be used to efficiently learn feature encodings which are useful for classification. Recently, Mirowski et al. (2010) learn dynamic autoencoders for documents in a bag-of-words format which, like ours, combine supervised and reconstruction objectives.

The idea of applying an autoencoder in a recursive setting was introduced by Pollack (1990). Pollack's recursive auto-associative memories (RAAMs) are similar to ours in that they are a connectionst, feed-forward model. However, RAAMs learn vector representations only for fixed recursive data structures, whereas our RAE builds this recursive data structure. More recently, (Voegtlin and Dominey, 2005) introduced a linear modification to RAAMs that is able to better generalize to novel combinations of previously seen constituents. One of the major shortcomings of previous applications of recursive autoencoders to natural language sentences was their binary word representation as discussed in Sec. 2.1.

Recently, (Socher et al., 2010; Socher et al., 2011) introduced a max-margin framework based on recursive neural networks (RNNs) for labeled structure prediction. Their models are applicable to natural language and computer vision tasks such as parsing or object detection. The current work is related in that it uses a recursive deep learning model. However, RNNs require labeled tree structures and use a supervised score at each node. Instead, RAEs learn hierarchical structures that are trying to capture as much of the the original word vectors as possible. The learned structures are not necessarily syntactically plausible but can capture more of the semantic content of the word vectors. Other recent deep learning methods for sentiment analysis include (Maas et al., 2011).

5.2 Sentiment Analysis

Pang et al. (2002) were one of the first to experiment with sentiment classification. They show that simple bag-of-words approaches based on Naive Bayes, MaxEnt models or SVMs are often insufficient for predicting sentiment of documents even though they work well for general topic-based document classification. Even adding specific negation words, bigrams or part-of-speech information to these models did not add significant improvements. Other document-level sentiment work includes (Turney, 2002; Dave et al., 2003; Beineke et al., 2004; Pang and Lee, 2004). For further references, see (Pang and Lee, 2008).

Instead of document level sentiment classification, (Wilson et al., 2005) analyze the contextual polarity of phrases and incorporate many well designed features including dependency trees. They also show improvements by first distinguishing be-

tween neutral and polar sentences. Our model naturally incorporates the recursive interaction between context and polarity words in sentences in a unified framework while simultaneously learning the necessary features to make accurate predictions. Other approaches for sentence-level sentiment detection include (Yu and Hatzivassiloglou, 2003; Grefenstette et al., 2004; Ikeda et al., 2008).

Most previous work is centered around a given sentiment lexicon or building one via heuristics (Kim and Hovy, 2007; Esuli and Sebastiani, 2007), manual annotation (Das and Chen, 2001) or machine learning techniques (Turney, 2002). In contrast, we do not require an initial or constructed sentiment lexicon of positive and negative words. In fact, when training our approach on documents or sentences, it jointly learns such lexica for both single words and n-grams (see Table 5). (Mao and Lebanon, 2007) propose isotonic conditional random fields and differentiate between local, sentence-level and global, document-level sentiment.

The work of (Polanyi and Zaenen, 2006; Choi and Cardie, 2008) focuses on manually constructing several lexica and rules for both polar words and related content-word negators, such as "prevent cancer", where *prevent* reverses the negative polarity of *cancer*. Like our approach they capture compositional semantics. However, our model does so without manually constructing any rules or lexica.

Recently, (Velikovich et al., 2010) showed how to use a seed lexicon and a graph propagation framework to learn a larger sentiment lexicon that also includes polar multi-word phrases such as "once in a life time". While our method can also learn multi-word phrases it does not require a seed set or a large web graph. (Nakagawa et al., 2010) introduced an approach based on CRFs with hidden variables with very good performance. We compare to their state-of-the-art system. We outperform them on the standard corpora that we tested on without requiring external systems such as POS taggers, dependency parsers and sentiment lexica. Our approach jointly learns the necessary features and tree structure.

In multi-aspect rating (Snyder and Barzilay, 2007) one finds several distinct aspects such as food or service in a restaurant and then rates them on a fixed linear scale such as 1-5 stars, where all aspects could obtain just 1 star or all aspects could obtain 5 stars independently. In contrast, in our method a single aspect (a complex reaction to a human experience) is predicted not in terms of a fixed scale but in terms of a *multinomial distribution* over several interconnected, sometimes mutually exclusive emotions. A single story cannot simultaneously obtain a strong reaction in different emotional responses (by virtue of having to sum to one).

6 Conclusion

We presented a novel algorithm that can accurately predict sentence-level sentiment distributions. Without using any hand-engineered resources such as sentiment lexica, parsers or sentiment shifting rules, our model achieves state-of-the-art performance on commonly used sentiment datasets. Furthermore, we introduce a new dataset that contains distributions over a broad range of human emotions. Our evaluation shows that our model can more accurately predict these distributions than other models.

Abstract

Polarity classification of opinionated sentences with both positive and negative sentiments[1] is a key challenge in sentiment analysis. This paper presents a novel unsupervised method for discovering intra-sentence level discourse relations for eliminating polarity ambiguities. Firstly, a discourse scheme with discourse constraints on polarity was defined empirically based on Rhetorical Structure Theory (RST). Then, a small set of cue-phrase-based patterns were utilized to collect a large number of discourse instances which were later converted to semantic sequential representations (SSRs). Finally, an unsupervised method was adopted to generate, weigh and filter new SSRs without cue phrases for recognizing discourse relations. Experimental results showed that the proposed methods not only effectively recognized the defined discourse relations but also achieved significant improvement by integrating discourse information in sentence-level polarity classification.

1 Introduction

As an important task of sentiment analysis, polarity classification is critically affected by discourse structure (Polanyi and Zaenen, 2006). Previous research developed discourse schema (Asher et al., 2008) (Somasundaran et al., 2008) and proved that the utilization of discourse relations could improve the performance of polarity classification on dialogues (Somasundaran et al., 2009). However, current state-of-the-art methods for sentence-level polarity classification are facing difficulties in ascertaining the polarity of some sentences. For example:

(a) [Although Fujimori was criticized by the international community], [he was loved by the domestic population], [because people hated the corrupted ruling class]. (儘管國際間對藤森口誅筆伐，他在國內一直深受百姓愛戴，原因是百姓對腐化的統治階級早就深惡痛絕。)

Example (a) is a positive sentence holding a *Contrast* relation between first two segments and a *Cause* relation between last two segments. The polarity of "criticized", "hated" and "corrupted" are recognized as negative expressions while "loved" is recognized as a positive expression. Example (a) is difficult for existing polarity classification methods for two reasons: (1) the number of positive expressions is less than negative expressions; (2) the importance of each sentiment expression is unknown. However, consider Figure 1, if we know that the polarity of the first two segments holding a *Contrast* relation is determined by the *nucleus* (Mann and Thompson, 1988) segment and the polarity of the last two segments holding a *Cause* relation is also determined by the *nucleus* segment, the polarity of the sentence will be determined by the polarity of "[he...population]". Thus, the polarity of Example (a) is positive.

Statistics showed that 43% of the opinionated sentences in NTCIR[2] MOAT (Multilingual Opinion Analysis Task) Chinese corpus[3] are *ambiguous*. Existing sentence-level polarity classification methods ignoring discourse structure often give wrong results for these sentences. We implemented state-of-the-

art method (Xu and Kit, 2010) in NTCIR-8 Chinese MOAT as the baseline polarity classifier (BPC) in this paper. Error analysis of BPC showed that 49% errors came from *ambiguous* sentences.

In this paper, we focused on the automation of recognizing intra-sentence level discourse relations for polarity classification. Based on the previous work of Rhetorical Structure Theory (RST) (Mann and Thompson, 1988), a discourse scheme with discourse constraints on polarity was defined empirically (see Section 3). The scheme contains 5 relations: *Contrast*, *Condition*, *Continuation*, *Cause* and *Purpose*. From a raw corpus, a small set of cue-phrase-based patterns were used to collect discourse instances. These instances were then converted to semantic sequential representations (SSRs). Finally, an unsupervised SSR learner was adopted to generate, weigh and filter high quality new SSRs without cue phrases. Experimental results showed that the proposed methods could effectively recognize the defined discourse relations and achieve significant improvement in sentence-level polarity classification comparing to BPC.

The remainder of this paper is organized as follows. Section 2 introduces the related work. Section 3 presents the discourse scheme with discourse constraints on polarity. Section 4 gives the detail of proposed method. Experimental results are reported and discussed in Section 5 and Section 6 concludes this paper.

2 Related Work

Research on polarity classification were generally conducted on 4 levels: document-level (Pang et al., 2002), sentence-level (Riloff et al., 2003), phrase-level (Wilson et al., 2009) and feature-level (Hu and Liu, 2004; Xia et al., 2007).

There was little research focusing on the automatic recognition of intra-sentence level discourse relations for sentiment analysis in the literature. Polanyi and Zaenen (2006) argued that valence calculation is critically affected by discourse structure. Asher et al. (2008) proposed a shallow semantic representation using a feature structure and use five types of rhetorical relations to build a fine-grained corpus for deep contextual sentiment analysis. Nevertheless, they did not propose a computational model for their discourse scheme. Snyder and Barzilay (2007) combined an agreement model based on contrastive RST relations with a local aspect model to make a more informed overall decision for sentiment classification. Nonetheless, contrastive relations were only one type of discourse relations which may help polarity classification. Sadamitsu et al. (2008) modeled polarity reversal using HCRFs integrated with inter-sentence discourse structures. However, our work is on intra-sentence level and our purpose is not to find polarity reversals but trying to adapt general discourse schemes (e.g., RST) to help determine the overall polarity of *ambiguous* sentences.

The most closely related works were (Somasundaran et al., 2008) and (Somasundaran et al., 2009), which proposed *opinion frames* as a representation of discourse-level associations on dialogue and modeled the scheme to improve opinion polarity classification. However, *opinion frames* was difficult to be implemented because the recognition of opinion target was very challenging in general text. Our work differs from their approaches in two key aspects: (1) we distinguished *nucleus* and *satellite* in discourse but *opinion frames* did not; (2) our method for discourse discovery was unsupervised while their method needed annotated data.

Most research works about discourse classification were not related to sentiment analysis. Supervised discourse classification methods (Soricut and Marcu, 2003; Duverle and Prendinger, 2009) needed manually annotated data. Marcu and Echihabi (2002) presented an unsupervised method to recognize discourse relations held between arbitrary spans of text. They showed that lexical pairs extracted from massive amount of data can have a major impact on discourse classification. Blair-Goldensohn et al. (2007) extended Marcu's work by using parameter opitimization, topic segmentation and syntactic parsing. However, syntactic parsers

were usually costly and impractical when dealing with large scale of text. Thus, in additional to lexical features, we incorporated sequential and semantic information in proposed method for discourse relation classification. Moreover, our method kept the characteristic of language independent, so it could be applied to other languages.

3 Discourse Scheme for Eliminating Polarity Ambiguities

Since not all of the discourse relations in RST would help eliminate polarity ambiguities, the discourse scheme defined in this paper was on a much coarser level. In order to ascertain which relations should be included in our scheme, 500 *ambiguous* sentences were randomly chosen from NTCIR MOAT Chinese corpus and the most common discourse relations for connecting independent clauses in compound sentences were annotated. We found that 13 relations from RST occupied about 70% of the annotated discourse relations which may help eliminate polarity ambiguities. Inspired by Marcu and Echihabi (2002), to construct relatively low-noise discourse instances for unsupervised methods using cue phrases, we grouped the 13 relations into the following 5 relations:

Contrast is a union of *Antithesis*, *Concession*, *Otherwise* and *Contrast* from RST.

Condition is selected from RST.

Continuation is a union of *Continuation*, *Parallel* from RST.

Cause is a union of *Evidence*, *Volitional-Cause*, *Nonvolitional-Cause*, *Volitional-result* and *Nonvolitional-result* from RST.

Purpose is selected from RST.

The discourse constraints on polarity presented here were based on the observation of annotated discourse instances: (1) discourse instances holding *Contrast* relation should contain two segments with opposite polarities; (2) discourse instances holding *Continuation* relation should contain two segments with the same polarity; (3) the polarity of discourse instances holding *Contrast*, *Condition*, *Cause* or *Purpose* was determined by the *nucleus* segment; (4) the polarity of discourse instances holding *Continuation* was determined by either segment.

Relation	Cue Phrases (English Translation)
Contrast	although[1], but[2], however[2]
Condition	if[1], (if[1], then[2])
Continuation	and, further more, (not only, but also)
Cause	because[1], thus[2], accordingly[2], as a result[2]
Purpose	in order to[2], in order that[2], so that[2]

[1] means *CUE1* and [2] means *CUE2*

Table 1: Examples of cue phrases

4 Methods

The proposed methods were based on two assumptions: (1) Cue-phrase-based patterns could be used to find limited number of high quality discourse instances; (2) discourse relations were determined by lexical, structural and semantic information between two segments.

Cue-phrase-based patterns could find only limited number of discourse instances with high precision (Marcu and Echihabi, 2002). Therefore, we could not rely on cue-phrase-based patterns alone. Moreover, there was no annotated corpus similar to Penn Discourse TreeBank (Miltsakaki et al., 2004) in other languages such as Chinese. Thus, we proposed a language independent unsupervised method to identify discourse relations without cue phrases while maintaining relatively high precision. For each discourse relation, we started with several cue-phrase-based patterns and collected a large number of discourse instances from raw corpus. Then, discourse instances were converted to semantic sequential representations (SSRs). Finally, an unsupervised method was adopted to generate, weigh and filter common SSRs without cue phrases. The mined common SSRs could be directly used in our SSR-based classifier in unsupervised manner or be employed as effective features for supervised methods.

4.1 Gathering and representing discourse instances

A discourse instance, denoted by D_i, consists of two successive segments $(D_{i[1]}, D_{i[2]})$ within a sentence. For example:

D_1: [*Although Boris is very brilliant at math*]$_s$, [*he*

BOS... , *[CUE2]*...EOS
BOS *[CUE1]*... , ...EOS
BOS... , *[CUE1]*...EOS
BOS *[CUE1]*... , *[CUE2]*...EOS

Table 2: Cue-phrase-based patterns. BOS and EOS denoted the beginning and end of two segments.

is a horrible teacher]$_n$
D_2: [*John is good at basketball*]$_s$, [*but he lacks team spirit*]$_n$

In D_1, "although" indicated the *satellite* section while in D_2, "but" indicated the *nucleus* section. Accordingly, different cue phrases may indicate different segment type. Table 1 listed some examples of cue phrases for each discourse relation. Some cue phrases were singleton (e.g. "although" and "as a result") and some were used as a pair (e.g. "not only, but also"). "*CUE1*" indicated *satellite* segments and "*CUE2*" indicated *nucleus* segments. Note that we did not distinguish *satellite* from *nucleus* for *Continuation* in this paper because the polarity could be determined by either segment.

Table 2 listed cue-phrase-based patterns for all relations. To simplify the problem of discourse segmentation, we split compound sentences into discourse segments using commas and semicolons. Although we collected discourse instances from compound sentences only, the number of instances for each discourse relation was large enough for the proposed unsupervised method. Note that we only collected instances containing at least one sentiment word in each segment.

In order to incorporate lexical and semantic information in our method, we represented each word in a discourse instance using a part-of-speech tag, a semantic label and a sentiment tag. Then, all discourse instances were converted to SSRs. The rules for converting were as follows:

(1) Cue phrases and punctuations were ingored. But the information of *nucleus*(n) and *satellite*(s) was preserved.

(2) Adverbs(*RB*) appearing in sentiment lexicon, verbs(V), adjectives(*JJ*) and nouns(*NN*) were represented by their part-of-speech (pos) tag with semantic label ($semlabel$) if available.

(3) Named entities (*NE*; *PER*: person name; *ORG*: organization), pronouns (*PRP*), and function words were represented by their corresponding named entity tags and part-of-speech tags, respectively.

(4) Added sentiment tag (P: Positive; N: Negative) to all sentiment words.

By applying above rules, the SSRs for D_1 and D_2 would be:

d_1: [*PER V|Ja01 RB|Ka01 JJ|Ee14|P IN NN|Dk03*]$_s$, [*PRP V|Ja01 DT JJ|Ga16|N NN|Ae13*]$_n$
d_2: [*PER V|Ja01 JJ|Ee14|P IN NN|Bp12*]$_s$, [*PRP V|He15|N NN|Di10 NN|Dd08*]$_n$

Refer to d_1 and d_2, "Boris" could match "John" in SSRs because they were converted to "*PER*" and they all appeared at the beginning of discourse instances. "*Ja01*", "*Ee14*" etc. were semantic labels from Chinese synonym list extended version (Che et al., 2010). There were similar resources in other languages such as Wordnet(Fellbaum, 1998) in English. The next problem became how to start from current SSRs and generate new SSRs for recognizing discourse relations without cue phrases.

4.2 Mining common SSRs

Recall assumption (2), in order to incorporate lexical, structural and semantic information for the similarity calculation of two SSRs holding the same discourse relation, three types of matches were defined for $\{(u,v)|u \in d_{i[k]}, v \in d_{j[k]}, k = 1,2\}$: (1)Full match: (i) $u = v$ or (ii) $u.pos = v.pos$ and $u.semlabel = v.semlabel$ or (iii) $u.pos = v.pos$ and u had a sentiment tag and v had a sentiment tag or (iv) $u.pos$ and $v.pos \in$ {*PRP, PER, ORG*} (2) Partial match: $u.pos = v.pos$ but not Full match; (3) Mismatch: $u.pos \neq v.pos$.

Generating common SSRs

Intuitively, a simple way of estimating the similarity between two SSRs was using the number of mismatches. Therefore, we utilized $match(d_i, d_j)$ where $i \neq j$, which integrated the three types of matches defined above to calculate the number of mismatches and generate common SSRs. Consider Table 3, in common SSRs, full matches were preserved, partial matches were replaced by part of speech tags and mismatches were replaced by '*'s. The common SSRs generated during the calculation of $match(d_i, d_j)$ consisted of two parts. The first part was generated by $d_{i[1]}$ and $d_{j[1]}$ and the second part was generated by $d_{i[2]}$ and $d_{j[2]}$. We stipulated

d_1	d_2	mis	$conf$	ssr
PER	*PER*	0	0	*PER*
V|Ja01	*V|Ja01*	0	0	*V|Ja01*
RB|Ka01		+1	-0.298	*
JJ|Ee14|P	*JJ|Ee14|P*	0	0	*JJ|Ee14|P*
IN	*IN*	0	0	*IN*
NN|Dk03	*NN|Bp12*	0	-0.50	*NN*
$conf(ssr_{[1]}) = -0.798$				
PRP	*PRP*	0	0	*PRP*
V|Ja01	*V|He15|N*	0	-0.50	*V*
DT		+1	-0.184	*
JJ|Ga16|N		+1	-1.0	*
NN|Ae13	*NN|Di10*	0	-0.50	*NN*
	NN|Dd08	+1	-1.0	*
$conf(ssr_{[2]}) = -3.184$				

Table 3: Calculation of $match(d_1, d_2)$. ssr denoted the common SSR between d_1 and d_2 , $conf(ssr_{[1]})$ and $conf(ssr_{[2]})$ denoted the confidence of ssr.

that d_i and d_j could generate a common SSR if and only if the orders of *nucleus* segment and *satellite* segment were the same.

In order to guarantee relatively high quality common SSRs, we empirically set the upper threshold of the number of mismatches as 0.5 (i.e., $\leq 1/2$ of the number of words in the generated SSR). It's not difficult to figure out that the number of mismatches generated in Table 3 satisfied this requirement. As a result, for each discourse relation r_n, a corresponding common SSR set S_n could be obtained by adopting $match(d_i, d_j)$ where $i \neq j$ for all discourse instances. An advantage of $match(d_1, d_2)$ was that the generated common SSRs preserved the sequential structure of original discourse instances. And common SSRs allows us to build high precision discourse classifiers (See Section 5).

Weighing and filtering common SSRs

A problem of $match(d_i, d_j)$ was that it ignored some important information by treating different mismatches equally. For example, the adverb "very" in "very brilliant" of D_1 was not important for discourse recognition. In other words, the number of mismatches in $match(d_i, d_j)$ could not precisely reflect the confidence of the generated common SSRs. Therefore, it was needed to weigh different mismatches for the confidence calculation of common SSRs.

Intuitively, if a partial match or a mismatch (denoted by u_m) occurred very frequently in the generation of common SSRs, the importance of u_m tends to diminish. Inspired by the *tf-idf* model, given $ssr_i \in S_n$, we utilized the following equation to estimate the weight (denoted by w_m) of u_m.

$$w_m = -uf_m \cdot \log\left(|S_n| / ssrf_m\right)$$

where uf_m denoted the frequency of u_m during the generation of ssr_i, $|S_n|$ denoted the size of S_n and $ssrf_m$ denoted the number of common SSRs in S_n containing u_m . All weights were normalized to $[-1, 0)$.

Nouns (except for named entities) and verbs were most representative words in discourse recognition (Marcu and Echihabi, 2002). In addition, adjectives and adverbs appearing in sentiment lexicons were important for polarity classification. Therefore, for these 4 kinds of words, we utilized -1.0 for a mismatch and -0.50 for a partial match.

As we had got the weights for all partial matches and mismatches, the confidence of $ssr_i \in S_n$ could be calculated using the cumulation of weights of partial matches and mismatches in $ssr_{i[1]}$ and $ssr_{i[2]}$. Recall Table 3, $conf(ssr_{[1]})$ and $conf(ssr_{[2]})$ represented the confidence scores of $match(d_{i[1]}, d_{j[1]})$ and $match(d_{i[2]}, d_{j[2]})$, respectively. In order to control the quantity and quality of mined SSRs, a threshold $minconf$ was introduced. ssr_i will be preserved if and only if $conf(ssr_{i[1]}) \geq minconf$ and $conf(ssr_{i[2]}) \geq minconf$. The value of $minconf$ was tuned using the development data.

Finally, we combined adjacent '*'s and preserved SSRs containing at least one notional word and at least two words in each segment to meet the demand of maintaining high precision (e.g., "[* *DT* *]", "[*PER* *]" will be dropped). Moreover, since many of the SSRs were duplicated, we ranked all the generated SSRs according to their occurrences and dropped those appearing only once in order to preserve common SSRs. At last, SSRs appearing in more than one common SSR set were removed for maintaining the uniqueness of each set. The common SSR set S_n for each discourse relation r_n could be directly used in SSR-based unsupervised classifiers or be employed as effective features in supervised methods.

Relation	Occurrence
Contrast	86 (8.2%)
Condition	27 (2.6%)
Continuation	445 (42.2%)
Cause	123 (11.7%)
Purpose	55 (5.2%)
Others	318 (30.2%)

Table 4: Distribution of discourse relations on NTC-7. *Others* represents discourse relations not included in our discourse scheme.

5 Experiments

5.1 Annotation work and Data

We extracted all compound sentences which may contain the defined discourse relations from opinionated sentences (neutral ones were dropped) of NTCIR7 MOAT simplified Chinese training data. 1,225 discourse instances were extracted and two annotators were trained to annotate discourse relations according to the discourse scheme defined in Section 3. Note that we annotate both explicit and implicit discourse relations. The overall inter annotator agreement was 86.05% and the *Kappa-value* was 0.8031. Table 4 showed the distribution of annotated discourse relations based on the inter-annotator agreement. The proportion of occurrences of each discourse relations varied greatly. For example, *Continuation* was the most common relation in annotated corpus, but the occurrences of *Condition* relation were rare.

The experiments of this paper were performed using the following data sets:

NTC-7 contained manually annotated discourse instances (shown in Table 4). The experiments of discourse identification were performed on this data set.

NTC-8 contained all opinionated sentences (neutral ones were dropped) extracted from NTCIR8 MOAT simplified Chinese test data. The experiments of polarity ambiguity elimination using the identified discourse relations were performed on this data set.

XINHUA contained simplified Chinese raw news text from Xinhua.com (2002-2005). A word segmentation tool, a part-of-speech tagging tool, a named entity recognizer and a word sense disambiguation tool (Che et al., 2010) were adopted to all sentences. The common SSRs were mined from this data set.

5.2 Experimental Settings

Discourse relation identification

In order to systematically justify the effectiveness of proposed unsupervised method, following experiments were performed on NTC-7:

Baseline used only cue-phrase-based patterns.

M&E proposed by Marcu and Echihabi (2002). Given a discourse instance D_i, the probabilities: $P(r_k|(D_{i[1]}, D_{i[2]}))$ for each relation r_k were estimated on all text from XINHUA. Then, the most likely discourse relation was determined by taking the maximum over $argmax_k\{P(r_k|(D_{i[1]}, D_{i[2]})\}$.

cSSR used both cue-phrase-based patterns together with common SSRs for recognizing discourse relations. Common SSRs were mined from discourse instances extracted from XINHUA using cue-phrase-based patterns. Development data were randomly selected for tuning $minconf$.

SVM was trained utilizing cue phrases, probabilities from *M&E*, topic similarity, structure overlap, polarity of segments and mined common SSRs (Optional). The parameters of the SVM classifier were set by a grid search on the training set. We performed 4-fold cross validation on NTC-7 to get an average performance.

The purposes of introducing *SVM* in our experiment were: (1) to compare the performance of *cSSR* to supervised method; (2) to examine the effectiveness of integrating common SSRs as features for supervised methods.

Polarity ambiguity elimination

BPC was trained mainly utilizing punctuation, uni-gram, bi-gram features with confidence score output. Discourse classifiers such as *Baseline*, *cSSR* or *SVM* were adopted individually for the post-processing of BPC. Given an *ambiguous* sentence which contained more than one segment, an intuitive three-step method was adopted to integrated a discourse classifier and discourse constraints on polarity for the post-processing of BPC:

(1) Recognize all discourse relations together with *nucleus* and *satellite* information using a discourse classifier. The *nucleus* and *satellite* information is

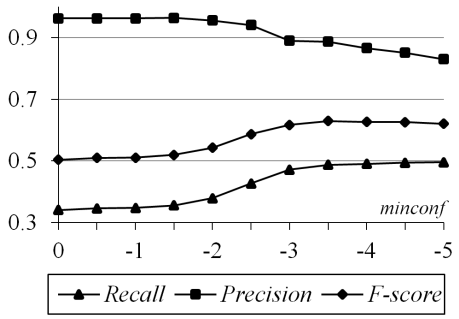

Figure 2: Influences of different values of $minconf$ to the performance of cSSR

acquired by cSSR if a segment pair could match a cSSR. Otherwise, we use the annotated *nucleus* and *satellite* information.

(2) Apply discourse constraints on polarity to ascertain the polarity for each discourse instance. There may be conflicts between polarities acquired by BPC and discourse constraints on polarity (e.g., Two segments with the same polarity holding a *Contrast* relation). To handle this problem, we chose the segment with higher polarity confidence and adjusted the polarity of the other segment using discourse constraints on polarity.

(3) If there was more than one discourse instance in a single sentence, the overall polarity of the sentence was determined by voting of polarities from each discourse instance under the majority rule.

5.3 Experimental Results

Refer to Figure 2, the performance of *cSSR* was significantly affected by $minconf$. Note that we performed the tuning process of $minconf$ on different development data ($1/4$ instances randomly selected from NTC-7) and Figure 2 showed the average performance. *cSSR* became *Baseline* when $minconf = 0$. A significant drop of precision was observed when $minconf$ was less than -2.5. The recall remained around 0.495 when $minconf \leq -4.0$. The best performance was observed when $minconf = -3.5$. As a result, -3.5 was utilized as the threshold value for *cSSR* in the following experiments.

Table 5 presented the experimental results for discourse relation classification. it showed that:

(1) Cue-phrase-based patterns could find only limited number of discourse relations (34.1% of average recall) with a very high precision (96.17% of average precision). This is a proof of assumption (1) given in Section 4. On the other side, *M&E* which only considered word pairs between two segments of discourse instances got a higher recall with a large drop of precision. The drop of precision may be caused by the neglect of structural and semantic information of discourse instances. However, *M&E* still outperformed *Baseline* in average $F\text{-}score$.

(2) *cSSR* enhanced *Baseline* by increasing the average recall by about 15% with only a small drop of precision. The performance of *cSSR* demonstrated that our method could effectively discover high quality common SSRs. The most remarkable improvement was observed on *Continuation* in which the recall increased by almost 20% with only a minor drop of precision. Actually, *cSSR* outperformed *Baseline* in all discourse relations except for *Contrast*. In Discourse Tree Bank (Carlson et al., 2001) only 26% of *Contrast* relations were indicated by cue phrases while in NTC-7 about 70% of *Contrast* were indicated by cue phrases. A possible reason was that we were dealing with Chinese news text which were usually well written. Another important observation was that the performance of *cSSR* was very close to the result of *SVM*.

(3) *SVM+SSRs* achieved the best $F\text{-}score$ on *Continuation* and average performance. The integration of SSRs to the feature set of *SVM* contributed to a remarkable increase in average $F\text{-}score$. The results of *cSSR* and *SVM+SSRs* demonstrated the effectiveness of common SSRs mined by the proposed unsupervised method.

Table 6 presented the performance of integrating discourse classifiers to polarity classification. For *Baseline* and *cSSR*, the information of *nucleus* and *satellite* could be obtained directly from cue-

phrase-based patterns and SSRs, respectively. For *SVM+cSSR*, the *nucleus* and *satellite* information was acquired by cSSR if a segment pair could match a cSSR. Otherwise, we used manually annotated *nucleus* and *satellite* information. It's clear that the performance of polarity classification was enhanced with the improvement of discourse relation recognition. *M&E* was not included in this experiment because the performance of polarity classification was decreased by the mis-classified discourse relations. *SVM+SSRs* achieved significant (p<0.01) improvement in polarity classification compared to BPC.

5.4 Discussion

Effect of weighing and filtering

To assess the contribution of weighing and filtering in mining SSRs using a minimum confidence threshold, i.e. $minconf$, we implemented *cSSR'* without weighing and filtering on the same data set. Consider Table 7, *cSSR* achieved obvious improvement in $Precision$ and $F\text{-}score$ than *cSSR'*. Moreover, the total number of SSRs was greatly reduced in *cSSR* with only a minor drop of recall. This was because *cSSR'* was affected by thousands of low quality common SSRs which would be filtered in *cSSR*. The result in Table 7 proved that weighing and filtering were essential in our proposed method.

	cSSR'	*cSSR*
Precision	0.6182	**0.8864**
Recall	**0.5014**	0.4878
F-score	0.5537	**0.6293**
NOS	$>$ 1 million	$\approx$ 0.12 million

Table 7: Comparison of *cSSR'* and *cSSR*. "NOS" denoted the number of mined common SSRs.

We further analyzed how the improvement was achieved in *cSSR*. In our experiment, the most common mismatches were auxiliary words, named entities, adjectives or adverbs without sentiments (e.g., "green", "very", etc.), prepositions, numbers and quantifiers. It's straightforward that these words were insignificant in discourse relation classification purpose. Moreover, these words did not belong to the 4 kinds of most representative words. In other words, the weights of most mismatches were calculated using the equation presented in Section 4.2 instead of utilizing a unified value, i.e. -1. Recall Table 3, the weight of "*RB|Ka01*" (original: "very") was -0.298 and "*DT*" (original: 'a') was -0.184. Comparing to the weights of mismatches for most representative words (-1.0), the proposed method successfully down weighed the words which were

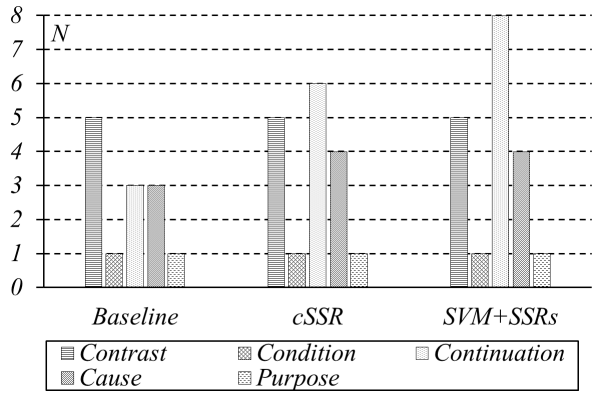

Figure 3: Improvement from individual discourse relations. N denoted the number of ambiguities eliminated.

not important for discourse identification. Therefore, weighing and filtering were able to preserve high quality SSRs while filter out low quality SSRs by setting the confidence threshold, i.e. $minconf$.

Contribution of different discourse relations

We also analyzed the contribution of different discourse relations in eliminating polarity ambiguities. Refer to Figure 3, the improvement of polarity classification mainly came from three discourse relations: *Contrast*, *Continuation* and *Cause*. It was straightforward that *Contrast* relation could eliminate polarity ambiguities because it held between two segments with opposite polarities. The contribution of *Cause* relation also result from two segments holding different polarities such as example (a) in Section 1. However, recall Table 4, although *Cause* occurred more often than *Contrast*, only a part of discourse instances holding *Cause* relation contained two segments with the opposite polarities. Another important relation in eliminating ambiguity was *Continuation*. We investigated sentences with polarities corrected by *Continuation* relation. Most of them fell into two categories: (1) sentences with mistakenly classified sentiments by BPC; (2) sentences with implicit sentiments. For example:

(b) [France and Germany have banned human cloning at present]，[on 20th, U.S. President George W. Bush called for regulations of the same content to Congress] (目前，法国和德国都禁止克隆人的胚胎，美国总统布什 20 日向国会提出，要求制定同样内容的法规。)

The first segment of example (b) was negative ("banned" expressed a negative sentiment) and a *Continuation* relation held between these two segments. Consequently, the polarity of the second segment should be negative.

6 Conclusions and Future work

This paper focused on unsupervised discovery of intra-sentence discourse relations for sentence level polarity classification. We firstly presented a discourse scheme based on empirical observations. Then, an unsupervised method was proposed starting from a small set of cue-phrase-based patterns to mine high quality common SSRs for each discourse relation. The performance of discourse classification was further improved by employing SSRs as features in supervised methods. Experimental results showed that our methods not only effectively recognized discourse relations but also achieved significant improvement ($p<0.01$) in sentence level polarity classification. Although we were dealing with Chinese text, the proposed unsupervised method could be easily generalized to other languages.

The future work will be focused on (1) integrating more semantic and syntactic information in proposed unsupervised method; (2) extending our method to inter-sentence level and then jointly modeling intra-sentence level and inter-sentence level discourse constraints on polarity to reach a global optimal inference for polarity classification.

Abstract

We present a general learning-based approach for phrase-level sentiment analysis that adopts an ordinal sentiment scale and is explicitly compositional in nature. Thus, we can model the compositional effects required for accurate assignment of phrase-level sentiment. For example, combining an adverb (e.g., "very") with a positive polar adjective (e.g., "good") produces a phrase ("very good") with increased polarity over the adjective alone. Inspired by recent work on distributional approaches to compositionality, we model each word as a matrix and combine words using iterated matrix multiplication, which allows for the modeling of both additive and multiplicative semantic effects. Although the multiplication-based matrix-space framework has been shown to be a theoretically elegant way to model composition (Rudolph and Giesbrecht, 2010), training such models has to be done carefully: the optimization is non-convex and requires a good initial starting point. This paper presents the first such algorithm for *learning* a matrix-space model for semantic composition. In the context of the phrase-level sentiment analysis task, our experimental results show statistically significant improvements in performance over a bag-of-words model.

1 Introduction

Sentiment analysis has been an active research area in recent years. Work in the area ranges from identifying the sentiment of individual words to determining the sentiment of phrases, sentences and documents (see Pang and Lee (2008) for a survey). The bulk of previous research, however, models just positive vs. negative sentiment, collapsing positive (or negative) words, phrases and documents of differing intensities into just one positive (or negative) class. For word-level sentiment, therefore, these methods would not recognize a difference in sentiment between words like "good" and "great", which have the same direction of polarity (i.e., positive) but different intensities. At the phrase level, the methods will fail to register compositional effects in sentiment brought about by intensifiers like "very", "absolutely", "extremely", etc. "Happy" and "very happy", for example, will both be considered simply "positive" in sentiment. In real-world settings, on the other hand, sentiment values extend across a polarity spectrum — from very negative, to neutral, to very positive. Recent research has shown, in particular, that modeling intensity at the phrase level is important for real-world natural language processing tasks including question answering and textual entailment (de Marneffe et al., 2010).

This paper describes a general approach for phrase-level sentiment analysis that takes these real-world requirements into account: *we adopt a five-level ordinal sentiment scale and present a learning-based method that assigns ordinal sentiment scores to phrases*.

Importantly, our approach will also be explicitly *compositional*[1] in nature so that it can accurately account for critical interactions among the words in

[1]The *Principle of Compositionality* asserts that the meaning of a complex expression is a function of the meanings of its constituent expressions and the rules used to combine them.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 172–182,
Edinburgh, Scotland, UK, July 27–31, 2011.

each sentiment-bearing phrase. Consider, for example, combining an adverb like "very" with a polar adjective like "good". "Good" has an *a priori* positive sentiment, so "very good" should be considered **more** positive even though "very", on its own, does not bear sentiment. Combining "very" with a negative adjective, like "bad", produces a phrase ("very bad") that should be characterized as more negative than the original adjective. Thus, it is convenient to think of the effect of combining an intensifying adverb with a polar adjective as being *multiplicative* in nature, if we assume the adjectives ("good" and "bad") to have positive and a negative sentiment scores, respectively.

Next, let us consider adverbial negators like "not" combined with polar adjectives. When modeling only positive and negative labels for sentiment, negators are generally treated as flipping the polarity of the adjective it modifies (Choi and Cardie, 2008; Nakagawa et al., 2010). However, recent work (Taboada et al., 2011; Liu and Seneff, 2009) suggests that the effect of the negator when ordinal sentiment scores are employed is more akin to dampening the adjective's polarity rather than flipping it. For example, if "perfect" has a strong positive sentiment, then the phrase "not perfect" is still positive, though to a lesser degree. And while "not terrible" is still negative, it is less negative than "terrible". For these cases, it is convenient to view "not" as shifting polarity to the opposite side of polarity scale by some value.

There are, of course, more interesting examples of compositional semantic effects on sentiment: e.g., *prevent cancer*, *ease the burden*. Here, the verbs *prevent* and *ease* act as content-word negators (Choi and Cardie, 2008) in that they modify the negative sentiment of their direct object arguments so that the phrase as a whole is perceived as somewhat positive.

Nonetheless, the vast majority of methods for phrase- and sentence-level sentiment analysis do not tackle the task compositionally: they, instead, employ a bag-of-words representation and, at best, incorporate additional features to account for negators, intensifiers, and for contextual valence shifters, which can change the sentiment over neighboring words (e.g., Polanyi and Zaenen (2004), Wilson et al. (2005) , Kennedy and Inkpen (2006), Shaikh et al. (2007)).

One notable exception is Moilanen and Pulman (2007), who propose a compositional semantic approach to assign a positive or negative sentiment to newspaper article titles. However, their knowledge-based approach presupposes the existence of a sentiment lexicon and a set of symbolic compositional rules.

But learning-based compositional approaches for sentiment analyis also exist. Choi and Cardie (2008), for example, propose an algorithm for phrase-based sentiment analysis that learns proper assignments of intermediate sentiment analysis decision variables given the *a priori* (i.e., out of context) polarity of the words in the phrase and the (correct) phrase-level polarity. As in Moilianen and Pulman (2007), semantic inference is based on (a small set of) hand-written compositional rules. In contrast, Nakagawa et. al (2010) use a dependency parse tree to guide the learning of compositional effects. Each of the above, however, uses a binary rather than an ordinal sentiment scale.

In contrast, our proposed method for phrase-level sentiment analysis is inspired by recent work on distributional approaches to compositionality. In particular, Baroni and Zamparelli (2010) tackle adjective-noun compositions using a vector representation for nouns and *learning* a matrix representation for each adjective. The adjective matrices are then applied as functions over the meanings of nouns — via matrix-vector multiplication — to derive the meaning of adjective-noun combinations. Rudolph and Giesbrecht (2010) show theoretically, that multiplicative matrix-space models are a general case of vector-space models and furthermore exhibit desirable properties for semantic analysis: they take into account word order and are algebraically, neurologically and psychologically plausible. This work, however, does not present an algorithm for learning such models; nor does it provide empirical evidence in favor of matrix-space models over vector-space models.

In the sections below, we propose a *learning-based* approach to assign *ordinal sentiment scores* to sentiment-bearing phrases using a general *compositional matrix-space model of language*. In contrast to previous work, all words are modeled as matrices, independent of their part-of-speech, and compositional inference is uniformly modeled as ma-

trix multiplication. To predict an ordinal scale sentiment value, we employ Ordered Logistic Regression, introducing a novel training algorithm to accommodate our compositional matrix-space representations (Section 2). To our knowledge, this is the first such algorithm for learning matrix-space models for semantic composition. We evaluate the approach on a standard sentiment corpus (Wiebe et al., 2005) (Section 3), making use of its manually annotated phrase-level annotations for polarity and intensity, and compare our approach to the more commonly employed bag-of-words model. We show (Section 4) that our matrix-space model significantly outperforms a bag-of-words model for the ordinal scale sentiment prediction task.

2 The Model for Ordinal Scale Sentiment Prediction

As described above, our task is to predict an ordinal scale sentiment value for a phrase. To this end, we employ a sentiment scale with five ordinal values: VERY NEGATIVE, NEGATIVE, NEUTRAL, POSITIVE and VERY POSITIVE. Given a set of phrase-level training examples with their gold-standard ordinal sentiment value, we then use an Ordered Logistic Regression (OLogReg) model for prediction. Unfortunately, our matrix-space representation precludes doing this directly.

We have chosen OLogReg, as opposed to say PRanking (Crammer and Singer, 2001), because optimization of the former is more attractive: the objective (likelihood) is smooth and the gradients are continuous. As will become clear shortly, learning our models is not trivial and it is important to use sophisticated off-the-shelf optimizers such as L-BFGS.

For a bag-of-words model, OLogReg learns one weight for each word and a set of thresholds by maximizing the likelihood of the training data. Typically, this is accomplished by using an optimizer like L-BFGS whose interface needs the value and gradient of the likelihood with respect to the parameters at their current values. In the next subsections, we instantiate OLogReg for our sentiment prediction task using a matrix-space word model (2.1 and 2.2) and a bag-of-words model (2.3). The learning formulation of bag-of-words OLogReg is convex therefore we will get the global optimum; in contrast, the optimization problem for matrix-space model is non-convex, it is important to initialize the model well. Initialization of the matrix-space model is discussed in Section 2.4.

2.1 Notation

In the subsequent subsections we will use the following notation. Let n be the number of phrases in the training set and let d be the number of words in the dictionary. Let x^i be the i-th phrase and y^i would be the label of x^i, where y^i takes r different values $y^i \in \{0, \ldots, r-1\}$. Then $|x^i|$ will denote the length of the phrase x^i, and the words in i-th phrase are: $x^i = x^i_1, x^i_2, \ldots, x^i_{|x^i|}$; $x^i_j, 1 \leq j \leq |x^i|$ is the j-th word of i-th phrase; where x^i_j is from the dictionary: $1 \leq x^i_j \leq d$.

In the case of the bag-of-words model, $\Phi(x^i) \in \mathbb{R}^d$ is the representation of the i-th phrase. $\Phi_j(x^i)$ counts the number of times the j-th word from the dictionary appears in the i-th phrase. Given a $w \in \mathbb{R}^d$ it assigns a score ξ_i to a phrase x^i by

$$\xi_i = w^T \Phi(x^i) = \sum_{j=1}^{|x^i|} w_{x^i_j} \tag{1}$$

In the case of the matrix-space model the $\Phi(x^i) \in \mathbb{R}^{|x^i| \times d}$ is the representation of the i-th phrase. $\Phi_{jk}(x^i)$ is 1, if x^i_j is the k-th word in the dictionary, and zero otherwise. Given $u, v \in \mathbb{R}^m$ and a set of matrices $\{W_p \in \mathbb{R}^{m \times m}\}_{p=1}^d$, one for each word, it assigns a score ξ_i to a phrase x^i by

$$\begin{aligned} \xi_i &= u^T \left(\prod_{j=1}^{|x^i|} \sum_{k=1}^{d} W_k \Phi_{jk}(x^i) \right) v \\ &= u^T \left(\prod_{j=1}^{|x^i|} W_{x^i_j} \right) v \end{aligned} \tag{2}$$

where $\prod_{j=1}^{|x^i|} W_{x^i_j} = W_{x^i_1} W_{x^i_2} \cdots W_{x^i_{|x^i|}}$ in **exactly this order**. We choose to map matrices to the real numbers by using vectors u and v from $\mathbb{R}^{m \times 1}$; so that $\xi = u^T M v$, where $M \in \mathbb{R}^{m \times m}$, which is sensitive to the order of matrices[2] , i.e. $u^T M_1 M_2 v \neq$

[2]Care must be taken in choosing way to map matrix to a real

$u^T M_2 M_1 v$.

Modeling composition. A $m \times m$ matrix, representing a word, can be considered as a linear function, mapping from $\mathbb{R}^m$ to $\mathbb{R}^m$. Composition of words is modeled by function composition, in our case composition of linear functions, i.e. matrix multiplication. Note, that unlike bag-of-words model, the matrix-space model takes word order into account, since matrix multiplication is not commutative operation.

2.2 Ordered Logistic Regression

Now we will describe our objective function for OLogReg and its derivatives. OLogReg has $r-1$ thresholds ($\kappa_0, \dots \kappa_{r-2}$), so introducing $\kappa_{-1} = -\infty$ and $\kappa_{r-1} = \infty$ leads to the unified expression for posterior probabilities for all values of k:

$$\begin{aligned} P(y^i = k|x) &= P(\kappa_{k-1} < \xi_i \leq \kappa_k) \\ &= F(\kappa_k - \xi_i) - F(\kappa_{k-1} - \xi_i) \end{aligned}$$

$F(x)$ is an inverse-logit function

$$F(x) = \frac{e^x}{1+e^x}$$

this is its derivative:

$$\frac{dF(x)}{dx} = F(x)(1 - F(x))$$

Therefore the negative loglikelihood of the training data will look like the following (Hardin and Hilbe, 2007):

$$L = -\sum_{i=1}^{n}\sum_{k=0}^{r-1} \ln(F(\kappa_k - \xi_i) - F(\kappa_{k-1} - \xi_i))I(y^i = k)$$

where r is the number of ordinal classes, ξ_i is the score of i-th phrase, I is the indicator function that is equal to 1 – when $y^i = k$, and zero otherwise. We need to minimize the objective L with respect to the following constraints:

$$\kappa_{k-1} \leq \kappa_k, \;\; 1 \leq k \leq r-2 \tag{3}$$

number. For example, one other way to map matrices to the real numbers is to use the determinant of a matrix; however, the determinant is not sensitive to the word order: $det(M_1 M_2) = det(M_1)det(M_2) = det(M_2 M_1)$; which is not desirable for a model that needs to account for word order.

(The constraints are similar to the ones in PRank algorithm). For ease of optimization we parametrize our model via κ_0, and $\tau_j, 1 \leq j \leq r-2$:

$\kappa_{-1} = -\infty$,
κ_0,
$\kappa_1 = \kappa_0 + \tau_1$,
$\kappa_2 = \kappa_0 + \sum_{j=1}^{2} \tau_j$,
$\dots$,
$\kappa_{r-2} = \kappa_0 + \sum_{j=1}^{r-2} \tau_j$
$\kappa_{r-1} = \infty$,

where $\tau_1, \dots, \tau_{r-2}$ are non-negative values, that represent how far the corresponding thresholds are from each other. Then the constraints (3) would be:

$$\tau_j \geq 0, \;\; 1 \leq j \leq r-2 \tag{4}$$

To simplify the equations we can rewrite the negative loglikelihood as follows:

$$L = -\sum_{i=1}^{n}\sum_{k=0}^{r-1} \ln(A_{ik} - B_{ik})I(y^i = k) \tag{5}$$

where

$$A_{ik} = \begin{cases} F(\kappa_0 + \sum_{j=1}^{k} \tau_j - \xi_i), & \text{if } k = 0, \dots, r-2 \\ 1, & \text{if } k = r-1 \end{cases}$$

$$B_{ik} = \begin{cases} 0, & \text{if } k = 0 \\ F(\kappa_0 + \sum_{j=1}^{k-1} \tau_j - \xi_i), & \text{if } k = 1, \dots, r-1 \end{cases}$$

Let's introduce $L_{ik} = -\ln(A_{ik} - B_{ik})I(y^i = k)$ and then the derivative of L_{ik} with respect to κ_0 will be:

$$\begin{aligned} \frac{\partial L_{ik}}{\partial \kappa_0} &= \frac{-[A_{ik}(1-A_{ik}) - B_{ik}(1-B_{ik})]}{A_{ik} - B_{ik}} I(y^i = k) \\ &= (A_{ik} + B_{ik} - 1)I(y^i = k) \end{aligned}$$

For $j = y^i$:

$$\frac{\partial L_{ik}}{\partial \tau_j} = \frac{-A_{ik}(1-A_{ik})}{A_{ik} - B_{ik}} I(y^i = k)$$

For all $j < y^i$:

$$\frac{\partial L_{ik}}{\partial \tau_j} = (A_{ik} + B_{ik} - 1)I(y^i = k)$$

For all $j > y^i$: $\frac{\partial L_{ik}}{\partial \tau_j} = 0$.

The derivative with respect to the score ξ_i is:

$$\frac{\partial L_{ik}}{\partial \xi_i} = (-A_{ik} - B_{ik} + 1)I(y^i = k) \tag{6}$$

2.2.1 Matrix-Space Word Model

Here we show the derivatives with respect to a word. For the OLogReg model with matrix-space word representations, we have:

$$\frac{\partial L}{\partial W_{x_j^i}} = \frac{\partial L}{\partial \xi_i} \cdot \frac{\partial \xi_i}{\partial W_{x_j^i}}$$

The expression for $\frac{\partial L}{\partial \xi_i}$ is given in (6); we will derive $\frac{\partial \xi_i}{\partial W_{x_j^i}}$ from (2). In the case of the Matrix-Space word model each word is represented as an $m \times m$ affine matrix W:

$$W = \begin{pmatrix} A & b \\ 0 & 1 \end{pmatrix} \tag{7}$$

We choose the class of **affine matrices** since for affine matrices matrix multiplication represents both operations: linear transformation and translation. Linear transformation is important for modeling changes in sentiment - translation is also useful (we make use of a translation vector during initialization, see Section 2.4). In this work we consider $m \geq 3$ since we want the matrix A from (7) to represent rotation and scaling. Applying the affine transformation W to vector $[x, 1]^T$ is equivalent to applying linear transformation A and translation b to x. [3]

Though vectors u and v can be learned together with word matrices W_j, **we choose to fix u and v.** The main intuition behind fixing u and v is *to reduce the degrees of freedom of the model*: different assignments of u, v and W_j-s can lead to the same score ξ, i.e. there exist $\hat{u}$ $\hat{v}$ and $\hat{W}_j$-s different from u, v and W_j-s respectively, such that $\xi(u, v, W)$ would be equal to $\xi(\hat{u}, \hat{v}, \hat{W})$. [4]

[3]
$$\begin{pmatrix} A & b \\ 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ 1 \end{pmatrix} = \begin{pmatrix} Ax + b \\ 1 \end{pmatrix}$$
where A is a linear transformation, b is a translation vector. Also the product of affine matrices is an affine matrix.

[4] The specific choice of u and v leads to an equivalent model for all $\hat{u}$ and $\hat{v}$ such that $\hat{u} = M^T u$, $\hat{v} = M^{-1} v$, where M is any invertible transformation (i.e. $\hat{u}, \hat{v}$ are derived from u,v by applying linear transformations M^T, M^{-1} respectively):

$$\begin{aligned} u^T W_1 W_2 v &= (u^T M)(M^{-1} W_1 M)(M^{-1} W_2 M)(M^{-1} v) \\ &= \hat{u}^T \hat{W}_1 \hat{W}_2 \hat{v} \end{aligned}$$

The derivative of the phrase ξ_i with respect to j-th word W_j would be (for brevity we drop the phrase index and W_j refers to $W_{x_j^i}$ and p refers to $|x_i|$):

$$\begin{aligned} \frac{\partial \xi_i}{\partial W_j} &= \left(\frac{\partial u^T W_1 W_2 \dots W_p v}{\partial W_j} \right) \\ &= \left[(u^T W_1 \dots W_{j-1})^T (W_{j+1} \dots W_p v)^T \right] \\ &= \left[(W_{j-1}^T \dots W_1^T)(u v^T)(W_p^T \dots W_{j+1}^T) \right] \end{aligned}$$

(see Peterson and Pederson(2008)).
In case if a certain word appears multiple times in the phrase, the derivative with respect to that word would be a sum of derivatives with respect to each appearance of a word, while all other appearances are fixed. For example,

$$\left(\frac{\partial u^T W W_1 W v}{\partial W} \right) = u(W_1 W v)^T + (u^T W W_1)^T v^T$$

where W is a representation of a word that is repeated.

So given the expression (6) for $\frac{\partial L}{\partial \xi_i}$, the derivative with respect to each word can be computed. Notice that the update for the j-th word in a sentence depends on the order words, which is in line with our desire to account for word order.

2.2.2 Optimization

The goal of training procedure is for the i-th phrase with p words $x_1 x_2 \dots x_p$ to learn word matrices W_1, W_2, ..., W_p such that resulting ξ_i-s will lead to the lowest negative loglikelihood. The goal of training procedure is to find word matrices W_1, W_2, ... W_p and thresholds κ_0, τ_1, ... τ_{r-2} such that the negative loglikelihood is minimized. So, given the negative loglikelihood and the derivatives with respect κ_0 and τ_j-s and word matrices W, we optimize objective (5) subject to $\tau_j \geq 0$. We use L-BFGS-B (Large-scale Bound-constrained Optimization) by Byrd et al. (1995) as an optimizer.

2.2.3 Regularization in Matrix-Space Model

In order to make sure that the L-BFGS-B updates do not cause numerical issues we perform the following regularization to the resulting matrices. An m by m matrix W_j that can be represented as:

$$W_j = \begin{pmatrix} A_{11} & a_{12} \\ a_{21}^T & a_{22} \end{pmatrix}$$

where $A_{11} \in \mathbb{R}^{m-1 \times m-1}$, $a_{12}, a_{21} \in \mathbb{R}^{m-1 \times 1}$, $a_{22} \in \mathbb{R}$. First make the matrix affine by updating the last row, then the updated matrix will look like:

$$\hat{W}_j = \begin{pmatrix} A_{11} & a_{12} \\ 0 & 1 \end{pmatrix}$$

It can be proven that such a projection returns the closest affine matrix in Frobenius norm.

However, we also want to regularize the model to avoid ill-conditioned matrices. Ill-conditioned matrices represent transformations whose output is very sensitive to small changes in the input and therefore they have a similar effect to having large weights in a bag-of-words model. To perform such a regularization we "shrink" the singular values of A_{11} towards one. More specifically, we first use the Singular Value Decomposition (SVD) of the A_{11}: $U\Sigma V^T = A_{11}$, where U and V are orthogonal matrices, Σ is a matrix with singular values on the diagonal. Then we update singular values in the following way to get $\tilde{\Sigma}$: $\tilde{\Sigma}_{ii} = \Sigma_{ii}^h$, where h is a parameter between 0 and 1. If $h = 1$ then Σ_{ii} remains the same. In the extreme case $h = 0$ then $\Sigma_{ii}^h = 1$. For intermediate values of h the singular values of A_{11} would be brought closer to one. Finally, we recompute $\tilde{A}_{11}$: $\tilde{A}_{11} = U\tilde{\Sigma}V^T$. So, W_j would be :

$$\tilde{W}_j = \begin{pmatrix} \tilde{A}_{11} & a_{12} \\ 0 & 1 \end{pmatrix}$$

2.2.4 Learning in the Matrix-Space Model

We use Algorithm 1 to learn the matrix-space model. What essentially happens is that we iterate two steps: optimizing the W matrices using L-BFGS-B and the projection step. L-BFGS-B returns a solution that is not necessarily an affine matrix. After projecting to the space of affine matrices we start L-BFGS-B from a better initial point. In practice, the first few iterations lead to large decrease in negative loglikelihood.

2.3 Bag-Of-Words Model

In the bag-of-words model the score of the i-th phrase is given in (1). Therefore, the partial derivative with respect to j-th word in i-th phrase $\frac{\partial \xi_i}{\partial w_{x_j^i}}$ is equal to the number c_j of times x_i^j appears in x^i, so:

$$\frac{\partial L}{\partial w_{x_j^i}} = \frac{\partial L}{\partial \xi_i} \cdot c_j$$

Algorithm 1 Training Algorithm for Matrix-Space OLogReg

```
Input: {(x_1, y_1), ..., (x_n, y_n)} //training data
Input: h //projection parameter
Input: T //number of iterations
Input: W, κ_0 and τ_j //initial values
for t = 1, ..., T do
    (W, κ_0, τ_j)=minimize L using L-BFGS-B
    for i = 1, ..., d do
        W_i=Project(W_i, h)
    end for
end for
Return W, κ_0, τ_j
```

Optimization. We minimize negative loglikelihood using L-BFGS-B subject to $\tau_j \geq 0$.

Regularization. To prevent overfitting for bag-of-words model we regularize w. The L_2-regularized negative loglikelihood will consist of the expression in (5) and an additional term $\frac{\lambda}{2}||w||_2^2$, where $||\cdot||_2$ is the L_2-norm of a vector. The derivative of the additional term with respect to w will be:

$$\frac{\partial \frac{\lambda}{2}||w||_2^2}{\partial w} = \lambda w$$

Hence the partial derivative with respect to $w_{x_j^i}$ will have an additional term $\lambda w_{x_j^i}$.

2.4 Initialization

Initialization of bag-of-words OLogReg. We initialize the weight for each word with zero and κ_0 with a random number and τ_j-s with non-negative random numbers. Since the learning problem for bag-of-words OLogReg is convex, we will get the global optimum.

Better Initialization of Matrix-Space Model. Preliminary experiments showed that the Matrix-Space model needs a good initialization. Initializing with different random matrices reaches different local minima and the quality of local minima depends on initialization. Therefore, it is important to initialize the model with a good initial point. *One way to initialize the Matrix-Space model is to use the weights learned by the bag-of-words model.* We use the following intuition for initializing the Matrix-Space model. As noted in Section 2.2.1 applying transformation A of affine matrix W can model a linear

transformation, while vector b represents a translation. Since matrix-space model can encode a vector-space model (Rudolph and Giesbrecht, 2010), we can initialize the matrices to exactly mimic the bag-of-words model. In order to do that we place the weight, learned by the bag-of-words model in the first component of b. Let's assume that w_{x_1} and w_{x_2} are the weights learned for two distinct words x_1 and x_2 respectively. To compute the polarity score of a phrase x_1, x_2 the bag-of-words model sums the weights of these two words: w_{x_1} and w_{x_2}. Now we want to have the same effect in matrix-space model. Here we assume $m = 3$.

$$Z = \begin{pmatrix} 1 & 0 & w_{x_1} \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & w_{x_2} \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

$$= \begin{pmatrix} 1 & 0 & w_{x_1} + w_{x_2} \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

Finally, there is a step of mapping matrix Z to a number using u and v, such that $\xi(Z) = w_{x_1} + w_{x_2}$.We also want vector u and v to be such that:

$$u^T \begin{pmatrix} 1 & 0 & w_{x_1} + w_{x_2} \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} v = w_{x_1} + w_{x_2} \quad (8)$$

The last equation can help us construct u and v. We also set u and v to be orthogonal: $u^T v = 0$. So, we arbitrarily choose two orthogonal vectors for which equation (8) holds: $u = [1, \sqrt{2}, 1]^T$ and $v = [1, -\sqrt{2}, 1]^T$.[5]

3 Experimental Methodology

For experimental evaluation of the proposed method we use the publicly available Multi-Perspective Question Answering (MPQA)[6] corpus (Wiebe et al., 2005) version 1.2, which contains 535 newswire documents that are manually annotated with phrase-level subjectivity and intensity. We use the expression-level boundary markings in MPQA to extract phrases. We evaluate on positive, negative and neutral opinion expressions that have intensities "medium", "high" or "extreme".[7] The schematic mapping of phrase polarity and intensity values on ordinal sentimental scale is shown in Table 1.

Polarity	Intensity	Ordinal label
negative	high, extreme	0
negative	medium	1
neutral	high, extreme, medium	2
positive	medium	3
positive	high, extreme	4

Table 1: Mapping of combination of polarities and intensities from MPQA dataset to our ordinal sentiment scale.

3.1 Training Details

We perform 10-fold cross-validation on phrases extracted from the MPQA corpus: eight folds for training; one as a validation set; and one as test set. In total there were 8022 phrases. Before training, we extract lemmas for each word. For evaluation we use Ranking Loss: $\frac{1}{n}\sum_i |\hat{y}^i - y^i|$, where $\hat{y^i}$ is the prediction.

Choice of dimensionality m. The reported experiments are done by setting $m = 3$. Preliminary experiments with higher values of m (5, 20, 50), did not lead to a better performance and increased the training time; therefore we did not use those values in our final experiments.

3.2 Methods

PRank. For each of the folds, we run 500 iterations of PRank and choose an early stopping iteration using a model that led to the lowest ranking loss on the validation set; afterwards report the average performance of on a test set.

Bag-of-words OLogReg. To prevent overfitting we search for the best regularization parameter among the following values of λ: 10^i, from 10^{-4} to 10^4. The lowest negative log-likelihood value on the validation set is attained for[8] $\lambda = 0.1$. With this value of λ fixed, the final model is the one with the lowest negative loglikelihood on the training set.

[5] If $m > 3$, u and v can be set using the same intuition.

[6] http://www.cs.pitt.edu/mpqa/

[7] We ignored low-intensity phrases similar to (Choi and Cardie, 2008; Nakagawa et al., 2010).

[8] We pick single λ that gives best average validation set performance, and then use it to compute the average test set performance.

Method	Ranking loss
PRank	0.7808
Bag-of-words OLogReg	0.6665
Matrix-space OLogReg+RandInit	0.7417
Matrix-space OLogReg+BowInit	0.6375†

Table 2: Ranking loss for vector-space Ordered Logistic Regression and Matrix-Space Logistic Regression.
† Stands for a significant difference w.r.t. the Bag-Of-Words OLogReg model with p-value less than 0.001 ($p < 0.001$)

Matrix-space OLogReg+RandInit. First, we initialized matrices with with random numbers from normal distribution $N(0, 0.1)$ and set u and v as in section 2.4, T is set to 25. We run with two different random seeds and three different values for the parameter h: [0.1, 0.5, 0.9] and report the performance of the model that had the lowest likelihood on the validation set. The setting of h that lead to the best model was 0.9.

Matrix-space OLogReg+BowInit. For the matrix-space models we initialize the model with the output of the regularized Bag-of-words OLogReg as described in Section 2.4, T is set to 25. Then we use the training procedure of Algorithm 1. We consider three different values for the parameter h [0.1, 0.5, 0.9] and choose as the model with the lowest validation set negative log-likelihood. The best setting of h was 0.1.

4 Results and Discussion

We report Ranking Loss for the four models in Table 2. The worst performance (denoted by the highest ranking loss value) is obtained by PRank, followed by matrix-space OLogReg with random initialization. Bag-of-words OLogReg obtains quite good performance, and matrix-space OLogReg, initialized using the bag-of-words model performs the best, showing statistically significant improvements over the bag-of-words OLogReg model according to a paired t-test. .

To see what the bag-of-word and matrix-space models are learning we performed inference on a few examples. In Table 3 we show the sentiment scores of the best performing bag-of-words **OLogReg** model and the best performing model based on matrices **Matrix-space OLogReg+BowInit**. By sentiment score, we mean equation (1) of Bag-of-words OLogReg and equation (2) of Matrix-space OLogReg+BowInit.

Phrase	Matrix-space OLogReg+BowInit	Bag-of-words OLogReg
not	-0.83	-0.42
very	0.23	0.04
good	2.81	1.51
very good	3.53	1.55
not good	-0.16	1.09
not very good	0.66	1.13
bad	-1.67	-1.42
very bad	-2.01	-1.38
not bad	-0.54	-1.85
not very bad	-1.36	-1.80

Table 3: Phrase and the sentiment scores of the phrase for 2 models Matrix-space OLogReg+BowInit and Bag-of-words OLogReg respectively. Notice that **relative ranking order what matters**

Here we choose two popular adjectives like 'good' and 'bad' that appeared in the training data, and examine the effect of applying the intensifier 'very' on the sentiment score. As we can see, the matrix-space model learns a matrix that intensifies both 'bad' and 'good' in the correct sentiment scale, i.e., $\xi(good) < \xi(very\ good)$ and $\xi(bad) < \xi(very\ bad)$, while the bag-of-words model gets the sentiment of 'very bad' wrong: it is more positive than 'bad'. We also looked at the effect of combining 'not' with these adjectives. The matrix-space model correctly encodes the effect of the negator for both positive and negative adjectives, such that $\xi(not\ good) < \xi(good)$ and $\xi(bad) < \xi(not\ bad)$. For the interesting case of applying a negator to a phrase with an intensifier, $\xi(not\ good)$ should be less than $\xi(not\ very\ good)$ and $\xi(not\ very\ bad)$ should be less than $\xi(not\ bad)$.[9] As shown in Table 3, these are predicted correctly by the matrix-space model, which the matrix-space model gets right, but the bag-of-words model misses in the case of "bad".

Also notice that since in the matrix-space model

[9] See the detailed discussion in Taboada et al. (2011) and Liu and Seneff (2009).

each word is represented as a function, more specifically a linear operator, and the function composition defined as matrix multiplication, we can think of "not very" being an operator itself, that is a composition of operator "not" and operator "very".

5 Related Work

Sentiment Analysis. There has been a lot of research in determining the sentiment of words and constructing polarity dictionaries (Hatzivassiloglou and McKeown, 1997; Wiebe, 2000; Rao and Ravichandran, 2009; Mohammad et al., 2009; Velikovich et al., 2010). Some recent work is trying to identify the degree of sentiment of adjectives and adverbs from text using co-occurrence statistics. Work by Taboada et. al (2011) and Liu and Seneff (2009), suggest ways of computing the sentiment of adjectives from data, and computing the effect of combining adjective with adverb as multiplicative effect and combining adjective with negation as additive effect. However these models require the knowledge of a part of speech of given words and the list of negators (since the negator is an adjective as well). In our work we propose a single unified model for handling all words of any part of speech.

On the other hand, there has been some research in trying to model compositional effects for sentiment at the phrase- and sentence-level. Choi and Cardie (2008) hand-code compositional rules in order to model compositional effects of combining different words in the phrase. The hand-coded rules are based on domain knowledge and used to *learn* the effects of combining words in the phrase. Another recent work that tries to model the compositional semantics of combining different words is Nakagawa et. al. (2010), which proposes a model that learns the effects of combining different words using phrase/sentence dependency parse trees and an initial polarity dictionary. They present a learning method that employs hidden variables for sentiment classification: given the polarity of a sentence and the *a priori* polarities of its words, they learn how to model the interactions between words with head-modifier relations in the dependency tree.

Some of the previous work looked at MPQA phrase-level classification. Wilson et al. (2004) tackles the problem of classifying clauses according to their subjective strength but not polarity; Wilson et al. (2005) classifies phrases according to their polarity/sentiment but not strength. Our task is different: we classify phrases according to a single ordinal scale that combines both polarity and strength.

Task of predicting document-level star ratings was considered in (Pang and Lee, 2005; Goldberg and Zhu, 2006). In the current work we look at fine-grained sentiment analysis, more specifically we study word representations for use in true compositional semantic settings.

Distributional Semantics and Compositionality. Research in the area of distributional semantics in NLP and Cognitive Science has looked at different word representations and different ways of combining words. Mitchell and Lapata (2010) propose a framework for vector-based semantic composition. They define composition as an additive or multiplicative function of two vectors and show that compositional approaches generally outperform non-compositional approaches that treat the phrase as the union of single lexical items.

Work by Baroni and Zamparelli (2010) models nouns as vectors in some semantic space and adjectives as matrices. It shows that modeling adjectives as linear transformations and applying those linear transformations to nouns results in final vectors for adjective-noun compositions that are close in semantic space to other similar phrases. The authors argue that modeling adjectives as a linear transformation is a better idea than using additive vector-space models. In this work, a separate matrix for each adjective is *learned* using the Partial Least Squares method in a completely unsupervised way. The recent paper by Rudolph and Giesbrecht (2010), described in the introduction, argues for *multiplicative matrix-space* models. In contrast to other work in this area, our work is concerned with a specific dimension of word meaning — sentiment. Our techniques, however, are quite general and should be applicable to other problems in lexical semantics.

6 Conclusions and Future work

In the current work we present a novel matrix-space model for ordinal scale sentiment prediction and an algorithm for learning such a model. The proposed

model learns a matrix for each word; the composition of words is modeled as iterated matrix multiplication. The matrix-space framework with iterated matrix multiplication defines an elegant framework for modeling composition; it is also quite general. We use the matrix-space framework in the context of sentiment prediction, a domain where interesting compositional effects can be observed. The main focus of this work was to study word representations (represent as a single weight vs. as a matrix) for use in true compositional semantic settings. One of the benefits of the proposed approach is that by learning matrices for words, the model can handle unseen word compositions (e.g. unseen bigrams) when the unigrams involved have been seen.

However, it is not trivial to learn a matrix-space model. Since the final optimization problem is non-convex, the initialization has to be done carefully. Here the weights learned in bag-of-words model come to rescue and provide good initial point for optimization procedure. The final model outperforms the bag-of-words based model, which suggests that this research direction is very promising.

Though in our model the order of composition is the same as the word order, we believe that a linguistically informed order of composition can give us further performance gains. For example, one can use the output of a dependency parser to guide the order of composition, similar to Nakagawa et al. (2010). Another possibility for improvement is to use the information about the scope of negation. In the current work we assume the scope of negation to be the expression following the negation; in reality, however, determining the scope of negation is a complex linguistic phenomenon (Moilanen and Pulman, 2007). So the proposed model can benefit from identifying the scope of negation, similar to (Councill et al., 2010).

Also we plan to consider other ways to initialize the matrix-space model. One interesting direction to explore might be to use non-negative matrix factorization (Lee and Seung, 2001), co-clustering techniques (Dhillon, 2001) to better initialize words that share similar contexts. The other possible direction is to use existing sentiment lexicons and employing a "curriculum learning" strategy (Bengio et al., 2009; Kumar et al., 2010) for our learning problem.

Abstract

We propose a simple training regime that can improve the extrinsic performance of a parser, given only a corpus of sentences and a way to automatically evaluate the extrinsic quality of a candidate parse. We apply our method to train parsers that excel when used as part of a reordering component in a statistical machine translation system. We use a corpus of weakly-labeled reference reorderings to guide parser training. Our best parsers contribute significant improvements in subjective translation quality while their intrinsic attachment scores typically regress.

1 Introduction

The field of syntactic parsing has received a great deal of attention and progress since the creation of the Penn Treebank (Marcus et al., 1993; Collins, 1997; Charniak, 2000; McDonald et al., 2005; Petrov et al., 2006; Nivre, 2008). A common—and valid—criticism, however, is that parsers typically get evaluated only on Section 23 of the Wall Street Journal portion of the Penn Treebank. This is problematic for many reasons. As previously observed, this test set comes from a very narrow domain that does not necessarily reflect parser performance on text coming from more varied domains (Gildea, 2001), especially web text (Foster, 2010). There is also evidence that after so much repeated testing, parsers are indirectly over-fitting to this set (Petrov and Klein, 2007). Furthermore, parsing was never meant as a stand-alone task, but is rather a means to an end, towards the goal of building systems that can process natural language input.

This is not to say that parsers are not used in larger systems. All to the contrary, as parsing technology has become more mature, parsers have become efficient and accurate enough to be useful in many natural language processing systems, most notably in machine translation (Yamada and Knight, 2001; Galley et al., 2004; Xu et al., 2009). While it has been repeatedly shown that using a parser can bring net gains on downstream application quality, it is often unclear how much intrinsic parsing accuracy actually matters.

In this paper we try to shed some light on this issue by comparing different parsers in the context of machine translation (MT). We present experiments on translation from English to three Subject-Object-Verb (SOV) languages,[1] because those require extensive syntactic reordering to produce grammatical translations. We evaluate parse quality on a number of extrinsic metrics, including word reordering accuracy, BLEU score and a human evaluation of final translation quality. We show that while there is a good correlation between those extrinsic metrics, parsing quality as measured on the Penn Treebank is not a good indicator of the final downstream application quality. Since the word reordering metric can be computed efficiently offline (i.e. without the use of the final MT system), we then propose to tune parsers specifically for that metric, with the goal of improving the performance of the overall system.

To this end we propose a simple training regime

[1] We experiment with Japanese, Korean and Turkish, but there is nothing language specific in our approach.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 183–192,
Edinburgh, Scotland, UK, July 27–31, 2011.

which we refer to as *targeted self-training* (Section 2). Similar to self-training, a baseline model is used to produce predictions on an unlabeled data set. However, rather than directly training on the output of the baseline model, we generate a list of hypotheses and use an external signal to select the best candidate. The selected parse trees are added to the training data and the model is then retrained. The experiments in Section 5 show that this simple procedure noticeably improves our parsers for the task at hand, resulting in significant improvements in downstream translation quality, as measured in a human evaluation on web text.

This idea is similar in vein to McClosky. et al. (2006) and Petrov et al. (2010), except that we use an extrinsic quality metric instead of a second parsing model for making the selection. It is also similar to Burkett and Klein (2008) and Burkett et al. (2010), but again avoiding the added complexity introduced by the use of additional (bilingual) models for candidate selection.

It should be noted that our extrinsic metric is computed from data that has been manually annotated with reference word reorderings. Details of the reordering metric and the annotated data we used are given in Sections 3 and 4. While this annotation requires some effort, such annotations are much easier to obtain than full parse trees. In our experiments in Section 6 we show that we can obtain similar improvements on downstream translation quality by targeted self-training with weakly labeled data (in form of word reorderings), as with training on the fully labeled data (with full syntactic parse trees).

2 Targeted Self-Training

Our technique for retraining a baseline parser is an extension of self-training. In standard parser self-training, one uses the baseline parsing model to parse a corpus of sentences, and then adds the 1-best output of the baseline parser to the training data. To target the self-training, we introduce an additional step, given as Algorithm 1. Instead of taking the 1-best parse, we produce a ranked n-best list of predictions and select the parser which gives the best score according to an external evaluation function. That is, instead of relying on the intrinsic model score, we use an extrinsic score to select the parse towards which to update. In the case of a tie, we prefer the parse ranked most highly in the n-best list.

Algorithm 1 Select parse that maximizes an extrinsic metric.

Input: baseline parser B
Input: sentence S
Input: function COMPUTEEXTRINSIC(parse P)
Output: a parse for the input sentence

```
P^n = {P_1, ..., P_n}   ← n-best parses of S by B
maxScore = 0
bestParse = ∅
for k = 1 to n do
    extrinsicScore = COMPUTEEXTRINSIC(P_k)
    if extrinsicScore > maxScore then
        maxScore = extrinsicScore
        bestParse = P_k
    end if
end for
return bestParse
```

The motivation of this selection step is that good performance on the downstream external task, measured by the extrinsic metric, should be predictive of an intrinsically good parse. At the very least, even if the selected parse is not syntactically correct, or even if it goes against the original treebanking guidelines, it results in a higher extrinsic score and should therefore be preferred.

One could imagine extending this framework by repeatedly running self-training on successively improving parsers in an EM-style algorithm. A recent work by Hall et al. (2011) on training a parser with multiple objective functions investigates a similar idea in the context of online learning.

In this paper we focus our attention on machine translation as the final application, but one could envision applying our techniques to other applications such as information extraction or question answering. In particular, we explore one application of targeted self-training, where computing the extrinsic metric involves plugging the parse into an MT system's reordering component and computing the accuracy of the reordering compared to a reference word order. We now direct our attention to the details of this application.

3 The MT Reordering Task

Determining appropriate target language word order for a translation is a fundamental problem in MT. When translating between languages with significantly different word order such as English and Japanese, it has been shown that metrics which explicitly account for word-order are much better correlated with human judgments of translation quality than those that give more weight to word choice, like BLEU (Lavie and Denkowski, 2009; Isozaki et al., 2010a; Birch and Osborne, 2010). This demonstrates the importance of getting reordering right.

3.1 Reordering as a separately evaluable component

One way to break down the problem of translating between languages with different word order is to handle reordering and translation separately: first reorder source-language sentences into target-language word order in a preprocessing step, and then translate the reordered sentences. It has been shown that good results can be achieved by reordering each input sentence using a series of tree transformations on its parse tree. The rules for tree transformation can be manually written (Collins et al., 2005; Wang, 2007; Xu et al., 2009) or automatically learned (Xia and McCord, 2004; Habash, 2007; Genzel, 2010).

Doing reordering as a preprocessing step, separately from translation, makes it easy to evaluate reordering performance independently from the MT system. Accordingly, Talbot et al. (2011) present a framework for evaluating the quality of reordering separately from the lexical choice involved in translation. They propose a simple *reordering metric* based on METEOR's reordering penalty (Lavie and Denkowski, 2009). This metric is computed solely on the source language side. To compute it, one takes the candidate reordering of the input sentence and partitions it into a set $\mathcal{C}$ of contiguous spans whose content appears contiguously in the same order in the reference. The reordering score is then computed as

$$\rho(\mathbf{e}_{\text{sys}}, \mathbf{e}_{\text{ref}}) = 1 - \frac{|\mathcal{C}| - 1}{|\mathbf{e}| - 1}.$$

This metric assigns a score between 0 and 1 where 1 indicates that the candidate reordering is identical to the reference and 0 indicates that no two words that are contiguous in the candidate reordering are contiguous in the reference. For example, if a reference reordering is `A B C D E`, candidate reordering `A B E C D` would get score $1-(3-1)/(5-1) = 0.5$.

Talbot et al. (2011) show that this reordering score is strongly correlated with human judgment of translation quality. Furthermore, they propose to evaluate the reordering quality of an MT system by computing its reordering score on a test set consisting of source language sentences and their reference reorderings. In this paper, we take the same approach for evaluation, and in addition, we use corpora of source language sentences and their reference reorderings for training the system, not just testing it. We describe in more detail how the reference reordering data was prepared in Section 4.1.

3.2 Reordering quality as predictor of parse quality

Figure 1 gives concrete examples of good and bad reorderings of an English sentence into Japanese word order. It shows that a bad parse leads to a bad reordering (lacking inversion of verb "wear" and object "sunscreen") and a low reordering score. Could we flip this causality around, and perhaps try to identify a good parse tree based on its reordering score? With the experiments in this paper, we show that indeed a high reordering score is predictive of the underlying parse tree that was used to generate the reordering being a good parse (or, at least, being good enough for our purpose).

In the case of translating English to Japanese or another SOV language, there is a large amount of reordering required, but with a relatively small number of reordering rules one can cover a large proportion of reordering phenomena. Isozaki et al. (2010b), for instance, were able to get impressive English→Japanese results with only a single reordering rule, given a suitable definition of a *head*. Hence, the reordering task depends crucially on a correct syntactic analysis and is extremely sensitive to parser errors.

4 Experimental Setup

4.1 Treebank data

In our experiments the baseline training corpus is the Wall Street Journal (WSJ) section of the Penn Treebank (Marcus et al., 1993) using standard training/development/testing splits. We converted the treebank to match the tokenization expected by our MT system. In particular, we split tokens containing hyphens into multiple tokens and, somewhat simplistically, gave the original token's part-of-speech tag to all newly created tokens. In Section 6 we make also use of the Question Treebank (QTB) (Judge et al., 2006), as a source of syntactically annotated out-of-domain data. Though we experiment with both dependency parsers and phrase structure parsers, our MT system assumes dependency parses as input. We use the Stanford converter (de Marneffe et al., 2006) to convert phrase structure parse trees to dependency parse trees (for both treebank trees and predicted trees).

4.2 Reference reordering data

We aim to build an MT system that can accurately translate typical English text that one finds on the Internet to SOV langauges. To this end, we randomly sampled 13595 English sentences from the web and created Japanese-word-order reference reorderings for them. We split the sentences arbitrarily into a 6268-sentence Web-Train corpus and a 7327-sentence Web-Test corpus.

To make the reference alignments we used the technique suggested by Talbot et al. (2011): ask annotators to translate each English sentence to Japanese extremely literally and annotate which English words align to which Japanese words. Golden reference reorderings can be made programmatically from these annotations. Creating a large set of reference reorderings is straightforward because annotators need little special background or training, as long as they can speak both the source and target languages. We chose Japanese as the target language through which to create the English reference reorderings because we had access to bilingual annotators fluent in English and Japanese.

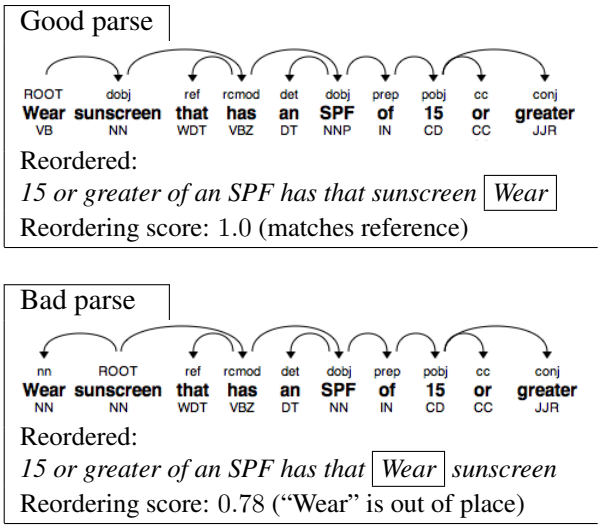

Figure 1: Examples of good and bad parses and corresponding reorderings for translation from English to Japanese. The good parse correctly identifies "Wear" as the main verb and moves it to the end of the sentence; the bad parse analyses "Wear sunscreen" as a noun phrase and does not reorder it. This example was one of the wins in the human evaluation of Section 5.2.

4.3 Parsers

The core dependency parser we use is an implementation of a transition-based dependency parser using an arc-eager transition strategy (Nivre, 2008). The parser is trained using the averaged perceptron algorithm with an early update strategy as described in Zhang and Clark (2008). The parser uses the following features: word identity of the first two words on the buffer, the top word on the stack and the head of the top word on the stack (if available); part-of-speech identities of the first four words on the buffer and top two words on the stack; dependency arc label identities for the top word on the stack, the left and rightmost modifier of the top word on the stack, and the leftmost modifier of the first word in the buffer. We also include conjunctions over all non-lexical features.

We also give results for the latent variable parser (a.k.a. BerkeleyParser) of Petrov et al. (2006). We convert the constituency trees output by the BerkeleyParser to labeled dependency trees using the same procedure that is applied to the treebanks.

While the BerkeleyParser views part-of-speech (POS) tagging as an integral part of parsing, our dependency parser requires the input to be tagged

with a separate POS tagger. We use the TnT tagger (Brants, 2000) in our experiments, because of its efficiency and ease of use. Tagger and parser are always trained on the same data.

For all parsers, we lowercase the input at train and test time. We found that this improves performance in parsing web text. In addition to general uppercase/lowercase noisiness of the web text negatively impacting scores, we found that the baseline case-sensitive parsers are especially bad at parsing imperative sentences, as discussed in Section 5.3.2.

4.4 Reordering rules

In this paper we focus on English to Japanese, Korean, and Turkish translation. We use a superset of the reordering rules proposed by Xu et al. (2009), which flatten a dependency tree into SOV word order that is suitable for all three languages. The rules define a precedence order for the dependents of each part of speech. For example, a slightly simplified version of the precedence order of child labels for a verbal head HEADVERB is: advcl, nsubj, prep, [other children], dobj, prt, aux, neg, HEADVERB, mark, ref, compl.

Alternatively, we could have used an automatic reordering-rule learning framework like that of Genzel (2010). Because the reordering accuracy metric can be computed for any source/target language pair, this would have made our approach language completely independent and applicable to any language pair. We chose to use manually written rules to eliminate the variance induced by the automatic reordering-rule learning framework.

4.5 MT system

We carried out all our translation experiments on a state-of-the-art phrase-based statistical MT system. During both training and testing, the system reorders source-language sentences in a preprocessing step using the above-mentioned rules. During decoding, we used an allowed jump width of 4 words. In addition to the regular distance distortion model, we incorporate a maximum entropy based lexicalized phrase reordering model (Zens and Ney, 2006) as a feature used in decoding.

Overall for decoding, we use between 20 to 30 features, whose weights are optimized using MERT (Och, 2003). All experiments for a given language pair use the same set of MERT weights tuned on a system using a separate parser (that is neither the baseline nor the experiment parser). This potentially underestimates the improvements that can be obtained, but also eliminates MERT as a possible source of improvement, allowing us to trace back improvements in translation quality directly to parser changes.[2]

For parallel training data, we use a custom collection of parallel documents. They come from various sources with a substantial portion coming from the web after using simple heuristics to identify potential document pairs. For all language pairs, we trained on approximately 300 million source words each.

5 Experiments Reordering Web Text

We experimented with parsers trained in three different ways:

1. Baseline: trained only on WSJ-Train.
2. Standard self-training: trained on WSJ-Train and 1-best parse of the Web-Train set by baseline parser.
3. Targeted self-training: trained on WSJ-Train and, for each sentence in Web-Train, the parse from the baseline parser's 512-best list that when reordered gives the highest reordering score.[3]

5.1 Standard self-training vs targeted self-training

Table 1 shows that targeted self-training on Web-Train significantly improves Web-Test reordering score more than standard self-training for both the shift-reduce parser and for the BerkeleyParser. The reordering score is generally divorced from the attachment scores measured on the WSJ-Test treebank: for the shift-reduce parser, Web-Test reordering score and WSJ-Test labeled attachment score

[2] We also ran MERT on all systems and the pattern of improvement is consistent, but sometimes the improvement is bigger or smaller after MERT. For instance, the BLEU delta for Japanese is +0.0030 with MERT on both sides as opposed to +0.0025 with no MERT.

[3] We saw consistent but diminishing improvements as we increased the size of the n-best list.

Parser	Web-Test reordering	WSJ-Test LAS
Shift-reduce WSJ baseline	0.757	85.31%
+ self-training 1x	0.760	85.26%
+ self-training 10x	0.756	84.14%
+ targeted self-training 1x	**0.770**	85.19%
+ targeted self-training 10x	**0.777**	84.48%
Berkeley WSJ baseline	0.780	88.66%
+ self-training 1x	0.785	89.21%
+ targeted self-training 1x	**0.790**	89.32%

Table 1: English→Japanese reordering scores on Web-Test for standard self-training and targeted self-training on Web-Train. Label "10x" indicates that the self-training data was weighted 10x relative to the WSJ training data. Bolded reordering scores are different from WSJ-only baseline with 95% confidence but are not significantly different from each other within the same group.

English to	BLEU		Human evaluation (scores range 0 to 6)		
	WSJ-only	Targeted	WSJ-only	Targeted	Sig. difference?
Japanese	0.1777	0.1802	2.56	2.69	yes (at 95% level)
Korean	0.3229	0.3259	2.61	2.70	yes (at 90% level)
Turkish	0.1344	0.1370	2.10	2.20	yes (at 95% level)

Table 2: BLEU scores and human evaluation results for translation between three language pairs, varying only the parser between systems. "WSJ-only" corresponds to the baseline WSJ-only shift-reduce parser; "Targeted" corresponds to the Web-Train targeted self-training 10x shift-reduce parser.

(LAS) are anti-correlated, but for BerkeleyParser they are correlated. Interestingly, weighting the self-training data more seems to have a negative effect on both metrics.[4]

One explanation for the drops in LAS is that some parts of the parse tree are important for downstream reordering quality while others are not (or only to a lesser extent). Some distinctions between labels become less important; for example, arcs labeled "amod" and "advmod" are transformed identically by the reordering rules. Some semantic distinctions also become less important; for example, any sane interpretation of "red hot car" would be reordered the same, that is, not at all.

5.2 Translation quality improvement

To put the improvement of the MT system in terms of BLEU score (Papineni et al., 2002), a widely used metric for automatic MT evaluation, we took 5000 sentences from Web-Test and had humans generate reference translations into Japanese, Korean, and Turkish. We then trained MT systems varying only the parser used for reordering in training and decoding. Table 2 shows that targeted self-training data increases BLEU score for translation into all three languages.

In addition to BLEU increase, a side-by-side human evaluation on 500 sentences (sampled from the 5000 used to compute BLEU scores) showed a statistically significant improvement for all three languages (see again Table 2). For each sentence, we asked annotators to simultaneously score both translations from 0 to 6, with guidelines that 6="Perfect", 4="Most Meaning/Grammar", 2="Some Meaning/Grammar", 0="Nonsense". We computed confidence intervals for the average score difference using bootstrap resampling; a difference is significant if the two-sided confidence interval does not include 0.

5.3 Analysis

As the divergence between the labeled attachment score on the WSJ-Test data and the reordering score on the WSJ-Test data indicates, parsing web text

[4]We did not attempt this experiment for the BerkeleyParser since training was too slow.

Parser	Click as N	Click as V	Imperative rate
case-sensitive shift-reduce WSJ-only	74	0	6.3%
case-sensitive shift-reduce + Web-Train targeted self-training	75	0	10.5%
case-insensitive shift-reduce WSJ-only	75	0	10.3%
case-insensitive shift-reduce + Web-Train targeted self-training	75	0	11.6%
Berkeley WSJ-only	35	35	11.9%
Berkeley + Web-Train targeted self-training	13	58	12.5%
(WSJ-Train)	1	0	0.7%

Table 3: Counts on Web-Test of "click" tagged as a noun and verb and percentage of sentences parsed imperatively.

poses very different challenges compared to parsing newswire. We show how our method improves parsing performance and reordering performance on two examples: the trendy word "click" and imperative sentences.

5.3.1 Click

The word "click" appears only once in the training portion of the WSJ (as a noun), but appears many times in our Web test data. Table 3 shows the distribution of part-of-speech tags that different parsers assign to "click". The WSJ-only parsers tag "click" as a noun far too frequently. The WSJ-only shift-reduce parser refuses to tag "click" as a verb even with targeted self-training, but BerkeleyParser does learn to tag "click" more often as a verb.

It turns out that the shift-reduce parser's stubbornness is not due to a fundamental problem of the parser, but due to an artifact in TnT. To increase speed, TnT restricts the choices of tags for known words to previously-seen tags. This causes the parser's n-best lists to never hypothesize "click" as a verb, and self-training doesn't click no matter how targeted it is. This shows that the targeted self-training approach heavily relies on the diversity of the baseline parser's n-best lists.

It should be noted here that it would be easy to combine our approach with the *uptraining* approach of Petrov et al. (2010). The idea would be to use the BerkeleyParser to generate the n-best lists; perhaps we could call this *targeted uptraining*. This way, the shift-reduce parser could benefit both from the generally higher quality of the parse trees produced by the BerkeleyParser, as well as from the information provided by the extrinsic scoring function.

5.3.2 Imperatives

As Table 3 shows, the WSJ training set contains only 0.7% imperative sentences.[5] In contrast, our test sentences from the web contain approximately 10% imperatives. As a result, parsers trained exclusively on the WSJ underproduce imperative parses, especially a case-sensitive version of the baseline. Targeted self-training helps the parsers to predict imperative parses more often.

Targeted self-training works well for generating training data with correctly-annotated imperative constructions because the reordering of main subjects and verbs in an SOV language like Japanese is very distinct: main subjects stay at the beginning of the sentence, and main verbs are reordered to the end of the sentence. It is thus especially easy to know whether an imperative parse is correct or not by looking at the reference reordering. Figure 1 gives an example: the bad (WSJ-only) parse doesn't catch on to the imperativeness and gets a low reordering score.

6 Targeted Self-Training vs Training on Treebanks for Domain Adaptation

If task-specific annotation is cheap, then it is reasonable to consider whether we could use targeted self-training to adapt a parser to a new domain as a cheaper alternative to making new treebanks. For example, if we want to build a parser that can reorder question sentences better than our baseline WSJ-only parser, we have these two options:

1. Manually construct PTB-style trees for 2000

[5] As an approximation, we count every parse that begins with a root verb as an imperative.

questions and train on the resulting treebank.

2. Create reference reorderings for 2000 questions and then do targeted self-training.

To compare these approaches, we created reference reordering data for our train (2000 sentences) and test (1000 sentences) splits of the Question Treebank (Judge et al., 2006). Table 4 shows that both ways of training on QTB-Train sentences give similarly large improvements in reordering score on QTB-Test. Table 5 confirms that this corresponds to very large increases in English→Japanese BLEU score and subjective translation quality. In the human side-by-side comparison, the baseline translations achieved an average score of 2.12, while the targeted self-training translations received a score of 2.94, where a score of 2 corresponds to "some meaning/grammar" and "4" corresponds to "most meaning/grammar".

But which of the two approaches is better? In the shift-reduce parser, targeted self-training gives higher reordering scores than training on the treebank, and in BerkeleyParser, the opposite is true. Thus both approaches produce similarly good results. From a practical perspective, the advantage of targeted self-training depends on whether the extrinsic metric is cheaper to calculate than treebanking. For MT reordering, making reference reorderings is cheap, so targeted self-training is relatively advantageous.

As before, we can examine whether labeled attachment score measured on the test set of the QTB is predictive of reordering quality. Table 4 shows that targeted self-training raises LAS from 64.78→69.17%. But adding the treebank leads to much larger increases, resulting in an LAS of 84.75%, without giving higher reordering score. We can conclude that high LAS is not necessary to achieve top reordering scores.

Perhaps our reordering rules are somehow deficient when it comes to reordering correctly-parsed questions, and as a result the targeted self-training process steers the parser towards producing pathological trees with little intrinsic meaning. To explore this possibility, we computed reordering scores after reordering the QTB-Test treebank trees directly. Table 4 shows that this gives reordering scores similar to those of our best parsers. Therefore it is at least possible that the targeted self-training process could have resulted in a parser that achieves high reordering score by producing parses that look like those in the QuestionBank.

7 Related Work

Our approach to training parsers for reordering is closely related to self/up-training (McClosky. et al., 2006; Petrov et al., 2010). However, unlike uptraining, our method does not use only the 1-best output of the first-stage parser, but has access to the n-best list. This makes it similar to the work of McClosky. et al. (2006), except that we use an extrinsic metric (MT reordering score) to select a high quality parse tree, rather than a second, reranking model that has access to additional features.

Targeted self-training is also similar to the retraining of Burkett et al. (2010) in which they jointly parse unannotated bilingual text using a multiview learning objective, then retrain the monolingual parser models to include each side of the jointly parsed bitext as monolingual training data. Our approach is different in that it doesn't use a second parser and bitext to guide the creation of new training data, and instead relies on n-best lists and an extrinsic metric.

Our method can be considered an instance of weakly or distantly supervised structured prediction (Chang et al., 2007; Chang et al., 2010; Clarke et al., 2010; Ganchev et al., 2010). Those methods attempt to learn structure models from related external signals or aggregate data statistics. This work differs in two respects. First, we use the external signals not as explicit constraints, but to compute an oracle score used to re-rank a set of parses. As such, there are no requirements that it factor by the structure of the parse tree and can in fact be any arbitrary metric. Second, our final objective is different. In weakly/distantly supervised learning, the objective is to use external knowledge to build better structured predictors. In our case this would mean using the reordering metric as a means to train better dependency parsers. Our objective, on the other hand, is to use the extrinsic metric to train parsers that are specifically better at the reordering task, and, as a result, better suited for MT. This makes our work more in the spirit of Liang et al. (2006), who train a per-

Parser	QTB-Test reordering	QTB-Test LAS
Shift-reduce WSJ baseline	0.663	64.78%
+ treebank 1x	0.704	77.12%

ceptron model for an end-to-end MT system where the alignment parameters are updated based on selecting an alignment from a n-best list that leads to highest BLEU score. As mentioned earlier, this also makes our work similar to Hall et al. (2011) who train a perceptron algorithm on multiple objective functions with the goal of producing parsers that are optimized for extrinsic metrics.

It has previously been observed that parsers often perform differently for downstream applications. Miyao et al. (2008) compared parser quality in the biomedical domain using a protein-protein interaction (PPI) identification accuracy metric. This allowed them to compare the utility of extant dependency parsers, phrase structure parsers, and deep structure parsers for the PPI identification task. One could apply the targeted self-training technique we describe to optimize any of these parsers for the PPI task, similar to how we have optimized our parser for the MT reordering task.

8 Conclusion

We introduced a variant of self-training that targets parser training towards an extrinsic evaluation metric. We use this targeted self-training approach to train parsers that improve the accuracy of the word reordering component of a machine translation system. This significantly improves the subjective quality of the system's translations from English into three SOV languages. While the new parsers give improvements in these external evaluations, their intrinsic attachment scores go down overall compared to baseline parsers trained only on treebanks. We conclude that when using a parser as a component of a larger external system, it can be advantageous to incorporate an extrinsic metric into parser training and evaluation, and that targeted self-training is an effective technique for incorporating an extrinsic metric into parser training.

Inducing Sentence Structure from Parallel Corpora for Reordering

Abstract

When translating among languages that differ substantially in word order, machine translation (MT) systems benefit from syntactic pre-ordering—an approach that uses features from a syntactic parse to permute source words into a target-language-like order. This paper presents a method for inducing parse trees automatically from a parallel corpus, instead of using a supervised parser trained on a treebank. These induced parses are used to pre-order source sentences. We demonstrate that our induced parser is effective: it not only improves a state-of-the-art phrase-based system with integrated reordering, but also approaches the performance of a recent pre-ordering method based on a supervised parser. These results show that the syntactic structure which is relevant to MT pre-ordering can be learned automatically from parallel text, thus establishing a new application for unsupervised grammar induction.

1 Introduction

Recent work in statistical machine translation (MT) has demonstrated the effectiveness of *syntactic pre-ordering*: an approach that permutes source sentences into a target-like order as a pre-processing step, using features of a source-side syntactic parse (Collins et al., 2005; Xu et al., 2009). Syntactic pre-ordering is particularly effective at applying structural transformations, such as the ordering change from a subject-verb-object (SVO) language like English to a subject-object-verb (SOV) language like Japanese. However, state-of-the-art pre-ordering methods require a supervised syntactic parser to provide structural information about each sentence. We propose a method that learns both a parsing model and a reordering model directly from a word-aligned parallel corpus. Our approach, which we call Structure Induction for Reordering (STIR), requires no syntactic annotations to train, but approaches the performance of a recent syntactic pre-ordering method in a large-scale English-Japanese MT system.

STIR predicts a pre-ordering via two pipelined models: (1) parsing and (2) tree reordering. The first model induces a binary parse, which defines the space of possible reorderings. In particular, only trees that properly separate verbs from their object noun phrases will license an SVO to SOV transformation. The second model locally permutes this tree. Our approach resembles work with binary synchronous grammars (Wu, 1997), but is distinct in its emphasis on monolingual parsing as a first phase, and in selecting reorderings without the aid of a target-side language model.

The parsing model is trained to maximize the conditional likelihood of trees that license the reorderings implied by observed word alignments in a parallel corpus. This objective differs from those of previous grammar induction models, which typically focus on succinctly explaining the observed source language corpus via latent hierarchical structure (Pereira and Schabes, 1992; Klein and Manning, 2002). Our convex objective allows us to train a feature-rich log-linear parsing model, even without supervised treebank data.

Focusing on pre-ordering for MT leads to a new

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 193–203,
Edinburgh, Scotland, UK, July 27–31, 2011.

perspective on the canonical NLP task of grammar induction—one which marries the wide-spread scientific interest in unsupervised parsing models with a clear application and extrinsic evaluation methodology. To support this perspective, we highlight several avenues of future research throughout the paper.

We evaluate STIR in a large-scale English-Japanese machine translation system. We measure how closely our predicted reorderings match those implied by hand-annotated word alignments. STIR approaches the performance of the state-of-the-art pre-ordering method described in Genzel (2010), which learns reordering rules for supervised treebank parses. STIR gives a translation improvement of 3.84 BLEU over a standard phrase-based system with an integrated reordering model.

2 Parsing and Reordering Models

STIR consists of two pipelined log-linear models for parsing and reordering, as well as a third model for inducing trees from parallel corpora, trees that serve to train the first two models. This section describes the domain and structure of each model, while Section 3 describes features and learning objectives.

Figure 1 depicts the relationship between the three models. For each aligned sentence pair in a parallel corpus, the *parallel parsing model* selects a binary tree t over the source sentence, such that t licenses the reordering pattern implied by the word alignment (Section 2.2). The *monolingual parsing model* is trained to generate t without inspecting the alignments or target sentences (Section 2.3). The *tree reordering model* is trained to locally permute t to produce the target order (Section 2.4). In the context of an MT system, the monolingual parser and tree reorderer are applied in sequence to pre-order source sentences.

2.1 Unlabeled Binary Trees

Unlabeled binary trees are central to the STIR pipeline. We represent trees via their constituent spans. Let $[k, \ell)$ denote a span of indices of a 0-indexed word sequence $\mathbf{e}$, where $i \in [k, \ell)$ if $k \leq i < \ell$. $[0, n)$ denotes the root span covering the whole sequence, where $n = |\mathbf{e}|$.

A tree $t = (\mathcal{T}, \mathcal{N})$ consists of a set of terminal spans $\mathcal{T}$ and non-terminal spans $\mathcal{N}$. Each non-terminal span $[k, \ell) \in \mathcal{N}$ has a split point m, where $k < m < \ell$ splits the span into child spans $[k, m)$ and $[m, \ell)$. Formally, a pair $(\mathcal{T}, \mathcal{N})$ is a well-formed tree over $[0, n)$ if:

- The root span $[0, n) \in \mathcal{T} \cup \mathcal{N}$.
- For each $[k, \ell) \in \mathcal{N}$, there exists exactly one m such that $\{[k, m), [m, \ell)\} \subset \mathcal{T} \cup \mathcal{N}$.
- Terminal spans $\mathcal{T}$ are disjoint, but cover $[0, n)$.

These trees include multi-word terminal spans. It is often convenient to refer to a split non-terminal triple (k, m, ℓ) that include a non-terminal span $[k, \ell)$ and its split point m. We denote the set of these triples as

$$\mathcal{N}^+ = \{(k, m, \ell) : \{[k, \ell), [k, m), [m, \ell)\} \in \mathcal{T} \cup \mathcal{N}\}.$$

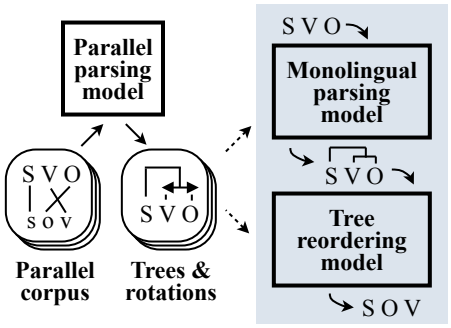

Figure 1: The training and reordering pipeline for STIR contains three models. The inputs and outputs of each model are indicated by solid arrows, while dashed arrows indicate the source of training examples. The parallel parsing model provides tree and reordering examples that are used to train the other models. In an MT system, the trained reordering pipeline (shaded) pre-orders a source sentence without target-side or alignment information.

2.2 Parallel Parsing Model

The first step in the STIR pipeline is to select a binary parse of each source sentence in a parallel corpus, one which licenses the reordering implied by a word alignment. Let the triple $(\mathbf{e}, \mathbf{f}, \mathcal{A})$ be an aligned sentence pair, where $\mathbf{e}$ and $\mathbf{f}$ are word sequences and $\mathcal{A}$ is a set of links (i, j) indicating that e_i aligns to f_j.

The set $\mathcal{A}$ provides ordering information over $\mathbf{e}$. To simplify definitions below, we first adjust $\mathcal{A}$ to

ignore all unaligned words in $\mathbf{f}$.

$$\mathcal{A}' = \{(i, c(j)) : (i,j) \in \mathcal{A}\}$$
$$c(j) = |\{j' : j' < j \ \wedge \ \exists i \text{ such that } (i,j') \in \mathcal{A}\}| \ .$$

$c(j)$ is the number of aligned words in $\mathbf{f}$ prior to position j. Next, we define a projection function:

$$\psi(i) = \left[\min_{j \in J_i} j, \max_{j \in J_i} j + 1\right)$$
$$J_i = \{j : (i,j) \in \mathcal{A}'\} \ ,$$

and let $\psi(i) = \emptyset$ if e_i is unaligned. We can extend this projection function to spans $[k, \ell)$ of $\mathbf{e}$ via union:

$$\psi(k, \ell) = \bigcup_{k \leq i < \ell} \psi(i) \ .$$

We say that a span $[k, \ell)$ aligns contiguously if

$$\forall (i,j) \in \mathcal{A}', j \in \psi(k,\ell) \text{ implies } i \in [k, \ell) \ ,$$

which corresponds to the familiar definition that $[k, \ell)$ is one side of an extractable phrase pair. Unaligned spans do not align contiguously.

Given this notion of projection, we can relate trees to alignments. A tree $(\mathcal{T}, \mathcal{N})$ over $\mathbf{e}$ respects an alignment $\mathcal{A}'$ if all $[k, \ell) \in \mathcal{T} \cup \mathcal{N}$ align contiguously, and for every (k, m, ℓ), the projections $\psi(k, m)$ and $\psi(m, \ell)$ are adjacent. Projections are adjacent if the left bound of one is the right bound of the other, or if either is empty.

The parallel parsing model is a linear model over trees that respect $\mathcal{A}'$, which factors over spans.

$$\mathrm{s}(t) = \sum_{[k,\ell) \in \mathcal{T}} w_T \phi_T(k, \ell) + \sum_{(k,m,\ell) \in \mathcal{N}^+} w_N \phi_N(k, m, \ell)$$

where the weight vector $w = (w_T \ w_N)$ scores features ϕ_T on terminal spans and ϕ_N on non-terminal spans and their split points.

Exact inference under this model can be performed via a dynamic program that exploits the following recurrence. Let $\mathrm{s}(k, \ell)$ be the score of the highest scoring binary tree over the span $[k, \ell)$ that respects $\mathcal{A}'$. Then,

$$\mathrm{s}_T(k, \ell) = \begin{cases} w_T \phi_T(k, \ell) & \text{if } [k, \ell) \text{ aligns contiguously} \\ -\infty & \text{otherwise} \end{cases}$$
$$f(k, m, \ell) = \mathrm{s}(k, m) + \mathrm{s}(m, \ell) + w_N \phi_N(k, m, \ell)$$
$$\mathrm{s}_N(k, \ell) = \max_{m : k < m < \ell} \begin{cases} f(k, m, \ell) & \text{if } \psi(k,m) \text{ is adjacent to } \psi(m, \ell) \\ -\infty & \text{otherwise} \end{cases}$$
$$\mathrm{s}(k, \ell) = \max\left[\mathrm{s}_T(k, \ell), \mathrm{s}_N(k, \ell)\right]$$

Above, s_T scores terminal spans while filtering out those which are not contiguous. The function f scores non-terminal spans by the sum of their child scores and additional features ϕ_N of the parent span. The recursive function s_N maximizes over split points while filtering out non-adjacent children. The recurrence will assign a score of $-\infty$ to any tree that does not respect $\mathcal{A}'$. Section 3 describes the features of this model. $\mathrm{s}(k, \ell)$ can be computed efficiently using the CKY algorithm.

2.3 Monolingual Parsing Model

The monolingual parsing model is trained to select the same trees as the parallel model, but without any features or constraints that reference word alignments. Hence, it can be applied to a source sentence before its translation is known.

This model also scores untyped binary trees according to a linear model parameterized by some $w = (w_T \ w_N)$ that weights features on terminal and non-terminal spans, respectively. We impose a maximum terminal length of L, but otherwise allow any binary tree. The score $\mathrm{s}(k, \ell)$ of the maximal tree over a span $[k, \ell)$ satisfies the familiar recurrence:

$$\mathrm{s}_M(k, \ell) = \begin{cases} w_T \phi_T(k, \ell) & \text{if } \ell - k \leq L \\ -\infty & \text{otherwise} \end{cases}$$
$$\mathrm{s}(k, \ell) = \max\left[\mathrm{s}_L(k, \ell), \max_{m : k < m < \ell} f(k, m, \ell)\right]$$

Inference under this recurrence can also be performed using the CKY algorithm. Section 3 describes the feature functions and training method.

2.4 Tree Reordering Model

Given a binary tree $(\mathcal{T}, \mathcal{N})$ over a sentence $\mathbf{e}$, we can reorder $\mathbf{e}$ by (a) permuting the children of non-terminals and (b) permuting the words of terminal spans. Formally, a reordering r assigns each terminal $[k, \ell) \in \mathcal{T}$ a permutation $\sigma(k, \ell)$ of its words and each split non-terminal (k, m, ℓ) a permutation $b(k, m, \ell)$ of its subspans, which can be either monotone or inverted, in the case of a binary tree. The permutation $\sigma(k, \ell)$ of a non-terminal span $[k, \ell) \notin \mathcal{T}$ is defined recursively as:

$$\begin{cases} \sigma(k, m)\ \sigma(m, \ell) & \text{if } b(k, m, \ell) \text{ is monotone} \\ \sigma(m, \ell)\ \sigma(k, m) & \text{if } b(k, m, \ell) \text{ is inverted} \end{cases}$$

In this paper, we use a reordering model that selects each terminal $\sigma(k, \ell)$ and each split non-terminal $b(k, m, \ell)$ independently, conditioned on the sentence $\mathbf{e}$. While the sub-problems of choosing $\sigma(k, \ell)$ and $b(k, m, \ell)$ are formally similar, we consider and evaluate them separately because the former deals only with local reordering, while the latter involves long-distance structural reordering.

Because our trees are binary, selecting $b(k, m, \ell)$ is a binary classification problem. Selecting $\sigma(k, \ell)$ for a terminal is a multiclass prediction problem that chooses among the $(\ell - k)!$ permutations of terminal $[k, \ell)$. Development experiments in English-Japanese yielded the best results with a maximum terminal span length $L = 2$. Hence, in experiments, terminal reordering is also binary classification.

Because each permutation is independent of all the others, reordering inference via a single pass through the tree is optimal. However, a more complex search procedure would be necessary to maintain optimality if the decision of $b(k, m, \ell)$ referenced other permutations, such as $\sigma([k, m))$ or $\sigma([m, \ell))$. Coupling together inference in this way represents a possible area of future study.

3 Features and Training Objectives

Each of these linear models factors over features on either terminal spans $[k, \ell)$ or split non-terminals (k, m, ℓ). Features vary in concert with the learning objectives and search spaces of each model.

Figure 2 shows an example sentence from our development corpus, including the target (Japanese) sentence, alignment, projections, parallel parser prediction, monolingual parser prediction, and predicted permutation. The feature descriptions below reference this example.

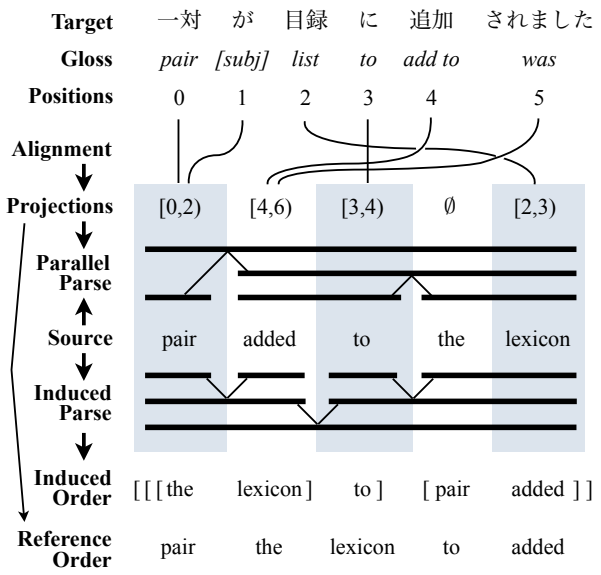

Figure 2: An example from our development corpus, annotated with the information flow (left) and annotations and predictions (right). Alignments inform projections, which are spans of the target associated with each source word. The parallel parse may only include contiguous spans. On the other hand, the induced parse may only condition on the source sentence. The induced order is restricted by the induced parse. In this example, the induced order is incorrect because the subject and verb form a constituent in the induced parse that cannot be separated correctly by the reordering model. This example demonstrates the important role of the induced parser in the STIR pipeline.

3.1 Tree Reordering Features

The tree reordering model consists of two local classifiers: the first can invert the two children of a non-terminal span, while the second can permute the words of a terminal span. The non-terminal classifier is trained on the trees that are selected by the parallel parsing model; the weights are chosen to minimize log loss of the correct permutation of each span (i.e., a maximum entropy model).

The terminal model is a multi-class maximum entropy model over the $n!$ possible permutations of the words in a terminal span. To make reordering more robust to monolingual parsing errors, the terminal

model is trained on all contiguous spans of each sentence up to length L, not just the terminal spans included in the parallel parsing tree.

The feature templates we apply to each span can be divided into the following five categories. Most features are shared across the two models.

Statistics. From a large aligned parallel corpus, we compute two statistics.

- $\mathrm{P}_C(e) = \frac{\text{count(e aligns contiguously)}}{\text{count}(e)}$ is the fraction of the time that a phrase e aligns contiguously to some target phrase, for all phrases up to length 4.
- $\mathrm{P}_D(e_i, e_j)$ is the fraction of the time that two co-occuring source words e_i and e_j align to adjacent positions in the target.

The first statistic indicates whether a contiguous phrase in the source should stay contiguous after reordering. Features based on this statistic apply to both terminal and short non-terminal spans. The second statistic indicates when a possibly discontiguous pair of words should be adjacent after reordering. This statistic is applied to pairs of words that would end up adjacent after an inversion: e_k and $e_{\ell-1}$ for span $[k, \ell)$. For instance, $\mathrm{P}_C(\text{added to}) = 0.68$ and $\mathrm{P}_D(\text{lexicon}, \text{to}) = 0.19$.

Cluster. All source word types are clustered into word classes, which together maximize likelihood of the source side of a large parallel corpus under a hidden Markov model, as in Uszkoreit and Brants (2008). Indicator features based on clusterings over c classes are defined over words e_k, e_{m-1}, e_m and $e_{\ell-1}$, as well as word sequences for spans up to length 4. Features are included for a variety of clusterings with sizes $c \in \{2^3, 2^4, \ldots, 2^{11}\}$.

POS. A supervised part-of-speech (POS) tagger provides coarse tags drawn from a 12 tag set $T = \{$Verb, Noun, Pronoun, Conjunction, Adjective, Adverb, Adposition, Determiner, Number, Particle/Function word, Punctuation, Other$\}$ (Petrov et al., 2011). Features based on these tags are computed identically to the features based on word classes.

Lexical. For a list of very common words in the source language, we include lexical indicator features for the boundary words e_k and $e_{\ell-1}$. For instance, the word "to" triggers a reordering, as do prepositions in general.

Length. Length computed as $\ell - k$, length as a fraction of sentence length, and quantized length features all contribute structural information.

All features except POS are computed directly from aligned parallel corpora. The Cluster and POS features play a similar role of expressing reordering patterns over collections of similar words. The ablation study in Section 5 compares these two feature sets directly.

3.2 Monolingual Parsing Features

The monolingual parsing model is also trained discriminatively, but involves structured prediction, as in a conditional random field (Lafferty et al., 2001). Conditional likelihood objectives have proven effective for supervised parsers (Finkel et al., 2008; Petrov and Klein, 2008). Recall that the score of a tree $t = (\mathcal{T}, \mathcal{N})$ factors over spans.

$$\mathrm{s}(t) = \sum_{[k,\ell) \in \mathcal{T}} w_T \phi_T(k, \ell) + \sum_{[k,\ell) \in \mathcal{N}} w_N \phi_N(k, m, \ell)$$

$$\mathrm{P}(t|\mathbf{e}) = \frac{\exp\left[\mathrm{s}(t)\right]}{\sum_{(t') \in \mathcal{B}(\mathbf{e})} \exp\left[\mathrm{s}(t')\right]}$$

where $\mathcal{B}(\mathbf{e})$ is the set of well-formed trees over $\mathbf{e}$.

The parallel parsing model (Section 2.2) produces a tree over the source sentence of each aligned sentence pair; these trees serve as our training examples. We can maximize their conditional likelihood according to this model via gradient methods. Each tree t over sentence $\mathbf{e}$ has a cumulative feature vector of dimension $|w| = |w_T| + |w_N|$, formed by stacking the terminal and non-terminal vectors:

$$\phi(t, \mathbf{e}) = \left(\sum_{[k,\ell) \in \mathcal{T}} \phi_T(k, \ell) \qquad \sum_{[k,\ell) \in \mathcal{N}} \phi_N(k, m, \ell) \right)$$

The contribution to the gradient objective from a tree t for a sentence $\mathbf{e}$ is the difference between observed

and expected feature vectors.

$$\mathcal{L}(w) = \sum_{(t,\mathbf{e})} \log \mathrm{P}(t|\mathbf{e})$$

$$\nabla\mathcal{L}(w) = \sum_{(t,\mathbf{e})} \left[\phi(t,\mathbf{e}) - \sum_{t' \in \mathcal{B}(\mathbf{e})} \mathrm{P}(t'|\mathbf{e}) \cdot \phi(t',\mathbf{e}) \right]$$

The second term in the gradient—the expected feature vector—can be computed efficiently because the feature vector $\phi(t')$ decomposes over the spans of t'. In particular, the inside-outside algorithm provides the quantities needed to compute the posterior probability of each terminal span $[k,\ell)$ and each split non-terminal (k,m,ℓ). Let, $\alpha(k,\ell)$ and $\beta(k,\ell)$ be the outside and inside scores of a span, respectively, computed using a log-sum semiring. Then, the log probablility that a terminal span $[k,\ell)$ appears in the tree for $\mathbf{e}$ under the posterior distribution $\mathrm{P}(t|\mathbf{e})$ is $\alpha(k,\ell) + w_T\phi_T(k,\ell)$. Note that this terminal posterior does not include the inside score of the span.

The log probability that a non-terminal span $[k,\ell)$ appears with split point m is

$$\alpha(k,\ell) + \beta(k,m) + \beta(m,\ell) + w_N\phi_N(k,m,\ell)$$

By the linearity of expectations, the expected feature vector for $\mathbf{e}$ can be computed by averaging the feature vectors of each terminal and split non-terminal span, weighted by their posterior probabilities.

In future work, one may consider training this model to maximize the likelihood of an entire forest of trees, in order to maintain uncertainty over which tree licensed a particular alignment.

We are currently using l-BFGS to optimize this objective over a relatively small training corpus, for 35 iterations. For this reason, we only include lexical features for very common words. Distributed or online training algorithms would perhaps allow for more training data (and therefore more lexicalized features) to be used in the future.

The features of this parsing model share the same types as the tree reordering models, but vary in their definition. The differences stem primarily from the different purpose of the model: here, features are not meant to decide how to reorder the sentence, but instead how to bracket the sentence hierarchically so that it can be reordered.

In particular, terminal spans have features on the sequence of POS tags and word clusters they contain, while a split non-terminal (k,m,ℓ) is scored based on the tags/clusters of the following words and word pairs: $e_k, e_{m-1}, e_m, e_{\ell-1}, (e_k,e_m), (e_k,e_{\ell-1})$, and (e_{m-1},e_m). The head word of a constituent often appears at one of its boundary positions, and so these features provide a proxy for explicitly tracking constituent heads in a parser.

Context features also appear, inspired by the constituent-context model of Klein and Manning (2001). For a span $[k,\ell)$, we add indicator features on the POS tags and word clusters of the words (e_{k-1},e_ℓ) which directly surround the constituent.

Features based on the statistic $\mathrm{P}_C(e)$ are also scored in the parsing model on all spans of length up to 4.

Length features score various structural aspects of each non-terminal (k,m,ℓ), such as $\frac{m-k}{\ell-k}$, $\frac{m-k}{k-m}$, etc.

One particularly interesting direction for future work is to train a single parsing model that licenses the reordering for several different languages. We might expect that a reasonable syntactic bracketing of English would simultaneously license the head-final transformations necessary to produce a Japanese or Korean ordering, and also the verb-subject-object ordering of formal Arabic.[1]

3.3 Parallel Parsing Features

The parallel parsing model does not run at translation time, but instead provides training examples to the other two models. Hence, defining an appropriate learning objective for this model is more challenging.

In the end, we are interested in selecting trees that we can learn to reproduce without an alignment (via the monolingual parsing model) and which can be reordered reliably (via the tree reordering model). Note that by construction, any tree selected by the parallel parsing model can be reordered perfectly. However, some of those trees will be easier to reproduce and reorder than others.

[1] An astute reviewer pointed out that no binary tree over an S-V-O sentence can license both S-O-V and V-S-O orderings. Hence, parse trees that are induced for multilingual reordering will need n-ary branches.

3.3.1 Reordering Loss Function

In order to measure the effectiveness of a reordering pipeline, we would like a metric over permutations. Fortunately, permutation loss for machine translation is already an established component of the METEOR metric, called a fragmentation penalty (Lavie and Agarwal, 2007). We define a slight variant of METEOR's fragmentation penalty that ranges from 0 to 1.

Given a sentence $\mathbf{e}$, a reference permutation σ^* of $(0, \cdots, |\mathbf{e}| - 1)$, and a hypothesized permutation $\hat{\sigma}$, let chunks$(\hat{\sigma}, \sigma^*)$ be the minimum number of "chunks" in $\hat{\sigma}$: the number of elements in a partition of $\hat{\sigma}$ such that each contiguous subsequence is also contiguous in σ^*.

We can define the reordering score between two permutations in terms of chunks.

$$R(\hat{\sigma}, \sigma^*) = \frac{|\sigma^*| - \text{chunks}(\hat{\sigma}, \sigma^*)}{|\sigma^*| - 1} \quad (1)$$

If $\hat{\sigma} = \sigma^*$, then chunks$(\hat{\sigma}, \sigma^*) = 1$. If no two adjacent elements of $\hat{\sigma}$ are adjacent in σ^*, then chunks$(\hat{\sigma}, \sigma^*) = |\sigma|$. Hence, the metric defined by Equation 1 ranges from 0 to 1.

The reference permutation σ^* of a source sentence $\mathbf{e}$ can be defined from an aligned sentence pair $(\mathbf{e}, \mathbf{f}, \mathcal{A})$ by sorting the words e_i of $\mathbf{e}$ by the left bound of their projection $\psi(i)$. Null-aligned words are placed to the left of the next aligned word to their right in the original order.

The reordering-specific loss functions defined in Equation 1 has been shown to correlate with human judgements of translation quality, especially for language pairs with substantial reordering like English-Japanese (Talbot et al., 2011). Other reordering-specific loss functions also correlate with human judgements (Birch et al., 2010). Future research could experiment with alternative reordering-based loss functions, such as Kendall's Tau, as suggested by Birch and Osborne (2011).

