Abstract

Prior XAI research often assumes inputs must be ”causes” and outputs must be ”effects”, severely limiting applicability to analyzing behaviors that emerge as reactions or consequences. Many linguistic tasks, such as dialogues and conversations, involve such behaviors. To address this, we propose that the assumed causality from inputs to outputs can be reversed and still remain valid by using outputs that cause changes in features. We show how this enables analysis of complex feature sets through simpler metrics, propose a framework that is generalizable to most linguistic tasks, and highlight best practices for applying our framework. By training a predictive model from complex effects to simple causes, we apply feature attributions to estimate how the inputs change with the outputs. We demonstrate an application of this by studying sports fans' comments made during a game and compare those comments to a simpler metric, win probability. We also expand on a prior study of intergroup bias, demonstrating how our framework can uncover behaviors that other XAI methods may overlook. We discuss the implications of these findings for advancing interpretability in computational linguistics and improving data-driven-decision-making in social contexts.

1 Introduction

Explainable AI (XAI) techniques have proven a valuable tool for creating trustworthy and reliable models and have seen growing popularity as the need for transparency becomes more prevalent. Researchers across a range of disciplines (Kalasampath et al., 2025) have discovered that these techniques also have the potential to highlight important features and patterns (Fryer et al., 2021) in a dataset. This is most prevalent in biomedicine (Hossain et al., 2025) where finding important features can save lives. Such tasks assume a causal relationship (Doshi-Velez and Kim, 2017) where complex features directly result in a simple metric. In this paper, we show that the direction of causality in this assumption can be reversed by applying feature attribution techniques to a classifier that takes results as inputs and predicts the cause, as observed in 1 We show that these techniques are viable for finding causal assumptions in the opposite direction, even in difficult tasks.

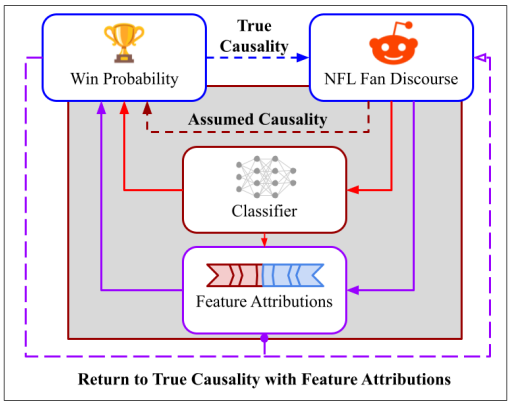

Figure 1: The proposed framework for evaluating the correlation between textual data and simple classifications like team performance. By assuming fan comments actually impact win probability, we can produce feature attributions for those comments to identify interesting behaviors. After we drop the assumed causality, we find that these attributions still accurately represent how win probability can influence fan behaviors.

Many forms of XAI share the perception that models must go from cause to effect (Carloni et al., 2025). The reasoning for this is clear in some applications, such as medical tools like risk analysis (Lundberg et al., 2018), where a limited set of features directly contribute to potential danger. However, models have been observed to learn correlation rather than causation (Molnar et al., 2020). This suggests a reversal of this framework is possible: Make a simple measurable task the 'predic-

Proceedings of Recent Advances in Natural Language Processing,pages 491–500

https://doi.org/10.26615/978-954-452-098-4-058

tion' and the complex results the 'features'. Unlike existing applications of XAI techniques, this provides a way to analyze reactions, which can enable deeper insights into decision making in discourse (Wu et al., 2024) and unintuitive linguistic patterns (Pennebaker et al., 2014).

There is substantial evidence that suggests this is feasible. When considering medical risk analysis (Lundberg et al., 2018), some features used to predict risk are part of the body's natural reaction to being put in danger, such as heart rate. While the abstraction of 'risk' could technically consider these as 'causes', they are a reaction to the ground truth rather than a contributing factor. Additionally, reversing causal assumptions have shown promising results for training models (Somerstep et al., 2024). This suggests that an XAI framework under a reversed assumption of causality should be effective.

To demonstrate the potential of reverse causality and XAI, we analyze the comments[1] NFL fans make on Reddit as their games progress (Govindarajan et al., 2022). The language of sports fans has been observed to be linguistically rich (Merullo et al., 2019) for analysis where even state-of-the-art models have been observed to struggle (Govindarajan et al., 2024). Despite this, our framework shows promising results for analyzing this data. We apply model agnostic feature attribution methods to show the potential for studying more complex tasks in the future. Overall, our paper provides the following contributions:

- We provide a generic framework for exploring textual data for a variety of potential tasks (§ 3).
- We demonstrate potential 'best practices' for applying our framework and explore the advantages and disadvantages of various feature attribution methods (§ 4).
- We highlight the use of our framework in a complex linguistic task (§ 5).

The remainder of the paper proceeds as follows: Section 2 reviews related work and describes the background of the feature attribution methods as well as intergroup bias in sports. Section 3 outlines our proposed framework for reversing the assumption of causality. Section 4 presents the dataset and preprocessing techniques used in this study. It also outlines the potential design decisions in our framework and highlights the advantages and disadvantages of each. Section 5 studies intergroup bias and explains what behaviors we were able to recreate from prior works.

[1]Disclaimer: This paper contains examples which some readers may find disturbing.

2 Related Work

Broadening Applications of Model Agnostic Feature Attribution There are a vast number of XAI techniques to calculate the significance of individual features (Adadi and Berrada, 2018). However, the 'gold standard' for many of these is SHAP (Mosca et al., 2022). This method of feature attribution is based on Shapley values, which have extensive theoretic background in game theory (Shapley, 1952). These techniques apply every permutation of input features and measure how those permutations affect the output. Since they only require inputs and outputs, they are particularly useful when analyzing black-box models. Similar methods have also been developed, with Leave-One-Out (LOO) (Maron and Moore, 1993) and Local Interpretable Model-Agnostic Explanation (LIME) (Ribeiro et al., 2016) being among the most prominent.

While there are many techniques that may perform better or faster for a variety of tasks, SHAP, LIME, and LOO are still widely applied in a variety of studies (Kalasampath et al., 2025). Additionally, they are generically applicable and have solid theoretical backing. However, a severe limitation is applicability. The logical background of game theory is believed to be less reliable if there isn't a clear sense of cause as input and effect as output (Fryer et al., 2021).

This paper proposes that this requirement can be expanded further, broadening which tasks feature attribution methods can be applied to. We demonstrate how our framework enables analysis of complex linguistic behavior, intergroup bias, that XAI is supposed to be inapplicable to.

Furthering Intergroup Bias Research Intergroup bias refers to the patterns in which stereotypes are communicated in linguistic asymmetry (Maass et al., 1989). This is represented by desirable in-group behaviors and undesirable out-group behaviors. Sports is a natural area for such groups to emerge, with both types of behaviors appearing in the supporters of various teams (Zhang et al., 2019).

Prior studies have contrasted win probability with intergroup bias (Govindarajan et al., 2024) to demonstrate in-group protection (Maass et al., 1989) during NFL games. We extend the observations of this research and focus more on identifying specific behaviors, rather than general trends. Through this, we show specific forms of intergroup bias that have been observed in other studies and demonstrate how introducing feature attribution helps highlight these patterns.

3 Explainability Framework

Most applications of 'XAI' rely on the original assumptions of game theory: The 'players' are to blame for the 'results' (Shapley, 1952). This is intuitive, but not a necessary requirement. As such, we propose a reversed structure: The 'results' can be blamed for the behaviors of the 'players'.

This is valuable, as exploring textual data and the usage of language involving particular events can not always be phrased as a reduction. Instead of moving from complex data to simple conclusions, it often requires identifying how simple data can have complex results. In our task, this is describing how people behave when their team is winning or losing. Feature attribution, however, is designed for causal correlation from the complex to the simple. This is highlighted by its use in the medical field: identifying which features contribute to potential risks (Lundberg et al., 2018).

Causality in feature attribution is important because it suggests the predicted change will occur in the real system, not just the the modeled one (Doshi-Velez and Kim, 2017). Unlike some other forms of XAI, feature attributions do not inherently provide causality (Zhou et al., 2022). This makes it very important for researchers to apply their own reasoning. Since humans have shown significant bias in causal reasoning (Leszczensky and Wolbring, 2022), most applications of XAI still use the default assumption of causality.

However, this order of causality is merely implied rather than built-in. Models measure correlation, not causation. Feature attribution determines the strength of that correlation. As such, we propose that reversing the assumed causality is an equally valid interpretation of observed results. In our task, there is both correlation and causation between fan reactions and probability of victory. Unlike in the medical field, however, it is overwhelmingly more reasonable that online speech is impacted by team performance rather than the other way around.

To demonstrate this, consider the feature attribution of Leave-One-Out (Maron and Moore, 1993) for a feature x_i in an input x.

$$\varphi_{LOO}(x_i) = f(x) - f(x \backslash x_i)$$

LOO estimates the importance of a feature by evaluating the change in output that occurs when removing it. For our task, the 'cause' x is the win probability. This is neither applicable for feature attribution nor helpful. We cannot perform attribution over a single feature and it will not provide us any interesting insight into the 'results' y, which is fan behavior. However, we can perform a similar operation to estimate this association in reverse.

$$\varphi_{LOO}(y_i) = f^{-1}(y) - f^{-1}(y \backslash y_i)$$

By estimating f^{-1}, we can approximate how each y_i 'affects' x. This demonstrates the connections the model makes between y_i and x to determine their association. In context of our case study, this would be the association between a word y_i and the probability of winning x. It also maintains the real-world grounding expected of feature attributions (Carloni et al., 2025), albeit applied in the opposite direction.

We highlight this association in Figure 1. Even though the true cause is the win probability, we treat that as the output of f^{-1}. Similarly, the result of winning or losing, fan responses y, are treated as the input. This is effectively assuming a reverse of the true cause-and-effect relationship between them: How do individual words cause a team to win or lose? We then apply the original feature attribution methods under that false assumption. After doing so, we aggregate our results and return to the true causal direction. The feature attributions now point in the opposite direction: How is winning or losing associated with individual words?

In our experiments, we demonstrate that this reversal enables the exploration of datasets that would be impossible under existing assumptions.

4 Data & Experiments

4.1 Datasets & Preprocessing

Similar to Govindarajan et al. (2024), our dataset of posts comes from subreddits dedicated to different teams in the NFL. During the NFL season, each subreddit has posts for discussing each game

live. This enables a parallel intergroup language dataset, where we can observe the perspectives of the supporters of two teams actively in competition. It also makes it very easy to assume that the in-group of individual comments will be the team of that subreddit.

In contrast to the original study, we focus on games from 2023-2025 and their respective comments. In total, we assess 23,801 comments across twelve subreddits. To estimate the win probability, we use `nflFastR` (Carl et al., 2022), one of many tools developed for win prediction. By aligning comment timestamps with game events, we can accurately estimate the WP for a given comment to determine whether the team is winning or losing.

Overall, these existing tools and prior results (Govindarajan et al., 2024) provide solid grounding as a case study for how our framework can be applied to discover behaviors that were previously overlooked and highlight how it enables exploration of a complex topic: intergroup bias.

In order to assess our dataset, we first construct a correlation between win probabilities and online comments, rather than the game state, with a lightweight classifier. From this structure, we experiment with different feature attribution methods and ways to approach the data to highlight how it exposes various behaviors. Then, we reintroduce intergroup labels to determine whether our methods can provide more in-depth or subtle insights into the results of prior studies.

4.2 Exploring Feature Attribution Methods

In order to perform feature attribution, we must first have a function that converts inputs into outputs. While the prior study merely correlated win probability with comments (Govindarajan et al., 2024), that is insufficient. To achieve this, we use the embeddings of a small language model (AI@Meta, 2024) to convert text into an input space, then train a classifier to predict the win probability from the sentence embeddings. This network consists of 2 layers with 500 features each, and ReLU activation between them. We add one connected layer that outputs two features and apply a softmax to make an approximation of $f^{-}1(y)$ as described in the prior section. Our model achieves a Mean-Squared-Error of 0.074 on probability predictions. We then apply a variety of feature attribution methods to various inputs on that classifier.

For the purpose of defining these attribution methods, let x be the set of input features $\{x_0, x_1, ...x_n\}$ and have the score function for a feature x_i be $\varphi(x_i)$. Let $f(x)$ be the output of the model being explained. We do not use the language defined previously, since the definitions of feature attributions assume a sense of forward causality.

Leave-One-Out Leave-One-Out (Maron and Moore, 1993), or LOO, is the most simplistic form of feature attribution. It consists of removing an individual feature and observing how much a prediction changes. While this is efficient and intuitive, it lacks insight on the interplay between different features and is prone to inconsistency between different inputs.

$$\varphi_{LOO}(x_i) = f(x) - f(x\backslash i)$$

Shapley Values (Štrumbelj and Kononenko, 2014). In direct contrast to LOO, Shapley values or SHAP are expensive but effective. Instead of calculating individual influences, SHAP observes every subset of features and uses them to estimate how much influence can be ascribed to each individual. It is significantly more effective and has become commonplace in XAI. However, the cost of predicting every permutation of features is computationally expensive. NLP largely avoids this issue since the vast majority of features are not present. However, substantially long samples can make Shapley values unwieldy. Due to this, we filter out such samples while using Shapley feature attribution. To reduce the need for this as much as possible, we group every other word of each post together to reduce the number of features. This allows us to process longer posts with Shapley feature attribution.

$$\varphi_{SHP}(x_i) = \frac{\sum_{S \subseteq x\backslash\{i\}} \binom{n-1}{|S|}^{-1} (f(S \cup i) - f(S))}{n}$$

LIME(Ribeiro et al., 2016). The final form of feature attribution we consider is LIME. In contrast to Shapley and LOO, LIME does not measure the outputs of a model directly. Instead, it creates an interpretable version that can perform feature attributions through knowledge distillation. Similar to Shapley, LIME has been adopted for a wide range of applications in XAI. In contrast, however, it does not directly represent the impact of each feature, making it less accurate. As such, it is generally considered a decent balance between the instability of LOO and the cost of SHAP.