3.3.2 Parallel Parsing Objective

We can train our reordering pipeline by dividing an aligned parallel corpus into two halves, A and B, where the monolingual parsing and tree reordering models are trained on A, and their effectiveness is evaluated on held-out set B. Then, the effectiveness of the parallel parsing model is best measured on B, given fully trained parsing and reordering models.

$$\sum_{(\mathbf{e},\sigma^*) \in B} R\left(\sigma\left(\arg\max_{t \in \mathcal{B}(\mathbf{e})} [w \cdot \phi(t)]\right), \sigma^*\right) \quad (2)$$

Evaluating this objective involves training the other two models. Therefore, we can only hope to optimize this objective directly over a small dimensional space, for instance using a grid search. For this reason, we currently only include 4 features in the parallel parsing model for a tree t:

1. The sum of $\log \text{P}_C(e)$ for all terminals e in t with length greater than 1.
2. The count of length-1 terminal spans in t.
3. The count of terminals of length greater than k.
4. An indicator feature of whether parentheses and brackets are balanced in each span.

The model weights of features 3 and 4 above are fixed to large negative constants to prefer terminal spans of length up to k and spans with balanced punctuation. The weight of feature 1 is fixed to 1, and weight 2 was set via line search to 0.3. Ties among trees were broken randomly.

Of course, the problem of selecting training trees need not be directly tied to the end task of reordering, as in Equation 2. Instead, we might consider selecting trees according to a likelihood objective on the source side of a parallel corpus, similar to how monolingual grammar induction models often optimize corpus likelihood. In such a case, we could imagine training models with far more parameters, but we leave this research direction to future work.

4 Related Work

Our approach to inducing hierarchical structure for pre-ordering relates to several areas of previous work, including other pre-ordering methods, reordering models more generally, and models for the unsupervised induction of syntactic structure.

4.1 Pre-Ordering Models

Our reordering pipeline is intentionally similar to approaches that use a treebank-trained supervised

parser to reorder source sentences at training and translation time (Xia and McCord, 2004; Collins et al., 2005; Lee et al., 2010). Given a supervised parser, a rule-based pre-ordering procedure can either be specified by hand (Xu et al., 2009) or learned automatically (Genzel, 2010). We consider our approach to be a direct extension of these approaches, but one which induces structure from parallel corpora rather than relying on a treebank.

Tromble (2009) show that some pre-ordering benefits can be realized without a parsing step at all, by instead casting pre-ordering as a permutation modeling problem. While not splitting the task of pre-ordering into parsing and tree rordering, that work shows that pre-ordering models can be learned directly from parallel corpora.

4.2 Integrated Reordering Models

Distortion models have been primary components in machine translation models since the advent of statistical MT (Brown et al., 1993). In modern systems, reordering models are integrated into decoders as additional features in a discriminative log-linear model, which also includes a language model, translation features, etc. In these cases, reordering models interact with the strong signal of a target-side language model. Because ordering prediciton is conflated with target-side generation, evaluations are conducted on the entire generated output, which cannot isolate reordering errors from other sorts of errors, like lexical selection.

Despite these differences, certain integrated reordering models are similar in character to syntactic pre-ordering models. In particular, the tree rotation model of Yamada and Knight (2001) posited that reordering decisions involve rotations of a source-side syntax tree. The parameters of such a model can be trained by treating tree rotations as latent variables in a factored translation model, which parameterizes reordering and transfer separately but performs joint inference (Dyer and Resnik, 2010). Syntactic reordering and transfer can also be modeled jointly, for instance in a tree-to-string translation system parameterized by a transducer grammar.

While the success of integrated reordering models certainly highlights the importance of reordering in machine translation systems, we see several advantages to a pipelined, pre-ordering approach. First, the pre-ordering model can be trained and evaluated directly. Second, pre-ordering models need not factor according to the same dynamic program as the translation model. Third, the same reordering can be applied during training (for word alignment and rule extraction) and translation time without adding complexity to the extraction and decoding algorithms. Of course, integrating our model into translation inference represents a potentially fruitful avenue of future research.

4.3 Grammar Induction

The language processing community actively works on the problem of automatically inducing grammatical structure from a corpus of text (Pereira and Schabes, 1992). Some success in this area has been demonstrated via generative models (Klein and Manning, 2002), which often benefit from well-chosen priors (Cohen and Smith, 2009) or posterior constraints (Ganchev et al., 2009). In principle, these models must discover the syntactic patterns that govern a language from the sequences of word tokens alone. These models are often evaluated relative to reference treebank annotations.

Grammar induction in the context of machine translation reordering offers different properties. The alignment patterns in a parallel corpus provide an additional signal to models that is strongly tied to syntactic properties of the aligned languages. Also, the evaluation is straightforward—any syntactic structure that supports the prediction of reordering is rewarded.

Kuhn (2004) applied alignment-based constraints to the problem of inducing probabilistic context-free grammars, and showed an improvement with respect to Penn Treebank annotations over monolingual induction. Their work is distinct from ours because it focused on projecting distituents across languages, but mirrors ours in demonstrating that there is a role for aligned parallel corpora in grammar induction.

Snyder et al. (2009) also demonstrated that parallel corpora can play a role in improving the quality of grammar induction models. Their work differs from ours in that it focuses on multilingual lexical statistics and dependency relationships, rather than reordering patterns.

		Parsing			Tree Reordering			Pipeline
		Prec	Rec	$F1$	acc_N	acc_T	R_O	R
Annotated word alignments	All features	82.0	87.8	84.8	97.3	93.6	87.7	80.5
	All but POS	81.3	87.7	84.4	97.0	92.6	86.6	79.4
	All but Cluster	81.2	87.9	84.4	95.9	93.2	83.8	77.8
	All but POS & Cluster	75.4	82.0	78.5	89.2	89.7	66.8	49.7
Learned alignments	All features	72.5	61.0	66.3	91.6	83.3	72.0	49.5
Monotone order								34.9
Inverted order								30.8
Syntactic pre-ordering (Genzel, 2010)								66.0

Table 1: Accuracy of individual monolingual parsing and reordering models, as well as complete pipelines trained on annotated and learned word alignments.

4.4 Bilingual Grammar Induction

Also related to STIR is previous work on bilingual grammar induction from parallel corpora using ITG (Blunsom et al., 2009). These models have focused on learning phrasal translations — which are the terminal productions of a synchronous ITG — rather than reordering patterns that occur higher in the tree. Hence, while this paper shares formal machinery and data sources with that line of work, the models themselves target orthogonal aspects of the translation problem.

5 Experimental Results

As training data for our models we used 14,000 English sentences that were sampled from the web, translated into Japanese, and manually annotated with word alignments. The annotation was carried out by the original translators to promote consistency of analysis. Talbot et al. (2011) describes this corpus in further detail. A held-out test set of 396 manually aligned sentence pairs was used to evaluate reordering accuracy. Statistics used for features were computed from the full, unreordered, automatically word aligned, parallel training corpus used for the translation experiments described below.

5.1 Individual Model Accuracy

We evaluate the accuracy of the monolingual parsing models by their span F1, relative to the trees induced by the parallel parsing model on the held-out set. The first row of Table 1 shows that the model was able to reliably replicate the parses induced from alignments, at 84.8% F1. The following three lines show that removing either POS or cluster features degrades performance by only 0.4% F1, indicating that POS features are largely redundant in the presence of automatically induced word class features. Hence, no syntactic annotations are necessary at all to train the model.

We report two accuracy measures for the tree reordering model, one for non-terminal spans (acc_N) and one for terminal spans (acc_T). The following column, labeled R_O, is the reordering score of the tree reordering model applied to the oracle parallel parser tree. This score is independent of the monolingual parsing model.

The fifth line, labeled *learned alignments*, shows the impact of replacing manual alignment annotations with learned Model 1 alignments, trained in both directions and combined with the *refined* heuristic (Brown et al., 1993; Och et al., 1999).

The *pipeline* column shows the reordering score of the full STIR pipeline compared to two simple baselines: *Monotone* applies no reordering, while *inverted* simply inverts the word order. STIR outperforms all three other systems.

In the final line, we compare to the syntax-based pre-ordering system described in Genzel (2010). This approach first parses source sentences with a supervised parser, then learns reordering rules that permute those trees.

5.2 Translation Quality

We apply STIR as a pre-ordering step in a state-of-the-art phrase-based translation system from English to Japanese (Koehn et al., 2003). At training

time, pre-ordering is applied to the source side of every sentence pair in the training corpus before word alignment and phrase extraction. Likewise, every input sentence is pre-ordered at translation time.

Our baseline is the same system, but without pre-ordering. Our implementation's integrated distortion model is expressed as a negative exponential function of the distance between the current and previous source phrase, with a maximum jump width of four words. Our in-house decoder is based on the alignment template approach to translation and uses a small set of standard feature functions during decoding (Och and Ney, 2004).

We compare to using an integrated lexicalized reordering model (Koehn and Monz, 2005), a forest-to-string translation model (Zhang et al., 2011) and finally the syntactic pre-ordering technique of Genzel (2010) applied to the phrase-based baseline. We evaluate the impact of the proposed approach on translation quality as measured by the BLEU score on the token level (Papineni et al., 2002).

The translation model is trained on 700 million tokens of parallel text, primarily extracted from the web using automated parallel document identification (Uszkoreit et al., 2010). Alignments were learned using two iterations of Model 1 and two iterations of the HMM alignment model (Vogel et al., 1996). Our *dev* and *test* data sets consist of 3100 and 1000 English sentences, respectively, that were randomly sampled from the web and translated into Japanese. The *eval* set is a larger, heterogenous set containing 12,784 sentences. In all cases, the final log-linear models were optimized on the *dev* set using lattice-based Minimum Error Rate Training (Macherey et al., 2008).

Table 2 shows that STIR improves over the baseline system by a large margin of 3.84% BLEU (test). These gains are comparable in magnitude to those reported in Genzel (2010). Our induced parses are competitive with both systems that use syntactic parsers and substantially outperform lexicalized reordering.

	BLEU %		
	dev	test	eval
Baseline	18.65	19.02	13.60
Lexicalized Reordering	19.45	18.92	13.99
Forest-to-String	**23.08**	22.85	**16.60**
Syntactic Pre-ordering	22.59	**23.28**	16.31
STIR: annotated	22.46	22.86	16.39
STIR: learned	20.28	20.66	14.64

Table 2: Translation quality, measured by BLEU, for English to Japanese. STIR results use both manually annotated and learned alignments.

6 Conclusion

We have demonstrated that induced parses suffice for pre-ordering. We hope that future work in grammar induction will also consider pre-ordering as an extrinsic evaluation.

Augmenting String-to-Tree Translation Models with Fuzzy Use of Source-side Syntax

Jiajun Zhang, Feifei Zhai and Chengqing Zong
Institute of Automation, Chinese Academy of Sciences
Beijing, China
{jjzhang, ffzhai, cqzong}@nlpr.ia.ac.cn

Abstract

Due to its explicit modeling of the grammaticality of the output via target-side syntax, the string-to-tree model has been shown to be one of the most successful syntax-based translation models. However, a major limitation of this model is that it does not utilize any useful syntactic information on the source side. In this paper, we analyze the difficulties of incorporating source syntax in a string-to-tree model. We then propose a new way to use the source syntax in a fuzzy manner, both in source syntactic annotation and in rule matching. We further explore three algorithms in rule matching: 0-1 matching, likelihood matching, and deep similarity matching. Our method not only guarantees grammatical output with an explicit target tree, but also enables the system to choose the proper translation rules via fuzzy use of the source syntax. Our extensive experiments have shown significant improvements over the state-of-the-art string-to-tree system.

1 Introduction

In recent years, statistical translation models based upon linguistic syntax have shown promising progress in improving translation quality. It appears that encoding syntactic annotations on either side or both sides in translation rules can increase the expressiveness of rules and can produce more accurate translations with improved reordering.

One of the most successful syntax-based models is the string-to-tree model (Galley et al., 2006; Marcu et al., 2006; Shen et al., 2008; Chiang et al., 2009). Since it explicitly models the grammaticality of the output via target-side syntax, the string-to-tree model (Xiao et al., 2010) significantly outperforms both the state-of-the-art phrase-based system Moses (Koehn et al., 2007) and the formal syntax-based system Hiero (Chiang, 2007). However, there is a major limitation in the string-to-tree model: it does not utilize any useful source-side syntactic information, and thus to some extent lacks the ability to distinguish good translation rules from bad ones.

The source syntax is well-known to be helpful in improving translation accuracy, as shown especially by tree-to-string systems (Quirk et al., 2005; Liu et al., 2006; Huang et al., 2006; Mi et al., 2008; Zhang et al., 2009). The tree-to-string systems are simple and efficient, but they also have a major limitation: they cannot guarantee the grammaticality of the translation output because they lack target-side syntactic constraints.

Thus a promising solution is to combine the advantages of the tree-to-string and string-to-tree approaches. A natural idea is the tree-to-tree model (Ding and Palmer, 2005; Cowan et al., 2006; Liu et al., 2009). However, as discussed by Chiang (2010), while tree-to-tree translation is indeed promising in theory, in practice it usually ends up over-constrained. Alternatively, Mi and Liu (2010) proposed to enhance the tree-to-string model with target dependency structures (as a language model). In this paper, we explore in the other direction: based on the strong string-to-tree model which builds an explicit target syntactic tree during decoding rather than apply only a syntactic language model, we aim to find a useful way to incorporate the source-side syntax.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 204–215,
Edinburgh, Scotland, UK, July 27–31, 2011.

First, we give a motivating example to show the importance of the source syntax for a string-to-tree model. Then we discuss the difficulties of integrating the source syntax into the string-to-tree model. Finally, we propose our solutions.

Figure 1 depicts a standard process that transforms a Chinese string into an English tree using several string-to-tree translation rules. The tree with solid lines is produced by the baseline string-to-tree system. Although the yield is grammatical, the translation is not correct since the system mistakenly applies rule r_2, thus translating the Chinese preposition 和(hé) in the example sentence into the English conjunction *and*. As a result, the Chinese prepositional phrase '和 恐怖 组织 网' ("with terrorist networks") is wrongly translated as a part of the relevant noun phrase ("[Hussein] and terrorists networks"). Why does this happen? We find that r_2 occurs 103316 times in our training data, while r_3 occurs only 1021 times. Thus, without source syntactic clues, the Chinese word 和(hé) is converted into the conjunction *and* in most cases. In general, this conversion is correct when the word 和(hé) is used as a conjunction. But 和(hé) is a preposition in the source sentence. If we are given this source syntactic clue, rule r_3 will be preferred. This example motivates us to provide a moderate amount of source-side syntactic information so as to obtain the correct English tree with dotted lines (as our proposed system does).

A natural question may arise that is it easy to incorporate source syntax in the string-to-tree model? To the best of our knowledge, no one has studied this approach before. In fact, it is not a trivial question if we look into the string-to-tree model. We find that the difficulties lie in at least three problems: 1) For a string-to-tree rule such as r_6 in figure 1, how should we syntactically annotate its source string? 2) Given the source-annotated string-to-tree rules, how should we match these rules according to the test source tree during decoding? 3) How should we binarize the source-annotated string-to-tree rules for efficient decoding?

For the first problem, one may require the source side of a string-to-tree rule to be a constituent. However, such excessive constraints will exclude many good string-to-tree rules whose source strings are not constituents. Inspired by Chiang (2010), we adopt a fuzzy way to label every source string with the complex syntactic categories of SAMT (Zollmann and Venugopal, 2006). This method leads to a one-to-one correspondence between the new rules and the string-to-tree rules. We will detail our fuzzy labeling method in Section 2.

For the second problem, it appears simple and intuitive to match rules by requiring a rule's source syntactic category to be the same as the category of the test string. However, this hard constraint will greatly narrow the search space during decoding. Continuing to pursue the fuzzy methodology, we adopt a fuzzy matching procedure to enable matching of all the rules whose source strings match the test string, and then determine the degree of matching between the test source tree and each rule. We will discuss three fuzzy matching algorithms, from simple to complex, in Section 3.

The third question is a technical problem, and we will give our solution in Section 4.

Our method not only guarantees the grammaticality of the output via the target tree structure, but also enables the system to choose appropriate translation rules during decoding through source syntactic fuzzy labeling and fuzzy matching.

The main contributions of this paper are as follows:

1) We propose a fuzzy method for both source syntax annotation and rule matching for augmenting string-to-tree models.
2) We design and investigate three fuzzy rule matching algorithms: 0-1 matching, likelihood matching, and deep similarity matching.

We hope that this paper will demonstrate how to effectively incorporate both source and target syntax into a translation model with promising results.

2 Rule Extraction

Since we annotate the source side of each string-to-tree rule with source parse tree information in a fuzzy way, we will henceforward denote the source-syntax-decorated string-to-tree rule as a **fuzzy-tree to exact-tree rule**. We first briefly review issues of string-to-tree rule extraction; then we discuss how to augment the string-to-tree rules to yield fuzzy-tree to exact-tree rules.

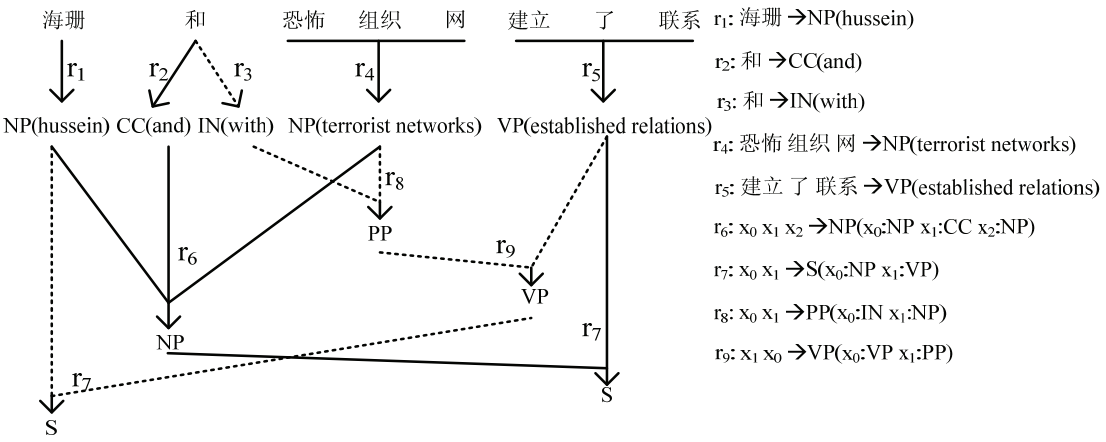

Figure 1: Two alternative derivations for a sample string-to-tree translation. The rules used are listed on the right. The target yield of the tree with solid lines is *hussein and terrorist networks established relations*. The target yield of the tree with dotted lines is *hussein established relations with terrorist networks*.

2.1 String-to-Tree Rule Extraction

Galley et al. (2004) proposed the GHKM algorithm for extracting (minimal) string-to-tree translation rules from a triple (*f, e_t, a*), where *f* is the source-language sentence, e_t is a target-language parse tree whose yield *e* is the translation of *f*, and *a* is the set of word alignments between *e* and *f*. The basic idea of GHKM is to obtain the set of minimally-sized translation rules which can explain the mappings between source string and target parse tree. The minimal string-to-tree rules are extracted in three steps: (1) frontier set computation; (2) fragmentation; and (3) extraction.

The frontier set (**FS**) is the set of potential points at which to cut the graph *G* constructed by the triple (*f, e_t, a*) into fragments. A node satisfying the word alignment is a frontier. ***Bold italic*** nodes in the English parse tree in Figure 2 are all frontiers.

Given the frontier set, a well-formed fragmentation of *G* is generated by restricting each fragment to take only nodes in **FS** as the root and leaf nodes.

With fragmentation completed, the rules are extracted through a depth-first traversal of e_t: for each frontier being visited, a rule is extracted. These extracted rules are called *minimal rules* (Galley et al., 2004). For example, rules $r_a \sim r_i$ in Figure 2 are part of the total of 13 minimal rules.

To improve the rule coverage, SPMT models can be employed to obtain *phrasal rules* (Marcu et at., 2006). In addition, the minimal rules which share the adjacent tree fragments can be connected together to form composed rules (Galley et al., 2006). In Figure 2, r_j is a rule composed by combining r_c and r_g.

2.2 Fuzzy-tree to Exact-tree Rule Extraction

Our fuzzy-tree to exact-tree rule extraction works on word-aligned tree-to-tree data (Figure 2 illustrates a Chinese-English tree pair). Basically, the extraction algorithm includes two parts:

(1) String-to-tree rule extraction (without considering the source parse tree);
(2) Decoration of the source side of the string-to-tree rules with syntactic annotations.

We use the same algorithm introduced in the previous section for extracting the base string-to-tree rules. The source-side syntactic decoration is much more complicated.

The simplest way to decorate, as mentioned in the Introduction, is to annotate the source-side of a string-to-tree rule with the syntactic tag that exactly covers the source string. This is what the exact tree-to-tree procedure does (Liu et al., 2009). However, many useful string-to-tree rules will become invalid if we impose such a tight restriction. For example, in Figure 2, the English phrase *discuss ... them* is a VP, but its Chinese counterpart is not a constituent. Thus we will miss the rule r_h although it is a useful reordering rule. According to the analysis of our training data, the rules with rigid source-side syntactic constraints account for only about 74.5% of the base string-to-tree rules. In this paper, we desire more general applicability.

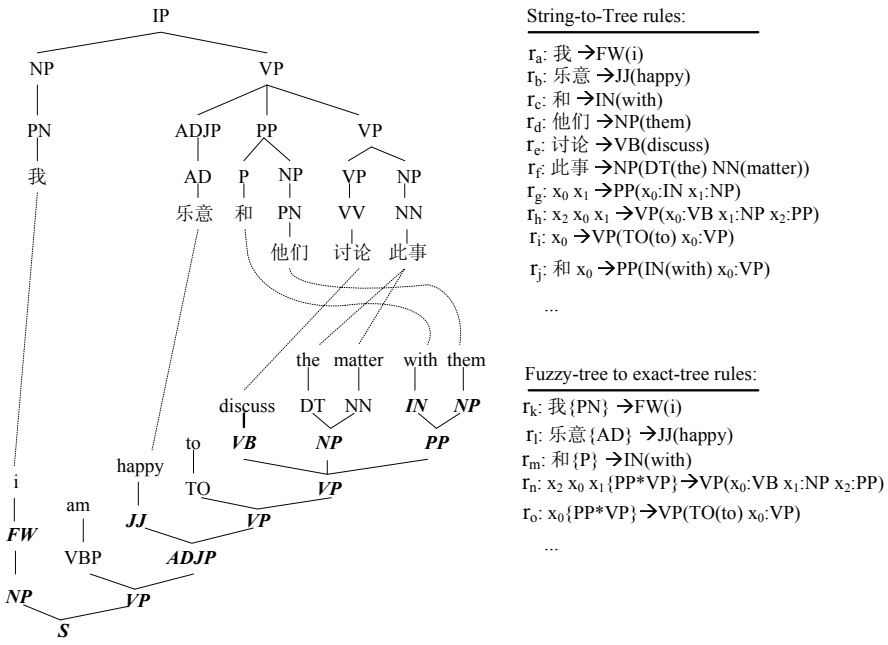

Figure 2: A sample Chinese-English tree pair for rule extraction. The ***bold italic*** nodes in the target English tree are frontiers. **Note that** string-to-tree rules are extracted without considering source-side syntax (upper-right). The new fuzzy-tree to exact-tree rules are extracted with both-side parse trees (bottom-right).

Inspired by (Zollmann and Venugopal, 2006; Chiang, 2010), we resort to SAMT-style syntactic categories in the style of categorial grammar (Bar-Hillel, 1953). The annotation of the source side of string-to-tree rules is processed in three steps: (1) If the source-side string corresponds to a syntactic category C in the source parse tree, we label the source string with C. (2) Otherwise, we check if there exists an extended category of the forms C_1*C_2, C_1/C_2 or $C_2\backslash C_1$[1], indicating respectively that the source string spans two adjacent syntactic categories, a partial syntactic category C_1 missing a C_2 on the right, or a partial C_1 missing a C_2 on the left. (3) If the second step fails, we check if there is an extended category of the forms C_1*C_2*C_3 or $C_1..C_2$, showing that the source string spans three adjacent syntactic categories or a partial category with C_1 and C_2 on each side. In the worst case, $C_1..C_2$ can denote every source string, thus all of the decorations in our training data can be explained within the above three steps. Using the SAMT-style grammar, each source string can be associated with a syntactic category. Thus our fuzzy-tree to exact-tree extraction does not lose any rules as compared with string-to-tree extraction. For example, rule r_o in Figure 2 uses the product category $PP*VP$ on the source side.

A problem may arise: How should we handle the situation where several rules are observed which only differ in their source-side syntactic categories? For example, besides the rule r_m in Figure 2, we encountered rules like $和\{CC\} \rightarrow IN(with)$ in the training data. Which source tag should we retain? We do not make a partial choice in the rule extraction phase. Instead, we simply make a union of the relevant rules and retain the respective tag counts. Applying this strategy, the rule takes the form of $和\{P:6, CC:4\} \rightarrow IN(with)$[2], indicating that the source-side preposition tag appears six times while the conjunction occurs four times. Note that the final rule format used in translation depends on the specific fuzzy rule matching algorithm adopted.

3 Fuzzy Rule Matching Algorithms

The extracted rules will ultimately be applied to derive translations during decoding. One way to apply the fuzzy-tree to exact-tree rules is to narrow the rule search space. Given a test source sentence

[1] The kinds of categories are checked in order. This means that if C_1*C_2, C_1/C_2 can both describe the same source string, we will choose C_1*C_2.

[2] 6 and 4 are not real counts. They are used for illustration only.

with its parse tree, we can according to this strategy choose only the rules whose source syntax matches the test source tree. However, this restriction will rule out many potentially correct rules. In this study, we keep the rule search space identical to that of the string-to-tree setting, and postpone the use of source-side syntax until the derivation stage. During derivation, a fuzzy matching algorithm will be adopted to compute a score to measure the compatibility between the rule and the test source syntax. The translation model will learn to distinguish good rules from bad ones via the compatibility scores.

In this section, three fuzzy matching algorithms, from simple to complex, are investigated in order.

3.1 0-1 Matching

0-1 matching is a straightforward approach that rewards rules whose source syntactic category exactly matches the syntactic category of the test string and punishes mismatches. It has mainly been employed in hierarchical phrase-based models for integrating source or both-side syntax (Marton and Resnik, 2008; Chiang et al., 2009; Chiang, 2010). Since it is verified to be very effective in hierarchical models, we borrow this idea in our source-syntax-augmented string-to-tree translation.

In 0-1 matching, the rule's source side must contain only one syntactic category, but a rule may have been decorated with more than one syntactic category on the source side. Thus we have to choose the most reliable category and discard the others. Here, we select the one with the highest frequency. For example, the tag *P* in the rule $和\{P:6, CC:4\} \rightarrow IN(with)$ appears more frequently, so the final rule used in 0-1 matching will be $和\{P\} \rightarrow IN(with)$. Accordingly, we design two features:

1. *match_count* calculates in a derivation the number of rules whose source-side syntactic category matches the syntactic category of the test string.
2. *unmatch_count* counts the number of mismatches.

For example, in the derivations of Figure 1, we know the Chinese word 和(hé) is a preposition in this sentence (and thus can be written as P(和)), therefore, *match_count += 1* if the above rule $和\{P\} \rightarrow IN(with)$ is employed.

These two features are integrated into the log-linear translation model and the corresponding feature weights will be tuned along with other model features to learn which rules are preferred.

3.2 Likelihood Matching

It appears intuitively that the 0-1 matching algorithm does not make full use of the source-side syntax because it keeps only the most-frequent syntactic label and discards some potentially useful information. Therefore, it runs the risk of treating all the discarded source syntactic categories of the rule as equally likely. For example, there is an extracted rule as follows:

$的\{DEC:11233, DEG:11073, DEV:65\} \rightarrow IN(of)$

0-1 matching converts it into $的\{DEC\} \rightarrow IN(of)$. The use of this rule will be penalized if the syntactic category of the test string 的(dē) is parsed as *DEG* or *DEV*. On one hand, the frequency of the tag *DEG* is just slightly less than that of *DEC*, but the 0-1 matching punishes the former while rewarding the latter. On the other hand, the frequency of *DEG* is much more than that of *DEV*, but they are penalized equally. It is obvious that the syntactic categories are not finely distinguished.

Considering this situation, we propose the likelihood matching algorithm. First, we compute the likelihood of the rule's source syntactic categories. Since we need to deal with the potential problem that the rule is hit by the test string but the syntactic category of the test string is not in the category set of the rule's source side, we apply the *m*-estimate of probability (Mitchell, 1997) to calculate a smoothed likelihood

$$likelihood_c = \frac{n_c + mp}{n + m} \quad (1)$$

in which n_c is the count of each syntactic category *c* in a specific rule, *n* denotes the total count of the rule, *m* is a constant called the equivalent sample size, and *p* is the prior probability of the category *c*. In our work, we set the constant *m=1* and the prior *p* to 1/12599 where 12599 is the total number of source-side syntactic categories in our training data. For example, the rule $和\{P:6, CC:4\} \rightarrow IN(with)$ becomes $和\{P:0.545, CC:0.364, 7.2e\text{-}6\} \rightarrow IN(with)$ after likelihood computation. Then, if we apply likelihood matching in the derivations in Figure 1 where the test string is 和 and its syntax is P(和),

the matching score with the above rule will be 0.545. When the test Chinese word 和 is parsed as a category other than *P* or *CC*, the matching score with the above rule will be 7.2e-6.

Similar to 0-1 matching, likelihood matching will serve as an additional model feature representing the compatibility between categories and rules.

3.3 Deep Similarity Matching

Considering the two algorithms above, we can see that the purpose of fuzzy matching is in fact to calculate a similarity. 0-1 matching assigns similarity 1 for exact matches and 0 for mismatch, while likelihood matching directly utilizes the likelihood to measure the similarity. Going one step further, we adopt a measure of deep similarity, computed using latent distributions of syntactic categories. Huang et al. (2010) proposed this method to compute the similarity between two syntactic tag sequences, used to impose soft syntactic constraints in hierarchical phrase-based models. Analogously, we borrow this idea to calculate the similarity between two SAMT-style syntactic categories, and then apply it to calculate the degree of matching between a translation rule and the syntactic category of a test source string for purposes of fuzzy matching. We call this procedure **deep similarity matching**.

Instead of directly using the SAMT-style syntactic categories, we represent each category by a real-valued feature vector. Suppose there is a set of *n* latent syntactic categories $V=(v_1,\cdots,v_n)$ (*n=16* in our experiments). For each SAMT-style syntactic category, we compute its distribution of latent syntactic categories $\vec{P}_c(V)=(P_c(v_1),\cdots,P_c(v_n))$. For example, $\vec{P}_{VP*NP}(V)=(0.4, 0.2, 0.3, 0.1)$ means that the latent syntactic categories v_1, v_2, v_3, v_4 are distributed as $p(v_1)$=0.4, $p(v_2)$=0.2, $p(v_3)$=0.3 and $p(v_4)$=0.1 for the SAMT-style syntactic category *VP*NP*. Then we further transform the distribution to a normalized feature vector $\vec{F}(c)=\vec{P}_c(V)/\left\|\vec{P}_c(V)\right\|$ to represent the SAMT-style syntactic category *c*.

With the real-valued vector representation for each SAMT-style syntactic category, the degree of similarity between two syntactic categories can be simply computed as a dot-product of their feature vectors:

$$\vec{F}(c)\cdot\vec{F}(c')=\sum_{1\le i\le n} f_i(c)f_i(c') \quad (2)$$

This computation yields a similarity score ranging from 0 (totally different syntactically) to 1 (totally identical syntactically).

Since we can now compute the similarity of any syntactic category pair, we are currently ready to compute the matching degree between the syntactic category of a test source string and a fuzzy-tree to exact-tree rule. To do this, we first convert the original fuzzy-tree to exact-tree rule to the rule of likelihood format without any smoothing. For example, the rule $和\{P:6, CC:4\}\rightarrow IN(with)$ becomes $和\{P:0.6, CC:0.4\}\rightarrow IN(with)$ after conversion. We then denote the syntax of a rule's source-side ***RS*** by weighting all the SAMT-style categories in RS

$$\vec{F}(RS)=\sum_{c\in RS} P_{RS}(c)\vec{F}(c) \quad (3)$$

where $P_{RS}(c)$ is the likelihood of the category *c*. Finally, the deep similarity between a SAMT-style syntactic category *tc* of a test source string and a fuzzy-tree to exact-tree rule is computed as follows:

$$DeepSim(tc, RS)=\vec{F}(tc)\cdot\vec{F}(RS) \quad (4)$$

This deep similarity score will serve as a useful feature in the string-to-tree model which will enable the model to learn how to take account of the source-side syntax during translation.

We have ignored the details of latent syntactic category induction in this paper. In brief, the set of latent syntactic categories is automatically induced from a source-side parsed, word-aligned parallel corpus. The EM algorithm is employed to induce the parameters. We simply follow the algorithm of (Huang et al., 2010), except that we replace the tag sequence with SAMT-style syntactic categories.

4 Rule Binarization

In the baseline string-to-tree model, the rules are not in Chomsky Normal Form. There are several ways to ensure cubic-time decoding. One way is to prune the extracted rules using a scope-3 grammar and do SCFG decoding without binarization (Hopkins and Lengmead, 2010). The other, and most popular way is to binarize the translation rules (Zhang et al., 2006). We adopt the latter approach for efficient decoding with integrated *n*-gram language models since this binarization technique has been well studied in string-to-tree

translation. However, when the rules' source string is decorated with syntax (fuzzy-tree to exact-tree rules), how should we binarize these rules?

We use the rule r_n in Figure 2 for illustration:

$r_n:\ x_2\ x_0\ x_1\ \{PP*VP\} \rightarrow VP(x_0:VB\ \ x_1:NP\ \ x_2:PP)$.

Without regarding the source-side syntax, we obtain the following two binarized rules:

$$B1:\quad x_2\ x_{0*1} \rightarrow VP\left(x_{0*1}:V_{x_0*x_1}\ \ x_2:PP\right)$$

$$B2:\quad x_0\ x_1 \rightarrow V_{x_0*x_1}\left(x_0:VB\ \ x_1:NP\right)$$

Since the source-side syntax *PP*VP* in rule r_n only accounts for the entire source side, it is unclear how to annotate the source side of a partial rule such as the second binary rule *B2*.

Analyzing the derivation process, we observe that a partial rule such as binary rule *B2* never appears in the final derivation unless the rooted binary rule *B1* also appears in the derivation. Based on this observation, we design a heuristic[3] strategy: we simply attach the syntax *PP*VP* in the rooted binary rule *B1*, and do not decorate other binary rules with source syntax. Thus rule r_n will be binarized as:

$$(1)\quad x_2\ x_{0*1}\ \{PP*VP\} \rightarrow VP\left(x_{0*1}:V_{x_0*x_1}\ \ x_2:PP\right)$$

$$(2)\quad x_0\ x_1 \rightarrow V_{x_0*x_1}\left(x_0:VB\ \ x_1:NP\right)$$

5 Translation Model and Decoding

The proposed translation system is an augmentation of the string-to-tree model. In the baseline string-to-tree model, the decoder searches for the optimal derivation d^* that parses a source string f into a target tree e_t from all possible derivations D:

$$d^* = \arg\max_{d\in D} \lambda_1 \log p_{LM}\left(\tau(d)\right) + \lambda_2\left|\tau(d)\right| + \lambda_3|d| + R(d\mid f) \quad (5)$$

where the first element is a language model score in which $\tau(d)$ is the target yield of derivation d; the second element is the translation length penalty; the third element is used to control the derivation length; and the last element is a translation score that includes six features:

$$\begin{aligned} R(d\mid f) = &\sum_{r\in d} \lambda_4 \log p\left(r \mid root(r)\right) + \lambda_5 \log p\left(r \mid lhs(r)\right) \\ &+ \lambda_6 \log p\left(r \mid rhs(r)\right) + \lambda_7 \log p_{lex}\left(lhs(r) \mid rhs(r)\right) \\ &+ \lambda_8 \log p_{lex}\left(rhs(r) \mid lhs(r)\right) + \lambda_9 \delta\left(is\_comp\right) \end{aligned} \quad (6)$$

In equation (6), the first three elements denote the conditional probability of the rule given the root, the source-hand side, and the target-hand side. The next two elements are bidirectional lexical translation probabilities. The last element is the preferred binary feature for learning: either the composed rule or the minimal rule.

In our source-syntax-augmented model, the decoder also searches for the best derivation. With the help of the source syntactic information, the derivation rules in our new model are much more distinguishable than that in the string-to-tree model:

$$d^* = \arg\max_{d\in D} \lambda_1 \log p_{LM}\left(\tau(d)\right) + \lambda_2\left|\tau(d)\right| + \lambda_3|d| + \overline{R}(d\mid f) \quad (7)$$

Here, all elements except the last one are the same as in the string-to-tree model. The last item is:

$$\begin{aligned} \overline{R}(d\mid f) = &R(d\mid f) \\ &+ \sum_{r\in d} \delta(DeepSim)\lambda_{10} \log\left(DeepSim(tag, r)\right) \\ &+ \delta(likelihood)\lambda_{11} \log\left(likelihood(tag, r)\right) \\ &+ \delta(01)\left\{\lambda_{12}\delta(match) + \lambda_{13}\delta(unmatch)\right\} \end{aligned} \quad (8)$$

The 0-1 matching[4] is triggered only when we set $\delta(01)=1$. The other two fuzzy matching algorithms are triggered in a similar way.

During decoding, we use a CKY-style parser with beam search and cube-pruning (Huang and Chiang, 2007) to decode the new source sentences.

6 Experiments

6.1 Experimental Setup

The experiments are conducted on Chinese-to-English translation, with training data consisting of about 19 million English words and 17 million Chinese words[5]. We performed bidirectional word alignment using GIZA++, and employed the *grow-diag-final* balancing strategy to generate the final

[3] We call it heuristic because there may be other syntactic annotation strategies for the binarized rules. It should be noted that our strategy makes the annotated binarized rules equivalent to the original rule.

[4] In theory, the features *unmatch_count*, *match_count* and *derivation_length* are linearly dependent, so the *unmatch_count* is redundant. In practice, since the derivation may include glue rules which are not scored by fuzzy matching. Thus, "*unmatch_count* + *match_count* + *glue_rule_number* = *derivation_length*".

[5] LDC catalog number: LDC2002E18, LDC2003E14, LDC2003E07, LDC2004T07 and LDC2005T06.

symmetric word alignment. We parsed both sides of the parallel text with the Berkeley parser (Petrov et al., 2006) and trained a 5-gram language model with the target part of the bilingual data and the Xinhua portion of the English Gigaword corpus.

For tuning and testing, we use NIST MT evaluation data for Chinese-to-English from 2003 to 2006 (MT03 to MT06). The development data set comes from MT06 in which sentences with more than 20 words are removed to speed up MERT[6] (Och, 2003). The test set includes MT03 to MT05.

We implemented the baseline string-to-tree system ourselves according to (Galley et al., 2006; Marcu et al., 2006). We extracted minimal GHKM rules and the rules of SPMT Model 1 with source language phrases up to length *L=4*. We further extracted composed rules by composing two or three minimal GHKM rules. We also ran the state-of-the-art hierarchical phrase-based system Joshua (Li et al., 2009) for comparison. In all systems, we set the beam size to 200. The final translation quality is evaluated in terms of case-insensitive BLEU-4 with shortest length penalty. The statistical significance test is performed using the re-sampling approach (Koehn, 2004).

6.2 Results

Table 1 shows the translation results on development and test sets. First, we investigate the performance of the strong baseline string-to-tree model (*s2t* for short). As the table shows, *s2t* outperforms the hierarchical phrase-based system *Joshua* by more than 1.0 BLEU point in all translation tasks. This result verifies the superiority of the baseline string-to-tree model.

With the *s2t* system providing a baseline, we further study the effectiveness of our source-syntax-augmented string-to-tree system with fuzzy-tree to exact-tree rules (we use *FT2ET* to denote our proposed system). The last three lines in Table 1 show that, for each fuzzy matching algorithm, our new system *TF2ET* performs significantly better than the baseline *s2t* system, with an improvement of more than 0.5 absolute BLEU points in all tasks. This result demonstrates the success of our new method of incorporating source-side syntax in a string-to-tree model.

[6] The average decoding speed is about 50 words per minute in the baseline string-to-tree system and our proposed systems.

System		MT06 (dev)	MT03	MT04	MT05

Table 2: Example of similar and dissimilar categories.

Specifically, the *FT2ET* system with *deep similarity matching* obtains the best translation quality in all tasks and surpasses the baseline *s2t* system by 0.93 BLEU points in development data and by more than 1.0 BLEU point in test sets. The *0-1 matching* algorithm is simple but effective, and it yields quite good performance (line 3). The contribution of *0-1 matching* as reflected in our experiments is consistent with the conclusions of (Marton and Resnik, 2008; Chiang, 2010). By contrast, the system with *likelihood matching* does not perform as well as the other two algorithms, although it also significantly improves the baseline *s2t* in all tasks.

6.3 Analysis and Discussion

We are a bit surprised at the large improvement gained by the 0-1 matching algorithm. This algorithm has several advantages: it is simple and easy to implement, and enhances the translation model by enabling its rules to take account of the source-side syntax to some degree. However, a major deficiency of this algorithm is that it does not make full use of the source side syntax, since it retains only the most frequent SAMT-style syntactic category to describe the rule's source syntax. Thus this algorithm penalizes all the other categories equally, although some may be more frequent than others, as in the case of *DEG* and *DEV* in the rule 的$\{DEC:11233, DEG:11073, DEV:65\}\rightarrow IN(of)$.

To some extent, the likelihood matching algorithm solves the main problem of 0-1 matching.

Instead of rewarding or penalizing, this algorithm uses the likelihood of the syntactic category to approximate the degree of matching between the test source syntactic category and the rule. For a category not in the rule's source syntactic category set, the likelihood algorithm computes a smoothed likelihood. However, the likelihood algorithm does not in fact lead to very promising improvement. We conjecture that this disappointing performance is due to the simple smoothing method we employed. Future work will investigate more fully.

Compared with the above two matching algorithms, the deep similarity matching algorithm based on latent syntactic distribution is much more beautiful in theory. This algorithm can successfully measure the similarity between any two SAMT-style syntactic categories (Table 2 gives some examples of similar and dissimilar category pairs). Then it can accurately compute the degree of matching between a test source syntactic category and a fuzzy-tree to exact-tree rule. Thus this algorithm obtains the best translation quality. However, the deep similarity matching algorithm has two practical shortcomings. First, it is not easy to determine the number of latent categories. We have to conduct multiple experiments to arrive at a number which can yield a tradeoff between translation quality and model complexity. In our work, we have tried the numbers *n=4, 8, 16, 32,* and have found *n=16* to give the best tradeoff. The second shortcoming is that the induction of latent syntactic categories has been very time consuming, since we have applied the EM algorithm to the entire source-parsed parallel corpus. Even with *n=8*, it took more than a week to induce the latent syntactic categories on our middle-scale training data when using a Xeon four-core computer ($2.5GHz \times 2CPU \times 16GB\ memory$). When the training data contains tens of millions of sentence pairs, the computation time may no longer be tolerable.

Table 3 shows some translation examples for comparison. In the first example, the Chinese preposition word *和* is mistakenly translated into English conjunction word *and* in *Joshua* and baseline string-to-tree system *s2t*, however, our source-syntax-augmented system *FT2ET-DeepSim* correctly converts the Chinese word *和* into English preposition *with* and finally yield the right translation. In the second example, our proposed system moves the prepositional phrase *at an early date* after the sibling verb phrase. It is more reasonable compared with the baseline system *s2t*. In the third example, the proposed system *FT2ET-DeepSim* successfully recognizes the Chinese long prepositional phrase *在 与 中国 总理 温家宝 举行 峰会 后 发布 的联合 声明 中* and short verb phrase *说*, and obtains the correct phrase reordering at last.

7 Related Work

Several studies have tried to incorporate source or target syntax into translation models in a fuzzy manner.

Zollmann and Venugopal (2006) augment the hierarchical string-to-string rules (Chiang, 2005) with target-side syntax. They annotate the target side of each string-to-string rule using SAMT-style syntactic categories and aim to generate the output more syntactically. Zhang et al. (2010) base their approach on tree-to-string models, and generate grammatical output more reliably with the help of tree-to-tree sequence rules. Neither of them builds target syntactic trees using target syntax, however. Thus they can be viewed as integrating target syntax in a fuzzy manner. By contrast, we base our approach on a string-to-tree model which does construct target syntactic trees during decoding.

(Marton and Resnik, 2008; Chiang et al., 2009 and Huang et al., 2010) apply fuzzy techniques for integrating source syntax into hierarchical phrase-based systems (Chiang, 2005, 2007). The first two studies employ 0-1 matching and the last tries deep similarity matching between two tag sequences. By contrast, we incorporate source syntax into a string-to-tree model. Furthermore, we apply fuzzy syntactic annotation on each rule's source string and design three fuzzy rule matching algorithms.

Chiang (2010) proposes a method for learning to translate with both source and target syntax in the framework of a hierarchical phrase-based system. He not only executes 0-1 matching on both sides of rules, but also designs numerous features such as $root_{X,X'}$ which counts the number of rules whose source-side root label is X and target-side root label is X'. This fuzzy use of source and target syntax enables the translation system to learn which tree labels are similar enough to be compatible, which ones are harmful to combine, and which ones can be ignored. The differences between us are twofold: 1) his work applies fuzzy syntax in both sides, while ours bases on the string-

to-tree model and applies fuzzy syntax on source side; and 2) we not only adopt the 0-1 fuzzy rule matching algorithm, but also investigate likelihood matching and deep similarity matching algorithms.

8 Conclusion and Future Work

In this paper, we have proposed a new method for augmenting string-to-tree translation models with fuzzy use of the source syntax. We first applied a fuzzy annotation method which labels the source side of each string-to-tree rule with SAMT-style syntactic categories. Then we designed and explored three fuzzy rule matching algorithms: 0-1 matching, likelihood matching, and deep similarity matching. The experiments show that our new system significantly outperforms the strong baseline string-to-tree system. This substantial improvement verifies that our fuzzy use of source syntax is effective and can enhance the ability to choose proper translation rules during decoding while guaranteeing grammatical output with explicit target trees. We believe that our work may demonstrate effective ways of incorporating both-side syntax in a translation model to yield promising results.

Next, we plan to further study the likelihood fuzzy matching and deep similarity matching algorithms in order to fully exploit their potential. For example, we will combine the merits of 0-1 matching and likelihood matching so as to avoid the setting of parameter *m* in likelihood matching. We also plan to explore another direction: we will annotate the source side of each string-to-tree rule with subtrees or subtree sequences. We can then apply tree-kernel methods to compute a degree of matching between a rule and a test source subtree or subtree sequence.

Acknowledgments

The research work has been funded by the Natural Science Foundation of China under Grant No. 60975053, 61003160 and 60736014 and supported by the External Cooperation Program of the Chinese Academy of Sciences. Abstract

Dependency structure, as a first step towards semantics, is believed to be helpful to improve translation quality. However, previous works on dependency structure based models typically resort to insertion operations to complete translations, which make it difficult to specify ordering information in translation rules. In our model of this paper, we handle this problem by directly specifying the ordering information in head-dependents rules which represent the source side as head-dependents relations and the target side as strings. The head-dependents rules require only substitution operation, thus our model requires no heuristics or separate ordering models of the previous works to control the word order of translations. Large-scale experiments show that our model performs well on long distance reordering, and outperforms the state-of-the-art constituency-to-string model (+1.47 BLEU on average) and hierarchical phrase-based model (+0.46 BLEU on average) on two Chinese-English NIST test sets without resort to phrases or parse forest. For the first time, a source dependency structure based model catches up with and surpasses the state-of-the-art translation models.

1 Introduction

Dependency structure represents the grammatical relations that hold between the words in a sentence. It encodes semantic relations directly, and has the best inter-lingual phrasal cohesion properties (Fox, 2002). Those attractive characteristics make it possible to improve translation quality by using dependency structures.

Some researchers pay more attention to use dependency structure on the target side. (Shen et al., 2008) presents a string-to-dependency model, which restricts the target side of each hierarchical rule to be a well-formed dependency tree fragment, and employs a dependency language model to make the output more grammatically. This model significantly outperforms the state-of-the-art hierarchical phrase-based model (Chiang, 2005). However, those string-to-tree systems run slowly in cubic time (Huang et al., 2006).

Using dependency structure on the source side is also a promising way, as tree-based systems run much faster (linear time vs. cubic time, see (Huang et al., 2006)). Conventional dependency structure based models (Lin, 2004; Quirk et al., 2005; Ding and Palmer, 2005; Xiong et al., 2007) typically employ both substitution and insertion operation to complete translations, which make it difficult to specify ordering information directly in the translation rules. As a result, they have to resort to either heuristics (Lin, 2004; Xiong et al., 2007) or separate ordering models (Quirk et al., 2005; Ding and Palmer, 2005) to control the word order of translations.

In this paper, we handle this problem by directly specifying the ordering information in head-dependents rules that represent the source side as head-dependents relations and the target side as string. The head-dependents rules have only one substitution operation, thus we don't face the problems appeared in previous work and get rid of the

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 216–226,
Edinburgh, Scotland, UK, July 27–31, 2011.

heuristics and ordering model. To alleviate data sparseness problem, we generalize the lexicalized words in head-dependents relations with their corresponding categories.

In the following parts, we first describe the motivation of using head-dependents relations (Section 2). Then we formalize our grammar (Section 3), present our rule acquisition algorithm (Section 4), our model (Section 5) and decoding algorithm (Section 6). Finally, large-scale experiments (Section 7) show that our model exhibits good performance on long distance reordering, and outperforms the state-of-the-art tree-to-string model (+1.47 BLEU on average) and hierarchical phrase-based model (+0.46 BLEU on average) on two Chinese-English NIST test sets. For the first time, a source dependency tree based model catches up with and surpasses the state-of-the-art translation models.

2 Dependency Structure and Head-Dependents Relation

2.1 Dependency Sturcture

A dependency structure for a sentence is a directed acyclic graph with words as nodes and modification relations as edges. Each edge direct from a head to a dependent. Figure 1 (a) shows an example dependency structure of a Chinese sentence.

2010年 FIFA 世界杯 在 南非 成功 举行

2010 FIFA [World Cup] in/at [South Africa] successfully hold

Each node is annotated with the part-of-speech (POS) of the related word.

For convenience, we use the lexicon dependency grammar (Hellwig, 2006) which adopts a bracket representation to express a projective dependency structure. The dependency structure of Figure 1 (a) can be expressed as:

((2010年) (FIFA) 世界杯) (在(南非)) (成功) 举行

where the lexicon in brackets represents the dependents, while the lexicon out the brackets is the head.

To construct the dependency structure of a sentence, the most important thing is to establish dependency relations and distinguish the head from the dependent. Here are some criteria (Zwicky, 1985; Hudson, 1990) for identifying a syntactic relation between a *head* and a *dependent* between a head-dependent pair:

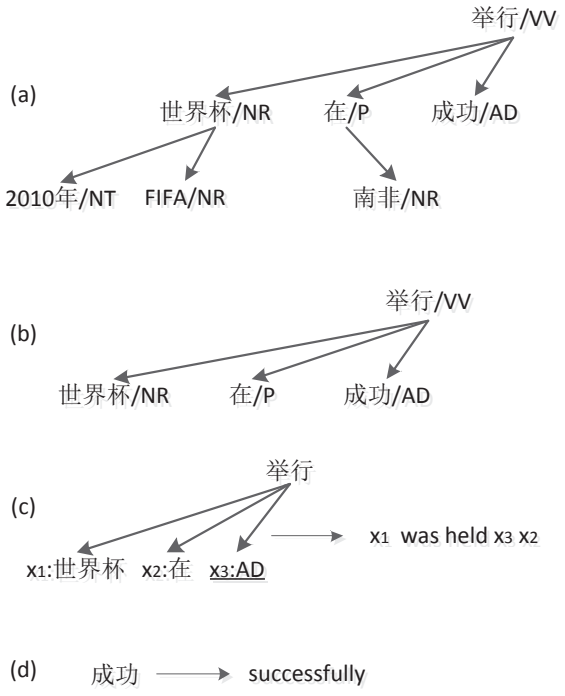

Figure 1: Examples of dependency structure (a), head-dependents relation (b), head-dependents rule (r_1 of Figure 2) and head rule (d). Where "x_1:世界杯" and "x_2:在" indicate substitution sites which can be replaced by a subtree rooted at "世界杯" and "在" respectively. "x_3:AD"indicates a substitution site that can be replaced by a subtree whose root has part-of-speech "AD". The underline denotes a leaf node.

1. *head* determines the syntactic category of *C*, and can often replace *C*;
2. *head* determines the semantic category of *C*; *dependent* gives semantic specification.

2.2 Head-Dependents Relation

A head-dependents relation is composed of a head and all its dependents as shown in Figure 1(b).

Since all the head-dependent pairs satisfy criteria 1 and 2, we can deduce that a head-dependents relation *L* holds the property that *the head determines the syntactic and semantic categories of L, and can often replace L.* Therefore, we can recur-

sively replace the bottom level head-dependent relations of a dependency structure with their heads until the root. This implies an representation of the generation of a dependency structure on the basis of head-dependents relation.

Inspired by this, we represent the translation rules of our dependency-to-string model on the foundation of head-dependents relations.

3 Dependency-to-String Grammar

Figure 1 (c) and (d) show two examples of the translation rules used in our dependency-to-string model. The former is an example of *head-dependent rules* that represent the source side as head-dependents relations and act as both translation rules and reordering rules. The latter is an example of *head rules* which are used for translating words.

Formally, a dependency-to-string grammar is defined as a tuple $\langle \Sigma, N, \Delta, R \rangle$, where Σ is a set of source language terminals, N is a set of categories for the terminals in Σ , Δ is a set of target language terminals, and R is a set of translation rules. A rule r in R is a tuple $\langle t, s, \phi \rangle$, where:

- t is a node labeled by terminal from Σ; or a head-dependents relation of the source dependency structures, with each node labeled by a terminal from Σ or a variable from a set $X = \{x_1, x_2, ...\}$ constrained by a terminal from Σ or a category from N;
- $s \in (X \cup \Delta)^*$ is the target side string;
- ϕ is a one-to-one mapping from nonterminals in t to variables in s.

For example, the head-dependents rule shown in Figure 1 (c) can be formalized as:

t = ((x_1:世界杯) (x_2:在) ($\underline{x_3}$:AD) 举行)
s = x_1 was held x_3 x_2
ϕ = {x_1:世界杯 $\leftrightarrow$ x_1, x_2:在 $\leftrightarrow$ x_2, x_3:AD $\leftrightarrow$ x_3}

where the underline indicates a leaf node, and x_i:*letters* indicates a pair of variable and its constraint.

A derivation is informally defined as a sequence of steps converting a source dependency structure into a target language string, with each step applying one translation rule. As an example, Figure 2 shows the derivation for translating a Chinese (CH) sentence into an English (EN) string.

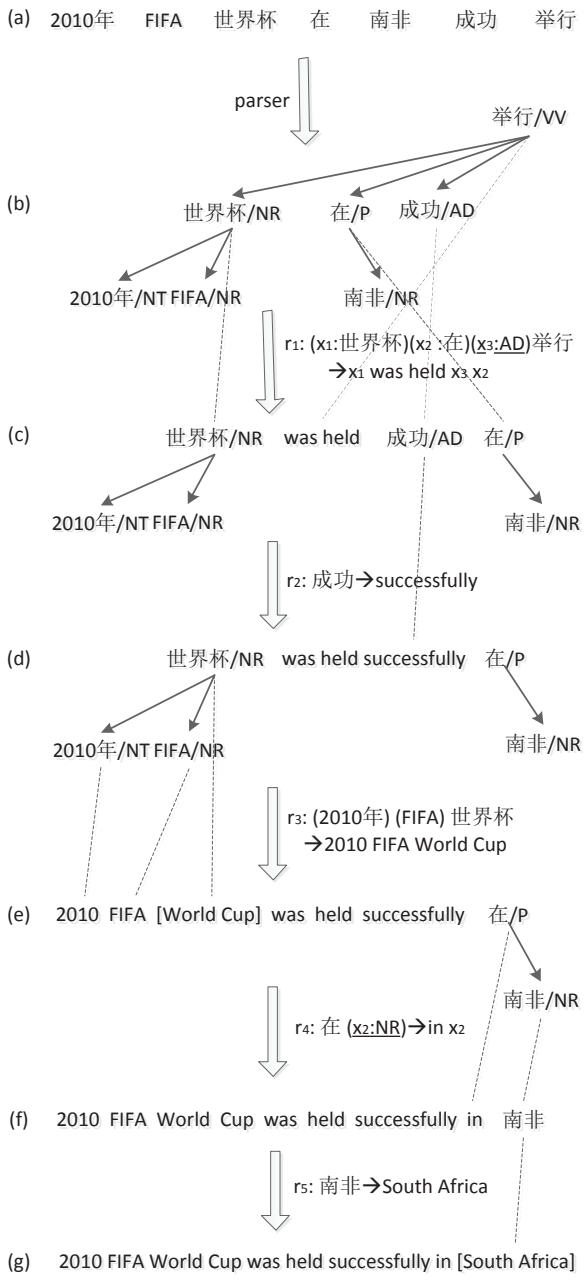

Figure 2: An example derivation of dependency-to-string translation. The dash lines indicate the reordering when employing a head-dependents rule.

CH 2010年 FIFA 世界杯 在 南非 成功 举行

EN *2010 FIFA World Cup was held successfully in South Africa*

The Chinese sentence (a) is first parsed into a dependency structure (b), which is converted into an English string in five steps. First, at the root node, we apply head-dependents rule r_1 shown in Figure 1(c) to translate the top level head-dependents relation and result in three unfinished substructures and target string in (c). The rule is particular interesting since it captures the fact: in Chinese prepositional phrases and adverbs typically modify verbs on the left, whereas in English prepositional phrases and adverbs typically modify verbs on the right. Second, we use head rule r_2 translating "成功" into "successfully" and reach situation (d). Third, we apply head-dependents rule r_3 translating the head-dependents relation rooted at "世界杯" and yield (e). Fourth, head-dependents rules r_5 partially translate the subtree rooted at "在" and arrive situation in (f). Finally, we apply head rule r_5 translating the residual node "南非" and obtain the final translation in (g).

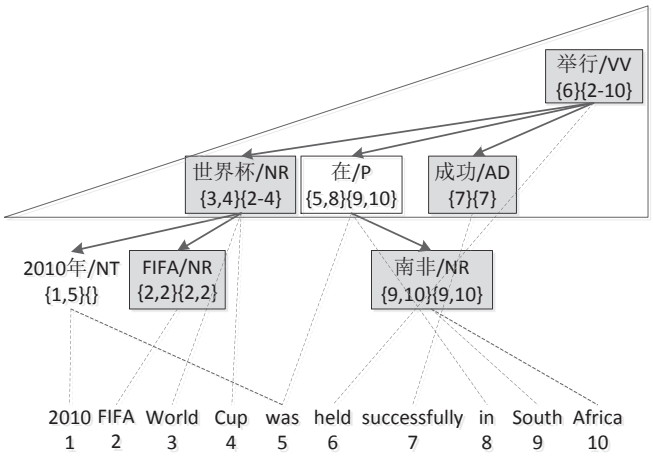

Figure 3: An annotated dependency structure. Each node is annotated with two spans, the former is head span and the latter dependency span. The nodes in *acceptable head set* are displayed in gray, and the nodes in *acceptable dependent set* are denoted by boxes. The triangle denotes the only acceptable head-dependents fragment.

4 Rule Acquisition

The rule acquisition begins with a word-aligned corpus: a set of triples $\langle T, S, A\rangle$, where T is a source dependency structure, S is a target side sentence, and A is an alignment relation between T and S. We extract from each triple $\langle T, S, A\rangle$ head rules that are consistent with the word alignments and head-dependents rules that satisfy the intuition that syntactically close items tend to stay close across languages. We accomplish the rule acquisition through three steps: tree annotation, head-dependents fragments identification and rule induction.

4.1 Tree Annotation

Given a triple $\langle T, S, A\rangle$ as shown in Figure 3, we first annotate each node n of T with two attributes: head span and dependency span, which are defined as follows.

Definition 1. *Given a node n, its **head span** $hsp(n)$ is a set of index of the target words aligned to n.*

For example, hsp(2010年)=$\{1, 5\}$, which corresponds to the target words "*2010*" and "*was*".

Definition 2. *A head span $hsp(n)$ is **consistent** if it satisfies the following property:*

$$\forall_{n' \neq n} hsp(n') \cap hsp(n) = \varnothing.$$

For example, hsp(南非) is consistent, while hsp(2010年) is not consistent since hsp(2010年) $\cap$ hsp(在) $= 5$.

Definition 3. *Given a head span $hsp(n)$, its **closure** cloz(hsp(n)) is the smallest contiguous head span that is a superset of $hsp(n)$.*

For example, $cloz(hsp$(2010年)) = $\{1, 2, 3, 4, 5\}$, which corresponds to the target side word sequence "*2010 FIFA World Cup was*". For simplicity, we use $\{$1-5$\}$ to denotes the contiguous span $\{1, 2, 3, 4, 5\}$.

Definition 4. *Given a subtree T' rooted at n, the **dependency span** $dsp(n)$ of n is defined as:*

$$dsp(n) = cloz(\bigcup_{\substack{n' \in T' \\ hsp(n') \text{ is consistent}}} hsp(n')).$$

If the head spans of all the nodes of T' is not consistent, $dsp(n) = \varnothing$.

For example, since hsp(在) is not consistent, dsp(在)=dsp(南非)=$\{9, 10\}$, which corresponds to the target words "*South*" and "*Africa*".

The tree annotation can be accomplished by a single postorder transversal of T. The extraction of *head rules* from each node can be readily achieved with the same criteria as (Och and Ney, 2004). In

the following, we focus on *head-dependents rules* acquisition.

4.2 Head-Dependents Fragments Identification

We then identify the head-dependents fragments that are suitable for rule induction from the annotated dependency structure.

To facilitate the identification process, we first define two sets of dependency structure related to head spans and dependency spans.

Definition 5. *A **acceptable head set** ahs(T) of a dependency structure T is a set of nodes, each of which has a consistent head span.*

For example, the elements of the acceptable head set of the dependency structure in Figure 3 are displayed in gray.

Definition 6. *A **acceptable dependent set** adt(T) of a dependency structure T is a set of nodes, each of which satisfies:* $dep(n) \neq \varnothing$.

For example, the elements of the acceptable dependent set of the dependency structure in Figure 3 are denoted by boxes.

Definition 7. *We say a head-dependents fragments is **acceptable** if it satisfies the following properties:*

1. *the root falls into acceptable head set;*
2. *all the sinks fall into acceptable dependent set.*

An acceptable head-dependents fragment holds the property that the head span of the root and the dependency spans of the sinks do not overlap with each other, which enables us to determine the reordering in the target side.

The identification of *acceptable* head-dependents fragments can be achieved by a single preorder transversal of the annotated dependency structure. For each accessed internal node n, we check whether the head-dependents fragment f rooted at n is acceptable. If f is acceptable, we output an acceptable head-dependents fragment; otherwise we access the next node.

Typically, each acceptable head-dependents fragment has three types of nodes: *internal nodes*, internal nodes of the dependency structure; *leaf nodes*, leaf nodes of the dependency structure; *head node*, a special internal node acting as the head of the related head-dependents relation.

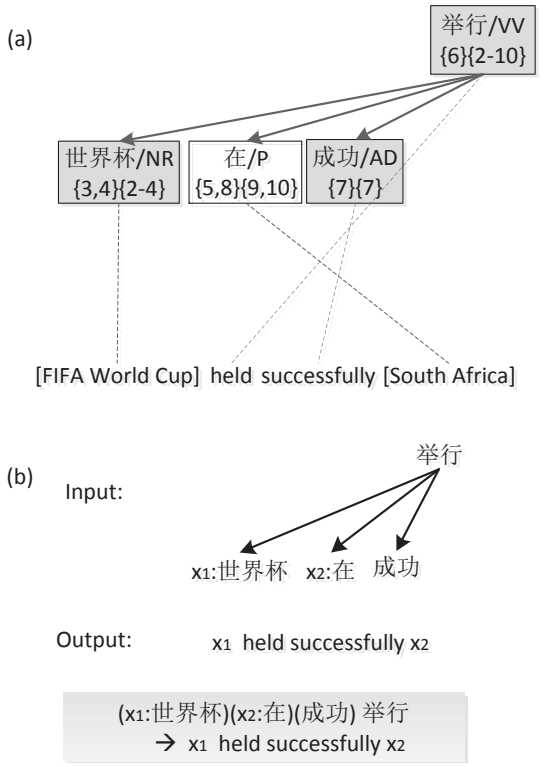

Figure 4: A lexicalized head-dependents rule (b) induced from the only acceptable head-dependents fragment (a) of Figure 3.

4.3 Rule Induction

From each acceptable head-dependents fragment, we induce a set of lexicalized and unlexicalized head-dependents rules.

4.3.1 Lexicalized Rule

We induce a lexicalized head-dependents rule from an acceptable head-dependents fragment by the following procedure:

1. extract the head-dependents relation and mark the internal nodes as substitution sites. This forms the input of a head-dependents rule;
2. place the nodes in order according to the head span of the root and the dependency spans of the sinks, then replace the internal nodes with variables and the other nodes with the target words covered by their head spans. This forms the output of a head-dependents rule.

Figure 4 shows an acceptable head-dependents fragment and a lexicalized head-dependents rule in-

duced from it.

4.3.2 Unlexicalized Rules

Since head-dependents relations with verbs as heads typically consist of more than four nodes, employing only lexicalized head-dependents rules will result in severe sparseness problem. To alleviate this problem, we generalize the lexicalized head-dependents rules and induce rules with unlexicalized nodes.

As we know, the modification relation of a head-dependents relation is determined by the edges. Therefore, we can replace the lexical word of each node with its categories (i.e. POS) and obtain new head-dependents relations with unlexicalized nodes holding the same modification relation. Here we call the lexicalized and unlexicalized head-dependents relations as instances of the modification relation. For a head-dependents relation with m node, we can produce $2^m - 1$ instances with unlexicalized nodes. Each instance represents the modification relation with a different specification.

Based on this observation, from each lexicalized head-dependent rule, we generate new head-dependents rules with unlexicalized nodes according to the following principles:

1. change the aligned part of the target string into a new variable when turning a head node or a leaf node into its category;

2. keep the target side unchanged when turning a internal node into its category.

Restrictions: Since head-dependents relations with verbs as heads typically consists of more than four nodes, enumerating all the instances will result in a massive grammar with too many kinds of rules and inflexibility in decoding. To alleviate these problems, we filter the grammar with the following principles:

1. nodes of the same type turn into their categories simultaneously.

2. as for leaf nodes, only those with open class words can be turned into their categories. In our experiments of this paper, we only turn those dependents with POS tag in the set of {CD,DT,OD,JJ,NN,NR,NT,AD,FW,PN} into their categories.

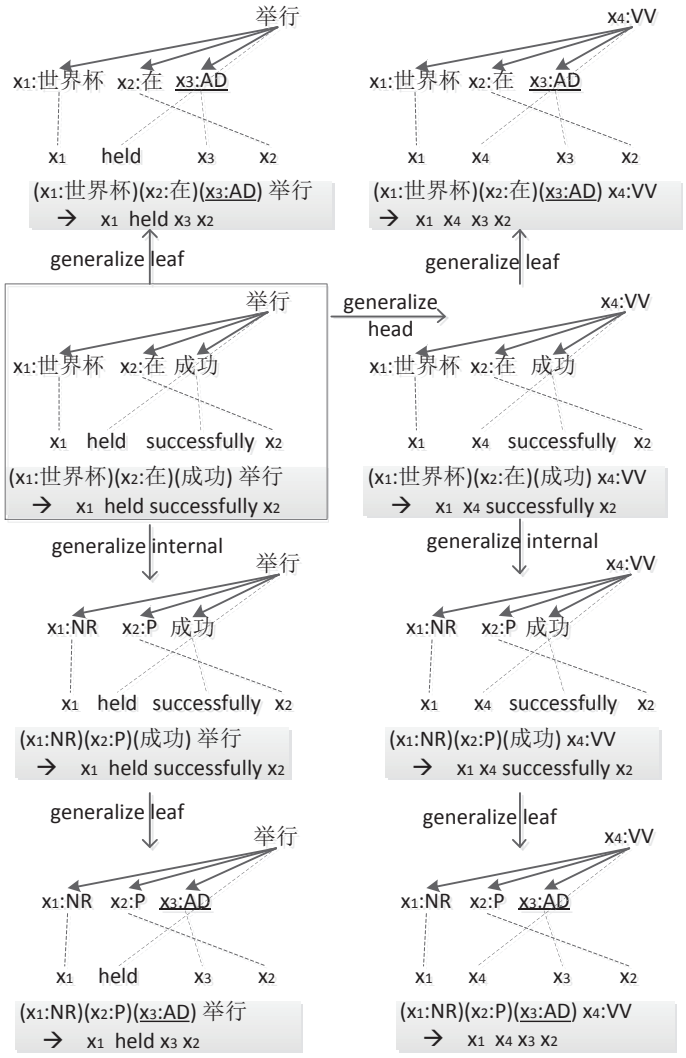

Figure 5: An illustration of rule generalization. Where "x_1:世界杯" and "x_2:在" indicate substitution sites which can be replaced by a subtree rooted at "世界杯" and "在" respectively. "x_3:AD"indicates a substitution site that can be replaced by a subtree whose root has part-of-speech "AD". The underline denotes a leaf node. The box indicates the starting lexicalized head-dependents rule.

Figure 5 illustrates the rule generalization process under these restrictions.

4.3.3 Unaligned Words

We handle the unaligned words of the target side by extending the head spans of the lexicalized head and leaf nodes on both left and right directions. This procedure is similar with the method of (Och and Ney, 2004) except that we might extend several

Algorithm 1: Algorithm for Rule Acquisition

Input: Source dependency structure T, target string S, alignment A
Output: Translation rule set R

```
HSet ← ACCEPTABLE_HEAD(T,S,A)
DSet ← ACCEPTABLE_DEPENDENT(T,S,A)
for each node n ∈ HSet do
    extract head rules
    append the extracted rules to R
    if ∀n' ∈ child(n) n' ∈ DSet
    then
        obtain a head-dependent fragment f
        induce lexicalized and unlexicalized head-dependents rules from f
        append the induced rules to R
    end
end
```

spans simultaneously. In this process, we might obtain $m(m \geq 1)$ head-dependents rules from a head-dependent fragment in handling unaligned words. Each of these rules is assigned with a fractional count $1/m$.

4.4 Algorithm for Rule Acquisition

The rule acquisition is a three-step process, which is summarized in Algorithm 1.

We take the extracted rule set as observed data and make use of relative frequency estimator to obtain the translation probabilities $P(t|s)$ and $P(s|t)$.

5 The model

Following (Och and Ney, 2002), we adopt a general log-linear model. Let d be a derivation that convert a source dependency structure T into a target string e. The probability of d is defined as:

$$P(d) \propto \prod_i \phi_i(d)^{\lambda_i} \quad (1)$$

where ϕ_i are features defined on derivations and λ_i are feature weights. In our experiments of this paper, we used seven features as follows:

- translation probabilities $P(t|s)$ and $P(s|t)$;
- lexical translation probabilities $P_{lex}(t|s)$ and $P_{lex}(s|t)$;
- rule penalty $exp(-1)$;
- language model $P_{lm}(e)$;
- word penalty $exp(|e|)$.

6 Decoding

Our decoder is based on bottom up chart parsing. It finds the best derivation d^* that convert the input dependency structure into a target string among all possible derivations D:

$$d^* = argmax_{d \in D} P(D) \quad (2)$$

Given a source dependency structure T, the decoder transverses T in post-order. For each accessed internal node n, it enumerates all instances of the related modification relation of the head-dependents relation rooted at n, and checks the rule set for matched translation rules. If there is no matched rule, we construct a *pseudo translation rule* according to the word order of the head-dependents relation. For example, suppose that we can not find any translation rule about to "(2010年) (FIFA) 世界杯", we will construct a pseudo translation rule "(x_1:2010年) (x_2:FIFA) x_3:世界杯 $\rightarrow$ x_1 x_2 x_3". A larger translation is generated by substituting the variables in the target side of a translation rule with the translations of the corresponding dependents. We make use of cube pruning (Chiang, 2007; Huang and Chiang, 2007) to find the k-best items with integrated language model for each node.

To balance performance and speed, we prune the search space in several ways. First, beam thresh-

old β , items with a score worse than β times of the best score in the same cell will be discarded; second, beam size b, items with a score worse than the bth best item in the same cell will be discarded. The item consist of the necessary information used in decoding. Each cell contains all the items standing for the subtree rooted at it. For our experiments, we set $\beta = 10^{-3}$ and $b = 300$. Additionally, we also prune rules that have the same source side ($b = 100$).

7 Experiments

We evaluated the performance of our dependency-to-string model by comparison with replications of the hierarchical phrase-based model and the tree-to-string models on Chinese-English translation.

7.1 Data preparation

Our training corpus consists of 1.5M sentence pairs from LDC data, including LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06.

We parse the source sentences with Stanford Parser (Klein and Manning, 2003) into projective dependency structures, whose nodes are annotated by POS tags and edges by typed dependencies. In our implementation of this paper, we make use of the POS tags only.

We obtain the word alignments by running GIZA++ (Och and Ney, 2003) on the corpus in both directions and applying "grow-diag-and" refinement(Koehn et al., 2003).

We apply SRI Language Modeling Toolkit (Stolcke, 2002) to train a 4-gram language model with modified Kneser-Ney smoothing on the Xinhua portion of the Gigaword corpus.

We use NIST MT Evaluation test set 2002 as our development set, NIST MT Evaluation test set 2004 (MT04) and 2005 (MT05) as our test set. The quality of translations is evaluated by the *case insensitive* NIST BLEU-4 metric (Papineni et al., 2002).[1]

We make use of the standard MERT (Och, 2003) to tune the feature weights in order to maximize the system's BLEU score on the development set.

System	Rule #	MT04(%)	MT05(%)
cons2str	30M	34.55	31.94
hiero-re	148M	35.29	33.22
dep2str	56M	**35.82**$^{+}$	**33.62**$^{+}$

Table 1: Statistics of the extracted rules on training corpus and the BLEU scores on the test sets. Where "+" means *dep2str* significantly better than *cons2str* with $p < 0.01$.

7.2 The baseline models

We take a replication of Hiero (Chiang, 2007) as the hierarchical phrase-based model baseline. In our experiments of this paper, we set the beam size $b = 200$ and the beam threshold $\beta = 0$. The maximum initial phrase length is 10.

We use constituency-to-string model (Liu et al., 2006) as the syntax-based model baseline which make use of composed rules (Galley et al., 2006) without handling the unaligned words. In our experiments of this paper, we set the tatTable-limit=20, tatTable-threshold=10^{-1}, stack-limit=100, stack-threshold=10^{-1},hight-limit=3, and length-limit=7.

7.3 Results

We display the results of our experiments in Table 1. Our dependency-to-string model *dep2str* significantly outperforms its constituency structure-based counterpart (*cons2str*) with +1.27 and +1.68 BLEU on MT04 and MT05 respectively. Moreover, without resort to phrases or parse forest, *dep2str* surpasses the hierarchical phrase-based model (*hiero-re*) over +0.53 and +0.4 BLEU on MT04 and MT05 respectively on the basis of a 62% smaller rule set.

Furthermore, We compare some actual translations generated by *cons2str*, *hiero-re* and *dep2str*. Figure 6 shows two translations of our test sets MT04 and MT05, which are selected because each holds a long distance dependency commonly used in Chinese.

In the first example, the Chinese input holds a complex long distance dependencies "巴 尼 耶 在... 与...后 表 示". This dependency corresponds to sentence pattern "noun+prepostional phrase+prepositional phrase+verb", where the former prepositional phrase specifies the position and the latter specifies the time. Both *cons2str* and *hiero-re* are confused by this sentence and mistak-

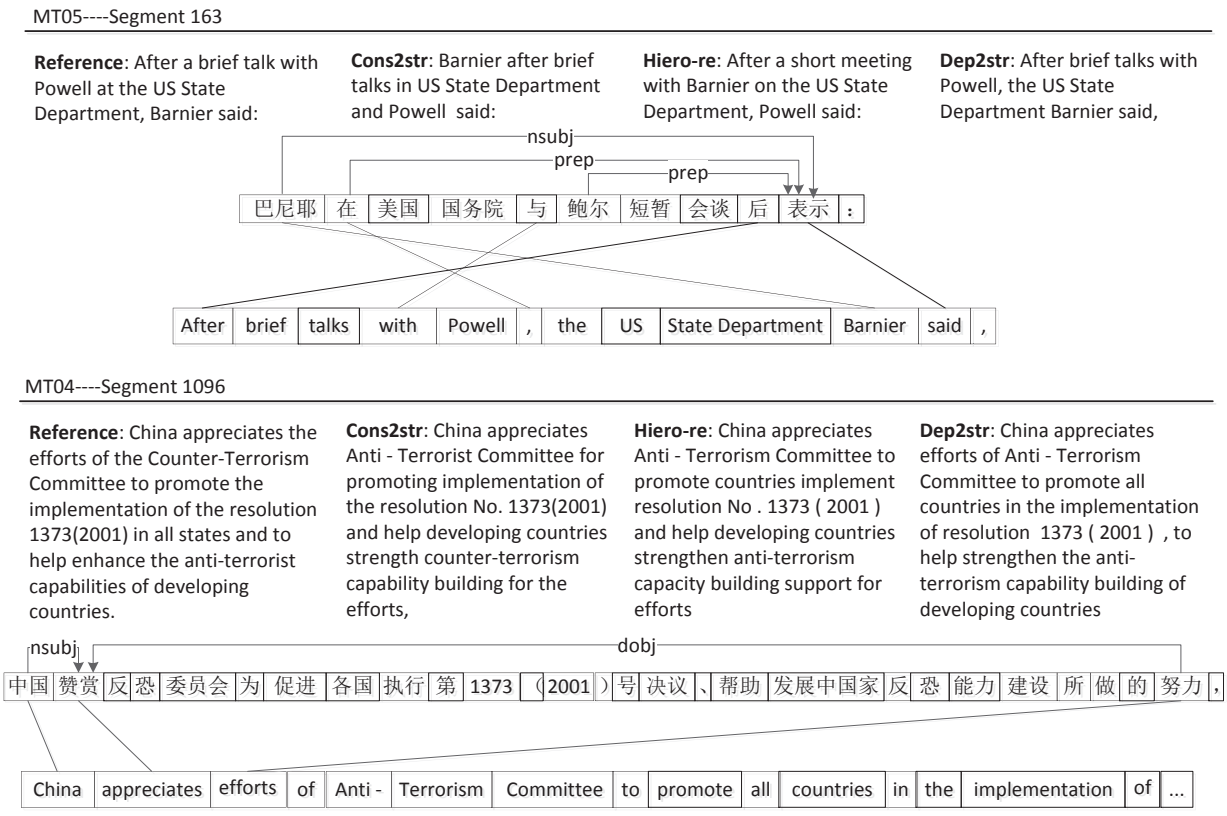

Figure 6: Actual translations produced by the baselines and our system. For our system, we also display the long distance dependencies correspondence in Chinese and English. Here we omit the edges irrelevant to the long distance dependencies.

enly treat "鲍尔(Powell)" as the subjective, thus result in translations with different meaning from the source sentence. Conversely, although "在" is falsely translated into a comma, *dep2str* captures this complex dependency and translates it into "After ... ,(should be *at*) Barnier said", which accords with the reordering of the reference.

In the second example, the Chinese input holds a long distance dependency "中国 赞赏 ... 努力" which corresponds to a simple pattern "noun phrase+verb+noun phrase". However, due to the modifiers of "努力" which contains two sub-sentences including 24 words, the sentence looks rather complicated. *Cons2str* and *hiero-re* fail to capture this long distance dependency and provide monotonic translations which do not reflect the meaning of the source sentence. In contrast, *dep2str* successfully captures this long distance dependency and translates it into "China appreciates efforts of ...", which is almost the same with the reference "China appreciates the efforts of ...".

All these results prove the effectiveness of our dependency-to-string model in both translation and long distance reordering. We believe that the advantage of *dep2str* comes from the characteristics of dependency structures tending to bring semantically related elements together (e.g., verbs become adjacent to all their arguments) and are better suited to lexicalized models (Quirk et al., 2005). And the incapability of *cons2str* and *hiero-re* in handling long distance reordering of these sentences does not lie in the representation of translation rules but the compromises in rule extraction or decoding so as to balance the speed or grammar size and performance. The hierarchical phrase-based model prohibits any nonterminal X from spanning a substring longer than 10 on the source side to make the decoding algorithm asymptotically linear-time (Chiang, 2005).

While constituency structure-based models typically constrain the number of internal nodes (Galley et al., 2006) and/or the height (Liu et al., 2006) of translation rules so as to balance the grammar size and performance. Both strategies limit the ability of the models in processing long distance reordering of sentences with long and complex modification relations.

8 Related Works

As a first step towards semantics, dependency structures are attractive to machine translation. And many efforts have been made to incorporating this desirable knowledge into machine translation.

(Lin, 2004; Quirk et al., 2005; Ding and Palmer, 2005; Xiong et al., 2007) make use of source dependency structures. (Lin, 2004) employs linear paths as phrases and view translation as minimal path covering. (Quirk et al., 2005) extends paths to treelets, arbitrary connected subgraphs of dependency structures, and propose a model based on treelet pairs. Both models require projection of the source dependency structure to the target side via word alignment, and thus can not handle non-isomorphism between languages. To alleviate this problem, (Xiong et al., 2007) presents a dependency treelet string correspondence model which directly map a dependency structure to a target string. (Ding and Palmer, 2005) presents a translation model based on Synchronous Dependency Insertion Grammar(SDIG), which handles some of the non-isomorphism but requires both source and target dependency structures. Most important, all these works do not specify the ordering information directly in translation rules, and resort to either heuristics (Lin, 2004; Xiong et al., 2007) or separate ordering models(Quirk et al., 2005; Ding and Palmer, 2005) to control the word order of translations. By comparison, our model requires only source dependency structure, and handles non-isomorphism and ordering problems simultaneously by directly specifying the ordering information in the head-dependents rules that represent the source side as head-dependents relations and the target side as strings.

(Shen et al., 2008) exploits target dependency structures as dependency language models to ensure the grammaticality of the target string. (Shen et al., 2008) extends the hierarchical phrase-based model and present a string-to-dependency model, which employs string-to-dependency rules whose source side are string and the target as well-formed dependency structures. In contrast, our model exploits source dependency structures, as a tree-based system, it run much faster (linear time vs. cubic time, see (Huang et al., 2006)).

9 Conclusions and future work

In this paper, we present a novel dependency-to-string model, which employs head-dependents rules that represent the source side as head-dependents relations and the target side as string. The head-dependents rules specify the ordering information directly and require only substitution operation. Thus, our model does not need heuristics or ordering model of the previous works to control the word order of translations. Large scale experiments show that our model exhibits good performance in long distance reordering and outperforms the state-of-the-art constituency-to-string model and hierarchical phrase-based model without resort to phrases and parse forest. For the first time, a source dependency-based model shows improvement over the state-of-the-art translation models.

In our future works, we will exploit the semantic information encoded in the dependency structures which is expected to further improve the translations, and replace 1-best dependency structures with dependency forests so as to alleviate the influence caused by parse errors.

Abstract

Real document collections do not fit the independence assumptions asserted by most statistical topic models, but how badly do they violate them? We present a Bayesian method for measuring how well a topic model fits a corpus. Our approach is based on posterior predictive checking, a method for diagnosing Bayesian models in user-defined ways. Our method can identify where a topic model fits the data, where it falls short, and in which directions it might be improved.

1 Introduction

Probabilistic topic models are a suite of machine learning algorithms that decompose a corpus into a set of topics and represent each document with a subset of those topics. The inferred topics often correspond with the underlying themes of the analyzed collection, and the topic modeling algorithm organizes the documents according to those themes.

Most topic models are evaluated by their predictive performance on held out data. The idea is that topic models are fit to maximize the likelihood (or posterior probability) of a collection of documents, and so a good model is one that assigns high likelihood to a held out set (Blei et al., 2003; Wallach et al., 2009).

But this evaluation is not in line with how topic models are frequently used. Topic models seem to capture the underlying themes of a collection—indeed the monicker "topic model" is retrospective—and so we expect that these themes are useful for exploring, summarizing, and learning about its documents (Mimno and McCallum, 2007; Chang et al., 2009). In such exploratory data analysis, however, we are not concerned with the fit to held out data.

In this paper, we develop and study new methods for evaluating topic models. Our methods are based on *posterior predictive checking*, which is a model diagnosis technique from Bayesian statistics (Rubin, 1984; Gelman et al., 1996). The goal of a posterior predictive check (PPC) is to assess the validity of a Bayesian model without requiring a specific alternative model. Given data, we first compute a posterior distribution over the latent variables. Then, we estimate the probability of the observed data under the data-generating distribution that is induced by the posterior (the "posterior predictive distribution"). A data set that is unlikely calls the model into question, and consequently the posterior. PPCs can show where the model fits and doesn't fit the observations. They can help identify the parts of the posterior that are worth exploring.

The key to a posterior predictive check is the *discrepancy function*. This is a function of the data that measures a property of the model which is important to capture. While the model is often chosen for computational reasons, the discrepancy function might capture aspects of the data that are desirable but difficult to model. In this work, we will design a discrepancy function to measure an independence assumption that is implicit in the modeling assumptions but is not enforced in the posterior. We will embed this function in a posterior predictive check and use it to evaluate and visualize topic models in new ways.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 227–237,
Edinburgh, Scotland, UK, July 27–31, 2011.

Specifically, we develop discrepancy functions for latent Dirichlet allocation (the simplest topic model) that measure how well its statistical assumptions about the topics are matched in the observed corpus and inferred topics. LDA assumes that each observed word in a corpus is assigned to a topic, and that the words assigned to the same topic are drawn independently from the same multinomial distribution (Blei et al., 2003). For each topic, we measure the whether this assumption holds by computing the mutual information between the words assigned to that topic and which document each word appeared in. If the assumptions hold, these two variables should be independent: low mutual information indicates that the assumptions hold; high mutual information indicates a mismatch to the modeling assumptions.

We embed this discrepancy in a PPC and study it in several ways. First, we focus on topics that model their observations well; this helps separate interpretable topics from noisy topics (and "boilerplate" topics, which exhibit too little noise). Second, we focus on individual terms within topics; this helps display a model applied to a corpus, and understand which terms are modeled well. Third, we replace the document identity with an external variable that might plausibly be incorporated into the model (such as time stamp or author). This helps point the modeler towards the most promising among more complicated models, or save the effort in fitting one. Finally, we validate this strategy by simulating data from a topic model, and assessing whether the PPC "accepts" the resulting data.

2 Probabilistic Topic Modeling

Probabilistic topic models are statistical models of text that assume that a small number of distributions over words, called "topics," are used to generate the observed documents. One of the simplest topic models is latent Dirichlet allocation (LDA) (Blei et al., 2003). In LDA, a set of K topics describes a corpus; each document exhibits the topics with different proportions. The words are assumed exchangeable within each document; the documents are assumed exchangeable within the corpus.

More formally, let $\phi_1, \ldots, \phi_K$ be K topics, each of which is a distribution over a fixed vocabulary. For each document, LDA assumes the following generative process

1. Choose topic proportions $\theta_d \sim \text{Dirichlet}(\alpha)$.
2. For each word
   (a) Choose topic assignment $z_{d,n} \sim \theta$.
   (b) Choose word $w_{d,n} \sim \phi_{z_{d,n}}$.

This process articulates the statistical assumptions behind LDA: Each document is endowed with its own set of topic proportions θ_d, but the same set of topics $\phi_{1:K}$ governs the whole collection.

Notice that the probability of a word is independent of its document θ_d given its topic assignment $z_{d,n}$ (i.e., $w_{d,n} \perp\!\!\!\perp \theta_d \,|\, z_{d,n}$). Two documents might have different overall probabilities of containing a word from the "vegetables" topic; however, all the words in the collection (regardless of their documents) drawn from that topic will be drawn from the same multinomial distribution.

The central computational problem for LDA is posterior inference. Given a collection of documents, the problem is to compute the conditional distribution of the hidden variables—the topics ϕ_k, topic proportions θ_d, and topic assignments $z_{d,n}$. Researchers have developed many algorithms for approximating this posterior, including sampling methods (Griffiths and Steyvers, 2004) (used in this paper), variational methods (Blei et al., 2003), distributed variants (Asuncion et al., 2008), and online algorithms (Hoffman et al., 2010).

3 Checking Topic Models

Once approximated, the posterior distribution is used for the task at hand. Topic models have been applied to many tasks, such as classification, prediction, collaborative filtering, and others. We focus on using them as an exploratory tool, where we assume that the topic model posterior provides a good decomposition of the corpus and that the topics provide good summaries of the corpus contents.

But what is meant by "good"? To answer this question, we turn to Bayesian model checking (Rubin, 1981; Gelman et al., 1996). The goal of Bayesian model checking is to assess whether the observed data matches the modeling assumptions in the directions that are important to the analysis. The

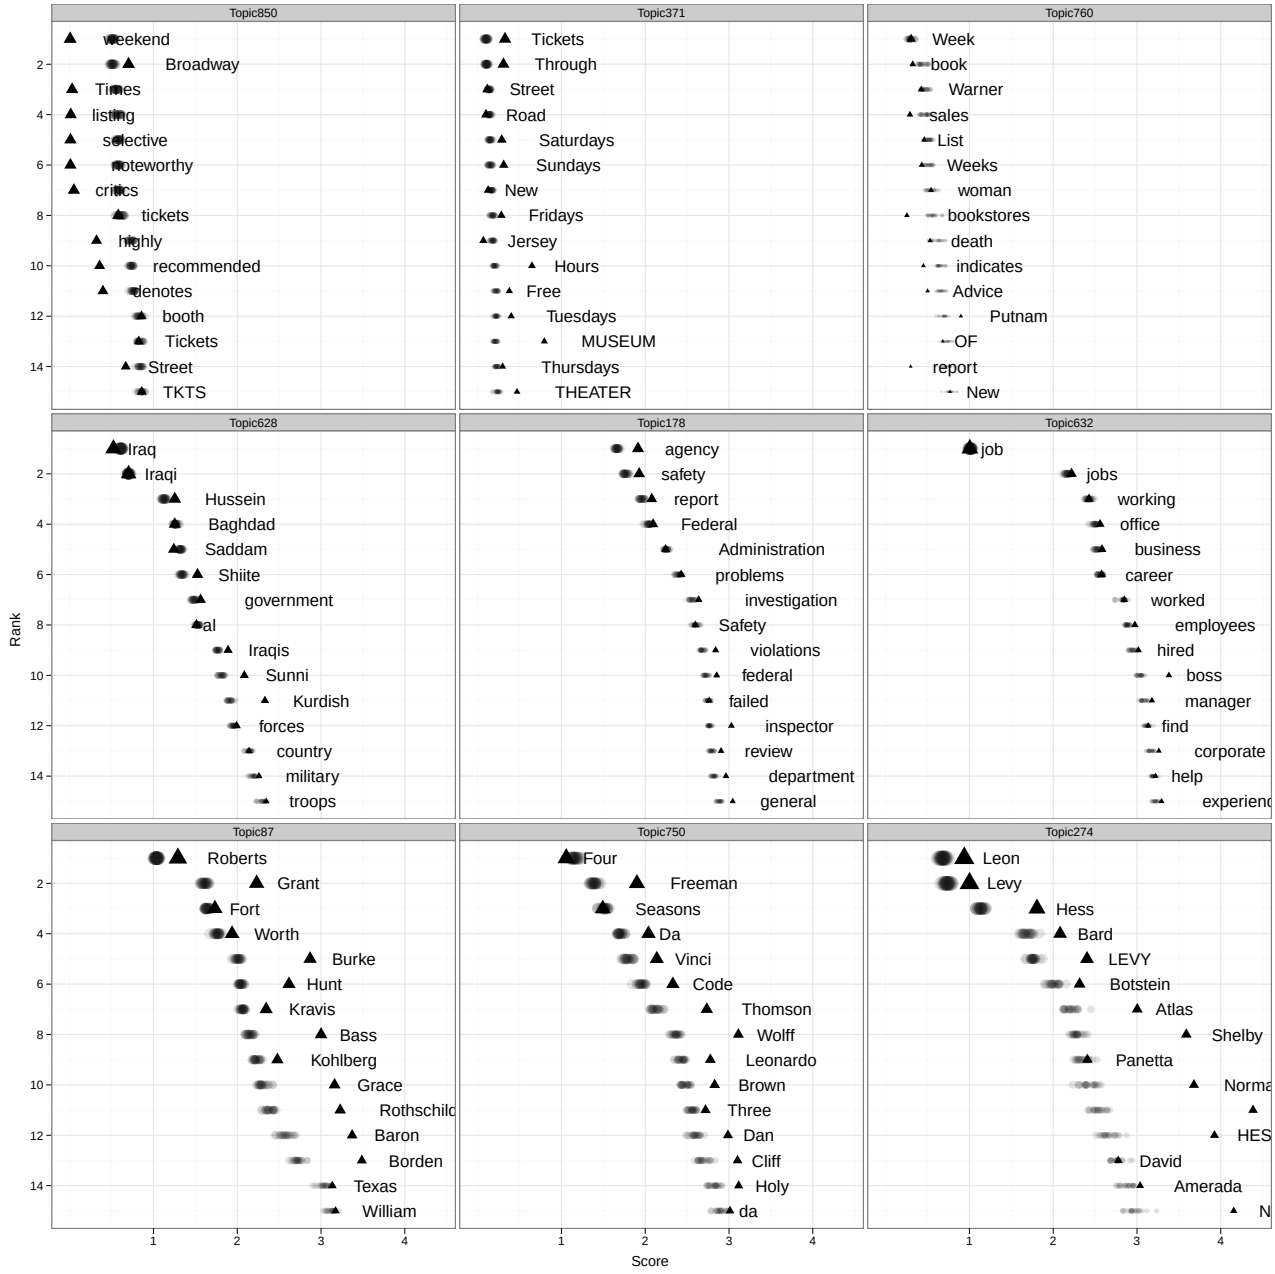

Figure 1: **Visualization of variability within topics.** Nine randomly selected topics from the New York Times with low (top row), medium (middle row) and high (bottom row) mutual information between words and documents. The y-axis shows term rank within the topic, with size proportional to log probability. The x-axis represents divergence from the multinomial assumption for each word: terms that are uniformly distributed across documents are towards the left, while more specialized terms are to the right. Triangles represent real values, circles represent 20 replications of this same plot from the posterior of the model.

intuition is that only when satisfied with the model should the modeler use the posterior to learn about her data. In complicated Bayesian models, such as topic models, Bayesian model checking can point to the parts of the posterior that better fit the observed data set and are more likely to suggest something meaningful about it.

In particular, we will develop posterior predictive checks (PPC) for topic models. In a PPC, we specify a *discrepancy function*, which is a function of the data that measures an important property that we want the model to capture. We then assess whether the observed value of the function is similar to values of the function drawn from the posterior, through the distribution of the data that it induces. (This distribution of the data is called the "posterior predictive distribution.")

An innovation in PPCs is the *realized discrepancy function* (Gelman et al., 1996), which is a function of the data and any hidden variables that are in the model. Realized discrepancies induce a traditional discrepancy by marginalizing out the hidden variables. But they can also be used to evaluate assumptions about *latent* variables in the posterior, especially when combined with techniques like MCMC sampling that provide realizations of them. In topic models, as we will see below, we use a realized discrepancy to factor the observations and to check specific components of the model that are discovered by the posterior.

3.1 A realized discrepancy for LDA

Returning to LDA, we design a discrepancy function that checks the independence assumption of words given their topic assignments. As we mentioned above, given the topic assignment z the word w should be independent of its document θ. Consider a decomposition of a corpus from LDA, which assigns every observed word $w_{d,n}$ to a topic $z_{d,n}$. Now restrict attention to all the words assigned to the kth topic and form two random variables: W are the words assigned to the topic and D are the document indices of the words assigned to that topic. If the LDA assumptions hold then knowing W gives no information about D because the words are drawn independently from the topic.

We measure this independence with the mutual information between W and D:[1]

$$\begin{aligned} &MI(W, D \mid k) \\ &= \sum_w \sum_d P(w, d \mid k) \log \frac{P(w \mid d, k) P(d \mid k)}{P(w \mid k) P(d \mid k)} \\ &= \sum_w \sum_d \frac{N(w, d, k)}{N(k)} \log \frac{N(w, d, k) N(k)}{N(d, k) N(w, k)}. \end{aligned} \quad (1)$$

Where $N(w, d, k)$ is the number of tokens of type w in topic k in document d, with $N(w, k) = \sum_d N(w, d, k)$, $N(d, k) = \sum_w N(w, d, k)$, and $N(k) = \sum_{w,d} N(w, d, k)$. This function measures the divergence between the joint distribution over word and document index and the product of the marginal distributions. In the limit of infinite samples, independent random variables have mutual information of zero, but we expect finite samples to have non-zero values even for truly independent variables. Notice that this is a realized discrepancy; it depends on the latent assignments of observed words to topics.

Eq. 1 is defined as a sum over a set of documents and a set of words. We can rearrange this summation as a weighted sum of the *instantaneous mutual information* between words and documents:

$$IMI(w, D \mid k) = H(D|k) - H(D \mid W = w, k). \quad (2)$$

This quantity can be understood by considering the per-topic distribution of document labels, $p(d|k)$. This distribution is formed by normalizing the counts of how many words assigned to topic k appeared in each document. The first term of Eq. 2 is the entropy—some topics are evenly distributed across many documents (high entropy); others are concentrated in fewer documents (low entropy).

The second term conditions this distribution on a particular word type w by normalizing the per-document number of times w appeared in each document (in topic k). If this distribution is close to $p(d|k)$ then $H(D|W = w, k)$ will be close to $H(D|k)$ and $IMI(w, D|k)$ will be low. If, on the other hand, word w occurs many times in only a few documents, it will have lower entropy over docu-

[1] There are other choices of discrepancies, such as word-word point-wise mutual information scores (Newman et al., 2010).

ments than the overall distribution over documents for the topic and $IMI(w, D|k)$ will be high.

We illustrate this discrepancy in Figure 1, which shows nine topics trained from the *New York Times*.[2] Each row contains randomly selected topics from low, middle, and high ranges of MI, respectively. Each triangle represents a word. Its place on the y-axis is its rank in the topic. Its place on the x-axis is its $IMI(w|k)$, with more uniformly distributed words (low IMI) to the left and more specific words (high IMI) to the right. (For now, ignore the other points in this figure.) IMI varies between topics, but tends to increase with rank as less frequent words appear in fewer documents.

The discrepancy captures different kinds of structure in the topics. The top left topic represents formulaic language, language that occurs verbatim in many documents. In particular, it models the boilerplate text "Here is a selective listing by critics of The Times of new or noteworthy..." Identifying repeated phrases is a common phenomenon in topic models. Most words show lower than expected IMI, indicating that word use in this topic is less variable than data drawn from a multinomial distribution. The middle-left topic is an example of a good topic, according to this discrepancy, which is related to Iraqi politics. The bottom-left topic is an example of the opposite extreme from the top-left. It shows a loosely connected series of proper names with no overall theme.

3.2 Posterior Predictive Checks for LDA

Intuitively, the middle row of topics in Figure 1 are the sort of topics we look for in a model, while the top and bottom rows contain topics that are less useful. Using a PPC, we can formally measure the difference between these topics. For each of the real topics in Figure 1 we regenerated the same figure 20 times. We sampled new words for every token from the posterior distribution of the topic, and recalculated the rank and IMI for each word. These "shadow" figures are shown as gray circles. The density of those circles creates a reference distribution indicating the expected IMI values at each rank under the multinomial assumption.

[2]Details about the corpus and model fitting are in Section 4.2. Similar figures for two other corpora are in the supplement.

By themselves, IMI scores give an indication of the distribution of a word between documents within a topic: small numbers are better, large numbers indicate greater discrepancy. These scores, however, are based on the specific allocation of words to topics. For example, lower-ranked, less frequent words within a topic tend to have higher IMI scores than higher-ranked, more frequent words. This difference may be due to greater violation of multinomial assumptions, but may also simply be due to smaller sample sizes, as the entropy $H(D|W = w, k)$ is estimated from fewer tokens. The reference distributions help distinguish between these two cases.

In more detail, we generate replications of the data by considering a Gibbs sampling state. This state assigns each observed word to a topic. We first record the number of instances of each term assigned to each topic, $N(w|k)$. Then for each word $w_{d,n}$ in the corpus, we sample a new observed word $w_{d,n}^{rep}$ where $P(w) \propto N(w|z_{d,n})$. (We did not use smoothing parameters.) Finally, we recalculate the mutual information and instantenous mutual information for each topic.

In the top-left topic, most of the words have much lower IMI than the word at the same rank in replications, indicating lower than expected variability. The exception is the word *Broadway*, which is more variable than expected. In the middle-left topic, IMI for the words *Iraqi* and *Baghdad* occur within the expected range. These words fit the multinomial assumption: any word assigned to this topic is equally likely to be *Iraqi*. Values for the words *Shiite*, *Sunni*, and *Kurdish* are more specific to particular documents than we expect under the model. In the bottom-left topic, almost all words occur with greater variability than expected. This topic combines many terms with only coincidental similarity, such as Mets pitcher Grant Roberts and the firm Kohlberg Kravis Roberts.

Turning to an analysis of the full mutual information, Figure 2 shows the three left-hand topics from Figure 1: *Weekend*, *Iraq*, and *Roberts*. The histogram represents MI scores for 100 replications of the topic, rescaled to have mean zero and unit variance. The observed value, also rescaled, and the mean replicated value (set to zero) are shown with vertical lines. The formulaic *Weekend* topic has significantly lower than expected MI. The *Iraq*

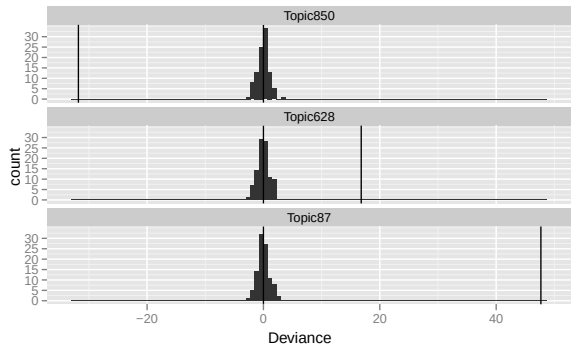

Figure 2: **News: Observed topic scores (vertical lines) relative to replicated scores, rescaled so that replications have zero mean and unit variance.** The *Weekend* topic (top) has lower than expected MI. The *Iraq* (middle) and *Roberts* (bottom) topics both have MI greater than expected.

and *Roberts* topics have significantly greater than expected MI.

For most topics the actual discrepancy is outside the range of any replicated discrepancies. In their original formulation, PPCs prescribe computing a tail probability of a replicated discrepancy being greater than (or less than) the observed discrepancy under the posterior predictive distribution. For example if an observed value is greater than 70 of 100 replicated values, we report a PPC p-value of 0.7.

When the observed value is far outside the range of any replicated values, as in Figure 2, that tail probability will be degenerate at 0 or 1. So, we report instead a *deviance* value, an alternative way of comparing an observed value to a reference distribution. We compute the distribution of the replicated discrepancies and compute its standard deviation. We then compute how many standard deviations the observed discrepancy is from the mean of the replicated discrepancies.

This score allows us to compare topics. The observed value for the *Weekend* topic is 31.8 standard deviations below the mean replicated value, and thus has deviance of -31.8, which is lower than expected. The *Iraq* topic has deviance of 16.8 and the *Roberts* topic has deviance of 47.7. This matches our intuition that the former topic is more useful than the latter.

4 Searching for Systematic Deviations

We demonstrated that the mutual information discrepancy function can detect violations of multinomial assumptions, in which instances of a term in a given topic are not independently distributed among documents. One way to address this lack of fit is to encode document-level extra-multinomial variance ("burstiness") into the model using Dirichlet compound multinomial distributions (Doyle and Elkan, 2009). If there is no pattern to the deviations from multinomial word use across documents, this method is the best we can do.

In many corpora, however, there are systematic deviations that can be explained by additional variables. LDA is the simplest generative topic model, and researchers have developed many variants of LDA that account for a variety of variables that can be found or measured with a corpus. Examples include models that account for time (Blei and Lafferty, 2006), books (Mimno and McCallum, 2007), and aspect or perspective (Mei and Zhai, 2006; Lin et al., 2008; Paul et al., 2010). In this section, we show how we can use the mutual information discrepancy function of Equation 1 and PPCs to guide our choice in which topic model to fit.

Greater deviance implies that a particular grouping better explains the variation in word use within a topic. The discrepancy functions are large when words appear more than expected in some groups and less than expected in others. We know that the individual documents show significantly more variation than we expect from replications from the model's posterior distribution. If we combine documents randomly in a meaningless grouping, such deviance should decrease, as differences between documents are "smoothed out." If a grouping of documents shows equal or greater deviation, we can assume that that grouping is maintaining the underlying structure of the systematic deviation from the multinomial assumption, and that further modeling or visualization using that grouping might be useful.

4.1 PPCs for systematic discrepancy

The idea is that the words assigned to a topic should be independent of both document and any other variable that might be associated with the document. We simply replace the document index d with another

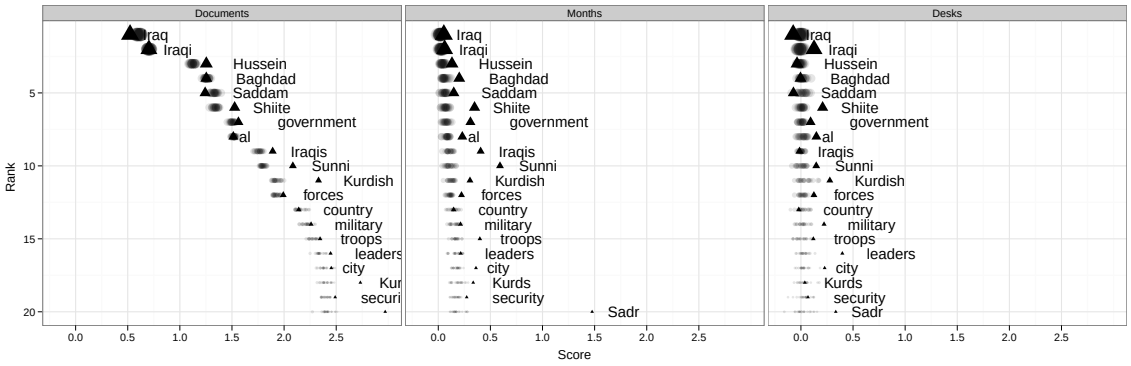

Figure 3: **Groupings decrease MI, but values are still larger than expected.** Three ways of grouping words in a topic from the *New York Times*. The word *leaders* varies more between desks than by time, while *Sadr* varies more by time than desk.

variable g in the discrepancy. For example, the New York Times articles are each associated with a particular news desk and also associated with a time stamp. If the topic modeling assumptions hold, the words are independent of both these variables. If we see a significant discrepancy relative to a grouping defined by a metadata feature, this systematic variability suggests that we might want to take that feature into account in the model.

Let $\mathcal{G}$ be a set of groups and let $\gamma \in \mathcal{G}^D$ be a grouping of D documents. Let $N(w, g, k) = \sum_d N(w, d, k) I_{\gamma_d = g}$, that is, the number of words of type w in topic k in documents in group g, and define the other count variables similarly. We can now substitute these group-specific counts for the document-specific counts in the discrepancy function in Eq. 1. Note that the previous discrepancy functions are equivalent to a trivial grouping, in which each document is the only member of its own group. In the following experiments we explore groupings by published volume, blog, preferred political candidate, and newspaper desk, and evaluate the effect of those groupings on the deviation between mean replicated values and observed values of those functions.

4.2 Case studies

We analyze three corpora, each with its own metadata: the New York Times Annotated Corpus (1987–2007)[3], the CMU 2008 political blog corpus (Eisenstein and Xing, 2010), and speeches from the British House of Commons from 1830–1891.[4] Descriptive statistics are presented in Table 1. The realization is represented by a single Gibbs sampling state after 1000 iterations of Gibbs sampling.

Table 1: Statistics for models used as examples.

Name	Docs	Tokens	Vocab	Topics
News	1.8M	76M	121k	1000
Blogs	13k	2.2M	90k	100
Parliament	540k	55M	52k	300

New York Times articles. Figure 3 shows three groupings of words for the middle-left topic in Figure 1: by document, by month of publication (e.g. May of 2005), and by desk (e.g. Editorial, Foreign, Financial). Instantaneous mutual information values are significantly smaller for the larger groupings, but the actual values are still larger than expected under the model. We are interested in measuring the degree to which word usage varies within topics as a function of both time and the perspective of the article. For example, we may expect that word choice may differ between opinion articles, which overtly reflect an author's views, and news articles, which take a more objective, factual approach.

We summarize each grouping by plotting the distribution of deviance scores for all topics. Results for all 1000 topics grouped by documents, months, and desks are shown in Figure 4.

[3] http://www.ldc.upenn.edu

[4] http://www.hansard-archive.parliament.uk/

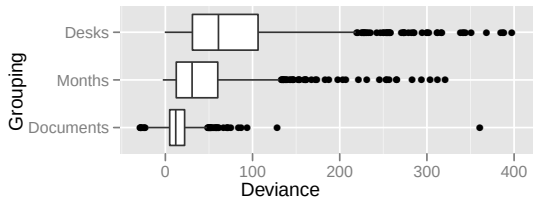

Figure 4: **News: Lack of fit correlates best with desks.** We calculate the number of standard deviations between the mean replicated discrepancy and the actual discrepancy for each topic under three groupings. Boxes represent typical ranges, points represent outliers.

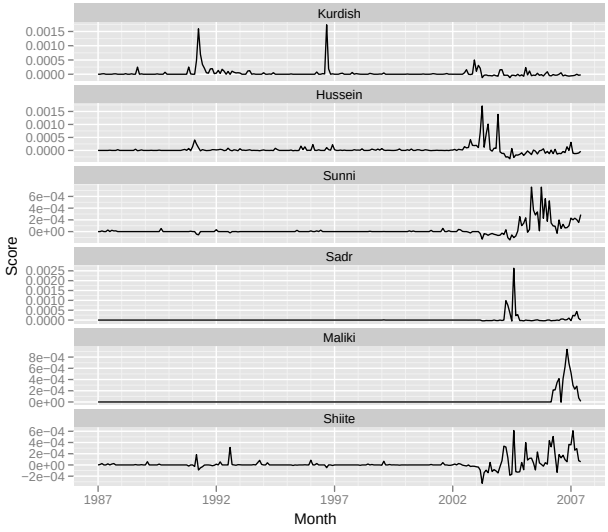

Figure 5: **News: Events change word distributions.** Words with the largest MI from a topic on Iraq's government are shown, with individual scores grouped by month.

Finally, we can analyze how individual words interact with groupings like time or desk. Figure 5 breaks down the per-word discrepancy shown in Figure 3 by month, for the words with the largest overall discrepancy. *Kurdish* is prominent during the Gulf War and the 1996 cruise missile strikes, but is less significant during the Iraq War. Individuals (*Hussein*, *Sadr*, and *Maliki*) move on and off the stage.

Political blogs. The CMU 2008 political blog corpus consists of six blogs, three of which supported Barack Obama and three of which supported John McCain. This corpus has previously been considered in the context of aspect-based topic models (Ahmed and Xing, 2010) that assign distinct word distributions to liberal and conservative bloggers. It is reasonable to expect that blogs with different political leanings will use measurably different language to describe the same themes, suggesting that there will be systematic deviations from a multinomial hypothesis of exchangeability of words within topics. Indeed, Ahmed and Xing obtained improved results with such a model. Figure 6 shows the distribution of standard deviations from the mean replicated value for a set of 150 topics grouped by document, blog, and preferred candidate. Deviance is greatest for blogs, followed by candidates and then documents.

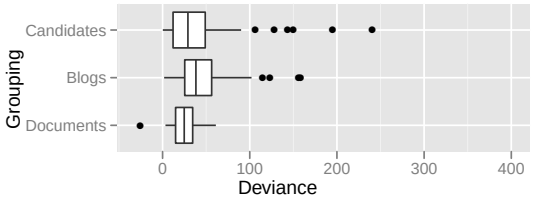

Figure 6: **Blogs: Lack of fit correlates more with blog than preferred candidate.** Grouping by preferred candidate has only slightly higher average deviance than by documents, but the variance is greater.

Grouping by blogs appears to show greater deviance from mean replicated values than grouping by candidates, indicating that there is further structure in word choice beyond a simple liberal/conservative split. Are these results, however, comparable? It may be that this difference is explained by the fact that there are six blogs and only

two candidates. To determine whether this particular assignment of documents to blogs is responsible for the difference in discrepancy functions or whether any such split would have greater deviance, we compared random groupings to the real groupings and recalculate the PPC. We generated 10 such groupings by permuting document blog labels and another 10 by permuting document candidate labels, each time holding the topics fixed. The average number of standard deviations across topics was 6.6 ± 14.4 for permuted "candidates" compared to 37.9 ± 39.2 for the real corpus, and 10.6 ± 12.9 for permuted "blogs" compared to 44.4 ± 29.6 for real blogs.

British parliament proceedings. The parliament corpus is divided into 305 volumes, each comprising about three weeks of debates, with between 600 and 4000 speeches per session. In addition to volumes, 10 Prime Ministers were in office during this period.

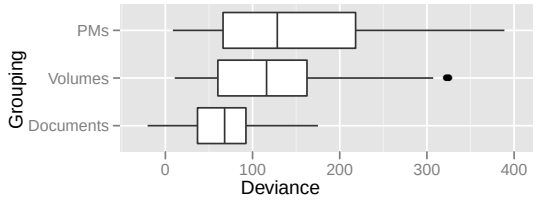

Figure 7: **Parliament: Lack-of-fit correlates with time (publication volume).** Correlation with prime ministers is not significantly better than with volume.

Grouping by prime minister shows greater average deviance than grouping by volumes, even though there are substantially fewer divisions. Although such results would need to be accompanied by permutation experiments as in the blog corpus, this methodology may be of interest to historians.

In order to provide insight into the nature of temporal variation, we can group the terms in the summation in Equation 1 by word and rank the words by their contribution to the discrepancy function. Figure 8 shows the most "mismatching" words for a topic with the most probable words *ships, vessels, admiralty, iron, ship, navy*, consistent with changes in naval technology during the Victorian era (that is, wooden ships to "iron clads"). Words that occur more prominently in the topic (*ships, vessels*) are also variable, but more consistent across time.

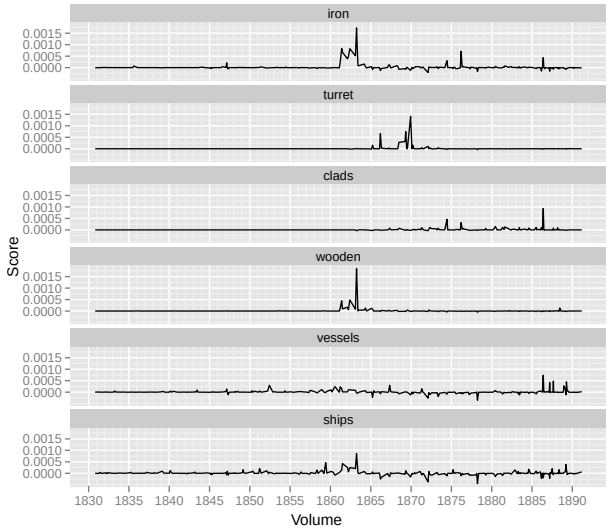

Figure 8: **Parliament: *iron-clads* introduced in 1860s.** High probability words (*ships, vessels*) are variable, but show less concentrated discrepancy than *iron, wooden*.

5 Calibration on Synthetic Data

A posterior predictive check asks "do observations sampled from the learned model look like the original data?" In the previous sections, we have considered PPCs that explore variability within a topic on a per-word basis, measure discrepancy at the topic level, and compare deviance over all topics between groupings of documents. Those results show that the PPC detects deviation from multinomial assumptions when it exists: as expected, variability in word choice aligns with known divisions in corpora, for example by time and author perspective. We now consider the opposite direction. When documents are generated from a multinomial topic model, PPCs should not detect systematic deviation.

We must also distinguish between lack of fit due to model misspecification and lack of fit due to approximate inference. In this section, we present synthetic data experiments where the learned model is precisely the model used to generate documents. We show that there is significant lack of fit introduced by approximate inference, which can be corrected by considering only parts of the model that are well-estimated.

We generated 10 synthetic corpora, each consisting of 100,000 100-word documents, drawn from 20

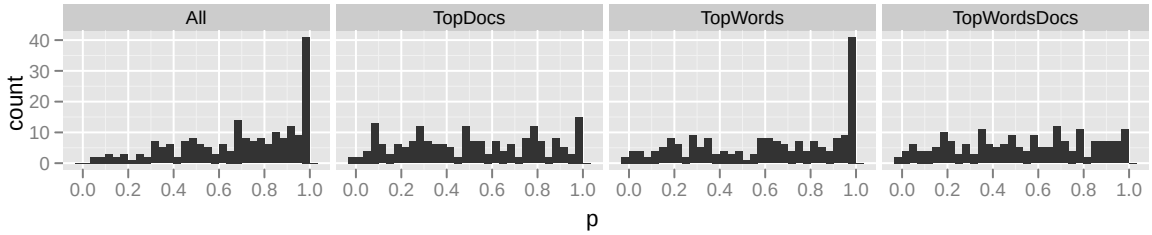

Figure 9: **Replicating only documents with large allocation in the topic leads to more uniform p-values.** p-values for 200 topics estimated from synthetic data generated from an LDA model are either uniform or skewed towards 1.0. Overly conservative p-values would be clustered around 0.5.

topics over a vocabulary of 100 terms. Hyperparameters for both the document-topic and topic-term Dirichlet priors were 0.1 for each dimension. We then trained a topic model with the same hyperparameters and number of topics on each corpus, saving a Gibbs sampling state.

We can measure the fit of a PPC by examining the distribution of empirical p-values, that is, the proportion of replications $\boldsymbol{w}^{rep}$ that result in discrepancies less than the observed value. p-values should be uniformly distributed on $(0, 1)$. Non-uniform p-values indicate a lack of *calibration*. Unlike real collections, in synthetic corpora the range of discrepancies from these replicated collections often includes the real values, so p-values are meaningful. A histogram of p-values for 200 synthetic topics after 100 replications is shown in the left panel of Figure 9.

PPCs have been criticized for reusing training data for model checking. For some models, the posterior distribution is too close to the data, so all replicated values are close to the real value, leading to p-values clustered around 0.5 (Draper and Krnjajic, 2006; Bayarri and Castellanos, 2007). We test divergence from a uniform distribution with a Kolmogorov-Smirnov test. Our results indicate that LDA is not overfitting, but that the distribution is not uniform (KS $p < 0.00001$).

The PPC framework allows us to choose discrepancy functions that reflect the relative importance of subsets of words and documents. The second panel in Figure 9 sums only over the 20 documents with the largest probability of the topic, the third sums over all documents but only over the top 10 most probable words, and the fourth sums over only the top words and documents. This test indicates that the distribution of p-values for the subset *TopWords* is not uniform (KS $p < 0.00001$), but that a uniform distribution is a good fit for *TopDocs* (KS $p = 0.358$) and *TopWordsDocs* (KS $p = 0.069$).

6 Conclusions

We have developed a Bayesian model checking method for probabilistic topic models. Conditioned on their topic assignment, the words of the documents are independently and identically distributed by a multinomial distribution. We developed a realized discrepancy function—the mutual information between words and document indices, conditioned on a topic—that checks this assumption. We embedded this function in a posterior predictive check.

We demonstrated that we can use this posterior predictive check to identify particular topics that fit the data, and particular topics that misfit the data in different ways. Moreover, our method provides a new way to visualize topic models.

We adapted the method to corpora with external variables. In this setting, the PPC provides a way to guide the modeler in searching through more complicated models that involve more variables.

Finally, on simulated data, we demonstrated that PPCs with the mutual information discrepancy function can identify model fit and model misfit.

Abstract

Dual decomposition has been recently proposed as a way of combining complementary models, with a boost in predictive power. However, in cases where lightweight decompositions are not readily available (*e.g.*, due to the presence of rich features or logical constraints), the original subgradient algorithm is inefficient. We sidestep that difficulty by adopting an augmented Lagrangian method that accelerates model consensus by regularizing towards the averaged votes. We show how first-order logical constraints can be handled efficiently, even though the corresponding subproblems are no longer combinatorial, and report experiments in dependency parsing, with state-of-the-art results.

1 Introduction

The last years have witnessed increasingly accurate models for syntax, semantics, and machine translation (Chiang, 2007; Finkel et al., 2008; Petrov and Klein, 2008; Smith and Eisner, 2008; Martins et al., 2009a; Johansson and Nugues, 2008; Koo et al., 2010). The predictive power of such models stems from their ability to break locality assumptions. The resulting combinatorial explosion typically demands some form of approximate decoding, such as sampling, heuristic search, or variational inference.

In this paper, we focus on parsers built from linear programming relaxations, the so-called "turbo parsers" (Martins et al., 2009a; Martins et al., 2010). Rush et al. (2010) applied dual decomposition as a way of combining models which alone permit efficient decoding, but whose combination is intractable. This results in a relaxation of the original problem that is elegantly solved with the subgradient algorithm. While this technique has proven quite effective in parsing (Koo et al., 2010; Auli and Lopez, 2011) as well as machine translation (Rush and Collins, 2011), we show here that its success is strongly tied to the ability of finding a "good" decomposition, *i.e.*, one involving few overlapping components (or *slaves*). With many components, the subgradient algorithm exhibits extremely slow convergence (cf. Fig. 2). Unfortunately, a lightweight decomposition is not always at hand, either because the problem does not factor in a natural way, or because one would like to incorporate features that cannot be easily absorbed in few tractable components. Examples include features generated by statements in first-order logic, features that violate Markov assumptions, or history features such as the ones employed in transition-based parsers.

To tackle the kind of problems above, we adopt DD-ADMM (Alg. 1), a recently proposed algorithm that accelerates dual decomposition (Martins et al., 2011). DD-ADMM retains the modularity of the subgradient-based method, but it speeds up consensus by regularizing each slave subproblem towards the averaged votes obtained in the previous round (cf. Eq. 14). While this yields more involved subproblems (with a quadratic term), we show that exact solutions can still be efficiently computed for all cases of interest, by using sort operations. As a result, we obtain parsers that can handle very rich features, do not require specifying a decomposition, and can be heavily parallelized. We demonstrate the success of the approach by presenting experiments in dependency parsing with state-of-the-art results.

2 Background

2.1 Structured Prediction

Let $x \in \mathcal{X}$ be an input object (*e.g.*, a sentence), from which we want to predict a structured output $y \in \mathcal{Y}$ (*e.g.*, a parse tree). The output set $\mathcal{Y}$ is assumed too large for exhaustive search to be tractable. We assume to have a model that assigns a score $f(y)$ to each candidate output, based on which we predict

$$\widehat{y} = \arg\max_{y \in \mathcal{Y}} f(y). \quad (1)$$

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 238–249,
Edinburgh, Scotland, UK, July 27–31, 2011.