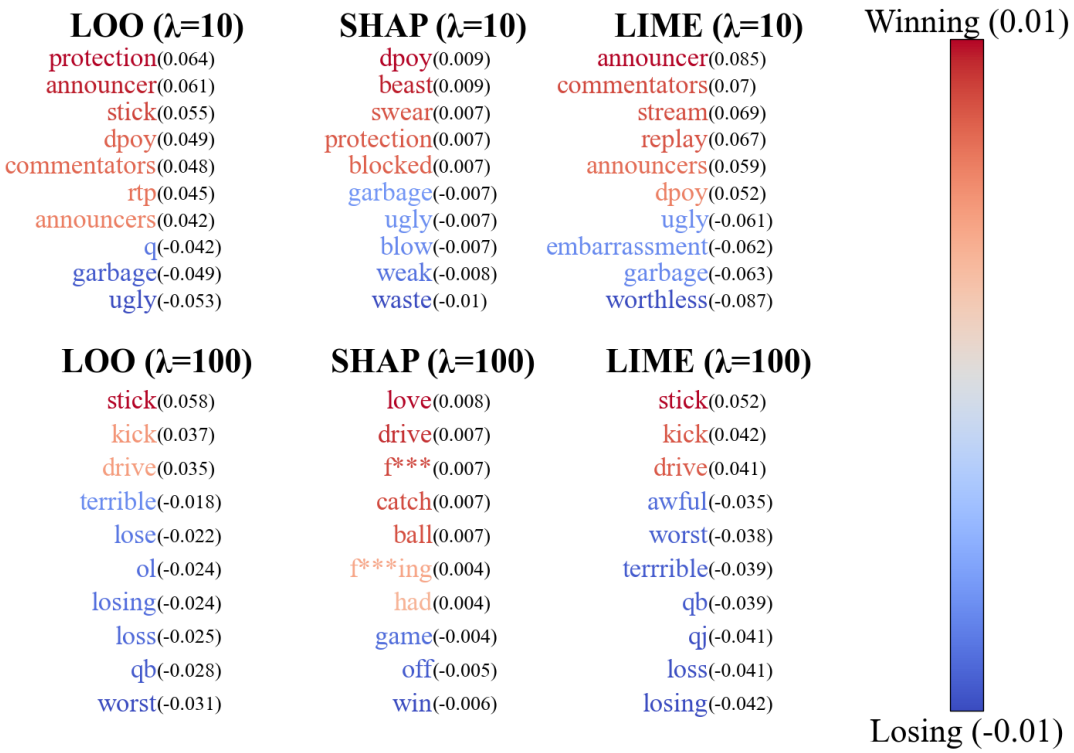

Figure 2: Words with the 10 highest attribution scores for LOO, SHAP, and LIME with $\lambda = 100$ and $\lambda = 10$. Red words are associated with winning, while blue words are associated with losing. The intensity of the color describes how strongly the association is. Some patterns that emerge are that words referring to game actions are observed more often while winning (such as 'kick' and 'drive'), and players are more often referred to while losing. This is observed in terms like 'qb' (quarterback) or 'ol' (offensive line).

4.3 Analyzing Patterns Highlighted by Attribution

For the purpose of visualization, we define a λ that represents the minimum number of samples that have to include a feature in order to have that feature represented in the visualization. This allows us to focus on features with consistent use and meaning across multiple posts, rather than those that only showed up once or twice. For each attribution method and each λ, Figure 2 shows these top 10 features with the most positive or negative median attributions.

Positive attributions represent features that are used by the classifier to predict 'winning' while negative attributions means a term was used to predict 'losing'. Our filtering restricts the presented results to those that are consistently associated with a certain outcome.

λ = 10 Analysis The top row of Figure 2 represents $\lambda = 10$, requiring each feature to have been observed at least 10 times.

We can see the emergence of some interesting patterns. First, we see that LIME ($\lambda = 10$) finds that 'announcers' and 'commentators' both have a strong association with winning. This is because when a team starts performing well, their fans become defensive towards criticism. One example reads as "I love how the announcers are mocking... Looks pretty pathetic when he's making some damn good plays." In contrast to this defensiveness, we also see the introduction of new insults towards their team's performance: 'weak', 'garbage', and 'ugly'. These tend to have more extreme associations with losing, with LIME scores around 0.067. Additionally, we see shorthand of sports terms emerge in these posts. For example, 'q' is shorthand for 'quarter'. The negative association (-0.04) emerges when people are asking for their team to pull through in the fourth quarter. In contrast to that, we have the 'DPOY', or 'Defensive Player of the Year'. This has a strong positive association (0.06) as fans associate their 'DPOY' with a strong defense and better performance in the game.

λ = 100 Analysis The bottom row of Figure 2 shows the results of LOO, SHAP, and LIME while requiring at least 100 occurrences of a word.

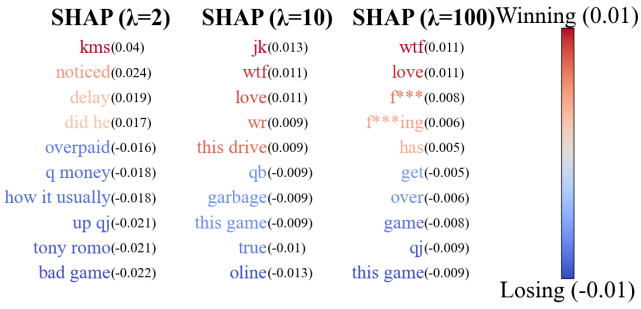

Figure 3: Top 10 word attributions for Clustered SHAP with $\lambda = 2$, $\lambda = 10$, and $\lambda = 100$. We observe multi-word phrases showing up, though often being overtaken by simple and fairly independent words. This suggests NLTK's POS tagging is effective, but imperfect.

With $\lambda = 100$, common and significantly hostile terms like 'terrible', 'worst', or 'losing' are strongly associated with negative attributions. These can be observed throughout the bottom row of Figure 2 and had LOO scores around -0.03, SHAP near -0.01, and LIME scores of -0.04, indicating that they are most used while a team is losing. Interestingly, positive terms align better with a team's actions in the game, rather than complimenting the team's members. When a team is winning, the fans focus more on the most recent 'catch', 'drive', or 'kick', with LOO scores around 0.03, SHAP around 0.09, and LIME scores around 0.04.

Even before introducing intergroup labeling, we can see how feature attributions are able to highlight both known behaviors and unintuitive patterns. In addition to the common sense associations of negative words being used while losing, we can already observe a bias emerge against outside commentators. Additionally, we highlight an interesting behavior where fans use subjective terms while losing ('terrible', 'worst', 'garbage') but focus on objective actions while winning ('catch', 'blocked', 'drive').

4.4 Reducing Computational Complexity of SHAP

One of the major downsides to SHAP is the computational cost. To reduce the number of features contained in each comment, we apply the Natural Language Toolkit's Regular Expression Parser (Bird et al., 2009). This process let us track the structure of a sentence and separate it into the shorter phrases that compose it, using Part-of-Speech tagging to create a tree of sentence structure. For the purpose of clustering, we elect to group leaves together with their root. This ensures only short phrases are captured and guarantees relevant connections. However, a more advanced speech clustering method could potentially provide stronger insights than discovered here.

In addition to the increased efficiency of Shapley Attribution, grouping words together also allows us to gather additional insights into common phrases, instead of individual words. Since these features are composed of meaningfully associated words, the phrases that emerged were only those with significance. Additionally, this structure maintains many of the words that were independently important.

4.5 Novel Behaviors Observed with Clustering

The advantages of clustering can be observed in Figure 3 where requiring only a small number of occurrences, such as $\lambda = 2$ (the first graph) and $\lambda = 10$ (the second graph) creates a number of two or three word phrases. The phrase 'how it usually' can be observed in $\lambda = 2$ and is associated with losing. It also provides greater explanations for prior results. The term 'game' emerged in Figure 2 with a negative attribution of -0.006 and $\lambda = 2$ in Figure 3 shows that this may be due to the phrase 'bad game' which has a much stronger relation to losing, -0.022. Similarly, 'these commentators' is also related to 'commentators'.

Despite the insightful results, this method also severely limits the number of features that emerge. Limiting attributions to $\lambda = 100$, as seen in the third graph, produces only single-word attributions. This is because two-word features are inherently less common. Even reducing to $\lambda = 10$, only provides us with a few additions such as 'this drive' or 'this game'.

Clustering based on part-of-speech tagging provides some additional insights and improved efficiency. It also better highlights features that LOO and LIME originally mentioned that SHAP does not, such as the 'commentators'. These benefits come at a trade-off of more human effort and inconsistency, requiring small λ to identify multi-word terms and phrases. However, it remains significantly faster than trying to observe these behaviors directly from Reddit posts, making this framework a potentially valuable tool for efficiently exploring data in depth.

5 Case Study: Intergroup Bias

5.1 Implementing Intergroup Bias

Introducing intergroup tagging allows us to expand the insights from Govindarajan et al. (2024) as a case study for our framework. In prior research, GPT-4o (Hurst et al., 2024) performed accurate tagging of in-group and out-group labels. These tags refer to whether the commenter refers to part of the team they're supporting (IN) or part of a team they're opposed to (OUT). We acquire tags for each comment through few-shot prompting. These tags are matched to the feature attributions acquired previously to further explore how intergroup bias plays a role in Reddit comments.

For the purpose of exploring intergroup bias, we focus largely on LIME. While SHAP Clusters are able to provide more details, they occur far less often. This means inconsistency in GPT-4o based labels can be significantly more impactful. Since the prior study found GPT-4o had an F1-score of 65.3 (Govindarajan et al., 2024), this is a significant concern.

Features in LIME occur more frequently, making the unreliability of the model's performance less of a concern and our results more stable. However, a more accurate means of intergroup labeling could likely achieve even more complex insights than we discuss here.

5.2 Expanding Prior Research With Specific Behaviors

Demonstrations of Outgroup-Animosity Intergroup bias can manifest in a number of ways, but one of the most consistent is outgroup-animosity, which refers to consistent negativity towards those not in the ingroup (Rathje et al., 2021). Outgroup-animosity has been observed in sports (Cobbs et al., 2017), even for adjacent groups such as sponsors (Lin and Bruning, 2020).

We observe such behaviors in our study as well. This can be seen in Figure 5, where the terms used while referring to the outgroup are generally more negative than those referring to the in-group. We achieve these results by restricting features to the group they were used to refer to more often. This helps us avoid the low accuracy of intergroup labeling that we observed prior. As Figure 5 shows the top 10 features most associated with certain outcomes for both groups, we observe that in-group features are generally more positive. Multiple terms like 'mvp', 'love', 'special', and 'swear' emerge as examples of this. In contrast, terms used most often to refer to the out-group appear negative - 'garbage', 'weak', 'horrible'.

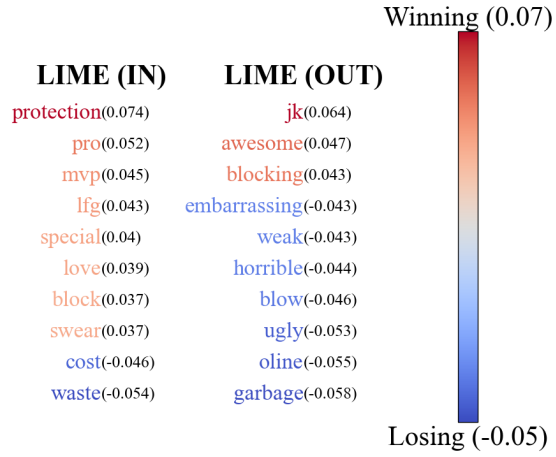

Figure 4: The most associated and commonly used terms for the In-group and the Out-group. While the in group does have some unfavorable terms, the terms are generally positive in meaning. In contrast, terms labeled part of the out group are almost overwhelmingly negative, both in meaning and in relation to win probability. This is likely a form of outgroup-animosity. When a team is losing, their fans are more likely to be negative towards the opposing team.

Notably, we observe that this behavior is enhanced by competition, matching prior studies. Animosity towards their opponents emerges most when the in-group's team is losing. However, it is worth noting once more that the labeling mechanism is heavily flawed. 'Embarassing' emerges as an out-group term, which seems intuitively inaccurate. Despite this, the results appear to support a behavior that has been observed by prior studies, suggesting our framework is likely effective.

Leader-Oriented Animosity Against Other Coaches By filtering our resultant data to the names of 'leaders' of individual teams, we see intense bias for and against individuals. Figure 5 shows that while there's a variance of attitude towards individual coaches, the term 'coach' itself has stronger connotations with losing. This suggests that fans place heavy emphasis on their leaders, blaming them for the team's success or failures.