Designing the model must obey certain practical considerations. If efficiency is the major concern, a simple model is usually chosen so that Eq. 1 can be solved efficiently, at the cost of limited expressive power. If we care more about accuracy, a model with richer features and more involved score functions may be designed. Decoding, however, will be more expensive, and approximations are often necessary. A typical source of intractability comes from the combinatorial explosion inherent in the composition of two or more tractable models (Bar-Hillel et al., 1964; Tromble and Eisner, 2006). Recently, Rush et al. (2010) have proposed a dual decomposition framework to address NLP problems in which the global score decomposes as $f(y) = f_1(z_1) + f_2(z_2)$, where z_1 and z_2 are two overlapping "views" of the output, so that Eq. 1 becomes:

$$\begin{array}{ll} \text{maximize} & f_1(z_1) + f_2(z_2) \\ \text{w.r.t.} & z_1 \in \mathcal{Y}_1, z_2 \in \mathcal{Y}_2 \\ \text{s.t.} & z_1 \sim z_2. \end{array} \quad (2)$$

Above, the notation $z_1 \sim z_2$ means that z_1 and z_2 "agree on their overlaps," and an isomorphism $\mathcal{Y} \simeq \{\langle z_1, z_2 \rangle \in \mathcal{Y}_1 \times \mathcal{Y}_2 \mid z_1 \sim z_2\}$ is assumed. We next formalize these notions and proceed to compositions of an *arbitrary* number of models. Of special interest is the unexplored setting where this number is very large and each component very simple.

2.2 Decomposition into Parts

A crucial step in the design of structured predictors is that of decomposing outputs into parts (Taskar et al., 2003). We assume the following setup:

Basic parts. We let $\mathcal{R}$ be a set of *basic parts*, such that each element $y \in \mathcal{Y}$ can be identified with a subset of $\mathcal{R}$. The exact meaning of a "basic part" is problem dependent. For example, in dependency parsing, $\mathcal{R}$ can be the set of all possible dependency arcs (see Fig. 1); in phrase-based parsing, it can be the set of possible spans; in sequence labeling, it can be the set of possible labels at each position. Our only assumption is that we can "read out" y from the basic parts it contains. For convenience, we represent y as a binary vector, $y = \langle y(r) \rangle_{r \in \mathcal{R}}$, where $y(r) = 1$ if part r belongs to y, and 0 otherwise.

Decomposition. We generalize the decomposition in Eq. 2 by considering sets $\mathcal{Y}_1, \ldots, \mathcal{Y}_S$ for $S \geq 2$.

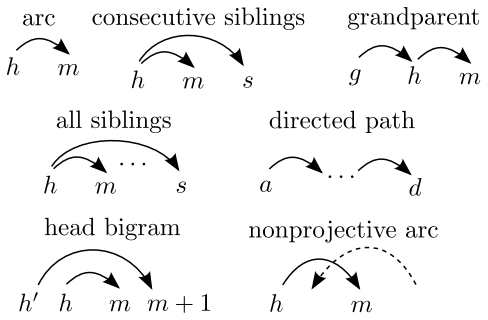

Figure 1: Parts used by our parser. *Arcs* are the basic parts: any dependency tree can be "read out" from the arcs it contains. *Consecutive siblings* and *grandparent* parts introduce horizontal and vertical Markovization (McDonald et al., 2006; Carreras, 2007). We break the horizontal Markov assumption via *all siblings* parts and the vertical one through parts which indicate a *directed path* between two words. Inspired by transition-based parsers, we also adopt *head bigram* parts, which look at the heads attached to consecutive words. Finally, we follow Martins et al. (2009a) and have parts which indicate if an arc is *non-projective* (*i.e.*, if it spans words that do not descend from its head).

Each $\mathcal{Y}_s$ is associated with its own set of parts $\mathcal{R}_s$, in the same sense as above; we represent the elements of $\mathcal{Y}_s$ as binary vectors $z_s = \langle z_s(r) \rangle_{r \in \mathcal{R}_s}$. Examples are vectors indicating a tree structure, a sequence, or an assignment of variables to a factor, in which case it may happen that only some binary vectors are legal. Some parts in $\mathcal{R}_s$ are basic, while others are not. We denote by $\bar{\mathcal{R}}_s = \mathcal{R}_s \cap \mathcal{R}$ the subset of the ones that are. In addition, we assume that:

- $\mathcal{R}_1, \ldots, \mathcal{R}_S$ jointly cover $\mathcal{R}$, *i.e.*, $\mathcal{R} \subseteq \bigcup_{s=1}^{S} \mathcal{R}_s$;
- Only basic parts may overlap, *i.e.*, $\mathcal{R}_s \cap \mathcal{R}_t \subseteq \mathcal{R}, \forall s, t \in \{1, \ldots, S\}$;
- Each $z_s \in \mathcal{Y}_s$ is completely defined by its entries indexed by elements of $\bar{\mathcal{R}}_s$, from which we can guess the ones in $\mathcal{R}_s \setminus \bar{\mathcal{R}}_s$. This implies that each $y \in \mathcal{Y}$ has a unique decomposition $\langle z_1, \ldots, z_S \rangle$.

Fig. 1 shows several parts used in dependency parsing models; in phrase-based parsing, these could be spans and production rules anchored in the surface string; in sequence labeling, they can be unigram, bigram, and trigram labels.[1]

[1]There is a lot of flexibility about how to decompose the model into S components: each set $\mathcal{R}_s$ can correspond to a sin-

Global consistency. We want to be able to read out $y \in \mathcal{Y}$ by "gluing" together the components $\langle z_1, \ldots, z_S \rangle$. This is only meaningful if they are "globally consistent," a notion which we make precise. Two components $z_s \in \mathcal{Y}_s$ and $z_t \in \mathcal{Y}_t$ are said to be *consistent* (denoted $z_s \sim z_t$) if they agree on their overlaps, *i.e.*, if $z_s(r) = z_t(r), \forall r \in \mathcal{R}_s \cap \mathcal{R}_t$. A complete assignment $\langle z_1, \ldots, z_S \rangle$ is *globally consistent* if all pairs of components are consistent. This is equivalent to the existence of a witness vector $\langle u(r) \rangle_{r \in \mathcal{R}}$ such that $z_s(r) = u(r), \forall s, r \in \bar{\mathcal{R}}_s$.

With this setup, assuming that the score function decomposes as $f(z) = \sum_{s=1}^{S} f_s(z_s)$, the decoding problem (which extends Eq. 2 for $S \geq 2$) becomes:

$$\begin{array}{lll} P: & \text{maximize} & \sum_{s=1}^{S} f_s(z_s) \\ & \text{w.r.t.} & z_s \in \mathcal{Y}_s, \quad \forall s \\ & & \langle u(r) \rangle_{r \in \mathcal{R}} \in \mathbb{R}^{|\mathcal{R}|}, \\ & \text{s.t.} & z_s(r) = u(r), \quad \forall s, r \in \bar{\mathcal{R}}_s. \end{array} \tag{3}$$

We call the equality constraints expressed in the last line the "agreement constraints." It is these constraints that complicate the problem, which would otherwise be exactly separable into S subproblems. The dual decomposition method (Komodakis et al., 2007; Rush et al., 2010) builds an approximation by dualizing out these constraints, as we describe next.

2.3 Dual Decomposition

We describe dual decomposition in a slightly different manner than Rush et al. (2010): we will first build a relaxation of P (called P'), in which the entire approximation is enclosed. Then, we dualize P', yielding problem D. In the second step, the duality gap is zero, *i.e.*, P' and D are equivalent.[2]

Relaxation. For each $s \in \{1, \ldots, S\}$ we consider the convex hull of $\mathcal{Y}_s$,

$$\mathcal{Z}_s = \left\{ \sum_{z_s \in \mathcal{Y}_s} p(z_s) z_s \;\middle|\; p(z_s) \geq 0, \sum_{z_s \in \mathcal{Y}_s} p(z_s) = 1 \right\}. \tag{4}$$

We have that $\mathcal{Y}_s = \mathcal{Z}_s \cap \mathbb{Z}^{|\mathcal{R}_s|}$; hence, problem P (Eq. 3) is equivalent to one in which each $\mathcal{Y}_s$ is replaced by $\mathcal{Z}_s$ and the z-variables are constrained to be integer. By dropping the integer constraints, we obtain the following relaxed problem:

$$\begin{array}{lll} P': & \text{maximize} & \sum_{s=1}^{S} f_s(z_s) \\ & \text{w.r.t.} & z_s \in \mathcal{Z}_s, \quad \forall s \\ & & \langle u(r) \rangle_{r \in \mathcal{R}} \in \mathbb{R}^{|\mathcal{R}|}, \\ & \text{s.t.} & z_s(r) = u(r), \quad \forall s, r \in \bar{\mathcal{R}}_s. \end{array} \tag{5}$$

If the score functions f_s are convex, P' becomes a convex program (unlike P, which is discrete); being a relaxation, it provides an upper bound of P.

Lagrangian. Introducing a Lagrange multiplier $\lambda_s(r)$ for each agreement constraint in Eq. 5, one obtains the Lagrangian function

$$\begin{aligned} \mathcal{L}(z, u, \lambda) = & \sum_{s=1}^{S} \left(f_s(z_s) + \sum_{r \in \bar{\mathcal{R}}_s} \lambda_s(r) z_s(r) \right) \\ & - \sum_{r \in \mathcal{R}} \left(\sum_{s: r \in \bar{\mathcal{R}}_s} \lambda_s(r) \right) u(r), \end{aligned} \tag{6}$$

and the dual problem (the *master*)

$$\begin{array}{lll} D: & \text{minimize} & \sum_{s=1}^{S} g_s(\lambda_s) \\ & \text{w.r.t.} & \lambda = \langle \lambda_1, \ldots, \lambda_S \rangle \\ & \text{s.t.} & \sum_{s: r \in \bar{\mathcal{R}}_s} \lambda_s(r) = 0, \ \forall r \in \mathcal{R}, \end{array} \tag{7}$$

where the $g_s(\lambda_s)$ are the solution values of the following subproblems (the *slaves*):

$$\begin{array}{ll} \text{maximize} & f_s(z_s) + \sum_{r \in \bar{\mathcal{R}}_s} \lambda_s(r) z_s(r) \\ \text{w.r.t.} & z_s \in \mathcal{Z}_s. \end{array} \tag{8}$$

We assume that strong duality holds (w.r.t. Eqs. 5–7), hence we have $P \leq P' = D$.[3]

Solving the dual. Why is the dual formulation D (Eqs. 7–8) more appealing than P' (Eq. 5)? The answer is that the components $1, \ldots, S$ are now decoupled, which makes things easier provided each slave subproblem (Eq. 8) can be solved efficiently. In fact, this is always a concern in the mind of the model's designer when she chooses a decomposition (the framework that we describe in §3, in some sense, alleviates her from this concern). If the score functions are linear, *i.e.*, of the form $f_s(z_s) = \sum_{r \in \mathcal{R}_s} \theta_s(r) z_s(r)$ for some vector $\theta_s = \langle \theta_s(r) \rangle_{r \in \mathcal{R}_s}$, then Eq. 8 becomes a linear program, for which a solution exists at a vertex of $\mathcal{Z}_s$ (which

gle factor in a factor graph (Smith and Eisner, 2008), or to a entire subgraph enclosing several factors (Koo et al., 2010), or even to a formula in Markov logic (Richardson and Domingos, 2006). In these examples, the basic parts may correspond to individual variable-value pairs.

[2] Instead of following the path $P \to P' \to D$, Rush et al. (2010) go straight from P to D via a Lagrangian relaxation. The two formulations are equivalent for linear score functions.

[3] This is guaranteed if the score functions f_s are linear.

in turn is an element of $\mathcal{Y}_s$). Depending on the structure of the problem, Eq. 8 may be solved by brute force, dynamic programming, or specialized combinatorial algorithms (Rush et al., 2010; Koo et al., 2010; Rush and Collins, 2011).

Applying the projected subgradient method (Komodakis et al., 2007; Rush et al., 2010) to the master problem (Eq. 7) yields a remarkably simple algorithm, which at each round t solves the subproblems in Eq. 8 for $s = 1, \ldots, S$, and then gathers these solutions (call them z_s^{t+1}) to compute an "averaged" vote for each basic part,

$$u^{t+1}(r) = \frac{1}{\delta(r)} \sum_{s:r \in \bar{\mathcal{R}}_s} z_s^{t+1}(r), \quad (9)$$

where $\delta(r) = |\{s : r \in \mathcal{R}_s\}|$ is the number of components which contain part r. An update of the Lagrange variables follows,

$$\lambda_s^{t+1}(r) = \lambda_s^t(r) - \eta_t(z_s^{t+1}(r) - u^{t+1}(r)), \quad (10)$$

where η_t is a stepsize. Intuitively, the algorithm pushes for a consensus among the slaves (Eq. 9), via an adjustment of the Lagrange multipliers which takes into consideration deviations from the average (Eq. 10). The subgradient method is guaranteed to converge to the solution of D (Eq. 7), for suitably chosen stepsizes (Shor, 1985; Bertsekas et al., 1999); it also provides a certificate of optimality in case the relaxation is tight (*i.e.*, $P = D$) and the *exact* solution has been found. However, convergence is slow when S is large (as we will show in the experimental section), and no certificates are available when there is a relaxation gap ($P < P'$). In the next section, we describe the DD-ADMM algorithm (Martins et al., 2011), which does not have these drawbacks and shares a similar simplicity.

3 Alternating Directions Method

There are two reasons why subgradient-based dual decomposition is not completely satisfying:

- it may take a long time to reach a consensus;
- it puts all its resources in solving the dual problem D, and does not attempt to make progress in the primal P', which is closer to our main concern.[4]

[4]Our main concern is P; however solving P' is often a useful step towards that goal, either because a good rounding scheme exists, or because one may build tighter relaxations to approach P (Sontag et al., 2008; Rush and Collins, 2011).

Taking a look back at the relaxed primal problem P' (Eq. 5), we see that any primal feasible solution must satisfy the agreement constraints. This suggests that penalizing violations of these constraints could speed up consensus.

Augmented Lagrangian. By adding a penalty term to Eq. 6, we obtain the *augmented Lagrangian function* (Hestenes, 1969; Powell, 1969):

$$\mathcal{A}_\rho(z, u, \lambda) = \mathcal{L}(z, u, \lambda) - \frac{\rho}{2} \sum_{s=1}^{S} \sum_{r \in \bar{\mathcal{R}}_s} (z_s(r) - u(r))^2, \quad (11)$$

where the parameter $\rho \geq 0$ controls the intensity of the penalty. Augmented Lagrangian methods are well-known in the optimization community (see, *e.g.*, Bertsekas et al. (1999), §4.2). They alternate updates to the λ-variables, while seeking to maximize $\mathcal{A}_\rho$ with respect to z and u. In our case, however, this joint maximization poses difficulties, since the penalty term couples the two variables. The *alternating directions method of multipliers* (ADMM), coined by Gabay and Mercier (1976) and Glowinski and Marroco (1975), sidesteps this issue by performing alternate maximizations,

$$z^{t+1} = \arg\max_z \mathcal{A}_\rho(z, u^t, \lambda^t), \quad (12)$$

$$u^{t+1} = \arg\max_u \mathcal{A}_\rho(z^{t+1}, u, \lambda^t), \quad (13)$$

followed by an update of the Lagrange multipliers as in Eq. 10. Recently, ADMM has attracted interest, being applied in a variety of problems; see the recent book by Boyd et al. (2011) for an overview. As derived in the App. A, the u-updates in Eq. 13 have a closed form, which is precisely the averaging operation performed by the subgradient method (Eq. 9). We are left with the problem of computing the z-updates. Like in the subgradient approach, the maximization in Eq. 12 can be separated into S independent slave subproblems, which now take the form:

$$\begin{array}{ll} \text{maximize} & f_s(z_s) + \sum_{r \in \bar{\mathcal{R}}_s} \lambda_s(r) z_s(r) \\ & -\frac{\rho}{2} \sum_{r \in \bar{\mathcal{R}}_s} (z_s(r) - u^t(r))^2 \\ \text{w.r.t.} & z_s \in \mathcal{Z}_s(x). \end{array} \quad (14)$$

Comparing Eq. 8 and Eq. 14, we observe that the only difference is the presence in the latter of a

quadratic term which regularizes towards the previous averaged votes $u^t(r)$. Because of this term, the solution of Eq. 14 for linear score functions may not be at a vertex (in contrast to the subgradient method). We devote §4 to describing exact and efficient ways of solving the problem in Eq. 14 for important, widely used slaves. Before going into details, we mention another advantage of ADMM over the subgradient algorithm: it knows when to stop.

Primal and dual residuals. Recall that the subgradient method provides optimality certificates when the relaxation is tight ($P = P'$) and an exact solution of P has been found. While this is good enough when tight relaxations are frequent, as in the settings explored by Rush et al. (2010), Koo et al. (2010), and Rush and Collins (2011), it is hard to know when to stop when a relaxation gap exists. We would like to have similar guarantees concerning the relaxed primal P'.[5] A general weakness of subgradient algorithms is that they do not have this capacity, and so are usually stopped by specifying a maximum number of iterations. In contrast, ADMM allows to keep track of primal and dual residuals (Boyd et al., 2011). This allows providing certificates not only for the exact solution of P (when the relaxation is tight), but also to terminate when a near optimal solution of the relaxed problem P' has been found. The *primal residual* r_P^t measures the amount by which the agreement constraints are violated:

$$r_P^t = \frac{\sum_{s=1}^{S} \sum_{r \in \bar{\mathcal{R}}_s} (z_s^t(r) - u^t(r))^2}{\sum_{r \in \mathcal{R}} \delta(r)}; \qquad (15)$$

the *dual residual* r_D^t is the amount by which a dual optimality condition is violated (see Boyd et al. (2011), p.18, for details). It is computed via:

$$r_D^t = \frac{\sum_{r \in \mathcal{R}} \delta(r)(u^t(r) - u^{t-1}(r))^2}{\sum_{r \in \mathcal{R}} \delta(r)}, \qquad (16)$$

Our stopping criterion is thus that these two residuals are below a threshold, *e.g.*, 1×10^{-3}. The complete algorithm is depicted as Alg. 1. As stated in Martins et al. (2011), convergence to the solution of P' is guaranteed with a fixed stepsize $\eta_t = \tau\rho$, with $\tau \in [1, 1.618]$ (Glowinski and Le Tallec, 1989, Thm. 4.2). In our experiments, we set $\tau = 1.5$, and adapt ρ as described in (Boyd et al., 2011, p.20).[6]

Algorithm 1 ADMM-based Dual Decomposition

input: score functions $\langle f_s(.)\rangle_{s=1}^S$, parameters ρ, η, thresholds ϵ_P and ϵ_D.
initialize $t \leftarrow 1$
initialize $u^1(r) \leftarrow 0.5$ and $\lambda_s^1(r) \leftarrow 0, \quad \forall s, \forall r \in \bar{\mathcal{R}}_s$
repeat
  for each $s = 1, \ldots, S$ **do**
    make a z_s-update, yielding z_s^{t+1} (Eq. 14)
  end for
  make a u-update, yielding u^{t+1} (Eq. 9)
  make a λ-update, yielding λ^{t+1} (Eq. 10)
  $t \leftarrow t + 1$
until $r_P^{t+1} < \epsilon_P$ and $r_D^{t+1} < \epsilon_D$ (Eqs. 15–16)
output: relaxed primal and dual solutions u, z, λ

4 Solving the Subproblems

In this section, we address the slave subproblems of DD-ADMM (Eq. 14). We show how these subproblems can be solved efficiently for several important cases that arise in NLP applications. Throughout, we assume that the score functions f_s are linear, *i.e.*, they can be written as $f_s(z_s) = \sum_{r \in \mathcal{R}_s} \theta_s(r) z_s(r)$. This is the case whenever a linear model is used, in which case $\theta_s(r) = \frac{1}{\delta(r)} \boldsymbol{w} \cdot \boldsymbol{\phi}(x, r)$, where $\boldsymbol{w}$ is a weight vector and $\boldsymbol{\phi}(x, r)$ is a feature vector. It is also the scenario studied in previous work in dual decomposition (Rush et al., 2010). Under this assumption, and discarding constant terms, the slave subproblem in Eq. 14 becomes:

$$\max_{z_s \in \mathcal{Z}_s} \sum_{r \in \mathcal{R}_s \setminus \bar{\mathcal{R}}_s} \theta_s(r) z_s(r) - \frac{\rho}{2} \sum_{r \in \bar{\mathcal{R}}_s} (z_s(r) - a_s(r))^2. \qquad (17)$$

where $a_s(r) = u^t(r) + \rho^{-1}(\theta_s(r) + \lambda_s^t(r))$. Since $\mathcal{Z}_s$ is a polytope, Eq. 17 is a quadratic program, which can be solved with a general purpose solver. However, that does not exploit the structure of $\mathcal{Z}_s$ and is inefficient when $|\mathcal{R}_s|$ is large. We next show that for many cases, a closed-form solution is available and

[5] This problem is more important than it may look. Problems with many slaves tend to be less exact, hence relaxation gaps are frequent. Also, when decoding is embedded in training, it is useful to obtain the *fractional* solution of the relaxed primal P (rather than an approximate integer solution). See Kulesza and Pereira (2007) and Martins et al. (2009b) for details.

[6] Briefly, we initialize $\rho = 0.03$ and then increase/decrease ρ by a factor of 2 whenever the primal residual becomes > 10 times larger/smaller than the dual residual.

can be computed in $O(|\mathcal{R}_s|)$ time, up to log factors.[7]

Pairwise Factors. This is the case where $\mathcal{R}_{\text{PAIR}} = \{r_1, r_2, r_{12}\}$, where r_1 and r_2 are basic parts and r_{12} is their conjunction, *i.e.*, we have $\mathcal{Y}_{\text{PAIR}} = \{\langle z_1, z_2, z_{12}\rangle \mid z_{12} = z_1 \wedge z_2\}$. This factor is useful to make conjunctions of variables participate in the score function (see *e.g.* the grandparent, sibling, and head bigram parts in Fig. 1). The convex hull of $\mathcal{Y}_{\text{PAIR}}$ is the polytope $\mathcal{Z}_{\text{PAIR}} = \{\langle z_1, z_2, z_{12}\rangle \in [0,1]^3 \mid z_{12} \leq z_1,\ z_{12} \leq z_2, z_{12} \geq z_1 + z_2 - 1\}$, as shown by Martins et al. (2010). In this case, problem (17) can be written as

$$\begin{array}{ll} \max & \theta_{12} z_{12} - \frac{\rho}{2}[(z_1 - a_1)^2 + (z_2 - a_2)^2] \\ \text{w.r.t.} & \langle z_1, z_2, z_{12}\rangle \in [0,1]^3 \\ \text{s.t.} & z_{12} \leq z_1,\ z_{12} \leq z_2,\ z_{12} \geq z_1 + z_2 - 1 \end{array} \tag{18}$$

and has a closed form solution (see App. B).

Uniqueness Quantification and XOR. Many problems involve constraining variables to take a single value: for example, in dependency parsing, a modifier can only take one head. This can be expressed as the statement $\exists! y : Q(y)$ in first-order logic,[8] or as a one-hot XOR factor in a factor graph (Smith and Eisner, 2008; Martins et al., 2010). In this case, $\mathcal{R}_{\text{XOR}} = \{r_1, \ldots, r_n\}$, and $\mathcal{Y}_{\text{XOR}} = \{\langle z_1, \ldots, z_n\rangle \in \{0,1\}^n \mid \sum_{i=1}^n z_i = 1\}$. The convex hull of $\mathcal{Y}_{\text{XOR}}$ is $\mathcal{Z}_{\text{XOR}} = \{\langle z_1, \ldots, z_n\rangle \in [0,1]^n \mid \sum_{i=1}^n z_i = 1\}$. Assume for the sake of simplicity that all parts in $\mathcal{R}_{\text{XOR}}$ are basic.[9] Up to a constant, the slave subproblem becomes:

$$\begin{array}{ll} \text{minimize} & \frac{1}{2}\sum_{i=1}^n (z_i - a_i)^2 \\ \text{w.r.t.} & \langle z_1, \ldots, z_n\rangle \in [0,1]^n \\ \text{s.t.} & \sum_i^n z_i = 1. \end{array} \tag{19}$$

This is the problem of projecting onto the probability simplex, which can be done in $O(n \log n)$ time via a sort operation (see App. C).[10]

[7] This matches the asymptotic time that would be necessary to solve the corresponding problems in the subgradient method, for which algorithms are straightforward to derive. The point is that with ADMM fewer instances of these subproblems need to be solved, due to faster convergence of the master problem.

[8] The symbol $\exists!$ means "there is one and only one."

[9] A similar derivation can be made otherwise.

[10] Also common is the need for constraining existence of "at most one" element. This can be reduced to uniqueness quantification by adding a dummy NULL label.

Existential Quantification and OR. Sometimes, only existence is required, not necessarily uniqueness. This can be expressed with disjunctions, existential quantifiers in first-order logic ($\exists y : Q(y)$), or as a OR factor. In this case, $\mathcal{R}_{\text{OR}} = \{r_1, \ldots, r_n\}$, $\mathcal{Y}_{\text{OR}} = \{\langle z_1, \ldots, z_n\rangle \in \{0,1\}^n \mid \bigvee_{i=1}^n z_i = 1\}$, and the convex hull is $\mathcal{Z}_{\text{OR}} = \{\langle z_1, \ldots, z_n\rangle \in [0,1]^n \mid \sum_{i=1}^n z_i \geq 1\}$ (see Tab. 1 in Martins et al. (2010)). The slave subproblem becomes:

$$\begin{array}{ll} \text{minimize} & \frac{1}{2}\sum_{i=1}^n (z_i - a_i)^2 \\ \text{w.r.t.} & \langle z_1, \ldots, z_n\rangle \in [0,1]^n \\ \text{s.t.} & \sum_i^n z_i \geq 1. \end{array} \tag{20}$$

We derive a procedure in App. D to compute this projection in $O(n \log n)$ runtime, also with a sort.

Negations. The two cases above can be extended to allow some of their inputs to be *negated*. By a change of variables in Eqs. 19–20 it is possible to reuse the same black box that solves those problems. The procedure is as follows:

1. For $i = 1, \ldots, n$, set $a'_i = 1 - a_i$ if the ith variable is negated, and $a'_i = a_i$ otherwise.
2. Obtain $\langle z'_1, \ldots, z'_n\rangle$ as the solution of Eqs. 19 or 20 providing $\langle a'_1, \ldots, a'_n\rangle$ as input.
3. For $i = 1, \ldots, n$, set $z_i = 1 - z'_i$ if the ith variable is negated, and $z_i = z'_i$ otherwise.

The ability to handle negated variables adds a great degree of flexibility. From De Morgan's laws, we can now handle conjunctions and implications (since $\bigwedge_{i=1}^n Q_i(x) \Rightarrow R(x)$ is equivalent to $\bigvee_{i=1}^n \neg Q_i(x) \vee R(x)$).

Logical Variable Assignments. All previous examples involve taking a group of existing variables and defining a constraint. Alternatively, we may want to define a new variable which is the result of an operation involving other variables. For example, $R(x) := \exists! y : Q(x, y)$. This corresponds to the XOR-WITH-OUTPUT factor in Martins et al. (2010). Interestingly, this can be expressed as a XOR where $R(x)$ is negated (*i.e.*, either $\neg R(x)$ holds or exactly one y satisfies $Q(x, y)$, but not both).

A more difficult problem is that of the OR-WITH-OUTPUT factor, expressed by the formula $R(x) := \exists y : Q(x, y)$. We have $\mathcal{R}_{\text{OR-OUT}} = \{r_0, \ldots, r_n\}$, and $\mathcal{Y}_{\text{OR-OUT}} = \{\langle z_0, \ldots, z_n\rangle \in \{0,1\}^n \mid z_0 =$

		# Slaves	Runtime	Description
Tree	$\exists! h : \texttt{arc}(h, m), \quad m \neq 0$	$O(n)$	$O(n \log n)$	Each non-root word has a head
	$\texttt{flow}(h, m, k) \Rightarrow \texttt{arc}(h, m)$	$O(n^3)$	$O(1)$	Only active arcs may carry flow
	$\texttt{path}(m, d) := \exists! h : \texttt{flow}(h, m, d), \quad m \neq 0$	$O(n^2)$	$O(n \log n)$	
	$\texttt{path}(h, d) := \exists! m : \texttt{flow}(h, m, d)$	$O(n^2)$	$O(n \log n)$	Paths and flows are consistent
	$\texttt{path}(0, m) := \text{TRUE}, \quad \texttt{flow}(h, m, m) := \text{TRUE}$			(see Martins et al. (2010))
All siblings	$\texttt{sibl}(h, m, s) := \texttt{arc}(h, m) \wedge \texttt{arc}(h, s)$	$O(n^3)$	$O(1)$	By definition
Grandp.	$\texttt{grand}(g, h, m) := \texttt{arc}(g, h) \wedge \texttt{arc}(h, m)$	$O(n^3)$	$O(1)$	By definition
Head Bigram	$\texttt{bigram}(b, h, m) := \texttt{arc}(b, m-1) \wedge \texttt{arc}(h, m), \quad m \neq 0$	$O(n^3)$	$O(1)$	By definition
Consec. Sibl.	$\texttt{lastsibl}(h, m, m) := \texttt{arc}(h, m)$			
	$\exists! m \in [h, k] : \texttt{lastsibl}(h, m, k)$	$O(n^2)$	$O(n \log n)$	Head automaton model
	$\texttt{lastsibl}(h, m, k) := \texttt{lastsibl}(h, m, k+1)$			(see supplementary material)
	$\quad \oplus \texttt{nextsibl}(h, m, k+1)$	$O(n^3)$	$O(1)$	
	$\texttt{arc}(h, m) := \exists! s \in [h, m] : \texttt{nextsibl}(h, s, m)$	$O(n^2)$	$O(n \log n)$	
Nonproj. Arc	$\texttt{nonproj}(h, m) := \texttt{arc}(h, m) \wedge \exists k \in [h, m] : \neg \texttt{path}(h, k)$	$O(n^2)$	$O(n \log n)$	By definition

Table 1: First-order logic formulae underlying our dependency parser. The basic parts are the predicate variables $\texttt{arc}(h, m)$ (indicating an arc linking head h to modifier m), $\texttt{path}(a, d)$ (indicating a directed path from ancestor a to descendant d), $\texttt{nextsibl}(h, m, s)$ (indicating that $\langle h, m \rangle$ and $\langle h, s \rangle$ are consecutive siblings), $\texttt{nonproj}(h, m)$ (indicating that $\langle h, m \rangle$ is a non-projective arc), as well as the auxiliary variables $\texttt{flow}(h, m, d)$ (indicating that arc $\langle h, m \rangle$ carries flow to d), and $\texttt{lastsibl}(h, m, k)$ (indicating that, up to position k, the last seen modifier of h occurred at position m). The non-basic parts are the pairwise factors $\texttt{sibl}(h, m, s)$, $\texttt{grand}(g, h, m)$, and $\texttt{bigram}(b, h, m)$; as well as each logical formula. Columns 3–4 indicate the number of parts of each kind, and the time complexity for solving each subproblem. For a sentence of length n, there are $O(n^3)$ parts and the total complexity is $O(n^3 \log n)$.

$\bigvee_{i=1}^n z_i\}$. The convex hull of $\mathcal{Y}_{\text{OR-OUT}}$ is the following set: $\mathcal{Z}_{\text{OR-OUT}} = \{\langle z_0, \ldots, z_n \rangle \in [0, 1]^n \mid z_0 \geq \sum_{i=1}^n z_i, z_0 \leq z_i, \ \forall i = 1, \ldots, n\}$ (Martins et al., 2010, Tab.1). The slave subproblem is:

$$\begin{array}{ll} \text{minimize} & \frac{1}{2} \sum_{i=0}^n (z_i - a_i)^2 \\ \text{w.r.t.} & \langle z_0, \ldots, z_n \rangle \in [0, 1]^n \\ \text{s.t.} & z_0 \geq \sum_{i=1}^n z_i; \ z_0 \leq z_i, \ \forall i = 1, \ldots, n. \end{array} \tag{21}$$

The problem in Eq. 21 is more involved than the ones in Eqs. 19–20. Yet, there is still an efficient procedure with runtime $O(n \log n)$ (see App. E). By using the result above for negated variables, we are now endowed with a procedure for many other cases, such that AND-WITH-OUTPUT and formulas with universal quantifiers (*e.g.*, $R(x) := \forall y : Q(x, y)$). Up to a log-factor, the runtimes will be linear in the number of predicates.

Larger Slaves. The only disadvantage of DD-ADMM in comparison with the subgradient algorithm is that there is not an obvious way of solving the subproblem in Eq. 14 exactly for large combinatorial factors, such as the TREE constraint in dependency parsing, or a sequence model. Hence, our method seems to be more suitable for decompositions which involve "simple slaves," even if their number is large. However, this does not rule out the possibility of using this method otherwise. Eckstein and Bertsekas (1992) show that the ADMM algorithm may still converge when the z-updates are inexact. Hence the method may still work if the slaves are solved numerically up to some accuracy. We defer this to future investigation.

5 Experiments: Dependency Parsing

We used 14 datasets with non-projective dependencies from the CoNLL-2006 and CoNLL-2008 shared tasks (Buchholz and Marsi, 2006; Surdeanu et al., 2008). We also used a projective English dataset derived from the Penn Treebank by applying the standard head rules of Yamada and Matsumoto (2003).[11] We did not force the parser to output projective trees or unique roots for any of the datasets; everything is learned from the data. We trained by running 10 iterations of the cost-augmented MIRA algorithm (Crammer et al., 2006) with LP-relaxed decoding, as in Martins et al. (2009b). Following common practice (Charniak and Johnson, 2005; Carreras et al., 2008), we employed a coarse-to-fine procedure to prune away unlikely candidate arcs, as described by Koo and Collins (2010). To ensure valid parse trees at test time, we rounded fractional

[11] As usual, we train on sections §02–21, use §22 as validation data, and test on §23. We ran SVMTool (Giménez and Marquez, 2004) to obtain automatic part-of-speech tags for §22–23.

solutions as described in Martins et al. (2009a) (yet, solutions were integral most of the time).

The parts used in our full model are the ones depicted in Fig. 1. Note that a subgradient-based method could handle some of those parts efficiently (*arcs*, *consecutive siblings*, *grandparents*, and *head bigrams*) by composing arc-factored models, head automata, and a sequence labeler. However, no lightweight decomposition seems possible for incorporating parts for *all siblings*, *directed paths*, and *non-projective arcs*. Tab. 1 shows the first-order logical formulae that encode the constraints in our model. Each formula gives rise to a subproblem which is efficiently solvable (see §4). By ablating some of rows of Tab. 1 we recover known methods:

- Resorting to the *tree* and *consecutive sibling* formulae gives one of the models in Koo et al. (2010), with the *same* linear relaxation (a proof of this fact is included in App. F);
- Resorting to *tree*, *all siblings*, *grandparent*, and *non-projective arcs*, recovers a multi-commodity flow configuration proposed by Martins et al. (2009a); the relaxation is also the same.[12]

The experimental results are shown in Tab. 2. For comparison, we include the best published results for each dataset (at the best of our knowledge), among transition-based parsers (Nivre et al., 2006; Huang and Sagae, 2010), graph-based parsers (McDonald et al., 2006; Koo and Collins, 2010), hybrid methods (Nivre and McDonald, 2008; Martins et al., 2008), and turbo parsers (Martins et al., 2010; Koo et al., 2010). Our full model achieved the best reported scores for 7 datasets. The last two columns show a consistent improvement (with the exceptions of Chinese and Arabic) when using the full set of features over a second order model with grandparent and consecutive siblings, which is our reproduction of the model of Koo et al. (2010).[13]

[12] Although Martins et al. (2009a) also incorporated consecutive siblings in one of their configurations, our constraints are tighter than theirs. See App. F.

[13] Note however that the actual results of Koo et al. (2010) are higher than our reproduction, as can be seen in the second column. The differences are due to the features that were used and on the way the models were trained. The cause is not search error: exact decoding with an ILP solver (CPLEX) revealed no significant difference with respect to our G+CS column. We leave further analysis for future work.

PTB §22	91.02	92.13	92.32	92.36	92.41
PTB §23	91.36	92.19	92.41	92.50	92.53

Table 3: Feature ablation experiments. AF is an arc-factored model; +G+CS adds grandparent and consecutive siblings; +AS adds all-siblings; +NP adds non-projective arcs; Full adds the bigram and directed paths.

Feature ablation and error analysis. We conducted a simple ablation study by training several models on the English PTB with different sets of features. Tab. 3 shows the results. As expected, performance keeps increasing as we use models with greater expressive power. We show some concrete examples in App. G of sentences that the full model parsed correctly, unlike less expressive models.

Convergence speed and optimality. Fig. 2 compares the performance of DD-ADMM and the subgradient algorithms in the validation section of the PTB.[14] For the second order model, the subgradient

[14] The learning rate in the subgradient method was set as $\eta_t = \eta_0/(1+N_{\text{incr}}(t))$, as in Koo et al. (2010), where $N_{\text{incr}}(t)$ is the number of dual increases up to the tth iteration, and η_0 is chosen to maximize dual decrease after 20 iterations (in a per sentence basis). Those preliminary iterations are not plotted in Fig. 2.

method has more slaves than in Koo et al. (2010): it has a slave imposing the TREE constraint (whose subproblems consists on finding a minimum spanning tree) and several for the all-sibling parts, yielding an average number of 310.5 and a maximum of 4310 slaves. These numbers are still manageable, and we observe that a "good" UAS is achieved relatively quickly. The ADMM method has many more slaves due to the multicommodity flow constraints (average 1870.8, maximum 65446), yet it attains optimality sooner, as can be observed in the right plot. For the full model, the subgradient-based method becomes extremely slow, and the UAS score severely degrades (after 1000 iterations it is 2% less than the one obtained with the ADMM-based method, with very few instances having been solved to optimality). The reason is the number of slaves: in this configuration and dataset the average number of slaves per instance is 3327.4, and the largest number is 113207. On the contrary, the ADMM method keeps a robust performance, with a large fraction of optimality certificates in early iterations.

Runtime and caching strategies. Despite its suitability to problems with many overlapping components, our parser is still 1.6 times slower than Koo et al. (2010) (0.34 against 0.21 sec./sent. in PTB §23), and is far beyond the speed of transition-based parsers (*e.g.*, Huang and Sagae (2010) take 0.04 sec./sent. on the same data, although accuracy is lower, 92.1%). Our implementation, however, is not fully optimized. We next describe how considerable speed-ups are achieved by caching the subproblems, following a strategy similar to Koo et al. (2010).

Fig. 3 illustrates the point. After a few iterations, many variables $u(r)$ see a consensus being achieved (*i.e.*, $u^t(r) = z_s^{t+1}(r), \forall s$) and enter an idle state: they are left unchanged by the u-update in Eq. 9, and so do the Lagrange variables $\lambda_s^{t+1}(r)$ (Eq. 10). If by iteration t all variables in a subproblem s are idle, then $z_s^{t+1}(r) = z_s^t(r)$, hence the subproblem does not need to be resolved.[15] Fig. 3 shows that many variables and subproblems are left untouched after the first few rounds.

[15]Even if not all variables are idle in s, caching may still be useful: note that the z-updates in Eq. 14 tend to be sparse for the subproblems described in §4 (these are Euclidean projections onto polytopes with 0/1 vertices, which tend to hit corners). Another trick that may accelerate the algorithm is warm-starting: since many subproblems involve a sort operation, storing the sorted indexes may speedup the next round.

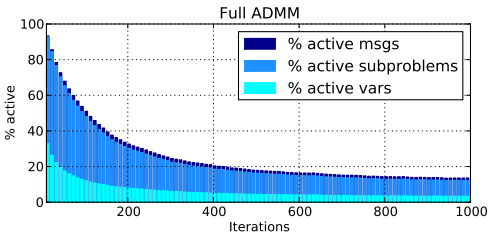

Figure 3: Fraction of active variables, subproblems and messages along DD-ADMM iterations (full model). The number of active messages denotes the total number of variables (active or not) that participate in an active factor.

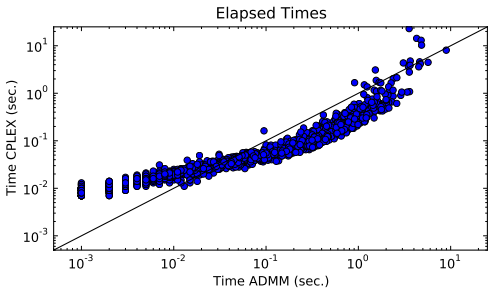

Figure 4: Runtimes of DD-ADMM and CPLEX on PTB §22 (each point is a sentence). Average runtimes are 0.362 (DD-ADMM) and 0.565 sec./sent. (CPLEX).

Finally, Fig. 4 compares the runtimes of our implementation of DD-ADMM with those achieved by a state-of-the-art LP solver, CPLEX, in its best performing configuration: the simplex algorithm applied to the dual LP. We observe that DD-ADMM is faster in some regimes but slower in others. For short sentences (< 15 words), DD-ADMM tends to be faster. For longer sentences, CPLEX is quite effective as it uses good heuristics for the pivot steps in the simplex algorithm; however, we observed that it sometimes gets trapped on large problems. Note also that DD-ADMM is not fully optimized, and that it is much more amenable to parallelization than the simplex algorithm, since it is composed of many independent slaves. This suggests potentially significant speed-ups in multi-core environments.

6 Related Work

Riedel and Clarke (2006) first formulated dependency parsing as an integer program, along with logical constraints. The multicommodity flow for-

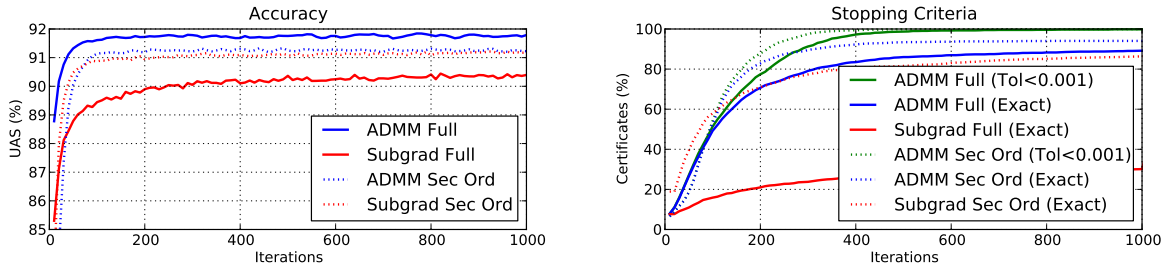

Figure 2: UAS including punctuation (left) and fraction of optimality certificates (right) accross iterations of the subgradient and DD-ADMM algorithms, in PTB §22. "Full" is our full model; "Sec Ord" is a second-order model with grandparents and all siblings, for which the subgradient method uses a coarser decomposition with a TREE factor. Since subgradient and DD-ADMM are solving the same problems, the solid lines (as the dashed ones) would meet in the limit, however subgradient converges very slowly for the full model. The right plot shows optimality certificates for both methods, indicating that an exact solution of P has been found; for DD-ADMM we also plot the fraction of instances that converged to an accurate solution of P' (primal and dual residuals $< 10^{-3}$) and hence can be stopped.

mulation was introduced by Martins et al. (2009a), along with some of the parts considered here. Koo et al. (2010) proposed a subgradient-based dual decomposition method that elegantly combines head automata with maximum spanning tree algorithms; these parsers, as well as the loopy belief propagation method of Smith and Eisner (2008), are all instances of turbo parsers (Martins et al., 2010).

DD-ADMM has been proposed and theoretically analyzed by Martins et al. (2011) for problems representable as factor graphs. The general ADMM method has a long-standing history in optimization (Hestenes, 1969; Powell, 1969; Glowinski and Marroco, 1975; Gabay and Mercier, 1976; Boyd et al., 2011). Other methods have been recently proposed to accelerate dual decomposition, such as Jojic et al. (2010) and Meshi and Globerson (2011) (the latter applying ADMM in the dual rather than the primal).

While our paper shows limitations of the subgradient method when there are many overlapping components, this method may still be advantageous over ADMM in problems that are nicely decomposable, since it often allows reusing existing combinatorial machinery. Yet, the scenario we consider here is realistic in NLP, where we often have to deal with not-lightly-decomposable constrained problems (e.g., exploiting linguistic knowledge).

7 Conclusion

We have introduced new feature-rich turbo parsers. Since exact decoding is intractable, we solve an LP relaxation through a recently proposed consensus algorithm, DD-ADMM, which is suitable for problems with many overlapping components. We study the empirical runtime and convergence properties of DD-ADMM, complementing the theoretical treatment in Martins et al. (2011). DD-ADMM compares favourably against the subgradient method in several aspects: it is faster to reach a consensus, it has better stopping conditions, and it works better in non-lightweight decompositions. While its slave subproblems are more involved, we derived closed-form solutions for many cases of interest, such as first-order logic formulas and combinatorial factors.

DD-ADMM may be useful in other frameworks involving logical constraints, such as the models for compositional semantics presented by Liang et al. (2011). Non-logical constraints may also yield efficient subproblems, *e.g.*, the length constraints in summarization and compression (Clarke and Lapata, 2008; Martins and Smith, 2009; Berg-Kirkpatrick et al., 2011). Finally, DD-ADMM can be adapted to tighten its relaxations towards exact decoding, as in Sontag et al. (2008) and Rush and Collins (2011). We defer this for future work.

University of Maryland
College Park, MD 20742
{amit,hal}@umiacs.umd.edu

Abstract

We exploit sketch techniques, especially the Count-Min sketch, a memory, and time efficient framework which approximates the frequency of a word pair in the corpus without explicitly storing the word pair itself. These methods use hashing to deal with massive amounts of streaming text. We apply Count-Min sketch to approximate word pair counts and exhibit their effectiveness on three important NLP tasks. Our experiments demonstrate that on all of the three tasks, we get performance comparable to Exact word pair counts setting and state-of-the-art system. Our method scales to 49 GB of unzipped web data using bounded space of 2 billion counters (8 GB memory).

1 Introduction

There is more data available today on the web than there has ever been and it keeps increasing. Use of large data in the Natural Language Processing (NLP) community is not new. Many NLP problems (Brants et al., 2007; Turney, 2008; Ravichandran et al., 2005) have benefited from having large amounts of data. However, processing large amounts of data is still challenging.

This has motivated NLP community to use commodity clusters. For example, Brants et al. (2007) used 1500 machines for a day to compute the relative frequencies of n-grams from 1.8TB of web data. In another work, a corpus of roughly 1.6 Terawords was used by Agirre et al. (2009) to compute pairwise similarities of the words in the test sets using the MapReduce infrastructure on $2,000$ cores. However, the inaccessibility of clusters to an average user has attracted the NLP community to use streaming, randomized, and approximate algorithms to handle large amounts of data (Goyal et al., 2009; Levenberg et al., 2010; Van Durme and Lall, 2010).

Streaming approaches (Muthukrishnan, 2005) provide memory and time-efficient framework to deal with terabytes of data. However, these approaches are proposed to solve a singe problem. For example, our earlier work (Goyal et al., 2009) and Levenberg and Osborne (2009) build approximate language models and show their effectiveness in Statistical Machine Translation (SMT). Stream-based translation models (Levenberg et al., 2010) has been shown effective to handle large parallel streaming data for SMT. In Van Durme and Lall (2009b), a Talbot Osborne Morris Bloom (TOMB) Counter (Van Durme and Lall, 2009a) was used to find the top-K verbs "y" given verb "x" using the highest approximate online Pointwise Mutual Information (PMI) values.

In this paper, we explore sketch techniques, especially the Count-Min sketch (Cormode and Muthukrishnan, 2004) to build a *single* model to show its effectiveness on three important NLP tasks:

- Predicting the Semantic Orientation of words (Turney and Littman, 2003)
- Distributional Approaches for word similarity (Agirre et al., 2009)
- Unsupervised Dependency Parsing (Cohen and Smith, 2010) with a little linguistics knowledge.

In all these tasks, we need to compute association measures like Pointwise Mutual Information (PMI),

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 250–261,
Edinburgh, Scotland, UK, July 27–31, 2011.

and Log Likelihood ratio (LLR) between words. To compute association scores (AS), we need to count the number of times pair of words appear together within a certain window size. However, explicitly storing the counts of all word pairs is both computationally expensive and memory intensive (Agirre et al., 2009; Pantel et al., 2009). Moreover, the memory usage keeps increasing with increase in corpus size.

We explore Count-Min (CM) sketch to address the issue of *efficient storage* of such data. The CM sketch stores counts of all word pairs within a *bounded space*. Storage space saving is achieved by *approximating* the frequency of word pairs in the corpus without explicitly storing the word pairs themselves. Both updating (adding a new word pair or increasing the frequency of existing word pair) and querying (finding the frequency of a given word pair) are constant time operations making it efficient online storage data structure for large data. Sketches are *scalable* and can easily be implemented in distributed setting.

We use CM sketch to store counts of word pairs (except word pairs involving stop words) within a window of size[1] 7 over different size corpora. We store exact counts of words (except stop words) in hash table (since the number of unique words is not large that is quadratically less than the number of unique word pairs). The approximate PMI and LLR scores are computed using these approximate counts and are applied to solve our three NLP tasks. Our experiments demonstrate that on all of the three tasks, we get performance comparable to Exact word pair counts setting and state-of-the-art system. Our method scales to 49 GB of unzipped web data using bounded space of 2 billion counters (8 GB memory). This work expands upon our earlier workshop papers (Goyal et al., 2010a; Goyal et al., 2010b).

2 Sketch Techniques

A sketch is a compact summary data structure to store the frequencies of all items in the input stream. Sketching techniques use hashing to map items in streaming data onto a small sketch vector that can be updated and queried in constant time. These techniques generally process the input stream in one direction, say from left to right, without re-processing previous input. The main advantage of using these techniques is that they require a storage which is sub-linear in size of the input stream. The following surveys comprehensively review the streaming literature: (Rusu and Dobra, 2007; Cormode and Hadjieleftheriou, 2008).

There exists an extensive literature on sketch techniques (Charikar et al., 2004; Li et al., 2008; Cormode and Muthukrishnan, 2004; Rusu and Dobra, 2007) in algorithms community for solving many large scale problems. However, in practice, researchers have preferred Count-Min (CM) sketch over other sketch techniques in many application areas, such as Security (Schechter et al., 2010), Machine Learning (Shi et al., 2009; Aggarwal and Yu, 2010), and Privacy (Dwork et al., 2010). This motivated us to explore CM sketch to solve three important NLP problems.[2]

2.1 Count-Min Sketch

The Count-Min sketch (Cormode and Muthukrishnan, 2004) is a compact summary data structure used to store the frequencies of all items in the input stream. The sketch allows fundamental queries on the data stream such as point, range and inner product queries to be approximately answered very quickly. It can also be applied to solve the finding frequent items problem (Manku and Motwani, 2002) in a data stream. In this paper, we are only interested in point queries. The aim of a point query is to estimate the count of an item in the input stream. For other details, the reader is referred to (Cormode and Muthukrishnan, 2004).

Given an input stream of word pairs of length N and user chosen parameters δ and ϵ, the algorithm stores the frequencies of all the word pairs with the following guarantees:

- All reported frequencies are within the true frequencies by at most ϵN with a probability of at least 1-δ.
- The space used by the algorithm is $O(\frac{1}{\epsilon}\log\frac{1}{\delta})$.

[1] 7 is chosen from intuition and not tuned.

[2] In future, in another line of research, we will explore comparing different sketch techniques for NLP problems.

- Constant time of O($\log(\frac{1}{\delta})$) per each update and query operation.

2.1.1 CM Data Structure

A Count-Min sketch (CM) with parameters (ϵ,δ) is represented by a two-dimensional array with width w and depth d :

$$\begin{bmatrix} \text{sketch}[1,1] & \cdots & \text{sketch}[1,w] \\ \vdots & \ddots & \vdots \\ \text{sketch}[d,1] & \cdots & \text{sketch}[d,w] \end{bmatrix}$$

Among the user chosen parameters, ϵ controls the amount of tolerable error in the returned count and δ controls the probability with which the returned count is not within the accepted error. These values of ϵ and δ determine the width and depth of the two-dimensional array respectively. To achieve the guarantees mentioned in the previous section, we set w=$\frac{2}{\epsilon}$ and d=$\log(\frac{1}{\delta})$. The depth d denotes the number of pairwise-independent hash functions employed by the algorithm and there exists a one-to-one correspondence between the rows and the set of hash functions. Each of these hash functions h_k:$\{\text{x}_1 \ldots \text{x}_N\} \rightarrow \{1 \ldots w\}, 1 \leq k \leq d$, takes a word pair from the input stream and maps it into a counter indexed by the corresponding hash function. For example, $h_2(\text{x}) = 10$ indicates that the word pair "x" is mapped to the 10^{th} position in the second row of the sketch array.

Initialize the entire sketch array with zeros.

Update Procedure: When a new word pair "x" with count c arrives, one counter in each row (as decided by its corresponding hash function) is updated by c.

$$\text{sketch}[k, h_k(\text{x})] \leftarrow \text{sketch}[k, h_k(\text{x})] + c, \;\; \forall 1 \leq k \leq d$$

Query Procedure: Since multiple word pairs can get hashed to the same position, the frequency stored by each position is guaranteed to overestimate the true count. Thus, to answer the point query for a given word pair, we return minimum over all the positions indexed by the k hash functions. The answer to Query(x): $\hat{c} = \min_k \; \text{sketch}[k, h_k(\text{x})]$

Both update and query procedures involve evaluating d hash functions and reading of all the values in those indices and hence both these procedures are linear in the number of hash functions. Hence both these steps require $O(\log(\frac{1}{\delta}))$ time. In our experiments (see Section 3.1), we found that a small number of hash functions are sufficient and we use d=5. Hence, the update and query operations take only a constant time. The space used by the algorithm is the size of the array i.e. wd counters, where w is the width of each row.

2.1.2 Properties

Apart from the advantages of being space efficient, and having constant update and constant querying time, the Count-Min sketch has also other advantages that makes it an attractive choice for NLP applications.

- Linearity: Given two sketches s_1 and s_2 computed (using the same parameters w and d) over different input streams, the sketch of the combined data stream can be easily obtained by adding the individual sketches in O($\frac{1}{\epsilon} \log \frac{1}{\delta}$) time which is independent of the stream size.

- The linearity is especially attractive because it allows the individual sketches to be computed independent of each other, which means that it is easy to implement it in distributed setting, where each machine computes the sketch over a sub set of corpus.

2.2 Conservative Update

Estan and Varghese introduced the idea of conservative update (Estan and Varghese, 2002) in the context of computer networking. This can easily be used with CM sketch to further improve the estimate of a point query. To update a word pair "x" with frequency c, we first compute the frequency $\hat{c}$ of this word pair from the existing data structure and the counts are updated according to:

$$\hat{c} = min_k \; \text{sketch}[k, h_k(\text{x})], \;\; \forall 1 \leq k \leq d$$

$$\text{sketch}[k, h_k(\text{x})] \leftarrow \max\{\text{sketch}[k, h_k(\text{x})], \hat{c} + c\}$$

The intuition is that, since the point query returns the minimum of all the d values, we will update a counter only if it is necessary as indicated by the above equation. Though this is a heuristic, it avoids the unnecessary updates of counter values and thus reduces the error.

In our experiments, we found that employing the conservative update reduces the Average Relative

Error (ARE) of these counts approximately by a factor of 1.5. (see Section 3.1). But unfortunately, this update can only be maintained over individual sketches in distributed setting.

3 Intrinsic Evaluations

To show the effectiveness of the CM sketch and CM sketch with conservative update (CU) in the context of NLP, we perform intrinsic evaluations. First, the intrinsic evaluations are designed to measure the error in the approximate counts returned by CM sketch compared to their true counts. Second, we compare the word pairs association rankings obtained using PMI and LLR with sketch and exact counts.

It is memory and time intensive to perform many intrinsic evaluations on large data (Ravichandran et al., 2005; Brants et al., 2007; Goyal et al., 2009). Hence, we use a subset of corpus of 2 million sentences (Subset) from Gigaword (Graff, 2003) for it. We generate words and word pairs over a window of size 7. We store exact counts of words (except stop words) in a hash table and store approximate counts of word pairs (except word pairs involving stop words) in the sketch.

3.1 Evaluating approximate sketch counts

To evaluate the amount of over-estimation error (see Section 2.1) in CM and CU counts compared to the true counts, we first group all word pairs with the same true frequency into a single bucket. We then compute the average relative error in each of these buckets. Since low-frequency word pairs are more prone to errors, making this distinction based on frequency lets us understand the regions in which the algorithm is over-estimating. Moreover, to focus on errors on low frequency counts, we have only plotted word pairs with count at most 100. Average Relative error (ARE) is defined as the average of absolute difference between the predicted and the exact value divided by the exact value over all the word pairs in each bucket.

$$\text{ARE} = \frac{1}{N}\sum_{i=1}^{N}\frac{|\text{Exact}_i - \text{Predicted}_i|}{\text{Exact}_i}$$

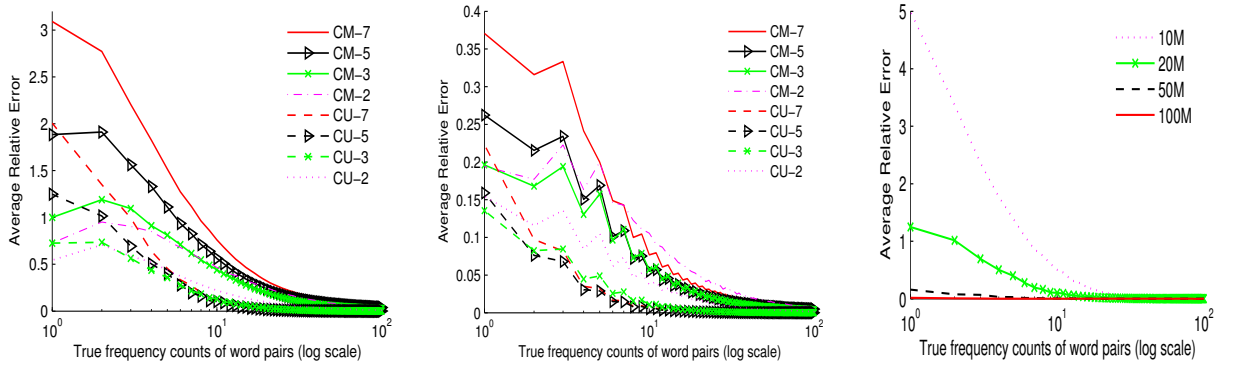
Where Exact and Predicted denotes values of exact and CM/CU counts respectively; N denotes the number of word pairs with same counts in a bucket.

In Fig. 1(a), we fixed the number of counters to 20 million ($20M$) with four bytes of memory per each counter (thus it only requires 80 MB of main memory). Keeping the total number of counters fixed, we try different values of depth (2, 3, 5 and 7) of the sketch array and in each case the width is set to $\frac{20M}{d}$. The ARE curves in each case are shown in Fig. 1(a). We can make three main observations from Figure 1(a): First it shows that most of the errors occur on low frequency word pairs. For frequent word pairs, in almost all the different runs the ARE is close to zero. Secondly, it shows that ARE is significantly lower (by a factor of 1.5) for the runs which use conservative update (CUx run) compared to the runs that use direct CM sketch (CMx run). The encouraging observation is that, this holds true for almost all different (width,depth) settings. Thirdly, in our experiments, it shows that using depth of 3 gets comparatively less ARE compared to other settings.

To be more certain about this behavior with respect to different settings of width and depth, we tried another setting by increasing the number of counters to 50 million. The curves in 1(b) follow a pattern which is similar to the previous setting. Low frequency word pairs are more prone to error compared to the frequent ones and employing conservative update reduces the ARE by a factor of 1.5. In this setting, depth 5 does slightly better than depth 3 and gets lowest ARE.

We use CU counts and depth of 5 for the rest of the paper. As 3 and 5 have lowest ARE in different settings and using 5 hash functions, we get $\delta = 0.01$ ($d = \log(\frac{1}{\delta})$ refer Section 2.1) that is probability of failure is 1 in 100, making the algorithm more robust to false positives compared with 3 hash functions, $\delta = 0.1$ with probability of failure 1 in 10.

Fig. 1(c) studies the effect of the number of counters in the sketch (the size of the two-dimensional sketch array) on the ARE with fixed depth 5. As expected, using more number of counters decreases the ARE in the counts. This is intuitive because, as the length of each row in the sketch increases, the probability of collision decreases and hence the array is more likely to contain true counts. By using 100 million counters, which is comparable to the length of the stream 88 million, we are able to achieve almost zero ARE over all the counts including the rare



(a) 20M counters (b) 50M counters (c) Different size models with depth 5

Figure 1: Compare 20 and 50 million counter models with different (width,depth) settings. The notation CMx represents the Count Min sketch with a depth of 'x' and CUx represents the CM sketch along with conservative update and depth 'x'.

ones[3]. Note that the space we *save* by not storing the exact counts is almost four times the memory that we use here because on an average each word pair is twelve characters long and requires twelve bytes (thrice the size of an integer) and 4 bytes for storing the integer count. Note, we get even bigger space savings if we work with longer phrases (phrase clustering), phrase pairs (paraphrasing/translation), and varying length n-grams (Information Extraction).

3.2 Evaluating word pairs association ranking

In this experiment, we compare the word pairs association rankings obtained using PMI and LLR with CU and exact word pair counts. We use two kinds of measures, namely recall and Spearman's correlation to measure the overlap in the rankings obtained by exact and CU counts. Intuitively, recall captures the number of word pairs that are found in both the sets and then Spearman's correlation captures if the relative order of these common word pairs is preserved in both the rankings. In our experimental setup, if the rankings match exactly, then we get a recall (R) of 100% and a correlation (ρ) of 1.

The results with respect to different sized counter (20 million ($20M$), 50 million ($50M$)) models are shown in Table 1. If we compare the second and third column of the table using PMI and LLR for $20M$ counters, we get exact rankings for LLR compared to PMI while comparing Top$K$ word pairs. The explanation for such a behavior is: since we are not throwing away any infrequent word pairs, PMI will rank pairs with low frequency counts higher (Church and Hanks, 1989). Hence, we are evaluating the PMI values for rare word pairs and we need counters linear in size of stream to get almost perfect ranking. This is also evident from the fourth column for $50M$ of the Table 1, where CU PMI ranking gets close to the optimal as the number of counters approaches stream size.

# Cs	20M				50M			
AS	PMI		LLR		PMI		LLR	
TopK	*R*	ρ	*R*	ρ	*R*	ρ	*R*	ρ
50	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0
100	.98	.94	1.0	1.0	1.0	1.0	1.0	1.0
500	.80	.98	1.0	1.0	.98	1.0	1.0	1.0
1000	.56	.99	1.0	1.0	.96	.99	1.0	1.0
5000	.35	.90	1.0	1.0	.85	.99	1.0	1.0
10000	.38	.55	1.0	1.0	.81	.95	1.0	1.0

Table 1: Evaluating the PMI and LLR rankings obtained using CM sketch with conservative update (CU) and Exact counts

However, in some NLP problems, we are not interested in low-frequency items. In such cases, even using space less than linear in number of counters would suffice. In our extrinsic evaluations, we show that using space less than the length of the stream does not degrade the performance.

4 Extrinsic Evaluations

4.1 Data

Gigaword corpus (Graff, 2003) and a 50% portion of a copy of web crawled by (Ravichandran et al.,

[3]Even with other datasets we found that using counters linear in the size of the stream leads to ARE close to zero $\forall$ counts.

2005) are used to compute counts of words and word pairs. For both the corpora, we split the text into sentences, tokenize and convert into lower-case. We generate words and word pairs over a window of size 7. We use four different sized corpora: SubSet (used for intrinsic evaluations in Section 3), Gigaword (GW), GigaWord + 20% of web data (GWB20), and GigaWord + 50% of web data (GWB50). Corpus Statistics are shown below. We store exact counts of words in a hash table and store approximate counts of word pairs in the sketch. Hence, the stream size in our case is the total number of word pairs in a corpus.

Corpus	Subset	GW	GWB20	GWB50
Unzipped Size (GB)	.32	9.8	22.8	49
# of sentences (Million)	2.00	56.78	191.28	462.60
Stream Size (Billion)	.088	2.67	6.05	13.20

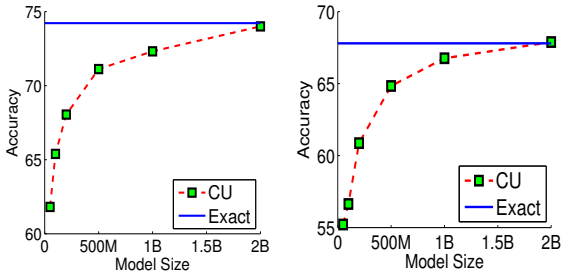
4.2 Semantic Orientation

Given a word, the task of finding the Semantic Orientation (SO) (Turney and Littman, 2003) of the word is to identify if the word is more likely to be used in positive or negative sense. We use a similar framework as used by the authors to infer the SO. We take the seven positive words (good, nice, excellent, positive, fortunate, correct, and superior) and the seven negative words (bad, nasty, poor, negative, unfortunate, wrong, and inferior) used in (Turney and Littman, 2003) work. The SO of a given word is calculated based on the strength of its association with the seven positive words, and the strength of its association with the seven negative words. We compute the SO of a word "w" as follows:

$$\text{SO-AS(w)} = \sum_{p \in Pwords} AS(p,w) - \sum_{n \in Nwords} AS(n,w)$$

Where, Pwords and Nwords denote the seven positive and negative prototype words respectively. We use PMI and LLR to compute association scores (AS). If this score is positive, we predict the word as positive. Otherwise, we predict it as negative.

We use the General Inquirer lexicon[4] (Stone et al., 1966) as a benchmark to evaluate the semantic orientation scores similar to (Turney and Littman, 2003) work. Words with multiple senses have multiple entries in the lexicon, we merge these entries for our experiment. Our test set consists of 1597 positive and 1980 negative words. Accuracy is used as an evaluation metric and is defined as the percentage of number of correctly identified SO words.



(a) SO PMI (b) SO LLR

Figure 2: Evaluating Semantic Orientation using PMI and LLR with different number of counters of CU sketch built using Gigaword.

4.2.1 Varying sketch size

We evaluate SO of words using PMI and LLR on Gigaword (9.8GB). We compare approximate SO computed using varying sizes of CU sketches: 50 million ($50M$), $100M$, $200M$, $500M$, 1 billion ($1B$) and 2 billion ($2B$) counters with Exact SO. To compute these scores, we count the number of individual words w_1 and w_2 and the pair (w_1,w_2) within a window of size 7. Note that computing the exact counts of all word pairs on these corpora is computationally expensive and memory intensive, so we consider only those pairs in which one word appears in the prototype list and the other word appears in the test set.

First, if we look at the Exact SO using PMI and LLR in Figure 2(a) and 2(b) respectively, it shows that using PMI, we get about 6 points higher accuracy than LLR on this task (The 95% statistical significance boundary for accuracy is about $\pm$ 1.5.). Second, for both PMI and LLR, having more number of counters improve performance.[5] Using $2B$ counters, we get the same accuracy as Exact.

[4]The General Inquirer lexicon is freely available at `http://www.wjh.harvard.edu/~inquirer/`

[5]We use maximum of $2B$ counters (8GB main memory), as most of the current desktop machines have at most 8GB RAM.

4.2.2 Effect of Increasing Corpus Size

We evaluate SO of words on three different sized corpora (see Section 4.1): GW (9.8GB), GWB20 (22.8GB), and GWB50 (49GB). First, since for this task using PMI performs better than LLR, so we will use PMI for this experiment. Second, we will fix number of counters to $2B$ (CU-2B) as it performs the best in Section 4.2.1. Third, we will compare the CU-2B counter model with the Exact over increasing corpus size.

We can make several observations from the Figure 3: • It shows that increasing the amount of data improves the accuracy of identifying the SO of a word. We get an absolute increase of 5.5 points in accuracy, when we add 20% Web data to GigaWord (GW). Adding 30% more Web data (GWB50), gives a small increase of 1.3 points in accuracy which is not even statistically significant. • Second, CU-2B performs as good as exact for all corpus sizes. • Third, the number of $2B$ counters (bounded space) is less than the length of stream for GWB20 ($6.05B$), and GWB50 ($13.2B$). Hence, it shows that using counters less than the stream length does not degrade the performance. • These results are also comparable to Turney's (2003) state-of-the-art work where they report an accuracy of 82.84%. Note, they use a billion word corpus which is larger than GWB50.

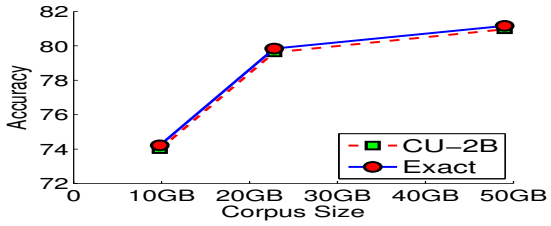


Figure 3: Evaluating Semantic Orientation of words with Exact and CU counts with increase in corpus size

4.3 Distributional Similarity

Distributional similarity is based on the distributional hypothesis that similar terms appear in similar contexts (Firth, 1968; Harris, 1954). The context vector for each term is represented by the strength of association between the term and each of the lexical, semantic, syntactic, and/or dependency units that co-occur with it[6]. We use PMI and LLR to compute association score (AS) between the term and each of the context to generate the context vector. Once, we have context vectors for each of the terms, cosine similarity measure returns distributional similarity between terms.

4.3.1 Efficient Distributional Similarity

We propose an efficient approach for computing distributional similarity between word pairs using CU sketch. In the first step, we traverse the corpus and store counts of all words (except stop words) in hash table and all word pairs (except word pairs involving stop words) in sketch. In the second step, for a target word "x", we consider all words (except infrequent contexts which appear less than or equal to 10.) as plausible context (since it is faster than traversing the whole corpus.), and query the sketch for vocabulary number of word pairs, and compute approximate AS between word-context pairs. We maintain only top K AS scores[7] contexts using priority queue for every target word "x" and save them onto the disk. In the third step, we use cosine similarity using these approximate top K context vectors to compute efficient distributional similarity.

The efficient distributional similarity using sketches has following advantages:

- It can return semantic similarity between any word pairs that are stored in the sketch.
- It can return the similarity between word pairs in time O(K).
- We do not store word pairs explicitly, and use fixed number of counters, hence the overall space required is bounded.
- The additive property of sketch (Sec. 2.1.2) enables us to parallelize most of the steps in the algorithm. Thus it can be easily extended to very large amounts of text data.

We use two test sets which consist of word pairs, and their corresponding human rankings. We generate the word pair rankings using efficient distributional similarity. We report the spearman's rank

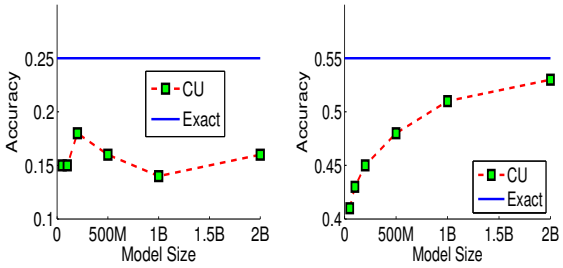
[6]Here, the context for a target word "x" is defined as words appear within a window of size 7.

[7]For this work, we use $K = 1000$ which is not tuned.

correlation[8] coefficient (ρ) between the human and distributional similarity rankings. The two test sets are:

1. **WS-353** (Finkelstein et al., 2002) is a set of 353 word pairs.

2. **RG-65**: (Rubenstein and Goodenough, 1965) is set of 65 word pairs.



(a) Word Similarity PMI (b) Word Similarity LLR

Figure 4: Evaluating Distributional Similarity between word pairs on WS-353 test set using PMI and LLR with different number of counters of CU sketch built using Gigaword data-set.

4.3.2 Varying sketch size

We evaluate efficient distributional similarity between between word pairs on WS-353 test set using PMI and LLR association scores on Gigaword (9.8GB). We compare different sizes of CU sketch (similar to SO evaluation): 50 million ($50M$), $100M$, $200M$, $500M$, 1 billion ($1B$) and 2 billion ($2B$) counters with the Exact word pair counts. Here again, computing the exact counts of all word-context pairs on these corpora is time, and memory intensive, we generate context vectors for only those words which are present in the test set.

First, if we look at word pair ranking using exact PMI and LLR across Figures 4(a) and 4(b) respectively, it shows that using LLR, we get better ρ of .55 compared to ρ of .25 using PMI on this task (The 95% statistical significance boundary on ρ for WS-353 is about $\pm$ .08). The explanation for such a behavior is: PMI rank context pairs with low frequency counts higher (Church and Hanks, 1989) compared to frequent ones which are favored by LLR. Second, for PMI in Fig. 4(a), having more counters does not improve ρ. Third, for LLR in Fig. 4(b), having more number of counters improve performance and using $2B$ counters, we get ρ close to the Exact.

[8]To calculate the Spearman correlations values are transformed into ranks (if tied ranks exist, average of ranks is taken), and we calculate the Pearson correlation on them.

Test Set	**WS-353**			**RG-65**		
Model	GW	$GWB20$	$GWB50$	GW	$GWB20$	$GWB50$
Agirre			.64			.75
Exact	.55	.55	.62	.65	.72	.74
CU-2B	.53	.58	.62	.66	.72	.74

Table 2: Evaluating word pairs ranking with Exact and CU counts. Scores are evaluated using ρ metric.

4.3.3 Effect of Increasing Corpus Size

We evaluate efficient distributional similarity between word pairs using three different sized corpora: GW (9.8GB), GWB20 (22.8GB), and GWB50 (49GB) on two test sets: WS-353, and RG-65. First, since for this task using LLR performs better than PMI, so we will use LLR for this experiment. Second, we will fix number of counters to $2B$ (CU-2B) as it performs the best in Section 4.2.1. Third, we will compare the CU-2B counter model with the Exact over increasing corpus size. We also compare our results against the state-of-the-art results (Agirre) for distributional similarity (Agirre et al., 2009). We report their results of context window of size 7.

We can make several observations from the Table 2: • It shows that increasing the amount of data is not substantially improving the accuracy of word pair rankings over both the test sets. • Here again, CU-2B performs as good as exact for all corpus sizes. • CU-2B and Exact performs same as the state-of-the-art system. • The number of $2B$ counters (bounded space) is less than the length of stream for GWB20 ($6.05B$), and GWB50 ($13.2B$). Hence, here again it shows that using counters less than the stream length does not degrade the performance.

5 Dependency Parsing

Recently, maximum spanning tree (MST) algorithms for dependency parsing (McDonald et al., 2005) have shown great promise, primarily in supervised settings. In the MST framework, words in a sentence form nodes in a graph, and connections between nodes indicate how "related" they are. A maximum spanning tree algorithm constructs a de-

pendency parse by linking together "most similar" words. Typically the weights on edges in the graph are parameterized as a linear function of features, with weight learned by some supervised learning algorithm. In this section, we ask the question: can word association scores be used to derive syntactic structures in an *unsupervised* manner?

A first pass answer is: clearly not. Metrics like PMI would assign high association scores to rare word pairs (mostly content words) leading to incorrect parses. Metrics like LLR would assign high association scores to frequent words, also leading to incorrect parses. However, with a *small amount* of linguistic side information (Druck et al., 2009; Naseem et al., 2010), we see that these issues can be overcome. In particular, we see that large data + a little linguistics > fancy unsupervised learning algorithms.

5.1 Graph Definition

Our approach is conceptually simple. We construct a graph over nodes in the sentence with a unique "root" node. The graph is directed and fully connected, and for any two words in positions i and j, the *weight* from word i to word j is defined as:

$$w_{ij} = \alpha^{\text{asc}}\text{asc}(w_i, w_j) - \alpha^{\text{dist}}\text{dist}(i-j) + \alpha^{\text{ling}}\text{ling}(t_i, t_j)$$

Here, $\text{asc}(w_i, w_j)$ is a association score such as PMI or LLR computed using approximate counts from the sketch. Similarly, $\text{dist}(i-j)$ is a simple parameterized model of distances that favors short dependencies. We use a simple unnormalized (log) Laplacian prior of the form $\text{dist}(i-j) = -|i-j-1|$, centered around 1 (encouraging short links to the right). It is negated because we need to convert distances to similarities.

The final term, $\text{ling}(t_i, t_j)$ asks: according to some simple linguistic knowledge, how likely is if that the (gold standard) part of speech tag associated with word i points at that associated with word j? For this, we use the same linguistic information used by (Naseem et al., 2010), which does *not* encode direction information. These rules are: `root` → { `aux, verb` }; `verb` → { `noun, pronoun, adverb, verb` }; `aux` → { `verb` }; `noun` → { `adj, art, noun, num` }; `prep` → { `noun` }; `adj` → { `adv` }. We simply give an additional weight of 1 to any edge that agrees with one of these linguistic rules.

	len ≤ 10	**len ≤ 20**	**all**
COHEN-DIRICHLET	45.9	39.4	34.9
COHEN-BEST	59.4	45.9	40.5

Table 3: Comparing CU-2B build on GWB50 + a little linguistics v/s fancy unsupervised learning algorithms.

5.2 Parameter Setting

The remaining issue is setting the interpolation parameters α associated with each of these scores. This is a difficult problem in purely unsupervised learning. We report results on three settings. First, the OPTIMAL setting is based on grid search for optimal parameters. This is an oracle result based on grid search over two of the three parameters (holding the third fixed at 1). In our second approach, BALANCED, we normalize the three components to "compete" equally. In particular, we scale and translate all three components to have zero mean and unit variance, and set the αs to all be equal to one. Finally, our third approach, SEMISUP, is based on using a small amount of labeled data to set the parameters. In particular, we use 10 labeled sentences to select parameters based on the same grid search as the OPTIMAL setting. Since this relies heavily on which 10 sentences are used, we repeat this experiment 20 times and report averages.

5.3 Experiments

Our experiments are on a dependency-converted version of section 23 of the Penn Treebank using modified Collins' head finding rules. We measure accuracies as *directed*, unlabeled dependency accuracy. We separately report results of sentences of length at most 10, at most 20 and finally of all length. Note that there is no training or cross-validation: we simply run our MST parser on test data directly.

The results of the parsing experiments are shown

in Table 3. We compare against the following alternative systems. The first, Cohen-Dirichlet and Cohen-Best, are previously reported state-of-the-art results for unsupervised Bayesian dependency parsing (Cohen and Smith, 2010). The first is results using a simple Dirichlet prior; the second is the best reported results for any system from that paper.

Next, we compare against an "oracle" system that uses LLR extracted from the training data for the Penn Treebank, where the LLR is based on the probability of observing an edge given two words. This is not a true oracle in the sense that we *might* be able to do better, but it is unlikely. The next two baseline system are simple right branching baseline trees. The Baseline system is a purely right-branching tree. The Baseline+Ling system is one that is right branching *except* that it can only create edges that are compatible with the linguistic rules, provided a relevant rule exists. For short sentences, this is competitive with the Dirichlet prior results.

Finally we report variants of our approach using association scores computed on the GWB50 using CU sketch with 2 billion counters. We experiment with two association scores: LLR and PMI. For each measure, we report results based on the three approaches described earlier for setting the α hyperparameters. Error bars for our approaches are 95% confidence intervals based on bootstrap resampling.

The results show that, for this task, PMI seems slightly better than LLR, across the board. The OPTIMAL performance (based on tuning two hyperparameters) is amazingly strong: clearly beating out all the baselines, and only about 15 points behind the ORACLE system. Using the BALANCED approach causes a degradation of only 3 points from the OPTIMAL on sentences of all lengths. In general, the balancing approach seems to be slightly worse than the semi-supervised approach, except on very short sentences: for those, it is substantially better. Overall, though, the results for both Balanced and Semisup are competitive with state-of-the-art unsupervised learning algorithms.

6 Discussion and Conclusion

The advantage of using sketch in addition to being memory and time efficient is that it contains counts for all word pairs and hence can be used to compute association scores like PMI and LLR between any word pairs. We show that using sketch counts in our experiments, on the three tasks, we get performance comparable to Exact word pair counts setting and state-of-the-art system. Our method scales to 49 GB of unzipped web data using bounded space of 2 billion counters (8 GB memory). Moreover, the linearity property of the sketch makes it scalable and usable in distributed setting. Association scores and counts from sketch can be used for more NLP tasks like small-space randomized language models, word sense disambiguation, spelling correction, relation learning, paraphrasing, and machine translation.

Abstract

Latent variable models have the potential to add value to large document collections by discovering interpretable, low-dimensional subspaces. In order for people to use such models, however, they must trust them. Unfortunately, typical dimensionality reduction methods for text, such as latent Dirichlet allocation, often produce low-dimensional subspaces (topics) that are obviously flawed to human domain experts. The contributions of this paper are threefold: (1) An analysis of the ways in which topics can be flawed; (2) an automated evaluation metric for identifying such topics that does not rely on human annotators or reference collections outside the training data; (3) a novel statistical topic model based on this metric that significantly improves topic quality in a large-scale document collection from the National Institutes of Health (NIH).

1 Introduction

Statistical topic models such as latent Dirichlet allocation (LDA) (Blei et al., 2003) provide a powerful framework for representing and summarizing the contents of large document collections. In our experience, however, the primary obstacle to acceptance of statistical topic models by users the outside machine learning community is the presence of poor quality topics. Topics that mix unrelated or loosely-related concepts substantially reduce users' confidence in the utility of such automated systems.

In general, users prefer models with larger numbers of topics because such models have greater resolution and are able to support finer-grained distinctions. Unfortunately, we have observed that there is a strong relationship between the size of topics and the probability of topics being nonsensical as judged by domain experts: as the number of topics increases, the smallest topics (number of word tokens assigned to each topic) are almost always poor quality. The common practice of displaying only a small number of example topics hides the fact that as many as 10% of topics may be so bad that they cannot be shown without reducing users' confidence.

The evaluation of statistical topic models has traditionally been dominated by either extrinsic methods (i.e., using the inferred topics to perform some external task such as information retrieval (Wei and Croft, 2006)) or quantitative intrinsic methods, such as computing the probability of held-out documents (Wallach et al., 2009). Recent work has focused on evaluation of topics as semantically-coherent concepts. For example, Chang et al. (2009) found that the probability of held-out documents is not always a good predictor of human judgments. Newman et al. (2010) showed that an automated evaluation metric based on word co-occurrence statistics gathered from Wikipedia could predict human evaluations of topic quality. AlSumait et al. (2009) used differences between topic-specific distributions over words and the corpus-wide distribution over words to identify overly-general "vacuous" topics. Finally, Andrzejewski et al. (2009) developed semi-supervised methods that avoid specific user-labeled semantic coherence problems.

The contributions of this paper are threefold: (1) To identify distinct classes of low-quality topics, some of which are not flagged by existing evaluation methods; (2) to introduce a new topic "coherence" score that corresponds well with human coherence judgments and makes it possible to identify

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 262–272,
Edinburgh, Scotland, UK, July 27–31, 2011.

specific semantic problems in topic models without human evaluations or external reference corpora; (3) to present an example of a new topic model that learns latent topics by directly optimizing a metric of topic coherence. With little additional computational cost beyond that of LDA, this model exhibits significant gains in average topic coherence score. Although the model does not result in a statistically-significant reduction in the number of topics marked "bad", the model consistently improves the topic coherence score of the ten lowest-scoring topics (i.e., results in bad topics that are "less bad" than those found using LDA) while retaining the ability to identify low-quality topics without human interaction.

2 Latent Dirichlet Allocation

LDA is a generative probabilistic model for documents $\mathcal{W} = \{\boldsymbol{w}^{(1)}, \boldsymbol{w}^{(2)}, \ldots, \boldsymbol{w}^{(D)}\}$. To generate a word token $w_n^{(d)}$ in document d, we draw a discrete topic assignment $z_n^{(d)}$ from a document-specific distribution over the T topics $\boldsymbol{\theta}_d$ (which is itself drawn from a Dirichlet prior with hyperparameter α), and then draw a word type for that token from the topic-specific distribution over the vocabulary $\boldsymbol{\phi}_{z_n^{(d)}}$. The inference task in topic models is generally cast as inferring the document–topic proportions $\{\boldsymbol{\theta}_1, ..., \boldsymbol{\theta}_D\}$ and the topic-specific distributions $\{\boldsymbol{\phi}_1 \ldots, \boldsymbol{\phi}_T\}$.

The multinomial topic distributions are usually drawn from a shared symmetric Dirichlet prior with hyperparameter β, such that conditioned on $\{\boldsymbol{\phi}_t\}_{t=1}^T$ and the topic assignments $\{\boldsymbol{z}^{(1)}, \boldsymbol{z}^{(2)}, \ldots, \boldsymbol{z}^{(D)}\}$, the word tokens are independent. In practice, however, it is common to deal directly with the "collapsed" distributions that result from integrating over the topic-specific multinomial parameters. The resulting distribution over words for a topic t is then a function of the hyperparameter β and the number of words of each type assigned to that topic, $N_{w|t}$. This distribution, known as the Dirichlet compound multinomial (DCM) or Pólya distribution (Doyle and Elkan, 2009), breaks the assumption of conditional independence between word tokens given topics, but is useful during inference because the conditional probability of a word w given topic t takes a very simple form: $P(w \mid t, \beta) = \frac{N_{w|t}+\beta}{N_t+|\mathcal{V}|\,\beta}$, where $N_t = \sum_{w'} N_{w'|t}$ and $|\mathcal{V}|$ is the vocabulary size.

The process for generating a sequence of words from such a model is known as the simple Pólya urn model (Mahmoud, 2008), in which the initial probability of word type w in topic t is proportional to β, while the probability of each subsequent occurrence of w in topic t is proportional to the number of times w has been drawn in that topic plus β. Note that this unnormalized weight for each word type depends only on the count of that word type, and is independent of the count of any other word type w'. Thus, in the DCM/Pólya distribution, drawing word type w must *decrease* the probability of seeing all other word types $w' \neq w$. In a later section, we will introduce a topic model that substitutes a *generalized* Pólya urn model for the DCM/Pólya distribution, allowing a draw of word type w to *increase* the probability of seeing certain other word types.

For real-world data, documents $\mathcal{W}$ are observed, while the corresponding topic assignments $\mathcal{Z}$ are unobserved and may be inferred using either variational methods (Blei et al., 2003; Teh et al., 2006) or MCMC methods (Griffiths and Steyvers, 2004). Here, we use MCMC methods—specifically Gibbs sampling (Geman and Geman, 1984), which involves sequentially resampling each topic assignment $z_n^{(d)}$ from its conditional posterior given the documents $\mathcal{W}$, the hyperparameters α and β, and $\mathcal{Z}_{\setminus d,n}$ (the current topic assignments for all tokens other than the token at position n in document d).

3 Expert Opinions of Topic Quality

Concentrating on 300,000 grant and related journal paper abstracts from the National Institutes of Health (NIH), we worked with two experts from the National Institute of Neurological Disorders and Stroke (NINDS) to collaboratively design an expert-driven topic annotation study. The goal of this study was to develop an annotated set of baseline topics, along with their salient characteristics, as a first step towards automatically identifying and inferring the kinds of topics desired by domain experts.[1]

3.1 Expert-Driven Annotation Protocol

In order to ensure that the topics selected for annotation were within the NINDS experts' area of expertise, they selected 148 topics (out of 500), all associated with areas funded by NINDS. Each topic

[1] All evaluated models will be released publicly.

t was presented to the experts as a list of the thirty most probable words for that topic, in descending order of their topic-specific "collapsed" probabilities, $\frac{N_{w|t}+\beta}{N_t+|\mathcal{V}|\,\beta}$. In addition to the most probable words, the experts were also given metadata for each topic: The most common sequences of two or more consecutive words assigned to that topic, the four topics that most often co-occurred with that topic, the most common IDF-weighted words from titles of grants, thesaurus terms, NIH institutes, journal titles, and finally a list of the highest probability grants and PubMed papers for that topic.

The experts first categorized each topic as one of three types: "research", "grant mechanisms and publication types" or "general".[2] The quality of each topic ("good", "intermediate", or "bad") was then evaluated using criteria specific to the type of topic. In general, topics were only annotated as "good" if they contained words that could be grouped together as a single coherent concept. Additionally, each "research" topic was only considered to be "good" if, in addition to representing a single coherent concept, the aggregate content of the set of documents with appreciable allocations to that topic clearly contained text referring to the concept inferred from the topic words. Finally, for each topic marked as being either "intermediate" or "bad", one or more of the following problems (defined by the domain experts) was identified, as appropriate:

- **Chained:** every word is connected to every other word through some pairwise word chain, but not all word pairs make sense. For example, a topic whose top three words are "acids", "fatty" and "nucleic" consists of two distinct concepts (i.e., acids produced when fats are broken down versus the building blocks of DNA and RNA) chained via the word "acids".
- **Intruded:** either two or more unrelated sets of related words, joined arbitrarily, or an otherwise good topic with a few "intruder" words.
- **Random:** no clear, sensical connections between more than a few pairs of words.
- **Unbalanced:** the top words are all logically connected to each other, but the topic combines very general and specific terms (e.g., "signal transduction" versus "notch signaling").

Examples of a good general topic, a good research topic, and a chained research topic are in Table 1.

3.2 Annotation Results

The experts annotated the topics independently and then aggregated their results. Interestingly, no topics were ever considered "good" by one expert and "bad" by the other—when there was disagreement between the experts, one expert always believed the topic to be "intermediate." In such cases, the experts discussed the reasons for their decisions and came to a consensus. Of the 148 topics selected for annotation, 90 were labeled as "good," 21 as "intermediate," and 37 as "bad." Of the topics labeled as "bad" or "intermediate," 23 were "chained," 21 were "intruded," 3 were "random," and 15 were "unbalanced". (The annotators were permitted to assign more than one problem to any given topic.)

4 Automated Metrics for Predicting Expert Annotations

The ultimate goal of this paper is to develop methods for building models with large numbers of specific, high-quality topics from domain-specific corpora. We therefore explore the extent to which information already contained in the documents being modeled can be used to assess topic quality.

In this section we evaluate several methods for ranking the quality of topics and compare these rankings to human annotations. No method is likely to perfectly predict human judgments, as individual annotators may disagree on particular topics. For an application involving removing low quality topics we recommend using a weighted combination of metrics, with a threshold determined by users.

4.1 Topic Size

As a simple baseline, we considered the extent to which topic "size" (as measured by the number of tokens assigned to each topic via Gibbs sampling) is a good metric for assessing topic quality. Figure 1 (top) displays the topic size (number of tokens assigned to that topic) and expert annotations ("good", "intermediate", "bad") for the 148 topics manually labeled by annotators as described above. This figure suggests that topic size is a reasonable predic-

[2] Equivalent to "vacuous topics" of AlSumait et al. (2009).

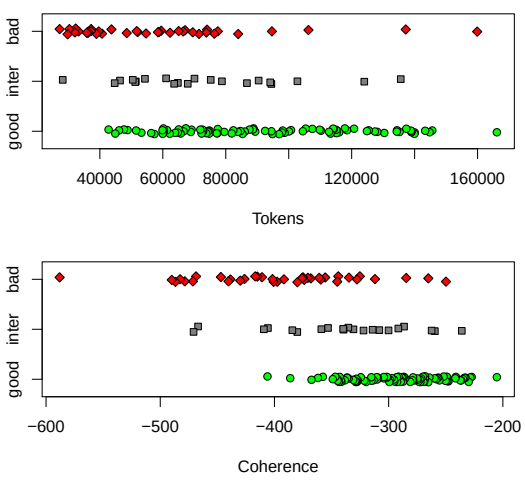

Figure 1: **Topic size is a good indicator of quality; the new *coherence* metric is better**. Top shows expert-rated topics ranked by topic size (AP 0.89, AUC 0.79), bottom shows same topics ranked by coherence (AP 0.94, AUC 0.87). Random jitter is added to the y-axis for clarity.

tor of topic quality. Although there is some overlap, "bad" topics are generally smaller than "good" topics. Unfortunately, this observation conflicts with the goal of building highly specialized, domain-specific topic models with many high-quality, fine-grained topics—in such models the majority of topics will have relatively few tokens assigned to them.

4.2 Topic Coherence

When displaying topics to users, each topic t is generally represented as a list of the $M = 5, \ldots, 20$ most probable words for that topic, in descending order of their topic-specific "collapsed" probabilities. Although there has been previous work on automated generation of labels or headings for topics (Mei et al., 2007), we choose to work only with the ordered list representation. Labels may obscure or detract from fundamental problems with topic coherence, and better labels don't make bad topics good.

The expert-driven annotation study described in section 3 suggests that three of the four types of poor-quality topics ("chained," "intruded" and "random") could be detected using a metric based on the co-occurrence of words within the documents being modeled. For "chained" and "intruded" topics, it is likely that although pairs of words belonging to a single concept will co-occur within a single document (e.g., "nucleic" and "acids" in documents about DNA), word pairs belonging to different concepts (e.g., "fatty" and "nucleic") will not. For random topics, it is likely that few words will co-occur.

This insight can be used to design a new metric for assessing topic quality. Letting $D(v)$ be the *document frequency* of word type v (i.e., the number of documents with least one token of type v) and $D(v, v')$ be *co-document frequency* of word types v and v' (i.e., the number of documents containing one or more tokens of type v and at least one token of type v'), we define *topic coherence* as

$$C(t; V^{(t)}) = \sum_{m=2}^{M} \sum_{l=1}^{m-1} \log \frac{D(v_m^{(t)}, v_l^{(t)}) + 1}{D(v_l^{(t)})}, \quad (1)$$

where $V^{(t)} = (v_1^{(t)}, \ldots, v_M^{(t)})$ is a list of the M most probable words in topic t. A smoothing count of 1 is included to avoid taking the logarithm of zero.

Figure 1 shows the association between the expert annotations and both topic size (top) and our coherence metric (bottom). We evaluate these results using standard ranking metrics, average precision and the area under the ROC curve. Treating "good" topics as positive and "intermediate" or "bad" topics as negative, we get average precision values of 0.89 for topic size vs. 0.94 for coherence and AUC 0.79 for topic size vs. 0.87 for coherence. We performed a logistic regression analysis on the binary variable "is this topic bad". Using topic size alone as a predictor gives AIC (a measure of model fit) 152.5. Coherence alone has AIC 113.8 (substantially better). Both predictors combined have AIC 115.8: the simpler coherence alone model provides the best performance. We tried weighting the terms in equation 1 by their corresponding topic–word probabilities and and by their position in the sorted list of the M most probable words for that topic, but we found that a uniform weighting better predicted topic quality.

Our topic coherence metric also exhibits good qualitative behavior: of the 20 best-scoring topics, 18 are labeled as "good," one is "intermediate" ("unbalanced"), and one is "bad" (combining "cortex" and "fmri", words that commonly co-occur, but are conceptually distinct). Of the 20 worst scoring topics, 15 are "bad," 4 are "intermediate," and only one (with the 19th worst coherence score) is "good."

Our coherence metric relies only upon word co-occurrence statistics gathered from the corpus being modeled, and does not depend on an external reference corpus. Ideally, all such co-occurrence information would already be accounted for in the model. We believe that one of the main contributions of our work is demonstrating that standard topic models *do not* fully utilize available co-occurrence information, and that a held-out reference corpus is therefore not required for purposes of topic evaluation.

Equation 1 is very similar to pointwise mutual information (PMI), but is more closely associated with our expert annotations than PMI (which achieves AUC 0.64 and AIC 170.51). PMI has a long history in language technology (Church and Hanks, 1990), and was recently used by Newman et al. (2010) to evaluate topic models. When expressed in terms of count variables as in equation 1, PMI includes an additional term for $D(v_m^{(t)})$. The improved performance of our metric over PMI implies that what matters is *not* the difference between the joint probability of words m and l and the product of marginals, but the *conditional* probability of each word given the each of the higher-ranked words in the topic.

In order to provide intuition for the behavior of our topic coherence metric, table 1 shows three example topics and their topic coherence scores. The first topic, related to grant-funded training programs, is one of the best-scoring topics. All pairs of words have high co-document frequencies. The second topic, on neurons, is more typical of quality "research" topics. Overall, these words occur less frequently, but generally occur moderately interchangeably: there is little structure to their covariance. The last topic is one of the lowest-scoring topics. Its co-document frequency matrix is shown in table 2. The top two words are closely related: 487 documents include "aging" at least once, 122 include "lifespan", and 55 include both. Meanwhile, the third word "globin" occurs with only one of the top seven words—the common word "human".

4.3 Comparison to word intrusion

As an additional check for both our expert annotations and our automated metric, we replicated the "word intrusion" evaluation originally introduced by Chang et al. (2009). In this task, one of the top ten most probable words in a topic is replaced with a

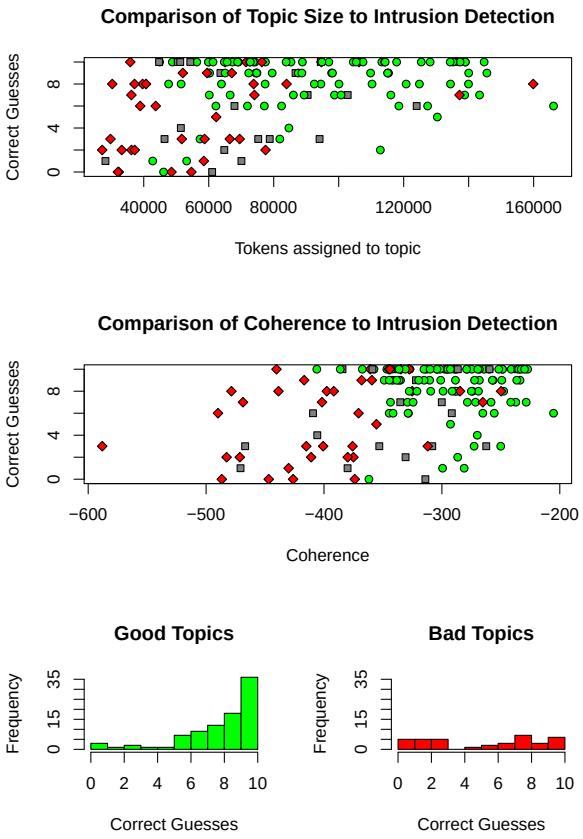

Figure 2: Top: results of the intruder selection task relative to two topic quality metrics. Bottom: marginal intruder accuracy frequencies of good and bad topics.

another word, selected at random from the corpus. The resulting set of words is presented, in a random order, to users, who are asked to identify the "intruder" word. It is very unlikely that a randomly-chosen word will be semantically related to any of the original words in the topic, so if a topic is a high quality representation of a semantically coherent concept, it should be easy for users to select the intruder word. If the topic is not coherent, there may be words in the topic that are also not semantically related to any other word, thus causing users to select "correct" words instead of the real intruder.

We recruited ten additional expert annotators from NINDS, not including our original annotators, and presented them with the intruder selection task, using the set of previously evaluated topics. Results are shown in figure 2. In the first two plots, the x-axis is one of our two automated quality met-

Table 1: Example topics (good/general, good/research, chained/research) with different coherence scores (numbers closer to zero indicate higher coherence). The chained topic combines words related to aging (indicated in plain text) and words describing blood and blood-related diseases (bold). The only connection is the common word *human*.

rics (topic size and coherence) and the y-axis is the number of annotators that correctly identified the true intruder word (accuracy). The histograms below these plots show the number of topics with each level of annotator accuracy for good and bad topics. For good topics (green circles), the annotators were generally able to detect the intruder word with high accuracy. Bad topics (red diamonds) had more uniform accuracies. These results suggest that topics with low intruder detection accuracy tend to be bad, but some bad topics can have a high accuracy. For example, spotting an intruder word in a chained topic can be easy. The low-quality topic *receptors, cannabinoid, cannabinoids, ligands, cannabis, endocannabinoid, cxcr4, [virus], receptor, sdf1*, is a typical "chained" topic, with *CXCR4* linked to *cannabinoids* only through *receptors*, and otherwise unrelated. Eight out of ten annotators correctly identified "virus" as the correct intruder. Repeating the logistic regression experiment using intruder detection accuracy as input, the AIC value is 163.18—much worse than either topic size or coherence.

5 Generalized Pólya Urn Models

Although the topic coherence metric defined above provides an accurate way of assessing topic quality, *preventing* poor quality topics from occurring in the first place is preferable. Our results in the previous section show that we can identify low-quality topics without making use of external supervision; the training data by itself contains sufficient information at least to reject poor combinations of words.

In this section, we describe a new topic model that incorporates the corpus-specific word co-occurrence information used in our coherence metric directly into the statistical topic modeling framework. It is important to note that simply disallowing words that never co-occur from being assigned to the same topic is not sufficient. Due to the power-law characteristics of language, most words are rare and will not co-occur with most other words regardless of their semantic similarity. It is rather the *degree* to which the most prominent words in a topic do not co-occur with the other most prominent words in that topic that is an indicator of topic incoherence. We therefore desire models that guide topics towards semantic similarity without imposing hard constraints.

As an example of such a model, we present a new topic model in which the occurrence of word type w in topic t increases not only the probability of seeing that word type again, but also increases the probability of seeing other related words (as determined by co-document frequencies for the corpus being modeled). This new topic model retains the document–topic component of standard LDA, but replaces the usual Pólya urn topic–word component with a *generalized* Pólya urn framework (Mahmoud, 2008).

A sequence of i.i.d. samples from a discrete distribution can be imagined as arising by repeatedly drawing a random ball from an urn, where the number of balls of each color is proportional to the probability of that color, replacing the selected ball after each draw. In a Pólya urn, each ball is replaced *along with another ball of the same color*. Samples from this model exhibit the "burstiness" property: the probability of drawing a ball of color w increases each time a ball of that color is drawn. This process represents the marginal distribution of a hierarchical model with a Dirichlet prior and a multinomial likelihood, and is used as the distribution over words for each topic in almost all previous topic models. In a *generalized* Pólya urn model, having drawn a ball of color w, A_{vw} additional balls of each color $v \in \{1, \ldots, W\}$ are returned to the urn. Given $\mathcal{W}$ and $\mathcal{Z}$, the conditional posterior probability of word w in topic t implied by this generalized model is

$$P(w \mid t, \mathcal{W}, \mathcal{Z}, \beta, \boldsymbol{A}) = \frac{\sum_v N_{v|t}\, A_{vw} + \beta}{N_t + |\mathcal{V}|\beta}, \quad (2)$$

where $\boldsymbol{A}$ is a $W \times W$ real-valued matrix, known as the *addition matrix* or *schema*. The simple Pólya urn model (and hence the conditional posterior probability of word w in topic t under LDA) can be recovered by setting the schema $\boldsymbol{A}$ to the identity matrix. Unlike the simple Pólya distribution, we do not know of a representation of the generalized Pólya urn distribution that can be expressed using a concise set of conditional independence assumptions. A standard graphical model with plate notation would therefore not be helpful in highlighting the differences between the two models, and is not shown.

Algorithm 1 shows pseudocode for a single Gibbs sweep over the latent variables $\mathcal{Z}$ in standard LDA. Algorithm 2 shows the modifications necessary to

support a generalized Pólya urn model: rather than subtracting exactly one from the count of the word given the old topic, sampling, and then adding one to the count of the word given the new topic, we subtract a column of the schema matrix from the entire count vector over words for the old topic, sample, and add the same column to the count vector for the new topic. As long as A is sparse, this operation adds only a constant factor to the computation.

Another property of the generalized Pólya urn model is that it is nonexchangeable—the joint probability of the tokens in any given topic is not invariant to permutation of those tokens. Inference of $\mathcal{Z}$ given $\mathcal{W}$ via Gibbs sampling involves repeatedly cycling through the tokens in $\mathcal{W}$ and, for each one, resampling its topic assignment conditioned on $\mathcal{W}$ and the current topic assignments for all tokens other than the token of interest. For LDA, the sampling distribution for each topic assignment is simply the product of two predictive probabilities, obtained by treating the token of interest as if it were the last. For a topic model with a generalized Pólya urn for the topic–word component, the sampling distribution is more complicated. Specifically, the topic–word component of the sampling distribution is no longer a simple predictive distribution—when sampling a new value for $z_n^{(d)}$, the implication of each possible value for subsequent tokens and their topic assignments must be considered. Unfortunately, this can be very computationally expensive, particularly for large corpora. There are several ways around this problem. The first is to use sequential Monte Carlo methods, which have been successfully applied to topic models previously (Canini et al., 2009). The second approach is to approximate the true Gibbs sampling distribution by treating each token as if it were the last, ignoring implications for subsequent tokens and their topic assignments. We find that this approximate method performs well empirically.

5.1 Setting the Schema A

Inspired by our evaluation metric, we define A as

$$\begin{aligned} \boldsymbol{A}_{vv} &\propto \lambda_v D(v) \\ \boldsymbol{A}_{vw} &\propto \lambda_v D(w, v) \end{aligned} \tag{3}$$

where each element is scaled by a row-specific weight λ_v and each column is normalized to sum to 1. Normalizing columns makes comparison to standard LDA simpler, because the relative effect of smoothing parameter $\beta = 0.01$ is equivalent. We set $\lambda_v = \log(D \,/\, D(v))$, the standard IDF weight used in information retrieval, which is larger for less frequent words. The column for word type w can be interpreted as word types with significant association with w. The IDF weighting therefore has the effect of increasing the strength of association for rare word types. We also found empirically that it is helpful to remove off-diagonal elements for the most common types, such as those that occur in more than 5% of documents (IDF < 3.0). Including nonzero off-diagonal values in $\boldsymbol{A}$ for very frequent types causes the model to disperse those types over many topics, which leads to large numbers of extremely similar topics. To measure this effect, we calculated the Jensen-Shannon divergence between all pairs of topic–word distributions in a given model. For a model using off-diagonal weights for all word

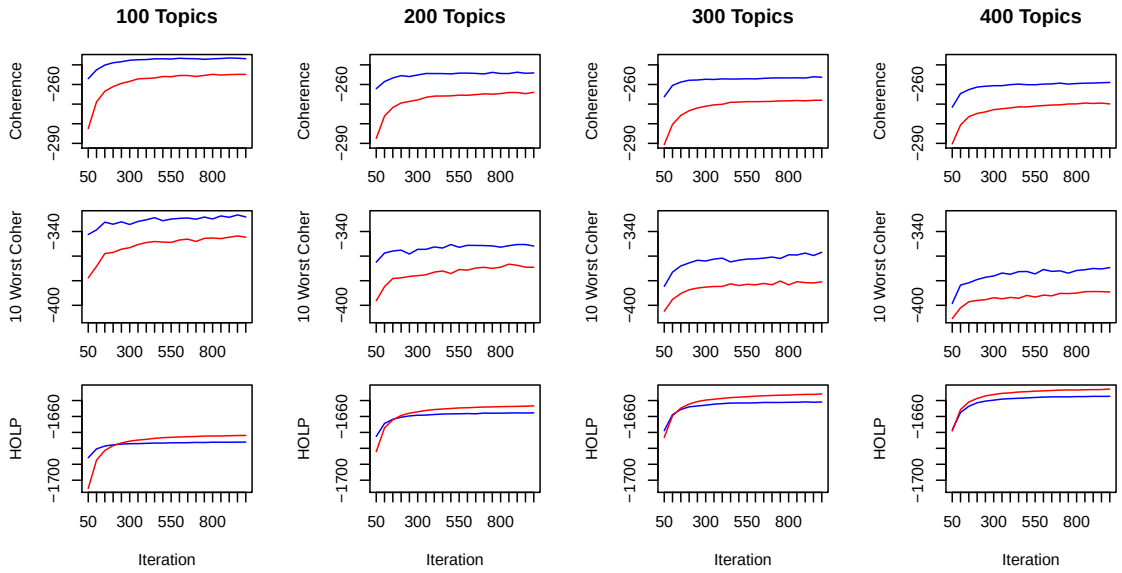

Figure 3: **Pólya urn topics (blue) have higher average coherence and converge much faster than LDA topics (red)**. The top plots show topic coherence (averaged over 15 runs) over 1000 iterations of Gibbs sampling. Error bars are not visible in this plot. The middle plot shows the average coherence of the 10 lowest scoring topics. The bottom plots show held-out log probability (in thousands) for the same models (three runs each of 5-fold cross-validation).

Name	Docs	Avg. Tok.	Tokens	Vocab
NIH	18756	114.64 ± 30.41	2150172	28702

Table 3: Data set statistics.

types, the mean of the 100 lowest divergences was $0.29 \pm .05$ (a divergence of 1.0 represents distributions with no shared support) at $T = 200$. The average divergence of the 100 most similar pairs of topics for standard LDA (i.e., $\boldsymbol{A} = \boldsymbol{I}$) is $0.67 \pm .05$. The same statistic for the generalized Pólya urn model without off-diagonal elements for word types with high document frequency is 0.822 ± 0.09.

Setting the off-diagonal elements of the schema $\boldsymbol{A}$ to zero for the most common word types also has the fortunate effect of substantially reducing preprocessing time. We find that Gibbs sampling for the generalized Pólya model takes roughly two to three times longer than for standard LDA, depending on the sparsity of the schema, due to additional bookkeeping needed before and after sampling topics.

5.2 Experimental Results

We evaluated the new model on a corpus of NIH grant abstracts. Details are given in table 3. Figure 3 shows the performance of the generalized Pólya urn model relative to LDA. Two metrics—our new topic coherence metric and the log probability of held-out documents—are shown over 1000 iterations at 50 iteration intervals. Each model was run over five folds of cross validation, each with three random initializations. For each model we calculated an overall coherence score by calculating the topic coherence for each topic individually and then averaging these values. We report the average over all 15 models in each plot. Held-out probabilities were calculated using the left-to-right method of Wallach et al. (2009), with each cross-validation fold using its own schema $\boldsymbol{A}$. The generalized Pólya model performs very well in average topic coherence, reaching levels within the first 50 iterations that match the final score. This model has an early advantage for held-out probability as well, but is eventually overtaken by LDA. This trend is consistent with Chang et al.'s observation that held-out probabilities are not always good predictors of human judgments (Chang et al., 2009). Results are consistent over $T \in \{100, 200, 300\}$.

In section 4.2, we demonstrated that our topic coherence metric correlates with expert opinions of topic quality for standard LDA. The generalized

Pólya urn model was therefore designed with the goal of directly optimizing that metric. It is possible, however, that optimizing for coherence directly could break the association between coherence metric and topic quality. We therefore repeated the expert-driven evaluation protocol described in section 3.1. We trained one standard LDA model and one generalized Pólya urn model, each with $T = 200$, and randomly shuffled the 400 resulting topics. The topics were then presented to the experts from NINDS, with no indication as to the identity of the model from which each topic came. As these evaluations are time consuming, the experts evaluated the only the first 200 topics, which consisted of 103 generalized Pólya urn topics and 97 LDA topics. AUC values predicting bad topics given coherence were 0.83 and 0.80, respectively. Coherence effectively predicts topic quality in both models.

Although we were able to improve the average overall quality of topics and the average quality of the ten lowest-scoring topics, we found that the generalized Pólya urn model was less successful reducing the overall number of bad topics. Ignoring one "unbalanced" topic from each model, 16.5% of the LDA topics and 13.5% from the generalized Pólya urn model were marked as "bad." While this result is an improvement, it is not significant at $p = 0.05$.

6 Discussion

We have demonstrated the following:

- There is a class of low-quality topics that cannot be detected using existing word-intrusion tests, but that can be identified reliably using a metric based on word co-occurrence statistics.
- It is possible to improve the coherence score of topics, both overall and for the ten worst, while retaining the ability to flag bad topics, all without requiring semi-supervised data or additional reference corpora. Although additional information may be useful, it is not necessary.
- Such models achieve better performance with substantially fewer Gibbs iterations than LDA.

We believe that the most important challenges in future topic modeling research are improving the semantic quality of topics, particularly at the low end, and scaling to ever-larger data sets while ensuring high-quality topics. Our results provide critical insight into these problems. We found that it should be possible to construct unsupervised topic models that do not produce bad topics. We also found that Gibbs sampling mixes faster for models that use word co-occurrence information, suggesting that such methods may also be useful in guiding online stochastic variational inference (Hoffman et al., 2010).

Abstract

Argumentative Zoning (AZ) – analysis of the argumentative structure of a scientific paper – has proved useful for a number of information access tasks. Current approaches to AZ rely on supervised machine learning (ML). Requiring large amounts of annotated data, these approaches are expensive to develop and port to different domains and tasks. A potential solution to this problem is to use weakly-supervised ML instead. We investigate the performance of four weakly-supervised classifiers on scientific abstract data annotated for multiple AZ classes. Our best classifier based on the combination of active learning and self-training outperforms our best supervised classifier, yielding a high accuracy of 81% when using just 10% of the labeled data. This result suggests that weakly-supervised learning could be employed to improve the practical applicability and portability of AZ across different information access tasks.

1 Introduction

Many practical tasks require accessing specific types of information in scientific literature. For example, a reader of scientific literature may be looking for information about the objective of the study in question, the methods used in the study, the results obtained, or the conclusions drawn by authors. Similarly, many Natural Language Processing (NLP) tasks focus on the extraction of specific types of information in documents only.

To date, a number of approaches have been proposed for sentence-based classification of scientific literature according to categories of information structure (or discourse, rhetorical, argumentative or conceptual structure, depending on the framework in question). Some of these classify sentences according to typical section names seen in scientific documents (Lin et al., 2006; Hirohata et al., 2008), while others are based e.g. on argumentative zones (Teufel and Moens, 2002; Mizuta et al., 2006; Teufel et al., 2009), qualitative dimensions (Shatkay et al., 2008) or conceptual structure (Liakata et al., 2010) of documents.

The best of current approaches have yielded promising results and proved useful for information retrieval, information extraction and summarization tasks (Teufel and Moens, 2002; Mizuta et al., 2006; Tbahriti et al., 2006; Ruch et al., 2007). However, relying on fully supervised machine learning (ML) and a large body of annotated data, existing approaches are expensive to develop and port to different scientific domains and tasks.

A potential solution to this bottleneck is to develop techniques based on weakly-supervised ML. Relying on a small amount of labeled data and a large pool of unlabeled data, weakly-supervised techniques (e.g. semi-supervision, active learning, co/tri-training, self-training) aim to keep the advantages of fully supervised approaches. They have been applied to a wide range of NLP tasks, including named-entity recognition, question answering, information extraction, text classification and many others (Abney, 2008), yielding performance levels similar or equivalent to those of fully supervised techniques.

To the best of our knowledge, such techniques

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 273–283,
Edinburgh, Scotland, UK, July 27–31, 2011.

have not yet been applied to the analysis of information structure of scientific documents by aforementioned approaches. Recent experiments have demonstrated the usefulness of weakly-supervised learning for classifying discourse relations in scientific texts, e.g. (Hernault et al., 2011). However, focusing on local (rather than global) structure of documents and being much more fine-grained in nature, this related task differs from ours considerably.

In this paper, we investigate the potential of weakly-supervised learning for Argumentative Zoning (AZ) of scientific abstracts. AZ is an approach to information structure which provides an analysis of the rhetorical progression of the scientific argument in a document (Teufel and Moens, 2002). It has been used to analyze scientific texts in various disciplines – including computational linguistics (Teufel and Moens, 2002), law, (Hachey and Grover, 2006), biology (Mizuta et al., 2006) and chemistry (Teufel et al., 2009) – and has proved useful for NLP tasks such as summarization (Teufel and Moens, 2002). Although the basic scheme is said to be discipline-independent (Teufel et al., 2009), its application to different domains has resulted in various modifications and laborious annotation exercises. This suggests that a weakly-supervised approach would be more practical than a fully supervised one for the real-world application of AZ.

Taking two supervised classifiers as a comparison point – Support Vector Machines (SVM) and Conditional Random Fields (CRF) – we investigate the performance of four weakly-supervised classifiers on the AZ task: two based on semi-supervised learning (transductive SVM and semi-supervised CRF) and two on active learning (Active SVM alone and in combination with self-training).

The results are promising. Our best weakly-supervised classifier (Active SVM with self-training) outperforms the best supervised classifier (SVM), yielding high accuracy of 81% when using just 10% of the labeled data. When using just one third of the labeled data, it performs equally well as a fully supervised SVM which uses 100% of the labeled data. Our investigation suggests that weakly-supervised learning could be employed to improve the practical applicability and portability of AZ to different information access tasks.

2 Data

We used in our experiments the recent dataset of (Guo et al., 2010). Guo et al. (2010) provide a corpus of 1000 biomedical abstracts (consisting of 7985 sentences and 225785 words) annotated according to three schemes of information structure – those based on section names (Hirohata et al., 2008), AZ (Mizuta et al., 2006) and Core Scientific Concepts (CoreSC) (Liakata et al., 2010). We focus here on AZ only, because it subsumes all the categories of the simple section name -based scheme, and according to the inter-annotator agreement and ML experiments reported by Guo et al. (2010) it performs better on this data than the fairly fine-grained CoreSC scheme.

AZ is a scheme which provides an analysis of the rhetorical progression of the scientific argument, following the knowledge claims made by authors. (Teufel and Moens, 2002) introduced AZ and applied it first to computational linguistics papers. (Hachey and Grover, 2006) applied the scheme later to legal texts and (Mizuta et al., 2006) modified it for biology papers. More recently, (Teufel et al., 2009) introduced a refined version of AZ and applied it to chemistry papers.

The biomedical dataset of (Guo et al., 2010) has been annotated according to the version of AZ developed for biology papers (Mizuta et al., 2006) (with only minor modifications concerning zone names). Seven categories of this scheme (out of the 10 possible) actually appear in abstracts and in the resulting corpus. These are shown and explained in Table 1. For example, the Method zone (METH) is for sentences which describe *a way of doing research, esp. according to a defined and regular plan; a special form of procedure or characteristic set of procedures employed in a field of study as a mode of investigation and inquiry*.

An example of a biomedical abstract annotated according to AZ is shown in Figure 1, with different zones highlighted in different colors. For example, the RES zone is highlighted in lemon green.

Table 2 shows the distribution of sentences per scheme category in the corpus: Results (RES) is by far the most frequent zone (accounting for 40% of the corpus), while Background (BKG), Objective (OBJ), Method (METH) and Conclusion (CON) cover

Table 1: Categories of AZ appearing in the corpus of (Guo et al., 2010)

Category	Abbr.	Definition
Background	BKG	The circumstances pertaining to the current work, situation, or its causes, history, etc.
Objective	OBJ	A thing aimed at or sought, a target or goal
Method	METH	A way of doing research, esp. according to a defined and regular plan; a special form of procedure or characteristic set of procedures employed in a field of study as a mode of investigation and inquiry
Result	RES	The effect, consequence, issue or outcome of an experiment; the quantity, formula, etc. obtained by calculation
Conclusion	CON	A judgment or statement arrived at by any reasoning process; an inference, deduction, induction; a proposition deduced by reasoning from other propositions; the result of a discussion, or examination of a question, final determination, decision, resolution, final arrangement or agreement
Related work	REL	A comparison between the current work and the related work
Future work	FUT	The work that needs to be done in the future

Figure 1: An example of an annotated abstract

Butadiene (BD) metabolism shows gender, species and concentration dependency, making the extrapolation of animal results to humans complex. BD is metabolized mainly by cytochrome P450 2E1 to three epoxides, 1,2-epoxy-3-butene (EB), 1,2;3,4-diepoxybutane (DEB) and 1,2-epoxy-butanediol (EB-diol). For accurate risk assessment it is important to elucidate species differences in the internal formation of the individual epoxides in order to assign the relative risks associated with their different mutagenic potencies. Analysis of N-terminal globin adducts is a common approach for monitoring the internal formation of BD ***Background***es. Our long term strategy is to develop an LC-MS/MS method for simultaneous detection of all three BD hemoglobin adducts. This approach is modeled after the recently reported immunoaffinity LC-MS/MS method for the cyclic N,N-(2,3-dihydroxy-1,4-butadyil)-valine (pyr-Val, derived from DEB). We report herein the analysis of the EB-derived 2-hydroxyl-3-butenyl-valine pep ***Objective***l). The procedure utilizes trypsin hydrolysis of globin and immunoaffinity (IA) purification of alkylated heptapeptides. Quantitation is based on LC-MS/MS monitoring of the transition from the singly charged molecular ion of HB-Val (1-7) to the a(1) fragment. Human HB-Val (1-11) was synthesized and used for antibody production. As internal standard, the labeled rat-[(13)C(5)(15)N]-Val (1-11) was prepared through direct alkylation of the corresponding peptide with EB. Standards were characterized and quantified by LC-MS/MS and LC-UV. The method was validated with different amounts of human HB-Val standard. The recovery was >75% and coefficient of variation <25%. The LOQ was set to 100 fmol/injection. For a proof of principal experiment, globin samples from male and female rats exposed to 1000 ppm BD for 90 days w***Method***ed. The amounts of HB-Val present were 268.2+/-56 and 350+/-70 pmol/g (mean+/-S.D.) for males and females, respectively. No HB-Val was detected i***Result***ls. These data are much lower compared to previously reported values measu***Related work***MS. The difference may be due higher specificity of the LC-MS/MS method to the N-terminal peptide from the alpha-chain versus derivatization of both alpha- and beta-chain by Edman degradation, and possible instability of HB-Val adducts during long term storage (about 10 years) betw***Conclusion***es. These differences will be resolved by examining recently collected samples, using the same internal standard for parallel analysis by GC-MS/M***Future work***MS. Based on our experience with pyr-Val adduct assay we anticipate that this assay will be suitable for evaluation of HB-Val in multiple species.

Table 2: Distribution of sentences in the AZ-annotated corpus

	BKG	OBJ	METH	RES	CON	REL	FUT
Word	36828	23493	41544	89538	30752	2456	1174
Sentence	1429	674	1473	3185	1082	95	47
Sentence	18%	8%	18%	40%	14%	1%	1%

8-18% of the corpus each. Two categories are very low in frequency, only covering 1% of the corpus each: Related work (REL) and Future work (FUT).

Guo et al. (2010) report the inter-annotator agreement between their three annotators: one linguist, one computational linguist and one domain expert. According to Cohen's kappa (Cohen, 1960) the agreement is relatively high: $\kappa = 0.85$.

3 Automatic identification of AZ

3.1 Features and feature extraction

Guo et al. (2010) used a variety of features in their fully supervised ML experiments on different schemes of information structure. Since their feature types cover the best performing feature types in earlier works e.g. (Teufel and Moens, 2002; Lin et al., 2006; Mullen et al., 2005; Hirohata et al., 2008; Merity et al., 2009) we re-implemented and used them in our experiment[1]. However, being aware of the fact that some of these features may not be optimal for weakly-supervised learning (i.e. when learning from smaller data), we evaluate their performance and suitability for the task later in section 4.3.

- **Location**. Zones tend to appear in typical positions in abstracts. Each abstract was there-

[1]The only exception is the history feature which was left out because it cannot be applied to all of our methods

fore divided into ten parts (1-10, measured by the number of words), and the location was defined by the parts where the sentence begins and ends.

- **Word**. All the words in the corpus.
- **Bi-gram**. Any combination of two adjacent words in the corpus.
- **Verb**. All the verbs in the corpus.
- **Verb Class**. 60 verb classes appearing in biomedical journal articles.
- **Part-of-Speech – POS**. The POS tag of each verb in the corpus.
- **Grammatical Relation – GR**. Subject (*ncsubj*), direct object (*dobj*), indirect object (*iobj*) and second object (*obj2*) relations in the corpus. e.g. *(ncsubj observed_14 difference_5 obj)*. The value of this feature equals 1 if it occurs in a particular sentence (and 0 if not).
- **Subj and Obj**. The subjects and objects appearing with any verbs in the corpus (extracted from above GRs).
- **Voice**. The voice of verbs (active or passive) in the corpus.

These features were extracted from the corpus using a number of tools. A tokenizer was used to detect the boundaries of sentences and to separate punctuation from adjacent words e.g. in complex biomedical terms such as *2-amino-3,8-diethylimidazo[4,5-f]quinoxaline*. The C&C tools (Curran et al., 2007) trained on biomedical literature were employed for POS tagging, lemmatization and parsing. The lemma output was used for creating Word, Bi-gram and Verb features. The GR output was used for creating the GR, Subj, Obj and Voice features. The "obj" marker in a subject relation indicates passive voice (e.g. *(ncsubj observed_14 difference_5 obj)*). The verb classes were acquired automatically from the corpus using the unsupervised spectral clustering method of (Sun and Korhonen, 2009). To control the number of features we lemmatized the lexical items for all the features, and removed the words and GRs with fewer than 2 occurrences and bi-grams with fewer than 5 occurrences.

3.2 Machine learning methods

Support Vector Machines (SVM) and Conditional Random Fields (CRF) have proved the best performing fully supervised methods in most recent works on information structure, e.g. (Teufel and Moens, 2002; Mullen et al., 2005; Hirohata et al., 2008; Guo et al., 2010). We therefore implemented these methods as well as weakly supervised variations of them: active SVM with and without self-training, transductive SVM and semi-supervised CRF.

3.2.1 Supervised methods

SVM constructs hyperplanes in a multidimensional space to separate data points of different classes. Good separation is achieved by the hyperplane that has the largest distance from the nearest data points of any class. The hyperplane has the form $w \cdot x - b = 0$, where w is its normal vector. We want to maximize the distance from the hyperplane to the data points, or the distance between two parallel hyperplanes each of which separates the data. The parallel hyperplanes can be written as: $w \cdot x - b = 1$ and $w \cdot x - b = -1$, and the distance between them is $\frac{2}{|w|}$. The problem reduces to:

Minimize $|w|$ (in w, b)

Subject to

$w \cdot x - b \geq 1$ for x of one class,

$w \cdot x - b \leq -1$ for x of the other,

which can be solved by using the SMO algorithm (Platt, 1999b). We used Weka software (Hall et al., 2009) (employing its linear kernel) for SVM experiments.

CRF is an undirected graphical model which defines a probability distribution over the hidden states (e.g. label sequences) given the observations. The probability of a label sequence y given an observation sequence x can be written as:

$p(y|x, \theta) = \frac{1}{Z(x)} exp(\sum_j \theta_j F_j(y, x))$,

where $F_j(y, x)$ is a real-valued feature function of the states and the observations; θ_j is the weight of F_j, and $Z(x)$ is a normalization factor. The θ parameters can be learned using the L-BFGS algorithm (Nocedal, 1980). We used Mallet software (McCallum, 2002) for CRF experiments.

3.2.2 Weakly-supervised methods

Active SVM (ASVM) starts with a small amount of labeled data, and iteratively chooses a proportion of

unlabeled data for which SVM has less confidence to be labeled (the labels can be restored from the original corpus) and used in the next round of learning, i.e. active learning. Query strategies based on the structure of SVM are frequently employed (Tong and Koller, 2001; Novak et al., 2006). For example, it is often assumed that the data points close to the separating hyperplane are those that the SVM is uncertain about. Unlike these methods, our learning algorithm compares the posterior probabilities of the best estimate given each unlabeled instance, and queries those with the lowest probabilities for the next round of learning. The probabilities can be obtained by fitting a Sigmoid after the standard SVM (Platt, 1999a), and combined using a pairwise coupling algorithm (Hastie and Tibshirani, 1998) in the multi-class case. We used the SVM linear kernel in Weka for classification, and the -M flag in Weka for calculating the posterior probabilities.

Active SVM with self-training (ASSVM) is an extension of ASVM where each round of training has two steps: (i) training on the labeled, and testing on the unlabeled data, and querying; (ii) training on both labeled and unlabeled/machine-labeled data by using the estimates from step (i). The idea of ASSVM is to make the best use of the labeled data, and to make the most use of the unlabeled data.

Transductive SVM (TSVM) is an extension of SVM which takes advantage of both labeled and unlabeled data (Vapnik, 1998). Similar to SVM, the problem is defined as:

Minimize $|w|$ (in $w, b, y^{(u)}$)
Subject to
$y^{(l)}(w \cdot x^{(l)} - b) \geq 1$,
$y^{(u)}(w \cdot x^{(u)} - b) \geq 1$,
$y^{(u)} \in \{-1, 1\}$,

where $x^{(u)}$ is unlabeled data and $y^{(u)}$ the estimate of its label. The problem can be solved by using the CCCP algorithm (Collobert et al., 2006). We used UniverSVM software (Sinz, 2011) for TSVM experiments.

Semi-supervised CRF (SSCRF) can be implemented with entropy regularization (ER). It extends the objective function on Labeled data $\sum_L \log p(y^{(l)}|x^{(l)}, \theta)$ with an additional term $\sum_U \sum_Y p(y|x^{(u)}, \theta) \log p(y|x^{(u)}, \theta)$ to minimize the conditional entropy of the model's predictions on Unlabeled data (Jiao et al., 2006; Mann and Mccallum, 2007). We used Mallet software (McCallum, 2002) for SSCRF experiments.

4 Experimental evaluation

4.1 Evaluation methods

We evaluated the ML results in terms of accuracy, precision, recall, and F-measure against manual AZ annotations in the corpus:

$$acc = \frac{no.\ of\ correctly\ classified\ sentences}{total\ no.\ of sentences\ in\ the\ corpus}$$

$$p = \frac{no.\ of\ sentences\ correctly\ identified\ as\ Class_i}{total\ no.\ of\ sentences\ identified\ as\ Class_i}$$

$$r = \frac{no.\ of\ sentences\ correctly\ identified\ as\ Class_i}{total\ no.\ of\ sentences\ in\ Class_i}$$

$$f = \frac{2*p*r}{p+r}$$

We used 10-fold cross validation for all the methods to avoid the possible bias introduced by relying on any particular split of the data. More specifically, the data was randomly assigned to ten folds of roughly the same size. Each fold was used once as test data and the remaining nine folds as training data. The results were then averaged.

Following (Dietterich, 1998), we used McNemar's test (McNemar, 1947) to measure the statistical significance between the results of different ML methods. The chosen significance level was .05.

4.2 Results

Table 3 shows the results for the four weakly-supervised and two supervised methods when 10% of the training data (i.e. ∼700 sentences) has been labeled. We can see that ASSVM is the best performing method with an accuracy of 81% and the macro

Table 3: Results when using 10% of the labeled data

	Acc.	F-score							
		MF	BKG	OBJ	METH	RES	CON	REL	FUT
SVM	.77	.74	.84	.68	.71	.82	.64	-	-
CRF	.70	.65	.75	.46	.48	.78	.76	-	-
ASVM	.80	.75	.88	.56	.68	.87	.78	.33	
ASSVM	.81	.76	.86	.56	.76	.88	.76	-	-
TSVM	.76	.73	.84	.61	.71	.79	.71	-	-
SSCRF	.73	.67	.76	.48	.52	.81	.78	-	-

MF: Macro F-score of the five high frequency categories: BKG, OBJ, METH, RES, CON.

Figure 2: Learning curve for different methods when using 0-100% of the labeled data

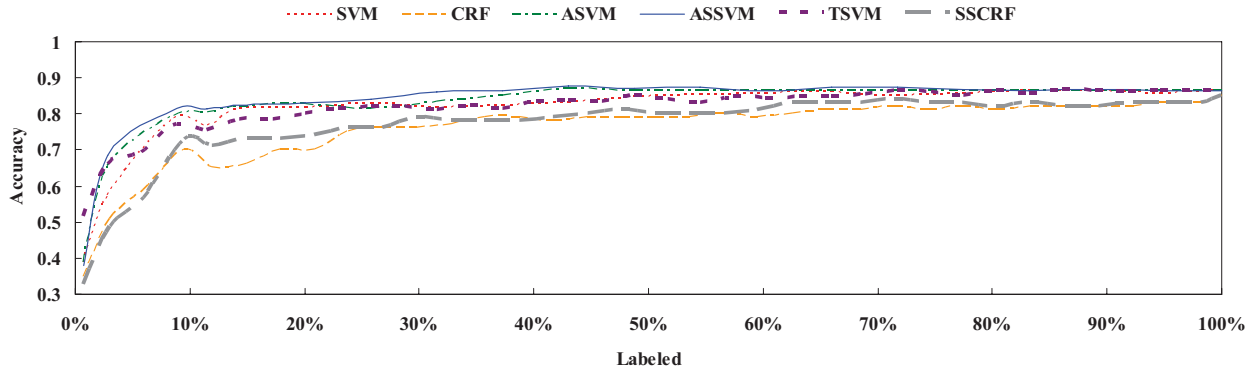

Figure 3: Area under learning curves at different intervals

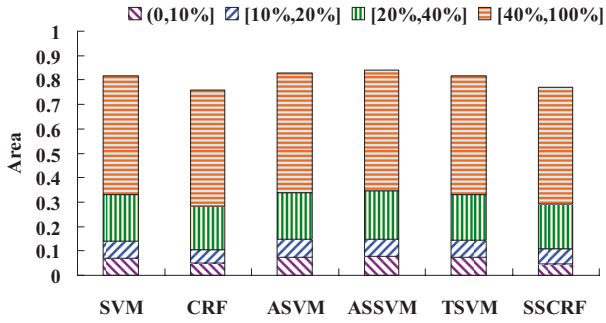

F-score of .76 (the macro F-score is calculated for the 5 scheme categories which are found by all the methods). ASVM performs nearly as well, with an accuracy of 80% and F-score of .75. Both methods outperform supervised SVM with a statistically significant difference ($p < .001$).

TSVM is the lowest performing SVM-based method. Yielding an accuracy of 76% and F-score of .73 its performance is lower than that of the supervised SVM. However, it does outperform both CRF-based methods. SSCRF performs better than CRF with 3% higher accuracy and .02 higher F-score. The difference in accuracy is statistically significant ($p < .001$).

Only one method (ASVM) identifies six out of the seven possible categories. Other methods identify five categories. The 1-2 missing categories are very low in frequency (accounting for 1% of the corpus data each, see table 2). Looking at the results for other categories, they seem to reflect the amount of corpus data available for each category (Table 2), with RES (Results) being the highest and OBJ (Objective) the lowest performing category with most methods. Interestingly, the only method that performs relatively well on OBJ is the supervised SVM.

The best method ASSVM outperforms other methods most clearly on METH (Method) category. Although METH is a high frequency category (accounting for 18% of the corpus data) other methods tend to confuse it with OBJ, presumably because a single sentence may contain elements of both (e.g. scientists may describe some of their method when describing the objective of the study).

Figure 2 shows the learning curve of different methods (in terms of accuracy) when the percentage of the labeled data (in the training set) ranges from 0 to 100%. ASSVM outperforms other methods, reaching its best performance of 88% accuracy when using ∼40% of the labeled data. Indeed when using 33% of the labeled data, it performs already equally well as fully-supervised SVM using 100% of the labeled data. The advantage of ASSVM over ASVM (the second best method) is clear especially when 20-40% of the labeled data is used. SVM and TSVM tend to perform quite similarly with each other when more than 25% of the labeled data is used, but when less data is available, SVM performs better. Looking at the CRF-based methods, SSCRF outperforms CRF in particular when 10-25% of the labeled data is used. However, neither of them reaches the performance level of SVM-based methods.

Figure 3 shows the area under the learning curves (by the trapezoidal rule) at different intervals, which gives a reasonable approximation to the overall performance of different methods. The area under ASSVM is the largest at each of the four intervals, with a value of .08 at (0,10%], .07 at [10%,20%],

.20 at [20%, 40%] and .50 at [40%,100%]. The difference between supervised and weakly-supervised methods is more significant at (0, 20%] than at [20%,100%].

4.3 Further analysis of the features

As explained in section 3.1, we employed in our experiments a collection of features which had performed well in previous supervised AZ experiments. We conducted further analysis to investigate which of these features are the most (and the least) useful for weakly-supervised learning. We took our best performing method ASSVM and conducted leave-one-out analysis of the features with 10% of the labeled data. The results are shown in Table 4.

Table 4: Leaving one feature out results for ASSVM when using 10% of the labeled data

	Acc.	F-score							
		MF	BKG	OBJ	METH	RES	CON	REL	FUT
Location	.73	.67	.67	.55	.62	.85	.65	-	-
Word	.80	.78	.87	.70	.74	.85	.72	-	-
Bigram	.81	.75	.83	.57	.71	.87	.78	.33	-
Verb	.81	.79	.84	.77	.73	.87	.75	-	-
VC	.79	.75	.86	.62	.72	.84	.70	-	-
POS	.74	.70	.66	.65	.66	.82	.73	-	-
GR	.79	.75	.83	.67	.69	.84	.72	-	-
Subj	.80	.76	.87	.65	.73	.85	.72	-	-
Obj	.80	.78	.84	.75	.70	.85	.75	-	-
Voice	.78	.75	.88	.70	.71	.83	.62	-	-
Φ	.81	.76	.86	.56	.76	.88	.76	-	-

MF: Macro F-score of the five high frequency categories: BKG, OBJ, METH, RES, CON.
Φ: Employing all the features.

We can see that the Location feature is by far the most useful feature for ASSVM. The performance drops 8% in accuracy and .09 in F-score in the absence of this feature. Location is particularly important for BKG (which nearly always appears in the same location: in the beginning of an abstract) and is highly useful for METH and CON as well. Removing POS has almost equally strong effect, in particular on BKG and METH, suggesting that verb tense is particularly useful for distinguishing these categories.

Also Voice, Verb class and GR contribute to general performance, especially to accuracy. Voice is particularly important for CON, which differs from other categories in the sense that it is marked by frequent usage of active voice. Verb class is helpful for METH, RES and CON while GR is helpful for all high frequency categories.

Among the least helpful features are those which suffer from sparse data problems, including e.g. Word, Bi-gram, and Verb. They perform particularly badly when applied to low frequency zones. However, this is not the case when using fully-supervised methods (i.e. 100% of the labeled data), suggesting that a good performance in fully supervised experiments does not necessarily translate into a good performance in weakly-supervised experiments, and that careful feature analysis and selection is important when aiming to optimize the performance when learning from sparse data.

5 Discussion

In our experiments, the majority of weakly-supervised methods outperformed their corresponding supervised methods when using just 10% of the labeled data. The SVM-based methods performed better than the CRF-based ones (regardless of whether they were weakly or fully supervised). Guo et al. (2010) made a similar discovery when comparing fully supervised versions of SVM and CRF.

Our best performing weakly-supervised methods were those based on active learning. Making a good use of both labeled and unlabeled data, active learning combined with self-training (ASSVM) proved to be the most useful method. Given 10% of the labeled data, ASSVM obtained an accuracy of 81% and F-score of .76, outperforming the best supervised method SVM with a statistically significant difference. It reached its top performance (88% accuracy) when using 40% of the labeled data, and performed equally well as fully supervised SVM (i.e. 100% of the labeled data) when using just one third of the labeled data.

This result is in line with the results of many other text classification works where active learning (alone or in combination with other techniques such as self-training) has proved similarly useful, e.g. (Lewis and Gale, 1994; Tong and Koller, 2002; Brinker, 2006; Novak et al., 2006; Esuli and Sebastiani, 2009; Yang et al., 2009).

While active learning iteratively explores the unknown aspects of the unlabeled data, semi-supervised learning attempts to make the best use

of what it already knows about the data. In our experiments, semi-supervised methods (TSVM and SSCRF) did not perform equally well as active learning – TSVM even produced a lower accuracy than SVM with the same amount of labeled data – although these methods have gained success in related works.

We therefore looked into related works using TSVM, e.g. (Chapelle and Zien, 2005), and discovered that our dataset is much higher in dimensionality than those employed in many other works. High dimensional data is more sensitive, and therefore fine-tuning with unlabeled data may cause a big deviation. We also looked into related works using SSCRF, in particular the work of (Jiao et al., 2006) who used the same SSCRF as the one we used in our experiments. Jiao et al. (2006) employed a much larger data set than we did – one including 5448 labeled instances (in 3 classes) and 5210-25145 unlabeled instances. Given more labeled and unlabeled data per class we might be able to obtain better performance using SSCRF also on our task. However, given the high cost of obtaining labeled data methods not needing it are preferable.

6 Conclusions and future work

Our experiments show that weakly-supervised learning can be used to identify AZ in scientific documents with good accuracy when only a limited amount of labeled data is available. This is helpful thinking of the real-world application and porting of the approach to different tasks and domains. To the best of our knowledge, no previous work has been done on weakly-supervised learning of information structure according to schemes of the type we have focused on (Teufel and Moens, 2002; Mizuta et al., 2006; Lin et al., 2006; Hirohata et al., 2008; Shatkay et al., 2008; Liakata et al., 2010).

Recently, some work has been done on the related task of classification of discourse relations in scientific texts: (Hernault et al., 2011) used structural learning (Ando and Zhang, 2005) for this task. They obtained 30-60% accuracy on the RST Discourse Treebank (including 41 relation types) when using 100-10000 labeled and 100000 unlabeled instances. The accuracy was 20-60% when using the labeled data only. However, although related, the task of discourse relation classification differs substantially from our task in that it focuses on local discourse relations while our task focuses on the global structure of the scientific document.

In the future, we plan to improve and extend this work in several directions. First, the approach to active learning could be improved in various ways. The query strategy we employed (uncertainty sampling) is a relatively straightforward method which only considers the best estimate for each unlabeled instance, disregarding other estimates that may contain useful information. In the future, we plan to experiment with more sophisticated strategies, e.g. the margin sampling algorithm by (Scheffer et al., 2001) and the query-by-committee (QBC) algorithm by (Seung et al., 1992). In addition, there are algorithms designed for reducing the redundancy in queries which may be worth investigating (Hoi et al., 2006).

Also, (Hoi et al., 2006) shows that Logistic Regression (LR) outperforms SVM when used with active learning, yielding higher F-score on the Reuters-21578 data set (binary classification, 10,788 documents in total, 100 of them labeled). It would be interesting to explore whether supervised methods other than SVM are optimal for active learning when applied to our task.

Secondly, we plan to investigate other semi-supervised methods, for example, the Expectation-Maximization (EM) algorithm. (Lanquillon, 2000) has shown that EM SVM performs better than supervised and transductive SVM on a text classification task when applied to the dataset of 20 Newsgroups (20 classes, 4000 documents for testing, 10000 unlabeled ones), yielding up to $\sim$10% higher accuracy when 200-5000 labeled documents are used for training.

In addition, other combinations of weakly-supervised methods might be worth looking into, such as EM+active learning (McCallum and Nigam, 1998) and co-training+EM+active learning (Muslea et al., 2002), which have proved promising in related text classification works.

Besides looking for optimal ML strategies, we plan to look for optimal features for the task. Our feature analysis showed that not all the features which had proved promising in fully supervised experiments were equally promising when applied to weakly-supervised learning from smaller data. We

plan to look into ways of reducing the sparse data problem in features, e.g. by classifying not only verbs but also other word classes into semantically-motivated categories.

One the key motivations for developing a weakly-supervised approach is to facilitate easy porting of schemes such as AZ to new tasks and domains. Recent research shows that active learning in a target domain can leverage information from a different but related (source) domain (Rai et al., 2010). Making use of existing annotated datasets in biology, chemistry, computational linguistics and law (Teufel and Moens, 2002; Mizuta et al., 2006; Hachey and Grover, 2006; Teufel et al., 2009) we will explore optimal ways of combining weakly-supervised learning with domain-adaptation.

The work presented in this paper has focused on the abstracts annotated according to the AZ scheme. In the future, we plan to investigate the usefulness of weakly-supervised learning for identifying other schemes of information structure, e.g. (Lin et al., 2006; Hirohata et al., 2008; Shatkay et al., 2008; Liakata et al., 2010), and not only in scientific abstracts but also in full journal papers which typically exemplify a larger set of scheme categories.

Finally, an important avenue of future research is to evaluate the usefulness of weakly-supervised identification of information structure for NLP tasks such as summarization and information extraction (Tbahriti et al., 2006; Ruch et al., 2007), and for practical tasks such as manual review of scientific papers for research purposes (Guo et al., 2010).

Abstract

This paper presents a new algorithm for linear text segmentation. It is an adaptation of Affinity Propagation, a state-of-the-art clustering algorithm in the framework of factor graphs. Affinity Propagation for Segmentation, or *APS*, receives a set of pairwise similarities between data points and produces segment boundaries and segment *centres* – data points which best describe all other data points within the segment. *APS* iteratively passes messages in a cyclic factor graph, until convergence. Each iteration works with information on all available similarities, resulting in high-quality results. *APS* scales linearly for realistic segmentation tasks. We derive the algorithm from the original Affinity Propagation formulation, and evaluate its performance on topical text segmentation in comparison with two state-of-the art segmenters. The results suggest that *APS* performs on par with or outperforms these two very competitive baselines.

1 Introduction

In complex narratives, it is typical for the topic to shift continually. Some shifts are gradual, others – more abrupt. *Topical text segmentation* identifies the more noticeable topic shifts. A topical segmenter's output is a very simple picture of the document's structure. Segmentation is a useful intermediate step in such applications as subjectivity analysis (Stoyanov and Cardie, 2008), automatic summarization (Haghighi and Vanderwende, 2009), question answering (Oh, Myaeng, and Jang, 2007) and others. That is why improved quality of text segmentation can benefit other language-processing tasks.

We present Affinity Propagation for Segmentation (*APS*), an adaptation of a state-of-the-art clustering algorithm, Affinity Propagation (Frey and Dueck, 2007; Givoni and Frey, 2009).[1] The original AP algorithm considerably improved exemplar-based clustering both in terms of speed and the quality of solutions. That is why we chose to adapt it to segmentation. At its core, *APS* is suitable for segmenting any sequences of data, but we present it in the context of segmenting documents. *APS* takes as input a matrix of pairwise similarities between sentences and, for each sentence, a *preference* value which indicates an *a priori* belief in how likely a sentence is to be chosen as a segment centre. *APS* outputs segment assignments and segment centres – data points which best explain all other points in a segment. The algorithm attempts to maximize *net similarity* – the sum of similarities between all data points and their respective segment centres.

APS operates by iteratively passing messages in a factor graph (Kschischang, Frey, and Loeliger, 2001) until a good set of segments emerges. Each iteration considers all similarities – takes into account all available information. An iteration includes sending at most $O(N^2)$ messages. For the majority of realistic segmentation tasks, however, the upper bound is $O(MN)$ messages, where M is a constant. This is more computationally expensive than the requirements of locally informed segmentation algorithms such as those based on HMM or CRF (see Section 2), but for a globally-informed algorithm the requirements are very reasonable. *APS* is an instance of loopy-belief propagation (belief propagation on cyclic graphs) which has

[1] An implementation of *APS* in Java, and the data sets, can be downloaded at ⟨www.site.uottawa.ca/∼ankazant⟩.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 284–293,
Edinburgh, Scotland, UK, July 27–31, 2011.

been used to achieved state-of-the-art performance in error-correcting decoding, image processing and data compression. Theoretically, such algorithms are not guaranteed to converge or to maximize the objective function. Yet in practice they often achieve competitive results.

APS works on an already pre-compiled similaritiy matrix, so it offers flexibility in the choice of similarity metrics. The desired number of segments can be set by adjusting preferences.

We evaluate the performance of *APS* on three tasks: finding topical boundaries in transcripts of course lectures (Malioutov and Barzilay, 2006), identifying sections in medical textbooks (Eisenstein and Barzilay, 2008) and identifying chapter breaks in novels. We compare *APS* with two recent systems: the Minimum Cut segmenter (Malioutov and Barzilay, 2006) and the Bayesian segmenter (Eisenstein and Barzilay, 2008). The comparison is based on the WindowDiff metric (Pevzner and Hearst, 2002). *APS* matches or outperforms these very competitive baselines.

Section 2 of the paper outlines relevant research on topical text segmentation. Section 3 briefly covers the framework of factor graphs and outlines the original Affinity Propagation algorithm for clustering. Section 4 contains the derivation of the new update messages for APSeg. Section 5 describes the experimental setting, Section 6 reports the results, Section 7 discusses conclusions and future work.

2 Related Work

This sections discusses selected text segmentation methods and positions the proposed *APS* algorithm in that context.

Most research on automatic text segmentation revolves around a simple idea: when the topic shifts, so does the vocabulary (Youmans, 1991). We can roughly subdivide existing approaches into two categories: locally informed and globally informed.

Locally informed segmenters attempt to identify topic shifts by considering only a small portion of complete document. A classical approach is TextTiling (Hearst, 1997). It consists of sliding two adjacent windows through text and measuring lexical similarity between them. Drops in similarity correspond to topic shifts. Other examples include text segmentation using Hidden Markov Models (Blei and Moreno, 2001) or Conditional Random Fields (Lafferty, McCallum, and Pereira, 2001). Locally informed methods are often very efficient because of lean memory and CPU time requirements. Due to a limited view of the document, however, they can easily be thrown off by short inconsequential digressions in narration.

Globally informed methods consider "the big picture" when determining the most likely location of segment boundaries. Choi (2000) applies divisive clustering to segmentation. Malioutov and Barzilay (2006) show that the knowledge about long-range similarities between sentences improves segmentation quality. They cast segmentation as a graph-cutting problem. The document is represented as a graph: nodes are sentences and edges are weighted using a measure of lexical similarity. The graph is cut in a way which maximizes the net edge weight within each segment and minimizes the net weight of severed edges. Such *Minimum Cut* segmentation resembles *APS* the most among others mentioned in this paper. The main difference between the two is in different objective functions.

Another notable direction in text segmentation uses generative models to find segment boundaries. Eisenstein and Barzilay (2008) treat words in a sentence as draws from a multinomial language model. Segment boundaries are assigned so as to maximize the likelihood of observing the complete sequence. Misra et al. (2009) use a Latent Dirichlet allocation topic model (Blei, Ng, and Jordan, 2003) to find coherent segment boundaries. Such methods output segment boundaries and suggest lexical distribution associated with each segment. Generative models tend to perform well, but are less flexible than the similarity-based models when it comes to incorporating new kinds of information.

Globally informed models generally perform better, especially on more challenging datasets such as speech recordings, but they have – unsurprisingly – higher memory and CPU time requirements.

The *APS* algorithm described in this paper combines several desirable properties. It is unsupervised and, unlike most other segmenters, does not require specifying the desired number of segments as an input parameter. On each iteration it takes into account the information about a large portion of the docu-

ment (or all of it). Because *APS* operates on a precompiled matrix of pair-wise sentence similarities, it is easy to incorporate new kinds of information, such as synonymy or adjacency. It also provides some information as to what the segment is about, because each segment is associated with a segment centre.

3 Factor graphs and affinity propagation for clustering

3.1 Factor graphs and the max-sum algorithm

The *APS* algorithm is an instance of belief propagation on a cyclic factor graph. In order to explain the derivation of the algorithm, we will first briefly introduce factor graphs as a framework.

Many computational problems can be reduced to maximizing the value of a multi-variate function $F(x_1, \ldots, x_n)$ which can be approximated by a sum of simpler functions. In Equation 1, H is a set of discrete indices and f_h is a local function with arguments $X_h \subset \{x_1, \ldots, x_n\}$:

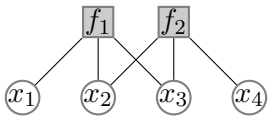
$$F(x_1, \ldots, x_n) = \sum_{h \in H} f_h(X_h) \tag{1}$$

Factor graphs offer a concise graphical representation for such problems. A global function F which can be decomposed into a sum of M local function f_h can be represented as a bi-partite graph with M function nodes and N variable nodes ($M = |H|$). Figure 1 shows an example of a factor graph for $F(x_1, x_2, x_3, x_4) = f_1(x_1, x_2, x_3) + f_2(x_2, x_3, x_4)$. The factor (or function) nodes are dark squares, the variable nodes are light circles.

The well-known max-sum algorithm (Bishop, 2006) seeks a configuration of variables which maximizes the objective function. It finds the maximum in acyclic factor graphs, but in graphs with cycles neither convergence nor optimality are guaranteed (Pearl, 1982). Yet in practice good approximations can be achieved. The max-sum algorithm amounts to propagating messages from function nodes to variable nodes and from variable nodes to function nodes. A message sent from a variable node x to a function node f is computed as a sum of the incoming messages from all neighbours of x other than f (the sum is computed for each possible value of x):

$$\mu_{x \to f} = \sum_{f' \in N(x) \setminus f} \mu_{f' \to x} \tag{2}$$

Figure 1: Factor graph for $F(x_1, x_2, x_3, x_4) = f_1(x_1, x_2, x_3) + f_2(x_2, x_3, x_4)$.



$N(x)$ is the set of all function nodes which are x's neighbours. The message reflects the evidence about the distribution of x from all functions which have x as an argument, except for the function corresponding to the receiving node f.

A message $\mu_{f \to x}$ from function f to variable x is computed as follows:

$$\mu_{f \to x} = \max_{N(f) \setminus x} (f(x_1, \ldots, x_m) + \sum_{x' \in N(f) \setminus x} \mu_{x' \to f}) \tag{3}$$

$N(f)$ is the set of all variable nodes which are f's neighbours. The message reflects the evidence about the distribution of x from function f and its neighbours other than x.

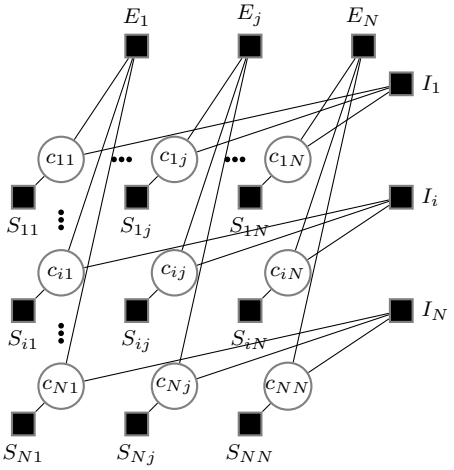
A common message-passing schedule on cyclic factor graphs is *flooding*: iteratively passing all variable-to-function messages, then all function-to-variable messages. Upon convergence, the summary message reflecting final beliefs about the maximizing configuration of variables is computed as a sum of all incoming function-to-variable messages.

3.2 Affinity Propagation

The *APS* algorithm described in this paper is a modification of the original Affinity Propagation algorithm intended for exemplar-based clustering (Frey and Dueck, 2007; Givoni and Frey, 2009). This section describes the binary variable formulation proposed by Givoni and Frey, and lays the groundwork for deriving the new update messages (Section 4).

Affinity Propagation for exemplar-based clustering is formulated as follows: to cluster N data points, one must specify a matrix of pairwise similarities $\{\mathcal{SIM}(i,j)\}_{i,j \in \{1,\ldots,N\}, i \neq j}$ and a set of self-similarities (so-called *preferences*) $\mathcal{SIM}(j,j)$ which reflect *a priori* beliefs in how likely each data point is to be selected as an exemplar. Preference values occupy the diagonal of the similarity matrix. The algorithm then assigns each data point to an exemplar so as to maximize net similarity – the sum of

Figure 2: Factor graph for affinity propagation.



similarities between all points and their respective exemplars; this is expressed by Equation 7. Figure 2 shows a schematic factor graph for this problem, with N^2 binary variables. $c_{ij} = 1$ iff point j is an exemplar for point i. Function nodes E_j enforce a *coherence constraint*: a data point cannot exemplify another point unless it is an exemplar for itself:

$$E_j(c_{1j}, \ldots, c_{Nj}) = \begin{cases} -\infty & \text{if } c_{jj} = 0 \ \wedge \ c_{ij} = 1 \\ & \text{for some } i \neq j \\ 0 & \text{otherwise} \end{cases} \tag{4}$$

An I node encodes a *single-cluster constraint*: each data point must belong to exactly one exemplar – and therefore to one cluster:

$$I_i(c_{i1}, \ldots, c_{iN}) = \begin{cases} -\infty & \text{if } \sum_j c_{ij} \neq 1 \\ 0 & \text{otherwise} \end{cases} \tag{5}$$

An S node encodes user-defined similarities between data-points and candidate exemplars ($\mathcal{SIM}(i,j)$ is the similarity between points i and j):

$$S_{ij}(c_{ij}) = \begin{cases} \mathcal{SIM}(i,j) & \text{if } c_{ij} = 1 \\ 0 & \text{otherwise} \end{cases} \tag{6}$$

Equation 7 shows the objective function which we want to maximize: a sum of similarities between data points and their exemplars, subject to the two constraints (coherence and single-cluster per point).

$$S(c_{11}, \ldots, c_{NN}) = \sum_{i,j} S_{i,j}(c_{ij}) + \sum_i I_i(c_{i1}, \ldots, c_{iN}) + \sum_j E_j(c_{1j}, \ldots, c_{Nj}) \tag{7}$$

According to Equation 3, the computation of a single factor-to-variable message involves maximizing over 2^n configurations. E and I, however, are binary constraints and evaluate to $-\infty$ for most configurations. This drastically reduces the number of configurations which can maximize the message values. Given this simple fact, Givoni and Frey (2009) show how to reduce the necessary update messages to only two types of scalar ones: *availabilities* (α) and *responsibilities* (ρ).[2]

A responsibility message ρ_{ij}, sent from a variable node c_{ij} to function node E_j, reflects the evidence of how likely j is to be an exemplar for i given all other potential exemplars:

$$\rho_{ij} = \mathcal{SIM}(i,j) - \max_{k \neq j}(\mathcal{SIM}(i,k) + \alpha_{ik}) \tag{8}$$

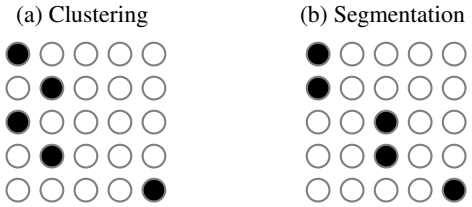
An availability message α_{ij}, sent from a function node E_j to a variable node c_{ij}, reflects how likely point j is to be an exemplar for i given the evidence from all other data points:

$$\alpha_{ij} = \begin{cases} \sum_{k \neq j} \max[\rho_{kj}, 0] & \text{if } i = j \\ \min[0, \rho_{jj} + \sum_{k \notin \{i,j\}} \max[\rho_{kj}, 0]] & \text{if } i \neq j \end{cases} \tag{9}$$

Let $\gamma_{ij}(l)$ be the message value corresponding to setting variable c_{ij} to l, $l \in \{0, 1\}$. Instead of sending two-valued messages (corresponding to the two possible values of the binary variables), we can send the difference for the two possible configurations: $\gamma_{ij} = \gamma_{ij}(1) - \gamma_{ij}(0)$ – effectively, a log-likelihood ratio.

[2]Normally, each iteration of the algorithm sends five types of two-valued messages: to and from functions E and I and a message from functions S. Fortunately, the messages sent to and from E factors to the variable nodes subsume the three other message types and it is not necessary to compute them explicitly. See (Givoni and Frey, 2009, p.195) for details.

Figure 3: Examples of valid configuration of hidden variables $\{c_{ij}\}$ for clustering and segmentation.



The algorithm converges when the set of points labelled as exemplars remains unchanged for a predetermined number of iterations. When the algorithm terminates, messages to each variable are added together. A positive final message indicates that the most likely value of a variable c_{ij} is 1 (point j is an exemplar for i), a negative message indicates that it is 0 (j is not an exemplar for i).

4 Affinity Propagation for Segmentation

This section explains how we adapt the Affinity Propagation clustering algorithm to segmentation.

In this setting, sentences are data points and we refer to exemplars as *segment centres*. Given a document, we want to assign each sentence to a segment centre so as to maximize net similarity.

The new formulation relies on the same underlying factor graph (Figure 2). A binary variable node c_{ij} is set to 1 iff sentence j is the segment centre for sentence i. When clustering is the objective, a cluster may consist of points coming from anywhere in the data sequence. When segmentation is the objective, a segment must consist of a solid block of points around the segment centre. Figure 3 shows, for a toy problem with 5 data points, possible valid configurations of variables $\{c_{ij}\}$ for clustering (3a) and for segmentation (3b).

To formalize this new linearity requirement, we elaborate Equation 4 into Equation 10. E_j evaluates to $-\infty$ in three cases. Case 1 is the original coherence constraint. Case 2 states that no point k may be in the segment with a centre is j, if k lies before the start of the segment (the sequence $c_{(s-1)j} = 0$, $c_{sj} = 1$ necessarily corresponds to the start of the segment). Case 3 handles analogously the end of the segment.

$$E_j = \begin{cases} -\infty & \textbf{1}.\ \text{if } c_{jj} = 0 \ \wedge\ c_{ij} = 1 \text{ for some } i \neq j \\ & \textbf{2}.\ \text{if } c_{jj} = 1 \ \wedge\ c_{sj} = 1 \ \wedge\ c_{(s-1)j} = 0 \\ & \wedge\, c_{kj} = 1 \text{ for some } s < j,\ k < s-1 \\ & \textbf{3}.\ \text{if } c_{jj} = 1 \ \wedge\ c_{ej} = 1 \ \wedge\ c_{(e+1)j} = 0 \\ & \wedge\, c_{kj} = 1 \text{ for some } e > j,\ k > e+1 \\ 0 & \text{otherwise} \end{cases} \tag{10}$$

The *E* function nodes are the only changed part of the factor graph, so we only must re-derive α messages (availabilities) sent from factors *E* to variable nodes. A function-to-variable message is computed as shown in Equation 11 (elaborated Equation 3), and the only incoming messages to E nodes are responsibilities (ρ messages):

$$\mu_{f\to x} = \max_{N(f)\setminus x}(f(x_1,\ldots,x_m) + \sum_{x'\in N(f)\setminus x} \mu_{x'\to f}) = \tag{11}$$

$$\max_{c_{ij},\, i\neq j}((E_j(c_{1j},\ldots,c_{Nj}) + \sum_{c_{ij},\, i\neq j} \rho_{ij}(c_{ij})))$$

We need to compute the message values for the two possible settings of binary variables – denoted as $\alpha_{ij}(1)$ and $\alpha_{ij}(0)$ – and propagate the difference $\alpha_{ij} = \alpha_{ij}(1)$ - $\alpha_{ij}(0)$.

Consider the case of factor E_j sending an α message to the variable node c_{jj} (i.e., $i = j$). If $c_{jj} = 0$ then point j is not its own segment centre and the only valid configuration is to set all other c_{ij} to 0:

$$\alpha_{jj}(0) = \max_{c_{ij}, i\neq j}(E_j(c_{1j},\ldots,c_{Nj}) + \sum_{c_{ij}, i\neq j} \rho_{ij}(c_{ij})) \tag{12}$$

$$= \sum_{i\neq j} \rho_{ij}(0)$$

To compute $\alpha_{ij}(1)$ (point j is its own segment centre), we only must maximize over configurations which will not correspond to cases 2 and 3 in Equation 10 (other assignments are trivially non-optimal because they would evaluate E_j to $-\infty$). Let the start of a segment be s, $1 \leq s < j$ and the end of the segment be e, $j+1 < e \leq N$. We only need to consider configurations such that all points between s and e are in the segment while all others are not.

The following picture shows a valid configuration.[3]

To compute the message $\alpha_{ij}(1), i = j$, we have:

$$\alpha_{jj}(1) = \max_{s=1}^{j}[\sum_{k=1}^{s-1}\rho_{kj}(0) + \sum_{k=s}^{j-1}\rho_{kj}(1)] + \quad (13)$$
$$\max_{e=j}^{N}[\sum_{k=j+1}^{e}\rho_{kj}(1) + \sum_{k=e+1}^{N}\rho_{kj}(0)]$$

Subtracting Equation 12 from Equation 13, we get:

$$\alpha_{jj} = \alpha_{jj}(1) - \alpha_{jj}(0) = \quad (14)$$
$$\max_{s=1}^{j}(\sum_{k=s}^{j-1}\rho_{kj}) + \max_{e=j}^{N}(\sum_{k=j+1}^{e}\rho_{kj})$$

Now, consider the case of factor E_j sending an α message to a variable node c_{ij} other than segment exemplar j (i.e., $i \neq j$). Two subcases are possible: point i may lie before the segment centre j ($i < j$), or it may lie after the segment centre ($i > j$).

The configurations which may maximize $\alpha_{ij}(1)$ (the message value for setting the hidden variable to 1) necessarily conform to two conditions: point j is labelled as a segment centre (c_{jj} = 1) and all points lying between i and j are in the segment. This corresponds to Equation 15 for $i < j$ and to Equation 16 for $i > j$. Pictorial examples of corresponding valid configurations precede the equations.

$$\alpha_{ij,\, i<j}(1) = \max_{s=1}^{i}[\sum_{k=1}^{s-1}\rho_{kj}(0) + \sum_{k=s}^{i-1}\rho_{kj}(1)] + \quad (15)$$
$$\sum_{k=i+1}^{j}\rho_{kj}(1) + \max_{e=j}^{N}[\sum_{k=j+1}^{e}\rho_{kj}(1) + \sum_{k=e+1}^{N}\rho_{kj}(0)]$$

[3]Variables c_{ij} set to 1 are shown as shaded circles, to 0 – as white circles. Normally, variables form a column in the factor graph; we transpose them to save space.

$$\alpha_{ij,\, i>j}(1) = \max_{s=1}^{j}[\sum_{k=1}^{s-1}\rho_{kj}(0) + \sum_{k=s}^{j-1}\rho_{kj}(1)] + \quad (16)$$
$$\sum_{k=j}^{i-1}\rho_{kj}(1) + \max_{e=i}^{N}[\sum_{k=i+1}^{e}\rho_{kj}(1) + \sum_{k=e+1}^{N}\rho_{kj}(0)]$$

To compute the message value for setting the hidden variable c_{ij} to 0, we again distinguish between $i < j$ and $i > j$ and consider whether c_{jj} = 1 or c_{jj} = 0 (point j is / is not a segment centre). For c_{jj} = 0 the only optimal configuration is c_{ij} = 0 for all $i \neq j$. For c_{jj} = 1 the set of possible optimal configurations is determined by the position of point i with respect to point j. Following the same logic as in the previous cases we get Equation 17 for $i < j$ and Equation 18 for $i > j$.

$$\alpha_{ij}(0) = \max(\sum_{k\notin i,j}\rho_{kj}(0), \quad (17)$$
$$\sum_{k=1}^{i-1}\rho_{kj}(0) + \max_{s=i+1}^{j}[\sum_{k=i+1}^{s-1}\rho_{kj}(0) + \sum_{k=s}^{j-1}\rho_{kj}(1)] +$$
$$\rho_{jj}(1) + \max_{e=j}^{N}[\sum_{k=j+1}^{e}\rho_{kj}(1) + \sum_{k=e+1}^{N}\rho_{kj}(0)])$$

$$\alpha_{ij}(0) = \max(\sum_{k\notin i,j}\rho_{kj}(0), \quad (18)$$
$$\max_{s=1}^{j}[\sum_{k=1}^{s-1}\rho_{kj}(0) + \sum_{k=s}^{j-1}\rho_{kj}(1)] +$$
$$\rho_{jj}(1) + \max_{e=j}^{i-1}[\sum_{k=j+1}^{e}\rho_{kj}(1) + \sum_{k=e+1}^{i-1}\rho_{kj}(0)]$$
$$\sum_{k=i+1}^{N}\rho_{kj}(0))$$

Due to space constraints, we will omit the details of subtracting Equation 17 from 15 and Equation 18 from 16. The final update rules for both $i < j$ and

Algorithm 1 Affinity Propagation for Segmentation

1: **input**: 1) a set of pairwise similarities $\{\mathcal{SIM}(i,j)\}_{(i,j)\in\{1,\ldots,N\}^2}$, $\mathcal{SIM}(i,j) \in \mathbb{R}$; 2) a set of preferences (self-similarities) $\{\mathcal{SIM}(i,i)\}_{i\in\{1,\ldots,N\}}$ indicating *a priori* likelihood of point i being a segment centre

2: **initialization**: $\forall i,j : \alpha_{ij} = 0$ (set all availabilities to 0)

3: **repeat**

4: iteratively update responsibilities (ρ) and availabilities (α)

5:
$$\forall i,j : \rho_{ij} = \mathcal{SIM}(i,j) + \max_{k\neq j}(\mathcal{SIM}(i,k) - \alpha_{ik})$$

6:
$$\forall i,j : \alpha_{ij} = \begin{cases} \max_{s=1}^{j}(\sum_{k=s}^{j-1}\rho_{kj}) + \max_{e=j}^{N}(\sum_{k=j+1}^{e}\rho_{kj}) & \text{if } i=j \\ \min[\max_{s=1}^{i}\sum_{k=s}^{i-1}\rho_{kj} + \sum_{k=i+1}^{j}\rho_{kj} + \max_{e=j}^{N}\sum_{k=j+1}^{e}\rho_{kj}, & \\ \quad \max_{s=1}^{i}\sum_{k=s}^{i-1}\rho_{kj} + \min_{s=i+1}^{j}\sum_{k=i+1}^{s-1}\rho_{kj}] & \text{if } i<j \\ \min[\max_{s=1}^{j}\sum_{k=s}^{j-1}\rho_{kj} + \sum_{k=j}^{i-1}\rho_{kj} + \max_{e=i}^{N}\sum_{k=i+1}^{e}\rho_{kj}, & \\ \quad \min_{e=j}^{i-1}\sum_{k=e+1}^{i-1}\rho_{kj} + \max_{e=i}^{N}\sum_{k=i+1}^{e}\rho_{kj}] & \text{if } i>j \end{cases}$$

7: **until** convergence

8: compute the final configuration of variables: $\forall i, j$ j is the exemplar for i iff $\rho_{ij} + \alpha_{ij} > 0$

9: **output**: exemplar assignments

$i > j$ appear in Algorithm 1, where we summarize the whole process.

The equations look cumbersome but they are trivial to compute. Every summand corresponds to finding the most likely start or end of the segment, taking into account *fixed* information. When computing messages for any given sender node, we can remember the maximizing values for neighbouring recipient nodes. For example, after computing the availability message from factor E_j to c_{ij}, we must only consider one more responsibility value when computing the message from E_j to variable $c_{(i+1)j}$. The cost of computing a message is thus negligible.

When the matrix is fully specified, each iteration requires passing $2N^2$ messages, so the algorithm runs in $O(N^2)$ time and requires $O(N^2)$ memory (to store the similarities, the availabilities and the responsibilities). When performing segmentation, however, the user generally has some idea about the average or maximum segment length. In such more realistic cases, the input matrix of similarities is sparse – it is constructed by sliding a window of size M. M usually needs to be at least twice the maximum segment length or thrice the average segment length. Each iteration, then, involves sending $2MN$ messages and the storage requirements are also $O(MN)$.

As is common in loopy belief propagation algorithms, both availability and responsibility messages are dampened to avoid overshooting and oscillating. The dampening factor is λ where $0.5 \leq \lambda < 1$.

$$newMsg = \lambda * oldMsg + (1-\lambda)newMsg \quad (19)$$

The *APS* algorithm is unsupervised. It only benefits

from a small development set to fine-tune a few parameters: preference values and the dampening factor. *APS* does not require (nor allow) specifying the number of segments beforehand. The granularity of segmentation is adjusted through preference values; this reflect how likely each sentence is to be selected as a segment centre. (This translates into the cost of adding a segment.)

Because each message only requires the knowledge about one column or row of the matrix, the algorithm can be easily parallelized.

5 Experimental Setting

Datasets. We evaluate the performance of the *APS* algorithm on three datasets. The first, compiled by Malioutov and Barzilay (2006), consists of manually transcribed and segmented lectures on Artificial Intelligence, 3 development files and 19 test files. The second dataset consists of 227 chapters from medical textbooks (Eisenstein and Barzilay, 2008), 5 of which we use for development. In this dataset the gold standard segment boundaries correspond to section breaks specified by the authors. The third dataset consists of 85 works of fiction downloaded from Project Gutenberg, 3 of which are used for development. The segment boundaries correspond to chapter breaks or to breaks between individual stories. They were inserted automatically using HTML markup in the downloaded files.

The datasets exhibit different characteristics. The lecture dataset and the fiction dataset are challenging because they are less cohesive than medical textbooks. The textbooks are cognitively more difficult to process and the authors rely on repetition of terminology to facilitate comprehension. Since lexical repetition is the main source of information for text segmentation, we expect a higher performance on this dataset. Transcribed speech, on the other hand, is considerably less cohesive. The lecturer makes an effort to speak in "plain language" and to be comprehensible, relying less on terminology. The use of pronouns is very common, as is the use of examples.

Repeated use of the same words is also uncommon in fiction. In addition, the dataset was compiled automatically using HTML markup. The markup is not always reliable and occasionally the e-book proofreaders skip it altogether, which potentially adds noise to the dataset.

Baselines. We compare the performance of *APS* with that of two state-of-the-art segmenters: the Minimum Cut segmenter (Malioutov and Barzilay, 2006) and the Bayesian segmenter (Eisenstein and Barzilay, 2008). The authors have made Java implementations publicly available. For the Minimum Cut segmenter, we select the best parameters using the script included with that distribution. The Bayesian segmenter automatically estimates all necessary parameters from the data.

Preprocessing and the choice of similarity metric. As described in Section 4, the *APS* algorithm takes as inputs a matrix of pairwise similarities between sentences in the document and also, for each sentence, a preference value.

This paper focuses on comparing globally informed segmentation algorithms, and leaves for future work the exploration of best similarity metrics. To allow fair comparison, then, we use the same metric as the Minimum Cut segmenter, cosine similarity. Each sentence is represented as a vector of token-type frequencies. Following (Malioutov and Barzilay, 2006), the frequency vectors are smoothed by adding counts of words from the adjacent sentences and then weighted using a tf.idf metric (for details, see *ibid.*) The similarity between sentence vectors s_1 and s_2 is computed as follows:

$$cos(s_1, s_2) = \frac{s_1 \bullet s_2}{||s_1|| \times ||s_2||} \tag{20}$$

The representation used by the Bayesian segmenter is too different to be incorporated into our model directly, but ultimately it is based on the distribution of unigrams in documents. This is close enough to our representation to allow fair comparison.

The fiction dataset consists of books: novels or collections of short stories. Fiction is known to exhibit less lexical cohesion. That is why – when working on this dataset – we work at the paragraph level: the similarity is measured not between sentences but between paragraphs. We use this representation with all three segmenters.

All parameters have been fine-tuned on the development portions of the datasets. For *APS* algorithm *per se* we needed to set three parameters: the size of the sliding window for similarity computations, the dampening factor λ and the preference values. The

	BayesSeg	MinCutSeg	*APS*
AI	0.443	0.437	**0.404**
Clinical	**0.353**	0.382	0.371
Fiction	0.377	0.381	**0.350**

Table 1: Results of segmenting the three datasets using the Bayesian segmenter, the Minimum Cut segmenter and *APS*.

parameters for the similarity metric (best variation of tf.idf, the window size and the decay factor for smoothing) were set using the script provided in the Minimum Cut segmenter's distribution.

Evaluation metric. We have measured the performance of the segmenters with the WindowDiff metric (Pevzner and Hearst, 2002). It is computed by sliding a window through reference and through segmentation output and, at each window position, comparing the number of reference breaks to the number of breaks inserted by the segmenter (hypothetical breaks). It is a penalty measure which reports the number of windows where the reference and hypothetical breaks do not match, normalized by the total number of windows. In Equation 21, ref and hyp denote the number of reference and hypothetical segment breaks within a window.

$$winDiff = \frac{1}{N-k} \sum_{i=1}^{N-k} (|ref - hyp| \neq 0) \quad (21)$$

6 Experimental Results and Discussion

Table 1 compares the performance of the three segmenters using WindowDiff values. On the lecture and fiction datasets, the *APS* segmenter outperforms the others by a small margin, around 8% over the better of the two. It is second-best on the clinical textbook dataset. According to a one-tailed paired t-test with 95% confidence cut-off, the improvement is statistically significant only on the fiction dataset. All datasets are challenging and the baselines are very competitive, so drawing definitive conclusions is difficult. Still, we can be fairly confident that *APS* performs at least as well as the other two segmenters. It also has certain advantages.

One important difference between *APS* and the other segmenters is that *APS* does not require the number of segments as an input parameter. This is very helpful, because such information is generally unavailable in any realistic deployment setting. The parameters are fine-tuned to maximize WindowDiff values, so this results in high-precision, low-recall segment assignments; that is because WindowDiff favours missing boundaries over near-hits.

APS also outputs segment centres, thus providing some information about a segment's topic. We have not evaluated how descriptive the segment centres are; this is left for future work.

APS performs slightly better than the other segmenters but not by much. We hypothesize that one of the reasons is that *APS* relies on the presence of descriptive segment centres which are not necessarily present for large, coarse-grained segments such as chapters in novels. It is possible for *APS* to have an advantage performing fine-grained segmentation.

7 Conclusions and Future Work

In this paper we have presented *APS* – a new algorithm for linear text segmentation. *APS* takes into account the global structure of the document and outputs segment boundaries and segment centres. It scales linearly in the number of input sentences, performs competitively with the state-of-the-art and is easy to implement. We also provide a Java implementation of the *APS* segmenter.

We consider two main directions for future work: using more informative similarity metrics and making the process of segmentation hierarchical. We chose to use cosine similarity primarily to allow fair comparison and to judge the algorithm itself, in isolation from the information it uses. Cosine similarity is a very simple metric which cannot provide an adequate picture of topic fluctuations in documents. It is likely that dictionary-based or corpus-based similarity measures would yield a major improvement in performance.

Reliance on descriptive segment centres may handicap *APS*'s performance when looking for coarse-grained segments. One possible remedy is to look for shorter segments first and then merge them. One can also modify the algorithm to perform hierarchical segmentation: consider net similarity with low-level segment centres as well as with high-level ones. We plan to explore both possibilities.

Acknowledgements

We thank Inmar Givoni for explaining the details of binary Affinity Propagation and for commenting on our early ideas in this project. Many thanks to Yongyi Mao for a helpful discussion on the use Affinity Propagation for text segmentation.

Abstract

This paper develops a minimally supervised approach, based on focused distributional similarity methods and discourse connectives, for identifying of causality relations between events in context. While it has been shown that distributional similarity can help identifying causality, we observe that discourse connectives and the particular discourse relation they evoke in context provide additional information towards determining causality between events. We show that combining discourse relation predictions and distributional similarity methods in a global inference procedure provides additional improvements towards determining event causality.

1 Introduction

An important part of text understanding arises from understanding the semantics of events described in the narrative, such as identifying the events that are mentioned and how they are related semantically. For instance, when given a sentence "The police arrested him because he killed someone.", humans understand that there are two events, triggered by the words "arrested" and "killed", and that there is a causality relationship between these two events. Besides being an important component of discourse understanding, automatically identifying causal relations between events is important for various natural language processing (NLP) applications such as question answering, etc. In this work, we automatically detect and extract causal relations between events in text.

Despite its importance, prior work on event causality extraction in context in the NLP literature is relatively sparse. In (Girju, 2003), the author used noun-verb-noun lexico-syntactic patterns to learn that "mosquitoes cause malaria", where the *cause* and *effect* mentions are nominals and not necessarily event evoking words. In (Sun et al., 2007), the authors focused on detecting causality between search query pairs in temporal query logs. (Beamer and Girju, 2009) tried to detect causal relations between verbs in a corpus of screen plays, but limited themselves to consecutive, or adjacent verb pairs. In (Riaz and Girju, 2010), the authors first cluster sentences into topic-specific scenarios, and then focus on building a dataset of causal text spans, where each span is headed by a verb. Thus, their focus was not on identifying causal relations between events in a given text document.

In this paper, given a text document, we first identify events and their associated arguments. We then identify causality or relatedness relations between event pairs. To do this, we develop a minimally supervised approach using focused distributional similarity methods, such as co-occurrence counts of events collected automatically from an unannotated corpus, to measure and predict existence of causality relations between event pairs. Then, we build on the observation that discourse connectives and the particular discourse relation they evoke in context provide additional information towards determining causality between events. For instance, in the example sentence provided at the beginning of this section, the words "arrested" and "killed" probably have a relatively high apriori likelihood of being ca-

Edinburgh, Scotland, UK, July 27–31, 2011.

sually related. However, knowing that the connective "because" evokes a contingency discourse relation between the text spans "The police arrested him" and "he killed someone" provides further evidence towards predicting causality. The contributions of this paper are summarized below:

- Our focus is on identifying causality between event pairs in context. Since events are often triggered by either verbs (e.g. "attack") or nouns (e.g. "explosion"), we allow for detection of causality between verb-verb, verb-noun, and noun-noun triggered event pairs. To the best of our knowledge, this formulation of the task is novel.
- We developed a minimally supervised approach for the task using focused distributional similarity methods that are automatically collected from an unannotated corpus. We show that our approach achieves better performance than two approaches: one based on a frequently used metric that measures association, and another based on the effect-control-dependency (ECD) metric described in a prior work (Riaz and Girju, 2010).
- We leverage on the interactions between event causality prediction and discourse relations prediction. We combine these knowledge sources through a global inference procedure, which we formalize via an Integer Linear Programming (ILP) framework as a constraint optimization problem (Roth and Yih, 2004). This allows us to easily define appropriate constraints to ensure that the causality and discourse predictions are coherent with each other, thereby improving the performance of causality identification.

2 Event Causality

In this work, we define an event as an action or occurrence that happens with associated participants or arguments. Formally, we define an event e as: $p(a_1, a_2, \ldots, a_n)$, where the predicate p is the word that triggers the presence of e in text, and $a_1, a_2, \ldots, a_n$ are the arguments associated with e. Examples of predicates could be *verbs* such as "attacked", "employs", *nouns* such as "explosion", "protest", etc., and examples of the arguments of "attacked" could be its *subject* and *object* nouns.

To measure the causality association between a pair of events e_i and e_j (in general, e_i and e_j could be extracted from the same or different documents), we should use information gathered about their predicates and arguments. A simple approach would be to directly calculate the pointwise mutual information (PMI)[1] between $p^i(a_1^i, a_2^i, \ldots, a_n^i)$ and $p^j(a_1^j, a_2^j, \ldots, a_m^j)$. However, this leads to very sparse counts as the predicate p^i with its list of arguments $a_1^i, \ldots, a_n^i$ would rarely co-occur (within some reasonable context distance) with predicate p^j and its entire list of arguments $a_1^j, \ldots, a_m^j$. Hence, in this work, we measure causality association using three separate components and focused distributional similarity methods collected about event pairs as described in the rest of this section.

2.1 Cause-Effect Association

We measure the causality or cause-effect association (CEA) between two events e_i and e_j using the following equation:

$$CEA(e_i, e_j) = s_{pp}(e_i, e_j) + s_{pa}(e_i, e_j) + s_{aa}(e_i, e_j) \quad (1)$$

where s_{pp} measures the association between event predicates, s_{pa} measures the association between the predicate of an event and the arguments of the other event, and s_{aa} measures the association between event arguments. In our work, we regard each event e as being triggered and rooted at a predicate p.

2.1.1 Predicate-Predicate Association

We define s_{pp} as follows:

$$s_{pp}(e_i, e_j) = PMI(p^i, p^j) \times \max(u^i, u^j) \times IDF(p^i, p^j) \times Dist(p^i, p^j) \quad (2)$$

which takes into account the PMI between predicates p^i and p^j of events e_i and e_j respectively, as well as various other pieces of information. In Suppes' *Probabilistic theory of Casuality* (Suppes, 1970), he highlighted that event e is a possible cause of event e', if e' happens more frequently with e than

[1] PMI is frequently used to measure association between variables.

by itself, i.e. $P(e'|e) > P(e')$. This can be easily rewritten as $\frac{P(e,e')}{P(e)P(e')} > 1$, similar to the definition of PMI:

$$PMI(e, e') = log\frac{P(e, e')}{P(e)P(e')}$$

which is only positive when $\frac{P(e,e')}{P(e)P(e')} > 1$.

Next, we build on the intuition that event predicates appearing in a large number of documents are probably not important or discriminative. Thus, we penalize these predicates when calculating s_{pp} by adopting the inverse document frequency (idf):

$$IDF(p^i, p^j) = idf(p^i) \times idf(p^j) \times idf(p^i, p^j),$$

where $idf(p) = log\frac{D}{1+N}$, D is the total number of documents in the collection and N is the number of documents that p occurs in.

We also award event pairs that are closer together, while penalizing event pairs that are further apart in texts, by incorporating the distance measure of Leacock and Chodorow (1998), which was originally used to measure similarity between concepts:

$$Dist(p^i, p^j) = -log\frac{|sent(p^i) - sent(p^j)| + 1}{2 \times ws},$$

where $sent(p)$ gives the sentence number (index) in which p occurs and ws indicates the window-size (of sentences) used. If p^i and p^j are drawn from the same sentence, the numerator of the above fraction will return 1. In our work, we set ws to 3 and thus, if p^i occurs in sentence k, the furthest sentence that p^j will be drawn from, is sentence $k + 2$.

The final component of Equation 2, $\max(u^i, u^j)$, takes into account whether predicates (events) p^i and p^j appear most frequently with each other. u^i and u^j are defined as follows:

$$u^i = \frac{P(p^i, p^j)}{\max_k[P(p^i, p^k)] - P(p^i, p^j) + \epsilon}$$
$$u^j = \frac{P(p^i, p^j)}{\max_k[P(p^k, p^j)] - P(p^i, p^j) + \epsilon},$$

where we set $\epsilon = 0.01$ to avoid zeros in the denominators. u^i will be maximized if there is no other predicate p^k having a higher co-occurrence probability with p^i, i.e. $p^k = p^j$. u^j is treated similarly.

2.1.2 Predicate-Argument and Argument-Argument Association

We define s_{pa} as follows:

$$s_{pa}(e_i, e_j) = \frac{1}{|A_{e_j}|}\sum_{a \in A_{e_j}} PMI(p^i, a) + \frac{1}{|A_{e_i}|}\sum_{a \in A_{e_i}} PMI(p^j, a), \quad (3)$$

where A_{e_i} and A_{e_j} are the sets of arguments of e_i and e_j respectively.

Finally, we define s_{aa} as follows:

$$s_{aa}(e_i, e_j) = \frac{1}{|A_{e_i}||A_{e_j}|}\sum_{a \in A_{e_i}}\sum_{a' \in A_{e_j}} PMI(a, a') \quad (4)$$

Together, s_{pa} and s_{aa} provide additional contexts and robustness (in addition to s_{pp}) for measuring the cause-effect association between events e_i and e_j.

Our formulation of CEA is inspired by the ECD metric defined in (Riaz and Girju, 2010):

$$ECD(a, b) = \max(v, w) \times -log\frac{dis(a, b)}{2 \times maxDistance}, \quad (5)$$

where

$$v = \frac{P(a, b)}{P(b) - P(a, b) + \epsilon} \times \frac{P(a, b)}{\max_t[P(a, b_t)] - P(a, b) + \epsilon}$$
$$w = \frac{P(a, b)}{P(a) - P(a, b) + \epsilon} \times \frac{P(a, b)}{\max_t[P(a_t, b)] - P(a, b) + \epsilon},$$

where ECD(a,b) measures the causality between two events a and b (headed by verbs), and the second component in the ECD equation is similar to $Dist(p^i, p^j)$. In our experiments, we will evaluate the performance of ECD against our proposed approach.

So far, our definitions in this section are generic and allow for any list of event argument types. In this work, we focus on two argument types: agent (subject) and patient (object), which are typical core arguments of any event. We describe how we extract event predicates and their associated arguments in the section below.

3 Verbal and Nominal Predicates

We consider that events are not only triggered by verbs but also by nouns. For a verb (verbal predicate), we extract its subject and object from its associated dependency parse. On the other hand, since

events are also frequently triggered by nominal predicates, it is important to identify an appropriate list of event triggering nouns. In our work, we gathered such a list using the following approach:

- We first gather a list of deverbal nouns from the set of most frequently occurring (in the Gigaword corpus) 3,000 verbal predicate types. For each verb type v, we go through all its WordNet[2] senses and gather all its derivationally related nouns $\mathcal{N}_v$ [3].

- From $\mathcal{N}_v$, we heuristically remove nouns that are less than three characters in length. We also remove nouns whose first three characters are different from the first three characters of v. For each of the remaining nouns in $\mathcal{N}_v$, we measured its Levenstein (edit) distance from v and keep the noun(s) with the minimum distance. When multiple nouns have the same minimum distance from v, we keep all of them.

- To further prune the list of nouns, we next removed all nouns ending in "er", "or", or "ee", as these nouns typically refer to a person, e.g. "writer", "doctor", "employee". We also remove nouns that are not hyponyms (children) of the first WordNet sense of the noun "event"[4].

- Since we are concerned with nouns denoting events, FrameNet (Ruppenhofer et al., 2010) (FN) is a good resource for mining such nouns. FN consists of frames denoting situations and events. As part of the FN resource, each FN frame consists of a list of lexical units (mainly verbs and nouns) representing the semantics of the frame. Various frame-to-frame relations are also defined (in particular the *inheritance* relation). Hence, we gathered all the children frames of the FN frame "Event". From these children frames, we then gathered all their noun lexical units (words) and add them to our list of nouns. Finally, we also add a few nouns denoting natural disaster from Wikipedia[5].

Using the above approach, we gathered a list of about 2,000 noun types. This current approach is heuristics based which we intend to improve in the future, and any such improvements should subsequently improve the performance of our causality identification approach.

Event triggering deverbal nouns could have associated arguments (for instance, acting as subject, object of the deverbal noun). To extract these arguments, we followed the approach of (Gurevich et al., 2008). Briefly, the approach uses linguistic patterns to extract subjects and objects for deverbal nouns, using information from dependency parses. For more details, we refer the reader to (Gurevich et al., 2008).

4 Discourse and Causality

Discourse connectives are important for relating different text spans, helping us to understand a piece of text in relation to its context:

[The police arrested him] <u>because</u> [he killed someone].

In the example sentence above, the discourse connective ("because") and the discourse relation it evokes (in this case, the *Cause* relation) allows readers to relate its two associated text spans, "The police arrested him" and "he killed someone". Also, notice that the verbs "arrested" and "killed", which *cross* the two text spans, are causally related. To aid in extracting causal relations, we leverage on the identification of discourse relations to provide additional contextual information.

To identify discourse relations, we use the Penn Discourse Treebank (PDTB) (Prasad et al., 2007), which contains annotations of discourse relations in context. The annotations are done over the Wall Street Journal corpus and the PDTB adopts a predicate-argument view of discourse relations. A discourse connective (e.g. because) takes two text spans as its arguments. In the rest of this section, we briefly describe the discourse relations in PDTB and highlight how we might leverage them to aid in determining event causality.

[2] http://wordnet.princeton.edu/

[3] The WordNet resource provides derivational information on words that are in different syntactic (i.e. part-of-speech) categories, but having the same root (lemma) form and that are semantically related.

[4] The first WordNet sense of the noun "event" has the meaning: "something that happens at a given place and time"

Coarse-grained relations	Fine-grained relations
Comparison	Concession, Contrast, Pragmatic-concession, Pragmatic-contrast
Contingency	Cause, Condition, Pragmatic-cause, Pragmatic-condition
Expansion	Alternative, Conjunction, Exception, Instantiation, List, Restatement
Temporal	Asynchronous, Synchronous

Table 1: Coarse-grained and fine-grained discourse relations.

4.1 Discourse Relations

PDTB contains annotations for four coarse-grained discourse relation types, as shown in the left column of Table 1. Each of these are further refined into several fine-grained discourse relations, as shown in the right column of the table.[6] Next, we briefly describe these relations, highlighting those that could potentially help to determine event causality.

Comparison A *Comparison* discourse relation between two text spans highlights prominent differences between the situations described in the text spans. An example sentence is:

Contrast: [According to the survey, *x*% of Chinese Internet users prefer Google] whereas [*y*% prefer Baidu].

According to the PDTB annotation manual (Prasad et al., 2007), the truth of both spans is independent of the established discourse relation. This means that the text spans are not causally related and thus, the existence of a *Comparison* relation should imply that there is no causality relation across the two text spans.

Contingency A *Contingency* relation between two text spans indicates that the situation described in one text span causally influences the situation in the other. An example sentence is:

Cause: [The first priority is search and rescue] because [many people are trapped under the rubble].

Existence of a *Contingency* relation potentially implies that there exists at least one causal event pair crossing the two text spans. The PDTB annotation manual states that while the *Cause* and *Condition* discourse relations indicate casual influence in their text spans, there is no causal influence in the text spans of the *Pragmatic-cause* and *Pragmatic-condition* relations. For instance, *Pragmatic-condition* indicates that one span provides the context in which the description of the situation in the other span is relevant; for example:

Pragmatic-condition: If [you are thirsty], [there's beer in the fridge].

Hence, there is a need to also identify fine-grained discourse relations.

Expansion Connectives evoking *Expansion* discourse relations expand the discourse, such as by providing additional information, illustrating alternative situations, etc. An example sentence is:

Conjunction: [Over the past decade, *x* women were killed] and [*y* went missing].

Most of the *Expansion* fine-grained relations (except for *Conjunction*, which could connect arbitrary pieces of text spans) should not contain causality relations across its text spans.

Temporal These indicate that the situations described in the text spans are related temporally. An example sentence is:

Synchrony: [He was sitting at his home] when [the whole world started to shake].

Temporal precedence of the (cause) event over the (effect) event is a necessary, but not sufficient requisite for causality. Hence by itself, *Temporal* relations are probably not discriminative enough for determining event causality.

4.2 Discourse Relation Extraction System

Our work follows the approach and features described in the state-of-the-art Ruby-based discourse system of (Lin et al., 2010), to build an in-house Java-based discourse relation extraction system. Our system identifies explicit connectives in text, predict their discourse relations, as well as their associated text spans. Similar to (Lin et al., 2010), we achieved a competitive performance of slightly over 80% F1-score in identifying fine-grained relations for explicit connectives. Our system is developed using the Learning Based Java modeling lan-

[6] PDTB further refines these fine-grained relations into a final third level of relations, but we do not use them in this work.

guage (LBJ) (Rizzolo and Roth, 2010) and will be made available soon. Due to space constraints, we refer interested readers to (Lin et al., 2010) for details on the features, etc.

In the example sentences given thus far in this section, all the connectives were explicit, as they appear in the texts. PDTB also provides annotations for implicit connectives, which we do not use in this work. Identifying implicit connectives is a harder task and incorporating these is a possible future work.

5 Joint Inference for Causality Extraction

To exploit the interactions between event pair causality extraction and discourse relation identification, we define appropriate constraints between them, which can be enforced through the Constrained Conditional Models framework (aka ILP for NLP) (Roth and Yih, 2007; Chang et al., 2008). In doing this, the predictions of CEA (Section 2.1) and the discourse system are forced to cohere with each other. More importantly, this should improve the performance of using only CEA to extract causal event pairs. To the best of our knowledge, this approach for causality extraction is novel.

5.1 CEA & Discourse: Implementation Details

Let $\mathcal{E}$ denote the set of event mentions in a document. Let $\mathcal{EP} = \{(e_i, e_j) \in \mathcal{E} \times \mathcal{E} \mid e_i \in \mathcal{E}, e_j \in \mathcal{E}, i < j, |sent(e_i) - sent(e_j)| \leq 2\}$ denote the set of event mention pairs in the document, where $sent(e)$ gives the sentence number in which event e occurs. Note that in this work, we only extract event pairs that are at most two sentences apart. Next, we define $\mathcal{L}_{ER}$ = {"causal", "¬ causal"} to be the set of event relation labels that an event pair $ep \in \mathcal{EP}$ can be associated with.

Note that the CEA metric as defined in Section 2.1 simply gives a score without it being bounded to be between 0 and 1.0. However, to use the CEA score as part of the inference process, we require that it be bounded and thus can be used as a binary prediction, that is, predicting an event pair as *causal* or ¬*causal*. To enable this, we use a few development documents to automatically find a threshold CEA score that separates scores indicating *causal* vs ¬*causal*. Based on this threshold, the original CEA scores are then rescaled to fall within 0 to 1.0. More details on this are in Section 6.2.

Let $\mathcal{C}$ denote the set of connective mentions in a document. We slightly modify our discourse system as follows. We define $\mathcal{L}_{DR}$ to be the set of discourse relations. We initially add all the fine-grained discourse relations listed in Table 1 to $\mathcal{L}_{DR}$. In the PDTB corpus, some connective examples are labeled with just a coarse-grained relation, without further specifying a fine-grained relation. To accommodate these examples, we add the coarse-grained relations *Comparison*, *Expansion*, and *Temporal* to $\mathcal{L}_{DR}$. We omit the coarse-grained *Contingency* relation from $\mathcal{L}_{DR}$, as we want to separate *Cause* and *Condition* from *Pragmatic-cause* and *Pragmatic-condition*. This discards very few examples as only a very small number of connective examples are simply labeled with a *Contingency* label without further specifying a fine-grained label. We then retrained our discourse system to predict labels in $\mathcal{L}_{DR}$.

5.2 Constraints

We now describe the constraints used to support joint inference, based on the predictions of the CEA metric and the discourse classifier. Let $s_c(dr)$ be the probability that connective c is predicated to be of discourse relation dr, based on the output of our discourse classifier. Let $s_{ep}(er)$ be the CEA prediction score (rescaled to range in [0,1]) that event pair ep takes on the *causal* or ¬*causal* label er. Let $x_{\langle c,dr\rangle}$ be a binary indicator variable which takes on the value 1 iff c is labeled with the discourse relation dr. Similarly, let $y_{\langle ep,er\rangle}$ be a binary variable which takes on the value 1 iff ep is labeled as er. We then define our objective function as follows:

$$\max \Big[|\mathcal{L}_{DR}| \sum_{c \in \mathcal{C}} \sum_{dr \in \mathcal{L}_{DR}} s_c(dr) \cdot x_{\langle c,dr\rangle} + |\mathcal{L}_{ER}| \sum_{ep \in \mathcal{EP}} \sum_{er \in \mathcal{L}_{ER}} s_{ep}(er) \cdot y_{\langle ep,er\rangle} \Big] \quad (6)$$

subject to the following constraints:

$$\sum_{dr \in \mathcal{L}_{DR}} x_{\langle c,dr\rangle} = 1 \quad \forall c \in \mathcal{C} \quad (7)$$

$$\sum_{er \in \mathcal{L}_{ER}} y_{\langle ep,er\rangle} = 1 \quad \forall ep \in \mathcal{EP} \quad (8)$$

$$x_{\langle c,dr\rangle} \in \{0,1\} \quad \forall c \in \mathcal{C}, dr \in \mathcal{L}_{DR} \quad (9)$$

$$y_{\langle ep,er\rangle} \in \{0,1\} \quad \forall ep \in \mathcal{EP}, er \in \mathcal{L}_{ER} \quad (10)$$

Equation (7) requires that each connective c can only be assigned one discourse relation. Equation (8) requires that each event pair ep can only be *causal* or $\neg$*causal*. Equations (9) and (10) indicate that $x_{\langle c,dr\rangle}$ and $y_{\langle ep,er\rangle}$ are binary variables.

To capture the relationship between event pair causality and discourse relations, we use the following constraints:

$$x_{\langle c,\text{“}Cause\text{”}\rangle} \leq \sum_{ep\in\mathcal{EP}_c} y_{\langle ep,\text{“}causal\text{”}\rangle} \quad (11)$$

$$x_{\langle c,\text{“}Condition\text{”}\rangle} \leq \sum_{ep\in\mathcal{EP}_c} y_{\langle ep,\text{“}causal\text{”}\rangle}, \quad (12)$$

where both equations are defined $\forall c \in \mathcal{C}$. $\mathcal{EP}_c$ is defined to be the set of event pairs that cross the two text spans associated with c. For instance, if the first text span of c contains two event mentions e_i, e_j, and there is one event mention e_k in the second text span of c, then $\mathcal{EP}_c = \{(e_i, e_k), (e_j, e_k)\}$. Finally, the logical form of Equation (11) can be written as: $x_{\langle c,\text{“}Cause\text{”}\rangle} \Rightarrow y_{\langle ep_i,\text{“}causal\text{”}\rangle} \vee \ldots \vee y_{\langle ep_j,\text{“}causal\text{”}\rangle}$, where $ep_i, \ldots, ep_j$ are elements in $\mathcal{EP}_c$. This states that if we assign the *Cause* discourse label to c, then at least one of $ep_i, \ldots, ep_j$ must be assigned as *causal*. The interpretation of Equation (12) is similar.

We use two more constraints to capture the interactions between event causality and discourse relations. First, we defined $\mathcal{C}_{ep}$ as the set of connectives c enclosing each event of ep in each of its text spans, i.e.: one of the text spans of c contain one of the event in ep, while the other text span of c contain the other event in ep. Next, based on the discourse relations in Section 4.1, we propose that when an event pair ep is judged to be *causal*, then the connective c that encloses it should be evoking one of the discourse relations in $\mathcal{L}_{DR_a}$ = {“Cause”, “Condition”, “Temporal”, “Asynchronous”, “Synchrony”, “Conjunction”}. We capture this using the following constraint:

$$y_{\langle ep,\text{“}causal\text{”}\rangle} \leq \sum_{dr_a\in\mathcal{L}_{DR_a}} x_{\langle c,dr_a\rangle} \quad \forall c \in \mathcal{C}_{ep} \quad (13)$$

The logical form of Equation (13) can be written as: $y_{\langle ep,\text{“}causal\text{”}\rangle} \Rightarrow x_{\langle c,\text{“}Cause\text{”}\rangle} \vee x_{\langle c,\text{“}Condition\text{”}\rangle} \ldots \vee x_{\langle c,\text{“}Conjunction\text{”}\rangle}$. This states that if we assign ep as *causal*, then we must assign to c one of the labels in $\mathcal{L}_{DR_a}$.

Finally, we propose that for any connectives evoking discourse relations $\mathcal{L}_{DR_b}$ = {“Comparison”, “Concession”, “Contrast”, “Pragmatic-concession”, “Pragmatic-contrast”, “Expansion”, “Alternative”, “Exception”, “Instantiation”, “List”, “Restatement”}, any event pair(s) that it encloses should be $\neg$*causal*. We capture this using the following constraint:

$$x_{\langle c,dr_b\rangle} \leq y_{\langle ep,\text{“}\neg causal\text{”}\rangle} \quad \forall\ dr_b \in \mathcal{L}_{DR_b},\ ep \in \mathcal{EP}_c, \quad (14)$$

where the logical form of Equation (14) can be written as: $x_{\langle c,dr_b\rangle} \Rightarrow y_{\langle ep,\text{“}\neg causal\text{”}\rangle}$.

6 Experiments

6.1 Experimental Settings

To collect the distributional statistics for measuring CEA as defined in Equation (1), we applied part-of-speech tagging, lemmatization, and dependency parsing (Marneffe et al., 2006) on about 760K documents in the English Gigaword corpus (LDC catalog number LDC2003T05).

We are not aware of any benchmark corpus for evaluating event causality extraction in contexts. Hence, we created an evaluation corpus using the following process: Using news articles collected from CNN[7] during the first three months of 2010, we randomly selected 20 articles (documents) as evaluation data, and 5 documents as development data.

Two annotators annotated the documents for causal event pairs, using two simple notions for causality: the Cause event should temporally precede the Effect event, and the Effect event occurs because the Cause event occurs. However, sometimes it is debatable whether two events are involved in a causal relation, or whether they are simply involved in an uninteresting temporal relation. Hence, we allowed annotations of C to indicate causality, and R to indicate relatedness (for situations when the existence of causality is debatable). The annotators will simply identify and annotate the *C* or *R* relations between predicates of event pairs. Event arguments are not explicitly annotated, although the annotators are free to look at the entire document text while making their annotation decisions. Finally, they are free

to annotate relations between predicates that have any number of sentences in between and are not restricted to a fixed sentence window-size.

After adjudication, we obtained a total of 492 $C+R$ relation annotations, and 414 C relation annotations on the evaluation documents. On the development documents, we obtained 92 $C+R$ and 71 C relation annotations. The annotators overlapped on 10 evaluation documents. On these documents, the first (second) annotator annotated 215 (199) $C+R$ relations, agreeing on 166 of these relations. Together, they annotated 248 distinct relations. Using this number, their agreement ratio would be 0.67 $(166/248)$. The corresponding agreement ratio for C relations is 0.58. These numbers highlight that causality identification is a difficult task, as there could be as many as N^2 event pairs in a document (N is the number of events in the document). We plan to make this annotated dataset available soon.[8]

6.2 Evaluation

As mentioned in Section 5.1, to enable translating (the unbounded) CEA scores into binary *causal*, ¬*causal* predictions, we need to rescale or calibrate these scores to range in [0,1]. To do this, we first rank all the CEA scores of all event pairs in the development documents. Most of these event pairs will be ¬*causal*. Based on the relation annotations in these development documents, we scanned through

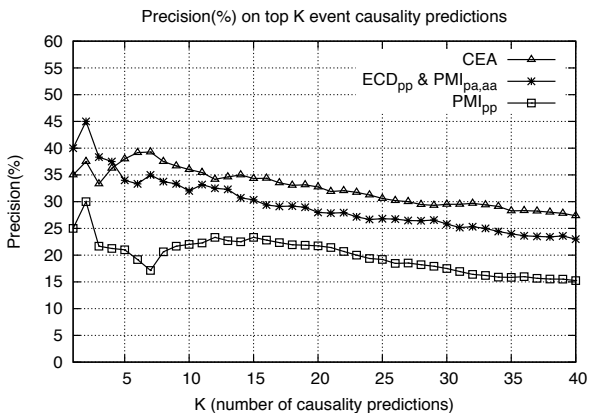

Figure 1: Precision of the top K causality C predictions.

this ranked list of scores to locate the CEA score *t* that gives the highest F1-score (on the development documents) when used as a threshold between *causal* vs ¬*causal* decisions. We then ranked all the CEA scores of all event pairs gathered from the 760K Gigaword documents, discretized all scores higher than *t* into B bins, and all scores lower than t into B bins. Together, these $2B$ bins represent the range [0,1]. We used $B = 500$. Thus, consecutive bins represent a difference of 0.001 in calibrated scores.

To measure the causality between a pair of events e_i and e_j, a simple baseline is to calculate $PMI(p^i, p^j)$. Using a similar thresholding and calibration process to translate $PMI(p^i, p^j)$ scores into binary causality decisions, we obtained a F1 score of 23.1 when measured over the causality C relations, as shown in the row PMI_{pp} of Table 2.

As mentioned in Section 2.1.2, Riaz and Girju (2010) proposed the ECD metric to measure causality between two events. Thus, as a point of comparison, we replaced s_{pp} of Equation (1) with $ECD(a, b)$ of Equation (5), substituting $a = p^i$ and $b = p^j$. After thresholding and calibrating the scores of this approach, we obtained a F1-score of 29.7, as shown in the row ECD_{pp}&$PMI_{pa,aa}$ of Table 2.

Next, we evaluated our proposed CEA approach and obtained a F1-score of 38.6, as shown in the row CEA of Table 2. Thus, our proposed approach obtained significantly better performance than the PMI baseline and the ECD approach. Next, we performed joint inference with the discourse relation predictions as described in Section 5 and obtained

[8] http://cogcomp.cs.illinois.edu/page/publication_view/663

an improved F1-score of 41.7. We note that we obtained improvements in both recall and precision. This means that with the aid of discourse relations, we are able to recover more causal relations, as well as reduce false-positive predictions.

Constraint Equations (11) and (12) help to recover causal relations. For improvements in precision, as stated in the last paragraph of Section 5.2, identifying other discourse relations such as "Comparison", "Contrast", etc., provides counter-evidence to causality. Together with constraint Equation (14), this helps to eliminate false-positive event pairs as classified by CEA and contributes towards CEA+Discourse having a higher precision than CEA.

The corresponding results for extracting both causality and relatedness $C + R$ relations are given in Table 3. For these experiments, the aim was for a more relaxed evaluation and we simply collapsed C and R into a single label.

Finally, we also measured the precision of the top K causality C predictions, showing the precision trends in Figure 1. As shown, CEA in general achieves higher precision when compared to PMI_{pp} and $ECD_{pp}\&PMI_{pa,aa}$. The trends for $C + R$ predictions are similar.

Thus far, we had included both verbal and nominal predicates in our evaluation. When we repeat the experiments for $ECD_{pp}\&PMI_{pa,aa}$ and CEA on just verbal predicates, we obtained the respective F1-scores of 31.8 and 38.3 on causality relations. The corresponding F1-scores for casuality and relatedness relations are 35.7 and 43.3. These absolute F1-scores are similar to those in Tables 2 and 3, differing by 1-2%.

7 Analysis

We randomly selected 50 false-positive predictions and 50 false-negative *causality* relations to analyze the mistakes made by CEA.

Among the false-positives (precision errors), the most frequent error type (56% of the errors) is that CEA simply assigns a high score to event pairs that are not causal; more knowledge sources are required to support better predictions in these cases. The next largest group of error (22%) involves events containing pronouns (e.g. "he", "it") as arguments. Applying coreference to replace these pronouns with their canonical entity strings or labeling them with semantic class information might be useful.

Among the false-negatives (recall errors), 23% of the errors are due to CEA simply assigning a low score to causal event pairs and more contextual knowledge seems necessary for better predictions. 19% of the recall errors arises from causal event pairs involving nominal predicates that are not in our list of event evoking noun types (described in Section 3). A related 17% of recall errors involves nominal predicates without any argument. For these, less information is available for CEA to make predictions. The remaining group (15% of errors) involves events containing pronouns as arguments.

8 Related Work

Although prior work in event causality extraction in context is relatively sparse, there are many prior works concerning other semantic aspects of event extraction. Ji and Grishman (2008) extracts event mentions (belonging to a predefined list of target event types) and their associated arguments. In other prior work (Chen et al., 2009; Bejan and Harabagiu, 2010), the authors focused on identifying another type of event pair semantic relation: event coreference. Chambers and Jurafsky (2008; 2009) chain events sharing a common (protagonist) participant. They defined events as verbs and given an existing chain of events, they predict the next likely event involving the protagonist. This is different from our task of detecting causality between arbitrary event pairs that might or might not share common arguments. Also, we defined events more broadly, as those that are triggered by either verbs or nouns. Finally, although our proposed CEA metric has resemblance the ECD metric in (Riaz and Girju, 2010), our task is different from theirs and our work differs in many aspects. They focused on building a dataset of causal text spans, whereas we focused on identifying causal relations between events in a given text document. They considered text spans headed by verbs while we considered events triggered by both verbs and nouns. Moreover, we combined event causality prediction and discourse relation prediction through a global inference procedure to further improve the performance of event causality prediction.

9 Conclusion

In this paper, using general tools such as the dependency and discourse parsers which are not trained specifically towards our target task, and a minimal set of development documents for threshold tuning, we developed a minimally supervised approach to identify causality relations between events in context. We also showed how to incorporate discourse relation predictions to aid event causality predictions through a global inference procedure. There are several interesting directions for future work, including the incorporation of other knowledge sources such as coreference and semantic class predictions, which were shown to be potentially important in our error analysis. We could also use discourse relations to aid in extracting other semantic relations between events.

Abstract

This paper introduces a psycholinguistic model of sentence processing which combines a Hidden Markov Model noun phrase chunker with a co-reference classifier. Both models are fully incremental and generative, giving probabilities of lexical elements conditional upon linguistic structure. This allows us to compute the information theoretic measure of surprisal, which is known to correlate with human processing effort. We evaluate our surprisal predictions on the Dundee corpus of eye-movement data show that our model achieve a better fit with human reading times than a syntax-only model which does not have access to co-reference information.

1 Introduction

Recent research in psycholinguistics has seen a growing interest in the role of *prediction* in sentence processing. Prediction refers to the fact that the human sentence processor is able to anticipate upcoming material, and that processing is facilitated when predictions turn out to be correct (evidenced, e.g., by shorter reading times on the predicted word or phrase). Prediction is presumably one of the factors that contribute to the efficiency of human language understanding. Sentence processing is *incremental* (i.e., it proceeds on a word-by-word basis); therefore, it is beneficial if unseen input can be anticipated and relevant syntactic and semantic structure constructed in advance. This allows the processor to save time and makes it easier to cope with the constant stream of new input.

Evidence for prediction has been found in a range of psycholinguistic processing domains. *Semantic prediction* has been demonstrated by studies that show anticipation based on selectional restrictions: listeners are able to launch eye-movements to the predicted argument of a verb before having encountered it, e.g., they will fixate an edible object as soon as they hear the word *eat* (Altmann and Kamide, 1999). Semantic prediction has also been shown in the context of semantic priming: a word that is preceded by a semantically related prime or by a semantically congruous sentence fragment is processed faster (Stanovich and West, 1981; Clifton et al., 2007). An example for *syntactic prediction* can be found in coordinate structures: readers predict that the second conjunct in a coordination will have the same syntactic structure as the first conjunct (Frazier et al., 2000). In a similar vein, having encountered the word *either*, readers predict that *or* and a conjunct will follow it (Staub and Clifton, 2006). Again, priming studies corroborate this: Comprehenders are faster at naming words that are syntactically compatible with prior context, even when they bear no semantic relationship to it (Wright and Garrett, 1984).

Predictive processing is not confined to the sentence level. Recent experimental results also provide evidence for *discourse prediction*. An example is the study by van Berkum et al. (2005), who used a context that made a target noun highly predictable, and found a mismatch effect in the ERP (event-related brain potential) when an adjective appeared that was inconsistent with the target noun. An example is (we give translations of their Dutch materials):

(1) The burglar had no trouble locating the secret family safe.
   a. Of course, it was situated behind a

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 304–312,
Edinburgh, Scotland, UK, July 27–31, 2011.

big$_{neu}$ but unobtrusive painting$_{neu}$.

b. Of course, it was situated behind a big$_{com}$ but unobtrusive bookcase$_{com}$.

Here, the adjective *big*, which can have neutral or common gender in Dutch, is consistent with the predicted noun *painting* in (1-a), but inconsistent with it in (1-b), leading to a mismatch ERP on *big* in (1-b) but not in (1-a).

Previous results on discourse effects in sentence processing can also be interpreted in terms of prediction. In a classical paper, Altmann and Steedman (1988) demonstrated that PP-attachment preferences can change through discourse context: if the context contains two potential referents for the target NP, then NP-attachment of a subsequent PP is preferred (to disambiguate between the two referents), while if the context only contains one target NP, VP-attachment is preferred (as there is no need to disambiguate). This result (and a large body of related findings) is compatible with an interpretation in which the processor predicts upcoming syntactic attachment based on the presence of referents in the preceding discourse.

Most attempts to model prediction in human language processing have focused on syntactic prediction. Examples include Hale's (2001) surprisal model, which relates processing effort to the conditional probability of the current word given the previous words in the sentence. This approach has been elaborated by Demberg and Keller (2009) in a model that explicitly constructs predicted structure, and includes a verification process that incurs additional processing cost if predictions are not met. Recent work has attempted to integrate semantic and discourse prediction with models of syntactic processing. This includes Mitchell et al.'s (2010) approach, which combines an incremental parser with a vector-space model of semantics. However, this approach only provides a loose integration of the two components (through simple addition of their probabilities), and the notion of semantics used is restricted to lexical meaning approximated by word co-occurrences. At the discourse level, Dubey (2010) has proposed a model that combines an incremental parser with a probabilistic logic-based model of co-reference resolution. However, this model does not explicitly model discourse effects in terms of prediction, and again only proposes a loose integration of co-reference and syntax. Furthermore, Dubey's (2010) model has only been tested on two experimental data sets (pertaining to the interaction of ambiguity resolution with context), no broad coverage evaluation is available.

The aim of the present paper is to overcome these limitations. We propose a computational model that captures discourse effects on syntax in terms of prediction. The model comprises a co-reference component which explicitly stores discourse mentions of NPs, and a syntactic component which adjust the probabilities of NPs in the syntactic structure based on the mentions tracked by the discourse component. Our model is HMM-based, which makes it possible to efficiently process large amounts of data, allowing an evaluation on eye-tracking corpora, which has recently become the gold-standard in computational psycholinguistics (e.g., Demberg and Keller 2008; Frank 2009; Boston et al. 2008; Mitchell et al. 2010).

The paper is structured as follows: In Section 2, we describe the co-reference and the syntactic models and evaluate their performance on standard data sets. Section 3 presents an evaluation of the overall model on the Dundee eye-tracking corpus. The paper closes with a comparison with related work and a general discussion in Sections 4 and 5.

2 Model

This model utilises an NP chunker based upon a hidden Markov model (HMM) as an approximation to syntax. Using a simple model such as an HMM facilitates the integration of a co-reference component, and the fact that the model is generative is a prerequisite to using surprisal as our metric of interest (as surprisal require the computation of prefix probabilities). The key insight in our model is that human sentence processing is, on average, facilitated when a previously-mentioned discourse entity is repeated. This facilitation depends upon keeping track of a list of previously-mentioned entities, which requires (at the least) shallow syntactic information, yet the facilitation itself is modeled primarily as a lexical phenomenon. This allows a straightforward separation of concerns: shallow syntax is captured using the HMM's hidden states, whereas the co-reference fa-

cilitation is modeled using the HMM's emissions. The vocabulary of hidden states is described in Section 2.1 and the emission distribution in Section 2.2

2.1 Syntactic Model

A key feature of the co-reference component of our model (described below) is that syntactic analysis and co-reference resolution happen simultaneously. This could potentially slow down the syntactic analysis, which tends to already be quite slow for exhaustive surprisal-based incremental parsers. Therefore, rather than using full parsing, we use an HMM-based NP chunker which allows for a fast analysis. NP chunking is sufficient to extract NP discourse mentions and, as we show below, surprisal values computed using HMM chunks provide a useful fit on the Dundee eye-movement data.

To allow the HMM to handle possessive constructions as well as NP with simple modifiers and complements, the HMM decodes NP subtrees with depth of 2, by encoding the start, middle and end of a syntactic category X as '(X', 'X' and 'X)', respectively. To reduce an explosion in the number of states, the category begin state '(X' only appears at the rightmost lexical token of the constituent's leftmost daughter. Likewise, 'X)' only appears at the leftmost lexical token of the constituent's rightmost daughter. An example use of this state vocabulary can be seen in Figure 1. Here, a small degree of recursion allows for the NP ((new york city's) general obligation fund) to be encoded, with the outer NP's left bracket being 'announced' at the token *'s*, which is the rightmost lexical token of the inner NP. Hidden states also include part-of-speech (POS) tags, allowing simultaneous POS tagging. In the example given in Figure 1, the full state can be read by listing the labels written above a word, from top to bottom. For example, the full state associated with *'s* is (NP-NP)-POS. As *'s* can also be a contraction of *is*, another possible state for *'s* is VBZ (without recursive categories as we are only interested in NP chunks).

The model uses unsmoothed bi-gram transition probabilities, along with a maximum entropy distribution to guess unknown word features. The resulting distribution has the form $P(tag|word)$ and is therefore unsuitable for computing surprisal values. However, using Bayes' theorem we can compute:

$$P(word|tag) = \frac{P(tag|word)P(word)}{P(tag)} \quad (1)$$

which is what we need for surprisal. The primary information from this probability comes from $P(tag|word)$, however, reasonable estimates of $P(tag)$ and $P(word)$ are required to ensure the probability distribution is proper. $P(tag)$ may be estimated on a parsed treebank. $P(word)$, the probability of a particular unseen word, is difficult to estimate directly. Given that our training data contains approximately 10^6 words, we assume that this probability must be bounded above by 10^{-6}. As an approximation, we use this upper bound as the probability of $P(word)$.

Training The chunker is trained on sections 2–22 of the Wall Street Journal section of the Penn Treebank. CoNLL 2000 included chunking as a shared task, and the results are summarized by Tjong Kim Sang and Buchholz (2000). Our chunker is not comparable to the systems in the shared task for several reasons: we use more training data, we tag simultaneously (the CoNLL systems used gold standard tags) and our notion of a chunk is somewhat more complex than that used in CoNLL. The best performing chunker from CoNLL 2000 achieved an F-score of 93.5%, and the worst performing system an F-score of 85.8%. Our chunker achieves a comparable F-score of 85.5%, despite the fact that it simultaneously tags and chunks, and only uses a bigram model.

2.2 Co-Reference Model

In a standard HMM, the emission probabilities are computed as $P(w_i|s_i)$ where w_i is the i^{th} word and s_i is the i^{th} state. In our model, we replace this with a choice between two alternatives:

$$P(w_i|s_i) = \begin{cases} \lambda P_{\text{seen before}}(w_i|s_i) \\ (1-\lambda) P_{\text{discourse new}}(w_i|s_i) \end{cases} \quad (2)$$

The 'discourse new' probability distribution is the standard HMM emission distribution. The 'seen before' distribution is more complicated. It is in part based upon caching language models. However, the contents of the cache are not individual words but

end for

Figure 2: Looking up entries from the NP Cache

rather a collection of all NPs mentioned so far in the document.

Using a collection of NPs rather than individual words complicates the decoding process. If m is the size of a document, and n is the size of the current sentence, decoding occurs in $O(mn)$ time as opposed to $O(n)$, as the collection of NPs needs to be accessed at each word. However, we do not store the NPs in a list, but rather a trie. This allows decoding to occur in $O(n \log m)$ time, which we have found to be quite fast in practise. The algorithm used to keep track of currently active NPs is presented in Figure 2. This shows how the distribution $P_{\text{seen before}}$ is updated on a word-by-word basis. At the end of each sentence, the NPs of the Viterbi parse are added to the mention trie after having their leading articles stripped. A weakness of the algorithm is that mentions are only added on a sentence-by-sentence basis (disallowing within-sentence references). Although the algorithm is intended to find whole-string matches, in practise, it will count any NP whose prefix matches as being co-referent.

A consequence of Equation 2 is that co-reference resolution is handled at the same time as HMM decoding. Whenever the 'seen before' distribution is applied, an NP is co-referent with one occurring earlier. Likewise, whenever the 'discourse new' distribution is applied, the NP is not co-referent with any NP appearing previously. As one choice or the other is made during decoding, the decoder therefore also selects a chain of co-referent entities. Generally, for words which *have* been used in this discourse, the magnitude of probabilities in the 'seen before' distribution are much higher than in the 'discourse new' distribution. Thus, there is a strong bias to classify NPs which match word-for-word as being co-referent. There remains a possibility that the model primarily captures lexical priming, rather than co-reference. However, we note that string match is a strong indicator of two NPs being corefer-

ent (cf. Soon et al. 2001), and, moreover, the matching is done on an NP-by-NP basis, which is more suitable for finding entity coreference, rather than a word-by-word basis, which would be more suitable for lexical priming.

An appealing side-effect of using a simple co-reference decision rule which is applied incrementally is that it is relatively simple to incrementally compute the transitive closure of co-reference chains, resulting in the entity sets which are then used in evaluation.

The co-reference model only has one free parameter, λ, which is estimated from the ACE-2 corpus. The estimate is computed by counting how often a repeated NP actually is discourse new. In the current implementation of the model, λ is constant throughout the test runs. However, λ could possibly be a function of the previous discourse, allowing for more complicated classification probabilities.

3 Evaluation

3.1 Data

Our evaluation experiments were conducted upon the Dundee corpus (Kennedy et al., 2003), which contains the eye-movement record of 10 participants each reading 2,368 sentences of newspaper text. This data set has previously been used by Demberg and Keller (2008) and Frank (2009) among others.

3.2 Evaluation

Eye tracking data is noisy for a number of reasons, including the fact that experimental participants can look at any word which is currently displayed. While English is normally read in a left-to-right manner, readers often skip words or make regressions (i.e., look at a word to the left of the one they are currently fixating). Deviations from a strict left-to-right progression of fixations motivate the need for several different measures of eye movement. The model presented here predicts the Total Time that participants spent looking at a region, which includes any re-fixations after looking away. In addition to total time, other possible measures include (a) First Pass, which measures the initial fixation and any re-fixations before looking at any other word (this occurs, for instance, if the eye initially lands at the start of a long word – the eye will tend to re-fixate on a more central viewing location), (b) Right Bounded reading time, which includes all fixations on a word before moving to the right of the word (i.e., re-fixations after moving left are included), and (c) Second Pass, which includes any re-fixation on a word after looking at any other word (be it to the left or the right of the word of interest). We found that the model performed similarly across all these reading time metrics, we therefore only report results for Total Time.

As mentioned above, reading measures are hypothesised to correlate with Surprisal, which is defined as:

$$S(w_t) = -\log(P(w_t|w_1...w_{t1}) \quad (3)$$

We compute the surprisal scores for the syntax-only HMM, which does not have access to co-reference information (henceforth referred to as 'HMM') and the full model, which combines the syntax-only HMM with the co-reference model (henceforth 'HMM+Ref'). To determine if our Dundee corpus simulations provide a reasonable model of human sentence processing, we perform a regression analysis with the Dundee corpus reading time measure as the dependent variable and the surprisal scores as the independent variable.

To account for noise in the corpus, we also use a number of additional explanatory variables which are known to strongly influence reading times. These include the logarithm of the frequency of a word (measured in occurrences per million) and the length of a word in letters. Two additional explanatory variables were available in the Dundee corpus, which we also included in the regression model. These were the position of a word on a line, and which line in a document a word appeared in. As participants could only view one line at a time (i.e., one line per screen), these covariates are known as line position and screen position, respectively.

All the covariates, including the surprisal estimates, were centered before including them in the regression model. Because the HMM and HMM+Ref surprisal values are highly collinear, the HMM+Ref surprisal values were added as residuals of the HMM surprisal values.

In a normal regression analysis, one must either assume that participants or the particular choice of

items add some randomness to the experiment, and either each participant's responses for all items must be averaged (treating participants as a random factor), or all participant's responses for each item is averaged (treating items as a random factor). However, in the present analysis we utilise a mixed effects model, which allows both items and participants to be treated as random factors.[1]

The are a number of criteria which can be used to test the efficacy of one regression model over another. These include the Aikake Information Criterion (AIC), the Bayesian Information Criterion (BIC), which trade off model fit and number of model parameters (lower scores are better). It is also common to compare the log-likelihood of the models (higher log-likelihood is better), in which case a χ^2 can be used to evaluate if a model offers a significantly better fit, given the number of parameters is uses. We test three models: (i) a baseline, with only low-level factors as independent variables; (ii) the HMM model, with the baseline factors plus surprisal computed by the syntax-only HMM; and (iii) the HMM+Ref model which includes the raw surprisal values of the syntax-only HMM and the surprisal of the HMM+Ref models as computed as a residual of the HMM surprisal score. We compare the HMM and HMM+Ref to the baseline, and the HMM+Ref model against the HMM model.

Some of the data needed to be trimmed. If, due to data sparsity, the surprisal of a word goes to infinity for one of the models, we entirely remove that word from the analysis. This occurred seven times form the HMM+Ref model, but did not occur at all with the HMM model. Some of the eye-movement data was trimmed, as well. Fixations on the first and last words of a line were excluded, as were tracklosses. However, we did not trim any items due to abnormally short or abnormally long fixation durations.

[1] We assume that each participant and item bias the reading time of the experiment. Such an analysis is known as having random intercepts of participant and item. It is also possible to assume a more involved analysis, known as random slopes, where the participants and items bias the slope of the predictor. The model did not converge when using random intercept and slopes on both participant and item. If random slopes on items were left out, the HMM regression model did converge, but not the HMM+Ref model. As the HMM+Ref is the model of interest random slopes were left out entirely to allow a like-with-like comparison between the HMM and HMM+Ref regression models.

3.3 Results

The result of the model comparison on Total Time reading data is summarised in Table 1. To allow this work to be compared with other models, the lower part of the table gives the abosolute AIC, BIC and log likelihood of the baseline model, while the upper part gives delta AIC, BIC and log likelihood scores of pairs of models.

We found that both the HMM and HMM+Ref provide a significantly better fit with the reading time data than the Baseline model; all three criteria agree: AIC and BIC lower than for the baseline, and log-likelihood is higher. Moreover, the HMM+Ref model provides a significantly better fit than the HMM model, which demonstrates the benefit of co-reference information for modeling reading times. Again, all three measures provide the same result.

Table 2 corroborates this result. It list the mixed-model coefficients for the HMM+Ref model and shows that all factors are significant predictors, including both HMM surprisal and residualized HMM+Ref surprisal.

4 Related Work

There have been few computational models of human sentence processing that have incorporated a referential or discourse-level component. Niv (1994) proposed a parsing model based on Combinatory Categorial Grammar (Steedman, 2001), in which referential information was used to resolve syntactic ambiguities. The model was able to capture effects of referential information on syntactic garden paths (Altmann and Steedman, 1988). This model differs from that proposed in the present paper, as it is intended to capture psycholinguistic preferences in a qualitative manner, whereas the aim of the present model is to provide a *quantitative* fit to measures of processing difficulty. Moreover, the model was not based on a large-scale grammar, and was not tested on unrestricted text. Spivey and Tanenhaus (1998) proposed a sentence processing model that examined the effects of referential information, as well as other constraints, on the resolution of ambiguous sentences. Unlike Niv (1994),

From	To	Δ AIC	Δ BIC	Δ logLik	χ^2	Significance
Baseline	HMM	-80	-69	41	82.112	$p < .001$
Baseline	HMM+Ref	-99	-89	51	101.54	$p < .001$
HMM	HMM+Ref	-19	-8	11	21.424	$p < .001$

Model	AIC	BIC	logLik
Baseline	10567789	10567880	-5283886

Table 1: Model comparison (upper part) and absolute scores for the Baseline model (lower part)

Coefficient	Estimate	Std Error	t-value
(Intercept)	991.4346	23.7968	41.66
log(Word Frequency)	-55.3045	1.4830	-37.29
Word Length	128.6216	1.4677	87.63
Screen Position	-1.7769	0.1326	-13.40
Line Position	10.1592	0.7387	13.75
HMM	12.1287	1.3366	9.07
HMM+Ref	19.2772	4.1627	4.63

Table 2: Coefficients of the HMM+Ref model on Total Reading Times. Note that $t > 2$ indicates that the factor in question is a significant predictor.

Spivey and Tanenhaus's (1998) model was specifically designed to provide a quantitative fit to reading times. However, the model lacked generality, being designed to deal with only one type of sentence. In contrast to both of these earlier models, the model proposed here aims to be general enough to provide estimated reading times for unrestricted text. In fact, as far as we are aware, the present paper represents the first wide-coverage model of human parsing that has incorporated discourse-level information.

5 Discussion

The primary finding of this work is that incorporating discourse information such as co-reference into an incremental probabilistic model of sentence processing has a beneficial effect on the ability of the model to predict broad-coverage human parsing behaviour.

Although not thoroughly explored in this paper, our finding is related to an ongoing debate about the structure of the human sentence processor. In particular, the model of Dubey (2010), which also simulates the effect of discourse on syntax, is aimed at examining *interactivity* in the human sentence processor. Interactivity describes the degree to which human parsing is influenced by non-syntactic factors. Under the *weakly interactive* hypothesis, discourse factors may prune or re-weight parses, but only when assuming the *strongly interactive* hypothesis would we argue that the sentence processor predicts upcoming material due to discourse factors. Dubey found that a weakly interactive model simulated a pattern of results in an experiment (Grodner et al., 2005) which was previously believed to provide evidence for the strongly interactive hypothesis. However, as Dubey does not provide broad-coverage parsing results, this leaves open the possibility that the model cannot generalise beyond the experiments expressly modeled in Dubey (2010).

The model presented here, on the other hand, is not only broad-coverage but could also be described as a strongly interactive model. The strong interactivity arises because co-reference resolution is strongly tied to lexical generation probabilities, which are part of the syntactic portion of our model. This cannot be achieve in a weakly interactive model, which is limited to pruning or re-weighting of parses based on discourse information. As our analysis on the Dundee corpus showed, the lexical probabilities (in the form of HMM+Ref surprisal) are key to improving the fit on eye-tracking data. We therefore argue that our results provide evidence

against a weakly interactive approach, which may be sufficient to model individual phenomena (as shown by Dubey 2010), but is unlikely to be able to match the broad-coverage result we have presented here. We also note that psycholinguistic evidence for discourse prediction (such as the context based lexical prediction shown by van Berkum et al. 2005, see Section 1) is also evidence for strong interactivity; prediction goes beyond mere pruning or reweighting and requires strong interactivity.

Simple Effective Decipherment via Combinatorial Optimization

Taylor Berg-Kirkpatrick and **Dan Klein**
Computer Science Division
University of California at Berkeley
{tberg, klein}@cs.berkeley.edu

Abstract

We present a simple objective function that when optimized yields accurate solutions to both decipherment and cognate pair identification problems. The objective simultaneously scores a matching between two alphabets and a matching between two lexicons, each in a different language. We introduce a simple coordinate descent procedure that efficiently finds effective solutions to the resulting combinatorial optimization problem. Our system requires only a list of words in both languages as input, yet it competes with and surpasses several state-of-the-art systems that are both substantially more complex and make use of more information.

1 Introduction

Decipherment induces a correspondence between the words in an unknown language and the words in a known language. We focus on the setting where a close correspondence between the alphabets of the two languages exists, but is unknown. Given only two lists of words, the lexicons of both languages, we attempt to induce the correspondence between alphabets and identify the cognates pairs present in the lexicons. The system we propose accomplishes this by defining a simple combinatorial optimization problem that is a function of both the alphabet and cognate matchings, and then induces correspondences by optimizing the objective using a block coordinate descent procedure.

There is a range of past work that has variously investigated cognate detection (Kondrak, 2001; Bouchard-Côté et al., 2007; Bouchard-Côté et al., 2009; Hall and Klein, 2010), character-level decipherment (Knight and Yamada, 1999; Knight et al., 2006; Snyder et al., 2010; Ravi and Knight, 2011), and bilingual lexicon induction (Koehn and Knight, 2002; Haghighi et al., 2008). We consider a common element, which is a model wherein there are character-level correspondences and word-level correspondences, with the word matching parameterized by the character one. This approach subsumes a range of past tasks, though of course past work has specialized in interesting ways.

Past work has emphasized the modeling aspect, where here we use a parametrically simplistic model, but instead emphasize inference.

2 Decipherment as Two-Level Optimization

Our method represents two matchings, one at the alphabet level and one at the lexicon level. A vector of variables x specifies a matching between alphabets. For each character i in the source alphabet and each character j in the target alphabet we define an indicator variable x_{ij} that is on if and only if character i is mapped to character j. Similarly, a vector y represents a matching between lexicons. For word u in the source lexicon and word v in the target lexicon, the indicator variable y_{uv} denotes that u maps to v. Note that the matchings need not be one-to-one.

We define an objective function on the matching variables as follows. Let $\textsc{EditDist}(u, v; x)$ denote the edit distance between source word u and target word v given alphabet matching x. Let the length of word u be l_u and the length of word w be l_w. This edit distance depends on x in the following way. Insertions and deletions always cost a constant ϵ.[1] Substitutions also cost ϵ unless the characters are matched in x, in which case the substitution is

[1] In practice we set $\epsilon = \frac{1}{l_u + l_v}$. $l_u + l_v$ is the maximum number of edit operations between words u and v. This normalization insures that edit distances are between 0 and 1 for all pairs of words.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 313–321,
Edinburgh, Scotland, UK, July 27–31, 2011.

free. Now, the objective that we will minimize can be stated simply: $\sum_u \sum_v y_{uv} \cdot \text{EDITDIST}(u, v; x)$, the sum of the edit distances between the matched words, where the edit distance function is parameterized by the alphabet matching.

Without restrictions on the matchings x and y this objective can always be driven to zero by either mapping all characters to all characters, or matching none of the words. It is thus necessary to restrict the matchings in some way. Let I be the size of the source alphabet and J be the size of the target alphabet. We allow the alphabet matching x to be many-to-many but require that each character participate in no more than two mappings and that the total number of mappings be $\max(I, J)$, a constraint we refer to as *restricted-many-to-many*. The requirements can be encoded with the following linear constraints on x:

$$\forall_i \sum_j x_{ij} \leq 2$$
$$\forall_j \sum_i x_{ij} \leq 2$$
$$\sum_i \sum_j x_{ij} = \max(I, J)$$

The lexicon matching y is required to be τ*-one-to-one*. By this we mean that y is an at-most-one-to-one matching that covers proportion τ of the smaller of the two lexicons. Let U be the size of the source lexicon and V be this size of the target lexicon. This requirement can be encoded with the following linear constraints:

$$\forall_u \sum_v y_{uv} \leq 1$$
$$\forall_v \sum_u y_{uv} \leq 1$$
$$\sum_u \sum_v y_{uv} = \tau \min(U, V)$$

Now we are ready to define the full optimization problem. The first formulation is called the *Implicit Matching Objective* since includes an implicit minimization over edit alignments inside the computation of EDITDIST.

(1) *Implicit Matching Objective*:

$$\min_{x,y} \sum_u \sum_v y_{uv} \cdot \text{EDITDIST}(u, v; x)$$
$$\text{s.t. } x \text{ is restricted-many-to-many}$$
$$y \text{ is } \tau\text{-one-to-one}$$

In order to get a better handle on the shape of the objective and to develop an efficient optimization procedure we decompose each edit distance computation and re-formulate the optimization problem in Section 2.2.

2.1 Example

Figure 1 presents both an example matching problem and a diagram of the variables and objective. Here, the source lexicon consists of the English words `(cat, bat, cart, rat, cab)`, and the source alphabet consists of the characters `(a, b, c, r, t)`. The target alphabet is `(0, 1, 2, 3)`. We have used digits as symbols in the target alphabet to make it clear that we treat the alphabets as disjoint. We have no prior knowledge about any correspondence between alphabets, or between lexicons.

The target lexicon consists of the words `(23, 1233, 120, 323, 023)`. The bipartite graphs show a specific setting of the matching variables. The bold edges correspond to the x_{ij} and y_{uv} that are one. The matchings shown achieve an edit distance of zero between all matched word pairs except for the pair `(cat, 23)`. The best edit alignment for this pair is also diagrammed. Here, '`a`' is aligned to '`2`', '`t`' is aligned to '`3`', and '`c`' is deleted and therefore aligned to the null position '`#`'. Only the initial deletion has a non-zero cost since all other alignments correspond to substitutions between characters that are matched in x.

2.2 Explicit Objective

Computing $\text{EDITDIST}(u, v; x)$ requires running a dynamic program because of the unknown edit alignments; here we define those alignments z explicitly, which makes the $\text{EDITDIST}(u, v; x)$ easy to write explicitly at the cost of more variables. However, by writing the objective in an explicit form that refers to these edit variables, we are able to describe a efficient block coordinate descent procedure that can be used for optimization.

$\text{EDITDIST}(u, v; x)$ is computed by minimizing over the set of monotonic alignments between the characters of the source word u and the characters of the target word v. Let u_n be the character at the nth position of the source word u, and similarly for

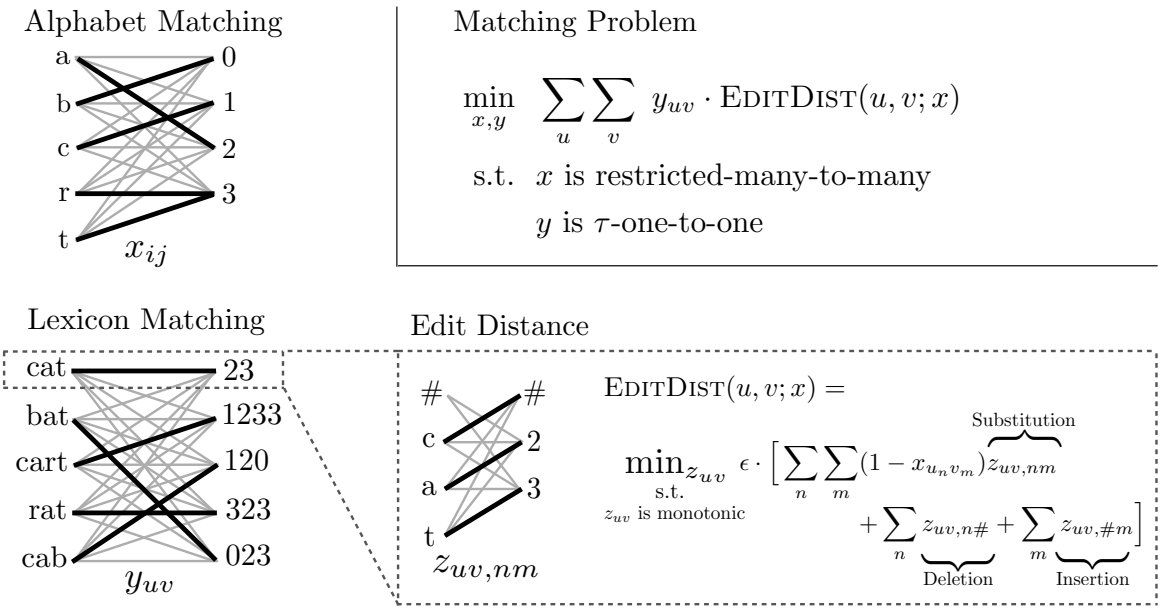

Figure 1: An example problem displaying source and target lexicons and alphabets, along with specific matchings. The variables involved in the optimization problem are diagrammed. x are the alphabet matching indicator variables, y are the lexicon matching indicator variables, and z are the edit alignment indicator variables. The index u refers to a word in the source lexicon, v refers to word in the target lexicon, i refers to a character in the source alphabet, and j refers to a character in the target alphabet. n and m refer to positions in source and target words respectively. The matching objective function is also shown.

v_m. Let z_{uv} be the vector of alignment variables for the edit distance computation between source word u and target word v, where entry $z_{uv,nm}$ indicates whether the character at position n of source word u is aligned to the character at position m of target word v. Additionally, define variables $z_{uv,n\#}$ and $z_{uv,\#m}$ denoting null alignments, which will be used to keep track of insertions and deletions.

$$\text{EDITDIST}(u, v; x) =$$
$$\min_{z_{uv}} \ \epsilon \cdot \Big(\text{SUB}(z_{uv}, x) + \text{DEL}(z_{uv}) + \text{INS}(z_{uv}) \Big)$$
$$\text{s.t. } z_{uv} \text{ is monotonic}$$

We define $\text{SUB}(z_{uv}, x)$ to be the number of substitutions between characters that are not matched in x, $\text{DEL}(z_{uv})$ to be the number of deletions, and $\text{INS}(z_{uv})$ to be the number of insertions.

$$\text{SUB}(z_{uv}, x) = \sum_{n,m} (1 - x_{u_n v_m}) z_{uv,nm}$$
$$\text{DEL}(z_{uv}) = \sum_n z_{uv,n\#}$$
$$\text{INS}(z_{uv}) = \sum_m z_{uv,\#m}$$

Notice that the variable $z_{uv,nm}$ being turned on indicates the substitute operation, while a $z_{uv,n\#}$ or $z_{uv,\#m}$ being turned on indicates an insert or delete operation. These variables are digrammed in Figure 1. The requirement that z_{uv} be a monotonic alignment can be expressed using linear constraints, but in our optimization procedure (described in Section 3) these constraints need not be explicitly represented.

Now we can substitute the explicit edit distance equation into the *implicit matching objective* (1).

Noticing that the mins and sums commute, we arrive at the explicit form of the matching optimization problem.

(2) *Explicit Matching Objective*:

$$\min_{x,y,z} \Big[\sum_{u,v} y_{uv} \cdot \epsilon \cdot \big(\textsc{Sub}(z_{uv}, x) + \textsc{Del}(z_{uv}) + \textsc{Ins}(z_{uv}) \big) \Big]$$

s.t. x is restricted-many-to-many

y is τ-one-to-one

$\forall_{uv}\ z_{uv}$ is monotonic

The implicit and explicit optimizations are the same, apart from the fact that the explicit optimization now explicitly represents the edit alignment variables z. Let the *explicit matching objective* (2) be denoted as $J(x, y, z)$. The relaxation of the explicit problem with 0-1 constraints removed has integer solutions,[2] however the objective $J(x, y, z)$ is non-convex. We thus turn to a block coordinate descent method in the next section in order to find local optima.

3 Optimization Method

We now state a block coordinate descent procedure to find local optima of $J(x, y, z)$ under the constraints on x, y, and z. This procedure alternates between updating y and z to their exact joint optima when x is held fixed, and updating x to its exact optimum when y and z are held fixed.

The psuedocode for the procedure is given in Algorithm 1. Note that the function EDITDIST returns both the min edit distance e_{uv} and the argmin edit alignments z_{uv}. Also note that c_{ij} is as defined in Section 3.2.

3.1 Lexicon Matching Update

Let x, the alphabet matching variable, be fixed. We consider the problem of optimizing $J(x, y, z)$ over the lexicon matching variable y and and the edit alignments z under the constraint that y is τ-one-to-one and each z_{uv} is monotonic.

[2]This can be shown by observing that optimizing x when y and z are held fixed yields integer solutions (shown in Section 3.2), and similarly for the optimization of y and z when x is fixed (shown in Section 3.1). Thus, every local optimum with respect to these block coordinate updates has integer solutions. The global optimum must be one of these local optima.

Algorithm 1 Block Coordinate Descent

Randomly initialize alphabet matching x.
repeat
  for all u, v **do**
    $(e_{uv}, z_{uv}) \leftarrow \textsc{EditDist}(u, v; x)$
  end for
  [Hungarian]
  $y \leftarrow \text{argmin}_{y\ \tau\text{-one-to-one}} \Big[\sum_{u,v} y_{uv} e_{uv} \Big]$
  [Solve LP]
  $x \leftarrow \text{argmax}_{x\ \text{restr.-many-to-many}} \Big[\sum_{i,j} x_{ij} c_{ij} \Big]$
until convergence

Notice that y simply picks out which edit distance problems affect the objective. The z_{uv} in each of these edit distance problems can be optimized independently. z_{uv} that do not have y_{uv} active have no effect on the objective, and z_{uv} with y_{uv} active can be optimized using the standard edit distance dynamic program. Thus, in a first step we compute the $U \cdot V$ edit distances e_{uv} and best monotonic alignment variables z_{uv} between all pairs of source and target words using $U \cdot V$ calls to the standard edit distance dynamic program. Altogether, this takes time $O\big((\sum_u l_u) \cdot (\sum_v l_v)\big)$.

Now, in a second step we compute the least weighted τ-one-to-one matching y under the weights e_{uv}. This can be accomplished in time $O(\max(U, V)^3)$ using the Hungarian algorithm (Kuhn, 1955). These two steps produce y and z that exactly achieve the optimum value of $J(x, y, z)$ for the given value of x.

3.2 Alphabet Matching Update

Let y and z, the lexicon matching variables and the edit alignments, be fixed. Now, we find the optimal alphabet matching variables x subject to the constraint that x is restricted-many-to-many.