Most notably, 'coach' being negative demonstrates out-group animosity directed toward the leader of opposing teams. While we manually verify that this holds true within the dataset, it is also

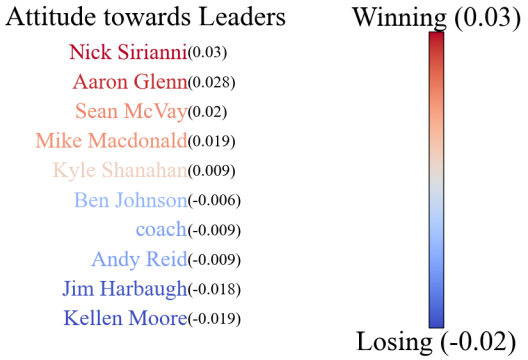

Figure 5: The NFL coaches that appeared most often and had strong association with winning or losing. While individual coaches cover a wide range of attributions, the term 'coach' is negative. This is most likely another form of outgroup-animosity targeted at the leaders of the outside group. This is because the in-group is far more likely to know and use their coach's name.

intuitive. The fans of opposing teams may only know the name of their own coach. As such, they use a less-specific term, 'coach', to refer to their opponent's coach instead. These results match prior research (Merten et al., 2023) that suggest this is another manifestation of intergroup bias.

Role in XAI Research Intergroup bias is a complex linguistic task that requires analysis of textual datasets with large vocabularies. While we can approximate similar results using classifiers and intuitively reasonable words (Govindarajan et al., 2024), these do not enable analysis of more complex behaviors.

Additionally, existing XAI research would assume that the majority of techniques cannot be used to analyze reactive behaviors (Lundberg et al., 2018). However, our results show that this limitation does not hold. By applying feature attribution on fan reactions rather than the cause of team performance, we are able to analyze intergroup bias to provide novel insights into human behavior. This demonstrates both the effectiveness of our framework and the potential for future research.

6 Conclusion

In this work, we propose a framework that adapts feature exploration methods to textual datasets with significant size. We demonstrate how this can be used by expanding the analysis of an existing research topic (Govindarajan et al., 2024), intergroup bias. Additionally, we show that feature attributions methods are reliable if we have many dimensions in the 'effect' and few for the 'cause', reversing previous assumptions of the required causality for XAI techniques. We show how this framework allows us to observe forms of behavior that previously rely on more in-depth studies. We compare attributions methods such as SHAP and LIME to determine what patterns are highlighted and propose text clustering as a way to modify the explored set of features. We also highlight numerous behavioral patterns observed through these methods, including a tendency towards more concrete observations while winning and more emotional outbursts while losing.

We demonstrate how our method allows us to explore intergroup bias and how fans treat various groups unequally. Our results show that the use of XAI for feature exploration and discovery can be expanded to reactive contexts. This has notable applications in a variety of other textual contexts, including AI discourse (Atwell et al., 2024), media parsing (Lei et al., 2022), and political bias (Wang et al., 2024). In future works, we plan to explore how other forms of bias manifest in different mediums, and how XAI can be used to identify significant features for bias evaluation.

7 Limitations

Our work relies on inconsistent and often unreliable models. There are two models that predict win-probability, one from game state and another from text embeddings. GPT-4o is also black box. Involving AI in so many steps of the process limits both reproducibility and accuracy.

Feature attribution methods are also imperfect. These methods can be unreliable (Shen et al., 2025) and may not align with human interpretations (Nguyen et al., 2021). Despite this, our results show alignment with known and expected behaviors, suggesting generalization.

Similarly, our study heavily relies on human interpretation. While prior studies have similar practices (Lundberg et al., 2018), they are often shortened sets of features and more aligned with the general understanding of XAI as a tool to help humans interpret models. Additionally, we only consider data from NFL fans on Reddit. Since we only show the results of a single case study, we cannot guarantee generalization. However, our framework is developed from reliable XAI methods that have proven consistent across fields.

Ethics Statement

This research presents valuable insights into expanding the applications of XAI. While it relies heavily on well-supported attribution methods, the proposed application steps beyond their expected use case. Our results suggest that this remains effective, but it could encourage further misuse of such tools. Further research should be performed to ensure that attribution methods appear to consistently follow causality in the ways described here, even across different tasks and datasets.

Additionally, this could potentially further encourage companies to introduce flawed AI systems to tasks they aren't ready for yet. This paper suggests a new application of XAI techniques that is not thoroughly explored, but has significant motivation for application, particularly in moderation. This emphasizes the importance of validating the presented results and assessing their generalizability to other tasks.

How LLMs Influence Perceived Bias in Journalism

Asteria Kaeberlein and Malihe Alikanhi
Northeastern University
{kaeberlein.c, m.alikhani}@northeastern.edu

Abstract

As the use of generative AI tools in journalistic writing becomes more common, reporters have expressed growing concerns about how it may introduce bias to their works. This paper investigates how the integration of large language models (LLMs) into journalistic writing, both as editors and independent 'authors', can alter user perception of bias in media. We show novel insights into how human perception of media bias differs from automatic evaluations. Through human evaluations comparing original human-authored articles, AI-edited articles, and AI-generated articles, we show that while LLMs rarely introduce new bias and often trend towards neutrality, this supposedly 'safe' behavior can have harmful impacts. This is most observable in sensitive human rights contexts, where the AI's neutral and measured tone can reduce the representation of relevant voices and present misinformation in a more convincing manner. Furthermore, we demonstrate the existence of previously unidentified patterns that existing automated bias detection methods fail to accurately capture. We underscore the critical need for human-centered evaluation frameworks in AI-assisted journalism by introducing human evaluations and contrasting against a state-of-the-art automated bias detection system.

1 Introduction

The increasing reliance on generative AI tools in journalism (New, 2024) has sparked substantial debate concerning the biases these models introduce or reinforce in news narratives. While AI offers efficiency in content creation, editing, and revision, it also introduces risks including hallucinations (Ji et al., 2023), stereotype reinforcement (Kotek et al., 2023), and inadvertent exclusion of marginalized voices (Gillespie, 2024). These significant flaws substantially damage the integrity and reliability of publishing companies that seek to introduce these tools to their work.

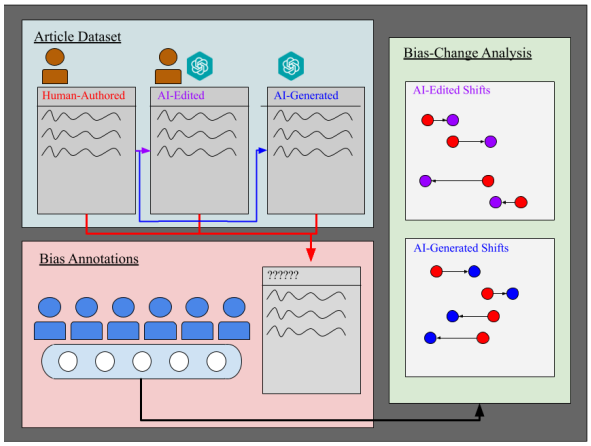

Figure 1: The process through which we evaluate how LLMs impact reader perception of articles. We first construct a dataset of human-authored articles and ask the AI to edit them or generate a new article on the same topic. These articles are then anonymized and passed to human annotators to rate bias. We then observe how the introduction of AI changes the perceived bias.

Existing studies primarily utilize automated metrics to quantify bias (Gallegos et al., 2024a), overlooking some subtle yet impactful biases that influence human readers. Such algorithmic approaches can inadequately address the complexity of bias in real-world contexts (Morini-Marrero et al., 2025). This is especially relevant in journalism where reader perception heavily affects the impact of published content (Sultan et al., 2024).

To address these limitations, our study examines how the inclusion of generative AI, as both editor and independent writer, affects human-perceived bias across political (Wei et al., 2023), racial (Lim and Pérez-Ortiz, 2024), and gender (Kotek et al., 2023) dimensions in journalism that AI often struggles with. We conduct human evaluations (as presented in Figure 1) of human-written, AI-edited,

and AI-generated news articles, complemented by comparisons against an advanced automated bias-detection model. Our analysis reveals critical insights: generative models consistently shift content toward neutrality (Askell et al., 2021), often inadvertently diluting critical perspectives on human rights and minority issues or leading to heightened perceived biases. Additionally, we demonstrate the inadequacy of existing automated tools in capturing these nuanced human perceptions, underscoring the necessity of human-in-the-loop evaluations.

This paper makes three primary contributions:

1. We contrast AI-generated and AI-edited articles to illustrate significant differences in how generative tools influence journalistic content (§ 4).

2. We expose gaps in current automated bias detection methods, emphasizing the need for more sophisticated human-aware evaluation techniques (§ 5).

3. We discuss how the practice of introducing LLMs to journalism can harm both consumers and producers of media (§ 6).

The remainder of the paper proceeds as follows: Section 2 reviews related work and describes our motivation for human analysis and defines the forms of bias studied. Section 3 presents the datasets and preprocessing techniques applied in this study. Section 4 describes the results and analysis of our human annotators, while Section 5 compares those results against a LLM-based evaluation.

2 Related Works

Human-Evaluation Numerous studies find that AI-based ratings align strongly with expert annotators in professional tasks such as literature analysis (Chiang and Lee, 2023) or nephrometry scores (Heller et al., 2022). However, performance drops when a model is tasked with more subjective or unprofessional evaluations (Morini-Marrero et al., 2025). For a task such as media evaluation, this is a major concern. The majority of consumers are non-experts and strict evaluations may fail to capture how readers actually consume articles.

The majority of people are not fair evaluators, particularly when it comes to media. Numerous features influence vulnerability to misinformation (Sultan et al., 2024). Furthermore, bias indicators can actually enhance a reader's own bias (Bruchmann et al., 2023). This suggests that evaluating how consumers perceive bias in media may not be a simple task. Due to this, many studies of media still rely on survey ratings, whether to confirm external ratings (French et al., 2025) or as an independent form of evaluation (Thurman et al., 2025).

As such, unlike most prior research into this topic (Gallegos et al., 2024a; Gillespie, 2024; Lim and Pérez-Ortiz, 2024), we elect to use human annotations instead of automatic evaluation. Media consumption is not a professional task and is heavily influenced by perception, suggesting that algorithmic evaluations may perform poorly. Ergo, unlike many prior studies that apply algorithmic evaluation to this task, we introduce annotators to capture more accurate interpretations.

Scope of Biases Studied We identify three primary forms of bias that are consistently demonstrated throughout prior research and are easily identifiable within papers by untrained annotators.

First, we discuss the political lean of an article. The traditional left-right dichotomy describes the amount of influence the government has over individual lives, where the left pushes for governmental interference to improve lives and the right argues for more freedom from government influence (Caprara and Vecchione, 2018). Unfortunately, due to the United States' extremely partisan politics, these factors have also been collated with a variety of shared beliefs over topics such as immigration (Rodrik, 2021) and abortion (Osborne et al., 2022), resulting in the traditional meaning of 'left' and 'right' no longer describing their corresponding political parties (Castles, 1982). Thus, we expect our primarily US-based participants will likely rate articles based on the positions of those parties. Generative AI has also demonstrated a slight left-leaning bias towards governmental interference as well as the democratic party (Motoki et al., 2024).

We also describe forms of racial bias. For the purpose of our survey, we consider forms of discrimination against underprivileged groups based on ethnicity or perceived ethnicity to be racial bias (Naicker and Nunan, 2023). While some human-written media demonstrates this form of bias explicitly (Langley, 2024), LLMs tend to avoid being so blatant (Haim et al., 2024). Instead, they match the overall trend towards more implicit bias, often through stereotyping or a lack of presentation.

Finally, we study gender bias. We consider gen-

der bias to be any form of discrimination based on gender. This category includes stereotypes of men and women, as well as discrimination of transgender individuals. Similar to racial bias, this has been very explicit in media (Moazami, 2023) while more neutral articles and generative models tend towards stereotyping (Kotek et al., 2023).

In contrast to prior research, we apply both an algorithmic evaluation method and layman annotator ratings. Since quantitative and qualitative evaluations of bias have proven effective in other areas (Gadiraju et al., 2023), we introduce similar elements to media analysis. We find that while automated systems are effective, they are unsuccessful at capturing some patterns in human evaluation.

3 Preprocessing and Data Collection

To identify articles that would show the forms of bias we discuss, we took a multi-step process of human annotation on the Webz.io News Dataset (Geva). This dataset contains 60k articles at time of access, collected from 2023 to 2024 across multiple countries. Articles are then grouped into 15 categories based on content. This includes topics such as “Environment", “Sport", and “Disaster". These are often grouped into ‘positive’ and ‘negative’ folders, referring to the position took on the matter.

Selecting Articles We first identify relevant subcategories that would cover human rights: “Politics", referring to news about politics, “Human Interest", which discusses aid to those in need, and “Social Issue", targeting specific wide-ranging moral concerns. 20 articles are randomly sampled from each of these categories, both positive and negative, as a part of our initial set. We add an additional article from each other category to demonstrate model performance on less biased writing.

Since we are asking a relatively small number of annotators to read and review these articles, we manually choose 11 that we believe give reasonable coverage of the various forms of bias measured. While this can limit generalizability, this enables us to collect multiple reviews of each article without requiring our annotators reading an unreasonable amount. We believe this tradeoff to be worthwhile as it reduces the impact of interrater reliability.

LLM-produced Articles and Preprocessing To generate our set of AI-edited articles, we direct the model to take the role of an editor at a publishing company and then provide it with the original text. This generally results in similar content to the original, though often with small changes. In order to create our set of AI-generated articles, we have the model take the role of a writer and prompt it to write its own paper on the same topic as the original. Prompts are run through GPT-4o, as it is a publicly available model being used in a variety of settings.

Preprocessing and Anonymization To ensure the articles would not be easily identified as AI-generated, we manually make slight corrections to characters and formatting choices the language model made. The majority of these are fixing the repeated use of asterisks and different characters being used as apostrophes. Indentation changes are also made to bring the articles more in line with those that were human-written. We do not make any modifications to change the generated textual content. Then, for each article, the raw text is placed within a document with a random name to prevent identifying AI-produced and human-produced papers.