It makes sense that to optimize $J(x, y, z)$ with respect to x we should prioritize mappings x_{ij} that would mitigate the largest substitution costs in the active edit distance problems. Indeed, with a little algebra it can be shown that solving a maximum weighted matching problem with weights c_{ij} that count potential substitution costs gives the correct update for x. In particular, c_{ij} is the total cost of substitution edits in the active edit alignment prob-

lems that would result if source character i were not mapped to target character j in the alphabet matching x. This can be written as:

$$c_{ij} = \sum_{u,v} \sum_{n,m \text{ s.t. } u_n=i, v_m=j} \epsilon \cdot y_{uv} \cdot z_{uv,nm}$$

If x were constrained to be one-to-one, we could again apply the Hungarian algorithm, this time to find a maximum weighted matching under the weights c_{ij}. Since we have instead allowed restricted-many-to-many alphabet matchings we turn to linear programming for optimizing x. We can state the update problem as the following linear program (LP), which is guaranteed to have integer solutions:

$$\begin{aligned} \min_{x} \quad & \sum_{ij} x_{ij} c_{ij} \\ \text{s.t.} \quad & \forall_i \sum_j x_{ij} \leq 2, \quad \forall_j \sum_i x_{ij} \leq 2 \\ & \sum_i \sum_j x_{ij} = \max(I, J) \end{aligned}$$

In experiments we used the GNU Linear Programming Toolkit (GLPK) to solve the LP and update the alphabet matching x. This update yields matching variables x that achieve the optimum value of $J(x, y, z)$ for fixed y and z.

3.3 Random Restarts

In practice we found that the block coordinate descent procedure can get stuck at poor local optima. To find better optima, we run the coordinate descent procedure multiple times, initialized each time with a random alphabet matching. We choose the local optimum with the best objective value across all initializations. This approach yielded substantial improvements in achieved objective value.

4 Experiments

We compare our system to three different state-of-the-art systems on three different data sets. We set up experiments that allow for as direct a comparison as possible. In some cases it must be pointed out that the past system's goals are different from our own, and we will be comparing in a different way than the respective work was intended. The three systems make use of additional, or slightly different, sources of information.

4.1 Phonetic Cognate Lexicons

The first data set we evaluate on consists of 583 triples of phonetic transcriptions of cognates in Spanish, Portuguese, and Italian. The data set was introduced by Bouchard-Côté et al. (2007). For a given pair of languages the task is to determine the mapping between lexicons that correctly maps each source word to its cognate in the target lexicon. We refer to this task and data set as ROMANCE.

Hall and Klein (2010) presented a state-of-the-art system for the task of cognate identification and evaluated on this data set. Their model explicitly represents parameters for phonetic change between languages and their parents in a phylogenetic tree. They estimate parameters and infer the pairs of cognates present in all three languages jointly, while we consider each pair of languages in turn.

Their model has similarities with our own in that it learns correspondences between the alphabets of pairs of languages. However, their correspondences are probabilistic and implicit while ours are hard and explicit. Their model also differs from our own in a key way. Notice that the phonetic alphabets for the three languages are actually the same. Since phonetic change occurs gradually across languages a helpful prior on the correspondence is to favor the identity. Their model makes use of such a prior. Our model, on the other hand, is unaware of any prior correspondence between alphabets and does not make use of this additional information about phonetic change.

Hall and Klein (2010) also evaluate their model on lexicons that do not have a perfect cognate mapping. This scenario, where not every word in one language has a cognate in another, is more realistic. They produced a data set with this property by pruning words from the ROMANCE data set until only about 75% of the words in each source lexicon have cognates in each target lexicon. We refer to this task and data set as PARTIALROMANCE.

4.2 Lexicons Extracted from Corpora

Next, we evaluate our model on a noisier data set. Here the lexicons in source and target languages are extracted from corpora by taking the top 2,000 words in each corpus. In particular, we used the English and Spanish sides of the Europarl parallel cor-

pus (Koehn, 2005). To make this set up more realistic (though fairly comparable), we insured that the corpora were non-parallel by using the first 50K sentences on the English side and the second 50K sentences on the Spanish side. To generate a gold cognate matching we used the intersected HMM alignment model of Liang et al. (2008) to align the full parallel corpus. From this alignment we extracted a translation lexicon by adding an entry for each word pair with the property that the English word was aligned to the Spanish in over 10% of the alignments involving the English word. To reduce this translation lexicon down to a cognate matching we went through the translation lexicon by hand and removed any pair of words that we judged to not be cognates. The resulting gold matching contains cognate mappings in the English lexicon for 1,026 of the words in the Spanish lexicon. This means that only about 50% of the words in English lexicon have cognates in the Spanish lexicon. We evaluate on this data set by computing precision and recall for the number of English words that are mapped to a correct cognate. We refer to this task and data set as EUROPARL.

On this data set, we compare against the state-of-the-art orthographic system presented in Haghighi et al. (2008). Haghighi et al. (2008) presents several systems that are designed to extract translation lexicons for non-parallel corpora by learning a correspondence between their monolingual lexicons. Since our system specializes in matching cognates and does not take into account additional information from corpus statistics, we compare against the version of their system that only takes into account orthographic features and is thus is best suited for cognate detection. Their system requires a small seed of correct cognate pairs. From this seed the system learns a projection using canonical correlation analysis (CCA) into a canonical feature space that allows feature vectors from source words and target words to be compared. Once in this canonical space, similarity metrics can be computed and words can be matched using a bipartite matching algorithm. The process is iterative, adding cognate pairs to the seed lexicon gradually and each time re-computing a refined projection. Our system makes no use of a seed lexicon whatsoever.

Both our system and the system of Haghighi et al. (2008) must solve bipartite matching problems between the two lexicons. For this data set, the lexicons are large enough that finding the exact solution can be slow. Thus, in all experiments on this data set, we instead use a greedy competitive linking algorithm that runs in time $O(U^2V^2\log(UV))$.

Again, for this dataset it is reasonable to expect that many characters will map to themselves in the best alphabet matching. The alphabets are not identical, but are far from disjoint. Neither our system, nor that of Haghighi et al. (2008) make use of this expectation. As far as both systems are concerned, the alphabets are disjoint.

4.3 Decipherment

Finally, we evaluate our model on a data set where a main goal is to decipher an unknown correspondence between alphabets. We attempt to learn a mapping from the alphabet of the ancient Semitic language Ugaritic to the alphabet of Hebrew, and at the same time learn a matching between Hebrew words in a Hebrew lexicon and their cognates in a Ugaritic lexicon. This task is related to the task attempted by Snyder et al. (2010). The data set consists of a Ugaritic lexicon of 2,214 words, each of which has a Hebrew cognate, the lexicon of their 2,214 Hebrew cognates, and a gold cognate dictionary for evaluation. We refer to this task and data set as UGARITIC.

The non-parameteric Bayesian system of Snyder et al. (2010) assumes that the morphology of Hebrew is known, making use of an inventory of suffixes, prefixes, and stems derived from the words in the Hebrew bible. It attempts to learn a correspondence between the morphology of Ugaritic and that of Hebrew while reconstructing cognates for Ugaritic words. This is a slightly different goal than that of our system, which learns a correspondence between lexicons. Snyder et al. (2010) run their system on a set 7,386 Ugaritic words, the same set that we extracted our 2,214 Ugaritic words with Hebrew cognates from. We evaluate the accuracy of the lexicon matching produced by our system on these 2,214 Ugaritic words, and so do they, measuring the number of correctly reconstructed cognates.

By restricting the source and target lexicons to sets of cognates we have made the task easier. This was necessary, however, because the Ugaritic and Hebrew corpora used by Snyder et al. (2010) are not

Model	τ	Accuracy
Hall and Klein (2010)	–	**90.3**
MATCHER	1.0	90.1

Table 1: Results on ROMANCE data set. Our system is labeled MATCHER. We compare against the phylogenetic cognate detection system of Hall and Klein (2010). We show the pairwise cognate accuracy across all pairs of languages from the following set: Spanish, Portuguese, and Italian.

comparable: only a small proportion of the words in the Ugaritic lexicon have cognates in the lexicon composed of the most frequent Hebrew words.

Here, the alphabets really are disjoint. The symbols in both languages look nothing alike. There is no obvious prior expectation about how the alphabets will be matched. We evaluate against a well-established correspondence between the alphabets of Ugaritic and Hebrew. The Ugaritic alphabet contains 30 characters, the Hebrew alphabet contains 22 characters, and the gold matching contains 33 entries. We evaluate the learned alphabet matching by counting the number of recovered entries from the gold matching.

Due to the size of the source and target lexicons, we again use the greedy competitive linking algorithm in place of the exact Hungarian algorithm in experiments on this data set.

5 Results

We present results on all four datasets ROMANCE, PARTIALROMANCE, EUROPARL, and UGARITIC. On the ROMANCE and PARTIALROMANCE data sets we compare against the numbers published by Hall and Klein (2010). We ran an implementation of the orthographic system presented by Haghighi et al. (2008) on our EUROPARL data set. We compare against the numbers published by Snyder et al. (2010) on the UGARITIC data set. We refer to our system as MATCHER in result tables and discussion.

5.1 ROMANCE

The results of running our system, MATCHER, on the ROMANCE data set are shown in Table 1. We recover 88.9% of the correct cognate mappings on the pair Spanish and Italian, 85.7% on Italian and Portuguese, and 95.6% on Spanish and Portuguese.

Model	τ	Precision	Recall	F1
Hall and Klein (2010)	–	66.9	**82.0**	73.6
MATCHER	0.25	**99.7**	34.0	50.7
	0.50	93.8	60.2	73.3
	0.75	81.1	78.0	**79.5**

Table 2: Results on PARTIALROMANCE data set. Our system is labeled MATCHER. We compare against the phylogenetic cognate detection system of Hall and Klein (2010). We show the pairwise cognate precision, recall, and F1 across all pairs of languages from the following set: Spanish, Portuguese, and Italian. Note that approximately 75% of the source words in each of the source lexicons have cognates in each of the target lexicons.

Our average accuracy across all pairs of languages is 90.1%. The phylogenetic system of Hall and Klein (2010) achieves an average accuracy of 90.3% across all pairs of languages. Our system achieves accuracy comparable to that of the phylogenetic system, despite the fact that the phylogenetic system is substantially more complex and makes use of an informed prior on alphabet correspondences.

The alphabet matching learned by our system is interesting to analyze. For the pairing of Spanish and Portuguese it recovers phonetic correspondences that are well known. Our system learns the correct cognate pairing of Spanish /bino/ to Portuguese /vinu/. This pair exemplifies two common phonetic correspondences for Spanish and Portuguese: the Spanish /o/ often transforms to a /u/ in Portuguese, and Spanish /b/ often transforms to /v/ in Portuguese. Our system, which allows many-to-many alphabet correspondences, correctly identifies the mappings /o/ $\rightarrow$ /u/ and /b/ $\rightarrow$ /v/ as well as the identity mappings /o/ $\rightarrow$ /o/ and /b/ $\rightarrow$ /b/ which are also common.

5.2 PARTIALROMANCE

In Table 2 we present the results of running our system on the PARTIALROMANCE data set. In this data set, only approximately 75% of the source words in each of the source lexicons have cognates in each of the target lexicons. The parameter τ trades off precision and recall. We show results for three different settings of τ: 0.25, 0.5, and 0.75.

Our system achieves an average precision across language pairs of 99.7% at an average recall of 34.0%. For the pairs Italian – Portuguese, and Span-

Model	Seed	τ	Precision	Recall	F1
Haghighi et al. (2008)	20	0.1	72.0	14.0	23.5
	20	0.25	63.6	31.0	41.7
	20	0.5	44.8	43.7	44.2
	50	0.1	90.5	17.6	29.5
	50	0.25	75.4	36.7	49.4
	50	0.5	56.4	55.0	55.7
MATCHER	0	0.1	**93.5**	18.2	30.5
	0	0.25	83.2	40.5	54.5
	0	0.5	56.5	**55.1**	**55.8**

Table 3: Results on EUROPARL data set. Our system is labeled MATCHER. We compare against the bilingual lexicon induction system of Haghighi et al. (2008). We show the cognate precision, recall, and F1 for the pair of languages English and Spanish using lexicons extracted from corpora. Note that approximately 50% of the words in the English lexicon have cognates in the Spanish lexicon.

ish – Portuguese, our system achieves prefect precision at recalls of 32.2% and 38.1% respectively. The best average F1 achieved by our system is 79.5%, which surpasses the average F1 of 73.6 achieved by the phylogenetic system of Hall and Klein (2010).

The phylogenetic system observes the phylogenetic tree of ancestry for the three languages and explicitly models cognate evolution and survival in a 'survival' tree. One might expect the phylogenetic system to achieve better results on this data set where part of the task is identifying which words do not have cognates. It is surprising that our model does so well given its simplicity.

5.3 EUROPARL

Table 3 presents results for our system on the EUROPARL data set across three different settings of τ: 0.1, 0.25, and 0.5. We compare against the orthographic system presented by Haghighi et al. (2008), across the same three settings of τ, and with two different sizes of seed lexicon: 20 and 50. In this data set, only approximately 50% of the source words have cognates in the target lexicon.

Our system achieves a precision of 93.5% at a recall of 18.2%, and a best F1 of 55.0%. Using a seed matching of 50 word pairs, the orthographic system of Haghighi et al. (2008) achieves a best F1 of 55.7%. Using a seed matching of 20 word pairs, it achieves a best F1 of 44.2%. Our system outperforms the orthographic system even though the orthographic system makes use of important additional information: a seed matching of correct cognate pairs. The results show that as the size of this seed is decreased, the performance of the orthographic system degrades.

Model	τ	Lexicon Acc.	Alphabet Acc.
Snyder et al. (2010)	–	60.4*	**29/33***
MATCHER	1.0	**90.4**	28/33

Table 4: Results on UGARITIC data set. Our system is labeled MATCHER. We compare against the decipherment system of Snyder et al. (2010). *Note that results for this system are on a somewhat different task. In particular, the MATCHER system assumes the inventories of cognates in both Hebrew and Ugaritic are known, while the system of Snyder et al. (2010) *reconstructs* cognates assuming only that the morphology of Hebrew is known, which is a harder task. We show cognate pair identification accuracy and alphabet matching accuracy for Ugaritic and Hebrew.

5.4 UGARITIC

In Table 4 we present results on the UGARITIC data set. We evaluate both accuracy of the lexicon matching learned by our system, and the accuracy of the alphabet matching. Our system achieves a lexicon accuracy of 90.4% while correctly identifying 28 out the 33 gold character mappings.

We also present the results for the decipherment model of Snyder et al. (2010) in Table 4. Note that while the evaluation data sets for our two models are the same, the tasks are very different. In particular, our system assumes the inventories of cognates in both Hebrew and Ugaritic are known, while the system of Snyder et al. (2010) reconstructs cognates assuming only that the morphology of Hebrew is known, which is a harder task. Even so, the results show that our system is effective at decipherment when semantically similar lexicons are available.

6 Conclusion

We have presented a simple combinatorial model that simultaneously incorporates both a matching between alphabets and a matching between lexicons. Our system is effective at both the tasks of cognate identification and alphabet decipherment, requiring only lists of words in both languages as input.

Abstract

In this paper, we consider the problem of unsupervised morphological analysis from a new angle. Past work has endeavored to design unsupervised learning methods which explicitly or implicitly encode inductive biases appropriate to the task at hand. We propose instead to treat morphological analysis as a structured prediction problem, where languages with labeled data serve as training examples for unlabeled languages, without the assumption of parallel data. We define a universal morphological feature space in which every language and its morphological analysis reside. We develop a novel structured nearest neighbor prediction method which seeks to find the morphological analysis for each unlabeled language which lies as close as possible in the feature space to a training language. We apply our model to eight inflecting languages, and induce nominal morphology with substantially higher accuracy than a traditional, MDL-based approach. Our analysis indicates that accuracy continues to improve substantially as the number of training languages increases.

1 Introduction

Over the past several decades, researchers in the natural language processing community have focused most of their efforts on developing text processing tools and techniques for English (Bender, 2009), a morphologically simple language. Recently, increasing attention has been paid to the wide variety of other languages of the world. Most of these languages still pose severe difficulties, due to (i) their lack of annotated textual data, and (ii) the fact that they exhibit linguistic structure not found in English, and are thus not immediately susceptible to many traditional NLP techniques.

Consider the example of nominal part-of-speech analysis. The Penn Treebank defines only four English noun tags (Marcus et al., 1994), and as a result, it is easy to treat the words bearing these tags as completely distinct word classes, with no internal morphological structure. In contrast, a comparable tagset for Hungarian includes 154 distinct noun tags (Erjavec, 2004), reflecting Hungarian's rich inflectional morphology. When dealing with such languages, treating words as atoms leads to severe data sparsity problems.

Because annotated resources do not exist for most morphologically rich languages, prior research has focused on unsupervised methods, with a focus on developing appropriate inductive biases. However, inductive biases and declarative knowledge are notoriously difficult to encode in well-founded models. Even putting aside this practical matter, a universally correct inductive bias, if there is one, is unlikely to be be discovered by *a priori* reasoning alone.

In this paper, we argue that languages for which we *have* gold-standard morphological analyses can be used as effective guides for languages *lacking* such resources. In other words, instead of treating each language's morphological analysis as a *de novo* induction problem to be solved with a purely hand-coded bias, we instead learn from our labeled languages what linguistically plausible morphological analyses looks like, and guide our analysis in this direction.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 322–332,
Edinburgh, Scotland, UK, July 27–31, 2011.

More formally, we recast morphological induction as a new kind of supervised structured prediction problem, where each annotated language serves as a single training example. Each language's noun lexicon serves as a single input x, and the analysis of the nouns into stems and suffixes serves as a complex structured label y.

Our first step is to define a universal morphological feature space, into which each language and its morphological analysis can be mapped. We opt for a simple and intuitive mapping, which measures the sizes of the stem and suffix lexicons, the entropy of these lexicons, and the fraction of word forms which appear without any inflection.

Because languages tend to cluster into well defined morphological groups, we cast our learning and prediction problem in the nearest neighbor framework (Cover and Hart, 1967). In contrast to its typical use in classification problems, where one can simply pick the label of the nearest training example, we are here faced with a structured prediction problem, where locations in feature space depend jointly on the input-label pair (x, y). Finding a nearest neighbor thus consists of *searching* over the space of morphological analyses, until a point in feature space is reached which lies closest to one of the labeled languages. See Figure 1 for an illustration.

To provide a measure of empirical validation, we applied our approach to eight languages with inflectional nominal morphology, ranging in complexity from very simple (English) to very complex (Hungarian). In all but one case, our approach yields substantial improvements over a comparable monolingual baseline (Goldsmith, 2005), which uses the minimum description length principle (MDL) as its inductive bias. On average, our method increases accuracy by 11.8 percentage points, corresponding to a 42% decrease in error relative to a supervised upper bound. Further analysis indicates that accuracy improves as the number of training languages increases.

2 Related Work

In this section, we briefly review prior work on unsupervised morphological induction, as well as multilingual analysis in NLP.

Unsupervised Morphological Induction: Unsupervised morphology remains an active area of research (Schone and Jurafsky, 2001; Goldsmith, 2005; Adler and Elhadad, 2006; Creutz and Lagus, 2005; Dasgupta and Ng, 2007; Creutz and Lagus, 2007; Poon et al., 2009). Many existing algorithms derive morpheme lexicons by identifying recurring patterns in words. The goal is to optimize the compactness of the data representation by finding a small lexicon of highly frequent strings, resulting in a *minimum description length* (MDL) lexicon and corpus (Goldsmith, 2001; Goldsmith, 2005). Later work cast this idea in a probabilistic framework in which the the MDL solution is equivalent to a MAP estimate in a suitable Bayesian model (Creutz and Lagus, 2005). In all these approaches, a locally optimal segmentation is identified using a task-specific greedy search.

Multilingual Analysis: An influential line of prior multilingual work starts with the observation that rich linguistic resources exist for some languages but not others. The idea then is to *project* linguistic information from one language onto others via parallel data. Yarowsky and his collaborators first developed this idea and applied it to the problems of part-of-speech tagging, noun-phrase bracketing, and morphology induction (Yarowsky and Wicentowski, 2000; Yarowsky et al., 2000; Yarowsky and Ngai, 2001), and other researchers have applied the idea to syntactic and semantic analysis (Hwa et al., 2005; Padó and Lapata, 2006) In these cases, the existence of a bilingual parallel text along with highly accurate predictions for one of the languages was assumed.

Another line of work assumes the existence of bilingual parallel texts without the use of any supervision (Dagan et al., 1991; Resnik and Yarowsky, 1997). This idea has been developed and applied to a wide variety tasks, including morphological analysis (Snyder and Barzilay, 2008b; Snyder and Barzilay, 2008a), part-of-speech induction (Snyder et al., 2008; Snyder et al., 2009b; Naseem et al., 2009), and grammar induction (Snyder et al., 2009a; Blunsom et al., 2009; Burkett et al., 2010). An even more recent line of work does away with the assumption of parallel texts and performs joint unsupervised induction for various languages through the use of coupled priors in the context of grammar in-

duction (Cohen and Smith, 2009; Berg-Kirkpatrick and Klein, 2010).

In contrast to these previous approaches, the method proposed in this paper does *not* assume the existence of any parallel text, but *does* assume that labeled data exists for a wide variety of languages, to be used as training examples for our test language.

3 Structured Nearest Neighbor

We reformulate morphological induction as a *supervised* learning task, where each annotated language serves as a single training example for our language-independent model. Each such example consists of an input-label pair (x, y), both of which contain complex internal structure: The input $x \in \mathcal{X}$ consists of a vocabulary list of all words observed in a particular monolingual corpus, and the label $y \in \mathcal{Y}$ consists of the correct morphological analysis of all the vocabulary items in x.[1] Because our goal is to generalize across languages, we define a feature function which maps each (x, y) pair to a universal feature space: $\mathbf{f} : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}^d$.

For each unlabeled input language x, our goal is to predict a complete morphological analysis $y \in \mathcal{Y}$ which maximizes a scoring function on the feature space, $score : \mathbb{R}^d \rightarrow \mathbb{R}$. This scoring function is trained using the n labeled-language examples: $(x, y)_1, \ldots, (x, y)_n$, and the resulting prediction rule for unlabeled input x is given by:

$$y^* = \underset{y \in \mathcal{Y}}{\operatorname{argmax}}\, score\big(\mathbf{f}(x, y)\big)$$

Languages can be typologically categorized by the type and richness of their morphology. On the assumption that for each test language, at least one typologically similar language will be present in the training set, we employ a *nearest neighbor* scoring function. In the standard nearest neighbor classification setting, one simply predicts the label of the closest training example in the input space.[2] In our structured prediction setting, the mapping to the universal feature space depends crucially on the structure of the proposed label y, not simply the input x. We thus generalize nearest-neighbor prediction to the structured scenario and propose the following prediction rule:

$$y^* = \underset{y \in \mathcal{Y}}{\operatorname{argmin}} \min_{\ell} \parallel \mathbf{f}(x, y) - \mathbf{f}(x_\ell, y_\ell) \parallel, \quad (1)$$

where the index ℓ ranges over the training languages. In words, we predict the morphological analysis y for our test language which places it as close as possible in the universal feature space to one of the training languages ℓ.

Morphological Analysis: In this paper we focus on nominal inflectional suffix morphology. Consider the word *utiskom* in Serbian, meaning *impression* with the instrumental case marking. A correct analysis of this word would divide it into a stem (*utisak* = *impression*), a suffix (*-om* = instrumental case), and a phonological deletion rule on the stem's penultimate vowel ($..ak\# \rightarrow ..k\#$).

More generally, as we define it, a morphological analysis of a word type w consists of (i) a stem t, (ii), a suffix f, and (iii) a deletion rule d. Either or both of the suffix and deletion rule can be $NULL$. We allow three types of deletion rules on stems: deletion of final vowels ($..V\# \rightarrow ..\#$), deletion of penultimate vowels ($..VC\# \rightarrow ..C\#$), and removals and additions of final accent marks (e.g. $..\tilde{a}\# \rightarrow ..a\#$). We require that stems be at least three characters long and that suffixes be no more than four. And, of course, we require that after (1) applying deletion rule d to stem t, and (2) adding suffix f to the result, we obtain word w.

Universal Feature Space: We employ a fairly simple and minimal set of features, all of which could plausibly generalize across a wide range of languages. Consider the set of stems T, suffixes F, and deletion rules D, induced by the morphological analyses y of the words x. Our first three features simply count the sizes of these three sets.

These counting features consider only the raw number of unique morphemes (and phonological rules) being used, but not their individual frequency or distribution. Our next set of features considers the empirical *entropy* of these occurrences as distributed across the lexicon of words x by analysis y.

[1] Technically, the label space of each input, $\mathcal{Y}$, should be thought of as a function of the input x. We suppress this dependence for notational clarity.

[2] More generally the majority label of the k-nearest neighbors.

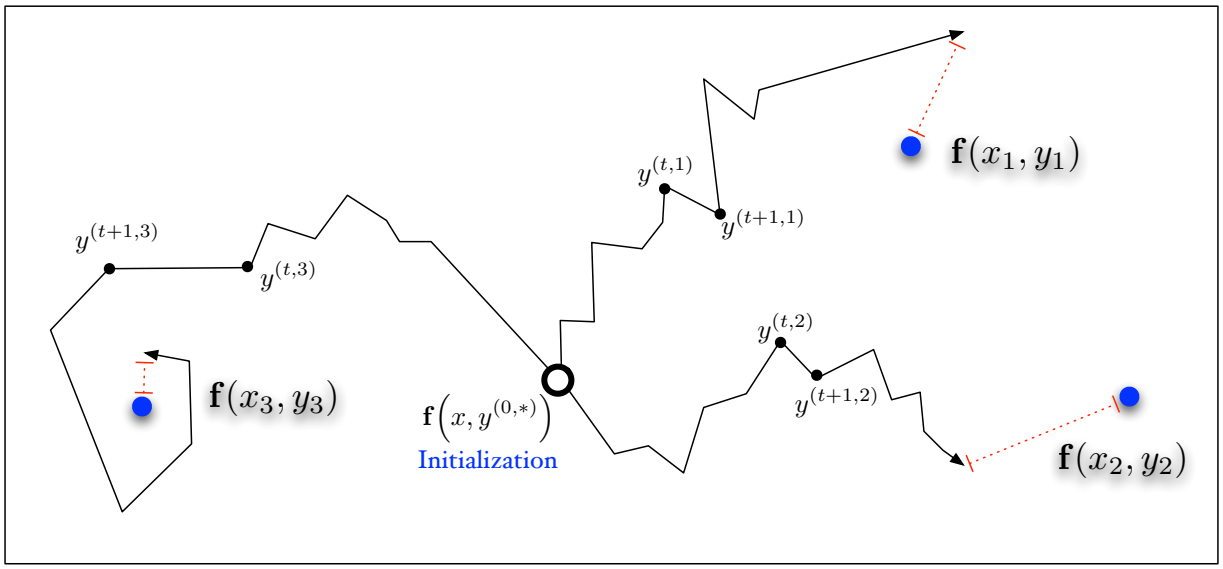

Figure 1: **Structured Nearest Neighbor Search:** The inference procedure for unlabeled test language x, when trained with three labeled languages, $(x_1, y_1), (x_2, y_2), (x_3, y_3)$. Our search procedure iteratively attempts to find labels for x which are as close as possible in feature space to each of the training languages. After convergence, the label which is closest in distance to a training language is predicted, in this case being the label near training language (x_3, y_3).

For example, if the (x, y) pair consists of the analyzed words {*kiss, kiss-es, hug*}, then the empirical distributions over stems, suffixes, and deletion rules would be:

- $P(t = kiss) = 2/3$
- $P(t = hug) = 1/3$
- $P(f = NULL) = 2/3$
- $P(f = -es) = 1/3$
- $P(d = NULL) = 1$

The three entropy features are defined as the shannon entropies of these stem, suffix, and deletion rule probabilities: $H(t), H(f), H(d)$.[3]

Finally, we consider two simple *percentage* features: the percentage of words in x which according to y are left unsegmented (i.e. have the null suffix, 2/3 in the example above), and the percentage of segmented words which employ a deletion rule (0 in the example above). Thus, in total, our model employs 8 universal morphological features. All features are scaled to the unit interval and are assumed to have equal weight.

[3]Note that here and throughout the paper, we operate over word types, ignoring their corpus frequencies.

3.1 Search Algorithm

The main algorithmic challenge for our model lies in efficiently computing the best morphological analysis y for each language-specific word set x, according to Equation 1. Exhaustive search through the set of all possible morphological analyses is impossible, as the number of such analyses grows exponentially in the size of the vocabulary. Instead, we develop a greedy search algorithm in the following fashion (the search procedure is visually depicted in Figure 1).

At each time-step t, we maintain a set of frontier analyses $\left\{y^{(t,\ell)}\right\}_\ell$, where ℓ ranges over the training languages. The goal is to iteratively modify each of these frontier analyses $y^{(t,\ell)} \rightarrow y^{(t+1,\ell)}$ so that the location of the training language in universal feature space — $\mathbf{f}\left(x, y^{(t+1,\ell)}\right)$ — is as close as possible to the location of the training language ℓ: $\mathbf{f}\left(x_\ell, y_\ell\right)$.

After iterating this procedure to convergence, we are left with a set of analyses $\left\{y^{(\ell)}\right\}_\ell$, each of which approximates the analyses which yield minimal distances to a particular training language:

$$y^{(\ell)} \approx \underset{y \in \mathcal{Y}}{\operatorname{argmin}} \parallel \mathbf{f}(x, y) - \mathbf{f}(x_\ell, y_\ell) \parallel .$$

We finally select from amongst these analyses and

make our prediction:

$$\ell^* = \operatorname*{argmin}_{\ell} \parallel \mathbf{f}(x, y^{(\ell)}) - \mathbf{f}(x_\ell, y_\ell) \parallel$$
$$y^* = y^{(\ell^*)}$$

The main outline of our search algorithm is based on the MDL-based greedy search heuristic developed and studied by (Goldsmith, 2005). At a high level, this search procedure alternates between individual analyses of words (keeping the set of stems and suffixes fixed), aggregate discoveries of new stems (keeping the suffixes fixed), and aggregate discoveries of new suffixes (keeping stems fixed). As input, we consider the test words x in our new language, and we run the search in parallel for each training language (x_ℓ, y_ℓ). For each such test-train language pair, the search consists of the following stages:

Stage 0: Initialization

We initially analyze each word $w \in x$ according to peaks in *successor frequency*.[4] If w's n-character prefix $w_{:n}$ has successor frequency > 1 and the surrounding prefixes, $w_{:n-1}$ and $w_{:n+1}$ both have successor frequency $= 1$, then we analyze w as a stem-suffix pair: $(w_{:n}, w_{n+1:})$.[5] Otherwise, we initialize w as an unsuffixed stem. As this procedure tends to produce an overly large set of suffixes F, we further prune F down to the number of suffixes found in the training language, retaining those which appear with the largest number of stems. This initialization stage is carried out once, and afterwards the following three stages are repeated until convergence.

Stage 1: Reanalyze each word

In this stage, we reanalyze each word (in random order). We use the set of stems T and suffixes F obtained from the previous stage, and don't permit the addition of any new items to these lists. Instead, we focus on obtaining better analyses of each word, while also building up a set of phonological deletion rules D. For each word $w \in x$, we consider all possible segmentations of w into a stem-suffix pair (t, f), for which $f \in F$, and where either $t \in T$ or some $t' \in T$ such that t is obtained from t' using a deletion rule d (e.g. by deleting a final or penultimate vowel). For each such possible analysis y', we compute the resulting location in feature space $\mathbf{f}(x, y')$, and select the analysis that brings us closest to our target training language: $y = \operatorname{argmin}_{y'} \parallel \mathbf{f}(x, y') - \mathbf{f}(x_\ell, y_\ell) \parallel$.

Stage 2: Find New Stems

In this stage, we keep our set of suffixes F and deletion rules D from the previous stage fixed, and attempt to find new stems to add to T through an aggregate analysis of unsegmented words. For every string s, we consider the set of words which are currently unsegmented, and can be analyzed as a stem-suffix pair (s, f) for some existing suffix $f \in F$, and some deletion rule $d \in D$. We then consider the joint segmentation of these words into a new stem s, and their respective suffixes. As before, we choose the segmentation if it brings us closer in feature space to our target training language.

Stage 3: Find New Suffixes

This stage is exactly analogous to the previous stage, except we now fix the set of stems T and seek to find new suffixes.

3.2 A Monolingual Supervised Model

In order to provide a plausible upper bound on performance, we also formulate a supervised monolingual morphological model, using the structured perceptron framework (Collins, 2002). Here we assume that we are given some training sequence of inputs and morphological analyses (all within one language): $(x_1, y_1), (x_2, y_2), \ldots, (x_n, y_n)$. We define each input x_i to be a noun w, along with a morphological tag z, which specifies the gender, case, and number of the noun. The goal is to predict the correct segmentation of w into stem, suffix, and phonological deletion rule: $y_i = (t, f, d)$.[6]

To do so, we define a feature function over input-label pairs, (x, y), with the following binary feature templates: (1) According to label y_i, the stem is t

[4] The *successor frequency* of a string prefix s is defined as the number of unique characters that occur immediately after s in the vocabulary.

[5] With the restriction that at this stage we only allow suffixes up to length 5, and stems of at least length 3.

[6] While the assumption of the correct morphological tag as input is somewhat unrealistic, this model still gives us a strong upper bound on how well we can expect our unsupervised model to perform.

	Type Counts				Entropy			Percentage	
	# words	# stems	# suffs	# dels	stem entropy	suff entropy	del entropy	unseg	deleted

Table 1: Corpus statistics for the eight languages. The first four columns give the number of unique word, stem, suffix, and phonological deletion rule types. The next three columns give, respectively, the entropies of the distributions of stems, suffixes (including $NULL$), and deletion rules (including $NULL$) over word types. The final two columns give, respectively, the percentage of word types occurring with the $NULL$ suffix, and the number of non-$NULL$ suffix words which use a phonological deletion rule. Note that the final eight columns define the universal feature space used by our model. BG = Bulgarian, CS = Czech, EN = English, ET = Estonian, HU = Hungarian, RO = Romanian, SL = Slovene, SR = Serbian

(one feature for each possible stem). (2) According to label y_i, the suffix and deletion rule are (f, d) (one feature for every possible pair of deletion rules and suffixes). (3) According to label y_i and morphological tag z, the suffix, deletion rule, and gender are respectively (f, d, G). (4) According to label y_i and morphological tag z, the suffix, deletion rule, and case are (f, d, C). (5) According to label y_i and morphological tag z, the suffix, deletion rule, and number are (f, d, N).

We train a set of linear weights on our features using the averaged structured perceptron algorithm (Collins, 2002).

4 Experiments

In this section we turn to experimental findings to provide empirical support for our proposed framework.

Corpus: To test our cross-lingual model, we apply it to a morphologically analyzed corpus of eight languages (Erjavec, 2004). The corpus includes a roughly 100,000 word English text, Orwell's novel "Nineteen Eighty Four," and its translation into seven languages: Bulgarian, Czech, Estonian, Hungarian, Romanian, Slovene, and Serbian. All the words in the corpus are tagged with morphological stems and a detailed morpho-syntactic analysis. Although the texts are parallel, we note that parallelism is nowhere assumed nor exploited by our model. See Table 1 for a summary of relevant corpus statistics. As indicated in the table, the raw number of nominal word types varies quite a bit across the languages, almost doubling from 4,178 (English) to 8,051 (Hungarian). In contrast, the number of stems appearing within these words is relatively stable across languages, ranging from a minimum of 3,112 (Bulgarian) to a maximum of 3,746 (Hungarian), an increase of just 20%.

In contrast, the number of suffixes across the languages varies quite a bit. Hungarian and Estonian, both Uralic languages with very complex nominal morphology, use 231 and 141 nominal suffixes, respectively. Besides English, the remaining languages employ between 21 and 32 suffixes, and English is the outlier in the other direction, with just three nominal inflectional suffixes.

Baselines and Results: As our unsupervised monolingual baseline, we use the Linguistica program (Goldsmith, 2001; Goldsmith, 2005). We apply Linguistica's default settings, and run the "suffix prediction" option. Our model's search procedure closely mirrors the one used by Linguistica, with the crucial difference that instead of attempting to greedily minimize description length, our algorithm instead tries to find the analysis as close as possible in the universal feature space to that of another language.

To apply our model, we treat each of the eight

	Linguistica	Our Model						Supervised

Table 2: **Prediction accuracy** over word types for the Linguistica baseline, our cross-lingual model, and the monolingual supervised perceptron model. For our model, we provide both prediction accuracy and resulting distance to the training language in three different scenarios: (i) **Nearest Neighbor:** The training languages include all seven other languages in our data set, and the predictions with minimal distance to a training language are chosen (the nearest neighbor is indicated in parentheses). (ii) **Self (oracle):** Each language is trained to minimize the distance to its *own* gold-standard analysis. (iii) **Average:** The feature values of all seven training languages are averaged together to create a single objective.

languages in turn as the test language, with the other seven serving as training examples. For each test language, we iterate the search procedure for each training language (performed in parallel), until convergence. The number of required iterations varies from 6 to 36 (depending on the test-training language pair), and each iteration takes no more than 30 seconds of run-time on a 2.4GHz Intel Xeon E5620 processor. We also consider two variants of our method. In the first (**Self (oracle)**), we train each test language to minimize the distance to its *own* gold standard feature values. In the second variant (**Avg.**), we average the feature values of all seven training languages into a single objective. As a plausible upper bound on performance, we implemented the structured perceptron described in Section 3.2. For each language, we train the perceptron on a randomly selected set of 80% of the nouns, and test on the remaining 20%.

The prediction accuracy for all models is calculated as the fraction of word types with correctly predicted suffixes. See Table 2 for the results. For all languages other than English (which is a morphological loner in our group of languages), our model improves over the baseline by a substantial margin, yielding an average increase of 11.8 absolute percentage points, and a reduction in error relative to the supervised upper bound of 42%. Some of the most striking improvements are seen on Serbian and Slovene. These languages are closely related to one another, and indeed our model discovers that they are each others' nearest neighbors. By guiding their morphological analyses towards one another, our model achieves a 21 percentage point increase in the case of Slovene and a 15 percentage point increase in the case of Slovene.

Perhaps unsurprisingly, when each language's gold standard feature values are used as its *own* target (**Self (oracle)** in Table 2), performance increases even further, to an average of 81.1%. By the same token, the resulting distance in universal feature space between training and test analyses is cut in half under this variant, when compared to the non-oracular nearest neighbor method. The remaining errors may be due to limitations of the search procedure (i.e. getting caught in local minima), or to the coarseness of the feature space (i.e. incorrect analyses might map to the same feature values as the correct analysis). Finally, we note that minimizing the distance to the *average* feature values of the seven training languages (**Avg.** in Table 2) yields subpar performance and very large distances between between predicted analyses and target feature values (4.14 compared to 0.40 for nearest neighbor). This

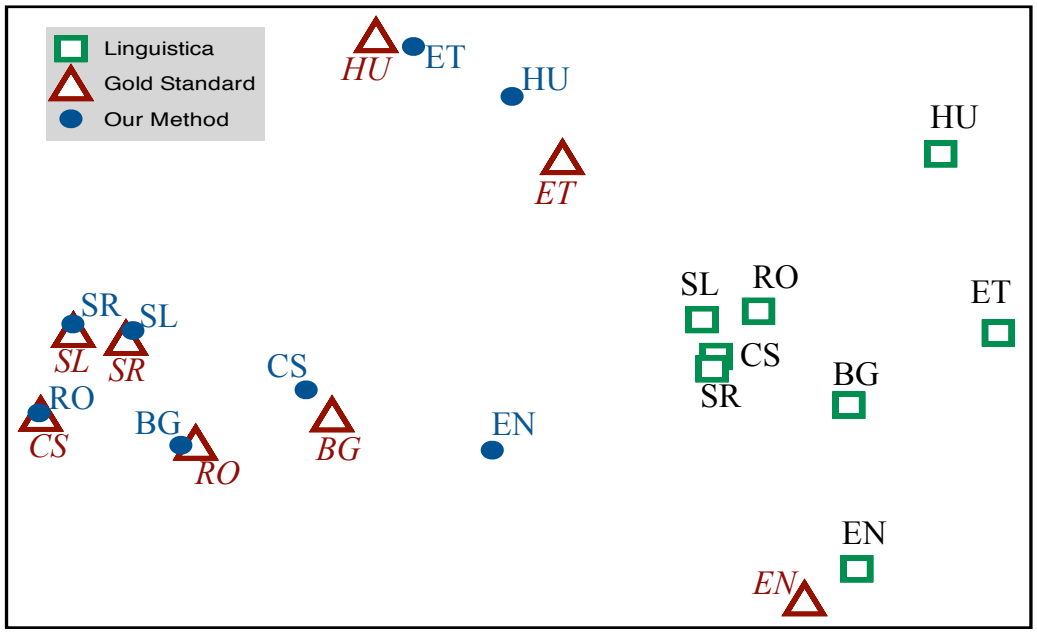

Figure 2: **Locations in Feature Space** of Linguistica predictions (green squares), gold standard analyses (red triangles), and our model's nearest neighbor predictions (blue circles). The original 8-dimensional feature space was reduced to two dimensions using Multidimensional Scaling.

result may indicate that the average feature point between training languages is simply unattainable as an analysis of a real lexicon of nouns.

Visualizing Locations in Feature Space: Besides assessing our method quantitatively, we can also visualize the the eight languages in universal feature space according to (i) their gold standard analyses, (ii) the predictions of our model and (iii) the predictions of Linguistica. To do so, we reduce the 8-dimensional features space down to two dimensions while preserving the distances between the predicted and gold standard feature vectors, using Multidimensional Scaling (MDS). The results of this analysis are shown in Figure 2. With the exception of English, our model's analyses lie closer in feature space to their gold standard counterparts than those of the baseline. It is interesting to note that Serbian and Slovene, which are very similar languages, have essentially swapped places under our model's analysis, as have Estonian and Hungarian (both highly inflected Uralic languages). English has (unfortunately) been pulled towards Bulgarian, the second least inflecting language in our set.

Learning Curves: We also measured the performance of our method as a function of the number of languages in the training set. For each target language, we consider all possible training sets of sizes ranging from 1 to 7 and select the predictions which bring our test language closest in distance to one of the languages in the set. We then average the resulting accuracy over all training sets of each size. Figure 3 shows the resulting learning curves averaged over all test languages (left), as well as broken down by test language (right). The overall trend is clear: as additional languages are added to the training set, test performance improves. In fact, with only one training language, our method performs worse (on average) than the Linguistica baseline. However, with two or more training languages available, our method achieves superior results.

Accuracy vs. Distance: We can gain some insight into these learning curves if we consider the relationship between accuracy (of the test language analysis) and distance to the training language (of the same predicted analysis). The more training languages available, the greater the chance that we can guide our test language into very close proximity to

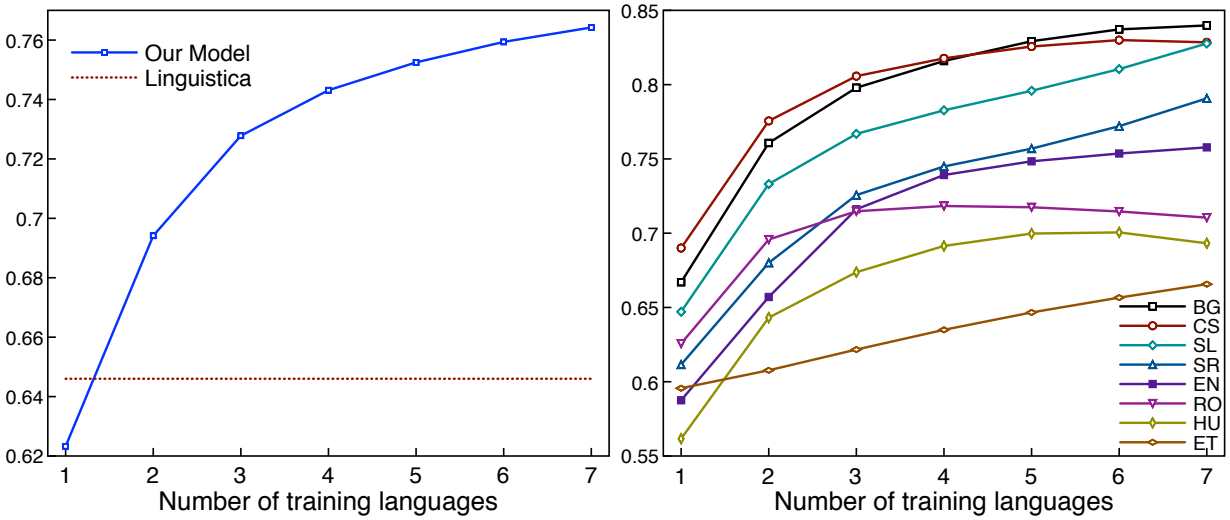

Figure 3: **Learning curves** for our model as the number of training languages increases. The figure on the left shows the average accuracy of all eight languages for increasingly larger training sets (results are averaged over all training sets of size 1,2,3,...). The dotted line indicates the average performance of the baseline. The figure on the right shows similar learning curves, broken down individually for each test language (see Figure 1 for language abbreviations).

one of them. It thus stands to reason that a strong (negative) correlation between distance and accuracy would lead to increased accuracy with larger training sets. In order to assess this correlation, we considered all 56 test-train language pairs and collected the resulting accuracy and distance for each pair. We separately scaled accuracy and distance to the unit interval for each test language (as some test languages are inherently more difficult than others). The resulting plot, shown in Figure 4, shows the expected correlation: When our test language can be guided very closely to the training language, the resulting predictions are likely to be good. If not, the predictions are likely to be bad.

5 Conclusions and Future Work

The approach presented in this paper recasts morphological induction as a structured prediction task. We assume the presence of morphologically labeled languages as *training examples* which guide the induction process for unlabeled test languages. We developed a novel structured nearest neighbor approach for this task, in which all languages and their morphological analyses lie in a universal feature space. The task of the learner is to search through the space of morphological analyses for the test language and return the result which lies closest to one

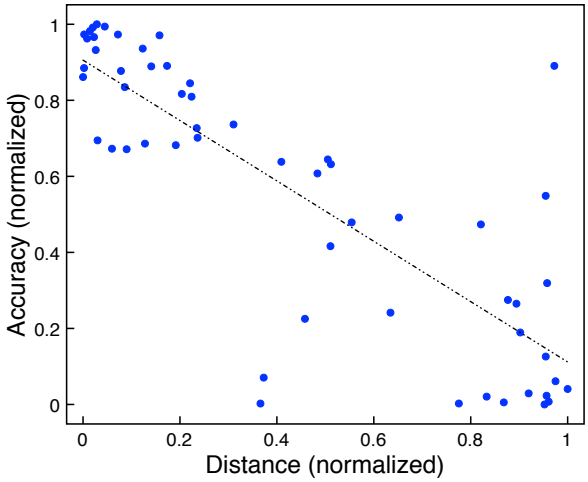

Figure 4: **Accuracy vs. Distance:** For all 56 possible test-train language pairs, we computed test accuracy along with resulting distance in universal feature space to the training language. Distance and accuracy are separately normalized to the unit interval for each test language, and all resulting points are plotted together. A line is fit to the points using least-squares regression.

of the training languages. Our empirical findings validate this approach: On a set of eight different languages, our method yields substantial accuracy gains over a traditional MDL-based approach in the task of nominal morphological induction.

One possible shortcoming of our approach is that it assumes a uniform weighting of the cross-lingual feature space. In fact, some features may be far more relevant than others in guiding our test language to an accurate analysis. In future work, we plan to integrate distance metric learning into our approach, allowing some features to be weighted more heavily than others. Besides potential gains in prediction accuracy, this approach may shed light on deeper relationships between languages than are otherwise apparent.

Training a Log-Linear Parser with Loss Functions via Softmax-Margin

Abstract

Log-linear parsing models are often trained by optimizing likelihood, but we would prefer to optimise for a task-specific metric like F-measure. Softmax-margin is a convex objective for such models that minimises a bound on expected risk for a given loss function, but its naïve application requires the loss to decompose over the predicted structure, which is not true of F-measure. We use softmax-margin to optimise a log-linear CCG parser for a variety of loss functions, and demonstrate a novel dynamic programming algorithm that enables us to use it with F-measure, leading to substantial gains in accuracy on CCGBank. When we embed our loss-trained parser into a larger model that includes supertagging features incorporated via belief propagation, we obtain further improvements and achieve a labelled/unlabelled dependency F-measure of 89.3%/94.0% on gold part-of-speech tags, and 87.2%/92.8% on automatic part-of-speech tags, the best reported results for this task.

1 Introduction

Parsing models based on Conditional Random Fields (CRFs; Lafferty et al., 2001) have been very successful (Clark and Curran, 2007; Finkel et al., 2008). In practice, they are usually trained by maximising the conditional log-likelihood (CLL) of the training data. However, it is widely appreciated that optimizing for task-specific metrics often leads to better performance on those tasks (Goodman, 1996; Och, 2003).

An especially attractive means of accomplishing this for CRFs is the softmax-margin (SMM) objective (Sha and Saul, 2006; Povey and Woodland, 2008; Gimpel and Smith, 2010a) (§2). In addition to retaining a probabilistic interpretation and optimizing towards a loss function, it is also convex, making it straightforward to optimise. Gimpel and Smith (2010a) show that it can be easily implemented with a simple change to standard likelihood-based training, provided that the loss function decomposes over the predicted structure.

Unfortunately, the widely-used F-measure metric does not decompose over parses. To solve this, we introduce a novel dynamic programming algorithm that enables us to compute the exact quantities needed under the softmax-margin objective using F-measure as a loss (§3). We experiment with this and several other metrics, including precision, recall, and decomposable approximations thereof. Our ability to optimise towards exact metrics enables us to verify the effectiveness of more efficient approximations. We test the training procedures on the state-of-the-art Combinatory Categorial Grammar (CCG; Steedman 2000) parser of Clark and Curran (2007), obtaining substantial improvements under a variety of conditions. We then embed this model into a more accurate model that incorporates additional supertagging features via loopy belief propagation. The improvements are additive, obtaining the best reported results on this task (§4).

2 Softmax-Margin Training

The softmax-margin objective modifies the standard likelihood objective for CRF training by reweighting

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 333–343,
Edinburgh, Scotland, UK, July 27–31, 2011.

each possible outcome of a training input according to its *risk*, which is simply the loss incurred on a particular example. This is done by incorporating the loss function directly into the linear scoring function of an individual example.

Formally, we are given m training pairs $(x^{(1)}, y^{(1)})...(x^{(m)}, y^{(m)})$, where each $x^{(i)} \in \mathcal{X}$ is drawn from the set of possible inputs, and each $y^{(i)} \in \mathcal{Y}(x^{(i)})$ is drawn from a set of possible instance-specific outputs. We want to learn the K parameters θ of a log-linear model, where each $\lambda_k \in \theta$ is the weight of an associated feature $h_k(x, y)$. Function $f(x, y)$ maps input/output pairs to the vector $h_1(x, y)...h_K(x, y)$, and our log-linear model assigns probabilities in the usual way.

$$p(y|x) = \frac{\exp\{\theta^\mathsf{T} f(x, y)\}}{\sum_{y' \in \mathcal{Y}(x)} \exp\{\theta^\mathsf{T} f(x, y')\}} \quad (1)$$

The conditional log-likelihood objective function is given by Eq. 2 (Figure 1). Now consider a function $\ell(y, y')$ that returns the loss incurred by choosing to output y' when the correct output is y. The softmax-margin objective simply modifies the unnormalised, unexponentiated score $\theta^\mathsf{T} f(x, y')$ by adding $\ell(y, y')$ to it. This yields the objective function (Eq. 3) and gradient computation (Eq. 4) shown in Figure 1.

This straightforward extension has several desirable properties. In addition to having a probabilistic interpretation, it is related to maximum margin and minimum-risk frameworks, it can be shown to minimise a bound on expected risk, and it is convex (Gimpel and Smith, 2010b).

We can also see from Eq. 4 that the only difference from standard CLL training is that we must compute feature expectations with respect to the cost-augmented scoring function. As Gimpel and Smith (2010a) discuss, if the loss function decomposes over the predicted structure, we can treat its decomposed elements as unweighted features that fire on the corresponding structures, and compute expectations in the normal way. In the case of our parser, where we compute expectations using the inside-outside algorithm, a loss function decomposes if it decomposes over spans or productions of a CKY chart.

3 Loss Functions for Parsing

Ideally, we would like to optimise our parser towards a task-based evaluation. Our CCG parser is evaluated on labeled, directed dependency recovery using F-measure (Clark and Hockenmaier, 2002). Under this evaluation we will represent output y' and ground truth y as variable-sized sets of dependencies. We can then compute precision $P(y, y')$, recall $R(y, y')$, and F-measure $F_1(y, y')$.

$$P(y, y') = \frac{|y \cap y'|}{|y'|} \quad (5)$$

$$R(y, y') = \frac{|y \cap y'|}{|y|} \quad (6)$$

$$F_1(y, y') = \frac{2PR}{P + R} = \frac{2|y \cap y'|}{|y| + |y'|} \quad (7)$$

These metrics are positively correlated with performance – they are *gain* functions. To incorporate them in the softmax-margin framework we reformulate them as loss functions by subtracting from one.

3.1 Computing F-Measure-Augmented Expectations at the Sentence Level

Unfortunately, none of these metrics decompose over parses. However, the individual statistics that are used to compute them *do* decompose, a fact we will exploit to devise an algorithm that computes the necessary expectations. Note that since y is fixed, F_1 is a function of two integers: $|y \cap y'|$, representing the number of correct dependencies in y'; and $|y'|$, representing the total number of dependencies in y', which we will denote as n and d, respectively.[1] Each pair $\langle n, d \rangle$ leads to a different value of F_1. Importantly, both n and d decompose over parses.

The key idea will be to treat F_1 as a non-local feature of the parse, dependent on values n and d.[2] To compute expectations we split each span in an otherwise usual inside-outside computation by all pairs $\langle n, d \rangle$ incident at that span.

Formally, our goal will be to compute expectations over the sentence $a_1...a_L$. In order to abstract away from the particulars of CCG we present the algorithm in relatively familiar terms as a variant of

[1] For *numerator* and *denominator*.

[2] This is essentially the same trick used in the oracle F-measure algorithm of Huang (2008), and indeed our algorithm is a sum-product variant of that max-product algorithm.

$$\min_{\theta} \sum_{i=1}^{m} \left[-\theta^{\mathsf{T}} f(x^{(i)}, y^{(i)}) + \log \sum_{y \in \mathcal{Y}(x^{(i)})} \exp\{\theta^{\mathsf{T}} f(x^{(i)}, y)\} \right] \quad (2)$$

$$\min_{\theta} \sum_{i=1}^{m} \left[-\theta^{\mathsf{T}} f(x^{(i)}, y^{(i)}) + \log \sum_{y \in \mathcal{Y}(x^{(i)})} \exp\{\theta^{\mathsf{T}} f(x^{(i)}, y) + \ell(y^{(i)}, y)\} \right] \quad (3)$$

$$\frac{\partial}{\partial \lambda_k} = \sum_{i=1}^{m} \left[-h_k(x^{(i)}, y^{(i)}) + \sum_{y \in \mathcal{Y}(x^{(i)})} \frac{\exp\{\theta^{\mathsf{T}} f(x^{(i)}, y) + \ell(y^{(i)}, y)\}}{\sum_{y' \in \mathcal{Y}(x^{(i)})} \exp\{\theta^{\mathsf{T}} f(x^{(i)}, y') + \ell(y^{(i)}, y')\}} h_k(x^{(i)}, y) \right] \quad (4)$$

Figure 1: Conditional log-likelihood (Eq. 2), Softmax-margin objective (Eq. 3) and gradient (Eq. 4).

the classic inside-outside algorithm (Baker, 1979). We use the notation $a : A$ for lexical entries and $BC \Rightarrow A$ to indicate that categories B and C combine to form category A via forward or backward composition or application.[3] The weight of a rule is denoted with w. The classic algorithm associates inside score $I(A_{i,j})$ and outside score $O(A_{i,j})$ with category A spanning sentence positions i through j, computed via the following recursions.

$$\begin{aligned}
I(A_{i,i+1}) &= w(a_{i+1} : A) \\
I(A_{i,j}) &= \sum_{k,B,C} I(B_{i,k}) I(C_{k,j}) w(BC \Rightarrow A) \\
I(GOAL) &= I(S_{0,L}) \\
O(GOAL) &= 1 \\
O(A_{i,j}) &= \sum_{k,B,C} O(C_{i,k}) I(B_{j,k}) w(AB \Rightarrow C) + \\
&\quad \sum_{k,B,C} O(C_{k,j}) I(B_{k,i}) w(BA \Rightarrow C)
\end{aligned}$$

The expectation of A spanning positions i through j is then $I(A_{i,j})O(A_{i,j})/I(GOAL)$.

Our algorithm extends these computations to state-split items $A_{i,j,n,d}$.[4] Using functions $n_+(\cdot)$ and $d_+(\cdot)$ to respectively represent the number of correct and total dependencies introduced by a parsing action, we present our algorithm in Fig. 3. The final inside equation and initial outside equation incorporate the loss function for all derivations having a particular F-score, enabling us to obtain the desired expectations. A simple modification of the goal equations enables us to optimise precision, recall or a weighted F-measure.

To analyze the complexity of this algorithm, we must ask: how many pairs $\langle n, d \rangle$ can be incident at each span? A CCG parser does not necessarily return one dependency per word (see Figure 2 for an example), so d is not necessarily equal to the sentence length L as it might be in many dependency parsers, though it is still bounded by $\mathcal{O}(L)$. However, this behavior is sufficiently uncommon that we expect all parses of a sentence, good or bad, to have close to L dependencies, and hence we expect the range of d to be constant on average. Furthermore, n will be bounded from below by zero and from above by $\min(|y|, |y'|)$. Hence the set of all possible F-measures for all possible parses is bounded by $\mathcal{O}(L^2)$, but on average it should be closer to $\mathcal{O}(L)$. Following McAllester (1999), we can see from inspection of the free variables in Fig. 3 that the algorithm requires worst-case $\mathcal{O}(L^7)$ and average-case $\mathcal{O}(L^5)$ time complexity, and worse-case $\mathcal{O}(L^4)$ and average-case $\mathcal{O}(L^3)$ space complexity.

Note finally that while this algorithm computes exact sentence-level expectations, it is approximate at the corpus level, since F-measure does not decompose over sentences. We give the extension to exact corpus-level expectations in Appendix A.

3.2 Approximate Loss Functions

We will also consider approximate but more efficient alternatives to our exact algorithms. The idea is to use cost functions which only utilise statistics

[3] These correspond respectively to unary rules $A \rightarrow a$ and binary rules $A \rightarrow BC$ in a Chomsky normal form grammar.

[4] Here we use *state-splitting* to refer to splitting an item $A_{i,j}$ into many items $A_{i,j,n,d}$, one for each $\langle n, d \rangle$ pair.

$$I(A_{i,i+1,n,d}) = w(a_{i+1} : A) \quad \text{iff} n = n_+(a_{i+1} : A), d = d_+(a_{i+1} : A)$$

$$I(A_{i,j,n,d}) = \sum_{k,B,C} \sum_{\substack{\{n',n'':n'+n''+n_+(BC \Rightarrow A)=n\},\\ \{d',d'':d'+d''+d_+(BC \Rightarrow A)=d\}}} I(B_{i,k,n',d'})I(C_{k,j,n'',d''})w(BC \Rightarrow A)$$

$$I(GOAL) = \sum_{n,d} I(S_{0,L,n,d}) \left(1 - \frac{2n}{d + |y|}\right)$$

$$O(S_{0,N,n,d}) = \left(1 - \frac{2n}{d + |y|}\right)$$

$$O(A_{i,j,n,d}) = \sum_{k,B,C} \sum_{\substack{\{n',n'':n'-n''-n_+(AB \Rightarrow C)=n\},\\ \{d',d'':d'-d''-d_+(AB \Rightarrow C)=d\}}} O(C_{i,k,n',d'})I(B_{j,k,n'',d''})w(AB \Rightarrow C) +$$

$$\sum_{k,B,C} \sum_{\substack{\{n',n'':n'-n''-n_+(BA \Rightarrow C)=n\},\\ \{d',d'':d'-d''-d_+(BA \Rightarrow C)=d\}}} O(C_{k,j,n',d'})I(B_{k,i,n'',d''})w(BA \Rightarrow C)$$

Figure 3: State-split inside and outside recursions for computing softmax-margin with F-measure.

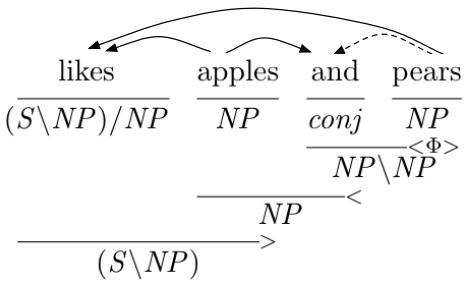

Figure 2: Example of flexible dependency realisation in CCG: Our parser (Clark and Curran, 2007) creates dependencies arising from coordination once all conjuncts are found and treats "and" as the syntactic head of coordinations. The coordination rule (Φ) does not yet establish the dependency "and - pears" (dotted line); it is the backward application ($<$) in the larger span, "apples and pears", that establishes it, together with "and - pears". CCG also deals with unbounded dependencies which potentially lead to more dependencies than words (Steedman, 2000); in this example a unification mechanism creates the dependencies "likes - apples" and "likes - pears" in the forward application ($>$). For further examples and a more detailed explanation of the mechanism as used in the C&C parser refer to Clark et al. (2002).

available within the current local structure, similar to those used by Taskar et al. (2004) for tracking constituent errors in a context-free parser. We design three simple losses to approximate precision, recall and F-measure on CCG dependency structures.

Let $T(y)$ be the set of parsing actions required to build parse y. Our decomposable approximation to precision simply counts the number of incorrect dependencies using the local dependency counts, $n_+(\cdot)$ and $d_+(\cdot)$.

$$DecP(y) = \sum_{t \in T(y)} d_+(t) - n_+(t) \qquad (8)$$

To compute our approximation to recall we require the number of gold dependencies, $c_+(\cdot)$, which should have been introduced by a particular parsing action. A gold dependency is due to be recovered by a parsing action if its head lies within one child span and its dependent within the other. This yields a decomposed approximation to recall that counts the number of missed dependencies.

$$DecR(y) = \sum_{t \in T(y)} c_+(t) - n_+(t) \qquad (9)$$

Unfortunately, the flexible handling of dependencies in CCG complicates our formulation of c_+, rendering it slightly more approximate. The unification mechanism of CCG sometimes causes dependencies to be realised later in the derivation, at a point when both the head and the dependent are in the same span, violating the assumption used to compute c_+ (see again Figure 2). Exceptions like this can cause mismatches between n_+ and c_+. We set $c_+ = n_+$ whenever $c_+ < n_+$ to account for these occasional discrepancies.

Finally, we obtain a decomposable approximation to F-measure.

$$DecF1(y) = DecP(y) + DecR(y) \qquad (10)$$

4 Experiments

Parsing Strategy. CCG parsers use a pipeline strategy: we first multitag each word of the sentence with a small subset of its possible lexical categories using a *supertagger*, a sequence model over these categories (Bangalore and Joshi, 1999; Clark, 2002). Then we parse the sentence under the requirement that the lexical categories are fixed to those preferred by the supertagger. In our experiments we used two variants on this strategy.

First is the *adaptive supertagging* (AST) approach of Clark and Curran (2004). It is based on a step function over supertagger beam widths, relaxing the pruning threshold for lexical categories only if the parser fails to find an analysis. The process either succeeds and returns a parse after some iteration or gives up after a predefined number of iterations. As Clark and Curran (2004) show, most sentences can be parsed with very tight beams.

Reverse adaptive supertagging is a much less aggressive method that seeks only to make sentences parsable when they otherwise would not be due to an impractically large search space. Reverse AST starts with a wide beam, narrowing it at each iteration only if a maximum chart size is exceeded. Table 1 shows beam settings for both strategies.

Adaptive supertagging aims for speed via pruning while the reverse strategy aims for accuracy by exposing the parser to a larger search space. Although Clark and Curran (2007) found no actual improvements from the latter strategy, we will show that with our softmax-margin-trained models it can have a substantial effect.

Parser. We use the C&C parser (Clark and Curran, 2007) and its supertagger (Clark, 2002). Our baseline is the hybrid model of Clark and Curran (2007), which contains features over both normal-form derivations and CCG dependencies. The parser relies solely on the supertagger for pruning, using exact CKY for search over the pruned space. Training requires calculation of feature expectations over packed charts of derivations. For training, we limited the number of items in this chart to 0.3 million, and for testing, 1 million. We also used a more permissive training supertagger beam (Table 2) than in previous work (Clark and Curran, 2007). Models were trained with the parser's L-BFGS trainer.

Evaluation. We evaluated on CCGbank (Hockenmaier and Steedman, 2007), a right-most normal-form CCG version of the Penn Treebank. We use sections 02-21 (39603 sentences) for training, section 00 (1913 sentences) for development and section 23 (2407 sentences) for testing. We supply gold-standard part-of-speech tags to the parsers. We evaluate on labelled and unlabelled predicate argument structure recovery and supertag accuracy.

4.1 Training with Maximum F-measure Parses

So far we discussed how to optimise towards task-specific metrics via changing the training objective. In our first experiment we change the *data* on which we optimise CLL. This is a kind of simple baseline to our later experiments, attempting to achieve the same effect by simpler means. Specifically, we use the algorithm of Huang (2008) to generate oracle F-measure parses for each sentence. Updating towards these oracle parses corrects the reachability problem in standard CLL training. Since the supertagger is used to prune the training forests, the correct parse is sometimes pruned away – reducing data utilisation to 91%. Clark and Curran (2007) correct for this by adding the gold tags to the parser input. While this increases data utilisation, it biases the model by training in an idealised setting not available at test time. Using oracle parses corrects this bias while permitting 99% data utilisation. The labelled F-score of the oracle parses lies at 98.1%. Though we expected that this might result in some improvement, results (Table 3) show that this has no

Condition	Parameter	Iteration 1	2	3	4	5
`AST`	β (beam width)	0.075	0.03	0.01	0.005	0.001
	k (dictionary cutoff)	20	20	20	20	150
`Reverse`	β	0.001	0.005	0.01	0.03	0.075
	k	150	20	20	20	20

Table 1: Beam step function used for standard (`AST`) and less aggressive (`Reverse`) AST throughout our experiments. Parameter β is a beam threshold while k bounds the number of lexical categories considered for each word.

Condition	Parameter	Iteration 1	2	3	4	5	6	7
`Training`	β	0.001	0.001	0.0045	0.0055	0.01	0.05	0.1

CCGbank+Max-F	87.45	87.96	86.94	93.09	93.63	92.55	99%

Table 3: Performance on section 00 of CCGbank when comparing models trained with treebank-parses (Baseline) and maximum F-score parses (Max-F) using adaptive supertagging as well as a combination of CCGbank and Max-F parses. Evaluation is based on labelled and unlabelled F-measure (LF/UF), precision (LP/UP) and recall (LR/UR).

effect. However, it does serve as a useful baseline.

4.2 Training with the Exact Algorithm

We first tested our assumptions about the feasibility of training with our exact algorithm by measuring the amount of state-splitting. Figure 4 plots the average number of splits per span against the relative span-frequency; this is based on a typical set of training forests containing over 600 million states. The number of splits increases exponentially with span size but equally so decreases the number of spans with many splits. Hence the small number of states with a high number of splits is balanced by a large number of spans with only a few splits: The highest number of splits per span observed with our settings was 4888 but we find that the average number of splits lies at 44. Encouragingly, this enables experimentation in all but very large scale settings.

Figure 5 shows the distribution of n and d pairs across all split-states in the training corpus; since

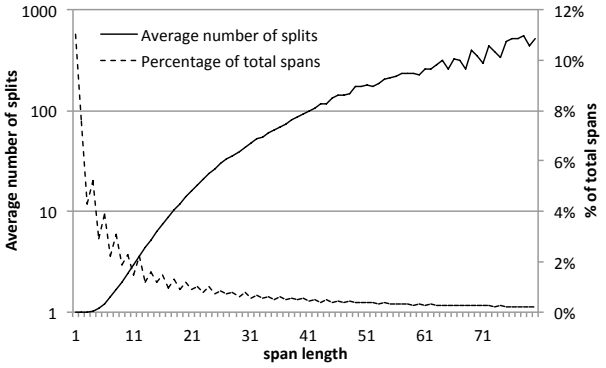

Figure 4: Average number of state-splits per span length as introduced by a sentence-level F-measure loss function. The statistics are averaged over the training forests generated using the settings described in §4.

n, the number of correct dependencies, over d, the number of all recovered dependencies, is precision, the graph shows that only a minority of states have either very high or very low precision. The range of values suggests that the softmax-margin criterion

will have an opportunity to substantially modify the expectations, hopefully to good effect.

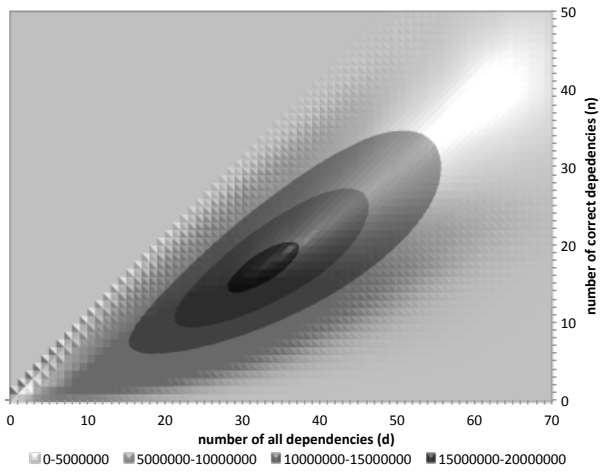

Figure 5: Distribution of states with d dependencies of which n are correct in the training forests.

We next turn to the question of optimization with these algorithms. Due to the significant computational requirements, we used the computationally less intensive normal-form model of Clark and Curran (2007) as well as their more restrictive training beam settings (Table 2). We train on all sentences of the training set as above and test with AST.

In order to provide greater control over the influence of the loss function, we introduce a multiplier τ, which simply amends the second term of the objective function (3) to:

$$\log \sum_{y \in Y(x^i)} \exp\{\theta^T f(x^i, y) + \tau \times \ell(y^i, y)\}$$

Figure 6 plots performance of the exact loss functions across different settings of τ on various evaluation criteria, for models restricted to at most 3000 items per chart at training time to allow rapid experimentation with a wide parameter set. Even in this constrained setting, it is encouraging to see that each loss function performs best on the criteria it optimises. The precision-trained parser also does very well on F-measure; this is because the parser has a tendency to perform better in terms of precision than recall.

4.3 Exact vs. Approximate Loss Functions

With these results in mind, we conducted a comparison of parsers trained using our exact and approximate loss functions. Table 4 compares their performance head to head when restricting training chart sizes to 100,000 items per sentence, the largest setting our computing resources allowed us to experiment with. The results confirm that the loss-trained models improve over a likelihood-trained baseline, and furthermore that the exact loss functions seem to have the best performance. However, the approximations are extremely competitive with their exact counterparts. Because they are also efficient, this makes them attractive for larger-scale experiments. Training time increases by an order of magnitude with exact loss functions despite increased theoretical complexity (§3.1); there is no significant change with approximate loss functions.

Table 5 shows performance of the approximate losses with the large scale settings initially outlined (§4). One striking result is that the softmax-margin trained models coax more accurate parses from the larger search space, in contrast to the likelihood-trained models. Our best loss model improves the labelled F-measure by over 0.8%.

4.4 Combination with Integrated Parsing and Supertagging

As a final experiment, we embed our loss-trained model into an integrated model that incorporates Markov features over supertags into the parsing model (Auli and Lopez, 2011). These features have serious implications on search: even allowing for the observation of Fowler and Penn (2010) that our CCG is weakly context-free, the search problem is equivalent to finding the optimal derivation in the weighted intersection of a regular and context-free language (Bar-Hillel et al., 1964), making search very expensive. Therefore parsing with this model requires approximations.

To experiment with this combined model we use loopy belief propagation (LBP; Pearl et al., 1985), previously applied to dependency parsing by Smith and Eisner (2008). A more detailed account of its application to our combined model can be found in (2011), but we sketch the idea here. We construct a graphical model with two factors: one is a distribu-

tion over supertag variables defined by a supertagging model, and the other is a distribution over these variables and a set of span variables defined by our parsing model.[5] The factors communicate by passing messages across the shared supertag variables that correspond to their marginal distributions over those variables. Hence, to compute approximate expectations across the entire model, we run forward-backward to obtain posterior supertag assignments. These marginals are passed as inside values to the inside-outside algorithm, which returns a new set of posteriors. The new posteriors are incorporated into a new iteration of forward-backward, and the algorithm iterates until convergence, or until a fixed number of iterations is reached – we found that a single iteration is sufficient, corresponding to a truncated version of the algorithm in which posteriors are simply passed from the supertagger to the parser. To decode, we use the posteriors in a minimum-risk parsing algorithm (Goodman, 1996).

Our baseline models are trained separately as before and combined at test time. For softmax-margin, we combine a parsing model trained with F1 and a supertagger trained with Hamming loss. Table 6 shows the results: we observe a gain of up to 1.5% in labelled F1 and 0.9% in unlabelled F1 on the test set. The loss functions prove their robustness by improving the more accurate combined models up to 0.4% in labelled F1. Table 7 shows results with automatic part-of-speech tags and a direct comparison with the Petrov parser trained on CCGbank (Fowler and Penn, 2010) which we outpeform on all metrics.

[5]These complex factors resemble those of Smith and Eisner (2008) and Dreyer and Eisner (2009); they can be thought of as case-factor diagrams (McAllester et al., 2008)

5 Conclusion and Future Work

The softmax-margin criterion is a simple and effective approach to training log-linear parsers. We have shown that it is possible to compute exact sentence-level losses under standard parsing metrics, not only approximations (Taskar et al., 2004). This enables us to show the effectiveness of these approximations, and it turns out that they are excellent substitutes for exact loss functions. Indeed, the approximate losses are as easy to use as standard conditional log-likelihood.

Empirically, softmax-margin training improves parsing performance across the board, beating the state-of-the-art CCG parsing model of Clark and Curran (2007) by up to 0.8% labelled F-measure. It also proves robust, improving a stronger baseline based on a combined parsing and supertagging model. Our final result of 89.3%/94.0% labelled and unlabelled F-measure is the best result reported for CCG parsing accuracy, beating the original C&C baseline by up to 1.5%.

In future work we plan to scale our exact loss functions to larger settings and to explore training with loss functions within loopy belief propagation. Although we have focused on CCG parsing in this work, we expect our methods to be equally applicable to parsing with other grammar formalisms including context-free grammar or LTAG.

A Computing F-Measure-Augmented Expectations at the Corpus Level

To compute exact corpus-level expectations for softmax-margin using F-measure, we add an additional transition before reaching the $GOAL$ item in our original program. To reach it, we must parse every sentence in the corpus, associating statistics of aggregate $\langle n, d\rangle$ pairs for the entire training set in intermediate symbols $\Gamma^{(1)}...\Gamma^{(m)}$ with the following inside recursions.

$$
\begin{aligned}
I(\Gamma^{(1)}_{n,d}) &= I(S^{(1)}_{0,|x(1)|,n,d}) \\
I(\Gamma^{(\ell)}_{n,d}) &= \sum_{n',n'':n'+n''=n} I(\Gamma^{(\ell-1)}_{n',d'}) I(S^{(\ell)}_{0,N,n'',d''}) \\
I(GOAL) &= \sum_{n,d} I(\Gamma^{(m)}_{n,d}) \left(1 - \frac{2n}{d+|y|}\right)
\end{aligned}
$$

Outside recursions follow straightforwardly. Implementation of this algorithm would require substantial distributed computation or external data structures, so we did not attempt it.

Large-Scale Cognate Recovery

David Hall and Dan Klein
Computer Science Division
University of California at Berkeley
{dlwh,klein}@cs.berkeley.edu

Abstract

We present a system for the large scale induction of cognate groups. Our model explains the evolution of cognates as a sequence of mutations and innovations along a phylogeny. On the task of identifying cognates from over 21,000 words in 218 different languages from the Oceanic language family, our model achieves a cluster purity score over 91%, while maintaining pairwise recall over 62%.

1 Introduction

The critical first step in the reconstruction of an ancient language is the recovery of related *cognate* words in its descendants. Unfortunately, this process has largely been a manual, linguistically-intensive undertaking for any sizable number of descendant languages. The traditional approach used by linguists—the comparative method—iterates between positing putative cognates and then identifying regular sound laws that explain correspondences between those words (Bloomfield, 1938).

Successful computational approaches have been developed for large-scale reconstruction of phylogenies (Ringe et al., 2002; Daumé III and Campbell, 2007; Daumé III, 2009; Nerbonne, 2010) and ancestral word forms of known cognate sets (Oakes, 2000; Bouchard-Côté et al., 2007; Bouchard-Côté et al., 2009), enabling linguists to explore deep historical relationships in an automated fashion. However, computational approaches thus far have not been able to offer the same kind of scale for identifying cognates. Previous work in cognate identification has largely focused on identifying cognates in pairs of languages (Mann and Yarowsky, 2001; Lowe and Mazaudon, 1994; Oakes, 2000; Kondrak, 2001; Mulloni, 2007), with a few recent exceptions that can find sets in a handful of languages (Bergsma and Kondrak, 2007; Hall and Klein, 2010).

While it may seem surprising that cognate detection has not successfully scaled to large numbers of languages, the task poses challenges not seen in reconstruction and phylogeny inference. For instance, morphological innovations and irregular sound changes can completely obscure relationships between words in different languages. However, in the case of reconstruction, an unexplainable word is simply that: one can still correctly reconstruct its ancestor using words from related languages.

In this paper, we present a system that uses two generative models for large-scale cognate identification. Both models describe the evolution of words along a phylogeny according to automatically learned sound laws in the form of parametric edit distances. The first is an adaptation of the generative model of Hall and Klein (2010), and the other is a new generative model called PARSIM with connections to parsimony methods in computational biology (Cavalli-Sforza and Edwards, 1965; Fitch, 1971). Our model supports simple, tractable inference via message passing, at the expense of being unable to model some cognacy relationships. To help correct this deficiency, we also describe an agglomerative inference procedure for the model of Hall and Klein (2010). By using the output of our system as input to this system, we can find cognate groups that PARSIM alone cannot recover.

We apply these models to identifying cognate groups from two language families using the Austronesian Basic Vocabulary Database (Greenhill et al., 2008), a catalog of words from about 40% of the Austronesian languages. We focus on data from two subfamilies of Austronesian: Formosan and

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 344–354,
Edinburgh, Scotland, UK, July 27–31, 2011.

Oceanic. The datasets are by far the largest on which automated cognate recovery has ever been attempted, with 18 and 271 languages respectively. On the larger Oceanic data, our model can achieve cluster purity scores of 91.8%, while maintaining pairwise recall of 62.1%. We also analyze the mistakes of our system, where we find that some of the erroneous cognate groups our system finds may not be errors at all. Instead, they may be previously unknown cognacy relationships that were not annotated in the data.

2 Background

Before we present our model, we first describe basic facts of the Austronesian language family, along with a description of the Austronesian Basic Vocabulary Database, which forms the dataset that we use for our experiments. For far more detailed coverage of the Austronesian languages, we direct the interested reader to Blust (2009)'s comprehensive monograph.

2.1 The Austronesian Language Family

The Austronesian language family is one of the largest in the world, comprising about one-fifth of the world's languages. Geographically, it stretches from its homeland on Formosa (Taiwan) to Madagascar in the west, and as far as Hawai'i and (at one point) the Easter Islands to the east. Until the advent of European colonialism spread Indo-European languages to every continent, Austronesian was the most widespread of all language families.

Linguistically, the language family is as diverse as it is large, but a few regularities hold. From a phonological perspective, two features stand out. First, the phoneme inventories of these languages are typically small. For example, it is well-known that Hawaiian has only 13 phonemes. Moreover, the phonotactics of these languages are often restrictive. Sticking with the same example, Hawaiian only allows (C)V syllables: consonants clusters are forbidden, and no syllable may end with a consonant.

2.2 The Austronesian Basic Vocabulary Database

The Austronesian Basic Vocabulary Database (ABVD) (Greenhill et al., 2008) is an ambitious, ongoing effort to catalog the lexicons and basic facts about all of the languages in the Austronesian language family. It also contains manual reconstructions for select ancestor languages produced by linguists.

The sample we use—from Bouchard-Côté et al. (2009)—contains about 50,000 words across 471 languages spanning all the major divisions of Austronesian. These words are grouped into cognate groups and arranged by gloss. For instance, there are 37 distinct cognate groups for the gloss "tail." One of these groups includes the words */ekor/*, */ingko/*, */iŋkot/*, */kiiki?u/*, and */?i?ina/*, among others. Most of these words have been transcribed into the International Phonetic Alphabet, though it appears that some words are transcribed using the Roman alphabet. For instance, the second word in the example is likely */iŋko/*, which is a much more likely sequence than what is transcribed.

In this sample, there are 6307 such cognate groups and 210 distinct glosses. The data is somewhat sparse: fewer than 50% of the possible gloss/language pairs are present. Moreover, there is some amount of *homoplasy*—that is, languages with a word from more than one cognate group for a given gloss.

Finally, it is important to note that the ABVD is still a work in progress: they have data from only 50% of extant Austronesian languages.

2.3 Subfamilies of Austronesian

In this paper we focus on two branches of the Austronesian language family, one as a development set and one as a test set. For our development set, we use the Formosan branch. The languages in this group are exclusively found on the Austronesian homeland of Formosa. The family encompasses a substantial portion of the linguistic diversity of Austronesian: Blust (2009) argues that Formosan contains 9 of the 10 first-order splits of the Austronesian family. Formosan's diversity is surprising since it contains a mere 18 languages. Thus, Formosan is a smaller development set that nevertheless is representative of larger families.

For our final test set, we use the Oceanic subfamily, which includes almost 50% of the languages in the Austronesian family, meaning that it represents around 10% of all languages in the world. Oceanic also represents a large fraction of the ge-

ographic diversity of Austronesian, stretching from New Zealand in the south to Hawai'i in the north. Our sample includes 21863 words from 218 languages in the Oceanic family.

3 Models

In this section we describe two models, one based on Hall and Klein (2010)—which we call HK10—and another new model that shares some connection to parsimony methods in computational biology, which we call PARSIM. Both are generative models that describe the evolution of words w_ℓ from a set of languages $\{\ell\}$ in a cognate group g along a fixed phylogeny T.[1] Each cognate group and word is also associated with a gloss or meaning m, which we assume to be fixed.[2] In both models, words evolve according to regular sound laws φ_ℓ, which are specific to each language. Also, both models will make use of a language model λ, which is used for generating words that are not dependent on the word in the parent language. (We leave φ_ℓ and λ as abstract parameters for now. We will describe them in subsequent sections.)

3.1 HK10

The first model we describe is a small modification of the phylogenetic model of Hall and Klein (2010). In HK10, there is an unknown number of cognate groups G where each cognate group g consists of a set of words $\{w_{g,\ell}\}$. In each cognate group, words evolve along a phylogeny, where each word in a language is the result of that word evolving from its parent according to regular sound laws. To model the fact that not all languages have a cognate in each group, each language in the tree has an associated "survival" variable $S_{g,\ell}$, where a word may be lost on that branch (and its descendants) instead of evolving. Once the words are generated, they are then "permuted" so that the cognacy relationships

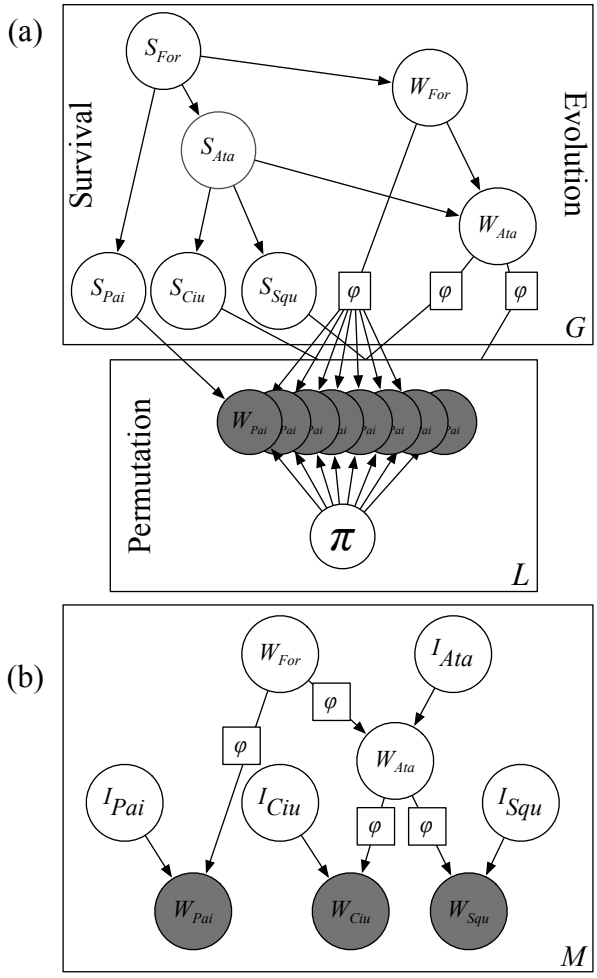

Figure 1: Plate diagrams for (a) HK10 (Hall and Klein, 2010) and (b) PARSIM, our new parsimony model, for a small set of languages. In HK10, words are generated following a phylogenetic tree according to sound laws φ, and then "scrambled" with a permutation π so that the original cognate groups are lost. In PARSIM, all words for each of the M glosses are generated in a single tree, with innovations I starting new cognate groups. The languages depicted are Formosan (For), Paiwan (Pai), Atayalic (Ata), Ciuli Atayalic (Ciu), and Squliq Atayalic (Squ).

[1] Both of these models therefore are insensitive to geographic and historical factors that cannot be easily approximated by this tree. See Nichols (1992) for an excellent discussion of these factors.

[2] One could easily envision allowing the meaning of a word to change as well. Modeling this semantic drift has been considered by Kondrak (2001). In the ABVD, however, any semantic drift has already been elided, since the database has coarsened glosses to the extent that there is no meaningful way to model semantic drift given our data.

are obscured. The task of inference then is to recover the original cognate groups.

The generative process for their model is as follows:

- For each cognate group g, choose a root word $W_{root} \sim p(W|\lambda)$, a language model over words.
- For each language ℓ in a pre-order traversal of the phylogeny:
  1. Choose $S_\ell \sim \text{Bernoulli}(\beta_\ell)$, indicating whether or not the word survives.
  2. If the word survives, choose $W_\ell \sim p(W|\varphi_\ell, W_{\text{par}(\ell)})$.
  3. Otherwise, stop generating words in that language and its descendants.
- For each language, choose a random permutation π of the observed data, and rearrange the cognates according to this permutation.

We reproduce the graphical model for HK10 for a small phylogeny in Figure 1a.

Inference in this model is intractable; to perform inference exactly, one has to reason over all partitions of the data into cognate groups. To address this problem, Hall and Klein (2010) propose an iterative bipartite matching scheme where one language is held out from the others, and then words are assigned to the remaining groups to maximize the probability of the attachment. That is, for some language ℓ and fixed assignments $\pi_{-\ell}$ for the other languages, they seek an assignment π_ℓ that maximizes:

$$\pi^* = \underset{\pi}{\text{argmax}} \sum_g \log p(w_{(\ell,\pi_\ell(g))}|\varphi, \pi, \mathbf{w}_{-\ell})$$

Unfortunately, while this approach was effective with only a few languages (they tested on three), this algorithm cannot scale to the eighteen languages in Formosan, let alone the hundreds of languages in Oceanic. Therefore, we make two simple modifications. First, we restrict the cognate assignments to stay within a gloss. Thus, there are many fewer potential matchings to consider. Second, we use an agglomerative inference procedure, which greedily merges cognate groups that result in the greatest gain in likelihood. That is, for all pairs of cognate groups g_a with words $\mathbf{w}_a$ and g_b with words $\mathbf{w}_b$, we compute the score:

$$\log p(\mathbf{w}_{a\cup b}|\varphi) - \log p(\mathbf{w}_a|\varphi) - \log p(\mathbf{w}_b|\varphi)$$

This score is the difference between the log probability of generating two cognate groups jointly and generating them separately. We then merge the two that generate the highest gain in likelihood. Like the iterative bipartite matching algorithm described above, this algorithm is not exact. However, it is $O(n^2 \log n)$ (where n is the size of the largest gloss, which for Oceanic is 153), while the bipartite matching algorithm is $O(n^3)$ (Kuhn, 1955).

Actually, the original HK10 is doubly intractable. They use weighted automata to represent distributions over strings, but these automata—particularly if they are non-deterministic—make inference in any non-trivial graphical model intractable. We discuss this issue in more detail in Section 6.

3.2 A Parsimony-Inspired Model

We now describe a new model called PARSIM that supports exact inference tractably, though it sacrifices some of the expressive power of HK10. In our model, each language has at most one word for each gloss, and this one word changes from one language to its children according to some edge-specific Markov process. These changes may either be mutations, which merely change the surface form of the word, or innovations, which start a new word in a new cognate group that is unrelated to the previous word. Mutations take the form of a conditional edit operation that models insertions, substitutions, and deletions that correspond to regular (and, with lower probability, irregular) sound changes that are likely to occur between a language and its parent. Innovations, on the other hand, are generated from a language model independent of the parent's word.

Specifically, our generative process takes the following form:

- For each gloss m, choose a root word $W_{root} \sim \lambda$, a language model over words.
- For each language ℓ in a pre-order traversal of the phylogeny:

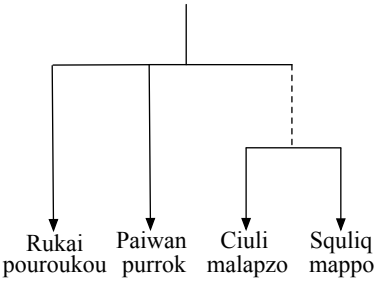

Figure 2: A small example of how PARSIM works. Listed here are the words for "ten" in four languages from the Formosan family, along with the tree that explains them. The dashed line indicates an innovation on the branch.

1. Choose $I_\ell \sim \text{Bernoulli}(\beta_\ell)$, indicating whether or not the word is an innovation or a mutation.
2. If it is a mutation, choose $W_\ell \sim p(W|\varphi_\ell, W_{\text{par}(\ell)})$.
3. Otherwise, choose $W_\ell \sim \lambda$.

We also depict our model as a plate diagram for a small phylogeny in Figure 1b.

Because there is only one tree per gloss, there is no assignment problem to consider, which is the main source of the intractability of HK10. Instead, pieces of the phylogeny are simply "cut" into subtrees whenever an innovation occurs. Thus, message passing can be used to perform inference.

As an example of how our process works, consider Figure 2. The Formosan word for "ten" probably resembled either */purrok/* or */pouroukou/*. There was an innovation in Ciuli and Squliq's ancestor Atayalic that produced a new word for ten. This word then mutated separately into the words */malapzo/* and */mappo/*, respectively.

4 Relation to Parsimony

PARSIM is related to the parsimony principle from computational biology (Cavalli-Sforza and Edwards, 1965; Fitch, 1971), where it is used to search for phylogenies. When using parsimony, a phylogeny is scored according to the derivation that requires the fewest number of changes of state, where a state is typically thought of as a gene or some other trait in a species. These genes are typically called "characters" in the computational biology literature, and two species would have the same value for a character if they share the same property that that state represents.

When inducing phylogenies of languages, a natural choice for characters are glosses from a restricted vocabulary like a Swadesh list, and two words are represented as the same value for a character if they are cognate (Ringe et al., 2002). Other features can be used (Daumé III and Campbell, 2007; Daumé III, 2009), but they are not relevant to our discussion.

Consider the small example in Figure 3a with just four languages. Here, cognacy is encoded using characters. In this example, at least two changes of state are required to explain the data: both C and B must have evolved from A. Therefore, the parsimony score for this tree is two.

Of course, there is no reason why all changes should be equally likely. For instance, it might be extremely likely that B changes into both A and C, but that A never changes into B or C, and so weighted variants of parsimony might be necessary (Sankoff and Cedergren, 1983).

With this in mind, PARSIM can be thought of a weighted variant of parsimony, with two differences. First, the characters do not indicate ahead of time which words are related. Instead, the characters are the words themselves. Second, the transitions between different states (words) are not uniform. Instead, they are weighted by the log probability of one word changing into another, including both mutations and innovations.

Thus, the task of inference in PARSIM is to find the most "parsimonious" explanation for the words we have observed, which is the same as finding the most likely derivation. Because the distances between words (that is, the transition probabilities) are not known ahead of time, they must instead be learned, which we discuss in Section 7.[3]

5 Limitations of the Parsimony Model

Potentially, our parsimony model sacrifices a certain amount of power to make inference tractable. Specifically, it cannot model *homoplasy*, the presence of more than one word in a language for a given

[3]It is worth noting that we are not the first to point out a connection between parsimony and likelihood. Indeed, many authors in the computational biology literature have formally demonstrated a connection (Farris, 1973; Felsenstein, 1973).

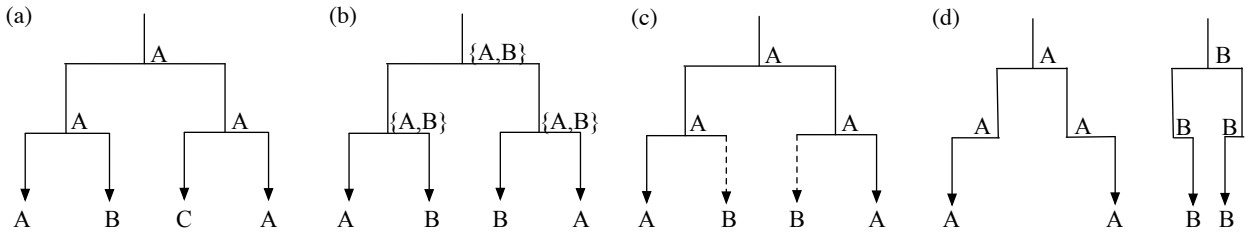

Figure 3: Trees illustrating parsimony and its limitations. In these trees, there are four languages, with words A, B, and C in various configurations. (a) The most parsimonious derivation for this tree has all intermediate states as A. There are thus two changes. (b) An example of homoplasy. Here, given this tree, it seems likely that the ancestral languages contained both A and B. (c) PARSIM cannot recover the example from (b), and so it encodes two innovations (shown as dashed lines). (d) The HK10 model can recover this relationship, but this power makes the model intractable.

gloss. Homoplasy can arise for a variety of reasons in phylogenetic models of cognates, and we describe some in this section.

Consider the example illustrated in Figure 3b, where the two central languages share a cognate, as do the two outer languages. This is the canonical example of homoplasy, and PARSIM cannot correctly recover this grouping. Instead, it can at best only select group A or group B as the value for the parent, and leave the other group fragmented as two innovations, as in Figure 3c. On the other hand, HK10 *can* recover this relationship (Figure 3d), but this power is precisely what makes it intractable.

There are two reasons this kind of homoplasy could arise. The first is that there were indeed two words in the parent language for this gloss, or that there were two words with similar meanings and the two meanings drifted together. Second, the tree could be an inadequate model of the evolution in this case. For instance, there could have been a certain amount of borrowing between two of these languages, or there was not a single coherent parent language, but rather a language continuum that cannot be explained by any tree.

However, homoplasy seems to be relatively uncommon (though not unheard of) in the Oceanic and Formosan families. Where it does appear, our model should simply fail to get one of the cognate groups, instead explaining all of them via innovation. To repair this shortcoming, we can simply run the agglomerative clustering procedure for the model of Hall and Klein (2010), starting from the groups that PARSIM has recovered. Using this procedure, we can hopefully recover many of the under-groupings caused by homoplasy.

6 Inference and Scale

6.1 Inference

In this section we describe the basics of inference in the PARSIM model. We have a nearly tree-structured graphical model (Figure 1); it is not a tree only because of the innovation parameters. Therefore, we apply the common trick of grouping variables to form a tree. Specifically, we group each word variable W_ℓ with its innovation parameter I_ℓ. The distribution of interest is then $p(W_\ell, I_\ell | W_{\mathbf{par}(\ell)}, \phi_\ell, \beta_\ell)$, and the primary operation is summing out messages μ from the children of a language and sending a new message to its parent:

$$\mu_\ell(w_{\mathbf{par}(\ell)}) = \sum_{w_\ell} p(w_\ell|\cdot) \prod_{\ell' \in \mathbf{child}(\ell)} \mu_{\ell'}(w_\ell)$$
$$p(w_\ell|\cdot) = p(w_\ell|I_\ell = 0, w_{\mathbf{par}(\ell)}, \phi_\ell) p(I_\ell = 0|\beta_\ell) + p(w_\ell|I_\ell = 1, \phi_\ell) P(I_\ell = 1|\beta_\ell) \quad (1)$$

The first term involves computing the probability of the word mutating from its parent, and the second involves the probability of the child word from a language model. We describe the parameters and procedures for these operations in 7.1.

6.2 Scale

Even though inference by message-passing in our model is tractable, we needed to make certain concessions to make inference acceptably fast. These choices mainly affect how we represent distributions over strings.

First, we need to model distributions and messages over words on the internal nodes of a phylogeny. The natural choice in this scenario is to use weighted finite automata (Mohri et al., 1996). Automata have been used to successfully model distributions of strings for inferring morphology (Dreyer and Eisner, 2009) as well as cognate detection (Hall and Klein, 2010). Even in models that would be tractable with "ordinary" messages, inference with automata quickly becomes intractable, because the size of the automata grow exponentially with the number of messages passed. Therefore, approximations must be used. Dreyer and Eisner (2009) used a mixture of a k-best list and a unigram language model, while Hall and Klein (2010) used an approximation procedure that projected complex automata to simple, tractable automata using a modified KL divergence.

While either approach could be used here in principle, we found that automata machinery was simply too slow for our application. Instead, we exploit the intuition that we do not need to accurately reconstruct the word for any ancestral language. Moreover, it is inefficient to keep track of probabilities for all strings. Therefore, we only track scores for words that actually exist in a given gloss, which means that internal nodes only have mass on those words. That is, if a gloss has 10 distinct words across all the languages in our dataset, we pass messages that only contain information about those 10 words.

Now, this representation—while more efficient than the automata representations—results in inference that is still quadratic in the number of words in a gloss, since we have distributions of the form $p(w_\ell | w_{\mathrm{par}(\ell)}, \phi_\ell)$. Intuitively, it is unlikely that a word from one distant branch of tree resembles a word in another branch. Therefore, rather than score all of these unlikely words, we use a beam where we only factor in words whose score is at most a factor of e^{-10} less than the maximum score. Our initial experiments found that using a beam provides large savings in time with little impact on prediction quality.

7 Learning

PARSIM has three kinds of parameters that we need to learn: the mutation parameters φ_ℓ, the innovation probabilities β_ℓ, and the global language model λ for generating new words. We learn these parameters via Expectation Maximization (Dempster et al., 1977), iterating between computing expected counts and adjusting parameters to maximize the posterior probability of the parameters. In this section, we describe those parameters.

7.1 Sound Laws

The core piece of our system is learning the sound laws associated with each edge. Since the foundation of historical linguists with the neogrammarians, linguists have argued for the regularity of sound change at the phonemic level (Schleicher, 1861; Bloomfield, 1938). That is to say, if in some language a $/t/$ changes to a $/d/$ in some word, it is almost certain that it will change in every other place that has the same surrounding context.

In practice, of course, sound change is not entirely regular, and complex extralinguistic events can lead to sound changes that are irregular. For example, in some cultures in which Oceanic languages are spoken, the name of the chief is taboo: one cannot speak his name, nor say any word that sounds too much like his name. Speakers of these languages do find ways around this prohibition, often resulting in sound changes that cannot be explained by sound laws alone (Keesing and Fifi'i, 1969).

Nevertheless, we find it useful to model sound change as a largely regular if stochastic process. We employ a sound change model whose expressive power is equivalent to that of Hall and Klein (2010), though with a different parameterization. We model the evolution of a word w_ℓ to its child $w_{\ell'}$ as a sequence of unigram edits that include insertions, deletions, and substitutions. Specifically, we use a standard three-state pair hidden Markov model that is closely related to the classic alignment algorithm of Needleman and Wunsch (1970) (Durbin et al., 2006).

The three states in this HMM correspond to matches/substitutions, insertions, and deletions. The transitions are set up such that insertions and deletions cannot be interleaved. This prevents spurious equivalent alignments, which would cause the model to assign unnecessarily higher probability to transitions with many insertions and deletions.

Actually learning these parameters involves learn-

ing the transition probabilities of this HMM (which model the overall probability of insertion and deletion) as well as the emission probabilities (which model the particular edits). Because there are relatively few words for each language (96 on average in Oceanic), we found it important to tie together the parameters for the various languages, in contrast to Hall and Klein (2010) who did not. In our maximization step, we fit a joint log-linear model for each language, using features that are both specific to a language and shared across languages. Our features included indicators on each substitution, insertion, and deletion operation, along with an indicator for the outcome of each edit operation. This last feature reflects the propensity of a particular phoneme to appear in a given language at all, no matter what its ancestral phoneme was. This parameterization is similar to the one used in the reconstruction system of Bouchard-Côté et al. (2009), except that they used edit operations that conditioned on the context of the surrounding word, which is crucial when trying to accurately reconstruct ancestral word forms. To encourage parameter sharing, we used an ℓ_2 regularization penalty.

7.2 Innovation Parameters

The innovation parameters β_ℓ are parameters for simple Bernoulli distribution that govern the propensity for a language to start a new word. These parameters can be learned separately, though due to data sparsity, we found it better to use a tied parameterization as with the sound laws. Specifically, we fit a log linear model whose features are indicators on the specific language, as well as a global innovation parameter that is shared across all languages. As with the sound laws, we used an ℓ_2 regularization penalty to encourage the use of the global innovation parameter.

7.3 Language Model

Finally, we have a single language model λ that is also shared across all languages. λ is a simple bigram language model over characters in the International Phonetic Alphabet. λ is used when generating new words either via innovation or from the root of the tree.

In principle, we could of course have language models specific to each language, but because there are so few words per language, we found that branch-specific language models caused the model to prefer to innovate at almost every node since the language models could essentially memorize the relatively small vocabularies of these languages.

Formosan				
System	Prec	Recall	F1	Purity
Agg. HK10	77.6	**83.2**	80.0	84.7
PARSIM	**87.8**	71.0	78.5	**94.6**

Oceanic				
System	Prec	Recall	F1	Purity
PARSIM	**84.4**	62.1	71.5	**91.8**
Combination	76.0	73.8	**74.9**	85.5

Table 1: Results on the Formosan and Oceanic families. PARSIM is the new parsimony model in this paper, Agg. HK10 is our agglomerative variant of Hall and Klein (2010) and Combination uses PARSIM's output to seed the agglomerative matcher. For the agglomerative systems, we report the point with maximal F1 score, but we also show precision/recall curves. (See Figure 4.)

8 Experiments

8.1 Cognate Recovery

We ran both PARSIM and our agglomerative version of HK10 on the Formosan datasets. For PARSIM, we initialized the mutation parameters φ to a model that preferred matches to insertions, substitutions and deletions by a factor of e^3, innovation parameters to 0.5, and the language model to a uniform distribution over characters. For the agglomerative HK10, we initialized its parameters to the values found by our model.[4]

Based on our observations about homoplasy, we also considered a combined system where we ran PARSIM, and then seeded the agglomerative clustering algorithm with the clusters found by PARSIM.

For evaluation, we report a few metrics. First, we report cluster purity, which is a kind of precision measure for clusterings. Specifically, each cluster is assigned to the cognate group that is the most common cognate word in that group, and then purity is computed as the fraction of words that

[4] Attempts to learn parameters directly with the agglomerative clustering algorithm were not effective.

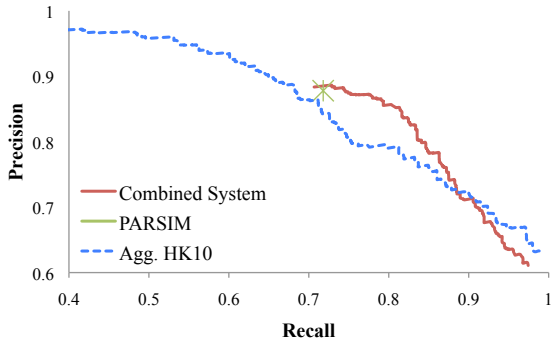

Figure 4: Precision/Recall curves for our systems. The Combined System starts from PARSIM's output, so it has fewer points to plot, and starts from a point with lower precision. As PARSIM outputs only one result, it is starred.

are in a cluster whose gold cognate group matches the cognate group of the cluster. For gold partitions $G = \{G_1, G_2, \ldots, G_g\}$ and found partitions $F = \{F_1, F_2, \ldots, F_f\}$, we have: $\text{purity}(G, F) = \frac{1}{N} \sum_f \max_g |G_g \cap F_f|$. We also report pairwise precision and recall computed over pairs of words.[5] Finally, because agglomerative clustering does not define a natural "stopping point" other than when the likelihood gain decreases to 0—which did not perform well in our initial tests—we will report both a precision/recall curve, as well the maximum pairwise F1 obtained by the agglomerative HK10 and the combined system.

The results are in Table 1. On Formosan, PARSIM has much higher precision and purity than our agglomerative version of HK10 at its highest point, though its recall and F1 suffer somewhat. Of course, the comparison is not quite fair, since we have selected the best possible point for HK10.

However, our combination of the two systems does even better. By feeding our high-precision results into the agglomerative system and sacrificing just a little precision, our combined system achieves much higher F1 scores than either of the systems alone.

Next, we also examined precision and recall curves for the two agglomerative systems on Formosan, which we have plotted in Figure 4, along with the one point output by PARSIM.

We then ran PARSIM and the combined system on the much larger Oceanic dataset. Performance on all metrics decreased somewhat, but this is to be expected since there is so much more data. As with Formosan, PARSIM has higher precision than the combined system, but it has much lower recall.

8.2 Reconstruction

We also wanted to see how well our cognates could be used to actually reconstruct the ancestral forms of words. To do so, we ran a version of Bouchard-Côté et al. (2009)'s reconstruction system using both the cognate groups PARSIM found in the Oceanic language family and the gold cognate groups provided by the ABVD. We then evaluated the average Levenshtein distance of the reconstruction for each word to the reconstruction of that word's Proto-Oceanic ancestor provided by linguists. Our evaluation differs from Bouchard-Côté et al. (2009) in that they averaged over cognate groups, which does not make sense for our task because there are different cognate groups. Instead, we average over per-modern-word reconstruction error.

Using this metric, reconstructions using our system's cognates are an average of 2.47 edit operations from the gold reconstruction, while with gold cognates the error is 2.19 on average. This represents an error increase of 12.8%. To see if there was some pattern to these errors, we also plotted the fraction of words with each Levenshtein distance for these reconstructions in Figure 5. While the plots are similar, the automatic cognates exhibit a longer tail. Thus, even with automatic cognates, the reconstruction system can reconstruct words faithfully in many cases, but in a few instances our system fails.

9 Analysis

We now consider some of the errors made by our system. Broadly, there are two kinds of mistakes in a model like ours: those affecting precision and those affecting recall.

9.1 Precision

Many of our precision errors seem to be due to our somewhat limited model of sound change. For instance, the language Pazeh has two words for

[5]The main difference between precision and purity is that pairwise precision is inherently quadratic, meaning that it penalizes mistakes in large groups much more heavily than mistakes in small groups.

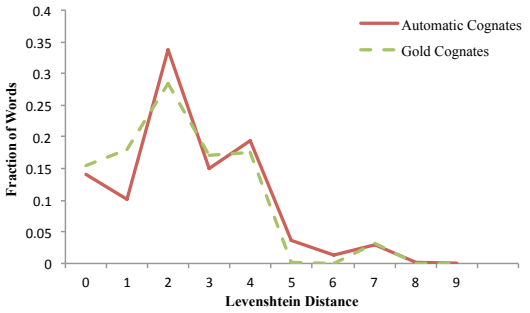

Figure 5: Percentage of words with varying levels of Levenshtein distance from the gold reconstruction. Gold Cognates were hand-annotated by linguists, while Automatic Cognates were found by our system.

"to sleep:" */mudamai/* and */midəm/*. Somewhat surprisingly the former word is cognate with Paiwan */qmereŋ/* and Saisiat */maʔrəm/* while the latter is not. Our system, however, makes the mistake of grouping */midəm/* with the Paiwan and Saisiat words. Our system has inferred that the insertions of */u/* and */ai/* (which are required to bring */mudamai/* into alignment with the Saisiat and Paiwan words) are less likely than substituting a few vowels and the consonant */r/* for */d/* (which are required to align */midəm/*). Perhaps a more sophisticated model of sound change could correctly learn this relationship.

However, a preliminary inspection of the data seems to indicate that not all of our precision errors are actually errors, but rather places where the data is insufficiently annotated (and indeed, the ABVD is still a work in progress). For instance, consider the words for "meat/flesh" in the Formosan languages: Squliq */hiʔ/*, Bunun */titiʔ/*, Paiwan */seti/*, Kavalan */ʔisiʔ/*, CentralAmi */titi/*, Our system groups all of these words except for Squliq */hiʔ/*. However, despite these words' similarity, there are actually three cognate groups here. One includes Squliq */hiʔ/* and Kavalan */ʔisiʔ/*, another includes just Paiwan */seti/*, and the third includes Bunun */titiʔ/* and CentralAmi */titi/*. Crucially, these cognate groups do not follow the phylogeny closely. Thus, either there was a significant amount of borrowing between these languages, or there was a striking amount of homoplasy in Proto-Formosan, or these words are in fact mostly cognate. While a more thorough, linguistically-informed analysis is needed to ensure that these are actually cognates, we believe that our system, in conjunction with a trained Austronesian specialist, could potentially find many more cognate groups, speeding up the process of completing the ABVD.

9.2 Recall

Our system can also fail to group words that should be grouped. One recurring problem seems to be reduplication, which is a fairly common phenomenon in Austronesian languages. For instance, there is a cognate group for "to eat" that includes Bunun */maun/*, Thao */kman/*, Favorlang */man/*, and Sediq */manakamakan/*, among others. Our system correctly finds this group, with the exception of */manakamakan/*, which is clearly the result of reduplication. Reduplication cannot be modeled using mere sound laws, and so a more complex transition model is needed to correctly identify these kinds of changes.

10 Conclusion

We have presented a new system for automatically finding cognates across many languages. Our system is comprised of two parts. The first, PARSIM, is a new high-precision generative model with tractable inference. The second, HK10, is a modification of Hall and Klein (2010) that makes their approximate inference more efficient. We discuss certain trade-offs needed to make both models scale, and demonstrated its performance on the Formosan and Oceanic language families.

Abstract

We explore efficient domain adaptation for the task of statistical machine translation based on extracting sentences from a large general-domain parallel corpus that are most relevant to the target domain. These sentences may be selected with simple cross-entropy based methods, of which we present three. As these sentences are not themselves identical to the in-domain data, we call them *pseudo in-domain* subcorpora. These subcorpora – 1% the size of the original – can then used to train small domain-adapted Statistical Machine Translation (SMT) systems which outperform systems trained on the entire corpus. Performance is further improved when we use these domain-adapted models in combination with a true in-domain model. The results show that more training data is not always better, and that best results are attained via proper domain-relevant data selection, as well as combining in- and general-domain systems during decoding.

1 Introduction

Statistical Machine Translation (SMT) system performance is dependent on the quantity and quality of available training data. The conventional wisdom is that more data is better; the larger the training corpus, the more accurate the model can be.

The trouble is that – except for the few all-purpose SMT systems – there is never enough training data that is directly relevant to the translation task at hand. Even if there is no formal genre for the text to be translated, any coherent translation task will have its own argot, vocabulary or stylistic preferences, such that the corpus characteristics will necessarily deviate from any all-encompassing model of language. For this reason, one would prefer to use more in-domain data for training. This would empirically provide more accurate lexical probabilities, and thus better target the task at hand. However, parallel in-domain data is usually hard to find[1], and so performance is assumed to be limited by the quantity of domain-specific training data used to build the model. Additional parallel data can be readily acquired, but at the cost of specificity: either the data is entirely unrelated to the task at hand, or the data is from a broad enough pool of topics and styles, such as the web, that any use this corpus may provide is due to its size, and not its relevance.

The task of domain adaptation is to translate a text in a particular (target) domain for which only a small amount of training data is available, using an MT system trained on a larger set of data that is not restricted to the target domain. We call this larger set of data a *general-domain* corpus, in lieu of the standard yet slightly misleading *out-of-domain* corpus, to allow a large uncurated corpus to include some text that may be relevant to the target domain.

Many existing domain adaptation methods fall into two broad categories. Adaptation can be done at the corpus level, by selecting, joining, or weighting the datasets upon which the models (and by extension, systems) are trained. It can be also achieved at the model level by combining multiple translation or language models together, often in a weighted manner. We explore both categories in this work.

[1] Unless one dreams of translating parliamentary speeches.

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 355–362,
Edinburgh, Scotland, UK, July 27–31, 2011.

First, we present three methods for ranking the sentences in a general-domain corpus with respect to an in-domain corpus. A cutoff can then be applied to produce a very small–yet useful– subcorpus, which in turn can be used to train a domain-adapted MT system. The first two data selection methods are applications of language-modeling techniques to MT (one for the first time). The third method is novel and explicitly takes into account the bilingual nature of the MT training corpus. We show that it is possible to use our data selection methods to subselect less than 1% (or discard 99%) of a large general training corpus and still increase translation performance by nearly 2 BLEU points.

We then explore how best to use these selected subcorpora. We test their combination with the in-domain set, followed by examining the subcorpora to see whether they are actually in-domain, out-of-domain, or something in between. Based on this, we compare translation model combination methods.

Finally, we show that these tiny translation models for model combination can improve system performance even further over the current standard way of producing a domain-adapted MT system. The resulting process is lightweight, simple, and effective.

2 Related Work

2.1 Training Data Selection

An underlying assumption in domain adaptation is that a general-domain corpus, if sufficiently broad, likely includes some sentences that could fall within the target domain and thus should be used for training. Equally, the general-domain corpus likely includes sentences that are so unlike the domain of the task that using them to train the model is probably more harmful than beneficial. One mechanism for domain adaptation is thus to select only a portion of the general-domain corpus, and use only that subset to train a complete system.

The simplest instance of this problem can be found in the realm of language modeling, using perplexity-based selection methods. The sentences in the general-domain corpus are scored by their perplexity score according to an in-domain language model, and then sorted, with only the lowest ones being retained. This has been done for language modeling, including by Gao et al (2002), and more recently by Moore and Lewis (2010). The ranking of the sentences in a general-domain corpus according to in-domain perplexity has also been applied to machine translation by both Yasuda et al (2008), and Foster et al (2010). We test this approach, with the difference that we simply use the source side perplexity rather than computing the geometric mean of the perplexities over both sides of the corpus. We also reduce the size of the training corpus far more aggressively than Yasuda et al's 50%. Foster et al (2010) do not mention what percentage of the corpus they select for their *IR-baseline*, but they concatenate the data to their in-domain corpus and report a decrease in performance. We both keep the models separate and reduce their size.

A more general method is that of (Matsoukas et al., 2009), who assign a (possibly-zero) weight to each sentence in the large corpus and modify the empirical phrase counts accordingly. Foster et al (2010) further perform this on extracted phrase pairs, not just sentences. While this soft decision is more flexible than the binary decision that comes from including or discarding a sentence from the subcorpus, it does not reduce the size of the model and comes at the cost of computational complexity as well as the possibility of overfitting. Additionally, the most effective features of (Matsoukas et al., 2009) were found to be meta-information about the source documents, which may not be available.

Another perplexity-based approach is that taken by Moore and Lewis (2010), where they use the cross-entropy difference as a ranking function rather than just cross-entropy. We apply this criterion for the first time to the task of selecting training data for machine translation systems. We furthermore extend this idea for MT-specific purposes.

2.2 Translation Model Combination

In addition to improving the performance of a single general model with respect to a target domain, there is significant interest in using two translation models, one trained on a larger general-domain corpus and the other on a smaller in-domain corpus, to translate in-domain text. After all, if one has access to an in-domain corpus with which to select data from a general-domain corpus, then one might as well use the in-domain data, too. The expectation is that the larger general-domain model should dom-

inate in regions where the smaller in-domain model lacks coverage due to sparse (or non-existent) ngram counts. In practice, most practical systems also perform target-side language model adaptation (Eck et al., 2004); we eschew this in order to isolate the effects of translation model adaptation alone.

Directly concatenating the phrase tables into one larger one isn't strongly motivated; identical phrase pairs within the resulting table can lead to unpredictable behavior during decoding. Nakov (2008) handled identical phrase pairs by prioritizing the source tables, however in our experience identical entries in phrase tables are not very common when comparing across domains. Foster and Kuhn (2007) interpolated the in- and general-domain phrase tables together, assigning either linear or log-linear weights to the entries in the tables before combining overlapping entries; this is now standard practice.

Lastly, Koehn and Schroeder (2007) reported improvements from using multiple decoding paths (Birch et al., 2007) to pass both tables to the Moses SMT decoder (Koehn et al., 2003), instead of directly combining the phrase tables to perform domain adaptation. In this work, we directly compare the approaches of (Foster and Kuhn, 2007) and (Koehn and Schroeder, 2007) on the systems generated from the methods mentioned in Section 2.1.

3 Experimental Framework

3.1 Corpora

We conducted our experiments on the International Workshop on Spoken Language Translation (IWSLT) Chinese-to-English DIALOG task [2], consisting of transcriptions of conversational speech in a travel setting. Two corpora are needed for the adaptation task. Our in-domain data consisted of the IWSLT corpus of approximately 30,000 sentences in Chinese and English. Our general-domain corpus was 12 million parallel sentences comprising a variety of publicly available datasets, web data, and private translation texts. Both the in- and general-domain corpora were identically segmented (in Chinese) and tokenized (in English), but otherwise unprocessed. We evaluated our work on the 2008 IWSLT spontaneous speech Challenge Task[3] test set, consisting of 504 Chinese sentences with 7 English reference translations each. This is the most recent IWSLT test set for which the reference translations are available.

3.2 System Description

In order to highlight the data selection work, we used an out-of-the-box Moses framework using GIZA++ (Och and Ney, 2003) and MERT (Och, 2003) to train and tune the machine translation systems. The only exception was the phrase table for the large out-of-domain system trained on 12m sentence pairs, which we trained on a cluster using a word-dependent HMM-based alignment (He, 2007). We used the Moses decoder to produce all the system outputs, and scored them with the NIST `mt-eval31a` [4] tool used in the IWSLT evalutation.

3.3 Language Models

Our work depends on the use of language models to rank sentences in the training corpus, in addition to their normal use during machine translation tuning and decoding. We used the SRI Language Modeling Toolkit (Stolcke, 2002) was used for LM training in all cases: corpus selection, MT tuning, and decoding. We constructed 4gram language models with interpolated modified Kneser-Ney discounting (Chen and Goodman, 1998), and set the Good-Turing threshold to 1 for trigrams.

3.4 Baseline System

The in-domain baseline consisted of a translation system trained using Moses, as described above, on the IWSLT corpus. The resulting model had a phrase table with 515k entries. The general-domain baseline was substantially larger, having been trained on 12 million sentence pairs, and had a phrase table containing 1.5 billion entries. The BLEU scores of the baseline single-corpus systems are in Table 1.

Corpus	Phrases	Dev	Test
IWSLT	515k	45.43	37.17
General	1,478m	42.62	40.51

4 Training Data Selection Methods

We present three techniques for ranking and selecting subsets of a general-domain corpus, with an eye towards improving overall translation performance.

4.1 Data Selection using Cross-Entropy

As mentioned in Section 2.1, one established method is to rank the sentences in the general-domain corpus by their perplexity score according to a language model trained on the small in-domain corpus. This reduces the perplexity of the general-domain corpus, with the expectation that only sentences similar to the in-domain corpus will remain. We apply the method to machine translation, even though perplexity reduction has been shown to not correlate with translation performance (Axelrod, 2006). For this work we follow the procedure of Moore and Lewis (2010), which applies the cosmetic change of using the cross-entropy rather than perplexity.

The perplexity of some string s with empirical n-gram distribution p given a language model q is:

$$2^{-\sum_x p(x)\log q(x)} = 2^{H(p,q)} \quad (1)$$

where $H(p,q)$ is the *cross-entropy* between p and q. We simplify this notation to just $H_I(s)$, meaning the cross-entropy of string s according to a language model LM_I which has distribution q. Selecting the sentences with the lowest perplexity is therefore equivalent to choosing the sentences with the lowest cross-entropy according to the in-domain language model. For this experiment, we used a language model trained (using the parameters in Section 3.3) on the Chinese side of the IWSLT corpus.

4.2 Data Selection using Cross-Entropy Difference

Moore and Lewis (2010) also start with a language model LM_I over the in-domain corpus, but then further construct a language model LM_O of similar size over the general-domain corpus. They then rank the general-domain corpus sentences using:

$$H_I(s) - H_O(s) \quad (2)$$

and again taking the lowest-scoring sentences. This criterion biases towards sentences that are both *like* the in-domain corpus and *unlike* the average of the general-domain corpus. For this experiment we reused the in-domain LM from the previous method, and trained a second LM on a random subset of 35k sentences from the Chinese side of the general corpus, except using the same vocabulary as the in-domain LM.

4.3 Data Selection using Bilingual Cross-Entropy Difference

In addition to using these two monolingual criteria for MT data selection, we propose a new method that takes in to account the bilingual nature of the problem. To this end, we sum cross-entropy difference over each side of the corpus, both source and target:

$$[H_{I-src}(s) - H_{O-src}(s)] + [H_{I-tgt}(s) - H_{O-tgt}(s)] \quad (3)$$

Again, lower scores are presumed to be better. This approach reuses the source-side language models from Section 4.2, but requires similarly-trained ones over the English side. Again, the vocabulary of the language model trained on a subset of the general-domain corpus was restricted to only cover those tokens found in the in-domain corpus, following Moore and Lewis (2010).

5 Results of Training Data Selection

The baseline results show that a translation system trained on the general-domain corpus outperforms a system trained on the in-domain corpus by over 3 BLEU points. However, this can be improved further. We used the three methods from Section 4 to identify the best-scoring sentences in the general-domain corpus.

We consider three methods for extracting domain-targeted parallel data from a general corpus: source-side cross-entropy (Cross-Ent), source-side cross-entropy difference (Moore-Lewis) from (Moore and Lewis, 2010), and bilingual cross-entropy difference (bML), which is novel.

Regardless of method, the overall procedure is the same. Using the scoring method, We rank the individual sentences of the general-domain corpus, select only the top N. We used the top $N = \{35k, 70k, 150k\}$ sentence pairs out of the 12 mil-

lion in the general corpus [5]. The net effect is that of domain adaptation via threshhold filtering. New MT systems were then trained solely on these small subcorpora, and compared against the baseline model trained on the entire 12m-sentence general-domain corpus. Table 2 contains BLEU scores of the systems trained on subsets of the general corpus.

Method	Sentences	Dev	Test
General	12m	42.62	40.51
Cross-Entropy	35k	39.77	40.66
Cross-Entropy	70k	40.61	**42.19**
Cross-Entropy	150k	42.73	**41.65**
Moore-Lewis	35k	36.86	40.08
Moore-Lewis	70k	40.33	39.07
Moore-Lewis	150k	41.40	40.17
bilingual M-L	35k	39.59	**42.31**
bilingual M-L	70k	40.84	**42.29**
bilingual M-L	150k	42.64	**42.22**

Table 2: Translation results using only a subset of the general-domain corpus.

All three methods presented for selecting a subset of the general-domain corpus (Cross-Entropy, Moore-Lewis, bilingual Moore-Lewis) could be used to train a state-of-the-art machine translation system. The simplest method, using only the source-side cross-entropy, was able to outperform the general-domain model when selecting 150k out of 12 million sentences. The other monolingual method, source-side cross-entropy difference, was able to perform nearly as well as the general-domain model with only 35k sentences. The bilingual Moore-Lewis method proposed in this paper works best, consistently boosting performance by 1.8 BLEU while using less than 1% of the available training data.

5.1 Pseudo In-Domain Data

The results in Table 2 show that all three methods (Cross-Entropy, Moore-Lewis, bilingual Moore-Lewis) can extract subsets of the general-domain corpus that are useful for the purposes of statistical machine translation. It is tempting to describe these as methods for finding in-domain data hidden in a general-domain corpus. Alas, this does not seem to be the case.

We trained a baseline language model on the in-domain data and used it to compute the perplexity of the same (in-domain) held-out dev set used to tune the translation models. We extracted the top N sentences using each ranking method, varying N from 10k to 200k, and then trained language models on these subcorpora. These were then used to also compute the perplexity of the same held-out dev set, shown below in Figure 1.

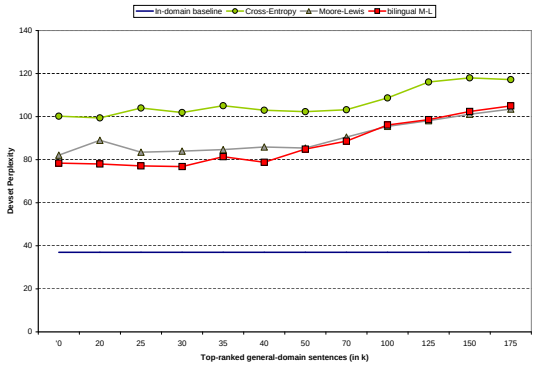

Figure 1: Corpus Selection Results

The perplexity of the dev set according to LMs trained on the top-ranked sentences varied from 77 to 120, depending on the size of the subset and the method used. The Cross-Entropy method was consistently worse than the others, with a best perplexity of 99.4 on 20k sentences, and bilingual Moore-Lewis was consistently the best, with a lowest perplexity of 76.8. And yet, none of these scores are anywhere near the perplexity of 36.96 according to the LM trained only on in-domain data.

From this it can be deduced that the selection methods are not finding data that is strictly in-domain. Rather they are extracting **pseudo in-domain** data which is relevant, but with a differing distribution than the original in-domain corpus.

As further evidence, consider the results of concatenating the in-domain corpus with the best extracted subcorpora (using the bilingual Moore-Lewis method), shown in Table 3. The change in

[5] Roughly 1x, 2x, and 4x the size of the in-domain corpus.

both the dev and test scores appears to reflect dissimilarity in the underlying data. Were the two datasets more alike, one would expect the models to reinforce each other rather than cancel out.

Method	Sentences	Dev	Test
IWSLT	30k	45.43	37.17
bilingual M-L	35k	39.59	**42.31**
bilingual M-L	70k	40.84	**42.29**
bilingual M-L	150k	42.64	**42.22**
IWSLT + bi M-L	35k	47.71	41.78
IWSLT + bi M-L	70k	47.80	**42.30**
IWSLT + bi M-L	150k	48.44	42.01

Table 3: Translation results concatenating the in-domain and pseudo in-domain data to train a single model.

6 Translation Model Combination

Because the pseudo in-domain data should be kept separate from the in-domain data, one must train multiple translation models in order to advantageously use the general-domain corpus. We now examine how best to combine these models.

6.1 Linear Interpolation

A common approach to managing multiple translation models is to interpolate them, as in (Foster and Kuhn, 2007) and (Lü et al., 2007). We tested the linear interpolation of the in- and general-domain translation models as follows: Given one model which assigns the probability $P_1(t|s)$ to the translation of source string s into target string t, and a second model which assigns the probability $P_2(t|s)$ to the same event, then the interpolated translation probability is:

$$P(t|s) = \lambda P_1(t|s) + (1 - \lambda)P_2(t|s) \qquad (4)$$

Here λ is a tunable weight between 0 and 1, which we tested in increments of 0.1. Linear interpolation of phrase tables was shown to improve performance over the individual models, but this still may not be the most effective use of the translation models.

6.2 Multiple Models

We next tested the approach in (Koehn and Schroeder, 2007), passing the two phrase tables directly to the decoder and tuning a system using both phrase tables in parallel. Each phrase table receives a separate set of weights during tuning, thus this combined translation model has more parameters than a normal single-table system.

Unlike (Nakov, 2008), we explicitly did not attempt to resolve any overlap between the phrase tables, as there is no need to do so with the multiple decoding paths. Any phrase pairs appearing in both models will be treated separately by the decoder. However, the exact overlap between the phrase tables was tiny, minimizing this effect.

6.3 Translation Model Combination Results

Table 4 shows baseline results for the in-domain translation system and the general-domain system, evaluated on the in-domain data. The table also shows that linearly interpolating the translation models improved the overall BLEU score, as expected. However, using multiple decoding paths, and no explicit model merging at all, produced even better results, by 2 BLEU points over the best individual model and 1.3 BLEU over the best interpolated model, which used $\lambda = 0.9$.

System	Dev	Test
IWSLT	45.43	37.17
General	42.62	40.51
Interpolate IWSLT, General	48.46	41.28
Use both IWSLT, General	49.13	**42.50**

Table 4: Translation model combination results

We conclude that it can be more effective to not attempt translation model adaptation directly, and instead let the decoder do the work.

7 Combining Multi-Model and Data Selection Approaches

We presented in Section 5 several methods to improve the performance of a single general-domain translation system by restricting its training corpus on an information-theoretic basis to a very small number of sentences. However, Section 6.3 shows that using two translation models over all the available data (one in-domain, one general-domain) outperforms any single individual translation model so far, albeit only slightly.

Method	Dev	Test
IWSLT	45.43	37.17
General	42.62	40.51
both IWSLT, General	49.13	42.50
IWSLT, Moore-Lewis 35k	48.51	40.38
IWSLT, Moore-Lewis 70k	49.65	40.45
IWSLT, Moore-Lewis 150k	49.50	41.40
IWSLT, bi M-L 35k	48.85	39.82
IWSLT, bi M-L 70k	49.10	**43.00**
IWSLT, bi M-L 150k	49.80	**43.23**

Table 5: Translation results from using in-domain and pseudo in-domain translation models together.

It is well and good to use the in-domain data to select pseudo in-domain data from the general-domain corpus, but given that this requires access to an in-domain corpus, one might as well use it. As such, we used the in-domain translation model alongside translation models trained on the subcorpora selected using the Moore-Lewis and bilingual Moore-Lewis methods in Section 4. The results are in Table 5.

A translation system trained on a pseudo in-domain subset of the general corpus, selected with the bilingual Moore-Lewis method, can be further improved by combining with an in-domain model. Furthermore, this system combination works better than the conventional multi-model approach by up to 0.7 BLEU on both the dev and test sets.

Thus a domain-adapted system comprising two phrase tables trained on a total of 180k sentences outperformed the standard multi-model system which was trained on 12 million sentences. This tiny combined system was also 3+ points better than the general-domain system by itself, and 6+ points better than the in-domain system alone.

8 Conclusions

Sentence pairs from a general-domain corpus that seem similar to an in-domain corpus may not actually represent the same distribution of language, as measured by language model perplexity. Nonetheless, we have shown that relatively tiny amounts of this *pseudo in-domain* data can prove more useful than the entire general-domain corpus for the purposes of domain-targeted translation tasks.

This paper has also explored three simple yet effective methods for extracting these pseudo in-domain sentences from a general-domain corpus. A translation model trained on any of these subcorpora can be comparable – or substantially better – than a translation system trained on the entire corpus.

In particular, the new bilingual Moore-Lewis method, which is specifically tailored to the machine translation scenario, is shown to be more efficient and stable for MT domain adaptation. Translation models trained on data selected in this way consistently outperformed the general-domain baseline while using as few as 35k out of 12 million sentences. This fast and simple technique for discarding over 99% of the general-domain training corpus resulted in an increase of 1.8 BLEU points.

We have also shown in passing that the linear interpolation of translation models may work less well for translation model adaptation than the multiple paths decoding technique of (Birch et al., 2007). These approaches of data selection and model combination can be stacked, resulting in a compact, two phrase-table, translation system trained on 1% of the available data that again outperforms a state-of-the-art translation system trained on all the data.

Besides improving translation performance, this work also provides a way to mine very large corpora in a computationally-limited environment, such as on an ordinary computer or perhaps a mobile device. The maximum size of a useful general-domain corpus is now limited only by the availability of data, rather than by how large a translation model can be fit into memory at once.

Abstract

We investigate the differences between language models compiled from original target-language texts and those compiled from texts manually translated to the target language. Corroborating established observations of Translation Studies, we demonstrate that the latter are significantly better predictors of translated sentences than the former, and hence fit the reference set better. Furthermore, translated texts yield better language models for statistical machine translation than original texts.

1 Introduction

Statistical machine translation (MT) uses large target language models (LMs) to improve the fluency of generated texts, and it is commonly assumed that for constructing language models, "more data is better data" (Brants and Xu, 2009). Not all data, however, are created the same. In this work we explore the differences between LMs compiled from texts originally written in the target language and LMs compiled from *translated* texts.

The motivation for our work stems from much research in Translation Studies that suggests that original texts are significantly different from translated ones in various aspects (Gellerstam, 1986). Recently, corpus-based computational analysis corroborated this observation, and Kurokawa et al. (2009) apply it to statistical machine translation, showing that for an English-to-French MT system, a *translation* model trained on an English-translated-to-French parallel corpus is better than one trained on French-translated-to-English texts. Our research question is whether a *language model* compiled from translated texts may similarly improve the results of machine translation.

We test this hypothesis on several translation tasks, where the target language is always English. For each language pair we build two English language models from two types of corpora: texts originally written in English, and human translations from the source language into English. We show that for each language pair, the latter language model better fits a set of reference translations in terms of perplexity. We also demonstrate that the differences between the two LMs are not biased by content but rather reflect differences on abstract linguistic features.

Research in Translation Studies suggests that all translated texts, irrespective of source language, share some so-called *translation universals*. Consequently, translated texts from several languages to a single target language resemble each other along various axes. To test this hypothesis, we compile additional English LMs, this time using texts translated to English from languages *other* than the source. Again, we use perplexity to assess the fit of these LMs to reference sets of translated-to-English sentences. We show that these LMs depend on the source language and differ from each other. Whereas they outperform original-based LMs, LMs compiled from texts that were translated from the *source* language still fit the reference set best.

Finally, we train phrase-based MT systems (Koehn et al., 2003) for each language pair. We use four types of LMs: original; translated from

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 363–374,
Edinburgh, Scotland, UK, July 27–31, 2011.

the source language; translated from other languages; and a mixture of translations from several languages. We show that the translated-from-source-language LMs provide a significant improvement in the quality of the translation output over all other LMs, and that the mixture LMs always outperform the original LMs. This improvement persists even when the original LMs are up to ten times larger than the translated ones.

The main contributions of this work are therefore a computational corroboration of the hypotheses that

1. original and translated texts exhibit significant, measurable differences;
2. LMs compiled from translated texts better fit translated references than LMs compiled from original texts of the same (and much larger) size (and, to a lesser extent, LMs compiled from texts translated from languages other than the source language); and
3. MT systems that use LMs based on manually translated texts significantly outperform LMs based on originally written texts.

It is important to emphasize that translated texts abound: Many languages, especially low-resource ones, are more likely to have translated texts (religious scripts, educational materials, etc.) than original ones. Some numeric data are listed in Pym and Chrupała (2005). Furthermore, such data can be automatically identified (see Section 2). The practical impact of our work on MT is therefore potentially dramatic.

This paper is organized as follows: Section 2 provides background and describes related work. We explain our research methodology and resources in Section 3 and detail our experiments and results in Section 4. Section 5 discusses the results and their implications.

2 Background and Related Work

Numerous studies suggest that translated texts are different from original ones. Gellerstam (1986) compares texts written originally in Swedish and texts translated from English into Swedish. He notes that the differences between them do not indicate poor translation but rather a statistical phenomenon, which he terms *translationese*. He focuses mainly on lexical differences, for example less colloquialism in the translations, or foreign words used in the translations "with new shades of meaning taken from the English lexeme" (p.91). Only later studies consider grammatical differences (see, e.g., Santos (1995)). The features of translationese were theoretically organized under the terms *laws of translation* and *translation universals*.

Toury (1980, 1995) distinguishes between two laws: the *law of interference* and the *law of growing standardization*. The former pertains to the fingerprints of the source text that are left in the translation product. The latter pertains to the effort to standardize the translation product according to existing norms in the target language (and culture). Interestingly, these two laws are in fact reflected in the architecture of statistical machine translation: interference corresponds to the translation model and standardization to the language model.

The combined effect of these laws creates a hybrid text that partly corresponds to the source text and partly to texts written originally in the target language but in fact belongs to neither (Frawley, 1984). Baker (1993, 1995, 1996) suggests several candidates for translation universals, which are claimed to appear in any translated text, regardless of the source language. These include *simplification*, the tendency of translated texts to simplify the language, the message or both; and *explicitation*, their tendency to spell out implicit utterances that occur in the source text.

Baroni and Bernardini (2006) use machine learning techniques to distinguish between original and translated Italian texts, reporting 86.7% accuracy. They manage to abstract from content and perform the task using only morpho-syntactic cues. Ilisei et al. (2010) perform the same task for Spanish but enhance it theoretically in order to check the simplification hypothesis. The most informative features are lexical variety, sentence length and lexical density.

van Halteren (2008) focuses on six languages from Europarl (Koehn, 2005): Dutch, English, French, German, Italian and Spanish. For each

of these languages, a parallel six-lingual subcorpus is extracted, including an original text and its translations into the other five languages. The task is to identify the source language of translated texts, and the reported results are excellent. This finding is crucial: as Baker (1996) states, translations do resemble each other; however, in accordance with the law of interference, the study of van Halteren (2008) suggests that translation from different source languages constitute different sublanguages. As we show in Section 4.2, LMs based on translations from the source language outperform LMs compiled from non-source translations, in terms of both fitness to the reference set and improving MT.

Kurokawa et al. (2009) show that the direction of translation affects the performance of statistical MT. They train systems to translate between French and English (and vice versa) using a French-translated-to-English parallel corpus, and then an English-translated-to-French one. They find that in translating into French it is better to use the latter parallel corpus, and when translating into English it is better to use the former. Whereas they focus on the translation model, we focus on the language model in this work. We show that using a LM trained on a text translated from the source language of the MT system does indeed improve the results of the translation.

3 Methodology and Resources

3.1 Hypotheses

We investigate the following three hypotheses:

1. Translated texts differ from original texts;
2. Texts translated from one language differ from texts translated from other languages;
3. LMs compiled from manually translated texts are better for MT as measured using BLEU than LMs compiled from original texts.

We test our hypotheses by considering translations from several languages to English. For each language pair we create a reference set comprising several thousands of sentences written originally in the source language and manually translated to English. Section 3.4 provides details on the reference sets.

To investigate the first hypothesis, we train two LMs for each language pair, one created from original English texts and the other from texts translated into English. Then, we check which LM better fits the reference set.

Fitness of a LM to a set of sentences is measured in terms of *perplexity* (Jelinek et al., 1977; Bahl et al., 1983). Given a language model and a test (reference) set, perplexity measures the predictive power of the language model over the test set, by looking at the average probability the model assigns to the test data. Intuitively, a better model assigns higher probablity to the test data, and consequently has a *lower* perplexity; it is *less* surprised by the test data. Formally, the perplexity PP of a language model L on a test set $W = w_1\, w_2 \ldots w_N$ is the probability of W normalized by the number of words N Jurafsky and Martin (2008, page 96):

$$PP(L, W) = \sqrt[N]{\prod_{i=1}^{N} \frac{1}{P_L(w_i | w_1 \ldots w_{i-1})}} \quad (1)$$

For the second hypothesis, we extend the experiment to LMs created from texts translated from other languages to English. For example, we test how well a LM trained on French-to-English-translated texts fits the German-to-English reference set; and how well a LM trained on German-to-English-translated texts fits the French-to-English reference set.

Finally, for the third hypothesis, we use these LMs for statistical MT (SMT). For each language pair we build several SMT systems. All systems use a translation model extracted from a parallel corpus which is oblivious to the direction of the translation; and one of the above-mentioned LMs. Then, we compare the translation quality of these systems in terms of the BLEU metric (Papineni et al., 2002).

3.2 Language Models

In all the experiments, we use SRILM (Stolcke, 2002) to train 4-gram language models (with the default backoff model) from various corpora. Our main corpus is Europarl (Koehn, 2005), specifically portions collected over years 1996 to

1999 and 2001 to 2009. This is a large multilingual corpus, containing sentences translated from several European languages. However, it is organized as a collection of bilingual corpora rather than as a single multilingual one, and it is hard to identify sentences that are translated to several languages.

We therefore treat each bilingual sub-corpus in isolation; each such sub-corpus contains sentences translated from various languages. We rely on the **language** attribute of the **speaker** tag to identify the source language of sentences in the English part of the corpus. Since this tag is rarely used with English-language speakers, we also exploit the **ID** attribute of the **speaker** tag, which we match against the list of British members of the European parliament.

We focus on the following languages: German (DE), French (FR), Italian (IT), and Dutch (NL). For each of these languages, L, we consider the L-English Europarl sub-corpus. In each sub-corpus, we extract chunks of approximately 2.5 million *English* tokens translated from each of these source languages (T-L), as well as sentences written originally in English (O-EN). The mixture corpus (MIX), which is designed to represent "general" translated language, is constructed by randomly selecting sentences translated from any language (excluding original English sentences). Table 1 lists the number of sentences, number of tokens and average sentence length, for each sub-corpus and each original language.

In addition, we use the Hansard corpus, containing transcripts of the Canadian parliament from 1996–2007[1]. This is a bilingual French–English corpus comprising about 80% original English texts (EO) and about 20% texts translated from French (FO). We first separate original English from the original French and then, for each original language, we randomly extract portions of texts of different sizes: 1M, 5M and 10M tokens from the FO corpus and 1M, 5M, 10M, 25M, 50M and 100M tokens from the EO corpus; see Table 2.

[1]We are grateful to Cyril Goutte, George Foster and Pierre Isabelle for providing us with an annotated version of this corpus.

Table 1: Europarl corpus statistics

To experiment with a non-European language (and a different genre) we choose Hebrew (HE). We use two English corpora: The *original* (O-EN) corpus comprises articles from the *International Herald Tribune*, downloaded over a period of seven months (from January to July 2009). The articles cover four topics: news (53.4%), business (20.9%), opinion (17.6%) and arts (8.1%). The *translated* (T-HE) corpus consists of articles collected from the Israeli newspaper *HaAretz* over the same period of time. *HaAretz* is published in Hebrew, but portions of

3.3 SMT Training Data

To focus on the effect of the *language* model on translation quality, we design SMT training corpora to be oblivious to the direction of translation. Again, we use Europarl (January 2000 to September 2000) as the main source of our parallel corpora. We also use the Hansard corpus: We randomy extract 50,000 sentences from the original French sub-corpora and another 50,000 sentences from the original English sub-corpora. For Hebrew we use the Hebrew–English parallel corpus (Tsvetkov and Wintner, 2010) which contains sentences translated from Hebrew to English (54%) and from English to Hebrew (46%). The English-to-Hebrew part comprises many short sentences (approximately 6 tokens per sentence) taken from a movie subtitle database. This explains the small token to sentence ratio of this particular corpus. Table 4 lists some details on those corpora.

Lang's	**Side**	**Sent's**	**Tokens**	**Len**

	EN	95,912	856,830	8.9

Table 4: SMT training data details

3.4 Reference Sets

The reference sets have two uses. First, they are used as the test sets in the experiments that measure the perplexity of the language models. Second, in the MT experiments we use them to randomly extract 1000 sentences for tuning and 1000 (different) sentences for evaluation.

For each language L we use the L-English subcorpus of Europarl (over the period of October to December 2000), containing only sentences originally produced in language L. The Hansard reference set is completely disjoint from the LM and SMT training sets and comprises only original French sentences. The Hebrew-to-English reference set is an independent (disjoint) part of the Hebrew-to-English parallel corpus. This set mostly comprises literary data (88.6%) and a small portion of news (11.4%). All sentences are originally written in Hebrew and are manually translated to English. See Table 5.

4 Experiments and Results

We detail in this section the experiments performed to test the three hypotheses: that translated texts can be distinguished from original ones, and provide better language models of other translated texts; that texts translated from other languages than the source are still better predictors of translations than original texts (Section 4.1); and that these differences are important for SMT (Section 4.2).

Table 5: Reference sets

4.1 Translated vs. Original texts

We train several 4-gram LMs for each Europarl sub-corpus, based on the corpora described in Section 3.2. For each language L, we train a LM based on texts translated from L, from languages other than L as well as texts originally written in English. The LMs are applied to the reference set of texts translated from L, and we compute the perplexity: the fitness of the LM to the reference set. Table 6 details the results, where for each sub-corpus and LM we list the number of unigrams in the test set, the number of out-of-vocabulary items (OOV) and the perplexity (PP). The lowest perplexity (reflecting the **best** fit) in each sub-corpus is typeset in boldface, and the highest (*worst* fit) is slanted.

These results overwhelmingly support our hypothesis. For each language L, the perplexity of the LM that was created from L translations is lowest, followed immediately by the MIX LM. Furthermore, the perplexity of the LM created from originally-English texts is highest in all experiments. In addition, the perplexity of LMs constructed from texts translated from languages other than L always lies between these two extremes: it is a better fit of the reference set than original texts, but not as good as texts translated from L (or mixture translations). This corroborates the hypothesis that translations form a language in itself, and translations from L_1 to L_2, form a sub-language, related to yet different from translations from other languages to L_2.

Table 6: Fitness of various LMs to the reference set

A possible explanation for the different perplexity results between the LMs could be the specific contents of the corpora used to compile the LMs. To rule out this possibility and to further emphasize that the corpora are indeed *structurally* different, we conduct more experiments, in which we gradually abstract away from the domain- and content-specific features of the texts and emphasize their syntactic structure. We focus on German-to-English.

First, we remove all punctuation to eliminate

possible bias due to differences in punctuation conventions. Then, we use the Stanford Named Entity Recognizer (Finkel et al., 2005) to identify named entities, which we replace with a unique token ('NE'). Next, we replace all nouns with their POS tag; we use the Stanford POS Tagger (Toutanova and Manning, 2000). Finally, for full lexical abstraction, we replace all words with their POS tags.

At each step, we train six language models on O- and T-texts and apply them to the reference set (adapted to the same level of abstraction, of course). As the abstraction of the text increases, we also increase the order of the LMs: From 4-grams for text without punctuation and NE abstraction to 5-grams for noun abstraction to 8-grams for full POS abstraction. The results, which are depicted in Table 7, consistently show that the T-based LM is a better fit to the reference set, albeit to a lesser extent. While we do not show the details here, the same pattern is persistent in all the other Europarl languages we experiment with.

We repeat this experiment with the Hebrew-to-English reference set. We train two 4-gram LMs on the O-EN and T-HE corpora. We then apply the two LMs to the reference set and compute the perplexity. The results are presented in Table 8. Although the T-based LM has more OOVs, it is a better fit to the translated text than the O-based LM: Its perplexity is lower by 20.1%. Interestingly, the O-corpus LM has more unique unigrams than the T-corpus LM, supporting the claim of Al-Shabab (1996) that translated texts have lower type-to-token ratio.

We also conduct the above-mentioned abstraction experiments. The results, which are depicted in Table 9, consistently show that the T-based LM is a better fit to the reference set.

Clearly, then, translated LMs better fit the references than original ones, and the differences can be traced back not just to (trivial) specific lexical choice, but also to syntactic structure, as evidenced by the POS abstraction experiments. In fact, in order to retain the low perplexity level of translated texts, a LM based on original texts must be approximately ten times larger. We establish this by experimenting with the Hansard corpus. The results are persistent, but are omitted for lack of space.

English MT systems using the Moses phrase-based SMT toolkit (Koehn et al., 2007). The systems are trained on the parallel corpora described in Section 3.3. We use the reference sets (Section 3.4) as follows: 1,000 sentences are randomly extracted for minimum error-rate tuning (Och, 2003), and another set of 1,000 sentences is randomly used for evaluation. Each system is built and tuned with six different LMs: MIX, O-based and four T-based (Section 3.2). We use BLEU (Papineni et al., 2002) to evaluate translation quality. The results are listed in Table 10.

These results are consistent: the translated-from-source systems outperform all other systems; mixture models come second; and systems that use original English LMs always perform worst. We test the statistical significance of differences between various MT systems using the bootstrap resampling method (Koehn, 2004). In all experiments, the best system (translated-from-source LM) is significantly better than all

other systems ($p < 0.05$); (even more) significantly better than the O-EN system ($p < 0.01$); and the mixture systems are significantly better than the O-EN systems ($p < 0.01$).

We also construct a Hebrew-to-English MT system using Moses' factored translation model (Koehn and Hoang, 2007). Every token in the training corpus is represented as two factors: surface form and lemma. Moreover, the Hebrew input is fully segmented. The system is built and tuned with O- and T-based LMs. Table 11 depicts the performance of the systems. The T-based LM yields a statistically better BLEU score than the O-based system.

LM	**BLEU**	**p-value**
O-based LM	*11.98*	0.012
T-based LM	**12.57**	

Table 11: Hebrew-to-English MT results

The LMs used in the above experiments are small. We now want to assess whether the benefits of using translated LMs carry over to scenarios where large original corpora exist. We build yet another set of French-to-English MT systems. We use the Hansard SMT translation model and Hansard LMs to train nine MT systems, three with varying sizes of translated texts and six with varying sizes of original texts.

We tune and evaluate on the Hansard reference set. In another set of experiments we use the Europarl French-to-English scenario (using Europarl corpora for the translation model and for tuning and evaluation), but we use the nine Hansard LMs to see whether our findings are consistent also when LMs are trained on out-of-domain (but similar genre) material.

Table 12 shows that the original English LMs should be enlarged by a factor of *ten* to achieve translation quality similar to that of translation-based LMs. In other words, much smaller translated LMs perform better than much larger original ones, and this is true for various LM sizes.

5 Discussion

We use language models computed from different types of corpora to investigate whether their fitness to a reference set of translated-to-English sentences can differentiate between them (and, hence, between the corpora on which they are based). Our main findings are that LMs compiled from manually translated corpora are much better predictors of translated texts than LMs compiled from original-language corpora of the same size. The results are robust, and are sustainable even when the corpora and the reference sentences are abstracted in ways that retain their syntactic structure but ignore specific word meanings. Furthermore, we show that translated LMs are better predictors of translated sentences even when the LMs are compiled from texts translated from languages *other* than the source language. However, LMs based on texts translated from the source language still outperform LMs translated from other languages.

We also show that MT systems based on translated-from-source-language LMs outperform MT systems based on originals LMs or LMs translated from other languages. Again, these results are robust and the improvements are statistically significant. This effect seems to be amplified as translation quality improves. Furthermore, our results show that original LMs require ten times more data to exhibit the same fitness to the reference set and the same translation quality as translated LMs.

More generally, this study confirms that insights drawn from the field of theoretical translation studies, namely the dual claim according to which (1) translations as such differ from originals, and (2) translations from different source languages differ from each other, can be verified experimentally and contribute to the performance of machine translation.

Future research is needed in order to understand *why* this is the case. One plausible hypothesis is that recurrent multiword expressions in the source language are frequently solved by human translations and each of these expressions converges to a set of high-quality translation equivalents which are represented in the LM. Another hypothesis is that since translation-based LMs represent a simplified mode of language use, the error potential is smaller. We therefore expect translation-based LMs to use more unmarked forms.

This work also bears on language typology: we conjecture that LMs compiled from texts translated not from the original language, but from a closely related one, can be better than texts translated from a more distant language. Some of our results support this hypothesis, but more research is needed in order to establish it.

Better Evaluation Metrics Lead to Better Machine Translation

Abstract

Many machine translation evaluation metrics have been proposed after the seminal BLEU metric, and many among them have been found to consistently outperform BLEU, demonstrated by their better correlations with human judgment. It has long been the hope that by tuning machine translation systems against these new generation metrics, advances in automatic machine translation evaluation can lead directly to advances in automatic machine translation. However, to date there has been no unambiguous report that these new metrics can improve a state-of-the-art machine translation system over its BLEU-tuned baseline.

In this paper, we demonstrate that tuning Joshua, a hierarchical phrase-based statistical machine translation system, with the TESLA metrics results in significantly better human-judged translation quality than the BLEU-tuned baseline. TESLA-M in particular is simple and performs well in practice on large datasets. We release all our implementation under an open source license. It is our hope that this work will encourage the machine translation community to finally move away from BLEU as the unquestioned default and to consider the new generation metrics when tuning their systems.

1 Introduction

The dominant framework of machine translation (MT) today is statistical machine translation (SMT) (Hutchins, 2007). At the core of the system is the decoder, which performs the actual translation. The decoder is parameterized, and estimating the optimal set of parameter values is of paramount importance in getting good translations. In SMT, the parameter space is explored by a tuning algorithm, typically MERT (Minimum Error Rate Training) (Och, 2003), though the exact method is not important for our purpose. The tuning algorithm carries out repeated experiments with different decoder parameter values over a *development data set*, for which reference translations are given. An automatic MT evaluation metric compares the output of the decoder against the reference(s), and guides the tuning algorithm towards iteratively better decoder parameters and output translations. The quality of the automatic MT evaluation metric therefore has an immediate effect on the whole system.

The first automatic MT evaluation metric to show a high correlation with human judgment is BLEU (Papineni et al., 2002). Together with its close variant the NIST metric, they have quickly become the standard way of tuning statistical machine translation systems. While BLEU is an impressively simple and effective metric, recent evaluations have shown that many new generation metrics can outperform BLEU in terms of correlation with human judgment (Callison-Burch et al., 2009; Callison-Burch et al., 2010). Some of these new metrics include METEOR (Banerjee and Lavie, 2005; Lavie and Agarwal, 2007), TER (Snover et al., 2006), MAXSIM (Chan and Ng, 2008; Chan and Ng, 2009), and TESLA (Liu et al., 2010).

Given the close relationship between automatic MT and automatic MT evaluation, the logical expectation is that a better MT evaluation metric would

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 375–384,
Edinburgh, Scotland, UK, July 27–31, 2011.

lead to better MT systems. However, this linkage has not yet been realized. In the SMT community, MT tuning still uses BLEU almost exclusively.

Some researchers have investigated the use of better metrics for MT tuning, with mixed results. Most notably, Padó et al. (2009) reported improved human judgment using their entailment-based metric. However, the metric is heavy weight and slow in practice, with an estimated runtime of 40 days on the NIST MT 2002/2006/2008 dataset, and the authors had to resort to a two-phase MERT process with a reduced n-best list. As we shall see, our experiments use the similarly sized WMT 2010 dataset, and most of our runs take less than one day.

Cer et al. (2010) compared tuning a phrase-based SMT system with BLEU, NIST, METEOR, and TER, and concluded that BLEU and NIST are still the best choices for MT tuning, despite the proven higher correlation of METEOR and TER with human judgment.

In this work, we investigate the effect of MERT using BLEU, TER, and two variants of TESLA, TESLA-M and TESLA-F, on Joshua (Li et al., 2009), a state-of-the-art hierarchical phrase-based SMT system (Chiang, 2005; Chiang, 2007). Our empirical study is carried out in the context of WMT 2010, for the French-English, Spanish-English, and German-English machine translation tasks. We show that Joshua responds well to the change of evaluation metric, in that a system trained on metric M typically does well when judged by the same metric M. We further evaluate the different systems with manual judgments and show that the TESLA family of metrics (both TESLA-M and TESLA-F) significantly outperforms BLEU when used to guide the MERT search.

The rest of this paper is organized as follows. In Section 2, we describe the four evaluation metrics used. Section 3 outlines our experimental set up using the WMT 2010 machine translation tasks. Section 4 presents the evaluation results, both automatic and manual. Finally, we discuss our findings in Section 5, future work in Section 6, and conclude in Section 7.

2 Evaluation metrics

This section describes the metrics used in our experiments. We do not seek to explain all their variants and intricate details, but rather to outline their core characteristics and to highlight their similarities and differences. In particular, since all our experiments are based on single references, we omit the complications due to multiple references and refer our readers instead to the respective original papers for the details.

2.1 BLEU

BLEU is fundamentally based on n-gram match precisions. Given a reference text R and a translation candidate T, we generate the bag of all n-grams contained in R and T for $n = 1, 2, 3, 4$, and denote them as $\mathrm{BNG}^{\mathrm{n}}_{\mathrm{R}}$ and $\mathrm{BNG}^{\mathrm{n}}_{\mathrm{T}}$ respectively. The n-gram precision is thus defined as

$$P_n = \frac{|\mathrm{BNG}^{\mathrm{n}}_{\mathrm{R}} \cap \mathrm{BNG}^{\mathrm{n}}_{\mathrm{T}}|}{|\mathrm{BNG}^{\mathrm{n}}_{\mathrm{T}}|}$$

To compensate for the lack of the recall measure, and hence the tendency to produce short translations, BLEU introduces a *brevity penalty*, defined as

$$\mathrm{BP} = \begin{cases} 1 & \text{if} |\mathrm{T}| > |\mathrm{R}| \\ e^{1-|R|/|T|} & \text{if} |\mathrm{T}| \leq |\mathrm{R}| \end{cases}$$

where the $|\cdot|$ operator denotes the size of a bag or the number of words in a text. The metric is finally defined as

$$\mathrm{BLEU}(\mathrm{R}, \mathrm{T}) = \mathrm{BP} \times \sqrt[4]{P_1 P_2 P_3 P_4}$$

BLEU is a very simple metric requiring neither training nor language-specific resources. Its use of the brevity penalty is however questionable, as subsequent research on n-gram-based metrics has consistently found that recall is in fact a more potent indicator than precision (Banerjee and Lavie, 2005; Zhou et al., 2006; Chan and Ng, 2009). As we shall see, despite the BP term, BLEU still exhibits a strong tendency to produce short translations.

2.2 TER

TER is based on counting transformations rather than n-gram matches. The metric is defined as the

minimum number of edits needed to change a candidate translation T to the reference R, normalized by the length of the reference, i.e.,

$$\mathrm{TER(R,T)} = \frac{\text{number of edits}}{|\mathrm{R}|}$$

One edit is defined as one insertion, deletion, or substitution of a single word, or the shift of a contiguous sequence of words, regardless of size and distance. Minimizing the edit distance so defined has been shown to be NP-complete, so the evaluation is carried out in practice by a heuristic greedy search algorithm.

TER is a strong contender as the leading new generation automatic metric and has been used in major evaluation campaigns such as GALE. Like BLEU, it is simple and requires no language specific resources. TER also corresponds well to the human intuition of an evaluation metric.

2.3 TESLA-M

TESLA[1] is a family of linear programming-based metrics proposed by Liu et al. (2010) that incorporates many newer ideas. The simplest variation is TESLA-M[2], based on matching bags of n-grams (BNG) like BLEU. However, unlike BLEU, TESLA-M formulates the matching process as a real-valued linear programming problem, thereby allowing the use of weights. An example weighted BNG matching problem is shown in Figure 1.

Two kinds of weights are used in TESLA-M. First, the metric emphasizes the content words by discounting the weight of an n-gram by 0.1 for every function word it contains. Second, the *similarity* between two n-grams is a function dependent on the lemmas, the WordNet synsets (Fellbaum, 1998), and the POS tag of every word in the n-grams.

Each node in Figure 1 represents one weighted n-gram. The four in the top row represent one BNG, and the three at the bottom represent the other BNG. The goal of the linear programming problem is to assign weights to the links between the two BNGs, so as to maximize the sum of the products of the link weights and their corresponding similarity scores.

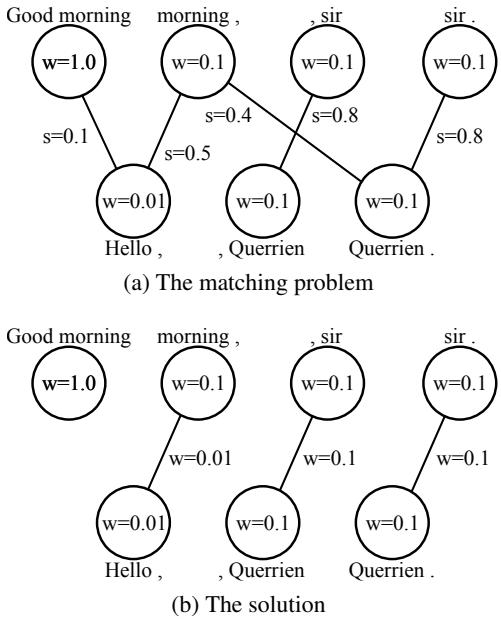

Figure 1: Matching two weighted bags of n-grams. w denotes the weight and s denotes the similarity.

The constraints of the linear programming problem are: (1) all assigned weights must be non-negative, and (2) the sum of weights assigned to all links connecting a node cannot exceed the node's weight. Intuitively, we allow splitting n-grams into fractional counts, and match them giving priority to the pairs with the highest similarities.

The linear programming formulation ensures that the matching can be solved uniquely and efficiently. Once the solution is found and let the maximized objective function value be S, the precision is computed as S over the sum of weights of the translation candidate n-grams. Similarly, the recall is S over the sum of weights of the reference n-grams. The precision and the recall are then combined to form the F-0.8 measure:

$$F_n = \frac{\text{Precision} \times \text{Recall}}{0.8 \times \text{Precision} + 0.2 \times \text{Recall}}$$

This F-measure gives more importance to the recall, reflecting its closer correlation with human judgment. F_n for $n = 1, 2, 3$ are calculated and averaged to produce the final score.

TESLA-M gains an edge over the previous two metrics by the use of lightweight linguistic features such as lemmas, synonym dictionaries, and POS

[1]The source code of TESLA is available at nlp.comp.nus.edu.sg/software/

[2]M stands for *minimal*.

1-TERp	.81
BLEU-4-v13a-c	.80
TESLA-F	.76

Table 2: Selected system-level Spearman's rho correlation with the human judgment for the out-of-English task, as reported in WMT 2010.

tags. While such tools are usually available even for languages other than English, it does make TESLA-M more troublesome to port to non-English languages.

TESLA-M did well in the WMT 2010 evaluation campaign. According to the system-level correlation with human judgments (Tables 1 and 2), it ranks top for the out-of-English task and very close to the top for the into-English task (Callison-Burch et al., 2010).

2.4 TESLA-F[3]

TESLA-F builds on top of TESLA-M. While word-level synonyms are handled in TESLA-M by examining WordNet synsets, no modeling of phrase-level synonyms is possible. TESLA-F attempts to remedy this shortcoming by exploiting a phrase table between the target language and another language, known as the pivot language.

Assume the target language is English and the pivot language is French, i.e., we are provided with an English-French phrase table. Let R and T be the

[3]TESLA-F refers to the metric called TESLA in (Liu et al., 2010). To minimize confusion, in this work we call the metric TESLA-F and refer to the whole family of metrics as TESLA. F stands for *full.*

Figure 2: A degenerate confusion network in French. The phrase table maps *Good morning , sir .* to *Bonjour , monsieur .*

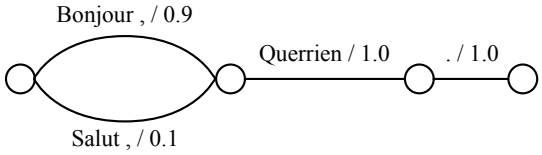

Figure 3: A confusion network in French. The phrase table maps *Hello ,* to *Bonjour ,* with $P = 0.9$ and to *Salut ,* with $P = 0.1$.

reference and the translation candidate respectively, both in English. As an example,

R: Good morning , sir .
T: Hello , Querrien .

TESLA-F first segments both R and T into phrases to maximize the probability of the sentences. For example, suppose both *Good morning , sir .* and *Hello ,* can be found in the English-French phrase table, and proper name *Querrien* is out-of-vocabulary, then a likely segmentation is:

R: ||| Good morning , sir . |||
T: ||| Hello , ||| Querrien ||| . |||

Each English phrase is then mapped to a bag of weighted French phrases using the phrase table, transforming the English sentences into confusion networks resembling Figures 2 and 3. French n-grams are extracted from these confusion network representations, known as pivot language n-grams. The bag of pivot language n-grams generated by R is then matched against that generated by T with the same linear programming formulation used in TESLA-M.

TESLA-F incorporates all the F-measures used in TESLA-M, with the addition of (1) the F-measures generated over the pivot language n-grams described above, and (2) the normalized language model score, defined as $\frac{1}{n} \log P$, where n is the length of the translation, and P the language model probability. Unlike BLEU and TESLA-M which rely on simple averages (geometric and arithmetic average respectively) to combine the component scores, TESLA-

F trains the weights over a set of human judgments using a linear ranking support vector machine (RSVM). This allows TESLA-F to exploit its components more effectively, but also makes it more tedious to work with and introduces potential domain mismatch problems.

TESLA-F makes use of even more linguistic information than TESLA-M, and has the capability of recognizing some forms of phrase synonyms. TESLA-F ranked top for the into-English evaluation task in WMT 2010 (Table 1). However, the added complexity, in particular the use of the language model score and the tuning of the component weights appear to make it less stable than TESLA-M in practice. For example, it did not perform as well in the out-of-English task.

3 Experimental setup

We run our experiments in the setting of the WMT 2010 news commentary machine translation campaign, for three language pairs:

1. French-English (fr-en): the training text consists of 84624 sentences of French-English bitext. The average French sentence length is 25 words.

2. Spanish-English (es-en): the training text consists of 98598 sentences of Spanish-English bitext. The average Spanish sentence length is 25 words.

3. German-English (de-en): the training text consists of 100269 sentences of German-English bitext. The average German sentence length is 22 words.

The average English sentence length is 21 words for all three language pairs. The text domain is newswire report, and the English sides of the training texts for the three language pairs overlap substantially. The development data are 2525 four-way translated sentences, in English, French, Spanish, and German respectively. Similarly, the test data are 2489 four-way translated sentences. As a consequence, all MT evaluations involve only single references.

We follow the standard approach for training hierarchical phrase-based SMT systems. First, we tokenize and lowercase the training texts and create word alignments using the Berkeley aligner (Liang et al., 2006; Haghighi et al., 2009) with five iterations of training. Then, we create suffix arrays and extract translation grammars for the development and test set with Joshua in its default setting. The maximum phrase length is 10. For the language model, we use SRILM (Stolcke, 2002) to build a trigram model with modified Kneser-Ney smoothing from the monolingual training data supplied in WMT 2010.

	fr-en	es-en	de-en
BLEU	3:49 (4)	5:09 (6)	2:41 (4)
TER	4:03 (4)	3:59 (4)	3:59 (5)
TESLA-M	13:00 (3)	17:34 (5)	13:40 (4)
TESLA-F	35:07 (4)	40:54 (4)	40:28 (5)

Table 3: Z-MERT training times in hours:minutes and number of iterations in parenthesis

Parameter tuning is carried out using Z-MERT (Zaidan, 2009). TER and BLEU are already implemented in the publicly released version of Z-MERT, and Z-MERT's modular design makes it easy to integrate TESLA-M and TESLA-F into the package. The maximum number of MERT iterations is set to 100, although we observe that in practice, the algorithm converges after 3 to 6 iterations. The number of intermediate initial points per iteration is set to 20 and the n-best list is capped to 300 translations. Table 3 shows the training times and the number of MERT iterations for each of the language pairs and evaluation metrics.

We use the publicly available version of TESLA-F, which comes with phrase tables and a ranking SVM model trained on the WMT 2010 development data.

4 Automatic and manual evaluations

The results of the automatic evaluations are presented in Table 4. The best score according to each metric is shown in bold. Note that smaller TER scores are better, as are larger BLEU, TESLA-M, and TESLA-F scores.[4]

We note that Joshua generally responds well to the change of tuning metric. A system tuned on met-

Spanish-English	0.6124	0.4185
German-English	0.3973	0.0960

Table 5: Inter-annotator agreement

ric M usually does the best or very close to the best when evaluated by M. On the other hand, the differences between different systems can be substantial, especially between BLEU/TER and TESLA-M/TESLA-F.

In addition to the automatic evaluation, we enlisted twelve judges to manually evaluate the first 200 test sentences. Four judges are assigned to each of the three language pairs. For each test sentence, the judges are presented with the source sentence, the reference English translation, and the output from the four competing Joshua systems. The order of the translation candidates is randomized so that the judges will not see any patterns. The judges are instructed to rank the four candidates, and ties are allowed.

The inter-annotator agreement is reported in Table 5. We consider the judgment for a pair of system outputs as one data point. Let $P(A)$ be the proportion of times that the annotators agree, and $P(E)$ be the proportion of times that they would agree by chance. The Kappa coefficient is defined as

$$\text{Kappa} = \frac{\text{P(A)} - \text{P(E)}}{1 - \text{P(E)}}$$

In our experiments, each data point has three possible values: A is preferred, B is preferred, and no preference, hence $P(E) = 1/3$. Our Kappa is calculated in the same way as the WMT workshops (Callison-Burch et al., 2009; Callison-Burch et al., 2010).

Kappa coefficients between 0.4 and 0.6 are considered *moderate*, and our values are in line with those reported in the WMT 2010 translation campaign. The exception is the German-English pair, where the annotators only reach *slight* agreement. This might be caused by the lower quality of German to English translations compared to the other two language pairs.

	fr-en	es-en	de-en
BLEU	44.1%	33.8%	49.6%
TER	41.4%	34.4%	47.8%
TESLA-M	65.8%	49.5%	57.8%
TESLA-F	66.4%	53.8%	55.1%

Table 6: Percentage of times each system produces the best translation

Table 6 shows the proportion of times each system produces the best translation among the four. We observe that the rankings are largely consistent across different language pairs: Both TESLA-F and TESLA-M strongly outperform BLEU and TER. Note that the values in each column do not add up to 100%, since the candidate translations are often identical, and even a different translation can receive the same human judgment.

Table 7 shows our main result, the pairwise comparison between the four systems for each of the language pairs. Again the rankings consistently show that both TESLA-F and TESLA-M strongly outperform BLEU and TER. All differences are statistically significant under the Sign Test at $p = 0.01$, with the exception of TESLA-M vs TESLA-F in the French-English task, BLEU vs TER in the Spanish-English task, and TESLA-M vs TESLA-F and BLEU vs TER in the German-English task. The results provide strong evidence that tuning machine

translation systems using the TESLA metrics leads to significantly better translation output.

5 Discussion

We examined the results manually, and found that the relationship between the types of mistakes each system makes and the characteristics of the corresponding metric to be intricate. We discuss our findings in this section.

First we observe that BLEU and TER tend to produce very similar translations, and so do TESLA-F and TESLA-M. Of the 2489 test sentences in the French-English task, BLEU and TER produced different translations for only 760 sentences, or 31%. Similarly, TESLA-F and TESLA-M gave different outputs for only 857 sentences, or 34%. In contrast, BLEU and TESLA-M gave different translations for 2248 sentences, or 90%. It is interesting to find that BLEU and TER should be so similar, considering that they are based on very different principles. As a metric, TESLA-M is certainly much more similar to BLEU than TER is, yet they behave very differently when used as a tuning metric.

We also observe that TESLA-F and TESLA-M tend to produce much longer sentences than do BLEU and TER. The average sentence lengths of the TESLA-F- and TESLA-M-tuned systems across all three language pairs are 26.5 and 26.6 words respectively, whereas those for BLEU and TER are only 22.4 and 21.7 words. Comparing the translations from the two groups, the tendency of BLEU and TER to pick shorter paraphrases and to drop function words is unmistakable, often to the detriment of the translation quality. Some typical examples from the French-English task are shown in Figure 4.

Interestingly, the human translations average only 22 words, so BLEU and TER translations are in fact much closer on average to the reference lengths, yet their translations often feel too short. In contrast, manual inspections reveal no tendency for TESLA-F and TESLA-M to produce overly long translations.

These observations suggest that the brevity penalty of BLEU is not aggressive enough. Neither is TER, which penalizes insertions and deletions equally. Interestingly, by placing much more emphasis on the recall, TESLA-M and TESLA-F produce translations that are statistically too long, but feel much more 'correct' lengthwise.

Another major difference between TESLA-M/TESLA-F and BLEU/TER is that the TESLAs heavily discount n-grams with function words. One might thus expect the TESLA-tuned systems to be less adept at function words; yet they translate them surprisingly well, as shown in Figure 4. One explanation is of course the sentence length effect we have discussed. Another reason may be that since the metric does not care much about function words, the language model is given more freedom to pick function words as it sees fit, without the fear of large penalties. Paradoxically, by reducing the weights of function words, we end up making better translations for them.

TER is the only metric that allows cheap block movements, regardless of size or distance. One might reasonably speculate that a TER-tuned system should be more prone to reordering phrases. However, we find no evidence that this is so.

The relative performance of TESLA-M vs TESLA-F is unsurprising. TESLA-F, being heavier and slower, produces somewhat better results than its minimalist counterpart, though the margin is far less pronounced than that between TESLA-M and the conventional BLEU and TER. Since extra resources including bitexts are needed in using TESLA-F, TESLA-M emerges as the MT evaluation metric of choice for tuning SMT systems.

6 Future work

We have presented empirical evidence that the TESLA metrics outperform BLEU for MT tuning in a hierarchical phrase-based SMT system. At the same time, some open questions remain unanswered. We intend to investigate them in our future work.

The work of (Cer et al., 2010) investigated the effect of tuning a phrase-based SMT system and found that of the MT evaluation metrics that they tried, none of them could outperform BLEU. We would like to verify whether TESLA tuning is still preferred over BLEU tuning in a phrase-based SMT system.

Based on our observations, it may be possible to improve the performance of BLEU-based tuning by (1) increasing the brevity penalty; (2) introducing

a recall measure and emphasizing it over precision; and/or (3) introducing function word discounting. In the ideal case, such a modified BLEU metric would deliver results similar to that of TESLA-M, yet with a runtime cost closer to BLEU. It would also make porting existing tuning code easier.

7 Conclusion

We demonstrate for the first time that a practical new generation MT evaluation metric can significantly improve the quality of automatic MT compared to BLEU, as measured by human judgment. We hope this work will encourage the MT research community to finally move away from BLEU and to consider tuning their systems with a new generation metric.

Abstract

Methods for evaluating dependency parsing using attachment scores are highly sensitive to representational variation between dependency treebanks, making cross-experimental evaluation opaque. This paper develops a robust procedure for cross-experimental evaluation, based on deterministic unification-based operations for harmonizing different representations and a refined notion of tree edit distance for evaluating parse hypotheses relative to multiple gold standards. We demonstrate that, for different conversions of the Penn Treebank into dependencies, performance trends that are observed for parsing results in isolation change or dissolve completely when parse hypotheses are normalized and brought into the same common ground.

1 Introduction

Data-driven dependency parsing has seen a considerable surge of interest in recent years. Dependency parsers have been tested on parsing sentences in English (Yamada and Matsumoto, 2003; Nivre and Scholz, 2004; McDonald et al., 2005) as well as many other languages (Nivre et al., 2007a). The evaluation metric traditionally associated with dependency parsing is based on scoring labeled or unlabeled attachment decisions, whereby each correctly identified pair of head-dependent words is counted towards the success of the parser (Buchholz and Marsi, 2006). As it turns out, however, such evaluation procedures are sensitive to the annotation choices in the data on which the parser was trained.

Different annotation schemes often make different assumptions with respect to how linguistic content is represented in a treebank (Rambow, 2010). The consequence of such annotation discrepancies is that when we compare parsing results across different experiments, even ones that use the same parser and the same set of sentences, the gap between results in different experiments may not reflect a true gap in performance, but rather a difference in the annotation decisions made in the respective treebanks.

Different methods have been proposed for making dependency parsing results comparable across experiments. These methods include picking a single gold standard for all experiments to which the parser output should be converted (Carroll et al., 1998; Cer et al., 2010), evaluating parsers by comparing their performance in an embedding task (Miyao et al., 2008; Buyko and Hahn, 2010), or neutralizing the arc direction in the native representation of dependency trees (Schwartz et al., 2011).

Each of these methods has its own drawbacks. Picking a single gold standard skews the results in favor of parsers which were trained on it. Transforming dependency trees to a set of pre-defined labeled dependencies, or into task-based features, requires the use of heuristic rules that run the risk of distorting correct information and introducing noise of their own. Neutralizing the direction of arcs is limited to unlabeled evaluation and local context, and thus may not cover all possible discrepancies.

This paper proposes a new three-step protocol for cross-experiment parser evaluation, and in particular for comparing parsing results across data sets that adhere to different annotation schemes. In the

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 385–396,
Edinburgh, Scotland, UK, July 27–31, 2011.

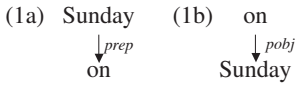
first step all structures are brought into a single formal space of events that neutralizes representation peculiarities (for instance, arc directionality). The second step formally computes, for each sentence in the data, the common denominator of the different gold standards, containing all and only linguistic content that is shared between the different schemes. The last step computes the normalized distance from this common denominator to parse hypotheses, minus the cost of distances that reflect mere annotation idiosyncrasies. The procedure that implements this protocol is fully deterministic and heuristics-free.

We use the proposed procedure to compare dependency parsing results trained on Penn Treebank trees converted into dependency trees according to five different sets of linguistic assumptions. We show that when starting off with the same set of sentences and the same parser, training on different conversion schemes yields apparently significant performance gaps. When results across schemes are normalized and compared against the shared linguistic content, these performance gaps decrease or dissolve completely. This effect is robust across parsing algorithms. We conclude that it is imperative that cross-experiment parse evaluation be a well thought-through endeavor, and suggest ways to extend the protocol to additional evaluation scenarios.

2 The Challenge: Treebank Theories

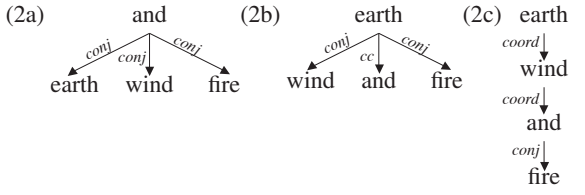
Dependency treebanks contain information about the grammatically meaningful elements in the utterance and the grammatical relations between them. Even if the formal representation in a dependency treebank is well-defined according to current standards (Kübler et al., 2009), there are different ways in which the trees can be used to express syntactic content (Rambow, 2010). Consider, for instance, algorithms for converting the phrase-structure trees in the Penn Treebank (Marcus et al., 1993) into dependency structures. Different conversion algorithms implicitly make different assumptions about how to represent linguistic content in the data. When multiple conversion algorithms are applied to the same data, we end up with different dependency trees for the same sentences (Johansson and Nugues, 2007; Choi and Palmer, 2010; de Marneffe et al., 2006). Some common cases of discrepancies are as follows.

Lexical vs. Functional Head Choice. In linguistics, there is a distinction between lexical heads and functional heads. A lexical head carries the semantic gist of a phrase while a functional one marks its relation to other parts of the sentence. The two kinds of heads may or may not coincide in a single word form (Zwicky, 1993). Common examples refer to prepositional phrases, such as the phrase "on Sunday". This phrase has two possible analyses, one selects a lexical head (1a) and the other selects a functional one (1b), as depicted below.



Similar choices are found in phrases which contain functional elements such as determiners, coordination markers, subordinating elements, and so on.

Multi-Headed Constructions. Some phrases are considered to have multiple lexical heads, for instance, coordinated structures. Since dependency-based formalisms require us to represent all content as binary relations, there are different ways we could represent such constructions. Let us consider the coordination of nominals below. We can choose between a functional head (1a) and a lexical head (2b, 2c). We can further choose between a flat representation in which the first conjunct is a single head (2b), or a nested structure where each conjunct/marker is the head of the following element (2c). All three alternatives empirically exist. Example (2a) reflects the structures in the CoNLL 2007 shared task data (Nivre et al., 2007a). Johansson and Nugues (2007) use structures like (2b). Example (2c) reflects the analysis of Mel'čuk (1988).



Periphrastic Marking. When a phrase includes periphrastic marking — such as the tense and modal marking in the phrase "would have worked" below — there are different ways to consider its division into phrases. One way to analyze this phrase would be to choose auxiliaries as heads, as in (3a). Another alternative would be to choose the final verb as the

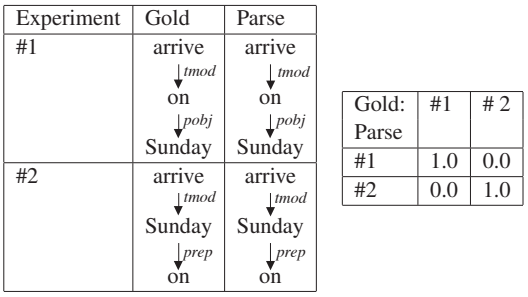


Figure 1: Calculating cross-experiment LAS results

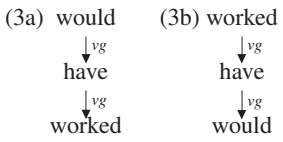
main head, and let the auxiliaries create a verb chain with different levels of projection. Each annotation decision dictates a different direction of the arcs and imposes its own internal division into phrases.



In standard settings, an experiment that uses a data set which adheres to a certain annotation scheme reports results that are compared against the annotation standard that the parser was trained on. But if parsers were trained on different annotation standards, the empirical results are not comparable across experiments. Consider, for instance, the example in Figure 1. If parse1 and parse2 are compared against gold2 using labeled attachment scores (LAS), then parse1 results are lower than the results of parse2, even though both parsers produced linguistically correct and perfectly useful output.

Existing methods for making parsing results comparable across experiments include heuristics for converting outputs into dependency trees of a predefined standard (Briscoe et al., 2002; Cer et al., 2010) or evaluating the performance of a parser within an embedding task (Miyao et al., 2008; Buyko and Hahn, 2010). However, heuristic rules for cross-annotation conversion are typically hand written and error prone, and may not cover all possible discrepancies. Task-based evaluation may be sensitive to the particular implementation of the embedding task and the procedures that extract specific task-related features from the different parses. Beyond that, conversion heuristics and task-based procedures are currently developed almost exclusively for English. Other languages typically lack such resources.

A recent study by Schwartz et al. (2011) takes a different approach towards cross-annotation evaluation. They consider different directions of head-dependent relations (such as on→Sunday and Sunday→on) and different parent-child and grandparent-child relations in a chain (such as arrive→on and arrive→sunday in "arrive on sunday") as equivalent. They then score arcs that fall within corresponding equivalence sets. Using these new scores Schwartz et al. (2011) neutralize certain annotation discrepancies that distort parse comparison. However, their treatment is limited to local context and does not treat structures larger than two sequential arcs. Additionally, since arcs in different directions are typically labeled differently, this method only applies for unlabeled dependencies.

What we need is a fully deterministic and formally precise procedure for comparing any set of labeled or unlabeled dependency trees, by consolidating the shared linguistic content of the complete dependency trees in different annotation schemes, and comparing parse hypotheses through sound metrics that can take into account multiple gold standards.

3 The Proposal: Cross-Annotation Evaluation in Three Simple Steps

We propose a new protocol for cross-experiment parse evaluation, consisting of three fundamental components: (i) abstracting away from annotation peculiarities, (ii) generalizing theory-specific structures into a single linguistically coherent gold standard that contains all and only consistent information from all sources, and (iii) defining a sound metric that takes into account the different gold standards that are being considered in the experiments.

In this section we first define *functional trees* as the common space of formal objects and define a deterministic conversion procedure from dependency trees to functional trees. Next we define a set of formal operations on functional trees that compute, for every pair of corresponding trees of the same yield, a single gold tree that resolves inconsistencies among gold standard alternatives and combines the information that they share. Finally, we define scores based on *tree edit distance*, refined to consider the distance from parses to the overall gold tree as well as the different annotation alternatives.

Preliminaries. Let $\mathcal{T}$ be a finite set of terminal symbols and let $\mathcal{L}$ be a set of grammatical relation labels. A dependency graph d is a directed graph which consists of nodes V_d and arcs $A_d \subseteq V_d \times V_d$. We assume that all nodes in V_d are labeled by terminal symbols via a function $label_V : V_d \rightarrow \mathcal{T}$. A well-formed dependency graph $d = (V_d, A_d)$ for a sentence $S = t_1, t_2, ..., t_n$ is any dependency graph that is a directed tree originating out of a node v_0 labeled $t_0 = ROOT$, and spans all terminals in the sentence, that is, for every $t_i \in S$ there exists $v_j \in V_d$ labeled $label_V(v_j) = t_i$. For simplicity we assume that every node v_j is indexed according to the position of the terminal label, i.e., that for each t_i labeling v_j, i always equals j. In a labeled dependency tree, arcs in A_d are labeled by elements of $\mathcal{L}$ via a function $label_A : A_d \rightarrow \mathcal{L}$ that encodes the grammatical relation between the terminals labeling the connected nodes. We define two auxiliary functions on nodes in dependency trees. The function $subtree : V_d \rightarrow \mathcal{P}(V_d)$ assigns to every node $v \in V_d$ the set of nodes accessible by it through the reflexive transitive closure of the arc relation A_d. The function $span : V_d \rightarrow \mathcal{P}(\mathcal{T})$ assigns to every node $v \in V_d$ a set of terminals such that $span(v) = \{t \in \mathcal{T} | t = label_V(u) \text{ and } u \in subtree(v)\}$.[1]

Step 1: Functional Representation Our first goal is to define a representation format that keeps all functional relationships that are represented in the dependency trees intact, but remains neutral with respect to the directionality of the head-dependent relations. To do so we define *functional trees* — linearly-ordered labeled trees which, instead of head-to-head binary relations, represent the complete functional structure of a sentence. Assuming the same sets of terminal symbols $\mathcal{T}$ and grammatical relation labels $\mathcal{L}$, and assuming extended sets of nodes V and arcs $A \subseteq V \times V$, a functional tree $\pi = (V, A)$ is a directed tree originating from a single root $v_0 \in V$ where all non-terminal nodes in π are labeled with grammatical relation labels that signify the grammatical function of the chunk they dominate inside the tree via $label_{NT} : V \rightarrow \mathcal{L}$. All terminal nodes in π are labeled with terminal symbols via a $label_T : V \rightarrow \mathcal{T}$ function. The function $span : V \rightarrow \mathcal{P}(V)$ now picks out the set of terminal labels of the terminal nodes accessible by a node $v \in V$ via A. We obtain functional trees from dependency trees using the following procedure:

- Initialize the set of nodes and arcs in the tree.

  $V := V_d$
  $A := A_d$

- Label each node $v \in V$ with the label of its incoming arc.

  $label_{NT}(v) = label_A(u, v)$

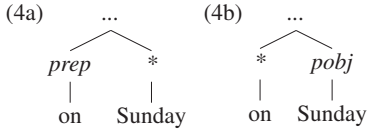
- In case $|span(v)| > 1$ add a new node u as a daughter designating the lexical head, labeled with the wildcard symbol *:

  $V := V \cup \{u\}$
  $A := A \cup \{(v, u)\}$
  $label_{NT}(u) = *$

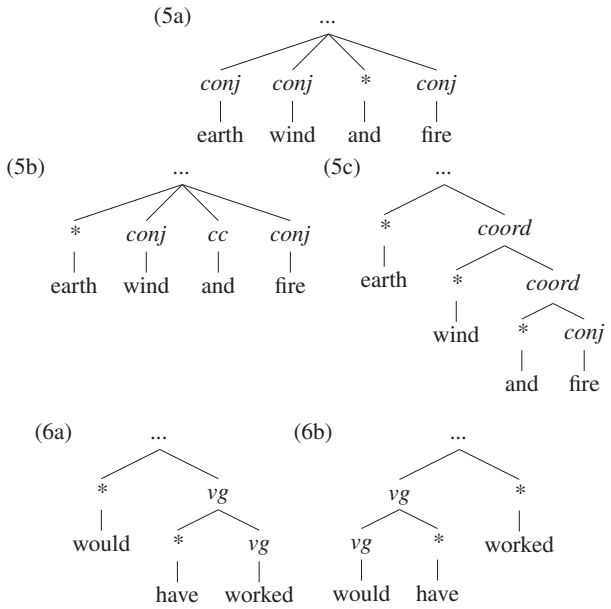
- For each node v such that $|span(v)| = 1$, add a new node u as a daughter, labeled with its own terminal:

  $V := V \cup \{u\}$
  $A := A \cup \{(v, u)\}$
  if $(label_{NT}(v) \neq *)$
  $label_T(u) := label_V(v)$
  else
  $label_T(u) := label_V(parent(v))$

That is to say, we label all nodes with spans greater than 1 with the grammatical function of their head, and for each node we add a new daughter u designating the head word, labeled with its grammatical function. Wildcard labels are compatible with any, more specific, grammatical function of the word inside the phrase. This gives us a constituency-like representation of dependency trees labeled with functional information, which retains the linguistic assumptions reflected in the dependency trees. When applying this procedure, examples (1)–(3) get transformed into (4)–(6) respectively.



[1] If a dependency tree d is projective, than for all $v \in V_d$ the terminals in $span(v)$ form a contiguous segment of S. The current discussion assumes that all trees are projective. We comment on non-projective dependencies in Section 4.



Considering the functional trees resulting from our procedure, it is easy to see that for tree pairs (4a)–(4b) and (5a)–(5b) the respective functional trees are identical modulo wildcards, while tree pairs (5b)–(5c) and (6a)–(6b) end up with different tree structures that realize different assumptions concerning the internal structure of the tree. In order to compare, combine or detect inconsistencies in the information inherent in different functional trees, we define a set of formal operations that are inspired by familiar notions from unification-based formalisms (Shieber (1986) and references therein).

Step 2: Formal Operations on Trees The intuition behind the formal operations we define is simple. A completely flat tree over a span is the most general structural description that can be given to it. The more nodes dominate a span, the more linguistic assumptions are made with respect to its structure. If an arc structure in one tree merely elaborates an existing flat span in another tree, the theories underlying the schemes are compatible, and their information can be combined. Otherwise, there exists a conflict in the linguistic assumptions, and we need to relax some of the assumptions, i.e., remove functional nodes, in order to obtain a coherent structure that contains the information on which they agree.

Let π_1, π_2 be functional trees over the same yield $t_1, .., t_n$. Let the function $span(v)$ pick out the terminals labeling terminal nodes that are accessible via a node $v \in V$ in the functional tree through the relation A. We define first the tree subsumption relation for comparing the amount of information inherent in the arc-structure of two trees.[2]

> **T-Subsumption**, denoted $\sqsubseteq_t$, is a relation between trees which indicates that a tree π_1 is consistent with and more general than tree π_2. Formally: $\pi_1 \sqsubseteq_t \pi_2$ iff for every node $n \in \pi_1$ there exists a node $m \in \pi_2$ such that $span(n) = span(m)$ and $label(n) = label(m)$.

Looking at the functional trees of (4a)–(4b) we see that their unlabeled skeletons mutually subsume each other. In their labeled versions, however, each tree contains labeling information that is lacking in the other. In the functional trees (5b)–(5c) a flat structure over a span in (5b) is more elaborated in (5c). In order to combine information in trees with compatible arc structures, we define tree unification.

> **T-Unification**, denoted $\sqcup_t$, is the operation that returns the most general tree structure π_3 that is subsumed by both π_1, π_2 if such exists, and fails otherwise. Formally: $\pi_1 \sqcup_t \pi_2 = \pi_3$ iff $\pi_1 \sqsubseteq_t \pi_3$ and $\pi_2 \sqsubseteq_t \pi_3$, and for all π_4 such that $\pi_1 \sqsubseteq_t \pi_4$ and $\pi_2 \sqsubseteq_t \pi_4$ it holds that $\pi_3 \sqsubseteq_t \pi_4$.

Tree unification collects the information from two trees into a single result if they are consistent, and detects an inconsistency otherwise. In case of an inconsistency, as is the case in the functional trees (6a) and (6b), we cannot unify the structures due to a conflict concerning the internal division of an expression into phrases. However, we still want to generalize these two trees into one tree that contains all and only the information that they share. For that we define the tree generalization operation.

> **T-Generalization**, denoted $\sqcap_t$, is the operation that returns the most specific tree that is more general than both trees. Formally, $\pi_1 \sqcap_t \pi_2 = \pi_3$ iff $\pi_3 \sqsubseteq_t \pi_1$ and $\pi_3 \sqsubseteq_t \pi_2$, and for every π_4 such that $\pi_4 \sqsubseteq_t \pi_1$ and $\pi_4 \sqsubseteq_t \pi_2$ it holds that $\pi_4 \sqsubseteq_t \pi_3$.

[2]Note that the wildcard symbol * is equal to any other symbol. In case the node labels consist of complex feature structures made of attribute-value lists, we replace $label(n) = label(m)$ in the subsumption definition with $label(n) \sqsubseteq label(m)$ in the sense of (Shieber, 1986).

Unlike unification, generalization can never fail. For every pair of trees there exists a tree that is more general than both: in the extreme case, pick the completely flat structure over the yield, which is more general than any other structure. For (6a)–(6b), for instance, we get that (6a)$\sqcap_t$(6b) is a flat tree over pre-terminals where "would" and "have" are labeled with *'vg'* and "worked" is the head, labeled with *'*'*.

The generalization of two functional trees provides us with one structure that reflects the common and consistent content of the two trees. These structures thus provide us with a formally well-defined gold standard for cross-treebank evaluation.

Step 3: Measuring Distances. Our functional trees superficially look like constituency-based trees, so a simple proposal would be to use Parseval measures (Black et al., 1991) for comparing the parsed trees against the new generalized gold trees. Parseval scores, however, have two significant drawbacks. First, they are known to be too restrictive with respect to some errors and too permissive with respect to others (Carroll et al., 1998; Kübler and Telljohann, 2002; Roark, 2002; Rehbein and van Genabith, 2007). Secondly, F_1 scores would still penalize structures that are correct with respect to the original gold, but are not there in the generalized structure. Here we propose to adopt measures that are based on tree edit distance (TED) instead. TED-based measures are, in fact, an extension of attachment scores for dependency trees. Consider, for instance, the following operations on dependency arcs.

> **reattach-arc** remove arc $(u, v) \in A_d$ and add an arc $A_d \cup \{(w, v)\}$.
>
> **relabel-arc** relabel arc $l_1(u, v)$ as $l_2(u, v)$

Assuming that each operation is assigned a cost, the attachment score of comparing two dependency trees is simply the cost of all edit operations that are required to turn a parse tree into its gold standard, normalized with respect to the overall size of the dependency tree and subtracted from a unity.[3] Here we apply the idea of defining scores by TED costs normalized relative to the size of the tree and substracted from a unity, and extend it from fixed-size dependency trees to ordered trees of arbitrary size.

[3]The size of a dependency tree, either parse or gold, is always fixed by the number of terminals.

Our formalization follows closely the formulation of the T-Dice measure of Emms (2008), building on his thorough investigation of the formal and empirical differences between TED-based measures and Parseval. We first define for any ordered and labeled tree π the following operations.

> **relabel-node** change the label of node v in π
>
> **delete-node** delete a non-root node v in π with parent u, making the children of v the children of u, inserted in the place of v as a subsequence in the left-to-right order of the children of u.
>
> **insert-node** insert a node v as a child of u in π making it the parent of a consecutive subsequence of the children of u.

An edit script $ES(\pi_1, \pi_2) = \{e_0, e_1....e_k\}$ between π_1 and π_2 is a set of edit operations required for turning π_1 into π_2. Now, assume that we are given a cost function defined for each edit operation. The cost of $ES(\pi_1, \pi_2)$ is the sum of the costs of the operations in the script. An optimal edit script is an edit script between π_1 and π_2 of minimum cost.

$$ES^*(\pi_1, \pi_2) = \text{argmin}_{ES(\pi_1,\pi_2)} \sum_{e \in ES(\pi_1,\pi_2)} cost(e)$$

The tree edit distance problem is defined to be the problem of finding the optimal edit script and computing the corresponding distance (Bille, 2005).

A simple way to calculate the error δ of a parse would be to define it as the edit distance between the parse hypothesis π_1 and the gold standard π_2.

$$\delta(\pi_1, \pi_2) = cost(ES^*(\pi_1, \pi_2))$$

However, in such cases the parser may still get penalized for recovering nodes that are lacking in the generalization. To solve this, we refine the distance between a parse tree and the generalized gold tree to discard edit operations on nodes that are there in the native gold tree but are eliminated through generalization. We compute the intersection of the edit script turning the parse tree into the generalize gold with the edit script turning the native gold tree into the generalized gold, and discard its cost. That is, if parse1 and parse2 are compared against gold1 and gold2 respectively, and if we set gold3 to be the result of gold1$\sqcap_t$gold2, then δ_{new} is defined as:

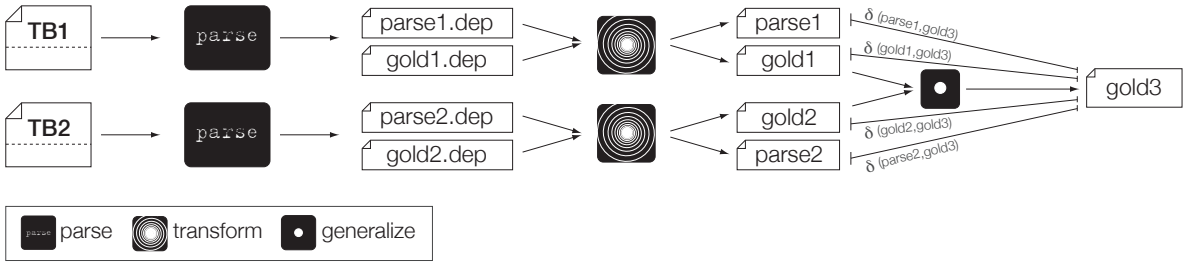


Figure 2: The evaluation pipeline. Different versions of the treebank go into different experiments, resulting in different parse and gold files. All trees are transformed into functional trees. All gold files enter generalization to yield a new gold. The different δ arcs represent the different tree distances used for calculating the TED-based scores.

δ_{new}(parse1, gold1,gold3) =
δ(parse1,gold3)
$-cost(ES^*$(parse1,gold3)$\cap ES^*$(gold1,gold3))

Now, if gold1 and gold3 are identical, then ES^*(gold1,gold3)=$\emptyset$ and we fall back on the simple tree edit distance score δ_{new}(parse1,gold1,gold3)=δ(parse1, gold3).
When parse1 and gold1 are identical, i.e., the parser produced perfect output with respect to its own scheme, then δ_{new}(parse1,gold1,gold3)=δ_{new}(gold1,gold1,gold3) =δ(gold1,gold3) $- cost(ES^*$(gold1,gold3))=0, and the parser does not get penalized for recovering a correct structure in gold1 that is lacking in gold3.

In order to turn distances into accuracy measures we have to normalize distances relative to the maximal number of operations that is conceivable. In the worst case, we would have to remove all the internal nodes in the parse tree and add all the internal nodes of the generalized gold, so our normalization factor ι is defined as follows, where $|\pi|$ is the size[4] of π.

$$\iota(\text{parse1,gold3}) = |\text{parse1}| + |\text{gold3}|$$

We now define the *score* of parse1 as follows:[5]

$$1 - \frac{\delta_{new}(\text{parse1,gold1,gold3})}{\iota(\text{parse1,gold3})}$$

Figure 2 summarizes the steps in the evaluation procedure we defined so far. We start off with two versions of the treebank, TB1 and TB2, which are parsed separately and provide their own gold standards and parse hypotheses in a labeled dependencies format. All dependency trees are then converted into functional trees, and we compute the generalization of each pair of gold trees for each sentence in the data. This provides the generalized gold standard for all experiments, here marked as gold3.[6] We finally compute the distances δ_{new}(parse1,gold1,gold3) and δ_{new}(parse2,gold2,gold3) using the different tree edit distances that are now available, and we repeat the procedure for each sentence in the test set.

To normalize the scores for an entire test set of size n we can take the arithmetic mean of the scores.

$$\frac{\sum_{i=1}^{|\text{test-set}|} score(\text{parse1}_i,\text{gold1}_i,\text{gold3}_i)}{|\text{test-set}|}$$

Alternatively we can globally average of all edit distance costs, normalized by the maximally possible edits on parse trees turned into generalized trees.

$$1 - \frac{\sum_{i=1}^{|\text{test-set}|} \delta_{new}(\text{parse1}_i,\text{gold1}_i,\text{gold3}_i)}{\sum_{i=1}^{|\text{test-set}|} \iota(\text{parse1}_i,\text{gold3}_i)}$$

The latter score, global averaging over the entire test set, is the metric we use in our evaluation procedure.

4 Experiments

We demonstrate the application of our procedure to comparing dependency parsing results on different versions of the Penn Treebank (Marcus et al., 1993).

The Data We use data from the PTB, converted into dependency structures using the LTH software, a general purpose tool for constituency-to-dependency conversion (Johansson and Nugues, 2007). We use LTH to implement the five different annotation standards detailed in Table 3.

[4]Following common practice, we equate size $|\pi|$ with the number of nodes in π, discarding the terminals and root node.

[5]If the trees have only root and leaves, $\iota = 0$, $score := 1$.

[6]Generalization is an associative and commutative operation, so it can be extended for n experiments in any order.

ID	Description
Default	The LTH conversion default settings
OldLTH	The conversion used in Johansson and Nugues (2007)
CoNLL07	The conversion used in the CoNLL shared task (Nivre et al., 2007a)
Lexical	Same as **CoNLL**, but selecting only lexical heads when a choice exists
Functional	Same as **CoNLL**, but selecting only functional heads when a choice exists

Table 3: LTH conversion schemes used in the experiments. The LTH conversion settings in terms of the complete feature-value pairs associated with the LTH parameters in different schemes are detailed in the supplementary material.

The Default, OldLTH and CoNLL schemes mainly differ in their coordination structure, and the Functional and Lexical schemes differ in their selection of a functional and a lexical head, respectively. All schemes use the same inventory of labels.[7] The LTH parameter settings for the different schemes are elaborated in the supplementary material.

The Setup We use two different parsers: (i) MaltParser (Nivre et al., 2007b) with the arc eager algorithm as optimized for English in (Nivre et al., 2010) and (ii) MSTParser with the second-order projective model of McDonald and Pereira (2006). Both parsers were trained on the different instances of sections 2-21 of the PTB obeying the different annotation schemes in Table 3. Each trained model was used to parse section 23. All non-projective dependencies in the training and gold sets were projectivized prior to training and parsing using the algorithm of Nivre and Nilsson (2005). A more principled treatment of non-projective dependency trees is an important topic for future research. We evaluated the parses using labeled and unlabeled attachment scores, and using our TEDEVAL software package.

Evaluation Our TEDEVAL software package implements the pipeline described in Section 3. We convert all parse and gold trees into functional trees using the algorithm defined in Section 3, and for each pair of parsing experiments we calculate a shared gold standard using generalization determined through a chart-based greedy algorithm.[8] Our scoring procedure uses the TED algorithm defined by Zhang and Shasha (1989).[9] The unlabeled score is obtained by assigning $cost(e) = 0$ for every e relabeling operation. To calculate pairwise statistical significance we use a shuffling test with 10,000 iterations (Cohen, 1995). A sample of all files in the evaluation pipeline for a subset of 10 PTB sentences is available in the supplementary materials.[10]

[7] In case the labels are not taken from the same inventory, e.g., subjects in one scheme are marked as SUB and in the other marked as SBJ, it is possible define a a set of zero-cost operation types — in such case, to the operation **relabel**(SUB,SBJ) — in order not to penalize string label discrepancies.

[8] Our algorithm has space and runtime complexity of $O(n^2)$.

Results Table 1 reports the results for the inter- and cross-experiment evaluation of parses produced by MaltParser. The left hand side of the table presents the parsing results for a set of experiments in which we compare parsing results trained on the Default, OldLTH and CoNLL07 schemes. In a second set of experiments we compare the CoNLL07, Lexical and Functional schemes. Table 2 reports the evaluation of the parses produced by MSTParser for the same experimental setup. Our goal here is not to compare the parsers, but to verify that the effects of switching from LAS to TEDEVAL are robust across parsing algorithms.

In each of the tables, the top three groups of four rows compare results of parsed dependency trees trained on a particular scheme against gold trees of the same and the other schemes. The next three groups of two rows report the results for comparing pairwise sets of experiments against a generalized gold using our proposed procedure. In the last group of two rows we compare all parsing results against a single gold obtained through a three-way generalization.

As expected, every parser appears to perform at its best when evaluated against the scheme it was trained on. This is the case for both LAS and TEDEVAL measures and the performance gaps are statistically significant. When moving to pairwise evaluation against a single generalized gold, for instance, when comparing CoNLL07 to the Default settings, there is still a gap in performance, e.g., between OldLTH and CoNLL07, and between OldLTH and Default. This gap is however a lot smaller and is not always statistically significant. In fact, when evaluating the effect of linguistically disparate annotation variations such as Lexical and Functional on the performance of MaltParser, Table 1 shows that when using TEDEVAL and a generalized gold the performance gaps are small and statistically insignificant.

Moreover, observed performance trends when evaluating individual experiments on their original training scheme may change when compared against a generalized gold. The Default scheme, for MaltParser, appears better than OldLTH when both are evaluated against their training schemes. But looking at the pairwise-evaluated experiments, it is the other way round (the difference is smaller, but statistically significant). In evaluating against a three-way

generalization, all the results obtained for different training schemes are on a par with one another, with minor gaps in performance, rarely statistically significant. This suggests that apparent performance trends between experiments when evaluating with respect to the training schemes may be misleading.

These observations are robust across parsing algorithms. In each of the tables, results obtained against the training schemes show significant differences whereas applying our cross-experimental procedure shows small to no gaps in performance across different schemes. Annotation variants which seem to have crucial effects have a relatively small influence when parsed structures are brought into the same formal and theoretical common ground for comparison. Of course, it may be the case that one parser is better trained on one scheme while the other utilizes better another scheme, but objective performance gaps can only be observed when they are compared against shared linguistic content.

5 Discussion and Extensions

This paper addresses the problem of cross-experiment evaluation. As it turns out, this problem arises in NLP in different shapes and forms; when evaluating a parser against different annotation schemes, when evaluating parsing performance across parsers and different formalisms, and when comparing parser performance across languages. We consider our contribution successful if after reading it the reader develops a healthy suspicion to blunt comparison of numbers across experiments, or better yet, across different papers. Cross-experiment comparison should be a careful and well thought-through endeavor, in which we retain as much information as we can from the parsed structures, avoid lossy conversions, and focus on an object of evaluation which is agreed upon by all variants.

Our proposal introduces one way of doing so in a streamlined, efficient and formally worked out way. While individual components may be further refined or improved, the proposed setup and implementation can be straightforwardly applied to cross-parser and cross-framework evaluation. In the future we plan to use this procedure for comparing constituency and dependency parsers. A conversion from constituency-based trees into functional trees is straightforward to define: simply replace the node labels with the grammatical function of their dominating arc – and the rest of the pipeline follows.

A pre-condition for cross-framework evaluation is that all representations encode the same set of grammatical relations by, e.g., annotating arcs in dependency trees or decorating nodes in constituency trees. For some treebanks this is already the case (Nivre and Megyesi, 2007; Skut et al., 1997; Hinrichs et al., 2004) while for others this is still lacking. Recent studies (Briscoe et al., 2002; de Marneffe et al., 2006) suggest that evaluation through a single set of grammatical relations as the common denominator is a linguistically sound and practically useful way to go. To guarantee extensions for cross-framework evaluation it would be fruitful to make sure that resources use the same set of grammatical relation labels across different formal representation types. Moreover, we further aim to inquire whether we can find a single set of grammatical relation labels that can be used across treebanks for multiple languages. This would then pave the way for the development of cross-language evaluation procedures.

6 Conclusion

We propose an end-to-end procedure for comparing dependency parsing results across experiments based on three steps: (i) converting dependency trees to functional trees, (ii) generalizing functional trees to harmonize information from different sources, and (iii) using distance-based metrics that take the different sources into account. When applied to parsing results of different dependency schemes, dramatic gaps observed when comparing parsing results obtained in isolation decrease or dissolve completely when using our proposed pipeline.

Acknowledgments We thank the developers of the LTH and TED software who made their code available for our use. We thank Richard Johansson for providing us with the LTH parameter settings of existing dependency schemes. We thank Ari Rappoport, Omri Abend, Roy Schwartz and members of the NLP lab at the Hebrew University of Jerusalem for stimulating discussion. We finally thank three anonymous reviewers for useful comments on an earlier draft. The research reported in the paper was partially funded by the Swedish Research Council.

Abstract

In order to obtain a fine-grained evaluation of parser accuracy over naturally occurring text, we study 100 examples each of ten reasonably frequent linguistic phenomena, randomly selected from a parsed version of the English Wikipedia. We construct a corresponding set of gold-standard target dependencies for these 1000 sentences, operationalize mappings to these targets from seven state-of-the-art parsers, and evaluate the parsers against this data to measure their level of success in identifying these dependencies.

1 Introduction

The terms "deep" and "shallow" are frequently used to characterize or contrast different approaches to parsing. Inevitably, such informal notions lack a clear definition, and there is little evidence of community consensus on the relevant dimension(s) of depth, let alone agreement on applicable metrics. At its core, the implied dichotomy of approaches alludes to differences in the interpretation of the parsing task. Its abstract goal, on the one hand, could be pre-processing of the linguistic signal, to enable subsequent stages of analysis. On the other hand, it could be making explicit the (complete) contribution that the grammatical form of the linguistic signal makes to interpretation, working out who did what to whom. Stereotypically, one expects corresponding differences in the choice of interface representations, ranging from various levels of syntactic analysis to logical-form representations of semantics.

In this paper, we seek to probe aspects of variation in automated linguistic analysis. We make the assumption that an integral part of many (albeit not all) applications of parsing technology is the recovery of structural relations, i.e. dependencies at the level of interpretation. We suggest a selection of ten linguistic phenomena that we believe (a) occur with reasonably high frequency in running text and (b) have the potential to shed some light on the depths of linguistic analysis. We quantify the frequency of these constructions in the English Wikipedia, then annotate 100 example sentences for each phenomenon with gold-standard dependencies reflecting core properties of the phenomena of interest. This gold standard is then used to estimate the recall of these dependencies by seven commonly used parsers, providing the basis for a qualitative discussion of the state of the art in parsing for English.

In this work, we answer the call by Rimell et al. (2009) for "construction-focused parser evaluation", extending and complementing their work in several respects: (i) we investigate both local and non-local dependencies which prove to be challenging for many existing state-of-the-art parsers; (ii) we investigate a wider range of linguistic phenomena, each accompanied with an in-depth discussion of relevant properties; and (iii) we draw our data from the 50-million sentence English Wikipedia, which is more varied and a thousand times larger than the venerable WSJ corpus, to explore a more level and ambitious playing field for parser comparison.

2 Background

All parsing systems embody knowledge about possible and probable pairings of strings and corresponding linguistic structure. Such linguistic and probabilistic knowledge can be hand-coded (e.g., as grammar rules) or automatically acquired from labeled or

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 397–408,
Edinburgh, Scotland, UK, July 27–31, 2011.

unlabeled training data. A related dimension of variation is the type of representations manipulated by the parser. We briefly review some representative examples along these dimensions, as these help to position the parsers we subsequently evaluate.[1]

2.1 Approaches to parsing

Source of linguistic knowledge At one end of this dimension, we find systems whose linguistic knowledge is encoded in hand-crafted rules and lexical entries; for English, the ParGram XLE system (Riezler et al., 2002) and DELPH-IN English Resource Grammar (ERG; Flickinger (2000))—each reflecting decades of continuous development—achieve broad coverage of open-domain running text, for example. At the other end of this dimension, we find fully unsupervised approaches (Clark, 2001; Klein and Manning, 2004), where the primary source of linguistic knowledge is co-occurrence patterns of words in unannotated text. As Haghighi and Klein (2006) show, augmenting this knowledge with hand-crafted prototype "seeds" can bring strong improvements. Somewhere between these poles, a broad class of parsers take some or all of their linguistic knowledge from annotated treebanks, e.g. the Penn Treebank (PTB), which encodes "surface grammatical analysis" (Marcus et al., 1993). Such approaches include those that directly (and exclusively) use the information in the treebank (e.g. Charniak (1997), Collins (1999), Petrov et al. (2006), inter alios) as well as those that complement treebank structures with some amount of hand-coded linguistic knowledge (e.g. O'Donovan et al. (2004), Miyao et al. (2004), Hockenmaier and Steedman (2007), inter alios). Another hybrid in terms of its acquisition of linguistic knowledge is the RASP system of Briscoe et al. (2006), combining a hand-coded grammar over PoS tag sequences with a probabilistic tagger and statistical syntactic disambiguation.

Design of representations Approaches to parsing also differ fundamentally in the style of representation assigned to strings. These vary both in their formal nature and the "granularity" of linguistic information (i.e. the number of distinctions assumed), encompassing variants of constituent structure, syntactic dependencies, or logical-form representations of semantics. Parser interface representations range between the relatively simple (e.g. phrase structure trees with a limited vocabulary of node labels as in the PTB, or syntactic dependency structures with a limited vocabulary of relation labels as in Johansson and Nugues (2007)) and the relatively complex, as for example elaborate syntactico-semantic analyses produced by the ParGram or DELPH-IN grammars.

There tends to be a correlation between the methodology used in the acquisition of linguistic knowledge and the complexity of representations: in the creation of a mostly hand-crafted treebank like the PTB, representations have to be simple enough for human annotators to reliably manipulate. Deriving more complex representations typically presupposes further computational support, often involving some hand-crafted linguistic knowledge—which can take the form of mappings from PTB-like representations to "richer" grammatical frameworks (as in the line of work by O'Donovan et al. (2004), and others; see above), or can be rules for creating the parse structures in the first place (i.e. a computational grammar), as for example in the treebanks of van der Beek et al. (2002) or Oepen et al. (2004).[2]

In principle, one might expect that richer representations allow parsers to capture complex syntactic or semantic dependencies more explicitly. At the same time, such "deeper" relations may still be recoverable (to some degree) from comparatively simple parser outputs, as demonstrated for unbounded dependency extraction from strictly local syntactic dependency trees by Nivre et al. (2010).

2.2 An armada of parsers

Stanford Parser (Klein and Manning, 2003) is a probabilistic parser which can produce both phrase structure trees and grammatical relations (syntactic dependencies). The parsing model we evaluate is the

[1] Additional sources of variation among extant parsing technologies include (a) the behavior with respect to ungrammatical inputs and (b) the relationship between probabilistic and symbolic knowledge in the parser, where parsers with a hand-coded grammar at their core typically also incorporate an automatically trained probabilistic disambiguation component.

[2] A noteworthy exception to this correlation is the annotated corpus of Zettlemoyer and Collins (2005), which pairs surface strings from the realm of natural language database interfaces directly with semantic representations in lambda calculus. These were hand-written on the basis of database query statements distributed with the original datasets.

English factored model which combines the preferences of unlexicalized PCFG phrase structures and of lexical dependencies, trained on sections 02–21 of the WSJ portion of the PTB. We chose Stanford Parser from among the state-of-the-art PTB-derived parsers for its support for grammatical relations as an alternate interface representation.

Charniak&Johnson Reranking Parser (Charniak and Johnson, 2005) is a two-stage PCFG parser with a lexicalized generative model for the first-stage, and a discriminative MaxEnt reranker for the second-stage. The models we evaluate are also trained on sections 02–21 of the WSJ. Top-50 readings were used for the reranking stage. The output constituent trees were then converted into Stanford Dependencies. According to Cer et al. (2010), this combination gives the best parsing accuracy in terms of Stanford dependencies on the PTB.

Enju (Miyao et al., 2004) is a probabilistic HPSG parser, combining a hand-crafted core grammar with automatically acquired lexical types from the PTB.[3] The model we evaluate is trained on the same material from the WSJ sections of the PTB, but the treebank is first semi-automatically converted into HPSG derivations, and the annotation is enriched with typed feature structures for each constituent. In addition to HPSG derivation trees, Enju also produces predicate argument structures.

C&C (Clark and Curran, 2007) is a statistical CCG parser. Abstractly similar to the approach of Enju, the grammar and lexicon are automatically induced from CCGBank (Hockenmaier and Steedman, 2007), a largely automatic projection of (the WSJ portion of) PTB trees into the CCG framework. In addition to CCG derivations, the C&C parser can directly output a variant of grammatical relations.

RASP (Briscoe et al., 2006) is an unlexicalized robust parsing system, with a hand-crafted "tag sequence" grammar at its core. The parser thus analyses a lattice of PoS tags, building a parse forest from which the most probable syntactic trees and sets of corresponding grammatical relations can be extracted. Unlike other parsers in our mix, RASP did not build on PTB data in either its PoS tagging or syntactic disambiguation components.

MSTParser (McDonald et al., 2005) is a data-driven dependency parser. The parser uses an edge-factored model and searches for a maximal spanning tree that connects all the words in a sentence into a dependency tree. The model we evaluate is the second-order projective model trained on the same WSJ corpus, where the original PTB phrase structure annotations were first converted into dependencies, as established in the CoNLL shared task 2009 (Johansson and Nugues, 2007).

XLE/ParGram (Riezler et al., 2002, see also Cahill et al., 2008) applies a hand-built Lexical Functional Grammar for English and a stochastic parse selection model. For our evaluation, we used the Nov 4, 2010 release of XLE and the Nov 25, 2009 release of the ParGram English grammar, with c-structure pruning turned off and resource limitations set to the maximum possible to allow for exhaustive search. In particular, we are evaluating the f-structures output by the system.

Each parser, of course, has its own requirements regarding preprocessing of text, especially tokenization. We customized the tokenization to each parser, by using the parser's own internal tokenization or pre-tokenizing to match the parser's desired input. The evaluation script is robust to variations in tokenization across parsers.

3 Phenomena

In this section we summarize the ten phenomena we explore and our motivations for choosing them. Our goal was to find phenomena where the relevant dependencies are relatively subtle, such that more linguistic knowledge is beneficial in order to retrieve them. Though this set is of course only a sampling, these phenomena illustrate the richness of structure, both local and non-local, involved in the mapping from English strings to their meanings. We discuss the phenomena in four sets and then briefly review their representation in the Penn Treebank.

3.1 Long distance dependencies

Three of our phenomena can be classified as involving long-distance dependencies: finite *that*-less relatives clauses ('barerel'), tough adjectives ('tough') and right node raising ('rnr'). These are illustrated

[3] This hand-crafted grammar is distinct from the ERG, despite sharing the general framework of HPSG. The ERG is not included in our evaluation, since it was used in the extraction of the original examples and thus cannot be fairly evaluated.

in the following examples:[4]

(1) barerel: This is the second *time* in a row Australia **has lost** their home tri-nations' series.

(2) tough: Original *copies* are very hard to **find**.

(3) rnr: Ilúvatar, as his names imply, exists **before** and **independently of** *all else*.

While the majority of our phenomena involve local dependencies, we include these long-distance dependency types because they are challenging for parsers and enable more direct comparison with the work of Rimell et al. (2009), who also address right node raising and bare relatives. Our barerel category corresponds to their "object reduced relative" category with the difference that we also include adverb relatives, where the head noun functions as a modifier within the relative clause, as does *time* in (1). In contrast, our rnr category is somewhat narrower than Rimell et al. (2009)'s "right node raising" category: where they include raised modifiers, we restrict our category to raised complements.

Part of the difficulty in retrieving long-distance dependencies is that the so-called extraction site is not overtly marked in the string. In addition to this baseline level of complication, these three construction types present further difficulties: Bare relatives, unlike other relative clauses, do not carry any lexical cues to their presence (i.e., no relative pronouns). *Tough* adjective constructions require the presence of specific lexical items which form a subset of a larger open class. They are rendered more difficult by two sources of ambiguity: alternative subcategorization frames for the adjectives and the purposive adjunct analysis (akin to *in order to*) for the infinitival VP. Finally, right node raising often involves coordination where one of the conjuncts is in fact not a well-formed phrase (e.g., *independently of* in (3)), making it potentially difficult to construct the correct coordination structure, let alone associate the raised element with the correct position in each conjunct.

3.2 Non-dependencies

Two of our phenomena crucially look for the lack of dependencies. These are *it* expletives ('itexpl') and verb-particle constructions ('vpart'):

(4) itexpl: Crew negligence is blamed, and *it* **is suggested** that the flight crew were drunk.

(5) vpart: He once **threw out** two *baserunners* at home in the same inning.

The English pronoun *it* can be used as an ordinary personal pronoun or as an expletive: a placeholder for when the language demands a subject (or occasionally object) NP but there is no semantic role for that NP. The expletive *it* only appears when it is licensed by a specific construction (such as extraposition, (4)) or selecting head. If the goal of parsing is to recover from the surface string the dependencies capturing who did what to whom, expletive *it* should not feature in any of those dependencies. Likewise, instances of expletive *it* should be detected and discarded in reference resolution. We hypothesize that detecting expletive *it* requires encoding linguistic knowledge about its licensers.

The other non-dependency we explore is between the particle in verb-particle constructions and the direct object. Since English particles are almost always homophonous with prepositions, when the object of the verb-particle pair follows the particle, there will always be a competing analysis which analyses the sequence as V+PP rather than V+particle+NP. Furthermore, since verb-particle pairs often have non-compositional semantics (Sag et al., 2002), misanalyzing these constructions could be costly to downstream components.

3.3 Phrasal modifiers

Our next category concerns modifier phrases:

(6) ned: *Light* ***colored*** **glazes** also have softening effects when painted over dark or bright images.

(7) absol: The format **consisted** of 12 games, each *team* ***facing*** the other teams twice.

The first, ('ned'), is a pattern which to our knowledge has not been named in the literature, where a noun takes the typically verbal *-ed* ending, is modified by another noun or adjective, and functions as a modifier or a predicate. We believe this phenomenon to be interesting because its unusual morphology is likely to lead PoS-taggers astray, and because the often-hyphenated Adj+N-ed constituent has productive internal structure constraining its interpretation.

The second phrasal modifier we investigate is the absolutive construction. An absolutive consists of an

[4] All examples are from our data. Words involved in the relevant dependencies are highlighted in italics (dependents) and boldface (heads).

NP followed by a non-finite predicate (such as could appear after the copula *be*). The whole phrase modifies a verbal projection that it attaches to. Absolutives may be marked with *with* or unmarked. Here, we focus on the unmarked type as this lack of lexical cue can make the construction harder to detect.

3.4 Subtle arguments

Our final three phenomena involve ways in which verbal arguments can be more difficult to identify than in ordinary finite clauses. These include detecting the arguments of verbal gerunds ('vger'), the interleaving of arguments and adjuncts ('argadj') and raising/control ('control') constructions.

(8) vger: ***Accessing*** *the website* without the "www" subdomain **returned** a copy of the main site for "EP.net".

(9) argadj: The story **shows**, *through* flashbacks, the different *histories* of the characters.

(10) control: *Alfred* "retired" in 1957 at age 60 but **continued** to **paint** full time.

In a verbal gerund, the *-ing* form a verb retains verbal properties (e.g., being able to take NP complements, rather than only PP complements) but heads a phrase that fills an NP position in the syntax (Malouf, 2000). Since gerunds have the same morphology as present participle VPs, their role in the larger clause is susceptible to misanalysis.

The argadj examples are of interest because English typically prefers to have direct objects directly adjacent to the selecting verb. Nonetheless, phenomena such as parentheticals and heavy-NP shift (Arnold et al., 2000), in which "heavy" constituents appear further to the right in the string, allow for adjunct-argument order in a minority of cases. We hypothesize that the relative infrequency of this construction will lead parsers to prefer incorrect analyses (wherein the adjunct is picked up as a complement, the complement as an adjunct or the structure differs entirely) unless they have access to linguistic knowledge providing constraints on possible and probable complementation patterns for the head.

Finally, we turn to raising and control verbs ('control') (e.g., Huddleston and Pullum (2002, ch. 14)). These verbs select for an infinitival VP complement and stipulate that another of their arguments (subject or direct object in the examples we explore) is identified with the unrealized subject position of the infinitival VP. Here it is the dependency between the infinitval VP and the NP argument of the "upstairs" verb which we expect to be particularly subtle. Getting this right requires specific lexical knowledge about which verbs take these complementation patterns. This lexical knowledge needs to be represented in such a way that it can be used robustly even in the case of passives, relative clauses, etc.[5]

3.5 Penn Treebank representations

We investigated the representation of these 10 phenomena in the PTB (Marcus et al., 1993) in two steps: First we explored the PTB's annotation guidelines (Bies et al., 1995) to determine how the relevant dependencies were intended to be represented. We then used Ghodke and Bird's (2010) Treebank Search to find examples of the intended annotations as well as potential examples of the phenomena annotated differently, to get a sense of the consistency of the annotation from both precision and recall perspectives. In this study, we take the phrase structure trees of the PTB to represent dependencies based on reasonable identification of heads.

The barerel, vpart, and absol phenomena are completely unproblematic, with their relevant dependencies explicitly and reliably represented. In addition, the tough construction is reliably annotated, though one of the dependencies we take to be central is not directly represented: The missing argument is linked to a null *wh* head at the left edge of the complement of the tough predicate, rather than to its subject. Two further phenomena (rnr and vger) are essentially correctly represented: the representations of the dependencies are explicit and mostly but not entirely consistently applied. Two out of a sample of 20 examples annotated as containing rnr did not, and two out of a sample of 35 non-rnr-annotated coordinations actually contained rnr. For vger the primary problem is with the PoS tagging, where the gerund is sometimes given a nominal tag, contrary to PTB guidelines, though the structure above it conforms.

The remaining four constructions are more problematic. In the case of object control, while the guide-

[5] Distinguishing between raising and control requires further lexical knowledge and is another example of a "non-dependency" (in the raising examples). We do not draw that distinction in our annotations.

lines specify an analysis in which the shared NP is attached as the object of the higher verb, the PTB includes not only structures conforming to that analysis but also "small clause" structures, with the latter obscuring the relationship of the shared argument to the higher verb. In the case of itexpl, the adjoined `(S(-NONE- *EXP*))` indicating an expletive use of *it* is applied consistently for extraposition (as prescribed in the guidelines). However, the set of lexical licensers of the expletive is incomplete. For argadj we run into the problem that the PTB does not explicitly distinguish between post-verbal modifiers and verbal complements in the way that they are attached. The guidelines suggest that the function tags (e.g., `PP-LOC`, etc.) should allow one to distinguish these, but examination of the PTB itself suggests that they are not consistently applied. Finally, the ned construction is not mentioned in the PTB guidelines nor is its internal structure represented in the treebank. Rather, strings like *gritty-eyed* are left unsegmented and tagged as `JJ`.

We note that the PTB representations of many of these phenomena (barerel, tough, rnr, argadj, control, itexpl) involve empty elements and/or function tags. Systems that strip these out before training, as is common practice, will not benefit from the information that is in the PTB.

Our purpose here is not to criticize the PTB, which has been a tremendously important resource to the field. Rather, we have two aims: The first is to provide context for the evaluation of PTB-derived parsers on these phenomena. The second is to highlight the difficulty of producing consistent annotations of any complexity as well as the hurdles faced by a hand-annotation approach when attempting to scale a resource to more complex representations and/or additional phenomena (though cf. Vadas and Curran (2008) on improving PTB representations).

4 Methodology

4.1 Data extraction

We processed 900 million tokens of Wikipedia text using the October 2010 release of the ERG, following the work of the WikiWoods project (Flickinger et al., 2010). Using the top-ranked ERG derivation trees as annotations over this corpus and simple patterns using names of ERG-specific constructions or lexical types, we randomly selected a set of candidate sentences for each of our ten phenomena. These candidates were then hand-vetted in sequence by two annotators to identify, for each phenomenon, 100 examples that do in fact involve the phenomenon in question and which are both grammatical and free of typos. Examples that were either deemed overly basic (e.g. plain V + V coordination, which the ERG treats as rnr) or inappropriately complex (e.g. non-constituent coordination obscuring the interleaving of arguments and adjuncts) were also discarded at this step. Table 1 summarizes relative frequencies of each phenomenon in about 47 million parsed Wikipedia sentences, as well as the total size of the candidate sets inspected. For the control and tough phenomena hardly any filtering for complexity was applied, hence these can serve as indicators of the rate of genuine false positives. For phenomena that partially overlap with those of Rimell et al. (2009), it appears our frequency estimates are comparable to what they report for the Brown Corpus (but not the WSJ portion of the PTB).

Phenomenon	Frequency	Candidates
barerel	2.12%	546
tough	0.07%	175
rnr	0.69%	1263
itexpl	0.13%	402
vpart	4.07%	765
ned	1.18%	349
absol	0.51%	963
vger	5.16%	679
argadj	3.60%	1346
control	3.78%	124

Table 1: Relative frequencies of phenomena matches in Wikipedia, and number of candidate strings vetted.

4.2 Annotation format

We annotated up to two dependency triples per phenomenon instance, identifying the heads and dependents by the surface form of the head words in the sentence suffixed with a number indicating word position (see Table 2).[6] Some strings contain more than one instance of the phenomenon they illustrate; in these cases, multiple sets of dependencies are

[6] As the parsers differ in tokenization strategies, our evaluation script treats these position IDs as approximate indicators.

Item ID	Phenomenon	Polarity	Dependency
1011079100200	absol	1	having-2|been-3|passed-4 ARG act-1
1011079100200	absol	1	withdrew-9 MOD having-2|been-3|passed-4
1011079100200	absol	1	carried+on-12 MOD having-2|been-3|passed-4

Table 2: Sample annotations for sentence # 1011079100200: *The-0 act-1 having-2 been-3 passed-4 in-5 that-6 year-7 Jessop-8 withdrew-9 and-10 Whitworth-11 carried-12 on-13 with-14 the-15 assistance-16 of-17 his-18 son-19.*

Phenomenon	Head	Type	Dependent	Distance
Bare relatives	gapped predicate in relative	ARG2/MOD	modified noun	3.0 (8)
(barerel)	modified noun	MOD	top predicate of relative	3.3 (8)
Tough adjectives	*tough* adjective	ARG2	*to*-VP complement	1.7 (5)
(tough)	gapped predicate in *to*-VP	ARG2	subject/modifiee of adjective	6.4 (21)
Right Node Raising	verb/prep2	ARG2	shared noun	2.8 (9)
(rnr)	verb/prep1	ARG2	shared noun	6.1 (12)
Expletive It	*it*-subject taking verb	!ARG1	*it*	1.2 (3)
(itexpl)	raising-to-object verb	!ARG2	*it*	–
Verb+particle constructions	particle	!ARG2	complement	2.7 (9)
(vpart)	verb+particle	ARG2	complement	3.7 (10)
Adj/Noun2 + Noun1-*ed*	head noun	MOD	Noun1-*ed*	2.4 (17)
(ned)	Noun1-*ed*	ARG1/MOD	Adj/Noun2	1.0 (1.5)
Absolutives	absolutive predicate	ARG1	subject of absolutive	1.7 (12)
(absol)	main clause predicate	MOD	absolutive predicate	9.8 (26)
Verbal gerunds	selecting head	ARG[1,2]	gerund	1.9 (13)
(vger)	gerund	ARG2/MOD	first complement/modifier of gerund	2.3 (8)
Interleaved arg/adj	selecting verb	MOD	interleaved adjunct	1.2 (7)
(argadj)	selecting verb	ARG[2,3]	displaced complement	5.9 (26)
Control	"upstairs" verb	ARG[2,3]	"downstairs" verb	2.4 (23)
(control)	"downstairs" verb	ARG1	shared argument	4.8 (17)

Table 3: Dependencies labeled for each phenomenon type, including average and maximum surface distances.

recorded. In addition, some strings evince more than one of the phenomena we are studying. However, we only annotate the dependencies associated with the phenomenon the string was selected to represent. Finally, in examples with coordinated heads or dependents, we recorded separate dependencies for each conjunct. In total, we annotated 2127 dependency triples for the 1000 sentences, including 253 negative dependencies (see below). Table 3 outlines the dependencies annotated for each phenomenon.

To allow for multiple plausible attachment sites, we give disjunctive values for heads or dependents in several cases: (i) with auxiliaries, (ii) with complementizers (*that* or *to*, as in Table 2), (iii) in cases of measure or classifier nouns or partitives, (iv) with multi-word proper names and (v) where there is genuine attachment ambiguity for modifiers. As these sets of targets are disjunctive, these conventions should have the effect of increasing measured parser performance. 580 (27%) of the annotated dependencies had at least one disjunction.

4.3 Annotation and reconciliation process

The entire data set was annotated independently by two annotators. Both annotators were familiar with the ERG, used to identify these sentences in the WikiWoods corpus, but the annotation was done without reference to the ERG parses. Before beginning annotation on each phenomenon, we agreed on which dependencies to annotate. We also communicated with each other about annotation conventions as the need for each convention became clear. The annotation conventions address how to handle coordination, semantically empty auxiliaries, passives and similar orthogonal phenomena.

Once the entire data set was dual-annotated, we compared annotations, identifying the following sources of mismatch: typographical errors, incompletely specified annotation conventions, inconsistent application of conventions (101 items, dropping in frequency as the annotation proceeded), and genuine disagreement about what to annotate, either different numbers of dependencies of interest identified

in an item (59 items) or conflicting elements in a dependency (54 items).[7] Overall, our initial annotation pass led to agreement on 79% of the items, and a higher per-dependency level of agreement. Agreement could be expected to approach 90% with more experience in applying annotation conventions.

We then reconciled the annotations, using the comparison to address all sources of difference. In most cases, we readily agreed which annotation was correct and which was in error. In a few cases, we decided that both annotations were plausible alternatives (e.g., in terms of alternative attachment sites for modifiers) and so created a single merged annotation expressing the disjunction of both (cf. § 4.2).

5 Evaluation

With the test data consisting of 100 items for each of our ten selected phenomena, we ran all seven parsing systems and recorded their dependency-style outputs for each sentence. While these outputs are not directly comparable with each other, we were able to associate our manually-annotated target dependencies with parser-specific dependencies, by defining sets of phenomenon-specific regular expressions for each parser. In principle, we allow this mapping to be somewhat complex (and forgiving to non-contentful variation), though we require that it work deterministically and not involve specific lexical information. An example set is given in Fig. 2.

```
"absol" =>
{'ARG1' => [
'\(ncsubj \W*{W1}\W*_(\d+) \W*{W2}\W*_(\d+) _\)',
'\(ncmod _ \W*{W2}\W*_(\d+) \W*{W1}\W*_(\d+)\)'],
'ARG' => [
'\(ncsubj \W*{W1}\W*_(\d+) \W*{W2}\W*_(\d+) _\)',
'\(ncmod _ \W*{W1}\W*_(\d+) \W*{W2}\W*_(\d+)\)'],
'MOD' => [
'\(xmod _ \W*{W1}\W*_(\d+) \W*{W2}\W*_(\d+)\)',
'\(ncmod _ \W*{W1}\W*_(\d+) \W*{W2}\W*_(\d+)\)',
'\(cmod _ \W*{W1}\W*_(\d+) \W*{W2}\W*_(\d+)\)']}
```

Figure 2: Regexp set to evaluate C&C for absol.

These expressions fit the output that we got from the C&C parser, illustrated in Fig. 3 with a relevant portion of the dependencies produced for the example in Table 2. Here the C&C dependency `(ncsubj passed_4 Act_1 _)` matches the first target in the gold-standard (Table 2), but no matching C&C dependency is found for the other two targets.

```
(xmod _ Act_1 passed_4)
(ncsubj passed_4 Act_1 _)
(ncmod _ withdrew,_9 Jessop_8)
(dobj year,_7 withdrew,_9)
```

Figure 3: Excerpts of C&C output for item in Table 2.

The regular expressions operate solely on the dependency labels and are not lexically-specific. They are specific to each phenomenon, as we did not attempt to write a general dependency converter, but rather to discover what patterns of dependency relations describe the phenomenon when it is correctly identified by each parser. Thus, though we did not hold out a test set, we believe that they would generalize to additional gold standard material annotated in the same way for the same phenomena.[8]

In total, we wrote 364 regular expressions to handle the output of the seven parsers, allowing some leeway in the role labels used by a parser for any given target dependency. The supplementary materials for this paper include the test data, parser outputs, target annotations, and evaluation script.

Fig. 1 provides a visualization of the results of our evaluation. Each column of points represents one dependency type. Dependency types for the same phenomenon are represented by adjacent columns. The order of the columns within a phenomenon follows the order of the dependency descriptions in Table 3: For each pair, the dependency type with the higher score for the majority of the parsers is shown first (to the left). The phenomena themselves are also arranged according to increasing (average) difficulty. itexpl only has one column, as we annotated just one dependency per instance here. (The two descriptions in Table 3 reflect different, mutually-incompatible instance types.) Since expletive *it* should not be the semantic dependent of any head, the targets are generalized for this phenomenon and the evaluation script counts as incor-

[7] We do not count typographical errors or incompletely specified conventions as failures of inter-annotator agreement.

[8] In the case of the XLE, our simplistic regular-expression approach to the interpretation of parser outputs calls for much more complex patterns than for the other parsers. This is owed to the rich internal structure of LFG f-structures and higher granularity of linguistic analysis, where feature annotations on nodes as well as reentrancies need to be taken into account. Therefore, our current results for the XLE admit small amounts of both over- and under-counting.

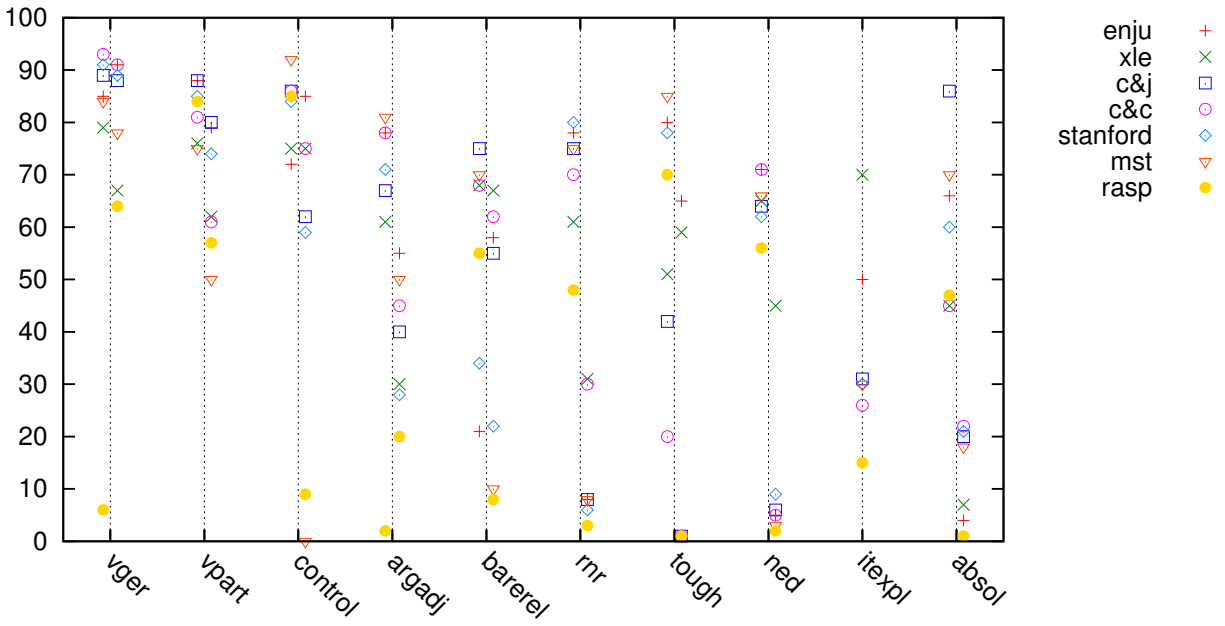

Figure 1: Individual dependency recall for seven parsers over ten phenomena.

rect any dependency involving referential *it*.

We observe fairly high recall of the dependencies for vpart and vger (with the exception of RASP), and high recall for both dependencies representing control for five systems. While Enju, Stanford, MST, and RASP all found between 70 and 85% of the dependency between the adjective and its complement in the tough construction, only Enju and XLE represented the dependency between the subject of the adjective and the gap inside the adjective's complement. For the remaining phenomena, each parser performed markedly worse on one dependency type, compared to the other. The only exceptions here are XLE and C&C's (and to a lesser extent, C&J's) scores for barerel. No system scored higher than 33% on the harder of the two dependencies in rnror absol, and Stanford, MST, and RASP all scored below 25% on the harder dependency in barerel. Only XLE scored higher than 10% on the second dependency for ned and higher than 50% for itexpl.

6 Discussion

From the results in Fig. 1, it is clear that even the best of these parsers fail to correctly identify a large number of relevant dependencies associated with linguistic phenomena that occur with reasonable frequency in the Wikipedia. Each of the parsers attempts with some success to analyze each of these phenomena, reinforcing the claim of relevance, but they vary widely across phenomena. For the two long-distance phenomena that overlap with those studied in Rimell et al. (2009), our results are comparable.[9] Our evaluation over Wikipedia examples thus shows the same relative lack of success in recovering long-distance dependencies that they found for WSJ sentences. The systems did better on relatively well-studied phenomena including control, vger, and vpart, but had less success with the rest, even though all but two of those remaining phenomena involve syntactically local dependencies (as indicated in Table 3).

Successful identification of the dependencies in these phenomena would, we hypothesize, benefit from richer (or deeper) linguistic information when parsing, whether it is lexical (tough, control, itexpl, and vpart), or structural (rnr, absol, vger, argadj, and barerel), or somewhere in between, as with ned. In the case of treebank-trained parsers, for the information to be available, it must be consistently encoded in the treebank and attended to during training. As

[9] Other than Enju, which scores 16 points higher in the evaluation of Rimell et al., our average scores for each parser across the dependencies for these phenomena are within 12 points of those reported by Rimell et al. (2009) and Nivre et al. (2010).

noted in Sections 2.1 and 3.5, there is tension between developing sufficiently complex representations to capture linguistic phenomena and keeping an annotation scheme simple enough that it can be reliably produced by humans, in the case of hand-annotation.

7 Related Work

This paper builds on a growing body of work which goes beyond (un)labeled bracketing in parser evaluation, including Lin (1995), Carroll et al. (1998), Kaplan et al. (2004), Rimell et al. (2009), and Nivre et al. (2010). Most closely related are the latter two of the above, as we adopt their "construction-focused parser evaluation methodology".

There are several methodological differences between our work and that of Rimell et al. First, we draw our evaluation data from a much larger and more varied corpus. Second, we automate the comparison of parser output to the gold standard, and we distribute the evaluation scripts along with the annotated corpus, enhancing replicability. Third, where Rimell et al. extract evaluation targets on the basis of PTB annotations, we make use of a linguistically precise broad-coverage grammar to identify candidate examples. This allows us to include both local and non-local dependencies not represented or not reliably encoded in the PTB, enabling us to evaluate parser performance with more precision over a wider range of linguistic phenomena.

These methodological innovations bring two empirical results. The first is qualitative: Where previous work showed that overall Parseval numbers hide difficulties with long-distance dependencies, our results show that there are multiple kinds of reasonably frequent *local* dependencies which are also difficult for the current standard approaches to parsing. The second is quantitative: Where Rimell et al. found two phenomena which were virtually unanalyzed (recall below 10%) for one or two parsers each, we found eight phenomena which were virtually unanalyzed by at least one system, including two unanalyzed by five and one by six. Every system had at least one virtually unanalyzed phenomenon. Thus we have shown that the dependencies being missed by typical modern approaches to parsing are more varied and more numerous than previously thought.

8 Conclusion

We have presented a detailed construction-focused evaluation of seven parsers over 10 phenomena, with 1000 examples drawn from English Wikipedia. Gauging recall of such "deep" dependencies, in our view, can serve as a proxy for downstream processing involving semantic interpretation of parser outputs. Our annotations and automated evaluation script are provided in the supplementary materials, for full replicability. Our results demonstrate that significant opportunities remain for parser improvement, and highlight specific challenges that remain invisible in aggregate parser evaluation (e.g. Parseval or overall dependency accuracy). These results suggest that further progress will depend on training data that is both more extensive and more richly annotated than what is typically used today (seeing, for example, that a large part of more detailed PTB annotation remains ignored in much parsing work).

There are obvious reasons calling for diversity in approaches to parsing and for different trade-offs in, for example, the granularity of linguistic analysis, average accuracy, cost of computation, or ease of adaptation. Our proposal is not to substitute construction-focused evaluation on Wikipedia data for widely used aggregate metrics and reference corpora, but rather to augment such best practices in the spirit of Rimell et al. (2009) and expand the range of phenomena considered in such evaluations. Across frameworks and traditions (and in principle languages), it is of vital importance to be able to evaluate the quality of parsing (and grammar induction) algorithms in a maximally informative manner.

Acknowledgments

We are grateful to Tracy King for her assistance in setting up the XLE system and to three anonymous reviewers for helpful comments. The fourth author thanks DFKI and the DFG funded Excellence Cluster on MMCI for their support of the work. Data preparation on the scale of Wikipedia was made possible through access to large-scale HPC facilities, and we are grateful to the Scientific Computing staff at UiO and the Norwegian Metacenter for Computational Science.

Abstract

Text simplification aims to rewrite text into simpler versions, and thus make information accessible to a broader audience. Most previous work simplifies sentences using handcrafted rules aimed at splitting long sentences, or substitutes difficult words using a predefined dictionary. This paper presents a data-driven model based on quasi-synchronous grammar, a formalism that can naturally capture structural mismatches and complex rewrite operations. We describe how such a grammar can be induced from Wikipedia and propose an integer linear programming model for selecting the most appropriate simplification from the space of possible rewrites generated by the grammar. We show experimentally that our method creates simplifications that significantly reduce the reading difficulty of the input, while maintaining grammaticality and preserving its meaning.

1 Introduction

Sentence simplification is perhaps one of the oldest text rewriting problems. Given a *source* sentence, the goal is to create a grammatical *target* that is easier to read with simpler vocabulary and syntactic structure. An example is shown in Table 1 involving a broad spectrum of rewrite operations such as deletion, substitution, insertion, and reordering. The popularity of the simplification task stems from its potential relevance to various applications. Examples include the development of reading aids for people with aphasia (Carroll et al., 1999), non-native speakers (Siddharthan, 2003) and more generally individuals with low literacy (Watanabe et al., 2009). A simplification component could be also used as a preprocessing step to improve the performance of parsers (Chandrasekar et al., 1996), summarizers (Beigman Klebanov et al., 2004) and semantic role labelers (Vickrey and Koller, 2008).

Also contributing to the firmness in copper, the analyst noted, was a report by Chicago purchasing agents, which precedes the full purchasing agents report that is due out today and gives an indication of what the full report might hold.

Table 1: Example of a source sentence (top) and its simplification (bottom).