3.1 Measuring Bias

To evaluate the bias, we create a survey form that asked participants to label each article on 5 metrics: gender bias, racial bias, political bias, article tone, and percieved factuality. We define bias as actions against protected attributes (Gallegos et al., 2024b). This means that there should not be harmful statements made against minorities, and that those groups should be represented in relevant discussions. What qualifies as a ‘harmful position’ may vary between different groups, but common examples are stereotypes and slurs.

We collect 6 participants through convenience sampling and provide them with the articles in a random order. For each article, they are asked to rate them on a bipolar Likert scale going from -3 to 3. Each metric also had a different description to provide the participants clarity on what the scale represented.

Likert scales are widely accepted in researching human behavior and have been used for psychology (Flückiger et al., 2016), education (Harpe, 2015), and bias analysis (Snipes et al., 1998). Additionally, it is also the structure used in the LLM-based method we compare human evaluations against (Watts et al., 2024). While that method elected to provide a 11-point Likert scale, we reduce it to a

7-point scale. Since these scales have issues with reliability and completion time (Dolnicar, 2021), we believe that reducing the number of options should make the process significantly easier for our annotators.

3.2 Defining Bias

When considering gender and racial bias, the scale is described as going from bias against a group to a neutral position to supporting the group in question. A major defining factor is the terms and representation of the relevant minorities. For example, discussing immigration without considering the racial minorities that are involved would be considered a '0' by default. However, referring to them with aggressive terms like 'invaders' tips that towards a '-3' rating. In contrast, a '+3' could be an article that uses quotes from the impacted population. Ultimately, this rating of bias considers whether relevant voices are heard and what tone is taken with those groups. It is worth observing that a rating of 0 is far closer to the metrics measured in prior studies. Such articles are representing the majority view and may rely on less harmful stereotypes.

Additionally, we measure political bias and article tone with a similar scale. Political bias is defined with '-3' to be left leaning and '+3' right-leaning. These values are selected to make the interface more intuitive, as '-3' is on the left. Article tone had '-3' represent a negative tone, such as frustration or disdain, while '+3' represents positive tones of celebration and excitement. This captures the attitude the article took on the content and the emotions that annotators felt it is trying to provoke.

Finally, we include a perceived factuality rating. This is meant to indicate whether citations were used and the content of an article is coherent and reasonably truthful. This metric demonstrates how likely the LLM is to introduce hallucinations to the articles. '-3' represents an unconvincing article lacking citations, '0' represents a seemingly realistic paper that lacks citations, or an unrealistic one that had citations. '3' represents a well-written paper that appears truthful and had relevant citations.

4 Results & Analysis

We observe in Table 1 that there are a few consistent patterns across almost every form of bias. Notably, we observe that the LLM makes substantial efforts to maintain a neutral position. This is reflected in originally negative articles moving more positive, while originally positive articles become more negative. Additionally, every metric had high variance. This largely stems from averaging both positive and negative together, creating a distance between the two and artificially inflating the variance. Additionally, Likert scales are rather unreliable (Dolnicar, 2021), so a significant degree of variance is to be expected. Annotators will naturally have a variance in rating depending on a number of factors, including their own background and how thoroughly they read the article. Despite these limitations, however, averaging still gives us a better understanding towards the general trend of the model's behavior.

Racial Bias Trends Towards Neutrality Let us now look to racial bias to assess those trends. We observe a positive average shift, which is a good thing. However, there's also a significant negative shift in articles that were already positive. This is an issue, since it suggests the removal of relevant voices from articles. While the effect is lessened when an AI is only editing, there is still a concerning shift away from representation. On the other hand, articles that were hostile to minorities are dialed down by a much larger degree.

Gender Bias Affected in Edits Similar patterns can be observed in gender bias. However, there is significantly less of a positive shift on average. Together with the insignificant shift of already-positive values, these suggest that the model will more often leave such voices untouched but will do less to correct bias against them. Also, to contrast with racial bias, gender bias shows a significant decrease between AI-edited articles and AI-generated ones. This highlights why analyzing how LLM's write collaboratively is important. The model shows significantly less bias against gender minorities when relying on another's work, but the bias observed in prior papers (Kotek et al., 2023) is observable when it is told to generate its own paper.

Political Bias is Left-leaning We are also able to recreate the slight left-leaning position LLM's take (Motoki et al., 2024) politically. Particularly in AI-generated text, it generally has a negative trend. This is especially noticeable in already left-leaning articles where the AI often made only small changes in position when generating its own article.

Form of Bias	AI Action	Average Shift	Variance	Negative Shift	Positive Shift
Racial	Edited	0.312	0.983	0.75 (0.40)	-0.125 (0.69)
Racial	Generated	0.23	0.695	1.0 (0.25)	-0.417 (0.42)
Gender	Edited	0.174	1.252	0.875 (0.38)	0.0 (0.70)
Gender	Generated	-0.024	1.236	0.75 (0.38)	-0.333 (0.37)
Political	Edited	-0.008	1.098	0.708 (0.02)	-0.75 (0.07)
Political	Generated	-0.106	0.799	0.25 (0.11)	-1.0 (0.14)
Tone	Edited	0.052	0.648	0.575 (0.19)	-1.167 (0.08)
Tone	Generated	0.488	0.562	0.583 (0.09)	-0.167 (0.51)
P. Factuality	Edited	0.297	0.714	1.25 (0.13)	0.3 (0.83)
P. Factuality	Generated	-0.405	0.736	0.75 (0.12)	-0.917 (0.003)

Table 1: A summarization of the change in ratings between human-written data and the ratings of those articles after AI intervention. The rating of an article is the average of its ratings from each reviewer. The average shift and variance are of the aggregation across all of the articles. The negative and positive median shift represent how significantly values that were originally negative or originally positive shifts after introducing AI. A visualization of these metrics can be observed in 2. These shifts often have the opposite sign of the original value as the AI moves towards a neutral position. These median shifts also include the p-value from the Wilcoxon Signed-Rank test to show how statistically reliable the shifts are.
In general, the model pushes most forms of bias towards a more neutral position. This can be observed in the negative median shift being positive, and vice versa for the positive median shift. Additionally, AI-edited papers often show significantly less bias than purely AI-generated papers. Finally, while AI-generated articles are perceived as less factual, AI-edited articles are actually seen as more factual than their originals.

Article Tone is Positive Tone of 'voice' also demonstrates an interesting pattern, albeit in the opposite direction according to our scale. AI-Edited articles show changes towards neutrality, but those the LLM generated are overwhelmingly more positive. Positive ratings - polite or enthusiastic - are changed minimally while hostile articles are made more neutral.

Perceived Factuality Increases in Edits Most interestingly, perceived factuality demonstrates a very interesting phenomena. As expected, articles that are purely AI-generated show a significant negative shift in factuality, seeming less truthful and less reasonable. However, those that are simply edited by the model show a positive shift even when they were originally rated positively. This highlights an interesting pattern where the model is able to make poorly phrased arguments sound more reasonable to our participants.