Simplification is related to, but different from paraphrase extraction (Barzilay, 2003). We must not only have access to paraphrases (i.e., rewrite rules), but also be able to combine them to generate new text, in a simpler language. The task is also distinct from sentence compression as it aims to render a sentence more accessible while preserving its meaning. On the contrary, compression unavoidably leads to some information loss as it creates shorter sentences without necessarily reducing complexity. In fact, one of the commonest simplification operations is sentence splitting which usually produces longer rather than shorter output! Moreover, mod-

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 409–420,
Edinburgh, Scotland, UK, July 27–31, 2011.

els developed for sentence compression have been mostly designed with one rewrite operation in mind, namely word deletion, and are thus unable to model consistent syntactic effects such as reordering, sentence splitting, changes in non-terminal categories, and lexical substitution (but see Cohn and Lapata 2008 and Zhao et al. 2009 for notable exceptions).

In this paper we propose a sentence simplification model that is able to handle structural mismatches and complex rewriting operations. Our approach is based on quasi-synchronous grammar (QG, Smith and Eisner 2006), a formalism that is well suited for text rewriting. Rather than postulating a strictly synchronous structure over the source and target sentences, QG identifies a "sloppy" alignment of parse trees assuming that the target tree is in some way "inspired by" the source tree. Specifically, our model is formulated as an integer linear program and uses QG to capture the space of all possible rewrites. Given a source tree, it finds the best target tree licensed by the grammar subject to constraints such as sentence length and reading ease. Our model is conceptually simple and computationally efficient. Furthermore, it finds globally optimal simplifications without resorting to heuristics or approximations during the decoding process.

Contrary to most previous approaches (see the discussion in Section 2) which rely heavily on hand-crafted rules, our model *learns* simplification rewrites automatically from examples of source-target sentences. Our work joins others in using Wikipedia to extract data appropriate for model training (Yamangil and Nelken, 2008; Yatskar et al., 2010; Zhu et al., 2010). Advantageously, the Simple English Wikipedia (henceforth SimpleEW) provides a large repository of simplified language; it uses fewer words and simpler grammar than the ordinary English Wikipedia (henceforth MainEW) and is aimed at non-native English speakers, children, translators, people with learning disabilities or low reading proficiency. We exploit Wikipedia and create a (parallel) simplification corpus in two ways: by aligning MainEW sentences to their SimpleEW counterparts, and by extracting training instances from SimpleEW revision histories, thus leveraging Wikipedia's collaborative editing process.

Our experimental results demonstrate that a simplification model can be learned from Wikipedia data alone without any manual effort. Perhaps unsurprisingly, the quality of the QG grammar rules greatly improves when these are learned from revision histories which are less noisy than sentence alignments. When compared against current state-of-the-art methods (Zhu et al., 2010) our model yields significantly simpler output that is both grammatical and meaning preserving.

2 Related Work

Sentence simplification has attracted a great deal of attention due to its potential impact on society. The literature is rife with attempts to simplify text using mostly hand-crafted syntactic rules aimed at splitting long and complicated sentences into several simpler ones (Carroll et al., 1999; Chandrasekar et al., 1996; Siddharthan, 2004; Vickrey and Koller, 2008). Other work focuses on lexical simplifications and substitutes difficult words by more common WordNet synonyms or paraphrases found in a predefined dictionary (Devlin, 1999; Inui et al., 2003; Kaji et al., 2002).

More recently, Yatskar et al. (2010) explore data-driven methods to learn lexical simplifications from Wikipedia revision histories. A key idea in their work is to utilize SimpleEW edits, while recognizing that these may serve other functions, such as vandalism removal or introduction of new content. Zhu et al. (2010) also use Wikipedia to learn a sentence simplification model which is able to perform four rewrite operations, namely substitution, reordering, splitting, and deletion. Inspired by syntax-based SMT (Yamada and Knight, 2001), their model consists of three components: a language model $P(\mathbf{s})$ whose role is to guarantee that the simplification output is grammatical, a direct translation model $P(\mathbf{s}|\mathbf{c})$ capturing the probability that the target sentence $\mathbf{s}$ is a simpler version of the source $\mathbf{c}$, and a decoder which searches for the simplification $\mathbf{s}$ which maximizes $P(\mathbf{s})P(\mathbf{s}|\mathbf{c})$. The translation model is the product of the aforementioned four rewrite operations whose probabilities are estimated from a parallel corpus of MainEW and SimpleEW sentences using an expectation maximization algorithm. Their decoder translates sentences into simpler alternatives by greedily selecting the branch in the source tree with the highest probability.

Our own work formulates sentence simplification in the framework of Quasi-synchronous grammar (QG, Smith and Eisner 2006). QG allows to describe non-isomorphic tree pairs (the grammar rules can comprise trees of arbitrary depth, and fragments can be mapped) and is thus suited to text-rewriting tasks which typically involve a number of local modifications to the input text. We use quasi-synchronous grammar to learn a wide range of rewrite operations capturing both lexical and structural simplifications naturally without any additional rule engineering. In contrast to Yatskar et al. (2010) and Zhu et al. (2010), simplification operations (e.g., substitution or splitting) are not modeled explicitly; instead, we leave it up to our grammar extraction algorithm to learn appropriate rules that reflect the training data. Compared to Zhu et al., our model is conceptually simpler and more general. The proposed ILP formulation not only allows to efficiently search through the space of many QG rules but also to incorporate constraints relating to grammaticality and the task at hand without the added computational cost of integrating a language model. Furthermore, our learning framework is not limited to simplification and could be easily adapted to other rewriting tasks. Indeed, the QG formalism has been previously applied to parser adaptation and projection (Smith and Eisner, 2009), paraphrase identification (Das and Smith, 2009), question answering (Wang et al., 2007), and title generation (Woodsend et al., 2010).

Finally, our work relates to a large body of recent literature on Wikipedia and its potential for a wide range of NLP tasks. Beyond text rewriting, examples include semantic relatedness (Ponzetto and Strube, 2007), information extraction (Wu and Weld, 2010), ontology induction (Nastase and Strube, 2008), and the automatic creation of overview articles (Sauper and Barzilay, 2009).

3 Sentence Simplification Model

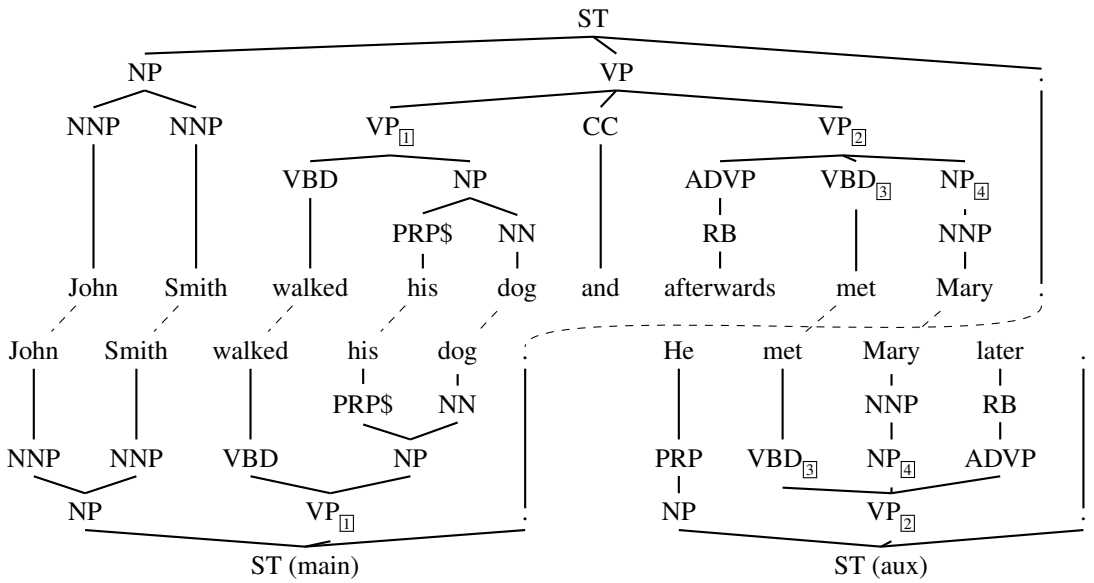
Our model takes a single sentence as input and creates a version that is simpler to read. This may involve rendering syntactically complex structures simpler (e.g., through sentence splitting), or substituting rare words with more common words or phrases (e.g., such that a second language learner may be familiar with), or deleting elements of the original text in order to produce a relatively simpler and shallower syntactic structure. In addition, the output must be grammatical and coherent. These constraints are *global* in their scope, and cannot be adequately satisfied by optimizing each one of them individually. Our approach therefore uses an ILP formulation which will provide a globally optimal solution. Given an input sentence, our model deconstructs it into component phrases and clauses, each of which is simplified (lexically and structurally) through QG rewrite rules. We generate all possible simplifications for a given input and use the ILP to find the best target subject to grammaticality constraints. In what follows we first detail how we extract QG rewrite rules as these form the backbone of our model and then formulate the ILP proper.

3.1 Quasi-synchronous Grammar

Phrase alignment Our model operates on individual sentences annotated with syntactic information i.e., phrase structure trees. In our experiments, we obtain this information from the Stanford parser (Klein and Manning, 2003) but any other broadly similar parser could be used instead. Given an input sentence S1 or its parse tree T1, the QG constructs a monolingual grammar for parsing, or generating, possible translation trees T2. A grammar node in the target tree T2 is modeled on a subset of nodes in the source tree, with a rather loose alignment between the trees.

We take aligned sentence pairs represented as phrase structure trees and build up a list of leaf node alignments based on lexical identity. We align direct parent nodes where more than one child node aligns. QG rules are created from aligned nodes above the leaf node level if the all the nodes in the target tree can be explained using nodes from the source. This helps to improve the quality in what is inherently a noisy process, and it is largely responsible for a relatively small resulting grammar (see Table 2). Examples of phrase alignments (indicated with dotted lines) are shown in Figure 1.

Syntactic simplification rules Each QG rule describes the transformations required from source to target phrase sub-trees. It allows child (and possibly grand-child) constituents to be deleted or re-



Rule involving lexical substitution: $\langle$VP, VP$\rangle \rightarrow \langle$[ADVP [RB *afterwards*] $\text{VBD}_{\boxed{3}}$ $\text{NP}_{\boxed{4}}$], [$\text{VBD}_{\boxed{3}}$ $\text{NP}_{\boxed{4}}$ ADVP [RB *later*]]$\rangle$
Rule for splitting into main constituent and auxiliary sentence: $\langle$VP, VP, ST$\rangle \rightarrow \langle$[$\text{VP}_{\boxed{1}}$ *and* $\text{VP}_{\boxed{2}}$], [$\text{VP}_{\boxed{1}}$], [NP [PRP *He*] $\text{VP}_{\boxed{2}}$.]$\rangle$

Figure 1: A source sentence (upper tree) is split into two sentences. Dotted lines show word alignments, while boxed subscripts show aligned nodes used to form QG rules. Below, two QG rules learned from this data.

ordered, and for nodes to be flattened. In addition, we allow insertion of punctuation and some function words, identified by a small set of POS tags. To distinguish sentences proper (which have final punctuation) from clauses, we modify the output of the parser, changing the root sentence parse tag from S to ST (a "top-level sentence"); this allows clauses to be extracted and rewritten as stand-alone sentences.

Lexical simplification rules Lexical substitutions are an important part of simplification. We learn them from aligned sub-trees, in the same way as described above for syntax rules, by allowing a small number of lexical substitutions to be present in the rules, and provided they do not include proper nouns. The resulting QG rules could be applied by matching the syntax of the whole sub-tree surrounding the substitution, but this approach is overly restrictive and suffers from data sparsity. Indeed, Yatskar et al. (2010) learn lexical simplifications without taking syntactic context into account. We therefore add a post-processing stage to the learning process. For rules where the syntactic structures of the source and target sub-trees match, and the only difference is a lexical substitution, we construct a more general rule by extracting the words and corresponding POS tags involved in the substitution. Then at the generation stage, identifying suitable rules depends only on the substitution words, rather than the surrounding syntactic context. An example of a lexical substitution rule is shown in Figure 1.

Sentence splitting rules Another important simplification technique is to split syntactically complicated sentences into several shorter ones. To learn QG rules for this operation, the source sentence is aligned with two consecutive target sentences.

Rather than expecting to discover a split point in the source sentence, we attempt to identify a node in the source parse tree that contributes to both of the two target sentences. Our intuition is that one of the target sentences will follow the general syntactic structure of the source sentence. We designate this as the *main* sentence. A node in the source sentence parse tree will be aligned with a (similar but simpler) node in the main target sentence, but at the same time it will fully explain the other target sentence, which we term the *auxiliary* sentence. It is

possible for the auxiliary sentence to come before or after the main sentence. In the learning procedure, we try both possible orderings, and record the order in any QG rules successfully produced.

The resulting QG rule is a tuple of three phrase structure elements: the source node, the node in the target main sentence (the top level of this node is typically the same as that of the source node), and the phrase structure of the entire auxiliary sentence.[1] In addition, there is a flag to indicate if the auxiliary sentence comes before or after the main sentence. This formalism is able to capture the operations required to split sentences containing coordinate or subordinate clauses, parenthetical content, relative clauses and apposition. An example of a sentence splitting rule is illustrated in Figure 1.

3.2 ILP-based Generation

We cast the problem of finding a suitable target simplification given a source sentence as an integer linear program (ILP). Specifically, simplified text is created from source sentence parse trees by identifying and applying QG grammar rules. These will have matching structure and may also require lexical matching (shown using italics in the example rules in Figure 1). The generation process starts at the root node of the parse tree, applying QG rules to subtrees until leaf nodes are reached. We do not use the Bayesian probability model proposed by Smith and Eisner (2006) to identify the best sequence of simplification rules. Instead, where there is more than one matching rule, and so more than one simplification is possible, the alternatives are all generated and incorporated into the target phrase structure tree. The ILP model operates over this phrase structure tree and selects the phrase nodes from which to form the target output.

Applying the QG rules on the source sentence generates a number of auxiliary sentences. Let $\mathcal{S}$ be this set of sentences. Let $\mathcal{P}$ be the set of nodes in the phrase structure trees of the auxiliary sentences, and $\mathcal{P}_s \subset \mathcal{P}$ be the set of nodes in each sentence $s \in \mathcal{S}$. Let the sets $\mathcal{D}_i \subset \mathcal{P}, \forall i \in \mathcal{P}$ capture the phrase dependency information for each node i, where each set $\mathcal{D}_i$ contains the nodes that depend on the presence of i. In a similar fashion, the sets $\mathcal{A}_i \subset \mathcal{S}, \forall i \in \mathcal{P}$ capture the indices of any auxiliary sentences that depend on the presence of node i. $\mathcal{C} \subset \mathcal{P}$ is the set of nodes involving a choice of alternative simplifications (nodes in the tree where more than one QG rewrite rule can be applied, as mentioned above); $\mathcal{C}_i \subset \mathcal{P}, i \in \mathcal{C}$ are the sets of nodes that are direct children of each such node, in other words they are the individual simplifications. Let $l_i^{(w)}$ be the length of each node i in words, and $l_i^{(sy)}$ its length in syllables. As we shall see below counts of words and syllables are important cues in assessing readability.

The model is cast as an binary integer linear program. A vector of binary decision variables $x \in \{0,1\}^{|\mathcal{P}|}$ indicates if each node is to be part of the output. A vector of auxiliary binary variables $y \in \{0,1\}^{|\mathcal{S}|}$ indicates which (auxiliary) sentences have been chosen.

$$\max_{x} \quad \sum_{i \in \mathcal{P}} g_i x_i + h_w + h_{sy} \tag{1a}$$

$$\text{s.t.} \quad x_j \rightarrow x_i \qquad \forall i \in \mathcal{P}, j \in \mathcal{D}_i \tag{1b}$$

$$x_i \rightarrow y_s \qquad \forall i \in \mathcal{P}, s \in \mathcal{A}_i \tag{1c}$$

$$x_i \rightarrow y_s \qquad \forall s \in \mathcal{S}, i \in \mathcal{P}_s \tag{1d}$$

$$\sum_{j \in \mathcal{C}_i} x_j = x_i \qquad \forall i \in \mathcal{C}, j \in \mathcal{C}_i \tag{1e}$$

$$\sum_{s \in \mathcal{S}} y_i \geq 1 \tag{1f}$$

$$x_i \in \{0,1\} \qquad \forall i \in \mathcal{P} \tag{1g}$$

$$y_s \in \{0,1\} \qquad \forall s \in \mathcal{S}. \tag{1h}$$

Our objective function, given in Equation (1a), is the summation of local and global components. Each phrase is locally given a *rewrite penalty* g_i, where common lexical substitutions, rewrites and simplifications are penalized less (as we trust them more), compared to rarer QG rules. The penalty is a simple log-probability measure, $g_i = \log\left(\frac{n_r}{N_r}\right)$, where n_r is the number of times the QG rule r was seen in the training data, and N_r the number of times all suitable rules for this phrase node were seen. If no suitable rules exist, we set $g_i = 0$.

The other two components of the objective, h_w and h_{sy}, are global in nature, and guide the ILP

[1] Note that the target component comprises the second and third elements as a pair, and variables from the source component are split between them.

towards simpler language. They draw inspiration from existing measures of readability (the ease with which a document can be read and understood). The primary aim of readability formulas is to assess whether texts or books are suitable for students at particular grade levels or ages (see Mitchell 1985 for an overview). Intuitively, texts ought to be simpler if they correspond to low reading levels. A commonly used reading level measure is the Flesch-Kincaid Grade Level (FKGL) index which estimates readability as a combination of the average number of syllables per word and the average number of words per sentence. Unfortunately, this measure is non-linear[2] and cannot be incorporated directly into the objective of the ILP. Instead, we propose a linear approximation. We provide the ILP with targets for the average number of words per sentence (wps), and syllables per word (spw). $h_w(x,y)$ then measures the number of words below this target level that the ILP has achieved:

$$h_w(x,y) = \text{wps} \times \sum_{i \in \mathcal{S}} y_i - \sum_{i \in \mathcal{P}} l_i^{(w)} x_i.$$

When positive, this indicates that sentences are shorter than target, and contributes positively to the readability objective whilst encouraging the application of sentence splitting and deletion-based QG rules. Similarly, $h_{sy}(x,y)$ measures the number of syllables below that expected, from the target average and the number of words the ILP has chosen:

$$h_{sy}(x) = \text{spw} \times \sum_{i \in \mathcal{P}} l_i^{(w)} x_i - \sum_{i \in \mathcal{P}} l_i^{(sy)} x_i.$$

This component of the objective encourages the deletion or lexical substitution of complex words. We can use the two target parameters (wps and spw) to control how much simplification the ILP should apply.

Constraint (1b) enforces grammatical correctness by ensuring that the phrase dependencies are respected and the resulting structure is a tree. Phrases that depend on phrase i are contained in the set $\mathcal{D}_i$. Variable x_i is true, and therefore phrase i will be included in the target output, if any of its dependents $x_j \in \mathcal{D}_i$ are true.[3] Constraint (1c) links main phrases to auxiliary sentences, so that the latter can only be included in the output if the main phrase has also been chosen. This helps to control coherence within the output text. Despite seeming similar to (1c), the role of constraint (1d) is quite different. It links phrase variables x to sentence variables y, to ensure the logical integrity of the model is correct. Where the QG provides alternative simplifications, it makes sense of course to select only one. This is controlled by constraint (1e), and by placing all alternatives in the set $\mathcal{D}_i$ for the node i.

With these constraints alone, and faced with a source sentence that is particularly difficult to simplify, it is possible for the ILP solver to return a "trivial" solution of no output at all, as all other available solutions result in a negative objective value. It is therefore necessary to impose a global minimum output constraint (1f). In combination with the dependency relations in (1c), this constraint ensures that at least an element of the root sentence is present in the output. Global maximum length constraints are a frequently occurring aspect of ILP models used in NLP applications. We decided not to incorporate any such constraints into our model, as we did not want to place limitations on the simplification of original content.

4 Experimental Setup

In this section we present our experimental setup for assessing the performance of the simplification model described above. We give details on the corpora and grammars we used, model parameters, the systems used for comparison with our approach, and explain how the output was evaluated.

Grammar Extraction QG rules were learned from revision histories and an aligned simplification corpus, which we obtained from snapshots[4] of MainEW and SimpleEW. Wiki-related mark-up and meta-information was removed to extract the plain text from the articles.

SimpleEW revisions not only simplify the text of existing articles, they may also introduce new content, vandalize or remove vandalism, or perform numerous automatic "house-keeping" modifications.

[2] $\text{FKGL} = 0.39\left(\frac{\text{total words}}{\text{total sentences}}\right) + 1.8\left(\frac{\text{total syllables}}{\text{total words}}\right) - 15.59$

[3] Constraints (1b), (1c) and (1d) are shown as dependencies for clarity, but they were implemented as inequalities in the ILP.

[4] The snapshots for MainEW (enwiki) and SimpleEW (simplewiki dated 2010-09-16 and 2010-09-13, respectively (both available from `http://download.wikimedia.org/`).

Corpora	Syntactic	Lexical	Splitting
Revision	316	269	184
Aligned	312	96	254

Table 2: Number of QG rules extracted (after removing singletons) from revision-based and aligned corpora.

We identified suitable revisions for simplification by selecting those where the author had mentioned a keyword (such as *simple*, *clarification* or *grammar*) in the revision comments. Each selected revision was compared to the previous version. Because the entire article is stored at each revision, we needed to identify and align modified sentences. We first identified modified sections using the Unix `diff` program, and then individual sentences within the sections were aligned using the program `dwdiff`[5]. This resulted in 14,831 paired sentences. With regard to the aligned simplification corpus, we paired 15,000 articles from SimpleEW and MainEW following the language link within the snapshot files. Within the paired articles, we identified aligned sentences using macro alignment (at paragraph level) then micro alignment (at sentence level), using tf.idf scores to measure similarity (Barzilay and Elhadad, 2003; Nelken and Schieber, 2006).

All source-target sentences (resulting from revisions or alignments) were parsed with the Stanford parser (Klein and Manning, 2003) in order to label the text with syntactic information. QG rules were created by aligning nodes in these sentences as described earlier. A breakdown of the number and type of rules we obtained from the revision and aligned corpora (after removing rules appearing only once) is given in Table 2. Examples of the most frequently learned QG rules are shown in Table 3. Rules (1)–(3) involve syntactic simplification and rules (4)–(6) involve sentence splitting. Examples of common lexical simplifications found by our grammar are: "*discovered*" → "*found*", "*defeated*" → "*won against*", "*may refer to*" → "*could mean*", "*original*" → "*first*", "*requires*" → "*needs*".

Sentence generation We generated simplified versions of MainEW sentences. For each (parsed) source sentence, we created and solved an ILP (see Equation (1)) parametrized as follows: the number of target words per sentence (wps) was set to 8, and syllables per word (spw) to 1.5. These two parameters were empirically tuned on the training set. To solve the ILP model we used the ZIB Optimization Suite software (Achterberg, 2007; Koch, 2004). The solution was converted into a sentence by removing nodes not chosen from the tree representation, then concatenating the remaining leaf nodes in order.

1.	$\langle \text{S, ST} \rangle \rightarrow \langle [\text{NP}_{\boxed{1}}\ \text{VP}_{\boxed{2}}], [\text{NP}_{\boxed{1}}\ \text{VP}_{\boxed{2}}\ .] \rangle$
2.	$\langle \text{S, ST} \rangle \rightarrow \langle [\text{VP}_{\boxed{1}}], [\textit{This}\ \text{VP}_{\boxed{1}}\ .] \rangle$
3.	$\langle \text{NP, ST} \rangle \rightarrow \langle [\text{NP}_{\boxed{1}}, \text{NP}_{\boxed{2}}], [\text{NP}_{\boxed{1}}\ \textit{was}\ \text{VP}_{\boxed{2}}\ .] \rangle$
4.	$\langle \text{ST, ST, ST} \rangle \rightarrow \langle [\text{S}_{\boxed{1}}\ \textit{, and}\ \text{S}_{\boxed{2}}], [\text{ST}_{\boxed{1}}], [\text{ST}_{\boxed{2}}] \rangle$
5.	$\langle \text{ST, ST, ST} \rangle \rightarrow \langle [\text{S}_{\boxed{1}}\ \textit{:}\ \text{S}_{\boxed{2}}], [\text{ST}_{\boxed{1}}], [\text{ST}_{\boxed{2}}] \rangle$
6.	$\langle \text{ST, ST, ST} \rangle \rightarrow \langle [\text{S}_{\boxed{1}}\ \textit{, but}\ \text{S}_{\boxed{2}}], [\text{ST}_{\boxed{1}}], [\text{ST}_{\boxed{2}}] \rangle$

Table 3: Examples of QG rules involving syntactic simplification (1)–(3) and sentence division (4)–(6). The latter are shown as the tuple ⟨source, target, aux⟩. The transform of nodes from S to ST (for example) rely on the application of syntactic simplification rules rules. Boxed subscripts show aligned nodes.

Evaluation We evaluated our model on the same dataset used in Zhu et al. (2010), an aligned corpus of MainEW and SimpleEW sentences. The corpus contains 100/131 source/target sentences and was created automatically. Sentences from this corpus (and their revisions) were excluded from training. We evaluated two versions of our model, one with rewrite rules acquired from revision histories of simplified documents and another one with rules extracted from MainEW-SimpleEW aligned sentences. These models were compared against Zhu et al. (2010)[6] who also learn simplification rules from Wikipedia, and a simple baseline that uses solely lexical simplifications[7] provided by the SimpleEW editor "SpencerK" (Spencer Kelly). An obvious idea would be to treat sentence simplification as an English-to-English translation problem and use an off-the-shelf system like Moses[8] for the task. However, we refrained from doing so as Zhu et al. (2010) show that Moses performs poorly, it cannot model rewrite operations that split sentences or drop words and in most cases generates output identical

RevILP	The London journeys In 1790, Prince Nikolaus died. He was succeeded by a thoroughly unmusical prince. He dismissed the whole musical establishment. He put Haydn on a pension.
SimpleEW	The London journeys In 1790, Prince Nikolaus died and his son became prince. Haydn was put on a pension.

Table 4: Example simplifications produced by the systems in this paper (RevILP, AlignILP) and Zhu et al.'s (2010) model, compared to real Wikipedia text (MainEW: input source, SimpleEW: simplified target).

to the source.

We evaluated model output in two ways, using automatic evaluation measures and human judgments. Intuitively, readability measures ought to be suitable for assessing the output of simplification systems. We report results with the well-known Flesch-Kincaid Grade Level index (FKGL). Experiments with other readability measures such as the Flesch Reading Ease and the Coleman-Liau index obtained similar results. In addition, we also assessed how the system output differed from the human SimpleEW gold standard by computing BLEU (Papineni et al., 2002) and TERp (Snover et al., 2009). Both measures are commonly used to automatically evaluate the quality of machine translation output. BLEU[9] scores the target output by counting n-gram matches with the reference, whereas TERp is similar to word error rate, the only difference being that it allows shifts and thus can account for word order differences. TERp also allows for stem, synonym, and paraphrase substitutions which are common rewrite operations in simplification.

In line with previous work on text rewriting (e.g., Knight and Marcu 2002) we also evaluated system output by eliciting human judgments. We conducted three experiments. In the first experiment participants were presented with a source sentence and its target simplification and asked to rate whether the latter was easier to read compared to the source. In the second experiment, they were asked to rate the grammaticality of the simplified output. In the third experiment, they judged how well the simplification preserved the meaning of the source. In all experiments participants used a five point rating scale where a high number indicates better performance. We randomly selected and automatically simplified 64 sentences from Zhu et al.'s (2010) test corpus using the four models described above. We also included gold standard simplifications. Our materials thus consisted of 320 (64×5) source-target sentences.[10] We collected ratings from 45 unpaid volunteers, all self reported native English speakers. The studies were conducted over the Internet using a custom built web interface. Examples of our experimental items are given in Table 4 (we omit the output of SpencerK as this is broadly similar to the source sentence, modulo lexical substitutions).

[9] We calculated single-reference BLEU using the *mteval-v13a* script (with the default settings).

[10] A Latin square design ensured that subjects did not see two different simplifications of the same sentence.

Models	FKGL	BLEU	TERP
MainEW	15.12	—	—
SimpleEW	11.25	—	—
SpencerK	14.67	0.47	0.51
Zhu et al	9.41	0.38	0.59
RevILP	10.92	0.42	0.60
AlignILP	12.36	0.34	0.85

Table 5: Model performance using automatic evaluation measures.

5 Results

The results of our automatic evaluation are summarized in Table 5. The first column reports the FKGL readability index of the source sentences (MainEW), of their target simplifications (SimpleEW) and the output of four models: a simple baseline that relies on lexical substitution (SpencerK), Zhu et al.'s (2010) model, and two versions of our model, one trained on revision histories (RevILP) and another one trained on the MainEW-SimpleEW aligned corpus (AlignILP). As can be seen, the source sentences have the highest reading level. Zhu et al.'s system has the lowest reading level followed by our own models and SpencerK. All models are significantly[11] different in reading level from SimpleEW with the exception of RevILP (using a one-way ANOVA with post-hoc Tukey HSD tests). SpencerK is not significantly different in readability from MainEW; RevILP is significantly different from Zhu et al. and AlignILP. In sum, these results indicate that RevILP is the closest to SimpleEW and that the provenance of the QG rules has an impact on the model's performance.

Table 5 also shows BLEU and TERp scores with SimpleEW as the reference. These scores can be used to examine how close to the gold standard our models are. SpencerK has the highest BLEU and lowest TERp scores.[12] This is expected as this baseline performs only a very limited type of rewriting, namely lexical substitution. AlignILP is most different from the reference, followed by Zhu et al. (2010) and RevILP. Taken together these results indicate that the ILP models perform a fair amount of rewriting without simply rehashing the source sentence.

[11] All significance differences reported throughout this paper are with a level less than 0.01.

[12] The perfect BLEU score is one and the perfect TERp score is zero.

Models	Simplicity	Grammaticality	Meaning
SimpleEW	3.74	4.89	4.41
SpencerK	1.41	4.87	4.84
Zhu et al	2.92	3.43	3.44
RevILP	3.64	4.55	4.19
AlignILP	2.69	4.03	3.98

Table 6: Average human ratings for gold standard SimpleEW sentences, a simple baseline (SpencerK) based on lexical substitution, Zhu et al.'s 2010 model, and two versions of our ILP model (RevILP and AlignILP).

	Zhu et al	AlignILP	RevILP	SimpleEW
SpencerK	□◇△	□◇△	□⧫△	□⧫△
Zhu et al		■◇△	□◇△	□◇△
AlignILP			□◇▲	□◇△
RevILP				■⧫▲

Table 7: □/■: is/not sig. diff. wrt simplicity; ◇/⧫: is/not sig. diff. wrt grammaticality; △/▲: is/not sig. diff. wrt meaning.

We now turn to the results of our judgment elicitation study. Table 6 reports the average ratings for Simplicity (is the target sentence simpler than the source?), Grammaticality (is the target sentence grammatical?), and Meaning (does the target preserve the meaning of the source?). With regard to simplicity, our participants perceive the gold standard (SimpleEW) to be the simplest, followed by RevILP, Zhu et al, and AlignILP. SpencerK is the least simple model and the most grammatical one as lexical substitutions do not change the structure of the sentence. Interestingly, RevILP and AlignILP are also rated highly with regard to grammaticality. Zhu et al. (2010) is the least grammatical model. Finally, RevILP preserves the meaning of the target as well as SimpleEW, whereas Zhu et al. yields the most distortions. Again SpencerK is rated highly amongst the other models as it is does not substantially simplify and thus change the meaning of the source.

Table 7 reports on pairwise comparisons between all models and their statistical significance (again using a one-way ANOVA with post-hoc Tukey HSD tests). RevILP is not significantly different from SimpleEW on any dimension (Simplicity, Grammat-

Original story: There was once a sweet little maid *who* lived with her father and mother in a pretty little cottage at the edge of the village. At the further end of the wood *was another pretty cottage and in it* lived her grandmother. Everybody loved this little *girl,* her grandmother perhaps loved her most of all *and gave* her a great many pretty things. Once she gave her a red cloak with a hood *which she always wore,* so *people* called her Little Red Riding Hood.
Generated simplification: There was once a sweet little maid. She lived with her father and mother in a pretty little cottage at the edge of the village. At the further end of the wood it lived her grandmother. Everybody loved this little girl. Her grandmother perhaps loved her most of all. She gave her a great many pretty things. Once she gave her a red cloak with a hood, so persons called her Little Red Riding Hood.

Table 8: Excerpt of *Little Red Riding Hood* simplified by the RevILP model. Modifications to the original story are highlighted in italics.

icality, Meaning), whereas Zhu et al. differs significantly from RevILP and SimpleEW on all dimensions. It is also significantly different from AlignILP in terms of grammaticality and meaning but not simplicity. RevILP is significantly more simple and grammatical than AlignILP but performs comparably with respect to preserving the meaning of the source.

In sum, our results show that RevILP is the best performing model. It creates sentences that are simple, grammatical and adhere to the meaning of the source. The QG rules obtained from the revision histories produce better output compared to the aligned corpus. As revision histories are created by Wikipedia contributors, they tend to be a more accurate data source than aligned sentences which are obtained via an automatic and unavoidably noisy procedure. Our results also show that a more general model not restricted to specific rewrite operations like Zhu et al. (2010) obtains superior results and has better coverage.

We also wanted to see whether a simplification model trained on Wikipedia could be applied to another domain. To this end, we used RevILP to simplify five children stories from the Gutenburg[13] collection. The model simplified one sentence at a time and was ran with the Wikipedia settings without any modification. The mean FKGL on the simplified stories was 3.78. compared to 7.04 for the original ones. An example of our system's output on *Little Red Riding Hood* is shown in Table 8.

Possible extensions and improvements to the current model are many and varied. We have presented an all-purpose simplification model without a target audience or application in mind. An interesting research direction would be to simplify text according to readability levels or text genres (e.g., newspaper vs literary text). We could do this by incorporating readability-specific constraints to the ILP or by changing the objective function (e.g., by favoring more domain-specific rules). Finally, we would like to extend the current model so as to simplify entire documents both in terms of style and content.

Bootstrapping Semantic Parsers from Conversations

Yoav Artzi and **Luke Zettlemoyer**
Computer Science & Engineering
University of Washington
Seattle, WA 98195
{yoav,lsz}@cs.washington.edu

Abstract

Conversations provide rich opportunities for interactive, continuous learning. When something goes wrong, a system can ask for clarification, rewording, or otherwise redirect the interaction to achieve its goals. In this paper, we present an approach for using conversational interactions of this type to induce semantic parsers. We demonstrate learning without any explicit annotation of the meanings of user utterances. Instead, we model meaning with latent variables, and introduce a loss function to measure how well potential meanings match the conversation. This loss drives the overall learning approach, which induces a weighted CCG grammar that could be used to automatically bootstrap the semantic analysis component in a complete dialog system. Experiments on DARPA Communicator conversational logs demonstrate effective learning, despite requiring no explicit meaning annotations.

1 Introduction

Conversational interactions provide significant opportunities for autonomous learning. A well-defined goal allows a system to engage in remediations when confused, such as asking for clarification, rewording, or additional explanation. The user's response to such requests provides a strong, if often indirect, signal that can be used to learn to avoid the original confusion in future conversations. In this paper, we show how to use this type of conversational feedback to learn to better recover the meaning of user utterances, by inducing semantic parsers from unannotated conversational logs. We believe that this style of learning will contribute to the long term goal of building self-improving dialog systems that continually learn from their mistakes, with little or no human intervention.

Many dialog systems use a semantic parsing component to analyze user utterances (e.g., Allen et al., 2007; Litman et al., 2009; Young et al., 2010). For example, in a flight booking system, the sentence

Sent: I want to go to Seattle on Friday
LF: $\lambda x.to(x, SEA) \wedge date(x, FRI)$

might be mapped to the logical form (LF) meaning representation above, a lambda-calculus expression defining the set of flights that match the user's desired constraints. This LF is a representation of the semantic content that comes from the sentence, and would be input to a context-dependent understanding component in a full dialog system, for example to find the date that the symbol FRI refers to.

To induce semantic parsers from interactions, we consider user statements in conversational logs and model their meaning with latent variables. We demonstrate that it is often possible to use the dialog that follows a statement (including remediations such as clarifications, simplifications, etc.) to learn the meaning of the original sentence. For example, consider the first user utterance in Figure 1, where the system failed to understand the user's request. To complete the task, the system must use a remediation strategy. Here, it takes the initiative by asking for and confirming each flight constraint in turn. This strategy produces an unnatural conversation but provides supervision for learning the meaning of the

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 421–432,
Edinburgh, Scotland, UK, July 27–31, 2011.

original utterance. We can easily record representations of the meanings the system intended to convey at each step, as seen in Figure 1, and use this indirect supervision for learning.

Learning from this weak signal is challenging. In any specific conversation, the system's remediations can fail to recover aspects of the original user meaning and can introduce spurious constraints, for example when users change their goals mid conversation. To learn effectively, the model must accumulate evidence from many interactions to best recover the meaning of each specific sentence.

We will learn semantic parsers defined by probabilistic Combinatory Categorial Grammars (PCCGs), which include both a lexicon and a weighted linear model for parse selection. The lexicon specifies the meanings of individual words and phrases, while the parameters of a parsing model define how to best combine word- and phrase-level meanings to analyze complete sentences. To learn without labeled meaning representations, we make use of a variant of the loss-sensitive Perceptron algorithm (Singh-Miller and Collins, 2007). We define loss functions to provide a rough measure of (1) how well a candidate meaning for a utterance matches the conversation that follows it and (2) how well the candidate matches our expectations about the types of things that are often said in the dialog's domain. These notions of loss drive not only the parameter estimation but also the grammar induction process that constructs the CCG lexicon. Experiments on conversation logs from the DARPA Communicator corpus (Walker et al., 2002) demonstrate the feasibility of our approach.

This paper makes the following contributions:

- A formalization of the problem of learning the meaning of user statements from conversational feedback, without requiring annotation.
- A new loss-sensitive learning algorithm for this problem that induces semantic parsers from conversation logs.
- Loss functions to measure the quality of hypothetical utterance meanings within the conversation in which they appear.
- An evaluation on logs from two dialog systems that demonstrate effective learning from conversations alone.

SYSTEM: how can i help you? (OPEN_TASK)

USER: september twenty fourth in the early evening
[conversation continues]

Figure 1: Conversational excerpt from a DARPA Communicator travel-planning dialog. Each system statement is labeled with representations of its speech act and logical meaning, in parentheses. The user utterances have no labels. Conversations of this type provide the training data to learn semantic parsers for user utterances.

2 Problem

Our goal is to learn a function that maps a sentence x to a lambda-calculus expression z. We assume access to logs of conversations with automatically generated annotation of system utterance meanings, but no explicit labeling of each user utterance meaning.

We define a conversation $\mathcal{C} = (\vec{U}, O)$ to be a sequence of utterances $\vec{U} = [u_0, \ldots, u_m]$ and a set of conversational objects O. An object $o \in O$ is an entity that is being discussed, for example there would be a unique object for each flight leg discussed in a travel planning conversation. Each utterance $u_i = (s, x, a, z)$ represents the speaker $s \in \{User, System\}$ producing the natural language statement x which asserts a speech act $a \in \{ASK, CONFIRM, \ldots\}$ with meaning representation z. For example, from the second system utterance in Figure 1 the question $x =$"Leaving what city?" is an a=ASK speech act with lambda-calculus meaning $z = \lambda x.from(fl, x)$. This meaning represents the fact that the system asked for the departure city for the conversational object $o = fl$ representing the flight leg that is currently being discussed. We will learn from conversations where the speech

acts a and logical forms z for user utterances are unlabeled. Such data can be generated by recording interactions, along with each system's internal representation of its own utterances.

Finally, since we will be analyzing sentences at a specific point in a complete conversation, we define our training data as a set $\{(j_i, \mathcal{C}_i)|i = 1 \ldots n\}$. Each pair is a conversation $\mathcal{C}_i$ and the index j_i of the user utterance x in $\mathcal{C}_i$ whose meaning we will attempt to learn to recover. In general, the same conversation $\mathcal{C}$ can be used in multiple examples, each with a different sentence index. Section 8 provides the details of how the data was gathered for our experiments.

3 Overview of Approach

We will present an algorithm for learning a weighted CCG parser, as defined in Section 5, that can be used to map sentences to logical forms. The approach induces a lexicon to represent the meanings of words and phrases while also estimating the parameters of a weighted linear model for selecting the best parse given the lexicon.

Learning As defined in Section 2, the algorithm takes a set of n training examples, $\{(j_i, \mathcal{C}_i) : i = 1, \ldots, n\}$. For each example, our goal is to learn to parse the user utterance x at position j_i in $\mathcal{C}_i$. The training data contains no direct evidence about the logical form z that should be paired with x, or the CCG analysis that would be used to construct z. We model all of these choices as latent variables.

To learn effectively in this complex, latent space, we introduce a loss function $\mathcal{L}(z, j, \mathcal{C}) \in \mathbb{R}$ that measures how well a logical form z models the meaning for the user utterance at position j in $\mathcal{C}$. In Section 6, we will present the details of the loss we use, which is designed to be sensitive to remediations in $\mathcal{C}$ (system requests for clarification, etc.) but also be robust to the fact that conversations often do not uniquely determine which z should be selected, for example when the user prematurely ends the discussion. Then, in Section 7, we present an approach for incorporating this loss function into a complete algorithm that induces a CCG lexicon and estimates the parameters of the parsing model.

This learning setup focuses on a subproblem in dialog; semantic interpretation. We do not yet learn to recover user speech acts or integrate the logical form into the context of the conversation. These are important areas for future work.

Evaluation We will evaluate performance on a test set $\{(x_i, z_i)|i = 1, \ldots, m\}$ of m sentences x_i that have been explicitly labeled with logical forms z_i. This data will allow us to directly evaluate the quality of the learned model. Each sentence is analyzed with the learned model alone; the loss function and any conversational context are not used during evaluation. Parsers that perform well in this setting will be strong candidates for inclusion in a more complete dialog system, as motivated in Section 1.

4 Related Work

Most previous work on learning from conversational interactions has focused on the dialog sub-problems of response planning (e.g., Levin et al., 2000; Singh et al., 2002) and natural language generation (e.g., Lemon, 2011). We are not aware of previous work on inducing semantic parsers from conversations.

There has been significant work on supervised learning for inducing semantic parsers. Various techniques were applied to the problem including machine translation (Papineni et al., 1997; Ramaswamy and Kleindienst, 2000; Wong and Mooney, 2006; 2007; Matuszek et al., 2010), higher-order unification (Kwiatkowski et al., 2010), parsing (Ruifang and Mooney, 2006; Lu et al., 2008), inductive logic programming (Zelle and Mooney, 1996; Thompson and Mooney, 2003; Tang and Mooney, 2000), probabilistic push-down automata (He and Young, 2005; 2006) and ideas from support vector machines and string kernels (Kate and Mooney, 2006; Nguyen et al., 2006). The algorithms we develop in this paper build on previous work on supervised learning of CCG parsers (Zettlemoyer and Collins, 2005; 2007), as we describe in Section 5.3.

There is also work on learning to do semantic analysis with alternate forms of supervision. Clarke et al. (2010) and Liang et al. (2011) describe approaches for learning semantic parsers from questions paired with database answers, while Goldwasser et al. (2011) presents work on unsupervised learning. Our approach provides an alternative method of supervision that could complement these approaches. Additionally, there has been significant recent work on learning to do other, re-

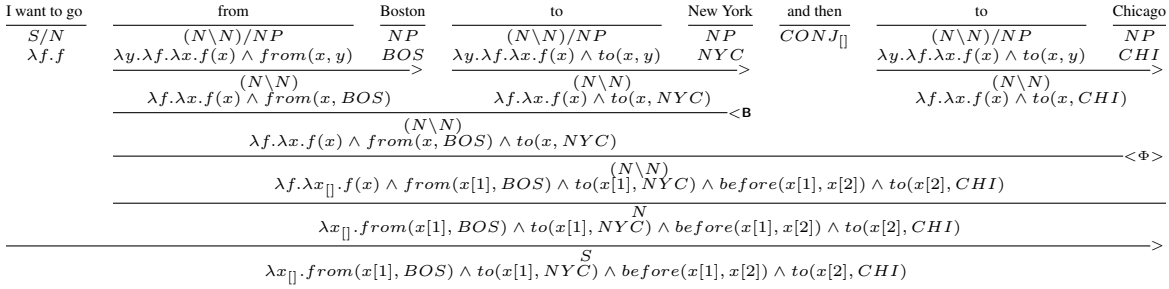

Figure 2: An example CCG parse. This parse shows the construction of a logical form with an array-typed variable $x_{[]}$ that specifies a list of flight legs, indexed by $x[1]$ and $x[2]$. The top-most parse steps introduce lexical items while the lower ones create new nonterminals according the CCG combinators ($>$, $<$, etc.), see Steedman (2000) for details.

lated, natural language semantic analysis tasks from context-dependent database queries (Miller et al., 1996; Zettlemoyer and Collins, 2009), grounded event streams (Chen et al., 2010; Liang et al., 2009), environment interactions (Branavan et al., 2009; 2010; Vogel and Jurafsky, 2010), and even unannotated text (Poon and Domingos, 2009; 2010).

Finally, the DARPA Communicator data (Walker et al., 2002) has been previously studied. Walker and Passonneau (2001) introduced a schema of speech acts for evaluation of the DARPA Communicator system performance. Georgila et al. (2009) extended this annotation schema to user utterances using an automatic process. Our speech acts extend this work to additionally include full meaning representations.

5 Mapping Sentences to Logical Form

We will use a weighted linear CCG grammar for semantic parsing, as briefly reviewed in this section.

5.1 Combinatory Categorial Grammars

Combinatory categorial grammars (CCGs) are a linguistically-motivated model for a wide range of language phenomena (Steedman, 1996; 2000). A CCG is defined by a lexicon and a set of combinators. The grammar defines a set of possible parse trees, where each tree includes syntactic and semantic information that can be used to construct logical forms for sentences.

The lexicon contains entries that define categories for words or phrases. For example, the second lexical entry in the parse in Figure 2 is:

$$\text{from} \;:=\; (N\backslash N)/NP : \lambda y.\lambda f.\lambda x.f(x) \wedge from(x, y)$$

Each category includes both syntactic and semantic information. For example, the phrase "from" is assigned the category with syntax $(N\backslash N)/NP$ and semantics $\lambda y.\lambda f.\lambda x.f(x) \wedge from(x, y)$. The outermost syntactic forward slash specifies that the entry must first be combined with an NP to the right (the departure city), while the inner back slash specifies that it will later modify a noun N to the left (to add a constraint to a set of flights). The lambda-calculus semantic expression is designed to build the appropriate meaning representation at each of these steps, as seen in the parse in Figure 2.

In general, we make use of typed lambda calculus to represent meaning (Carpenter, 1997), both in the lexicon and in intermediate parse tree nodes. We also introduce an extension for modeling array-typed variables to represent lists of individual entries. These constructions are used, for example, to model sentences describing a sequence of segments while specifying flight preferences.

Figure 2 shows how a CCG parse builds a logical form for a complete sentence with an array-typed variable. Each intermediate node in the tree is constructed with one of a small set of CCG combinator rules, see the explanation from Steedman (1996; 2000). We make use of the standard application, composition and coordination combinators, as well as type-shifting rules introduced by Zettlemoyer and Collins (2007) to model spontaneous, unedited text.

5.2 Weighted Linear CCGs

A weighted linear CCG (Clark and Curran, 2007) provides a ranking on the space of possible parses under the grammar, which can be used to select the best logical form for a sentence. This type of model is closely related to several other approaches (Ratnaparkhi et al., 1994; Johnson et al., 1999;

Lafferty et al., 2001; Collins, 2004; Taskar et al., 2004). Let x be a sentence, y be a CCG parse, and GEN$(x; \Lambda)$ be the set of all possible CCG parses for x given the lexicon Λ. Define $\phi(x, y) \in \mathbb{R}^d$ to be a d-dimensional *feature–vector* representation and $\theta \in \mathbb{R}^d$ to be a parameter vector. The optimal parse for sentence x is

$$y^*(x) = \arg \max_{y \in \text{GEN}(x;\Lambda)} \theta \cdot \phi(x, y)$$

and the final output logical form z is the lambda-calculus expression at the root of $y^*(x)$.

We compute $y^*(x)$ with a CKY-style chart parsing algorithm. Since each chart entry contains a full lambda-calculus meaning expression, we use N-best pruning to control the number of options we consider at each span. Learning a model of this form involves learning the parameters θ and the lexicon Λ. We will show that this is possible from conversational logs that do not contain any explicit labeling of the logical forms for user utterances.

5.3 Supervised learning with GENLEX

Previous work on lexical induction, including the GENLEX approach which we briefly review here, has required labeled logical meaning representations. In Section 7, we will introduce a new way of using GENLEX to learn from unannotated conversation logs.

The supervised CCG learning algorithms of Zettlemoyer and Collins (2005; 2007) induce a weighted CCG from training examples (x_i, z_i) for $i = 1 \ldots n$, where x_i is a sentence and z_i is the corresponding lambda-calculus meaning representation. The output from the algorithm is a pair (θ, Λ) containing the learned parameters and CCG lexicon.

They defined the function GENLEX(x, z) to map a sentence x and its meaning z to a large set of potential lexical entries. These entries are generated with rules that consider the logical form z and guess potential CCG categories. For example, the rule $p \rightarrow (N\backslash N)/NP : \lambda y.\lambda f.\lambda x.f(x) \wedge p(x, y)$ introduces categories commonly used to model certain types of prepositions. This rule would, for example, introduce the category $(N\backslash N)/NP : \lambda y.\lambda f.\lambda x.f(x) \wedge to(x, y)$ for any logical form z that contains the constant to. GENLEX uses a small set of rules of this type to generate categories that are paired with all possible substrings in x to form an overly general lexicon. The complete learning algorithm then simultaneously selects a small subset of all entries generated by GENLEX and estimates parameter values θ. Zettlemoyer and Collins (2005) present a more detailed explanation.

Example Conversation:

(1) SYSTEM: how can i help you? (OPEN_TASK)

(2) USER: i would like to fly from boston arriving to new york and back from new york to boston

(3) SYSTEM: leaving boston (CONFIRM:$from(fl1, BOS)$) on what date? (ASK:$\lambda x.departdate(fl1, x)$)

(4) USER: september twenty four

(5) SYSTEM: leaving boston (CONFIRM:$from(fl1, BOS)$) on september twenty four (CONFIRM:$departdate(fl1, sept\_24)$) to new york (CONFIRM:$to(fl1, NYC)$) is new york your final destination? (ASK:$\neg\exists x.fr(x, NYC)$)

(6) USER: yes i want to return to boston

(7) SYSTEM: sorry, i didn't understand. (APOLOGY) where are you flying to from new york? (ASK:$\lambda x.fr(fl2, NYC) \wedge to(fl2, x)$)

[conversation ends]

Candidate Logical Expressions for Utterance #2:

(a) $\lambda x.to(x, BOS) \wedge from(x, NYC)$

(b) $\lambda x.from(x, BOS) \wedge to(x, NYC)$

(c) $\lambda x.to(x, BOS) \wedge to(x, NYC)$

(d) $\lambda x[].from(x[1], BOS) \wedge to(x[1], NYC)$
$\wedge before(x[1], x[2]) \wedge return(x[2])$
$\wedge from(x[2], NYC) \wedge to(x[2], BOS))$

(e) $\lambda x[].from(x[1], BOS) \wedge to(x[1], NYC)$
$\wedge before(x[1], x[2]) \wedge return(x[2])$
$\wedge from(x[2], BOS) \wedge to(x[2], NYC)$

Figure 3: Conversation reflecting an interaction as seen in the DARPA Communicator travel-planning dialogs.

6 Measuring Loss

In Section 7, we will present a loss-sensitive learning algorithm that models the meaning of user utterances as latent variables to be estimated from conversational interactions.

We first introduce a loss function to measure the quality of potential meaning representations. This loss function $\mathcal{L}(z, j, \mathcal{C}) \in \mathbb{R}$ indicates how well a logical expression z represents the meaning of the j-th user utterance in conversation $\mathcal{C}$. For example,

consider the first user utterance ($j = 2$) in Figure 3, which is a request for a return trip from Boston to New York. We would like to assign the lowest loss to the meaning representation (d) in Figure 3 that correctly encodes all of the stated constraints.

We make use of a loss function with two parts: $\mathcal{L}(z, j, \mathcal{C}) = \mathcal{L}_c(z, j, \mathcal{C}) + \mathcal{L}_d(z)$. The conversation loss $\mathcal{L}_c$ (defined in Section 6.1) measures how well the candidate meaning representation fits the conversation, for example incorporating information recovered through conversational remediations as motivated in Section 1. The domain loss $\mathcal{L}_d$ (described in Section 6.2) measures how well a logical form z matches domain expectations, such as the fact that flights can only have a single origin. These functions guide the types of meaning representations we expect to see, but in many cases will fail to specify a unique best option, for example in conversations where the user prematurely terminates the interaction. In Section 7, we will present a complete, loss-driven learning algorithm that is robust to these types of ambiguities while inducing a weighted CCG parser from conversations.

6.1 Conversation Loss

We will use a conversation loss function $\mathcal{L}_c(z, j, \mathcal{C})$ that provides a rough indication of how well the logical expression z represents a potential meaning for the user utterance at position j in $\mathcal{C}$. For example, the first user utterance ($j = 2$) in Figure 3 is a request for a return trip from Boston to New York where the user has explicitly mentioned both legs. The figure also shows five options (a-e) for the logical form z. We want to assign the lowest loss to option (d), which includes all of the stated constraints.

The loss is computed in four steps for a user utterance x at position j by (1) selecting a subset of system utterances in the conversation $\mathcal{C}$, (2) extracting and computing loss for semantic content from selected system utterances, (3) aligning the subexpressions in z to the extracted semantic content, and (4) computing the minimal loss value from the best alignment. In Figure 3, the loss for the candidate logical forms is computed by considering the segment of system utterances up until the conversation end. Within this segment, the matching for expression (d) involves mapping the origin and departure constraints for the first leg (Boston - New York) onto the earlier system confirmations while also aligning the ones for the second leg to system utterances later in the selected portion of the conversation. Finally, the overall score depends on the quality of the alignment, for example how many of the constraints match to confirmations. This section presents the full approach.

Segmentation For a user utterance at position j, we select all system utterances from $j - 1$ until the system believes it has completed the current subtask, as indicated by a reset action or final offer. We call this selected segment $\bar{\mathcal{C}}$. In Figure 3, $\bar{\mathcal{C}}$ ends with a reset, but in a successful interaction it would have ended with the offer of a specific flight.

Extracting Properties A property is a predicate-entity-value triplet, where the entity can be a variable from z or a conversational object. For example, $\langle from, fl, BOS \rangle$ is a property where fl is a object from $\bar{\mathcal{C}}$ and $\langle from, x, BOS \rangle$ is a property from $z = \lambda x.from(x, BOS)$. We define $P_{\bar{\mathcal{C}}}$ to be the set of properties from logical forms for system utterances in $\bar{\mathcal{C}}$. Similarly, we define P_z to be the set of properties in z.

Scoring System Properties For each system property $p \in P_{\bar{\mathcal{C}}}$ we compute its position value $pos(p)$, which is a normalized weighted average over all the positions where it appears in a logical form. For each mention the weight is obtained from its speech act. For example, properties that are explicitly confirmed contribute more to the average than those that were merely offered to the user in a select statement.

We use $pos(p)$ to compute a loss $loss(p)$ for each property $p \in P_{\bar{\mathcal{C}}}$. We first define $P^e_{\bar{\mathcal{C}}}$ to be all properties in $P_{\bar{\mathcal{C}}}$ with entity e. For entity e and position d, we define the entity-normalization function:

$$n_e(d) = \frac{d - \min_{p \in P^e_{\bar{\mathcal{C}}}} pos(p)}{\max_{p \in P^e_{\bar{\mathcal{C}}}} pos(p) - \min_{p \in P^e_{\bar{\mathcal{C}}}} pos(p)} \ .$$

For a given property $p \in P_{\bar{\mathcal{C}}}$ with an entity e we compute the loss value:

$$loss(p) = n_e^{-1}(1 - n_e(pos(p))) - 1 \ .$$

Where n_e^{-1} is the inverse of n_e. This loss value is designed to, first, provide less loss for later properties so that it, for example, favors the last property in a series of statements that finally resolves a confusion

in the conversation. Second, the loss value is lower for objects mentioned closer to the user utterance x, thereby preferring objects discussed sooner.

Matching Properties An alignment $\mathcal{A}$ maps variables in z to conversational objects in $\bar{\mathcal{C}}$, for example the flight legs $fl1$ and $fl2$ being discussed in Figure 3. We will use alignments to match properties of z and $\bar{\mathcal{C}}$. To do this we extend the alignment function $\mathcal{A}$ to apply to properties, for example $\mathcal{A}(\langle from, x, BOS\rangle) = \langle from, \mathcal{A}(x), BOS\rangle$.

Scoring Alignments Finally, we compute the conversation loss $\mathcal{L}_c(z, j, \mathcal{C})$ as follows:

$$\mathcal{L}_c(z, j, \mathcal{C}) = \min_{\mathcal{A}} \sum_{p_u \in P_z} \sum_{p_s \in P_{\bar{\mathcal{C}}}} s(\mathcal{A}(p_u), p_s) \quad .$$

The function $s(\mathcal{A}(p_u), p_s) \in \mathbb{R}$ computes the compatibility of the two input properties. It is zero if $\mathcal{A}(p_u) \neq p_s$. Otherwise, it returns $loss(p_s)$.

We approximate the $\min$ computation in $\mathcal{L}_c$ over alignments $\mathcal{A}$ as follows. For a logical form z at position j, we align the outer-most variable to the conversational object in $\bar{\mathcal{C}}$ that is being discussed at j. The remaining variables are aligned greedily to minimize the loss, by selecting a single conversational object for each in turn.

Finally, for each aligned variable, we increase the loss by one for each unmatched property from P_z. This increases the loss of logical forms that include spurious information. However, since a conversation might stop prematurely and therefore won't discuss the entire user request, we only increase the loss for variables that are already aligned. For this purpose, we define an aligned variable to be one that has at least one property matched successfully.

6.2 Domain Loss

We also make use of a domain loss function $\mathcal{L}_d(z) \in \mathbb{R}$. The function takes a logical form z and returns the number of violations there are in z to a set of constraints on logical forms that occur commonly in the dialog domain. For example, in a travel domain, a violation might occur if a flight leg has two different destination cities. The set of possible violations must be specified for each dialog system, but can often be compiled from existing resources, such as a database of valid flight ticketing options.

In our experiments, we will use a set of eight simple constraints to check for violations in flight itineraries, which can have multiple legs. These include, for example, checking that the legs have unique origins and destinations that match across the entire itinerary. For example, in Figure 3 the logical forms (a), (b) and (d) will have no violations; they describe valid flights. Example (c) has a single violation: a flight has two origins. Example (e) violates a more complex constraint: the second flight's origin is different from the first flight's destination.

Inputs: Training set $\{(j_i, \mathcal{C}_i) : i = 1 \ldots n\}$ where each example includes the index j_i of a sentence x_i in the conversation $\mathcal{C}_i$. Initial lexicon Λ_0. Number of iterations T. Margin γ. Beam size k for lexicon generation. Loss function $\mathcal{L}(x, j, \mathcal{C})$, as described in Section 6.

Definitions: $GENLEX(x, \mathcal{C})$ takes as input a sentence and a conversation and returns a set of lexical items as described in Section 7. GEN$(x; \Lambda)$ is the set of all possible CCG parses for x given the lexicon Λ. $LF(y)$ returns the logical form z at the root of the parse tree y. Let $\Phi_i(y)$ be shorthand for the feature function $\Phi(x_i, y)$ defined in Section 5. Define $LEX(y)$ to be the set of lexical entries used in parse y. Finally, let $MIN\mathcal{L}_i(Y)$ be $\{y | \forall y' \in Y, \mathcal{L}(LF(y), j_i, \mathcal{C}_i) \leq \mathcal{L}(LF(y'), j_i, \mathcal{C}_i)\}$, the set of minimal loss parses in Y.

Algorithm:

$\theta = \bar{0}$, $\Lambda = \Lambda_0$

For $t = 1 \ldots T, i = 1 \ldots n$:

Step 1: (Lexical generation)

a. Set $\lambda = \Lambda \cup GENLEX(x_i, \mathcal{C}_i)$
b. Let Y be the k highest scoring parses of x_i using λ
c. Select new lexical entries from the lowest loss parses $\lambda_i = \bigcup_{y \in MIN\mathcal{L}_i(Y)} \{l | l \in LEX(y)\}$
d. Set lexicon to $\Lambda = \Lambda \cup \lambda_i$

Step 2: (Update parameters)

a. Define $G_i = MIN\mathcal{L}_i(GEN(x_i, \Lambda, \theta))$ and $\mathcal{L}_{min}$ to be the minimal loss
b. Set $B_i = GEN(x_i, \Lambda, \theta) - G_i$
c. Set the relative loss function: $\Delta_i(y) = \mathcal{L}(y, \mathcal{C}_i) - \mathcal{L}_{min}$
d. Construct sets of margin violating good and bad parses:
$R_i = \{r | r \in G_i \wedge \exists y' \in B_i \; s.t. \; \langle \theta, \Phi_i(r) - \Phi_i(y') \rangle < \gamma \Delta_i(r)\}$
$E_i = \{e | e \in B_i \wedge \exists y' \in G_i \; s.t. \; \langle \theta, \Phi_i(y') - \Phi_i(e) \rangle < \gamma \Delta_i(e)\}$
e. Apply the additive update:
$\theta = \theta + \sum_{r \in R_i} \frac{1}{|R_i|} \Phi_i(r) - \sum_{e \in E_i} \frac{1}{|E_i|} \Phi_i(e)$

Output: Parameters θ and lexicon Λ

Figure 4: The learning algorithm.

7 Learning

Figure 4 presents the complete learning algorithm. We assume access to training examples, $\{(j_i, \mathcal{C}_i) : i = 1, \ldots, n\}$, where each example includes the in-

dex j_i of a sentence x_i in the conversation $\mathcal{C}_i$. The algorithm learns a weighted CCG parser, described in Section 5, including both a lexicon Λ and parameters θ. The approach is online, considering each example in turn and performing two steps: (1) expanding the lexicon and (2) updating the parameters.

Step 1: Lexical Induction We introduce new lexical items by selecting candidates from the function $GENLEX$, following previous work (Zettlemoyer and Collins, 2005; 2007) as reviewed in Section 5.3. However, we face the new challenge that there is no labeled logical-form meaning z. Instead, let $Z_{\bar{\mathcal{C}}}$ be set of all logical forms that appear in system utterances in the relevant conversation segment $\bar{\mathcal{C}}$. We will now define the conversational lexicon set:

$$GENLEX(x, \bar{\mathcal{C}}) = \bigcup_{z \in Z_{\bar{\mathcal{C}}}} GENLEX(x, z)$$

where we use logical forms from system utterances to guess possible CCG categories for analyzing the user utterance. This approach will overgeneralize, when the system talks about things that are unrelated to what the user said, and will also often be incomplete, for example when the system does not repeat parts of the original content. However, it provides a way of guessing lexical items that can be combined with previously learned ones, which can fill in any gaps and help select the best analysis.

Step 1(a) in Figure 4 uses $GENLEX$ to temporarily create a large set of potential categories based on the conversation. Steps (b-d) select a small subset of these entries to add to the current lexicon Λ: we find the k-best parses under the model, rerank them according to loss, find the lexical items used in the best trees, and add them to Λ. This approach favors lexical items that are used in high-scoring but low-loss analyses, as computed given the current model.

Step 2: Parameter Updates Given the loss function $\mathcal{L}(x, i, \mathcal{C})$, we use a variant of a loss-sensitive perceptron to update the parameters (Singh-Miller and Collins, 2007). In Steps (a-c), for the current example i, we compute the relative loss function Δ_i that scales with the loss achieved by the best and worst possible parses under the model. In contrast to previous work, we do not only compute the loss over a fixed n-best list of possible outputs, but instead use the current model score to recompute the options at each update. Then, Steps (d-e) find the set R_i of least loss analyses and E_i of higher-loss candidates whose models scores are not separated by at least $\gamma\Delta_i$, where γ is a margin scale constant. The final update (Step f) is additive and increases the parameters for features indicative of the analyses with less loss while down weighting those for parses that were not sufficiently separated.

Discussion This algorithm uses the conversation to drive learning in two ways: it guides the lexical items that are proposed while also providing the conversational feedback that defines the loss used to update the parameters. The resulting approach is, at every step, using information about how the conversation progressed after a user utterance to reconstruct the meaning of the original statement.

8 Data Sets

For evaluation, we used conversation logs from the Lucent and BBN dialog systems in the DARPA Communicator corpus (Walker et al., 2002). We selected these systems since they provide significant opportunities for learning. They asked relatively open ended questions, allowing for more complex user responses, while also using a number of simple remediating strategies to recover from misunderstandings. The original conversational logs included unannotated transcripts of system and user utterances. Inspired by the speech act labeling approach of Walker and Passonneau (2001), we wrote a set of scripts to label the speech acts and logical forms for system statements. This could be done with high accuracy since the original text was generated with templates. These labels represent what the system explicitly said and do not require complex, potentially error-prone annotation of the full state of the original dialog system. The set of speech acts includes confirmations, information requests, selects, offers, instructions, and a miscellaneous category.

The data sets include a total of 376 conversations, divided into training and testing sets. Table 1 provides details about the training and testing sets, as well as general data set statistics. We developed our system using 4-fold cross validation on the training sets. Although there are approximately 12,000 user

	Lucent	BBN
# Conversations	214	162
Total # of utterances	11,974	12,579
Avg. utterances per conversation	55.95	77.65
Avg. tokens per user utterance	3.24	2.39
Total # of training utterances	208	67
Total # of testing utterances	96	67
Avg. tokens per selected utterance	11.72	9.53

Table 1: Data set statistics for Lucent and BBN systems.

utterances in the data sets, the vast majority are simple, short phrases (such as "yes" or "no") which are not useful for learning a semantic parser. We select user utterances with a small set of heuristics, including a threshold (6 for Lucent, 4 for BBN) on the number of words and requiring that at least one noun phrase is present from our initial lexicon. This approach was manually developed to perform well on the training sets, but is not perfect and does introduce a small amount of noise into the data.

9 Experimental Setup

This section describes our experimental setup and comparisons. We follow the setup of Zettlemoyer and Collins (2007) where possible, including feature design, initialization of the semantic parser, and evaluation metrics, as reviewed below.

Features and Parser The features include indicators for lexical item use, properties of the logical form that is being constructed, and indicators for parsing operators used to build the tree. The parser attempts to boost recall with a two-pass strategy that allows for word skipping if the initial parse fails.

Initialization and Parameters We use an initial lexicon that includes a list of domain-specific noun phrases, such as city and airport names, and a list of domain-independent categories for closed-class words such as "the" and "and". We also used a time and number parser to expand this lexicon for each input sentence with the BIU Number Normalizer.[1] The learning parameters were tuned using the development sets: the margin constant γ is set to 0.5, we use 6 iterations and take the top 30 parses for lexical generation (step 1, figure 4). The parser used for parameter update (step 2, figure 4) has a beam of 250. The parameter vector is initialized to $\bar{0}$.

[1] http://www.cs.biu.ac.il/~nlp/downloads/

Evaluation Metrics For evaluation, we measure performance against gold standard labels. We report both the number of exact matches, fully correct logical forms, and a partial-credit number. We measure partial-credit accuracy by mapping logical forms to attribute-value pairs (for example, the expression $from(x, LA)$ will be mapped to $from = LA$) and report precision and recall on attribute sets. This more lenient measure does not test the overall structure of the logical expression, only its components.

Systems We compare performance with the following systems:

Full Supervision: We measured how a fully supervised approach would perform on our data by hand-labeling the training data and using a 0-1 loss function that tests if the output logical form matches the labeled one. For lexicon generation, the labels were used instead of the conversation.

No Conversation Baseline: We also report results for a no conversation baseline. This baseline system is constructed by making two modifications to the full approach. We remove the conversation loss function and apply the GENLEX templates to every possible logical constant, instead of only those in the conversation. This baseline allows us to measure the importance of having access to the conversations by completely ignoring the context for each sentence.

Ablations: In addition to the baseline above, we also do ablation tests by turning off various individual components of the complete algorithm.

10 Results

Table 2 shows exact match results for the development sets, including different system configurations. We report mean results across four folds. To verify their contributions, we include results where we ablate the conversational loss and domain loss functions. Both are essential.

The test results are listed in Table 3. The full method significantly outperforms the baseline, indicating that we are making effective use of the conversational feedback, although we do not yet match the fully supervised result. The poor baseline performance is not surprising, given the difficulty of the task and lack of guidance when the conversations are removed. The partial-credit numbers also demonstrate an empirical trend that we observed; in many

cases where we do not produce the correct logical form, the output is often close to correct, with only one or two missed flight constraints.

The difference between the two systems is evident. The BBN system presents a simpler approach to the dialog problem by creating a more constrained conversation. This is done by handling one flight at a time, in the case of flight planing, and posing simple and close ended questions to the user. Such an approach encourages the user to make simpler requests, with relatively few constraints in each request. In contrast, the Lucent system presents a less-constrained approach: interactions start with an open ended prompt and the conversations flow in a more natural, less constrained fashion. BBN's simplified approach makes it easier for learning, giving us superior performance when compared to the Lucent system, despite the smaller training set. This is true for both our approach and supervised learning.

We compared the logical forms recovered by the best conversational model to the labeled ones in the training set. Many of the errors came from cases where the dialog system never fully recovered from confusions in the conversation. For example, the Lucent system almost never understood user utterances that specified flight arrival times. Since it was unable to consistently recover and introduce this constraint, the user would often just recalculate and specify a departure time that would achieve the original goal. This type of failure provides no signal for our learning algorithm, whereas the fully supervised algorithm would use labeled logical forms to resolve the confusion. Interestingly, the test set had more sentences that suffered such failures than the development set, which contributed to the performance gap.

11 Discussion

We presented a loss-driven learning approach that induces the lexicon and parameters of a CCG parser for mapping sentences to logical forms. The loss was defined over the conversational context, without requiring annotation of user utterances meaning.

The overall approach assumes that, in aggregate, the conversations contain sufficient signal (remediations such as clarification, etc.) to learn effectively. In this paper, we satisfied this requirement by using logs from automated systems that deployed reasonably effective recovery strategies. An important area for future work is to consider how this learning can be best integrated into a complete dialog system. This would include designing remediation strategies that allow for the most effective learning and considering how similar techniques could be used simultaneously for other dialog subproblems.

Abstract

We investigate an important and challenging problem in summary generation, i.e., Evolutionary Trans-Temporal Summarization (ETTS), which generates news timelines from massive data on the Internet. ETTS greatly facilitates fast news browsing and knowledge comprehension, and hence is a necessity. Given the collection of time-stamped web documents related to the evolving news, ETTS aims to return news evolution along the timeline, consisting of individual but correlated summaries on each date. Existing summarization algorithms fail to utilize trans-temporal characteristics among these component summaries. We propose to model trans-temporal correlations among component summaries for timelines, using *inter-date* and *intra-date* sentence dependencies, and present a novel combination. We develop experimental systems to compare 5 rival algorithms on 6 instinctively different datasets which amount to 10251 documents. Evaluation results in ROUGE metrics indicate the effectiveness of the proposed approach based on trans-temporal information.

1 Introduction

Along with the rapid growth of the World Wide Web, document floods spread throughout the Internet. Given a large document collection related to a news subject (for example, *BP Oil Spill*), readers get lost in the sea of articles, feeling confused and powerless. General search engines can rank these news webpages by *relevance* to a user specified aspect, i.e., a query such as "*first relief effort for BP Oil Spill*", but search engines are not quite capable of ranking documents given the whole news subject without particular aspects. Faced with thousands of news documents, people usually have a myriad of interest aspects about the beginning, the development or the latest situation. However, traditional information retrieval techniques can only rank webpages according to their understanding of relevance, which is obviously insufficient (Jin et al., 2010).

Even if the ranked documents could be in a satisfying order to help users understand news evolution, readers prefer to monitor the evolutionary trajectories by simply browsing rather than navigate every document in the overwhelming collection. Summarization is an ideal solution to provide an abbreviated, informative reorganization for faster and better representation of news documents. Particularly, a timeline (see Table 1) can summarize evolutionary news as a series of *individual* but *correlated* component summaries (items in Table 1) and offer an option to understand the big picture of evolution.

With unique characteristics, summarizing timelines is significantly different from traditional summarization methods which are awkward in such scenarios. We first study a manual timeline of BP Oil Spill in Mexico Gulf in Table 1 from Reuters News[1] to understand why timelines generation is observably different from traditional summarization. No traditional method has considered to partition corpus into subsets by timestamps for trans-temporal correlations. However, we discover two unique trans-

Table 1: Part of human generated timeline about BP Oil Spill in 2010 from Reuters News website.

April 22, 2010
The Deepwater Horizon rig, valued at more than $560 million, sinks and a five mile long (8 km) oil slick is seen.
April 25, 2010
The Coast Guard approves a plan to have remote underwater vehicles activate a blowout preventer and stop leak. Efforts to activate the blowout preventer fail.
April 28, 2010
The Coast Guard says the flow of oil is 5,000 barrels per day (bpd) (210,000 gallons/795,000 litres) – five times greater than first estimated. A controlled burn is held on the giant oil slick.
April 29, 2010
U.S. President Barack Obama pledges "every single available resource," including the U.S. military, to contain the spreading spill. Obama also says BP is responsible for the cleanup. Louisiana declares state of emergency due to the threat to the state's natural resources.
April 30, 2010
An Obama aide says no drilling will be allowed in new areas, as the president had recently proposed, until the cause of the Deepwater Horizon accident is known.

temporal characteristics of component summaries from the handcrafted timeline. **Individuality.** The component summaries are summarized *locally*: the component item on date t is constituted by sentences with timestamp t. **Correlativeness.** The component summaries are correlative across dates, based on the *global* collection. To the best of our knowledge, no traditional method has examined the relationships among these timeline items.

Although it is profitable, summarizing timeline faces with new challenges:

• The first challenge for timeline generation is to deliver important contents and avoid information overlaps among component summaries under the trans-temporal scenario based on global/local source collection. Component items are individual but not completely isolated due to the dynamic evolution.

• As we have *individuality* and *correlativeness* to evaluate the qualities of component summaries, both locally and globally, the second challenge is to formulate the combination task into a balanced optimization problem to generate the timelines which satisfy both standards with maximum utilities.

We introduce a novel approach for the web mining problem Evolutionary Trans-Temporal Summarization (ETTS). Taking a collection relevant to a news subject as input, the system automatically outputs a timeline with items of component summaries which represent evolutionary trajectories on specific dates. We classify sentence relationships as *inter-date* and *intra-date* dependencies. Particularly, the inter-date dependency calculation includes temporal decays to project sentences from all dates onto the same time horizon (Figure 1 (a)). Based on intra-/inter-date sentence dependencies, we then model affinity and diversity to compute the saliency score of each sentence and merge local and global rankings into one unified ranking framework. Finally we select top ranked sentences. We build an experimental system on 6 real datasets to verify the effectiveness of our methods compared with other 4 rivals.

2 Related Work

Multi-document summarization (MDS) aims to produce a summary delivering the majority of information content from a set of documents and has drawn much attention in recent years. Conferences such as ACL, SIGIR, EMNLP, etc., have advanced the technology and produced several experimental systems.

Generally speaking, MDS methods can be either extractive or abstractive summarization. Abstractive summarization (e.g. NewsBlaster[2]) usually needs information fusion, sentence compression and reformulation. We focus on extraction-based methods, which usually involve assigning saliency scores to some units (e.g. sentences, paragraphs) of the documents and extracting the units with highest scores.

To date, various extraction-based methods have been proposed for generic multi-document summarization. The centroid-based method MEAD (Radev et al., 2004) is an implementation of the centroid-based method that scores sentences based on features such as cluster centroids, position, and TF.IDF, etc. NeATS (Lin and Hovy, 2002) adds new features such as topic signature and term clustering to select important content, and use MMR (Goldstein et al., 1999) to remove redundancy.

Graph-based ranking methods have been proposed to rank sentences/passages based on "votes" or "recommendations" between each other. TextRank (Mihalcea and Tarau, 2005) and LexPageRank (Erkan and Radev, 2004) use algorithms similar to PageRank and HITS to compute sentence importance. Wan et al. have improved the graph-ranking

[2]http://www1.cs.columbia.edu/nlp/newsblaster/

algorithm by differentiating intra-document and inter-document links between sentences (2007b), and have proposed a manifold-ranking method to utilize sentence-to-sentence and sentence-to-topic relationships (Wan et al., 2007a).

ETTS seems to be related to a very recent task of "update summarization" started in DUC 2007 and continuing with TAC. However, update summarization only dealt with a single update and we make a novel contribution with multi-step evolutionary updates. Further related work includes similar timeline systems proposed by (Swan and Allan, 2000) using named entities, by (Allan et al., 2001) measured in *usefulness* and *novelty*, and by (Chieu and Lee, 2004) measured in *interest* and *burstiness*. We have proposed a timeline algorithm named "Evolutionary Timeline Summarization (ETS)" in (Yan et al., 2011b) but the refining process based on generated component summaries is time consuming. We aim to seek for more efficient summarizing approach.

To the best of our knowledge, neither update summarization nor traditional systems have considered the relationship among "component summaries", or have utilized trans-temporal properties. ETTS approach can also naturally and simultaneously take into account global/local summarization with biased information richness and information novelty, and combine both summarization in optimization.

3 Trans-temporal Summarization

We conduct trans-temporal summarization based on the global biased graph using *inter-date* dependency and local biased graph using *intra-date* dependency. Each graph is the complementary graph to the other.

3.1 Global Biased Summarization

The intuition for global biased summarization is that the selected summary should be correlative with sentences from neighboring dates, especially with those informative ones. To generate the component summary on date t, we project all sentences in the collection onto the time horizon of t to construct a global affinity graph, using temporal decaying kernels.

3.1.1 Temporal Proximity Based Projection

Clearly, a major technical challenge in ETTS is how to define the temporal biased projection function $\Gamma(\Delta t)$, where Δt is the distance between the pending date t and neighboring date t', i.e., $\Delta t = |t' - t|$. As in (Lv and Zhai, 2009), we present 5 representative kernel functions: Gaussian, Triangle, Cosine, Circle, and Window, shown in Figure 2. Different kernels lead to different projections.

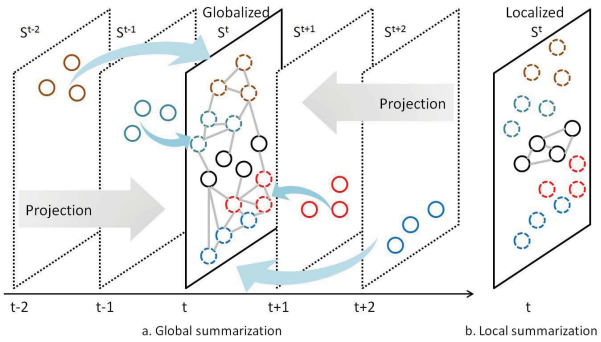

Figure 1: Construct global/local biased graphs. Solid circles denote intra-date sentences on the pending date t and dash ones represent inter-date sentences from other dates.

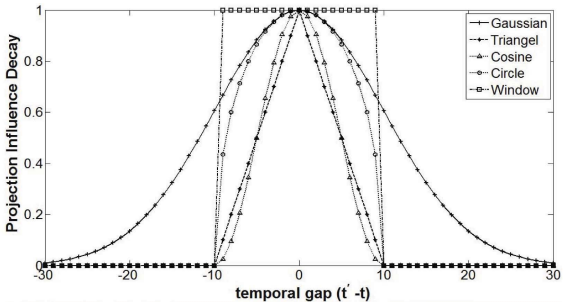

Figure 2: Proximity-based kernel functions, where σ=10.

1. Gaussian kernel

$$\Gamma(\Delta t) = \exp[\frac{-\Delta t^2}{2\sigma^2}]$$

2. Triangle kernel

$$\Gamma(\Delta t) = \begin{cases} 1 - \frac{\Delta t}{\sigma} & \text{if } \Delta t \leq \sigma \\ 0 & \text{otherwise} \end{cases}$$

3. Cosine (Hamming) kernel

$$\Gamma(\Delta t) = \begin{cases} \frac{1}{2}[1 + \cos(\frac{\Delta t \cdot \pi}{\sigma})] & \text{if } \Delta t \leq \sigma \\ 0 & \text{otherwise} \end{cases}$$

4. Circle kernel

$$\Gamma(\Delta t) = \begin{cases} \sqrt{1 - (\frac{\Delta t}{\sigma})^2} & \text{if } \Delta t \leq \sigma \\ 0 & \text{otherwise} \end{cases}$$

5. Window kernel

$$\Gamma(\Delta t) = \begin{cases} 1 & \text{if } \Delta t \leq \sigma \\ 0 & \text{otherwise} \end{cases}$$

All kernels have one parameter σ to tune, which controls the spread of kernel curves, i.e., it restricts the projection scope of each sentence. In general, the optimal setting of σ may vary according to the news set because sentences presumably would have wider semantic scope in certain news subjects, thus requiring a higher value of σ and vice versa.

3.1.2 Modeling Global Affinity

Given the sentence collection C partitioned by the timestamp set T, $C = \{C^1, C^2, \ldots, C^{|T|}\}$, we obtain $C^t = \{s_i^t | 1 \leq i \leq |C^t|\}$ where s_i is a sentence with the timestamp $t = t_{s_i}$. When we generate component summary on t, we project all sentences onto time horizon t. After projection, all sentences are weighted by their influence on t. We use an affinity matrix M^t with the entry of the inter-date transition probability on date t. The sum of each row equals to 1. Note that for the global biased matrix, we measure the affinity between local sentences from t and global sentences from other dates. Therefore, intra-date transition probability between sentences with the timestamp t is set to 0 for local summarization.

$M_{i,j}^t$ is the transition probability of s_i to s_j based on the perspective of date t, i.e., $p(s_i \rightarrow s_j|t)$:

$$p(s_i \rightarrow s_j|t) = \begin{cases} \frac{f(s_i \rightarrow s_j|t)}{\sum_{|C|} f(s_i \rightarrow s_k|t)} & \text{if } \sum f \neq 0 \\ 0 & \text{if } t_{s_i} = t_{s_j} = t \end{cases} \quad (1)$$

$f(s_i \rightarrow s_j|t)$ is defined as the temporal weighted cosine similarity between two sentences:

$$f(s_i \rightarrow s_j|t) = \sum_{w \in s_i \cap s_j} \pi(w, s_i|t) \cdot \pi(w, s_j|t) \quad (2)$$

where the weight π associated with term w is calculated with the temporal weighted *tf.isf* formula:

$$\pi(w, s|t) = \frac{\Gamma|t - t_s| \cdot tf(w, s)(1 + log(\frac{|C|}{N_w}))}{\sqrt{\sum_{|s|}(tf(w, s)(1 + log(\frac{|C|}{N_w})))^2}}. \quad (3)$$

where t_s is the timestamp of sentence s, and $tf(w, s)$ is the term frequency of w in s. t_s can be any date from T. $|C|$ is the sentences set size and N_w is the number of sentences containing term w.

We let $p(s_i \rightarrow s_i|t)$=0 to avoid self transition. Note that although $f(.)$ is a symmetric function, $p(s_i \rightarrow s_j|t)$ is usually not equal to $p(s_j \rightarrow s_i|t)$, depending on the degrees of nodes s_i and s_j.

Now we establish the affinity matrix $M_{i,j}^t$ and by using the general form of PageRank, we obtain:

$$\vec{\lambda} = \mu M^{-1} \vec{\lambda} + \frac{1 - \mu}{|C|} \vec{e} \quad (4)$$

where $\vec{\lambda}$ is the selective probability of all sentence nodes and $\vec{e}$ is a column vector with all elements equaling to 1. μ is the damping factor set as 0.85. Usually the convergence of the iteration algorithm is achieved when difference between the scores computed at two successive iterations for any sentences falls below a given threshold (0.0001 in this study).

3.1.3 Modeling Diversity

Diversity is to reflect both biased information richness and sentence novelty, which aims to reduce information redundancy. However, using standard PageRank of Equation (4) will not result in diversity. The aggregational effect of PageRank assigns high salient scores to closely connected node communities (Figure 3 (b)). A greedy vertex selection algorithm may achieve diversity by iteratively selecting the most prestigious vertex and then penalizing the vertices "covered" by the already selected ones, such as Maximum Marginal Relevance and its applications in Wan et al. (2007b; 2007a). Most recently diversity rank $DivRank$ is another solution to diversity penalization in (Mei et al., 2010).

We incorporate DivRank in our general ranking framework, which creates a dynamic M during each iteration, rather than a static one. After z times of iteration, the matrix M becomes:

$$M^{(z)} = \mu M^{(z-1)} \cdot \vec{\lambda}^{(z-1)} + \frac{1 - \mu}{|C|} \vec{e} \quad (5)$$

Equation (5) raises the probability for nodes with higher centrality and nodes already having high weights are likely to "absorb" the weights of its neighbors directly, and the weights of neighbors' neighbors indirectly. The process is to iteratively adjust matrix M according to $\vec{\lambda}$ and then to update $\vec{\lambda}$ according to the changed M. As iteration increases

there emerges a **rich-gets-richer** phenomenon (Figure 3 (c) and (d)). By incorporating DivRank, we obtain rank $r_i^\dagger$ and the global biased ranking score $\mathcal{G}_i$ for sentence s_i from date t to summarize C^t.

3.2 Local Biased Summarization

Naturally, the component summary for date t should be informative within C^t. Given the sentence collection $C^t = \{s_i^t | 1 \leq i \leq |C^t|\}$, we build an affinity matrix for Figure 1 (b), with the entry of intra-date transition probability calculated from standard cosine similarity. We incorporate DivRank within local summarization and we obtain the local biased rank and ranking score for s_i, denoted as $r_i^\ddagger$ and $\mathcal{L}_i$.

3.3 Optimization of Global/Local Combination

We do not directly add the global biased ranking score and local biased ranking score, as many previous works did (Wan et al., 2007b; Wan et al., 2007a), because even the same ranking score gap may indicate different rank gaps in two ranking lists.

Given subset C^t, let $R = \{r_i\}$(i = 1,...,$|C^t|$), r_i is the final ranking of s_i to estimate, optimize the following objective cost function $O(R)$,

$$\begin{aligned} O(R) =& \alpha \sum_{i=1}^{|C^t|} \mathcal{G}_i \| \frac{r_i}{\Psi_i} - \frac{r_i^\dagger}{\mathcal{G}_i} \|^2 \\ &+ \beta \sum_{i=1}^{|C^t|} \mathcal{L}_i \| \frac{r_i}{\Psi_i} - \frac{r_i^\ddagger}{\mathcal{L}_i} \|^2 \end{aligned} \tag{6}$$

where $\mathcal{G}_i$ is the global biased ranking score while $\mathcal{L}_i$ is the local biased ranking score. Ψ_i is expected to be the merged ranking score, namely sentence *importance*, which will be defined later. Among the two components in the objective function, the first component means that the refined rank should not deviate too much from the global biased rank. We use $\| \frac{r_i}{\Psi_i} - \frac{r_i^\dagger}{\mathcal{G}_i} \|^2$ instead of $\|r_i - r_i^\dagger\|^2$ in order to distinguish the differences between sentences from the same rank gap. The second component is similar by refining rank from local biased summarization.

Our goal is to find $R = R^*$ to minimize the cost function, i.e., $R^* = argmin\{O(R)\}$. R^* is the final rank merged by our algorithm. To minimize $O(R)$, we compute its first-order partial derivatives.

$$\frac{\partial O(R)}{\partial r_i} = \frac{2\alpha}{\Psi_i}(\frac{\mathcal{G}_i}{\Psi_i} r_i - r_i^\dagger) + \frac{2\beta}{\Psi_i}(\frac{\mathcal{L}_i}{\Psi_i} r_i - r_i^\ddagger) \tag{7}$$

Let $\frac{\partial O(R)}{\partial r_i} = 0$, we get

$$r_i^* = \frac{\alpha \Psi_i r_i^\dagger + \beta \Psi_i r_i^\ddagger}{\alpha \mathcal{G}_i + \beta \mathcal{L}_i} \tag{8}$$

Two special cases are that if (1) $\alpha = 0$, $\beta \neq 0$: we obtain $r_i = \Psi_i r_i^\ddagger / \mathcal{L}_i$, indicating we only use the local ranking score. (2) $\alpha \neq 0$, $\beta = 0$, indicating we ignore local ranking score and only consider global biased summarization using inter-date dependency.

There can be many ways to calculate the sentence importance Ψ_i. Here we define Ψ_i as the weighted combination of itself with ranking scores from global biased and local biased summarization:

$$\Psi_i^{(z)} = \frac{\alpha \mathcal{G}_i + \beta \mathcal{L}_i + \gamma \Psi_i^{(z-1)}}{\alpha + \beta + \gamma}. \tag{9}$$

To save one parameter we let $\alpha + \beta + \gamma = 1$. In the z-th iteration, $r_i^{(z)}$ is dependent on $\Psi_i^{(z-1)}$ and $\Psi_i^{(z)}$ is indirectly dependent on $r_i^{(z)}$ via $\Psi_i^{(z-1)}$. $\Psi_i^{(0)} = 0$. We iteratively approximate final Ψ_i for the ultimate rank list R^*. The expectation of stable Ψ_i is obtained when $\Psi_i^{(z)} = \Psi_i^{(z-1)}$. Final Ψ_i is expected to satisfy $\Psi_i = \alpha \mathcal{G}_i + \beta \mathcal{L}_i + \gamma \Psi_i$:

$$\Psi_i = \frac{\alpha \mathcal{G}_i + \beta \mathcal{L}_i}{1 - \gamma} = \frac{\alpha \mathcal{G}_i + \beta \mathcal{L}_i}{\alpha + \beta} \tag{10}$$

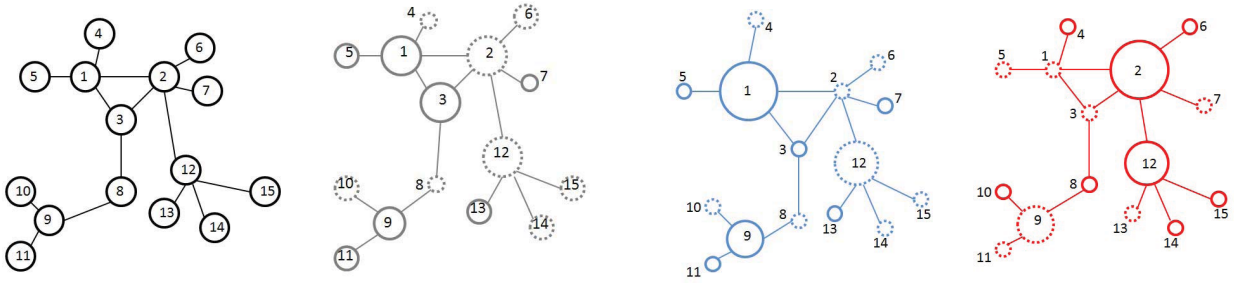
Final Ψ_i is dependent only on original global/local biased ranking scores. Equation (8) becomes more concise with no Ψ or γ: r^* is a weighted combination of global and local ranks by $\frac{\alpha}{\beta}$ ($\alpha \neq 0$, $\beta \neq 0$):

$$\begin{aligned} r_i^* &= \frac{\alpha}{\alpha + \beta} r_i^\dagger + \frac{\beta}{\alpha + \beta} r_i^\ddagger \\ &= \frac{1}{1 + \beta/\alpha} r_i^\dagger + \frac{1}{1 + \alpha/\beta} r_i^\ddagger \end{aligned} \tag{11}$$

4 Experiments and Evaluation

4.1 Datasets

There is no existing standard test set for ETTS methods. We randomly choose 6 news subjects with special coverage and handcrafted timelines by editors from 10 selected news websites: these 6 test sets consist of news datasets and golden standards to evaluate our proposed framework empirically, which amount to 10251 news articles. As shown in Table 2, three of the sources are in UK, one of them



(a) An illustrative network. (a) PageRank on t. (b) DivRank on t (c) DivRank on t'

Figure 3: An illustration of diverse ranking in a toy graph (a). Comparing (b) from general PageRank with (c),(d) from DivRank, we find a better diversity by selecting {1,9} in (c) rather than {1,3} in (b). Moreover, (c) and (d) reflect temporal biased processes on t {1,9} in (c) and t' {2,12} in (d).

is in China and the rest are in the US. We choose these sites because many of them provide timelines edited by professional editors, which serve as reference summaries. The news belongs to different categories of Rule of Interpretation (ROI) (Kumaran and Allan, 2004). More detailed statistics are in Table 3.

Table 2: News sources of 6 datasets

News Sources	Nation	News Sources	Nation
BBC	UK	Fox News	US
Xinhua	China	MSNBC	US
CNN	US	Guardian	UK
ABC	US	New York Times	US
Reuters	UK	Washington Post	US

Table 3: Detailed basic information of 6 datasets.

News Subjects	#size	#docs	#stamps	#RT	AL
1.Influenza A	115026	2557	331	5	83
2.Financial Crisis	176435	2894	427	2	118
3.BP Oil Spill	63021	1468	135	6	76
4.Haiti Earthquake	12073	247	83	2	32
5.Jackson Death	37819	925	168	3	64
6.Obama Presidency	79761	2160	349	5	92

size: the whole sentence counts; #stamps: the number of timestamps; Note **average size** of subsets is calculated as: avg.size=#size/#stamps; RT: reference timelines; AL: avg. length of RT measured in sentences.

4.2 Experimental System Setups

• **Preprocessing.** As ETTS faces with much larger corpus compared with traditional MDS, we apply further data preprocessing besides stemming and stop-word removal. We extract *text snippets* representing atomic "events" from all documents with a toolkit provided by Yan et al. (2010; 2011a), by which we attempt to assign more fine-grained and accurate timestamps for every sentence within the text snippets. After the snippet extraction procedure, we filter the corpora by discarding non-event texts.

• **Compression Rate and Date Selection.** After preprocessing, we obtain numerous snippets with fine-grained timestamps, and then decompose them into temporally tagged sentences as the global collection C. We partition C according to timestamps of sentences, i.e., $C = C^1 \cup C^2 \cup \cdots \cup C^{|T|}$. Each component summary is generated from its corresponding sub-collection. The sizes of component summaries are not necessarily equal, and moreover, not all dates may be represented, so date selection is also important. We apply a simple mechanism that users specify the overall compression rate ϕ, and we extract more sentences for important dates while fewer sentences for others. The *importance* of dates is measured by the *burstiness*, which indicates probable significant occurrences (Chieu and Lee, 2004). The compression rate on t_i is set as $\phi_i = \frac{|C^i|}{|C|}$.

4.3 Evaluation Metrics

The ROUGE measure is widely used for evaluation (Lin and Hovy, 2003): the DUC contests usually officially employ ROUGE for automatic summarization evaluation. In ROUGE evaluation, the summarization quality is measured by counting the number of overlapping units, such as N-gram, word sequences, and word pairs between the candidate timelines CT and the reference timelines RT. There are several kinds of ROUGE metrics, of which the most important one is ROUGE-N with 3 sub-metrics:

1 ROUGE-N-R is an N-gram recall metric:

$$\text{ROUGE-N-R} = \frac{\sum_{\text{I}\in\text{RT}} \sum_{\text{N-gram}\in\text{I}} \text{Count}_{\text{match}}(\text{N-gram})}{\sum_{\text{I}\in\text{RT}} \sum_{\text{N-gram}\in\text{I}} \text{Count (N-gram)}}$$

2 ROUGE-N-P is an N-gram precision metric:

$$\text{ROUGE-N-P} = \frac{\sum_{\text{I}\in\text{CT}} \sum_{\text{N-gram}\in\text{I}} \text{Count}_{\text{match}}(\text{N-gram})}{\sum_{\text{I}\in\text{CT}} \sum_{\text{N-gram}\in\text{I}} \text{Count (N-gram)}}$$

3 ROUGE-N-F is an N-gram F_1 metric:

$$\text{ROUGE-N-F} = \frac{2 \times \text{ROUGE-N-P} \times \text{ROUGE-N-R}}{\text{ROUGE-N-P} + \text{ROUGE-N-R}}$$

I denotes a timeline. N in these metrics stands for the length of N-gram and N-gram$\in$RT denotes the N-grams in reference timelines while N-gram$\in$CT denotes the N-grams in the candidate timeline. $\text{Count}_{\text{match}}$(N-gram) is the maximum number of N-gram in the candidate timeline and in the set of reference timelines. $\text{Count}_{\text{(N-gram)}}$ is the number of N-grams in reference timelines or candidate timelines.

According to (Lin and Hovy, 2003), among all sub-metrics, unigram-based ROUGE (ROUGE-1) has been shown to agree with human judgment most and bigram-based ROUGE (ROUGE-2) fits summarization well. We report three ROUGE F-measure scores: ROUGE-1, ROUGE-2, and ROUGE-W, where ROUGE-W is based on the weighted longest common subsequence. The weight W is set to be 1.2 in our experiments by ROUGE package (version 1.55). Intuitively, the higher the ROUGE scores, the similar the two summaries are.

4.4 Algorithms for Comparison

We implement the following widely used summarization algorithms as baseline systems. They are designed for traditional summarization without trans-temporal dimension. The first intuitive way to generate timelines by these methods is via a global summarization on collection C and then distribution of selected sentences to their source dates. The other one is via an equal summarization on all local sub-collections. For baselines, we average both intuitions as their performance scores. For fairness we conduct the same preprocessing for all baselines.

Random: The method selects sentences randomly for each document collection.

Centroid: The method applies MEAD algorithm (Radev et al., 2004) to extract sentences according to the following three parameters: centroid value, positional value, and first-sentence overlap.

GMDS: The graph-based MDS proposed by (Wan and Yang, 2008) first constructs a sentence connectivity graph based on cosine similarity and then selects important sentences based on the concept of eigenvector centrality.

Chieu: (Chieu and Lee, 2004) present a similar timeline system with different goals and frameworks, utilizing *interest* and *burstiness* ranking but neglecting trans-temporal news evolution.

ETTS: ETTS is an algorithm with optimized combination of global/local biased summarization.

RefTL: As we have used multiple human timelines as references, we not only provide ROUGE evaluations of the competing systems but also of the human timelines against each other, which provides a good indicator as to the upper bound ROUGE score that any system could achieve.

4.5 Overall Performance Comparison

We use a **cross validation** manner among 6 datasets, i.e., train parameters on one subject set and examine the performance on the others. After 6 training-testing processes, we take the average F-score performance in terms of ROUGE-1, ROUGE-2, and ROUGE-W on all sets. The overall results are shown in Figure 4 and details are listed in Tables 4$\sim$6.

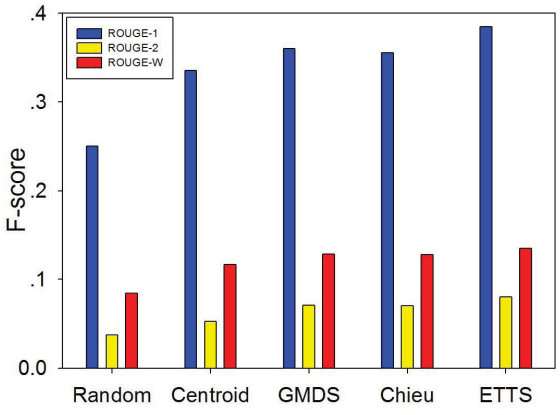


Figure 4: Overall performance on 6 datasets.

From the results, we have following observations:

• Random has the worst performance as expected.

• The results of Centroid are better than those of Random, mainly because the Centroid method takes

into account positional value and first-sentence overlap, which facilitate main aspects summarization.

• The GMDS system outperforms centroid-based summarization methods. This is due to the fact that PageRank-based framework ranks the sentence using eigenvector centrality which implicitly accounts for information subsumption among all sentences.

Traditional MDS only consider sentence selection from either the global or the local scope, and hence bias occurs. Mis-selected sentences result in a low recall. Generally the performance of global priority intuition (i.e. only global summarization and then distribution to temporal subsets) is better than local priority methods (only local summarization). Probable bias is enlarged by searching for worthy sentence in single dates. However, precision drops due to excessive choice of global timeline-worthy sentences.

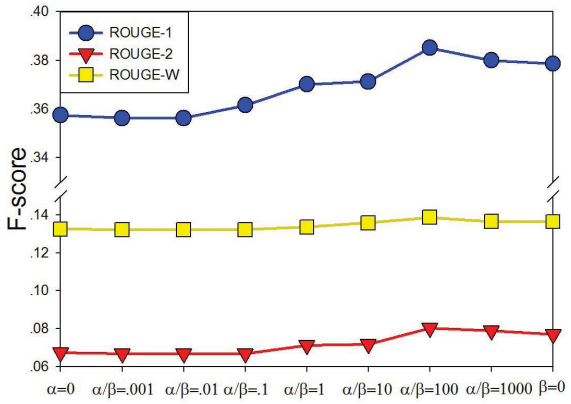

Figure 5: α/β: global/local combination.

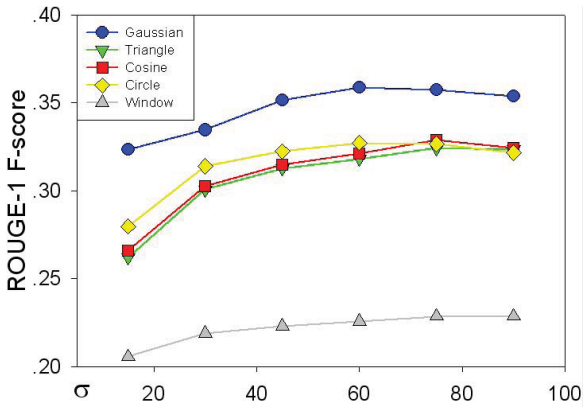

Figure 6: σ on long topics ($\geq$1 year).

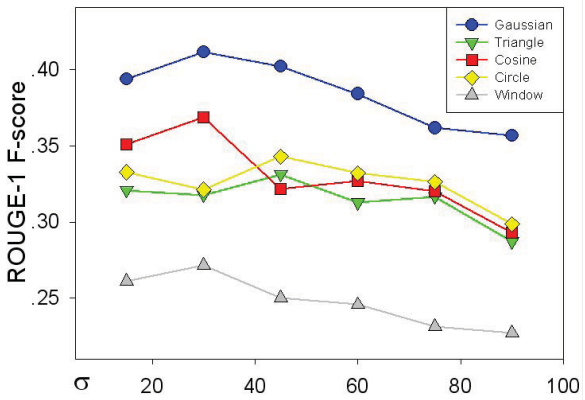

Figure 7: σ on short topics ($<$1 year).

• In general, the result of Chieu is better than Centroid but unexpectedly, worse than GMDS. The reason may be that Chieu does not capture sufficient timeline attributes. The "interest" modeled

in the algorithms actually performs flat clustering-based summarization which is proved to be less useful (Wang and Li, 2010). GMDS utilizes sentence linkage, and partly captures "correlativeness".

• ETTS under our proposed framework outperforms baselines, indicating that the properties we use for timeline generation are beneficial. We also add a direct comparison between ETTS and ETS (Yan et al., 2011b). We notice that both balanced algorithms achieve comparable performance (0.386 v.s. 0.412: a gap of 0.026 in terms of ROUGE-1), but ETTS is much faster than ETS. It is understandable that ETS refines timelines based on neighboring component summaries iteratively while for ETTS neighboring information is incorporated in temporal projection and hence there is no such procedure. Furthermore, ETS has 8 free parameters to tune while ETTS has only 2 parameters. In other words, ETTS is more simple to control.

• The performance on intensive focused news within short time range (|last timestamp−first timestamp |<1 year) is better than on long lasting news.

Having proved the effectiveness of our proposed methods, we carry the next move to identity how *global−local combination ratio* α/β and *projection kernels* take effects to enhance the quality of a summary in parameter tuning.

4.6 Parameter Tuning

Each time we tune one parameter while others are fixed. To identify how *global* and *local* biased summarization combine, we provide experiments on the performance of varying α/β in Figure 5. Results indicate that a balance between global and local biased summarization is essential for timeline generation because the performance is best when $\frac{\alpha}{\beta} \in [10, 100]$ and outperforms global and local summarization in isolation, i.e., when α=0 or $\beta = 0$ in Figure 5. Interestingly, we conclude an opposite observation compared with ETS. Different approaches might lead to different optimum of global/local combination.

Another key parameter σ measures the temporal projection influence from global collection to local collection and hence the size of neighboring sentence set. 6 datasets are classified into two groups. Subject 1, 2, 6 are grouped as long news with a time span of more than one year and the others are short news. The effect of σ varies on long news sets and short news sets. In Figure 6 σ is best around 60 and in Figure 7 it is best at about 20∼40, indicating long news has relatively wider semantic scope.

We then examine the effect of different projection kernels. Generally, Gaussian kernel outperforms others and window kernel is the worst, probably because Gaussian kernel provides the best smoothing effect with no arbitrary cutoffs. Window kernel fails to distinguish different weights of neighboring sets by temporal proximity, so its performance is as expected. Other 3 kernels are comparable.

4.7 Sample Output and Case Study

Sample output is presented in Table 7 and it shares major information similarity with the human timeline in Table 1. Besides, we notice that a dynamic ϕ_i is reasonable. Important burstiness is worthy of more attention. Fewer sentences are selected on the dates when nothing new occurs.

Interesting Findings. We notice that humans have biases to generate timelines for they have (1) preference on local occurrences and (2) different writing styles. For instance, news outlets from United States tend to summarize reactions by US government while UK websites tend to summarize British affairs. Some editors favor statistical reports while others prefer narrative style, and some timelines have detailed explanations while others are extremely concise with no more than two sentences for each entry. Our system-generated timelines have a large variance among all golden standards. Probably a new evaluation metric should be introduced to measure the quality of human generated timelines to mitigate the corresponding biases. A third interesting observation is that subjects have different volume patterns, e.g., $H1N1$ has a slow start and a bursty evolution and *BP Oil* has a bursty start and a quick decay. $Obama$ is different in nature because the report volume is temporally stable and scattered.

5 Conclusion

We present a novel solution for the important web mining problem, Evolutionary Trans-Temporal Summarization (ETTS), which generates trajectory timelines for news subjects from massive data. We formally formulate ETTS as a combination of *global* and *local* summarization, incorporating affinity and

April 20, 2010	**April 24, 2010**
s_1: An explosion on the Deepwater Horizon offshore oil drilling rig in the Gulf of Mexico, around 40 miles south east of Louisiana, causing several kills and injuries. s_2: The rig was drilling in about 5,000ft (1,525m) of water, pushing the boundaries of deepwater drilling technology. s_3: The rig is owned and operated by Transocean, a company hired by BP to carry out the drilling work. s_4: Deepwater Horizon oil rig fire leaves 11 missing.	s_1: Oil is found to be leaking from the well.
April 22, 2010	**April 26, 2010**
s_1: The US Coast Guard estimates that the rig is leaking oil at the rate of up to 8,000 barrels a day. s_2: The Deepwater Horizon sinks to the bottom of the Gulf after burning for 36 hours, raising concerns of a catastrophic oil spill. s_3: Deepwater Horizon rig sinks in 5,000ft of water.	s_1: BP's shares fall 2% amid fears that the cost of cleanup and legal claims will hit the London-based company hard. s_2: Roughly 15,000 gallons of dispersants and 21,000ft of containment boom are placed at the spill site.
April 23, 2010	**April 27, 2010**
s_1: The US coast guard suspends the search for missing workers, who are all presumed dead. s_2: The Coast Guard says it had no indication that oil was leaking from the well 5,000ft below the surface of the Gulf. s_3: Underwater robots try to shut valves on the blowout preventer to stop the leak, but BP abandons that failed effort two weeks later. s_4: The US Coast Guard estimates that the rig is leaking oil at the rate of up to 8,000 barrels a day. s_5: Deepwater Horizon clean-up workers fight to prevent disaster.	s_1: BP reports a rise in profits, due in large part to oil price increases, as shares rise again. s_2: The US departments of interior and homeland security announce plans for a joint investigation of the explosion and fire. s_3: Minerals Management Service (MMS) approves a plan for two relief wells. s_4: BP chairman Tony Hayward says the company will take full responsibility for the spill, paying for legitimate claims and cleanup cost.
	April 28, 2010
	s_1: The coast guard says the flow of oil is 5,000bpd, five times greater than first estimated, after a third leak is discovered. s_2: BP's attempts to repair a hydraulic leak on the blowout preventer valve are unsuccessful. s_3: BP reports that its first-quarter profits more than double to £3.65 billion following a rise in oil prices. s_4: Controlled burns begin on the giant oil slick.

diversity into a unified ranking framework. We implement a system under such framework for experiments on real web datasets to compare all approaches. Through our experiment we notice that the combination plays an important role in timeline generation, and global optimization weights slightly higher ($\alpha/\beta \in [10, 100]$), but auxiliary local information does help to enhance performance in ETTS.

Abstract

We propose a sentence generation strategy that describes images by predicting the most likely nouns, verbs, scenes and prepositions that make up the core sentence structure. The input are initial noisy estimates of the objects and scenes detected in the image using state of the art trained detectors. As predicting actions from still images directly is unreliable, we use a language model trained from the English Gigaword corpus to obtain their estimates; together with probabilities of co-located nouns, scenes and prepositions. We use these estimates as parameters on a HMM that models the sentence generation process, with hidden nodes as sentence components and image detections as the emissions. Experimental results show that our strategy of combining vision and language produces readable and descriptive sentences compared to naive strategies that use vision alone.

1 Introduction

What happens when you see a picture? The most natural thing would be to *describe* it using *words*: using speech or text. This description of an image is the output of an extremely complex process that involves: 1) perception in the Visual space, 2) grounding to World Knowledge in the Language Space and 3) speech/text production (see Fig. 1). Each of these components are challenging in their own right and are still considered open problems in the vision and linguistics fields. In this paper, we introduce a computational framework that attempts to integrate these components together. Our hypothesis is based on the assumption that natural images accurately reflect common everyday scenarios which are captured in language. For example, knowing that boats usually occur over `water` will enable us to constrain the possible scenes a boat can occur and exclude highly unlikely ones – `street, highway`. It also enables us to predict likely actions (Verbs) given the current object detections in the image: detecting a dog with a person will likely induce `walk` rather than `swim, jump, fly`. Key to our approach is the use of a large generic corpus such as the English Gigaword [Graff, 2003] as the *semantic grounding* to predict and correct the initial and often noisy visual detections of an image to produce a reasonable sentence that succinctly describes the image.

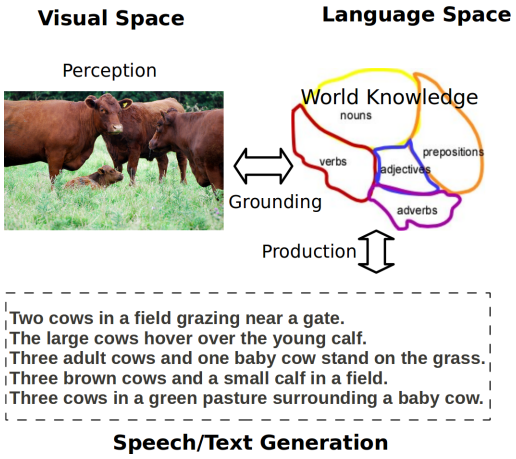

Figure 1: The processes involved for describing a scene.

In order to get an idea of the difficulty of this task, it is important to first define what makes up

a description of an image. Based on our observations of annotated image data (see Fig. 4), a descriptive sentence for an image must contain at minimum: 1) the important *objects* (Nouns) that participate in the image, 2) Some description of the *actions* (Verbs) associated with these objects, 3) the *scene* where this image was taken and 4) the *preposition* that relates the objects to the scene. That is, a quadruplet of $\mathcal{T} = \{n, v, s, p\}$ (Noun-Verb-Scene-Preposition) that represents the core sentence structure. Generating a sentence from this quadruplet is obviously a simplification from state of the art generation work, but as we will show in the experimental results (sec. 4), it is sufficient to describe images. The key challenge is that detecting objects, actions and scenes *directly* from images is often noisy and unreliable. We illustrate this using example images from the Pascal-Visual Object Classes (VOC) 2008 challenge [Everingham et al., 2008]. First, Fig. 2(a) shows the *variability* of images in their raw image representations: pixels, edges and local features. This makes it difficult for state of the art object detectors [Felzenszwalb et al., 2010; Schwartz et al., 2009] to reliably detect important objects in the scene: boat, humans and water – average precision scores reported in [Felzenszwalb et al., 2010] manages around 42% for humans and only 11% for boat over a dataset of almost 5000 images in 20 object categories. Yet, these images are *semantically* similar in terms of their high level description. Second, cognitive studies [Urgesi et al., 2006; Kourtzi, 2004] have proposed that inferring the action from static images (known as an "implied action") is often achieved by detecting the *pose* of humans in the image: the position of the limbs with respect to one another, under the assumption that a unique pose occurs for a unique action. Clearly, this assumption is weak as 1) similar actions may be represented by different poses due to the inherent dynamic nature of the action itself: e.g. walking a dog and 2) different actions may have the same pose: e.g. walking a dog versus running (Fig. 2(b)). The missing component here is whether the key object (dog) under interaction is considered. Recent works [Yao and Fei-Fei, 2010; Yang et al., 2010] that used poses for recognition of actions achieved 70% and 61% accuracy respectively under extremely limited testing conditions with only 5-6 action classes each. Finally, state of the art scene detectors [Oliva and Torralba, 2001; Torralba et al., 2003] need to have enough representative training examples of scenes from pre-defined scene classes for a classification to be successful – with a reported average precision of 83.7% tested over a dataset of 2600 images.

Addressing all these visual challenges is clearly a formidable task which is beyond the scope of this paper. Our focus instead is to show that with the addition of *language* to ground the noisy initial visual detections, we are able to improve the quality of the generated sentence as a faithful description of the image. In particular, we show that it is possible to avoid predicting actions directly from images – which is still unreliable – and to use the corpus instead to guide our predictions. Our proposed strategy is also *generic*, that is, we make no prior assumptions on the image domain considered. While other works (sec. 2) depend on strong annotations between images and text to ground their predictions (and to remove wrong sentences), we show that a large generic corpus is also able to provide the same grounding over larger domains of images. It represents a relatively new style of learning: distant supervision [Liang et al., 2009; Mann and Mccallum, 2007]. Here, we do not require "labeled" data containing images and captions but only separate data from each side. Another contribution is a computationally feasible way via dynamic programming to determine the most likely quadruplet $\mathcal{T}^* = \{n^*, v^*, s^*, p^*\}$ that describes the image for generating possible sentences.

2 Related Work

Recently, several works from the Computer Vision domain have attempted to use language to aid image scene understanding. [Kojima et al., 2000] used predefined production rules to describe actions in videos. [Berg et al., 2004] processed news captions to discover names associated with faces in the images, and [Jie et al., 2009] extended this work to associate poses detected from images with the verbs in the captions. Both approaches use annotated examples from a limited news caption corpus to learn a joint image-text model so that one can annotate new unknown images with textual information easily. Neither of these works have been tested on complex everyday images where the large variations of objects and poses makes it nearly impossible to learn a more general model. In addition, no attempt was made to generate a descriptive sentence from the learned model. The work of [Farhadi et al., 2010] attempts to "generate" sentences by first learning from a set of human annotated examples, and producing the *same* sentence if both images and sentence share common properties in terms of their triplets: (Nouns-Verbs-Scenes). No attempt was made to generate *novel* sentences from images beyond what has been annotated by humans. [Yao et al., 2010] has recently introduced a framework for parsing images/videos to textual description that requires significant annotated data, a requirement that our proposed approach avoids.

Natural language generation (NLG) is a long-standing problem. Classic approaches [Traum et al., 2003] are based on three steps: selection, planning and realization. A common challenge in generation problems is the question of: what is the input? Recently, approaches for generation have focused on formal specification inputs, such as the output of theorem provers [McKeown, 2009] or databases [Golland et al., 2010]. Most of the effort in those approaches has focused on selection and realization. We address a tangential problem that has not received much attention in the generation literature: how to deal with *noisy inputs*. In our case, the inputs themselves are often uncertain (due to misrecognitions by object/scene detectors) and the content selection and realization needs to take this uncertainty into account.

3 Our Approach

Our approach is summarized in Fig. 3. The input is a test image where we detect objects and scenes using trained detection algorithms [Felzenszwalb et al., 2010; Torralba et al., 2003]. To keep the framework computationally tractable, we limit the elements of the quadruplet (Nouns-Verbs-Scenes-Prepositions) to come from a finite set of objects $\mathcal{N}$, actions $\mathcal{V}$, scenes $\mathcal{S}$ and prepositions $\mathcal{P}$ classes that are commonly encountered. They are summarized in Table. 1. In addition, the sentence that is generated for each image is limited to at most two objects occurring in a unique scene.

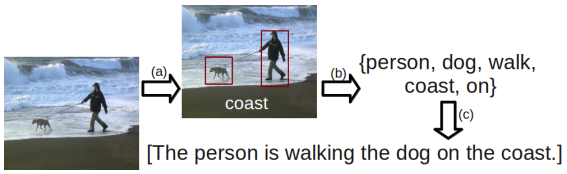

Figure 3: Overview of our approach. (a) Detect objects and scenes from input image. (b) Estimate optimal sentence structure quadruplet $\mathcal{T}^*$. (c) Generating a sentence from $\mathcal{T}^*$.

Denoting the current test image as I, the initial visual processing first detects objects $n \in \mathcal{N}$ and scenes $s \in \mathcal{S}$ using these detectors to compute $P_r(n|I)$ and $P_r(s|I)$, the probabilities that object n and scene s exist under I. From the observation that an action can often be predicted by its key objects, $N_k = \{n_1, n_2, \cdots, n_i\}, n_i \in \mathcal{N}$ that participate in the action, we use a trained Language model L_m to estimate $P_r(v|N_k)$. L_m is also used to compute $P_r(s|n, v)$, the predicted scene using the corpus given the object and verb; and $P_r(p|s)$, the predicted preposition given the scene. This process is repeated over all n, v, s, p where we used a modified HMM inference scheme to determine the most likely quadruplet: $\mathcal{T}^* = \{n^*, v^*, s^*, p^*\}$ that makes up the core sentence structure. Using the contents and structure of $\mathcal{T}^*$, an appropriate sentence is then generated that describes the image. In the following sections, we first introduce the image dataset used for testing followed by details of how these components are derived.

Objects $n \in \mathcal{N}$	Actions $v \in \mathcal{V}$	Scenes $s \in \mathcal{S}$	Preps $p \in \mathcal{P}$
'aeroplane' 'bicycle' 'bird'	'sit' 'stand' 'park'	'airport'	'in' 'at' 'above'
'boat' 'bottle' 'bus' 'car'	'ride' 'hold' 'wear'	'field'	'around' 'behind'
'cat' 'chair' 'cow' 'table'	'pose' 'fly' 'lie' 'lay'	'highway'	'below' 'beside'
'dog' 'horse', 'motorbike'	'smile' 'live' 'walk'	'lake' 'room'	'between'
'person' 'pottedplant'	'graze' 'drive' 'play'	'sky' 'street'	'before' 'to'
'sheep' 'sofa' 'train'	'eat' 'cover' 'train'	'track'	'under' 'on'
'tvmonitor'	'close' ...

3.1 Image Dataset

We use the *UIUC Pascal Sentence dataset*, first introduced in [Farhadi et al., 2010] and available online[1]. It contains 1000 images taken from a subset of the Pascal-VOC 2008 challenge image dataset and are hand annotated with sentences that describe the image by paid human annotators using Amazon Mechanical Turk. Fig. 4 shows some sample images with their annotations. There are 5 annotations per image, and each annotation is usually short – around 10 words long. We randomly selected 900 images (4500 sentences) as the learning corpus to construct the verb and scene sets, $\{\mathcal{V}, \mathcal{S}\}$ as described in sec. 3.3, and kept the remaining 100 images for testing and evaluation.

3.2 Object and Scene Detections from Images

We use the Pascal-VOC 2008 trained object detectors [Felzenszwalb et al., 2008] of 20 common everyday object classes that are defined in $\mathcal{N}$. Each of the detectors are essentially SVM classifiers trained on a large number of the objects' image representations from a large variety of sources. Although 20 classes may seem small, their existence in many natural images (e.g. humans, cars and plants) makes them particularly *important* for our task, since humans tend to describe these common objects as well. As object representations, the part-based descriptor of [Felzenszwalb et al., 2010] is used. This representation decomposes any object, e.g. a cow, into its constituent parts: head, torso, legs, which are shared by other objects in a hierarchical manner. At each level, image gradient orientations are computed. The relationship between each parts is modeled probabilistically using graphical models where parts are the nodes and the edges are the conditional probabilities that relate their spatial compatibility (Fig. 5(a)). For example, in a cow, the probability of finding the torso near the head is higher than finding the legs near the head. This model's intuition lies in the assumption that objects can be deformed but the relative position of each constituent parts should remain the same. We convert the object detection scores to probabilities using Platt's method [Lin et al., 2007] which is numerically more stable to obtain $P_r(n|I)$. The parameters of Platt's method are obtained by estimating the number of positives and negatives from the UIUC annotated dataset, from

[1] http://vision.cs.uiuc.edu/pascal-sentences/

which we determine the appropriate probabilistic threshold, which gives us approximately 50% recall and precision.

For detecting scenes defined in $\mathcal{S}$, we use the GIST-based scene descriptor of [Torralba et al., 2003]. GIST computes the windowed 2D Gabor filter responses of an input image. The responses of Gabor filters (4 scales and 6 orientations) encode the texture gradients that describe the *local* properties of the image. Averaging out these responses over larger spatial regions gives us a set of *global* image properties. These high dimensional responses are then reprojected to a low dimensional space via PCA, where the number of principal components are obtained empirically from training scenes. This representation forms the GIST descriptor of an image (Fig. 5(b)) which is used to train a set of SVM classifiers for each scene class in $\mathcal{S}$. Again, $P_r(s|I)$ is computed from the SVM scores using [Lin et al., 2007]. The set of common scenes defined in $\mathcal{S}$ is learned from the UIUC annotated data (sec. 3.3).

3.3 Corpus-Guided Predictions

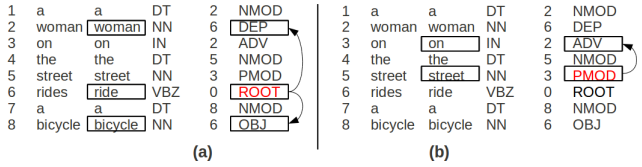

Figure 6: (a) Selecting the ROOT verb from the dependency parse `ride` reveals its subject `woman` and direct object `bicycle`. (b) Selecting the head noun (PMOD) as the scene `street` reveals ADV as the preposition `on`

Predicting Verbs: The key component of our approach is the trained language model L_m that predicts the most likely verb v, associated with the objects N_k detected in the image. Since it is possible that different verbs may be associated with varying number of object arguments, we limit ourselves to verbs that take on at most *two* objects (or more specifically two noun phrase arguments) as a simplifying assumption: $N_k = \{n_1, n_2\}$ where n_2 can be NULL. That is, n_1 and n_2 are the subject and direct objects associated with $v \in \mathcal{V}$. Using this assumption, we can construct the set of verbs, $\mathcal{V}$. To do this, we use human labeled descriptions of the training images from the UIUC Pascal-VOC dataset (sec. 3.1) as a learning corpus that allows us to determine the appropriate target verb set that is amenable to our problem. We first apply the CLEAR parser [Choi and Palmer, 2010] to obtain a dependency parse of these annotations, which also performs stemming of all the verbs and nouns in the sentence. Next, we process all the parses to select verbs which are marked as ROOT and check the existence of a subject (DEP) and direct object (PMOD, OBJ) that are linked to the ROOT verb (see Fig. 6(a)). Finally, after removing common "stop" verbs such as {`is, are, be`} we rank these verbs in terms of their occurrences and select the top 50 verbs which accounts for 87.5% of the sentences in the UIUC dataset to be in $\mathcal{V}$.

Object class $n \in \mathcal{N}$	Synonyms, $\langle n \rangle$
`bus`	`autobus charabanc double-decker jitney motorbus motorcoach omnibus passenger-vehicle schoolbus trolleybus streetcar ...`
`chair`	`highchair chaise daybed throne rocker armchair wheelchair seat ladder-back lawn-chair fauteuil ...`
`bicycle`	`bike wheel cycle velocipede tandem mountain-bike ...`

Table 2: Samples of synonyms for 3 object classes.

Next, we need to explain how n_1 and n_2 are selected from the 20 object classes defined previously in $\mathcal{N}$. Just as the 20 object classes are defined *visually* over several different kinds of specific objects, we expand n_1 and n_2 in their textual descriptions using *synonyms*. For example, the object class n_1=`aeroplane` should include the synonyms {`plane, jet, fighter jet, aircraft`}, denoted as $\langle n_1 \rangle$. To do this, we expand each object class using their corresponding WordNet synsets up to at most three hyponymns levels. Example synonyms for some of the classes are summarized in Table 2.

We can now compute from the Gigaword corpus [Graff, 2003] the probability that a verb exists given the detected nouns, $P_r(v|n_1, n_2)$. We do this by computing the log-likelihood ratio [Dunning, 1993] , λ_{nvn}, of *trigrams* $(\langle n_1 \rangle, v, \langle n_2 \rangle)$, computed from each sentence in the English Gigaword corpus [Graff, 2003]. This is done by extracting only the words in the corpus that are defined in $\mathcal{N}$ and $\mathcal{V}$ (in-

cluding their synonyms). This forms a *reduced* corpus sequence from which we obtain our target trigrams. For example, the sentence:

`the large brown dog chases a small young cat around the messy room, forcing the cat to run away towards its owner.`

will be reduced to the stemmed sequence `dog chase cat cat run owner`[2] from which we obtain the target trigram relationships: {`dog chase cat`}, {`cat run owner`} as these trigrams respect the (n_1, v, n_2) ordering. The log-likelihood ratios, λ_{nvn}, computed for all possible $(\langle n_1 \rangle, v, \langle n_2 \rangle)$ are then normalized to obtain $P_r(v|n_1, n_2)$. An example of ranked λ_{nvn} in Fig. 7(a) shows that λ_{nvn} predicts v that makes sense: with the most likely predictions near the top of the list.

Predicting Scenes: Just as an action is strongly related to the objects that participate in it, a scene can be predicted from the objects and verbs that occur in the image. For example, detecting N_k={`boat, person`} with v={`row`} would have predicted the scene s={`coast`}, since boats usually occur in water regions. To learn this relationship from the corpus, we use the UIUC dataset to discover what are the common scenes that should be included in $\mathcal{S}$. We applied the CLEAR dependency parse [Choi and Palmer, 2010] on the UIUC data and extracted all the head nouns (PMOD) in the PP phrases for this purpose and excluded those nouns with prepositions (marked as ADV) such as {`with, of`} which do not co-occur with scenes in general (see Fig. 6(b)). We then ranked the remaining scenes in terms of their frequency to select the top 8 scenes used in $\mathcal{S}$.

To improve recall and generalization, we expand each of the 8 scene classes using their WordNet synsets $\langle s \rangle$ (up to a max of three hyponymns levels). Similar to the procedure of predicting the verbs described above, we compute the log-likelihood ratio of ordered *bigrams*, $\{n, \langle s \rangle\}$ and $\{v, \langle s \rangle\}$: λ_{ns} and λ_{vs}, by reducing the corpus sentence to the target nouns, verbs and scenes defined in $\mathcal{N}, \mathcal{V}$ and $\mathcal{S}$. The probabilities $P_r(s|n)$ and $P_r(v|n)$ are then obtained by normalizing λ_{ns} and λ_{vs}. Under the assumption that the priors $P_r(n)$ and $P_r(v)$ are independent and applying Bayes rule, we can compute the probability that a scene co-occurs with the object and action, $P_r(s|n, v)$ by:

$$\begin{aligned} P_r(s|n,v) &= \frac{P_r(n,v|s)P_r(s)}{P_r(n,v)} \\ &= \frac{P_r(n|s)P_r(v|s)P_r(s)}{P_r(n)P_r(v)} \\ &\propto P_r(s|n) \times P_r(s|v) \end{aligned} \quad (1)$$

where the constant of proportionality is justified under the assumption that $P_r(s)$ is equiprobable for all s. (1) is computed for all nouns in N_k. As shown in Fig. 7(b), we are able to predict scenes that co-locate with reasonable correctness given the nouns and verbs.

Predicting Prepositions: It is straightforward to predict the appropriate prepositions associated with a given scene. When we construct $\mathcal{S}$ from the UIUC annotated data, we simply collect and rank all the associated prepositions (ADV) in the PP phrase of the dependency parses. We then select the top 12 prepositions used to define $\mathcal{P}$. Using $\mathcal{P}$, we then compute the log-likelihood ratio of ordered *bigrams*, $\{p, \langle s \rangle\}$ for prepositions that co-locate with the scene synonyms over the corpus. Normalizing λ_{ps} yields $P_r(p|s)$, the probability that a preposition co-locates with a scene. Examples of ranked λ_{ps} are shown in Fig. 7(c). Again, we see that reasonable predictions of p can be found.

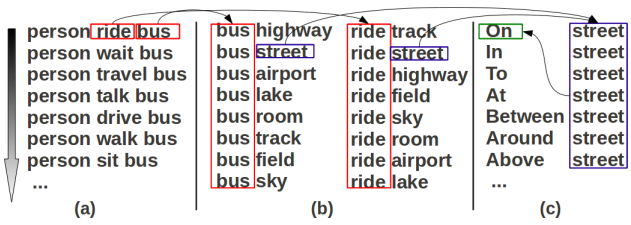

Figure 7: Example of how ranked log-likelihood values (in descending order) suggest a possible $\mathcal{T}$: (a) λ_{nvn} for $n_1 =$ `person`, $n_2 =$ `bus` predicts $v =$ `ride`. (b) λ_{ns} and λ_{vs} for $n =$ `bus`, $v =$ `ride` then jointly predicts $s =$ `street` and finally (c) λ_{ps} with $s =$ `street` predicts $p =$ `on`.

3.4 Determining $\mathcal{T}^*$ using HMM inference

Given the computed conditional probabilities: $P_r(n|I)$ and $P_r(s|I)$ which are observations from an input test image with the parameters of the trained language model, L_m:

[2] stemming is done using [Choi and Palmer, 2010]

$P_r(v|n_1, n_2), P_r(s|n, v), P_r(p|s)$, we seek to find the most likely sentence structure $\mathcal{T}^*$ by:

$$\begin{aligned}\mathcal{T}^* &= \arg\max_{n,v,s,p} P_r(\mathcal{T}|n, v, s, p) \\ &= \arg\max_{n,v,s,p}\{P_r(n_1|I)P_r(n_2|I)P_r(s|I)\times \\ &\qquad P_r(v|n_1, n_2)P_r(s|n, v)P_r(p|s)\} \quad (2)\end{aligned}$$

where the last equality holds by assuming independence between the visual detections and corpus predictions. Obviously a brute force approach to try all possible combinations to maximize eq. (2) will not be feasible due to the large number of possible combinations: $(20*21*8)*(50*20*20)*(8*20*50)*(12*8) \approx 5 \times 10^{13}$. A better solution is needed.

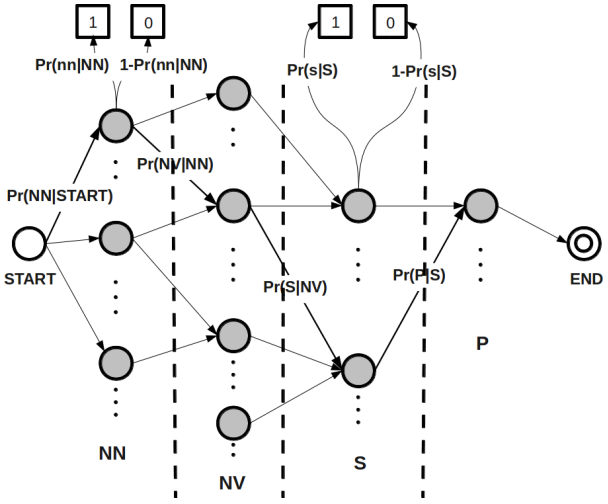

Figure 8: The HMM used for optimizing $\mathcal{T}$. The relevant transition and emission probabilities are also shown. See text for more details.

Our proposed strategy is to pose the optimization of $\mathcal{T}$ as a dynamic programming problem, akin to a Hidden Markov Model (HMM) where the hidden states are related to the (simplified) sentence structure we seek: $\mathcal{T} = \{n_1, n_2, s, v, p\}$, and the emissions are related to the observed detections: $\{n_1, n_2, s\}$ in the image if they exist. To simplify our notations, as we are concerned with object pairs we will write NN as the hidden states for all n_1, n_2 pairs and nn as the corresponding emissions (detections); and all object+verb pairs as hidden states NV. The hidden states are therefore denoted as: $\{\texttt{NN}, \texttt{NV}, \texttt{S}, \texttt{P}\}$ with values taken from their respective word classes from Table 1. The emission states are $\{\texttt{nn}, \texttt{s}\}$ with binary values: 1 if the detections occur or 0 otherwise. The full HMM is summarized in Fig. 8. The rationale for using a HMM is that we can reuse all previous computation of the probabilities at each level to compute the required probabilities at the current level. From START, we assume all object pair detections are equiprobable: $P_r(\texttt{NN}|\texttt{START}) = \frac{1}{|\mathcal{N}|*(|\mathcal{N}|+1)}$ where we have added an additional NULL value for objects (at most 1). At each NN, the HMM emits a detection from the image and by independence we have: $P_r(\texttt{nn}|\texttt{NN}) = P_r(n_1|I)P_r(n_2|I)$. After NN, the HMM transits to the corresponding verb at state NV with $P_r(\texttt{NV}|\texttt{NN}) = P_r(v|n_1, n_2)$ obtained from the corpus statistic[3]. As no action detections are performed on the image, NV has no emissions. The HMM then transits from NV to S with $P_r(\texttt{S}|\texttt{NV}) = P_r(s|n, v)$ computed from the corpus which emits the scene detection score from the image: $P_r(\texttt{s}|\texttt{S}) = P_r(s|I)$. From S, the HMM transits to P with $P_r(\texttt{P}|\texttt{S}) = P_r(p|s)$ before reaching the END state.

Comparing the HMM with eq. (2), one can see that all the corpus and detection probabilities are accounted for in the transition and emission probabilities respectively. Optimizing $\mathcal{T}$ is then equivalent to finding the best (most likely) path through the HMM given the image observations using the Viterbi algorithm which can be done in $O(10^5)$ time which is significantly faster than the naive approach. We show in Fig. 9 (right-upper) examples of the top viterbi paths that produce $\mathcal{T}^*$ for four test images.

Note that the proposed HMM is suitable for generating sentences that contain the core components defined in $\mathcal{T}$ which produces a sentence of the form NP−VP−PP, which we will show in sec. 4 is sufficient for the task of generating sentences for describing images. For more complex sentences with more components: such as adjectives or adverbs, the HMM can be easily extended with similar computations derived from the corpus.

3.5 Sentence Generation

Given the selected sentence structure $\mathcal{T} = \{n_1, n_2, v, s, p\}$, we generate sentences using the

[3]each verb, v, in NV will have 2 entries with the same value, one for each noun.

{aeroplane,fly,airport,at}
the aeroplane is flying at the airport.

{person,motorbike,ride,field,in}
the person is riding the motorbike in the field.

{person,bicycle,ride,street,on}
the person is riding the bicycle on the street.

{person,table,sit,room,in}
three people are sitting at the table in the room.

Figure 9: Four test images (left) and results. (Right-upper): Sentence structure $\mathcal{T}^*$ predicted using Viterbi and (Right-lower): Generated sentences. Words marked in red are considered to be incorrect predictions. Complete results are available at `http://www.umiacs.umd.edu/~yzyang/sentence_generateOut.html`.

following strategy for each component:

1) We add in appropriate determiners and cardinals: `the, an, a, CARD`, based on the content of n_1,n_2 and s. For e.g., if $n_1 = n_2$, we will use `CARD=two`, and modify the nouns to be in the plural form. When several possible choices are available, a random choice is made that depends on the object detection scores: `the` is preferred when we are confident of the detections while `an, a` is preferred otherwise.

2) We predict the most likely preposition inserted between the verbs and nouns learned from the Gigaword corpus via $P_r(p|v,n)$ during sentence generation. For example, our method will pick the preposition `at` between verb `sit` and noun `table`.

3) The verb v is converted to a form that agrees with in number with the nouns detected. The present gerund form is preferred such as `eating, drinking, walking` as it conveys that an action is being performed in the image.

4) The sentence structure is therefore of the form: `NP-VP-PP` with variations when only one object or multiple detections of the same objects are detected. A special case is when *no* objects are detected (below the predefined threshold). No verbs can be predicted as well. In this case, we simply generate a sentence that describes the *scene* only: for e.g. `This is a coast, This is a field`. Such sentences account for 20% of the entire UIUC testing dataset which are scored lower in our evaluation metrics (sec. 4.1) since they do not fully *describe* the image content in terms of the objects and actions.

Some examples of sentences generated using this strategy are shown in Fig. 9(right-lower).

4 Experiments

We performed several experiments to evaluate our proposed approach. The different metrics used for evaluation and comparison are also presented, followed by a discussion of the experimental results.

4.1 Sentence Generation Results

Three experiments are performed to evaluate the effectiveness of our approach. As a baseline, we simply generated $\mathcal{T}^*$ *directly* from images without using the corpus. There are two variants of this baseline where we seek to determine if listing *all* objects in the image is crucial for scene description. $\mathcal{T}_{b1}$ is a baseline that uses *all* possible objects and scene detected: $\mathcal{T}_{b1} = \{n_1, n_2, \cdots, n_m, s\}$ and our sentence will be of the form: {`Object 1, object 2 and object 3 are IN the scene.`} and we simply selected `IN` as the only admissible preposition. For the second baseline, $\mathcal{T}_{b2}$, we limit the number of objects to just any two: $\mathcal{T}_{b2} = \{n_1, n_2, s\}$ and the sentence generated will be of the form {`Object 1 and object 2 are IN the scene`}. In the second experiment, we applied the HMM strategy described above but made all transition probabilities *equiprobable*, removing the effects of the corpus, and producing a sentence structure which we denote as $\mathcal{T}^*_{eq}$. The third experiment produces the full $\mathcal{T}^*$ with transition probabilities learned from the corpus. All experiments were performed on the 100 unseen testing images from the UIUC dataset and we used only the most likely (top) sentence generated for all evaluation.

We use two evaluation metrics as a measure of the accuracy of the generated sentences: 1) ROUGE-1 [Lin and Hovy, 2003] precision scores and 2) *Relevance* and *Readability* of the generated sentences. ROUGE-1 is a recall based metric that is commonly used to measure the effectiveness of text summarization. In this work, the short descriptive sentence of an image can be viewed as summarizing the image

content and ROUGE-1 is able to capture how well this sentence can describe the image by comparing it with the human annotated ground truth of the UIUC dataset. Due to the short sentences generated, we did not consider other ROUGE metrics (ROUGE-2, ROUGE-SU4) which captures fluency and is not an issue here.

Experiment	R_1,(length)	Relevance	Readability
Baseline 1, $\mathcal{T}_{b1}^*$	0.35,(8.2)	$\mathbf{2.84} \pm 1.40$	3.64 ± 1.20
Baseline 2, $\mathcal{T}_{b2}^*$	0.39,(6.8)	2.14 ± 1.13	3.94 ± 0.91
HMM no corpus, $\mathcal{T}_{eq}^*$	0.42,(6.5)	2.44 ± 1.25	3.88 ± 1.18
Full HMM, $\mathcal{T}^*$	**0.44**,(6.9)	2.51 ± 1.30	$\mathbf{4.10} \pm 1.03$
Human Annotation	0.68,(10.1)	4.91 ± 0.29	4.77 ± 0.42

Table 3: Sentence generation evaluation results with human gold standard. Human R_1 scores are averaged over the 5 sentences using a leave one out procedure. Values in bold are the top scores.

A main shortcoming of using ROUGE-1 is that the generated sentences are compared only to a finite set of human labeled ground truth which obviously does not capture all possible sentences that one can generate. In other words, ROUGE-1 does not take into account the fact that sentence generation is innately a *creative* process, and a better recall metric will be to ask humans to judge these sentences. The second evaluation metric: Relevance and Readability is therefore proposed as an empirical measure of how much the sentence: 1) conveys the image content (relevance) in terms of the objects, actions and scene predicted and 2) is grammatically correct (readability). We engaged the services of Amazon Mechanical Turks (AMT) to judge the generated sentences based on a discrete scale ranging from 1–5 (low relevance/readability to high relevance/readability). The averaged results of ROUGE-1, R_1 and mean length of the sentences with the Relevance+Readability scores for all experiments are summarized in Table 3. For comparison, we also asked the AMTs to judge the ground truth sentences as well.

4.2 Discussion

The results reported in Table 3 reveals both the strengths and some shortcomings of the approach which we will briefly discuss here. Firstly, the R_1 scores indicate that based on a purely summarization (unigram-overlap) point of view, the proposed approach of using the HMM to predict $\mathcal{T}^*$ achieves the best results compared to all other approaches with $R_1 = 0.44$. This means that our sentences are the closest in agreement with the human annotated ground truth, correctly predicting the sentence structure components. In addition sentences generated by $\mathcal{T}^*$ are also succinct: with an average length of 6.9 words per sentence. However, we are still some way off the human gold standard since we do not predict other parts-of-speech such as adjectives and adverbs. Given this fact, our proposed approach performance is comparable to other state of the art summarization work in the literature [Bonnie and Dorr, 2004].

Next, we consider the Relevance+Readability metrics based on human judges. Interestingly, the first baseline, $\mathcal{T}_{b1}^*$ is considered the most relevant description of the image and the least readable at the same time. This is most likely due to the fact that this recall oriented strategy will almost certainly describe some objects but the lack of any verb description; and longer sentences that average 8.2 words per sentence, makes it less readable. It is also possible that humans tend to penalize less irrelevant objects compared to missing objects, and further evaluations are necessary to confirm this. Since $\mathcal{T}_{b2}^*$ is limited to two objects just like the proposed HMM, it is a more suitable baseline for comparison. Clearly, the results show that adding the HMM to predict the optimal sentence structure increases the relevance of the produced sentence. Finally, in terms of *readability*, $\mathcal{T}^*$ generates the most readable sentences, and this is achieved by leveraging on the corpus to guide our predictions of the most *reasonable* nouns, verbs, scenes and prepositions that agree with the detections in the image.

5 Future Work

In this work, we have introduced a computationally feasible framework that integrates visual perception together with semantic grounding obtained from a large textual corpus for the purpose of generating a descriptive sentence of an image. Experimental results show that our approach produces sentences that are both relevant and readable. There are, however, instances where our strategy fails to predict the ap-

propriate verbs or nouns (see Fig. 9). This is due to the fact that object/scene detections can be wrong and noise from the corpus itself remains a problem. Compared to human gold standards, therefore, much work still remains in terms of detecting these objects and scenes with high precision. Currently, at most two object classes are used to generate simple sentences which was shown in the results to have penalized the relevance score of our approach. This can be addressed by designing more complex HMMs to handle larger numbers of object and verb classes. Another interesting direction of future work would be to detect *salient* objects, learned from training image+corpus or eye-movement data, and to verify if these objects aid in improving the descriptive sentences we generate. Another potential application

Figure 10: Images retrieved from 3 verbal search terms: `ride,sit,fly`.

of representing images using $\mathcal{T}^*$ is that we can easily sort and retrieve images that are similar in terms of their *semantic* content. This would enable us to retrieve, for example, more relevant images given a verbal search query such as {`ride,sit,fly`}, returning images where these verbs are found in $\mathcal{T}^*$. Some results of retrieved images based on their verbal components are shown in Fig. 10: many images with dissimilar visual content are correctly classified based on their semantic meaning.

Abstract

Automatically produced texts (e.g. translations or summaries) are usually evaluated with n-gram based measures such as BLEU or ROUGE, while the wide set of more sophisticated measures that have been proposed in the last years remains largely ignored for practical purposes. In this paper we first present an in-depth analysis of the state of the art in order to clarify this issue. After this, we formalize and verify empirically a set of properties that every text evaluation measure based on similarity to human-produced references satisfies. These properties imply that corroborating system improvements with additional measures always increases the overall reliability of the evaluation process. In addition, the greater the *heterogeneity* of the measures (which is measurable) the higher their combined reliability. These results support the use of heterogeneous measures in order to consolidate text evaluation results.

1 Introduction

The automatic evaluation of textual outputs is a core issue in many Natural Language Processing (NLP) tasks such as Natural Language Generation, Machine Translation (MT) and Automatic Summarization (AS). State-of-the-art automatic evaluation methods all operate by rewarding similarities between automatically-produced candidate outputs and manually-produced reference solutions, so-called human references or models.

Over the last decade, a wide variety of measures, based on different quality assumptions, have been proposed. Recent work suggests exploiting external knowledge sources and/or deep linguistic annotation, and measure combination (see Section 2). However, original measures based on lexical matching, such as BLEU (Papineni et al., 2001a) and ROUGE (Lin, 2004) are still preferred as de facto standards in MT and AS, respectively. There are, in our opinion, two main reasons behind this fact. First, the use of a common measure certainly allows researchers to carry out objective comparisons between their work and other published results. Second, the advantages of novel measures are not easy to demonstrate in terms of correlation with human judgements.

Our goal is not to answer which is the most reliable metric or to propose yet another novel measure. Rather than this, we first analyze in depth the state of the art, concluding that it is not easy to determine the reliability of a measure. In absence of a clear proof of the advantages of novel measures, system developers naturally tend to prefer well-known standard measures. Second, we formalize and check empirically two intrinsic properties that any evaluation measure based on similarity to human-produced references satisfies. Assuming that a measure satisfies a set of basic formal constraints, these properties imply that corroborating a system comparison with additional measures always increases the overall reliability of the evaluation process, even when the added measures have a low correlation with human judgements. In most papers, evaluation results are corroborated with similar n-gram based measures (eg. BLEU and ROUGE). However, according to our second property, the greater the *heterogeneity* of

Proceedings of the 2011 Conference on Empirical Methods in Natural Language Processing, pages 455–466,
Edinburgh, Scotland, UK, July 27–31, 2011.

the measures (which is measurable) the higher their reliability. The practical implication is that, corroborating evaluation results with measures based on higher linguistic levels increases the heterogeneity, and therefore, the reliability of evaluation results.

2 State of the Art

2.1 Individual measures

Among NLP disciplines, MT probably has the widest set of automatic evaluation measures. The dominant approach to automatic MT evaluation is, today, based on lexical metrics (also called n-gram based metrics). These metrics work by rewarding lexical similarity between candidate translations and a set of manually-produced reference translations. Lexical metrics can be classified according to how they compute similarity. Some are based on edit distance, e.g., WER (Nießen et al., 2000), PER (Tillmann et al., 1997), and TER (Snover et al., 2006). Other metrics are based on computing lexical precision, e.g., BLEU (Papineni et al., 2001b) and NIST (Doddington, 2002), lexical recall, e.g., ROUGE (Lin and Och, 2004a) and CDER (Leusch et al., 2006), or a balance between the two, e.g., GTM (Melamed et al., 2003; Turian et al., 2003b), METEOR (Banerjee and Lavie, 2005), BLANC (Lita et al., 2005), SIA (Liu and Gildea, 2006), MAXSIM (Chan and Ng, 2008), and O_l (Giménez, 2008).

The lexical measure BLEU has been criticized in many ways. Some drawbacks of BLEU are the lack of interpretability (Turian et al., 2003a), the fact that it is not necessary to increase BLEU to improve systems (Callison-burch and Osborne, 2006), the overscoring of statistical MT systems (Le and Przybocki, 2005), the low reliability over rich morphology languages (Homola et al., 2009), or even the fact that a poor system translation of a book can obtain higher BLEU results than a manually produced translation (Culy and Riehemann, 2003).

The reaction to these criticisms has been focused on the development of more sophisticated measures in which candidate and reference translations are automatically annotated and compared at different linguistic levels. Some of the features employed include parts of speech (Popovic and Ney, 2007; Giménez and Màrquez, 2007), syntactic dependencies (Liu and Gildea, 2005; Giménez and Màrquez, 2007; Owczarzak et al., 2007a; Owczarzak et al., 2007b; Owczarzak et al., 2008; Chan and Ng, 2008; Kahn et al., 2009), CCG parsing (Mehay and Brew, 2007), syntactic constituents (Liu and Gildea, 2005; Giménez and Màrquez, 2007), named entities (Reeder et al., 2001; Giménez and Màrquez, 2007), semantic roles (Giménez and Màrquez, 2007), discourse representations (Giménez, 2008), and textual entailment features (Padó et al., 2009). In general, when a higher linguistic level is incorporated, linguistic features at lower levels are preserved.

The proposals for summarization evaluation are less numerous. Some proposals for AS tasks are based on syntactic units (Tratz and Hovy, 2008), dependency triples (Owczarzak, 2009) or convolution kernels (Hirao et al., 2005) which reported some reliability improvement over ROUGE in terms of correlation with human judgements.

In general, however, it is not easy to determine clearly the contribution of deeper linguistic knowledge in those proposals. In the case of MT, improvements versus BLEU have been reported (Liu and Gildea, 2005; Kahn et al., 2009), but not over a more elaborated metric such as METEOR (Mehay and Brew, 2007; Chan and Ng, 2008). Besides, controversial results on their performance at sentence vs system level have been reported in shared evaluation tasks (Callison-Burch et al., 2008; Callison-Burch et al., 2009; Callison-Burch et al., 2010).

2.2 Combined measures

Several researchers have suggested integrating heterogeneous measures. Some of them optimize the measure combination function according to the metric's ability to emulate the behavior of human assessors (i.e., correlation with human assessments). For instance, using linear combinations (Padó et al., 2009; Liu and Gildea, 2007; Giménez and Màrquez, 2008), Decision Trees (Akiba et al., 2001; Quirk, 2004), regression based algorithms (Paul et al., 2007; Albrecht and Hwa, 2007a; Albrecht and Hwa, 2007b) or a variety of supervised machine learning algorithms(Quirk et al., 2005; Corston-Oliver et al., 2001; Kulesza and Shieber, 2004; Gamon et al., 2005; Amigó et al., 2005).

Some of these works report evidence on the contribution of combining heterogeneous measures. For instance, Albrecht and Hwa included syntax-based

measures together with lexical measures, outperforming other combination schemes (Albrecht and Hwa, 2007a; Albrecht and Hwa, 2007b). Liu and Gildea, after examining the contribution of each component metric, found that *"metrics showing different properties of a sentence are more likely to make a good combined metric"*(Liu and Gildea, 2007). Akiba et al., which combined multiple edit-distance features based on lexical, morphosyntactic and lexical semantic information, observed that their approach improved single editing distance for several data sets (Akiba et al., 2001). More evidence was provided by Corston and Oliver. They showed that results on the task of discriminating between manual and automatic translations improve when combining linguistic and n-gram based features. In addition, they showed that this mixed combination improved over the combination of linguistic or n-gram based measures alone (Corston-Oliver et al., 2001). (Padó et al., 2009) reported a reliability improvement by including measures based on textual entailment in the set. In (Giménez and Màrquez, 2008), a simple arithmetic mean of scores for combining measures at different linguistic levels was applied with remarkable results in recent shared evaluation tasks (Callison-Burch et al., 2010).

2.3 Meta-evaluation criteria

Meta-evaluation methods have been gradually introduced together with evaluation measures. For instance, Papineni et al. (2001b) evaluated the reliability of the BLEU metric according to its ability to emulate human assessors, as measured in terms of Pearson correlation with human assessments of adequacy and fluency at the document level. The measure NIST (Doddington, 2002) was meta-evaluated also in terms of correlation with human assessments, but over different document sources and for a varying number of references and segment sizes. Melamed et al. (2003) argued, at the time of introducing the GTM metric, that Pearson correlation coefficients can be affected by scale properties. They suggested using the non-parametric Spearman correlation coefficients instead. Lin and Och meta-evaluated ROUGE over both Pearson and Spearman correlation over a wide set of metrics, including NIST, WER, PER, and variants of ROUGE, BLEU and GTM. They obtained similar results in both cases (Lin and Och, 2004a). Banerjee and Lavie (2005) argued that the reliability of metrics at the document level can be due to averaging effects but might not be robust across sentence translations. In order to address this issue, they computed the translation-by-translation correlation with human assessments (i.e., correlation at the sentence level).

However, correlation with human judgements is not enough to determine the reliability of measures. First, correlation at sentence level (unlike correlation at system level) tends to be low and difficult to interpret. Second, correlation at system and segment levels can produce contradictory results. In (Amigó et al., 2009) it is observed that higher linguistic levels in measures increases the correlation with human judgements at the system level at the cost of correlation at the segment level. As far as we know, a clear explanation for these phenomena has not been provided yet.

Third, a high correlation at system level does not ensure a high reliability. Culy and Rieheman observed that, although BLEU can achieve a high correlation at system level in some test suites, it over-scores a poor automatic translation of "Tom Sawyer" against a human produced translation (Culy and Riehemann, 2003). This meta-evaluation criterion based on the ability to discern between manual and automatic translations have been referred to as *human likeness* (Amigó et al., 2006), in contrast to correlation with human judgements which is referred to as *human acceptability*. Examples of meta-measures based on this criterion are ORANGE (Lin and Och, 2004b) and KING (Amigó et al., 2005). In addition, many of the approaches to metric combination described in Section 2.2 take human likeness as the optimization criterion (Corston-Oliver et al., 2001; Kulesza and Shieber, 2004; Gamon et al., 2005). The main advantage of meta-evaluation based on human likeness is that, since human assessments are not required, metrics can be evaluated over larger test beds. However, the meta-evaluation in terms of *human likeness* is difficult to interpret.

2.4 The use of evaluation measures

In general, the state of the art includes a wide set of results that show the drawbacks of n-gram based measures as BLEU, and a wide set of proposals for new single and combined measures which are meta-

evaluated in terms of human acceptability (i.e., their ability to emulate human judges, typically measured in terms of correlation with human judgements) or human-likeness (i.e., their ability to discern between automatic and human translations) (Amigó et al., 2006). However, the original measures BLEU and ROUGE are still preferred.

We believe that one of the reasons is the lack of an in-depth study on to what extent providing additional evaluation results with other metrics contributes to the reliability of such results. The state of the art suggests that the use of heterogeneous measures can improve the evaluation reliability. However, as far as we know, there is no comprehensive analysis on the contribution of novel measures when corroborating evaluation results with additional measures.

3 Similarity Based Evaluation Measures

In general, automatic evaluation measures applied in tasks like MT or AS are similarity measures between system outputs and human references. These measures are related with precision, recall or overlap over specific types of linguistic units. For instance, ROUGE measures n-gram recall. Other measures that work at higher linguistic levels apply precision, recall or overlap of linguistic components such as dependency relations, grammatical categories, semantic roles, etc.

In order to delimit our hypothesis, let us first define what is a similarity measure in this context. Unfortunately, as far as we know, there is no formal concept covering the properties of current evaluation similarity measures. A close concept is that of *"metric"* or *"distance function"*. But, actually, measures such as ROUGE or BLEU are not proper *"metrics"*, because they do not satisfy the *symmetry* and the *triangle inequality* properties. Therefore, we need a new definition.

Being Ω the universe of system outputs s and gold-standards g, we assume that a *similarity measure*, in our context, is a function $x : \Omega^2 \longrightarrow \Re$ such that there exists a decomposition function $f : \Omega \longrightarrow \{e_1..e_n\}$ (e.g., words or other linguistic units or relationships) satisfying the following constraints: (i) maximum similarity is achieved only when then the decomposition of the system output resembles exactly the gold-standard decomposition; and (ii) growing overlap or removing non overlapped elements implies growing x. Formally, if x ranges from 0 to 1:

$$f(s) = f(g) \leftrightarrow x(s,g) = 1$$
$$(f(s) = f(s') \cup \{e \in f(g) \setminus f(s')\}) \rightarrow x(s,g) > x(s',g)$$
$$(f(s) = f(s') - \{e \in f(s') \setminus f(g)\}) \rightarrow x(s,g) > x(s',g)$$

For instance, a random function and the reversal of a similarity funtion ($f'(s) = \frac{1}{f(s)}$) do not satisfy these constraints. While the F measure over *Precision* and *Recall* satisfies these constraints[1], precision and recall in isolation do not satisfy all of them: maximum recall can be achieved without resembling the goldstandard text decomposition; and maximum precision can be achieved with only a few overlapped elements.

BLEU (Papineni et al., 2001a) computes the n-gram precision while the metric ROUGE (Lin and Och, 2004a) computes the n-gram recall. However, in general, both metrics satisfy all the constraints, given that BLEU includes a brevity penalty and ROUGE penalizes or limits the system output length. The measure METEOR creates an alignment between the two strings (Banerjee and Lavie, 2005). This overlap-based measure satisfies also the previous constraints. Measures based on edit distance over n-grams (Tillmann et al., 1997; Nießen et al., 2000) or other linguistic units (Akiba et al., 2001; Popovic and Ney, 2007) match also our definition of similarity measure. The editing distance is minimum when the two compared text are equal. The more the evaluated text contains elements from the gold-standard the more the editing distance is reduced (higher similarity). The word ordering can be also expressed in terms of a decomposition function. A similar reasoning applies to every relevant measure in the state-of-the art.

4 Data Sets and Measures

4.1 Data sets

In this paper, we provide empirical results for MT and AS. For MT, we use the data sets from the Arabic-to-English (AE) and Chinese-to-English (CE) NIST MT Evaluation campaigns in 2004 and

[1]There is an exception. In an extreme case, when recall is zero, removing non overlapped elements does not modify the F measure.

2005[2]. Both include two translations exercises: for the 2005 campaign we contacted each participant individually and asked for permission to use their data[3]. In our experiments, we take the sum of adequacy and fluency, both in a 1-5 scale, as a global measure of quality (LDC, 2005). Thus, human assessments are in a 2-10 scale. For AS, we have used the AS test suites developed in the DUC 2005 and DUC 2006 evaluation campaigns[4]. This AS task was to generate a question focused summary of 250 words from a set of 25-50 documents to a complex question. Summaries were evaluated according to several criteria. Here, we will consider the responsiveness judgements, in which the quality score was an integer between 1 and 5. See Tables 1 and 2 for a brief quantitative description of these test beds.

[4] http://duc.nist.gov/

4.2 Measures

As for evaluation measures, for MT we have used a rich set of 64 measures provided within the ASIYA Toolkit (Giménez and Màrquez, 2010)[5]. This includes measures operating at different linguistic levels: lexical, syntactic, and semantic. At the lexical level this set includes variants of 8 measures employed in the state of the art: BLEU, NIST, GTM, METEOR, ROUGE, WER, PER and TER. In addition, we have included a basic measure O_l that computes the lexical overlap without considering word ordering. All these measures have similar granularity. They use n-grams of a varying length as the basic unit with additional information provided by linguistic tools. The underlying similarity criteria include precision, recall, overlap, or edit rate, and the decomposition functions include words, dependency tree nodes (DP_HWC, DP-Or, etc.), constituency parsing (CP-STM), discourse roles (DR-Or), semantic roles (SR-Or), named entities, etc. Further details on the measure set may be found in the ASIYA technical manual (Giménez and Màrquez, 2010).

According to our computations, our measures cover high and low correlations at both levels. Correlation at system level spans between 0.63 and 0.95. Correlations at sentence level ranges from 0.18 up to 0.54. We will discriminate between two subsets of

[5] http://www.lsi.upc.edu/~nlp/Asiya

measures. The first one includes those that decompose the text into words, n-grams, stems or lexical semantic tags. This set includes BLEU, ROUGE, NIST, GTM, PER and WER families. We will refer to them as "lexical" measures. The second set are those that consider deeper linguistic levels such as parts of speech, syntactic dependencies, syntactic constituents, etc. We will refer to them as "linguistic" measures.

In the case of automatic summarization (AS), we have employed the standard variants of ROUGE (Lin, 2004). These 7 measures are ROUGE-$\{1..4\}$, ROUGE-SU, ROUGE-L and ROUGE-W. In addition we have included the reversed precision version for each variant and the F measure of both. Notice that the original ROUGE measures are oriented to recall. In total, we have 21 measures for the summarization task. All of them are based on n-gram overlap.

5 Additive reliability

As discussed in Section 2, a number of recent publications address the problem of measure combination with successful results, specially when heterogeneous measures are combined. The following property clarifies this issue and justifies the use of heterogeneous measures when corroborating evaluation results. It asserts that *the reliability of system improvements always increases when the evaluation result is corroborated by an additional similarity measure, regardless of the correlation achieved by the additional measure in isolation*.

For the sake of clarity, in the rest of the paper, we will denote the similarity $x(s, g)$ between system output s and human reference g by $x(s)$. The quality of a system output s will be referred to as $Q(s)$. Let us define the *reliability* $R(X)$ of a measure set as the probability of a real improvement (as measured by human judges) when a score improvement is observed simultaneously for all measures in the set X. :

$$R(X) \equiv P(Q(s) \geq Q(s')|x(s) \geq x(s')\ \forall x \in X)$$

According to this definition, we may not be able to predict the quality of any system output (i.e. a translation) with a highly *reliable* measure set, but we can ensure a system improvement when all measures corroborate the result. Then the *additive reliability* property can be stated as:

$$R(X \cup \{x\}) \geq R(X)$$

We could think of violating this property by adding, for instance, a measure consisting of a random function ($x'(s) = rand(0..1)$) or a reversal of the original measure ($x'(s) = 1/x(s)$). These kind of measures, however, would not satisfy the constraints defined in Section 3.

This property is based on the idea that similarity with human references according to any aspect should not imply statistically a quality decrease. Although our test suites includes measures with low correlation at segment and system level, we can confirm empirically that all of them satisfy this property.

We have developed the following experiment: taking all possible measure pairs in the test suites, we have compared their reliability as a set versus the maximal reliability of any of them (by computing the difference $R(X) - max(R(x_1), R(x_2))$. Figure 1 shows the obtained distribution of this difference for our MT and AS test suites. Remarkably, in almost every case this difference is positive.

This result has a key implication: Corroborating evaluation results with a new measure, even when it has lower correlation with human judgements, increases the reliability of results. Therefore, if the correlation with judgements is not determinant, the question is now what factor determines the contribution of the new measures. According to the following property, this factor is the heterogeneity of measures.

6 Heterogeneity

This property states that *the reliability of any measure combination is lower bounded by the heterogeneity of the measure set*. In other words, a single measure can be more or less reliable, but a system improvement according to all measures in an heterogeneous set is reliable.

Let us define the *heterogeneity* $H(X)$ of a set of measures X as, given two system outputs s and s' such that $g \neq s \neq s' \neq g$ (g is the reference text), the probability that there exist two measures that contradict each other. That is:

$$H(X) \equiv P(\exists x, x' \in X . x(s) > x(s') \wedge x'(s) < x'(s'))$$

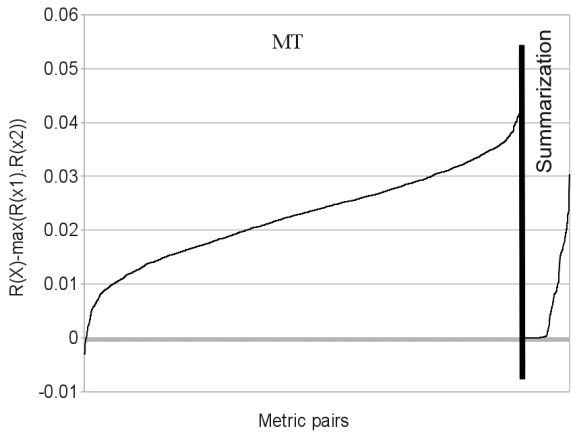

Figure 1: Additive reliability for metric pairs.

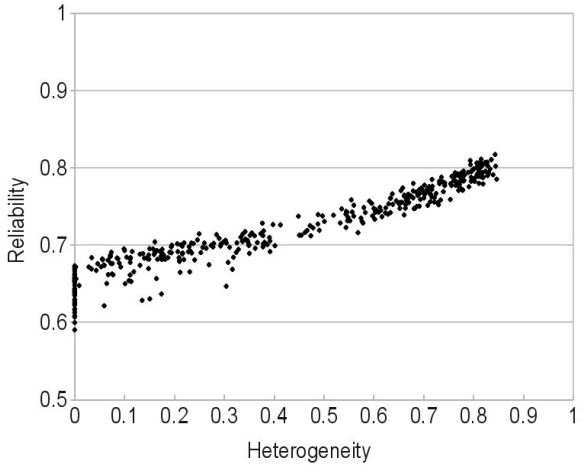

Figure 2: Heterogeneity vs. reliability in MT test suites.

Thus, given a set X of measures, the property states that there exists a strict growing function F such that:

$$R(X) \geq F(H(X)) \text{ and } H(X) = 1 \rightarrow R(X) = 1$$

In other words, the more the similarity measures tend to contradict each other, the more a unanimous improvement over all similarity measures is reliable. Clearly, the harder it is that measures agree, the more meaningful it is when they do.

The first part is derived from the *Additive Reliability* property. Intuitively, any individual measure has zero heterogeneity. Increasing the heterogeneity implies joining measures or measure sets progressively. According to the *Additive Reliability* property, this joining implies a reliability increase. Therefore, the higher the heterogeneity, the higher the minimum Reliability achieved by the corresponding measure sets.

The second part is derived from the *Heterogeneity* definition. If $H(X) = 1$ then, for any distinct pair of outputs that differ from the reference, there exist at least two measures in the set contradicting each other. That is, $H(X) = 1$ implies that:

$$\forall s \neq s' \neq g (\exists x, x' \in X . x(s) > x(s') \wedge x'(s) < x'(s'))$$

Therefore, if one output improves the other according to all measures, then the output must be equal than the reference.

$$\neg(\exists x, x' \in X . x(s) > x(s') \wedge x'(s) < x'(s')) \rightarrow$$

$$\neg(g \neq s \neq s' \neq g) \rightarrow g = s \vee g = s'$$

According to the first constraint of similarity measures, a text that is equal to the reference achieves the maximum score:

$$g = s \rightarrow f(g) = g(s) \rightarrow \forall x . x(s) \geq x(s')$$

Finally, if we assume that the reference (human produced texts) has a maximum quality, then it will have equal or higher quality than the other output.

$$g = s \rightarrow Q(s) \geq Q(s')$$

Therefore, the reliability of the measure set is maximal. In summary, if $H(X) = 1$ then:

$$R(X) = P(Q(s) \geq Q(s') | x(s) \geq x(s') \, \forall x \in X) =$$

$$= P(Q(s) \geq Q(s') | s = g) = 1$$

Figures 2 and 3 show the relationship between the heterogeneity of randomly selected measure sets and their reliability for the MT and summarization test suites. As the figures show, the higher the heterogeneity, the higher the reliability of the measure set. The results in AS are less pronounced due to the redundancy in ROUGE measure.

Notice that the heterogeneity property does not necessarily imply a high correlation between reliability and heterogeneity. For instance, an ideal single measure would have zero heterogeneity and

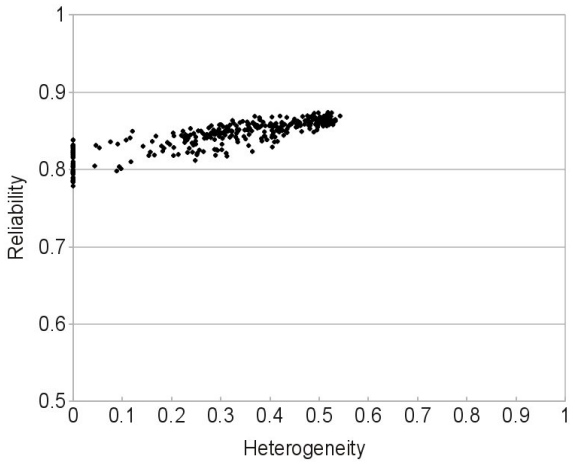

Figure 3: Heterogeneity vs. reliability in summarization test suites.

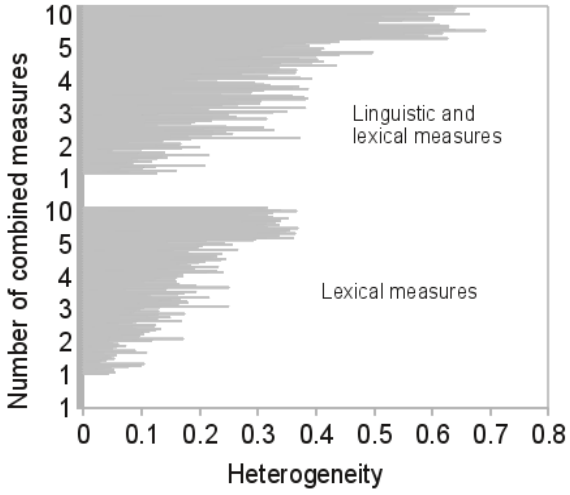

Figure 4: Heterogeneity of lexical measures vs. lexical and linguistic measures.

achieve maximum reliability, appearing in the top left area. The property rather brings us to the following situation: let us suppose that we have a set of single measures available which achieve a certain range of reliability. We can improve our system according to any of these measures. Without human assessments, we do not know what is the most reliable measure. But if we combine them, increasing the heterogeneity, the minimal reliability of the selected measures will be higher. This implies that combining heterogeneous measures (e.g. at high linguistic levels) that do not achieve high correlation in isolation, is better than corroborating results with any individual measure alone, such as ROUGE and BLEU, which is the common practice in the state of the art.

The main drawback of this property is that increasing the heterogeneity implies a sensitivity reduction. For instance, if $H(X) = 0.9$, then only for 10% of output pairs in the corpus there exists an improvement according to all measures. In other words, unanimous evaluation results from heterogeneous measures are reliable but harder to achieve for the system developer. The next section investigates on this issue.

Finally, Figure 4 shows that linguistic measures increase the heterogeneity of measure sets. We have generated sets of metrics of size 1 to 10 made up by lexical or lexical and linguistic metrics. As the figure shows, in the second case, the measure sets achieve a higher heterogeneity.

7 Score thresholds vs. Additive Reliability

According to the previous properties, corroborating evaluation results with several measures increases the reliability of evaluation results at the cost of sensitivity. On the other hand, increasing the score threshold of a single measure should have a similar effect. Which is then the best methodology to improve reliability? In this section we provide experimental evidence on the relationship between both ways of increasing reliability: we have found that, corroborating evaluation results over single texts with additional measures is more reliable than requiring higher score differences according to any individual measure in the set. More specifically, we have found that *the reliability of a measure set is higher than the reliability of each of the individual measures at a similar level of sensitivity.*

Formally, we define the sensitivity $S(X)$ of a metric set X as the probability of finding a score improvement within text pairs with a real (i.e. human assessed) quality improvement:

$$S(X) = P(x(s) \geq x(s')\forall x \in X | Q(s) \geq Q(s'))$$

Being $R_{th}(x)$ and $S_{th}(x)$ the reliability and sensitivity of a single measure x for a certain increase score threshold th:

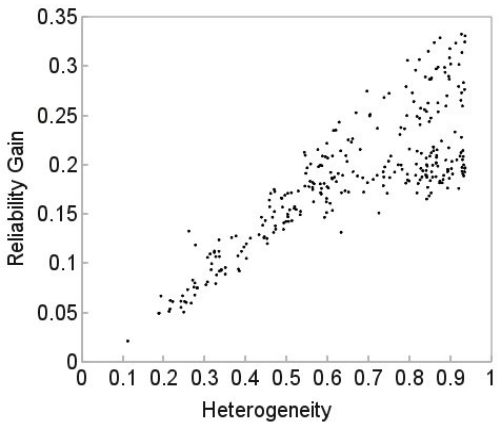

Figure 5: Heterogeneity vs. reliability Gain for MT test suites.

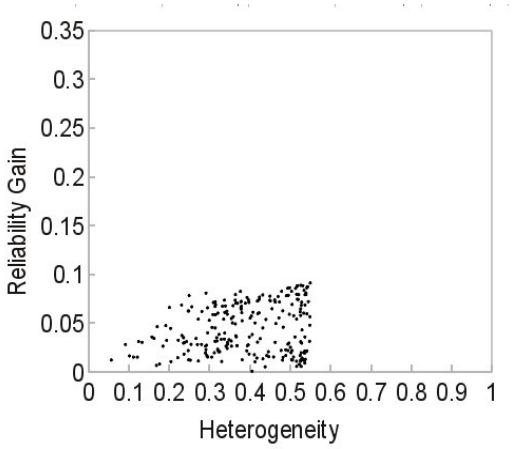

Figure 6: Heterogeneity vs. reliability Gain for MT test suites.

$$R_{th}(x) = P(Q(s) \geq Q(s')|x(s) - x(s') \geq th)$$
$$S_{th}(x) = P(x(s) - x(s') \geq th|Q(s) \geq Q(s'))$$

The property that we want to check is that, at the same sensitivity level, combining measures is more reliable than increasing the score threshold of single measures:

$$S(X) = S_{th}(x).x \in X \longrightarrow R(X) \geq R_{th}(x)$$

Note that if we had a perfect measure x_p such that $R(x_p) = S(x_p) = 1$, then combining this measure with a low reliability measure x_l would produce a lower sensitivity, but the maximal reliability would be preserved.

In order to confirm empirically this property, we have developed the following experiment: (i) We compute the reliability and sensitivity of randomly chosen measure sets over single text pairs. We have generated sets of 2,3,5,10,20 and 40 measures. In the case of summarization corpora we have combined up to 20 measures. In addition, we compute also the heterogeneity $H(X)$ of each measure set; (ii) Experimenting with different values for the threshold th, we compute the reliability of single measures for all potential sensitivity levels; (iii) For each measure set, we compare the reliability of the measure set versus the reliability of single measures at the same sensitivity level. We will refer to this as the *Reliability Gain*:

$$\text{Reliability Gain} =$$
$$R(X) - max\{R_{th}(x)/x \in X \wedge S_{th}(x) = S(X)\}$$

If there are several reliability values with the same sensitivity for a given single measures, we choose the highest reliability value for the single measure.

Figures 5 and 6 illustrate the results for the MT and AS corpora. The horizontal axis represents the Heterogeneity of measure sets, while the vertical axis represents the reliability gain. Remarkably, the reliability gain is positive for all cases in our test suites. The maximum reliability gain is 0.34 in the case of MT and 0.08 for AS (note that summarization measures are more redundant in our corpora). In both test suites, the largest information gains are obtained with highly heterogeneous measure sets.

In summary, given comparable measures in terms of reliability, corroborating evaluation results with several measures is more effective than optimizing systems according to the best measure in the set. This empirical property provides an additional evidence in favour of the use of heterogeneous measures and, in particular, of the use of linguistic measures in combination with standard lexical measures.

8 Conclusions

In this paper, we have analyzed the state of the art in order to clarify why novel text evaluation measures

are not exploited by the community. Our first conclusion is that it is not easy to determine the reliability of measures, which is highly corpus-dependent and often contradictory when comparing correlation with human judgements at segment vs. system levels.

In order to tackle this issue, we have studied a number of properties that suggest the convenience of using heterogeneous measures to corroborate evaluation results. According to these properties, we can ensure that, even when if we can not determine the reliability of individual measures, corroborating a system improvement with additional measures always increases the reliability of the results. In addition, the more heterogeneous the measures employed (which is measurable), the higher the reliability of the results. But perhaps the most important practical finding is that the reliability at similar sensitivity levels by corroborating evaluation results with several measures is always higher than improving systems according to any of the combined measures in isolation.

These properties point to the practical advantages of considering linguistic knowledge (beyond lexical information) in measures, even if they do not achieve a high correlation with human judgements. Our experiments show that linguistic knowledge increases the heterogeneity of measure sets, which in turn increases the reliability of evaluation results when corroborating system comparisons with several measures.

Abstract

The Text Analysis Conference (TAC) ranks summarization systems by their average score over a collection of document sets. We investigate the statistical appropriateness of this score and propose an alternative that better distinguishes between human and machine evaluation systems.

1 Introduction

For the past several years, the National Institute of Standards and Technology (NIST) has hosted the Text Analysis Conference (TAC) (previously called the Document Understanding Conference (DUC)) (Nat, 2010). A major theme of this conference is multi-document summarization: machine summarization of sets of related documents, sometimes query-focused and sometimes generic. The summarizers are judged by how well the summaries match human-generated summaries in either automatic metrics such as ROUGE (Lin and Hovy, 2003) or manual metrics such as responsiveness or pyramid evaluation (Nenkova et al., 2007). Typically the systems are ranked by their average score over all document sets.

Ranking by average score is quite appropriate under certain statistical hypotheses, for example, when each sample is drawn from a distribution which differs from the distribution of other samples only through a location shift (Randles and Wolfe, 1979). However, a non-parametric (rank-based) analysis of variance on the summarizers' scores on each document set revealed an impossibly small p-value (less

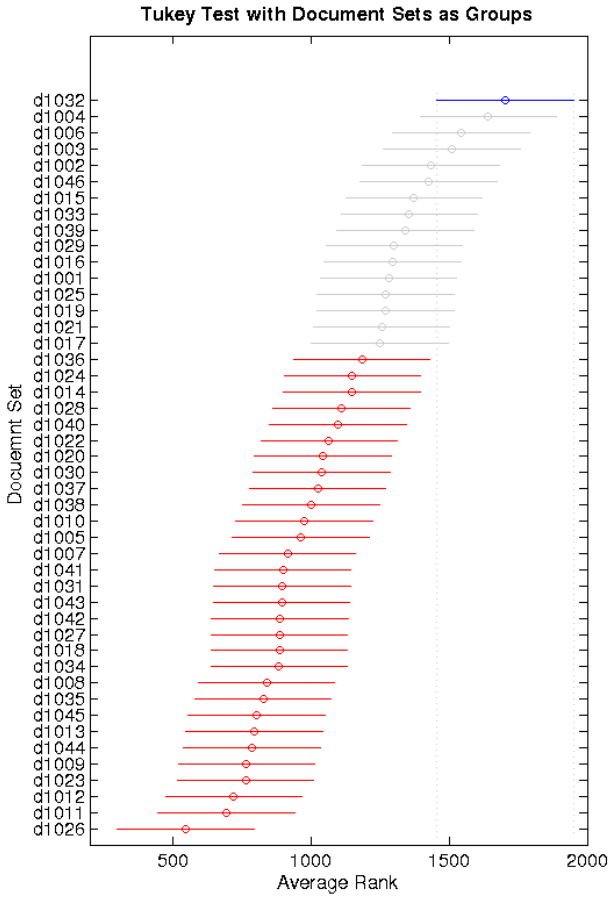

Figure 1: Confidence Intervals from a non-parametric Tukey's honestly significant difference test for 46 TAC 2010 update document sets. The blue confidence interval (for document set d1032) does not overlap any of the 30 red intervals. Hence, the test concludes that 30 document sets have mean significantly different from the mean of d1032.

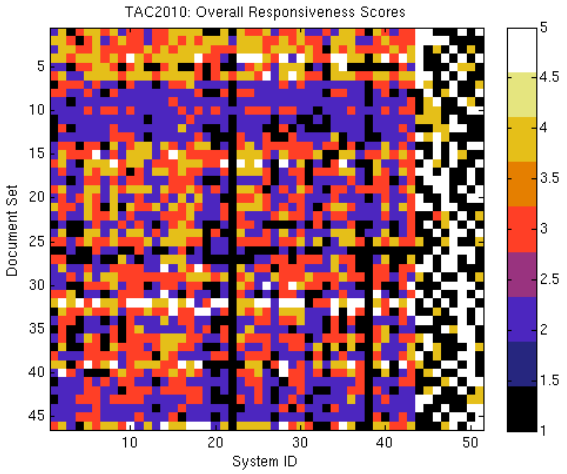

Figure 2: Overall Responsiveness scores.

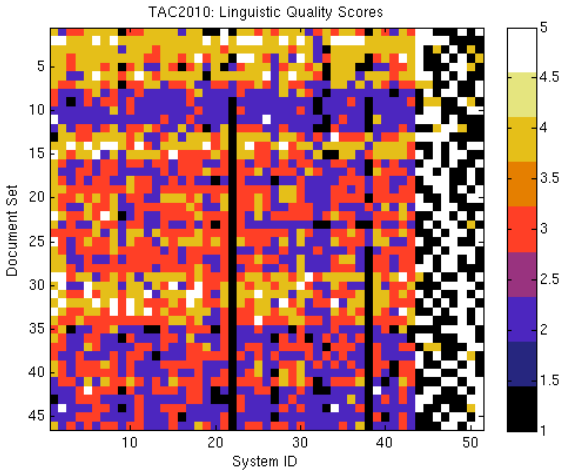

Figure 3: Linguistic scores.

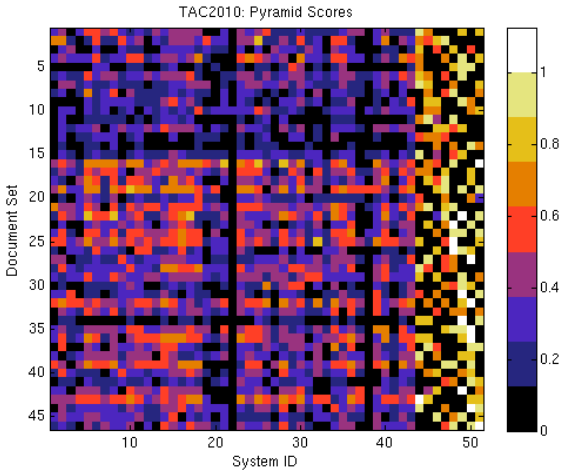

Figure 4: Pyramid scores.

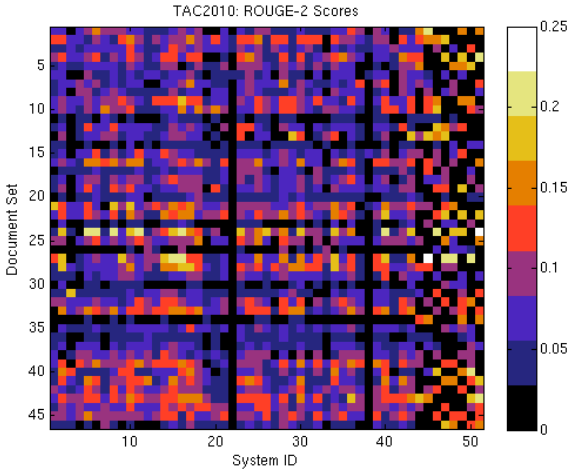

Figure 5: ROUGE-2 scores for the TAC 2010 update summary task, organized by document set (y-axis) and summarizer (x-axis). The 51 summarizers fall into two distinct groups: machine systems (first 43 columns) and humans (last 8 columns). Note that each human only summarized half of the document sets, thus creating 23 missing values in each of the last 8 columns. Black is used to indicate missing values in the last 8 columns and low scores in the first 43 columns.

than 10^{-12} using Matlab's `kruskalwallis` [1]), providing evidence that a summary's score is not independent of the document set. This effect can be seen in Figure 1, showing the confidence bands, as computed by a Tukey honestly significant difference test for each document set's difficulty as measured by the mean rank responsiveness score for TAC 2010. The test clearly shows that the summarizer performances on different document sets have different averages.

We further illustrate this in Figures 2 – 5, which show the scores of various summarizers on various document sets using standard human and automatic evaluation methods (Dang and Owczarzak, 2008) of overall responsiveness, linguistic quality, pyramid scores, and ROUGE-2 using color to indicate the value of the score. Some rows are clearly darker, indicating overall lower scores for the sum-

[1]The Kruskal-Wallis test performs a one-way analysis of variance of document-set differences after first converting the summary scores for each sample to their ranks within the pooled sample. Computed from the converted scores, the Kruskal-Wallis test statistic is essentially the ratio of the between-group sum of squares to the combined within-group sum of squares.

maries of these documents, and the variances of the scores differ row-by-row. These plots show qualitatively what the non-parametric analysis of variance demonstrates statistically. While the data presented was for the TAC 2010 update document sets, similar results hold for all the TAC 2008, 2009, and 2010 data. Hence, it may be advantageous to measure summarizer quality by accounting for heterogeneity of documents within each test set. A non-parametric paired test like the Wilcoxon signed-rank is one way to do this. Another way would be paired t-tests.

In the paper (Conroy and Dang, 2008) the authors noted that while there is a significant gap in performance between machine systems and human summarizers when measured by average manual metrics, this gap is not present when measured by the averages of the best automatic metric (ROUGE). In particular, in the DUC 2005-2007 data some systems have ROUGE performance within the 95% confidence intervals of several human summarizers, but their pyramid, linguistic, and responsiveness scores do not achieve this level of performance. Thus, the inexpensive automatic metrics, as currently employed, do not predict well how machine summaries compare to human summaries.

In this work we explore the use of document-paired testing for summarizer comparison. Our main approach is to consider each pair of two summarizers' sets of scores (over all documents) as a balanced two-sample dataset, and to assess that pair's mean difference in scores through a two-sample T or Wilcoxon test, paired or unpaired. Our goal has been to confirm that human summarizer scores are uniformly different and better on average than machine summarizer scores, and to rate the quality of the statistical method (T or W, paired or unpaired) by the consistency with which the human versus machine scores show superior human performance. Our hope is that paired testing, using either the standard paired two-sample t-test or the distribution-free Wilcoxon signed-rank test, can provide greater power in the statistical analysis of automatic metrics such as ROUGE.

2 Size and Power of Tests

Statistical tests are generally compared by choosing rejection thresholds to achieve a certain small probability of Type I error (usually as $\alpha = .05$). Given multiple tests with the same Type I error, one prefers the test with the smallest probability of Type II error. Since power is defined to be one minus the Type II error probability, we prefer the test with the most power. Recall that a *test-statistic* S depending on available data-samples gives rise to a *rejection region* by defining rejection of the null hypothesis H_0 as the event $\{S \geq c\}$ for a *cutoff* or *rejection threshold* c chosen so that

$$P(S \geq c) \leq \alpha$$

for all probability laws compatible with the null hypothesis where the (nominal) *significance level* α is chosen in advance by the statistician, usually as $\alpha = .05$. However, in many settings, the null hypothesis comprises many possible probability laws, as here where the null hypothesis is that the underlying probability laws for the score-samples of two separate summarizers are equal, without specifying exactly what that probability distribution is. In this case, the significance level is an upper bound for the attained *size* of the test, defined as $\sup_{P \in H_0} P(S \geq c)$, the largest rejection probability $P(S \geq c)$ achieved by any probability law compatible with the null hypothesis. The power of the test then depends on the specific probability law Q from the considered alternatives in H_A. For each such Q, and given a threshold c, the power for the test at Q is the rejection probability $Q(S \geq c)$. These definitions reflect the fact that the null and alternative hypotheses are *composite*, that is, each consists of multiple probability laws for the data. One of the advantages of considering a *distribution-free* two-sample test statistic such as the Wilcoxon is that the probability distribution for the statistic S is then the same for all (continuous, or non-discrete) probability laws $P \in H_0$, so that one cutoff c serves for all of H_0 with all rejection probabilities equal to α. [2]

Two test statistics, say S and $\tilde{S}$, are generally compared in terms of their powers at fixed alternatives Q in the alternative hypothesis H_A, when their respective thresholds c, c^* have been defined so that the sizes of the respective tests, $\sup_{P \in H_0} P(S \geq$

[2] The Wilcoxon test is not distribution-free for discrete data. However, the discrete TAC data can be thought of as rounded continuous data, rather than as truly discrete data.

c) and $\sup_{P \in H_0} P(\tilde{S} \geq c^*)$, are approximately equal. In this paper, the test statistics under consideration are – in one-sided testing — the (unpaired) two-sample t test with pooled sample variance (T), the paired two-sample t test (T^p), and the (paired) signed-rank Wilcoxon test (W); and for two-sided testing, S is defined by the absolute value of one of these statistics. The thresholds c for the tests can be defined either by theoretical distributions, by large-sample approximations, or by data-resampling (*bootstrap*) techniques, and (only) in the last case are these thresholds data-dependent, or random. We explain these notions with respect to the two-sample data-structure in which the scores from the first summarizer are denoted $X_1, \ldots, X_n$, where n is the number of documents with non-missing scores for both summarizers, and the scores from the second summarizer are $Y_1, \ldots, Y_n$. Let $Z_k = X_k - Y_k$ denote the document-wise differences between the summarizers' scores, and $\bar{Z} = n^{-1} \sum_{k=1}^{n} Z_k$ be their average. Then the paired statistics are defined as

$$T^p = \sqrt{n(n-1)}\, \bar{Z} / (\sum_{k=1}^{n} (Z_k - \bar{Z})^2)^{1/2}$$

and

$$W = \sum_{k=1}^{n} \mathrm{sgn}(Z_k)\, R_k^+$$

where R_k^+ is the rank of $|Z_k|$ among $|Z_1|, \ldots, |Z_n|$. Note that under both null and alternative hypotheses, the variates Z_k are assumed independent identically distributed (*iid*), while under H_0, the random variables Z_k are symmetric about 0.

The t-statistic T^p is 'parametric' in the sense that exact theoretical calculations of probabilities $P(a < T^p < b)$ depend on the assumption of normality of the differences Z_k, and when that holds, the two-sided cutoff $c = c(T^p)$ is defined as the $1 - \alpha/2$ quantile of the t_{n-1} distribution with $n - 1$ degrees of freedom. However, when n is moderately or very large, the cutoff is well approximated by the standard-normal $1 - \alpha/2$ quantile $z_{\alpha/2}$, and T^p becomes approximately nonparametrically valid with this cutoff, by the Central Limit Theorem. The Wilcoxon signed-rank statistic W has theoretical cutoff $c = c(W)$ which depends only on n, whenever the data Z_k are continuously distributed; but for large n, the cutoff is given simply as $\sqrt{n^3/12} \cdot z_{\alpha/2}$. When there are ties (as might be common in discrete data), the calculation of cutoffs and p-values for Wilcoxon becomes slightly more complicated and is no longer fully nonparametric except in a large-sample approximate sense.

The situation for the two-sample unpaired t-statistic T currently used in TAC evaluation is not so neat. Even when the two samples $\mathbf{X} = \{X_k\}_{k=1}^n$ and $\mathbf{Y} = \{Y_k\}_{k=1}^n$ are independent, exact theoretical distribution of cutoffs is known only under the parametric assumption that the scores are normally distributed (and in the case of the pooled-sample-variance statistic, that $\mathrm{Var}(X_k) = \mathrm{Var}(Y_k)$.) However, an essential element of the summarization data is the heterogeneity of documents. This means that while $\{X_k\}_{k=1}^n$ can be viewed as *iid* scores when documents are selected randomly – and not necessarily equiprobably – from the ensemble of all possible documents, the Y_k and X_k samples are *dependent*. Still, the pairs $\{(X_k, Y_k)\}_{k=1}^n$, and therefore the differences $\{Z_k\}_{k=1}^n$, are *iid* which is what makes paired testing valid. However, there is no theoretical distribution for T from which to calculate valid quantiles c for cutoffs, and therefore the use of the unpaired t-statistic cannot be recommended for TAC evaluation.

What can be done in a particular dataset, like the TAC summarization score datsets we consider, to ascertain the approximate validity of theoretically derived large-sample cutoffs for test statistics? In the age of plentiful and fast computers, quite a lot, through the powerful computational machinery of the *bootstrap* (Efron and Tibshirani, 1993).

The idea of bootstrap hypothesis testing (Efron and Tibshirani, 1993), (Bickel and Ren, 2001) is to randomly sample with replacement (the rows with non-missing data in) the dataset $\{(X_k, Y_k)\}_{k=1}^n$ in such a way as to generate representative data that plausibly *would* have been seen if two-sample score data had been generated from two equally effective summarizers with score distributional characteristics like the pooled scores from the two observed summarizers. We have done this in two distinct ways, each creating 2000 datasets with n paired scores:

MC *Monte Carlo Method.* For each of many it-

erations (in our case 2000), define a new dataset $\{(X'_k, Y'_k)\}_{k=1}^n$ by independently swapping X_k and Y_k with probability $1/2$. Hence, $(X'_k, Y'_k) = (X_k, Y_k)$ with probability $1/2$ and (Y_k, X_k) with probability $1/2$.

HB *Hybrid MC/Bootstrap.* For each of 2000 iterations, create a re-sampled dataset $\{(X''_k, Y''_k)\}_{k=1}^n$ in the following way. First, sample n pairs (X_k, Y_k) with replacement from the original dataset. Then, as above, randomly swap the components of each pair, each with $1/2$ probability.

Both of these two methods can be seen to generate two-sample data satisfying H_0, with each score-sample's distribution obtained as a mixture of the distributions actually generating the **X** and **Y** samples. The *empirical* q^{th} *quantiles* for a statistic $S = S(\mathbf{X}, \mathbf{Y})$ such as $|W|$ or $|T^p|$ are estimated from the resampled data as $\hat{F}_S^{-1}(q)$, where $\hat{F}_S(t)$ is simply the fraction of times (out of 2000) that the statistic S applied to the constructed dataset had a value less than or equal to t. The upshot is that the $1-\alpha$ empirical quantile for S based on either of these simulation methods serves as a data-dependent cutoff c attaining approximate size α for all H_0-generated data. The MC and HB methods will be employed in Section 4 to check the theoretical p-values.

3 Relative Efficiency of W versus T^p

Statistical theory does have something to say about the comparative powers of paired W versus T^p statistics. These statistics have been studied (Randles and Wolfe, 1979), in terms of their *asymptotic relative efficiency* for location-shift alternatives based on symmetric densities ($f(z-\vartheta)$ is a location-shift of $f(z)$). For many pairs of parametric and rank-based statistics $S, \tilde{S}$, including W and T^p, the following assertion has been proved for testing H_0 at significance level α.

First assume the Z_k are distributed according to some density $f(z-\vartheta)$, where $f(z)$ is a symmetric function ($f(-z) = f(z)$). Next assume $\vartheta = 0$ under H_0. When n gets large the powers at any alternatives with very small $\vartheta = \gamma/\sqrt{n},\ \gamma \neq 0$, can be made asymptotically equal by using samples of size n with statistic S and of size $\rho \cdot n$ with statistic $\tilde{S}$. Here $\rho = ARE(S, \tilde{S})$ is a constant not depending on n or γ but definitely depending on f, called *asymptotic relative efficiency* of S with respect to $\tilde{S}$. (The smaller $\rho < 1$ is, the more statistic $\tilde{S}$ is preferred among the two.)

Using this definition, it is known (Randles and Wolfe 1979, Sec. 5.4 leading up to Table 5.4.7 on p. 167) that the Wilcoxon signed-rank statistic W provides greater robustness and often much greater efficiency than the paired T, with ARE which is 0.95 with f a standard normal density, and which is never less than 0.864 for any symmmetric density f. However, in our context, continuous scores such as pyramid exhibit document-specific score differences between summarizers which often have approximately normal-looking histograms, and although the alternatives perhaps cannot be viewed as pure location shifts, it is unsurprising in view of the ARE theory cited above that the W and T paired tests have very similar performance. Nevertheless, as we found by statistical analysis of the TAC data, both are far superior to the unpaired T-statistic, with either theoretical or empirical bootstrapped p-values.

4 Testing Setup and Results

To evaluate our ideas, we used the TAC data from 2008-2010 and focused on three manual metrics (overall responsiveness, pyramid score, and linguistic quality score) and two automatic metrics (ROUGE-2 and ROUGE-SU4). We make the assumption, backed by both the scores given and comments made by NIST summary assessors [3], that automatic summarization systems do not perform at the human level of performance. As such, if a statistic based on an automatic metric, such as ROUGE-2, were to show fewer systems performing at human level of performance than the statistic of averaging scores, such a statistic would be preferable because

[3] Assessors have commented privately at the Text Analysis Conference 2008, that while the origin of the summary is hidden from them, "we know which ones are machine generated." Thus, automatic summarization fails the Turing test of machine intelligence (Turing, 1950). This belief is also supported by (Conroy and Dang, 2008) and (Dang and Owczarzak, 2008). Finally, our own results show no matter how you compare human and machine scores all machines systems score significantly worse than humans.

Table 2: Number of significant differences resulting from $8 \times (N - 8)$ tests for human-machine system means or signed-rank comparisons.

of its greater power in the machine vs. human summarization domain.

For each of these metrics, we first created a score matrix whose (i, j)-entry represents the score for summarizer j on document set i (these matrices generated the colorplots in Figures 2 – 5). We then performed a Wilcoxon signed-rank test on certain pairs of columns of this matrix (any pair consisting of one machine system and one human summarizer). As a baseline, we did the same testing with a paired and an unpaired t-test. Each of these tests resulted in a p-value, and we counted how many were less than .05 and called these the significant differences.

The results of these tests (shown in Table 2), were somewhat surprising. Although we expected the nonparametric signed-rank test to perform better than an unpaired t-test, we were surprised to see that a paired t-test performed even better. All three tests always reject the null hypotheses when human metrics are used. This is what we'd like to happen with automatic metrics as well. As seen from the table, the paired t-test and Wilcoxon signed-rank test offer a good improvement over the unpaired t-test.

The results in Table 1 are less clear, but still positive. In this case, we are comparing pairs of machine summarization systems. In contrast to the human vs. machine case, we do not know the truth here. However, since the number of significant differences increases with paired testing here as well, we believe this also reflects the greater discriminatory power of paired testing.

We now apply the Monte Carlo and Hybrid Monte Carlo to check the theoretical p-values reported in Tables 1 and 2. The empirical quantiles found by these methods generally confirm the theoretical p-value test results reported there, especially in Table 2. In the overall tallies of all comparisons (Table 1), it seems that the bootstrap results (comparing only W and the un-paired T) make W look still stronger for linguistic and overall responsiveness versus the T; but for the pyramid and ROUGE scores, the bootstrap p-values bring T slightly closer to W although it still remains clearly inferior, achieving roughly 10% fewer rejections.

5 Conclusions and Future Work

In this paper we observed that summarization systems' performance varied significantly across document sets on the Text Analysis Conference (TAC) data. This variance in performance suggested that paired testing may be more appropriate than the t-test currently employed at TAC to compare the

performance of summarization systems. We proposed a non-parametric test, the Wilcoxon signed-rank test, as a robust more powerful alternative to the t-test. We estimated the statistical power of the t-test and the Wilcoxon signed-rank test by calculating the number of machine systems whose performance was significantly different than that of human summarizers. As human assessors score machine systems as not achieving human performance in either content or responsiveness, automatic metrics such as ROUGE should ideally indicate this distinction. We found that the paired Wilcoxon test significantly increases the number of machine systems that score significantly different than humans when the pairwise test is performed on ROUGE-2 and ROUGE-SU4 scores. Thus, we demonstrated that the Wilcoxon paired test shows more statistical power than the t-test for comparing summarization systems.

Consequently, the use of paired testing should not only be used in formal evaluations such as TAC, but also should be employed by summarization developers to more accurately assess whether changes to an automatic system give rise to improved performance.

Further study needs to analyze more summarization metrics such as those proposed at the recent NIST evaluation of automatic metrics, Automatically Evaluating Summaries of Peers (AESOP) (Nat, 2010). As metrics become more sophisticated and aim to more accurately predict human judgements such as overall responsiveness and linguistic quality, paired testing seems likely to be a more powerful statistical procedure than the unpaired t-test for head-to-head summarizer comparisons.

Throughout our research in this paper, we treated each separate kind of scores on a document set as data for one summarizer to be compared with the same kind of scores for other summarizers. However, it might be more fruitful to treat *all* the scores as multivariate data and compare the summarizers that way. Multivariate statistical techniques such as Principal Component Analysis may play a constructive role in suggesting highly discriminating new composite scores, perhaps leading to statistics with even more power to measure a summary's quality.

ROUGE was inspired by the success of the BLEU (BiLingual Evaluation Understudy), an n-gram based evaluation for machine translation (Papineni et al., 2002). It is likely that paired testing may also be appropriate for BLEU as well and will give additional discriminating power between machine translations and human translations.

Quasi-Synchronous Phrase Dependency Grammars for Machine Translation

Kevin Gimpel Noah A. Smith
Language Technologies Institute
Carnegie Mellon Univeristy
Pittsburgh, PA 15213, USA
{kgimpel,nasmith}@cs.cmu.edu

Abstract

We present a quasi-synchronous dependency grammar (Smith and Eisner, 2006) for machine translation in which the leaves of the tree are *phrases* rather than words as in previous work (Gimpel and Smith, 2009). This formulation allows us to combine structural components of phrase-based and syntax-based MT in a single model. We describe a method of extracting phrase dependencies from parallel text using a target-side dependency parser. For decoding, we describe a coarse-to-fine approach based on lattice dependency parsing of phrase lattices. We demonstrate performance improvements for Chinese-English and Urdu-English translation over a phrase-based baseline. We also investigate the use of *unsupervised* dependency parsers, reporting encouraging preliminary results.

1 Introduction

Two approaches currently dominate statistical machine translation (MT) research. Phrase-based models (Koehn et al., 2003) excel at capturing local reordering phenomena and memorizing multi-word translations. Models that employ syntax or syntax-like representations (Chiang, 2005; Galley et al., 2006; Zollmann and Venugopal, 2006; Huang et al., 2006) handle long-distance reordering better than phrase-based systems (Auli et al., 2009) but often require constraints on the formalism or rule extraction method in order to achieve computational tractability. As a result, certain instances of syntactic divergence are more naturally handled by phrase-based systems (DeNeefe et al., 2007).

In this paper we present a new way of combining the advantages of phrase-based and syntax-based MT. We propose a model in which phrases are organized into a tree structure inspired by dependency syntax. Instead of standard dependency trees in which *words* are vertices, our trees have *phrases* as vertices. We describe a simple heuristic to extract phrase dependencies from an aligned parallel corpus parsed on the target side, and use them to compute target-side tree features. We define additional string-to-tree features and, if a source-side dependency parser is available, tree-to-tree features to capture properties of how phrase dependencies interact with reordering.

To leverage standard phrase-based features alongside our novel features, we require a formalism that supports flexible feature combination and efficient decoding. Quasi-synchronous grammar (QG) provides this backbone (Smith and Eisner, 2006); we describe a coarse-to-fine approach for decoding within this framework, advancing substantially over earlier QG machine translation systems (Gimpel and Smith, 2009). The decoder involves generating a phrase lattice (Ueffing et al., 2002) in a coarse pass using a phrase-based model, followed by lattice dependency parsing of the phrase lattice. This approach allows us to feasibly explore the combined search space of segmentations, phrase alignments, and target phrase dependency trees.

Our experiments demonstrate an average improvement of +0.65 BLEU in Chinese-English translation across three test sets and an improvement of +0.75 BLEU in Urdu-English translation over a phrase-based baseline. We also describe experiments in which we replace supervised dependency parsers with *unsupervised* parsers, reporting promising results: using a supervised Chinese parser and a state-of-the-art unsupervised English parser provides our best results, giving an averaged gain of +0.79 BLEU over the baseline. We also discuss how our model improves translation quality and discuss future possibilities for combining approaches to ma-

chine translation using our framework.

2 Related Work

We previously applied quasi-synchronous grammar to machine translation (Gimpel and Smith, 2009), but that system performed translation fundamentally at the word level. Here we generalize that model to function on phrases, enabling a tighter coupling between the phrase segmentation and syntactic structures. We also present a decoder efficient enough to scale to large data sets and present performance improvements in large-scale experiments over a state-of-the-art phrase-based baseline.

Aside from QG, there have been many efforts to use dependency syntax in machine translation. Quirk et al. (2005) used a source-side dependency parser and projected automatic parses across word alignments in order to model dependency syntax on phrase pairs. Shen et al. (2008) presented an extension to Hiero (Chiang, 2005) in which rules have target-side dependency syntax and therefore enable the use of a dependency language model.

More recently, researchers have sought the benefits of dependency syntax while preserving the advantages of phrase-based models, such as efficiency and coverage. Galley and Manning (2009) loosened standard assumptions about dependency parsing so that the efficient left-to-right decoding procedure of phrase-based translation could be retained while a dependency language model is incorporated. Carreras and Collins (2009) presented a string-to-dependency system that permits non-projective dependency trees (thereby allowing a larger space of translations) and use a rule extraction procedure that includes rules for every phrase in the phrase table.

We take an additional step in this direction by working with dependency grammars on the phrases themselves, thereby bringing together the structural components of phrase-based and dependency-based MT in a single model. While others have worked on combining rules from multiple syntax-based systems (Liu et al., 2009) or using posteriors from multiple models to score translations (DeNero et al., 2010), we are not aware of any other work that seeks to directly integrate phrase-based and syntax-based machine translation at the modeling level.[1]

[1]Dymetman and Cancedda (2010) present a formal analysis of the problem of intersecting phrase-based and hierarchical translation models, but do not provide experimental results.

3 Model

Given a sentence $\boldsymbol{s}$ and its dependency tree $\tau_{\boldsymbol{s}}$, we formulate the translation problem as finding the target sentence $\boldsymbol{t}^*$, the segmentation $\boldsymbol{\gamma}^*$ of $\boldsymbol{s}$ into phrases, the segmentation $\boldsymbol{\phi}^*$ of $\boldsymbol{t}^*$ into phrases, the dependency tree $\tau^*_{\boldsymbol{\phi}}$ on the target phrases $\boldsymbol{\phi}^*$, and the one-to-one phrase alignment $\boldsymbol{a}^*$ such that

$$\langle \boldsymbol{t}^*, \boldsymbol{\gamma}^*, \boldsymbol{\phi}^*, \tau^*_{\boldsymbol{\phi}}, \boldsymbol{a}^* \rangle = \operatorname*{argmax}_{\langle \boldsymbol{t}, \boldsymbol{\gamma}, \boldsymbol{\phi}, \tau_{\boldsymbol{\phi}}, \boldsymbol{a} \rangle} p(\boldsymbol{t}, \boldsymbol{\gamma}, \boldsymbol{\phi}, \tau_{\boldsymbol{\phi}}, \boldsymbol{a} \,|\, \boldsymbol{s}, \tau_{\boldsymbol{s}})$$

We use a linear model (Och and Ney, 2002):

$$p(\boldsymbol{t}, \boldsymbol{\gamma}, \boldsymbol{\phi}, \tau_{\boldsymbol{\phi}}, \boldsymbol{a} \mid \boldsymbol{s}, \tau_{\boldsymbol{s}}) \propto \exp\{\boldsymbol{\theta}^\top \boldsymbol{g}(\boldsymbol{s}, \tau_{\boldsymbol{s}}, \boldsymbol{t}, \boldsymbol{\gamma}, \boldsymbol{\phi}, \tau_{\boldsymbol{\phi}}, \boldsymbol{a})\}$$

where $\boldsymbol{g}$ is a vector of arbitrary feature functions on the full set of structures and $\boldsymbol{\theta}$ holds corresponding feature weights. Table 1 summarizes our notation.

In modeling $p(\boldsymbol{t}, \boldsymbol{\gamma}, \boldsymbol{\phi}, \tau_{\boldsymbol{\phi}}, \boldsymbol{a} \mid \boldsymbol{s}, \tau_{\boldsymbol{s}})$, we make use of **quasi-synchronous grammar** (QG; Smith and Eisner, 2006). Given a source sentence and its parse, a QG induces a probabilistic monolingual grammar over sentences "inspired" by the source sentence and tree. We denote this grammar by $G_{\boldsymbol{s},\tau_{\boldsymbol{s}}}$; its (weighted) language is the set of translations of $\boldsymbol{s}$.

Quasi-synchronous grammar makes no restrictions on the form of the target monolingual grammar, though dependency grammars have been used in most previous applications of QG (Wang et al., 2007; Das and Smith, 2009; Smith and Eisner, 2009), including previous work in MT (Smith and Eisner, 2006; Gimpel and Smith, 2009). We previously presented a word-based machine translation model based on a quasi-synchronous dependency grammar. However, it is well-known in the MT community that translation quality is improved when larger units are modeled. Therefore, we use a dependency grammar in which the leaves are *phrases* rather than words.

We define a **phrase dependency grammar** as a model $p(\boldsymbol{\phi}, \tau_{\boldsymbol{\phi}} | \boldsymbol{t})$ over the joint space of segmentations of a sentence into phrases and dependency trees on the phrases.[2] Phrase dependency grammars

[2]We restrict our attention to projective trees in this paper, but the generalization to non-projective trees is easily made.

$\boldsymbol{s} = \langle s_1, \ldots, s_n \rangle$	source language sentence
$\boldsymbol{t} = \langle t_1, \ldots, t_m \rangle$	target language sentence, translation of $\boldsymbol{s}$
$\boldsymbol{\gamma} = \langle \gamma_1, \ldots, \gamma_{n'} \rangle$ $\forall i, \gamma_i = \langle s_j, \ldots, s_k \rangle$ s.t. $\gamma_1 \cdot \ldots \cdot \gamma_{n'} = \boldsymbol{s}$	segmentation of $\boldsymbol{s}$ into phrases
$\boldsymbol{\phi} = \langle \phi_1, \ldots, \phi_{m'} \rangle$ $\forall i, \phi_i = \langle t_j, \ldots, t_k \rangle$ s.t. $\phi_1 \cdot \ldots \cdot \phi_{m'} = \boldsymbol{t}$	segmentation of $\boldsymbol{t}$ into phrases
$\tau_{\boldsymbol{s}} : \{1, \ldots, n\} \rightarrow \{0, \ldots, n\}$	dependency tree on source words $\boldsymbol{s}$, where $\tau_{\boldsymbol{s}}(i)$ is the index of the parent of word s_i (0 is the root, \$)
$\tau_{\boldsymbol{\phi}} : \{1, \ldots, m'\} \rightarrow \{0, \ldots, m'\}$	dependency tree on target phrases $\boldsymbol{\phi}$, where $\tau_{\boldsymbol{\phi}}(i)$ is the index of the parent of phrase ϕ_i
$\boldsymbol{a} : \{1, \ldots, m'\} \rightarrow \{1, \ldots, n'\}$	one-to-one alignment from phrases in $\boldsymbol{\phi}$ to phrases in $\boldsymbol{\gamma}$
$\boldsymbol{\theta} = \langle \boldsymbol{\lambda}, \boldsymbol{\psi} \rangle$	parameters of the full model ($\boldsymbol{\lambda}$ = phrase-based, $\boldsymbol{\psi}$ = QPDG)

Table 1: Key notation.

have recently been used by Wu et al. (2009) for feature extraction for opinion mining. When used for translation modeling, they allow us to capture phenomena like local reordering and idiomatic translations within each phrase as well as long-distance relationships among the phrases in a sentence.

We then define a **quasi-synchronous phrase dependency grammar** (QPDG) as a conditional model $p(\boldsymbol{t}, \boldsymbol{\gamma}, \boldsymbol{\phi}, \tau_{\boldsymbol{\phi}}, \boldsymbol{a} \mid \boldsymbol{s}, \tau_{\boldsymbol{s}})$ that induces a probabilistic monolingual phrase dependency grammar over sentences inspired by the source sentence and (lexical) dependency tree. The source and target sentences are segmented into phrases and the phrases are aligned in a one-to-one alignment.

We note that we actually depart here slightly from the original definition of QG. The alignment variable in QG links target tree nodes to source tree nodes. However, we never commit to a source phrase dependency tree, instead using a source lexical dependency tree output by a dependency parser, so our alignment variable $\boldsymbol{a}$ is a function from target tree nodes (phrases in $\boldsymbol{\phi}$) to source phrases in $\boldsymbol{\gamma}$, which might not be source tree nodes. The features in our model may consider a large number of source phrase dependency trees as long as they are consistent with $\tau_{\boldsymbol{s}}$.

4 Features

Our model contains all of the standard phrase-based features found in systems like Moses (Koehn et al., 2007), including four phrase table probability features, a phrase penalty feature, an n-gram language model, a distortion cost, six lexicalized reordering features, and a word penalty feature.

We now describe in detail the additional features in our model that are used to score phrase dependency trees. We shall refer to these as QPDG features and will find it useful later to notationally distinguish their feature weights from those of the phrase-based model. We use $\boldsymbol{\lambda}$ for weights of the standard phrase-based model features and $\boldsymbol{\psi}$ for weights of the QPDG features. We include three categories of features, differentiated by what pieces of structure they consider.

4.1 Target Tree Features

We first include features that only consider $\boldsymbol{t}$, $\boldsymbol{\phi}$, and $\tau_{\boldsymbol{\phi}}$. These features can be categorized as "syntactic language model" features (Shen et al., 2008; Galley and Manning, 2009), though unlike previous work our features model both the phrase segmentation and dependency structure. Typically, these sorts of features are probabilities estimated from a corpus parsed using a supervised parser. However, there do not currently exist treebanks with annotated phrase

dependency trees.

Our solution is to use a standard supervised dependency parser and extract phrase dependencies using bilingual information.[3] We begin by obtaining symmetrized word alignments and extracting phrase pairs using the standard heuristic from phrase-based MT (Koehn et al., 2003). Given the set of extracted phrase pairs for a sentence, denote by W the set of unique target-side phrases among them. We parse the target sentence with a dependency parser and, for each pair of phrases $u, v \in W$, we extract a phrase dependency (along with its direction) if u and v do not overlap and there is at least one lexical dependency between a word in u and a word in v. If there are lexical dependencies in both directions, we extract a phrase dependency only for the single longest one. Since we use a projective dependency parser, the longest lexical dependency between two phrases is guaranteed to be unique. Table 2 shows a listing of the most frequent phrase dependencies extracted (lexical dependencies are omitted).

We note that during training we never explicitly commit to any single phrase dependency tree for a target sentence. Rather, we extract phrase dependencies from all phrase dependency trees consistent with the word alignments and the lexical dependency tree. Thus we treat phrase dependency trees analogously to phrase segmentations in standard phrase extraction.

We perform this procedure on all sentence pairs in the parallel corpus. Given a set of extracted phrase dependencies of the form $\langle u, v, d \rangle$, where u is the head phrase, v is the child phrase, and $d \in \{left, right\}$ is the direction, we then estimate conditional probabilities $p(v|u, d)$ using relative frequency estimation. Table 3 shows the most probable child phrases for an example parent phrase. To combat data sparseness, we perform the same procedure with each word replaced by its word cluster ID obtained from Brown clustering (Brown et al., 1992).

We include a feature in the model for the sum of the scaled log-probabilities of each attachment:

$$\sum_{i=1}^{m'} \max\left(0, C + \log p(\phi_i | \phi_{\tau_{\boldsymbol{\phi}}(i)}, d(i)\right) \quad (1)$$

where $d(i) = I[\tau_{\boldsymbol{\phi}}(i) - i > 0]$ is the direction of the dependency arc.

Although we use log-probabilities in this feature function, we first add a constant C to each to ensure they are all positive.[4] The $\max$ expression protects unseen parent-child phrase dependencies from causing the score to be negative infinity. Our motivation is a desire for the features to be used to prefer one derivation over another but not to rule out a derivation completely if it merely happens to contain a dependency unobserved in the training data.

We also include lexical weighting features similar to those used in phrase-based MT (Koehn et al., 2003). Whenever we extract a phrase dependency, we extract the longest lexical dependency contained within it. For all ⟨parent, child, direction⟩ lexical dependency tuples $\langle x, y, d \rangle$, we estimate conditional probabilities $p_{lex}(y|x, d)$ from the parsed corpus using relative frequency estimation. Then, for a phrase dependency with longest lexical dependency $\langle x, y, d \rangle$, we add a feature for $p_{lex}(y|x, d)$ to the model, using a formula similar to Eq. 1. Different instances of a phrase dependency may have different lexical dependencies extracted with them. We add the lexical weight for the most frequent, breaking ties by choosing the lexical dependency that maximizes $p(y|x, d)$, as was also done by Koehn et al. (2003).

In all, we include 4 target tree features: one for phrase dependencies, one for lexical dependencies,

[3] For a monolingual task, Wu et al. (2009) used a shallow parser to convert lexical dependencies from a dependency parser into phrase dependencies.

[4] The reasoning here is that whenever we use a phrase dependency that we have observed in the training data, we want to boost the score of the translation. If we used log-probabilities, each observed dependency would incur a penalty.

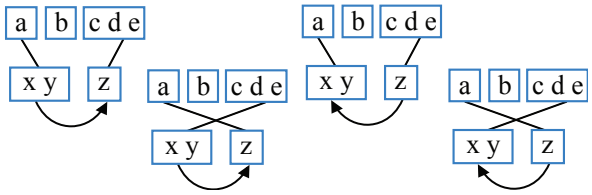

Figure 1: String-to-tree configurations; each is associated with a feature that counts its occurrences in a derivation.

Input: sentence $\boldsymbol{s}$, dependency parse $\tau_{\boldsymbol{s}}$, coarse parameters $\boldsymbol{\lambda}_M$, fine parameters $\langle \boldsymbol{\lambda}, \boldsymbol{\psi} \rangle$
Output: translation $\boldsymbol{t}$

$L_{\text{MERT}} \leftarrow \texttt{GenerateLattices}\,(\boldsymbol{s}, \boldsymbol{\lambda}_M)$;
$L_{\text{FB}} \leftarrow \texttt{FBPrune}\,(L_{\text{MERT}}, \boldsymbol{\lambda}_M)$;
$\langle \boldsymbol{t}, \boldsymbol{\gamma}, \boldsymbol{\phi}, \tau_{\boldsymbol{\phi}}, \boldsymbol{a} \rangle \leftarrow \text{QGDepParse}(L_{\text{FB}}, \langle \boldsymbol{\lambda}, \boldsymbol{\psi} \rangle)$;
return $\boldsymbol{t}$;

Algorithm 1: `CoarseToFineDecode`

and the same features computed from a transformed version of the corpus in which each word is replaced by its Brown cluster.

4.2 String-to-Tree Configurations

We consider features that count instances of reordering configurations involving phrase dependencies. In addition to the target-side structures, these features consider $\boldsymbol{\gamma}$ and $\boldsymbol{a}$, though not $\boldsymbol{s}$ or $\tau_{\boldsymbol{s}}$. For example, when building a parent-child phrase dependency with the child to the left, one feature value is incremented if their aligned source-side phrases are in the same order. This configuration is the leftmost in Fig. 1; we include features for the other three configurations there as well, for a total of 4 features in this category.

4.3 Tree-to-Tree Configurations

We include features that consider $\boldsymbol{s}$, $\boldsymbol{\gamma}$, and $\tau_{\boldsymbol{s}}$ in addition to $\boldsymbol{t}$, $\boldsymbol{\phi}$, and $\tau_{\boldsymbol{\phi}}$. We begin with features for each of the quasi-synchronous configurations from Smith and Eisner (2006), adapted to phrase dependency grammars. That is, for a parent-child pair $\langle \tau_{\boldsymbol{\phi}}(i), i \rangle$ in $\tau_{\boldsymbol{\phi}}$, we consider the relationship between $\boldsymbol{a}(\tau_{\boldsymbol{\phi}}(i))$ and $\boldsymbol{a}(i)$, the source-side phrases to which $\tau_{\boldsymbol{\phi}}(i)$ and i align. We use the following named configurations from Smith and Eisner: root-root, parent-child, child-parent, grandparent-grandchild, sibling, and c-command.[5] We define a feature to count instances of each of these configurations, including an additional feature for "other" configurations that do not fit into these categories.[6]

When using a QPDG, there are multiple ways to compute tree-to-tree configuration features, since we use a phrase dependency tree for the target side, a lexical dependency tree for the source side, and a phrase alignment. We use the following heuristic approach. Given a pair of source words, one with index j in source phrase $\boldsymbol{a}(\tau_{\boldsymbol{\phi}}(i))$ and the other with index k in source phrase $\boldsymbol{a}(i)$, we have a parent-child configuration if $\tau_{\boldsymbol{s}}(k) = j$; if $\tau_{\boldsymbol{s}}(j) = k$, a child-parent configuration is present. In order for the grandparent-grandchild configuration to be present, the intervening parent word must be outside both phrases. For sibling and other c-command configurations, the shared parent or ancestor must also be outside both phrases.

After obtaining a list of all configurations present for each pair of words $\langle j, k \rangle$, we fire the feature for the single configuration corresponding to the maximum distance $|j - k|$. If no configurations are present between any pair of words, the "other" feature fires. Therefore, only one configuration feature fires for each phrase dependency attachment.

Finally, we include features that consider the dependency path distance between phrases in the source-side dependency tree that are aligned to parent-child pairs in $\tau_{\boldsymbol{\phi}}$. We include a feature that sums, for each target phrase i, the inverse of the minimum undirected path length between each word in $\boldsymbol{a}(i)$ and each word in $\tau_{\boldsymbol{\phi}}(\boldsymbol{a}(i))$. The minimum undirected path length is defined as the number of dependency arcs that must be crossed to travel from one word to the other in $\tau_{\boldsymbol{s}}$. We use one feature for undirected path length and one other for directed path length. If there is no (un)directed path from a word in $\boldsymbol{a}(i)$ to a word in $\tau_{\boldsymbol{\phi}}(\boldsymbol{a}(i))$, we use ∞ as the minimum length.

There are 15 features in this category, for a total of 23 QPDG features.

[5] See Fig. 3 in Smith and Eisner (2006) for illustrations.

[6] We actually include two versions of each configuration feature other than "root-root": one for the source phrases being in the same order as the target phrases and one for them being swapped.

5 Decoding

For a QPDG model, decoding consists of finding the highest-scoring tuple $\langle \boldsymbol{t}, \boldsymbol{\gamma}, \boldsymbol{\phi}, \tau_{\boldsymbol{\phi}}, \boldsymbol{a} \rangle$ for an input sentence $\boldsymbol{s}$ and its parse $\tau_{\boldsymbol{s}}$, i.e., finding the most probable derivation under the $\boldsymbol{s}/\tau_{\boldsymbol{s}}$-specific grammar $G_{\boldsymbol{s},\tau_{\boldsymbol{s}}}$. We follow Gimpel and Smith (2009) in constructing a lattice to represent $G_{\boldsymbol{s},\tau_{\boldsymbol{s}}}$ and using lattice parsing to search for the best derivation, but we construct the lattice differently and employ a coarse-to-fine strategy (Petrov, 2009) to speed up decoding.

It has become common in recent years for MT researchers to exploit efficient data structures for encoding concise representations of the pruned search space of the model, such as phrase lattices for phrase-based MT (Ueffing et al., 2002; Macherey et al., 2008; Tromble et al., 2008). Each edge in a phrase lattice corresponds to a phrase pair and each path through the lattice corresponds to a tuple $\langle \boldsymbol{t}, \boldsymbol{\gamma}, \boldsymbol{\phi}, \boldsymbol{a} \rangle$ for the input $\boldsymbol{s}$. Decoding for a phrase lattice consists of finding the highest-scoring path, which is done using dynamic programming. To also maximize over $\tau_{\boldsymbol{\phi}}$, we perform lattice dependency parsing, which allows us to search over the space of tuples $\langle \boldsymbol{t}, \boldsymbol{\gamma}, \boldsymbol{\phi}, \boldsymbol{a}, \tau_{\boldsymbol{\phi}} \rangle$. Given the lattice and $G_{\boldsymbol{s},\tau_{\boldsymbol{s}}}$, lattice parsing is a straightforward generalization of the standard arc-factored dynamic programming algorithm from Eisner (1996).

The lattice parsing algorithm requires $O(E^2V)$ time and $O(E^2 + VE)$ space, where E is the number of edges in the lattice and V is the number of nodes.[7] Typical phrase lattices might easily contain tens of thousands of nodes and edges, making exact search prohibitively expensive for all but the smallest lattices. So, we use approximate search based on coarse-to-fine decoding. We now discuss each step of this procedure; an outline is shown as Alg. 1.

Pass 1: Lattice Pruning After generating phrase lattices using a phrase-based MT system, we prune lattice edges using forward-backward pruning (Sixtus and Ortmanns, 1999), which has also been used in previous work using phrase lattices (Tromble et al., 2008). This pruning method computes the max-marginal for each lattice edge, which is the score of the best full path that uses that edge. Max-marginals offer the advantage that the best path in the lattice is preserved during pruning. For each lattice, we use a grid search to find the most liberal threshold that leaves fewer than 1000 edges in the resulting lattice. As complexity is quadratic in E, forcing E to be less than 1000 improves runtime substantially. After pruning, the lattices still contain more than 10^{16} paths on average and oracle BLEU scores are typically 12-15 points higher than the model-best paths.

Pass 2: Parent Ranking Given a pruned lattice, we then remove some candidate dependency arcs from consideration. It is common in dependency parsing to use a coarse model to rank the top k parents for each word, and to only consider these during parsing (Martins et al., 2009; Bergsma and Cherry, 2010). Unlike string parsing, our phrase lattices impose several types of constraints on allowable arcs. For example, each node in the phrase lattice is annotated with a coverage vector—a bit vector indicating which words in the source sentence have been translated—which implies a topological ordering of the nodes. To handle constraints like these, we first use the Floyd-Warshall algorithm (Floyd, 1962) to find the best score between every pair of nodes in the lattice. This algorithm also tells us whether each edge is reachable from each other edge, allowing us to immediately prune dependency arcs between edges that are unreachable from each other.

After eliminating impossible arcs, we turn to pruning away unlikely ones. In standard (string) dependency parsing, every word is assigned a parent. In lattice parsing, however, most lattice edges will not be assigned any parent. Certain lattice edges are much more likely to be contained within paths, so we allow some edges to have more candidate parent edges than others. We introduce hyperparameters α, β, and μ to denote, respectively, the minimum, maximum, and average number of parent edges to be considered for each lattice edge ($\alpha \leq \mu \leq \beta$). We rank the full set of E^2 arcs according to their scores (using the QPDG features and their weights $\boldsymbol{\psi}$) and choose the top μE of these arcs while ensuring that each edge has at least α and at most β potential parent edges.

This step reduces the time complexity from $O(E^2V)$ to $O(\mu EV)$, where $\mu < E$. In our experiments, we set $\mu = 300$, $\alpha = 100$, and $\beta = 400$.

[7] To prevent confusion, we use the term *edge* to refer to a phrase lattice edge and *arc* to refer to a parent-child dependency in the phrase dependency tree.

Input: tuning set $D = \langle S, T \rangle$, initial weights $\boldsymbol{\lambda}_0$ for coarse model, initial weights $\boldsymbol{\psi}_0$ for additional features in fine model
Output: coarse model learned weights: $\boldsymbol{\lambda}_M$, fine model learned weights: $\langle \boldsymbol{\lambda}^*, \boldsymbol{\psi}^* \rangle$

$\boldsymbol{\lambda}_M \leftarrow$ `MERT` (S, T, $\boldsymbol{\lambda}_0$, 100, MOSES);
$L_{\text{MERT}} \leftarrow$ `GenerateLattices` (S, $\boldsymbol{\lambda}_M$);
$L_{\text{FB}} \leftarrow$ `FBPrune` (L_{MERT}, $\boldsymbol{\lambda}_M$);
$\langle \boldsymbol{\lambda}^*, \boldsymbol{\psi}^* \rangle \leftarrow$
  `MERT` (L_{FB}, T, $\langle \boldsymbol{\lambda}_M, \boldsymbol{\psi}_0 \rangle$, 200, QGDEPPARSE);
return $\boldsymbol{\lambda}_M$, $\langle \boldsymbol{\lambda}^*, \boldsymbol{\psi}^* \rangle$;

Algorithm 2: `CoarseToFineTrain`

Pass 3: Lattice Dependency Parsing After completing the coarse passes, we parse using bottom-up dynamic programming based on the agenda algorithm (Nederhof, 2003; Eisner et al., 2005). We only consider arcs that survived the filtering in Pass 2. We weight agenda items by the sum of their scores and the Floyd-Warshall best path scores both from the start node of the lattice to the beginning of the item and the end of the item to any final node. This heuristic helps us to favor exploration of items that are highly likely under the phrase-based model.

If the score of the partial structure can only get worse when combining it with other structures (e.g., in a PCFG), then the first time that we pop an item of type GOAL from the agenda, we are guaranteed to have the best parse. However, in our model, some features are positive and others negative, making this property no longer hold; as a result, GOAL items may be popped out of order from the agenda. Therefore, we use an approximation, simply popping G GOAL items from the agenda and then stopping. The items are sorted by their scores and the best is returned by the decoder (or the k best in the case of MERT). In our experiments, we set $G = 4000$.

The combined strategy yields average decoding times in the range of 30 seconds per sentence, which is comparable to other syntax-based MT systems.

6 Training

For tuning the coarse and fine parameters, we use minimum error rate training (MERT; Och, 2003) in a procedure shown as Alg. 2. We first use MERT to train parameters for the coarse phrase-based model used to generate phrase lattices. Then, after generating the lattices, we prune them and run MERT a second time to tune parameters of the fine model, which includes all phrase-based and QPDG parameters. The arguments to `MERT` are a vector of source sentences (or lattices), a vector of target sentences, the initial parameter values, the size of the k-best list, and finally the decoder. We initialize $\boldsymbol{\lambda}$ to the default Moses feature weights and for $\boldsymbol{\psi}$ we initialize the two target phrase dependency weights to 0.004, the two lexical dependency weights to 0.001, and the weights for all configuration features to 0.0. Our training procedure requires two executions of MERT, and the second typically takes more iterations to converge (10 to 20 is typical) than the first due to the use of a larger feature set and increased possibility for search error due to the enlarged search space.

7 Experiments

For experimental evaluation, we consider Chinese-to-English (ZH-EN) and Urdu-to-English (UR-EN) translation and compare our system to Moses (Koehn et al., 2007). For ZH-EN, we used 303k sentence pairs from the FBIS corpus (LDC2003E14). We segmented the Chinese data using the Stanford Chinese segmenter in "CTB" mode (Chang et al., 2008), giving us 7.9M Chinese words and 9.4M English words. For UR-EN, we used parallel data from the NIST MT08 evaluation consisting of 1.2M Urdu words and 1.1M English words.

We trained a baseline Moses system using default settings and features. Word alignment was performed using GIZA++ (Och and Ney, 2003) in both directions and the `grow-diag-final-and` heuristic was used to symmetrize the alignments. We used a max phrase length of 7 when extracting phrases. Trigram language models were estimated using the SRI language modeling toolkit (Stolcke, 2002) with modified Kneser-Ney smoothing (Chen and Goodman, 1998). To estimate language models for each language pair, we used the English side of the parallel corpus concatenated with 200M words of randomly-selected sentences from the Gigaword v4 corpus (excluding the NY Times and LA Times).

We used this baseline Moses system to generate phrase lattices for our system, so our model includes all of the Moses features in addition to the

	MT03 (tune)	MT02	MT05	MT06	Average
Moses	33.84	33.35	31.81	28.82	31.33
QPDG (TT)	34.63 (+0.79)	34.10 (+0.75)	32.15 (+0.34)	29.33 (+0.51)	31.86 (+0.53)
QPDG (TT+S2T+T2T)	34.98 (+1.14)	34.26 (+0.91)	32.34 (+0.53)	29.35 (+0.53)	31.98 (+0.65)

Table 4: Chinese-English Results (% BLEU).

QPDG features described in §4. In our experiments, we compare our QPDG system (lattice parsing on each lattice) to the Moses baseline (finding the best path through each lattice). The conventional wisdom holds that hierarchical phrase-based translation (Chiang, 2005) performs better than phrase-based translation for language pairs that require large amounts of reordering, such as ZH-EN and UR-EN. However, researchers have shown that this performance gap diminishes when using a larger distortion limit (Zollmann et al., 2008) and may disappear entirely when using a lexicalized reordering model (Lopez, 2008; Galley and Manning, 2010). So, we increase the Moses distortion limit from 6 (the default) to 10 and use Moses' default lexicalized reordering model (Koehn et al., 2005).

We parsed the Chinese text using the Stanford parser (Levy and Manning, 2003) and the English text using TurboParser (Martins et al., 2009). We note that computing our features requires parsing the target (English) side of the parallel text, but not the source side. We only need to parse the source side of the tuning and test sets, and the only features that look at the source-side parse are those from §4.3.

To obtain Brown clusters for the target tree features in §4.1, we used code from Liang (2005).[8] We induced 100 clusters from the English side of the parallel corpus concatenated with 10M words of randomly-selected Gigaword sentences. Only words that appeared at least twice in this data were considered during clustering. An additional cluster was created for all other words; this allowed us to use phrase dependency cluster features even for out-of-vocabulary words. We used a max phrase length of 7 when extracting phrase dependencies to match the max phrase length used in phrase extraction. Approximately 87M unique phrase dependencies were extracted from the ZH-EN data and 7M from the UR-EN data.

We tuned the weights of our model using the procedure described in §6. For ZH-EN we used MT03 for tuning and MT02, MT05, and MT06 for testing. For UR-EN we used half of the documents (882 sentence pairs) from the MT08 test set for tuning ("Dev") and MT09 for testing. We evaluated translation output using case-insensitive IBM BLEU (Papineni et al., 2001).

	Dev (tune)	MT09
Moses	24.21	23.56
QPDG (TT+S2T)	24.94 (+0.73)	24.31 (+0.75)

Table 5: Urdu-English Results (% BLEU).

7.1 Results

Results for ZH-EN and UR-EN translation are shown in Tables 4 and 5. We show results when using only the target tree features from §4.1 (TT), as well as when adding the string-to-tree features from §4.2 (S2T) and the tree-to-tree features from §4.3 (T2T). We note that T2T features are unavailable for UR-EN because we do not have an Urdu parser. We find that we can achieve moderate but consistent improvements over the baseline Moses system, for an average increase of 0.65 BLEU points for ZH-EN and 0.75 for UR-EN.

Fig. 2 shows an example sentence from the MT05 test set along with its translation output and derivations produced by Moses and our QPDG system with the full feature set. This example shows the kind of improvements that our system makes. In Chinese, modifiers such as prepositional phrases and clauses are generally placed in front of the words they modify, frequently the opposite of English. In addition, Chinese occasionally uses postpositions where English uses prepositions. The Chinese sentence in Fig. 2 exhibits both of these, as the prepositional phrase "after the Palestinian election" appears before the verb "strengthen" in the Chinese sentence and "after" appears as a postposition. Moses (Fig. 2(a)) does not properly reorder the prepositional phrase, while our system (Fig. 2(b)) properly handles both reorderings.[9] We shall discuss these

[8] http://www.cs.berkeley.edu/~pliang/software

[9] Our system's derivation is not perfect, in that "in" is incor-

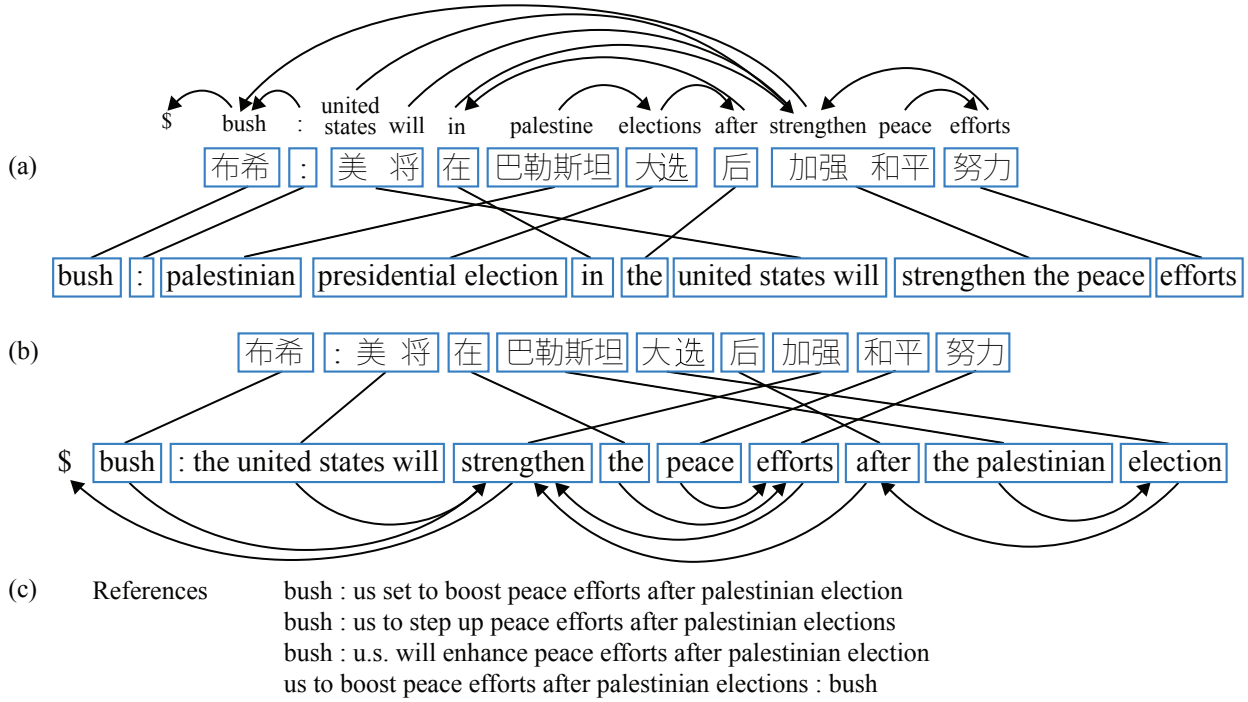

Figure 2: (a) Moses translation output along with γ, ϕ, and $\boldsymbol{a}$. An English gloss is shown above the Chinese sentence and above the gloss is shown the dependency parse from the Stanford parser. (b) QPDG system output with additional structure τ_{ϕ}. (c) reference translations.

types of improvements further in §8.

7.2 Unsupervised Parsing

Our results thus far use supervised parsers for both Chinese and English, but parsers are only available for a small fraction of the languages we would like to translate. Fortunately, unsupervised dependency grammar induction has improved substantially in recent years due to a flurry of recent research. While attachment accuracies on standard treebank test sets are still relatively low, it may be the case that even though unsupervised parsers do not match treebank annotations very well, they may perform well when used for extrinsic applications. We believe that syntax-based MT offers a compelling platform for development and extrinsic evaluation of unsupervised parsers.

In this paper, we use the standard dependency model with valence (DMV; Klein and Manning, 2004). When training is initialized using the output of a simpler, concave dependency model, the DMV can approach state-of-the-art unsupervised accuracy (Gimpel and Smith, 2011). For English, the resulting parser achieves 53.1% attachment accuracy on Section 23 of the Penn Treebank (Marcus et al., 1993), which approaches the 55.7% accuracy of a recent state-of-the-art unsupervised model (Blunsom and Cohn, 2010). The Chinese parser, initialized and trained the same way, achieves 44.4%, which is the highest reported accuracy on the Chinese Treebank (Xue et al., 2004) test set.

Most unsupervised grammar induction models assume gold standard POS tags and sentences stripped of punctuation. We use the Stanford tagger (Toutanova et al., 2003) to obtain tags for both English and Chinese, parse the sentences without punctuation using the DMV, and then attach punctuation tokens to the root word of the tree in a post-processing step. For English, the predicted parents agreed with those of TurboParser for 48.7% of the tokens in the corpus.

We considered all four scenarios: supervised and unsupervised English parsing paired with supervised and unsupervised Chinese parsing. Table 6 shows

rectly translated and reordered, but the system was nonetheless able to use it to improve the fluency of the output.

		EN	
		unsupervised	supervised
ZH	unsupervised	31.18 (33.76)	31.86 (34.78)
	supervised	**32.12** (34.74)	31.98 (34.98)
Moses		31.33 (33.84)	

Table 6: Results when using unsupervised dependency parsers. Cells contain averaged % BLEU on the three test sets and % BLEU on tuning data (MT03) in parentheses.

Feature	Initial	Learned
Left child, same order	9.0	8.9
Left child, swap phrases	1.1	0.0
Right child, same order	7.3	7.3
Right child, swap phrases	1.6	2.3
Root-root	0.4	0.8
Parent-child	4.2	6.1
Child-parent	1.2	0.4
Grandparent-grandchild	1.0	0.2
Sibling	2.4	1.9
C-command	6.1	6.7
Other	1.5	0.9

Table 7: Average feature values across best translations of sentences in the MT03 tuning set, both before MERT (column 2) and after (column 3). "Same" versions of tree-to-tree configuration features are shown; the rarer "swap" features showed a similar trend.

BLEU scores averaged over the three test sets with tuning data BLEU in parentheses. Surprisingly, we achieve our best results when using the unsupervised English parser in place of the supervised one (+0.79 over Moses), while keeping the Chinese parser supervised. Competitive performance is also found by using the unsupervised Chinese parser and supervised English parser (+0.53 over Moses).

However, when using unsupervised parsers for both languages, performance was below that of Moses. During tuning for this configuration, we found that MERT struggled to find good parameter estimates, typically converging to suboptimal solutions after a small number of iterations. We believe this is due to the large number of features (37), the noise in the parse trees, and known instabilities of MERT. In future work we plan to experiment with training algorithms that are more stable and that can handle larger numbers of features.

8 Analysis

To understand what our model learns during MER training, we computed the feature vectors of the best derivation for each sentence in the tuning data at both the start and end of tuning. Table 7 shows these feature values averaged across all tuning sentences. The first four features are the configurations from Fig. 1, in order from left to right. From these rows, we can observe that the model learns to encourage swapping when generating right children and penalize swapping for left children. In addition to objects, right children in English are often prepositional phrases, relative clauses, or other modifiers; as we noted above, Chinese generally places these modifiers before their heads, requiring reordering during translation. Here the model appears to be learning this reordering behavior.

From the second set of features, we see that the model learns to favor producing dependency trees that are mostly isomorphic to the source tree, by favoring root-root and parent-child configurations at the expense of most others.

9 Discussion

In looking at BLEU score differences between the two systems, the unigram precisions were typically equal or only slightly different, while precisions for higher-order n-grams contained the bulk of the improvement. This suggests that our system is not finding substantially better translations for individual words in the input, but rather is focused on reordering the existing translations. This is not surprising given our choice of features, which focus on syntactic language modeling and syntax-based reordering. The obvious next step for our framework is to include bilingual rules that include source syntax (Quirk et al., 2005), target syntax (Shen et al., 2008), and syntax on both sides. Our framework allows integrating together all of these and other types of structures, with the ultimate goal of combining the strengths of multiple approaches to translation in a single model.

Abstract

Preordering of source side sentences has proved to be useful in improving statistical machine translation. Most work has used a parser in the source language along with rules to map the source language word order into the target language word order. The requirement to have a source language parser is a major drawback, which we seek to overcome in this paper. Instead of using a parser and then using rules to order the source side sentence we learn a model that can directly reorder source side sentences to match target word order using a small parallel corpus with high-quality word alignments. Our model learns pairwise costs of a word immediately preceding another word. We use the Lin-Kernighan heuristic to find the best source reordering efficiently during training and testing and show that it suffices to provide good quality reordering.

We show gains in translation performance based on our reordering model for translating from Hindi to English, Urdu to English (with a public dataset), and English to Hindi. For English to Hindi we show that our technique achieves better performance than a method that uses rules applied to the source side English parse.

1 Introduction

Languages differ in the way they order words to produce sentences representing the same meaning. Machine translation systems need to reorder words in the source sentence to produce fluent output in the target language that preserves the meaning of the source sentence.

Current phrase based machine translation systems can capture short range reorderings via the phrase table. Even the capturing of these local reordering phenomena is constrained by the amount of training data available. For example, if adjectives precede nouns in the source language and follow nouns in the target language we still need to see a particular adjective noun pair in the parallel corpus to handle the reordering via the phrase table. Phrase based systems also rely on the target side language model to produce the right target side order. This is known to be inadequate (Al-Onaizan and Papineni, 2006), and this inadequacy has spurred various attempts to overcome the problem of handling differing word order in languages.

One approach is through distortion models, that try to model which reorderings are more likely than others. The simplest models just penalize long jumps in the source sentence when producing the target sentence. These models have also been generalized (Al-Onaizan and Papineni, 2006; Tillman, 2004) to allow for lexical dependencies on the source. While these models are simple, and can be integrated with the decoder they are insufficient to capture long-range reordering phenomena especially for language pairs that differ significantly.

The weakness of these simple distortion models has been overcome using syntax of either the source or target sentence (Yamada and Knight, 2002; Galley et al., 2006; Liu et al., 2006; Zollmann and Venugopal, 2006). While these methods have shown to be useful in improving machine translation perfor-

mance they generally involve joint parsing of the source and target language which is significantly more computationally expensive when compared to phrase based translation systems. Another approach that overcomes this weakness, is to to reorder the source sentence based on rules applied on the source parse (either hand written or learned from data) both when training and testing (Collins et al., 2005; Genzel, 2010; Visweswariah et al., 2010).

In this paper we propose a novel method for dealing with the word order problem that is efficient and does not rely on a source or target side parse being available. We cast the word ordering problem as a Traveling Salesman Problem (TSP) based on previous work on word-based and phrased-based statistical machine translation (Tillmann and Ney, 2003; Zaslavskiy et al., 2009). Words are the cities in the TSP and the objective is to learn the distance between words so that the shortest tour corresponds to the ordering of the words in the source sentence in the target language. We show that the TSP distances for reordering can be learned from a small amount of high-quality word alignment data by means of pairwise word comparisons and an informative feature set involving words and part-of-speech (POS) tags adapted and extended from prior work on dependency parsing (McDonald et al., 2005b). Obtaining high-quality word alignments that we require for training is fairly easy compared with obtaining a treebank required to obtain parses for use in syntax based methods.

We show experimentally that our reordering model, even when used to reorder sentences for training and testing (rather than being used as an additional score in the decoder) improves machine translation performance for: Hindi $\rightarrow$ English, English $\rightarrow$ Hindi, and Urdu $\rightarrow$ English. Although Urdu is similar to Hindi from the point of reordering phenomena we include it in our experiments since there are publicly available datasets for Urdu-English. For English $\rightarrow$ Hindi we obtained better machine translation performance with our reordering model as compared to a method that uses reordering rules applied to the source side parse.

The rest of the paper is organized as follows. Section 2 reviews related work and places our work in context. Section 3 outlines reordering issues due to syntactic differences between Hindi and English. Section 4 presents our reordering model, Section 5 presents experimental results and Section 6 presents our conclusions and possible future work.