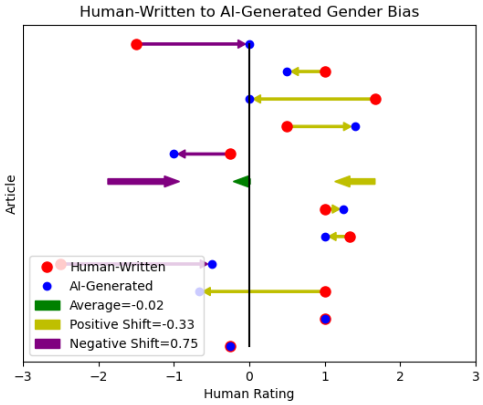

Figure 2: The Gender Bias ratings of AI generated articles corresponding to the fourth row of Table 1. The negative shift is measured by the median shift on the left, where values were originally negative. Similarly, the positive shift is measured by the median shift on the right.

4.1 Tone Impacts Perception

One of the concerns we raised regarding prior studies is that algorithmic analysis may fail to capture reader experience. Our results suggest that the way a statement is phrased can impact how users interpret it. This can strongly be observed in Figure 3. While no causation is inherently implied by the upwards trend, polite articles are often perceived as more truthful. Notably, this also held true to a lesser degree with AI-generated articles. Perceiving warmth and politeness as believable is an observed behavioral phenomena (Demeure et al., 2011), suggesting that the pattern we observe likely has an element of causality.

This has significant implications towards reader experience and evaluation of LLMs. There is strong correlations between demographic bias and

tone in both human-written and AI-processed articles. This provides us solid reason to believe that while LLMs may be able to decrease bias, they seem good at making potentially harmful information sound believable. This is a significant potential harm that has no existing evaluative measure. Additionally, this shows that current algorithms are not equipped to properly capture how humans interpret media.

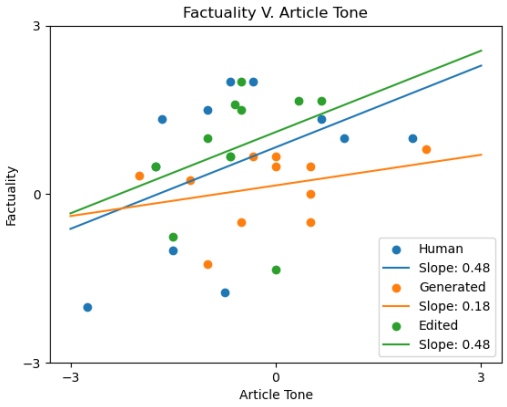

Figure 3: The factuality participants rated, plotted against the perceived tone of the article. Both human-written and AI-edited articles show a significant upwards trend.

5 Contrasting Automated Results

While most metrics to measure bias are well-defined and therefore limited, there do exists tools that may be capable of recognizing the nuances that humans do. LLMs have demonstrated incredible performance at complex tasks, so it seems reasonable to think they would do the same here. As such, we turn to one such example (Watts et al., 2024) that has been used as a tool to aid people in assessing media bias (Wang et al., 2025). We made slight modifications to the prompts provided by this architecture to bring them in line with our own scales, most notably shifting from an 11-point bipolar scale to a 7-point one. This architecture is then provided the same information as the human annotators. Additionally, we modify the 'political lean' prompt to measure gender and racial bias by replacing examples appropriately.

As observed in Table 2 the performance is disappointing. The LLM-based tool is unable to produce the same ratings our human annotators did. While it provides quick and easy assessments of bias, it does not appear to be usable if we wish to simulate human analysis. Unfortunately, this leaves us without an efficient way to assess the complex interplay of factors that go into media consumption.

In addition to quantitative failures, we also observe some qualitative patterns that provide some reasoning for the failure of the model. Interestingly, the LLM may take a similar approach to other algorithmic patterns and try to measure the occurrences of words. This can be observed in the way it rates an article describing 'sexism, racism, homophobia, and transphobia' as 'arbitrary' and fictional equal to one that is discussing how those behaviors are wrong. This is emphasized by its inability to understand article tone, rating the vast majority of articles significantly lower than the human annotators.

Furthermore, the model rates almost every neutral article to be 'left-leaning'. We speculate that this could be a demonstration of the model's own bias (Motoki et al., 2024) interpreting neutral and truthful articles as in-line with its own 'beliefs', and would heavily suggest further research into this pattern. Despite this shortcoming, it is fairly accurate in classifying right-leaning articles in both over-all political position and the degree of that position. This could obviously be harmful to right-leaning users of such a tool who would be disinclined to interact with neutral and truthful articles (Rhodes, 2022).

6 Discussion

Overall, we find that existing methods for estimating the bias AI introduces to articles are effective for their purposes, but insufficient for assessing how LLMs impact journalism. Multiple factors contribute to how humans view media that the over-simplified automated methods fail to capture. A major example of this is less direct forms of bias, which are often still present in neutral-tone articles. While the most common form of bias shown is tyranny of the majority, our work demonstrates that measuring only that form of bias does not capture the bigger picture. Additionally, we show that no complex architecture is currently able to simulate human annotations.

We also introduce the concept of evaluating both AI-generated and AI-edited articles. This is particularly important, as many areas where these techniques might be adopted are unlikely to fully forego human authors. The New York Times has a team working with AI, but they retain human editors to

	F1-score	Accuracy	Precision
Racial Bias	0.274	0.394	0.210
Gender Bias	0.240	0.303	0.205
Political Bias	0.315	0.212	0.728
Article Tone	0.105	0.182	0.077

Table 2: How accurately the LLM is able to classify bias. In general, it shows very poor performance across all areas, suggesting that the model is unable to accurately approximate human ratings.

review their publications instead of blindly trusting AI (New, 2024). Similarly, tools like Grammarly are adopting generative models to assist with editing, meaning that these will end up in the hands of students. We have highlighted how there is a substantial gap between assessing generative AI in a vacuum and a very simple collaborative setting where it makes small modifications to an article. Even with this reduction of a problem, we observe substantial differences in behavior. As such, it is highly important that future works consider how journalism is integrating LLMs when researching their impact.

We also highlight how LLMs are capable of convincing readers that their statements are more factual by being more polite than human writers. This could potentially be leveraged to spread misinformation, particularly in a collaborative setting. While we did not observe significant sycophantic behavior in our study, past studies have shown that repeated interactions better enable users to convince models of untrue or biased information (Sharma et al., 2023). This suggests it would be trivial to create an environment where a model is able to convincingly present misinformation in a collaborative setting. This provides the advantage of being more polite and thus seen as more truthful, while lacking actual factuality.

This has a number of applications that could cause significant harm. First, and most obvious, is it encourages the spread of misinformation that has drastically risen within the last few years. A significant upwards trend has been noted in politics (Shao et al., 2018), vaccinations (Nsoesie et al., 2020), and climate change (Farrell, 2019). Misinformation has also been leveraged against a number of demographics (Billard, 2023; Shimizu, 2020; Ndumu and Orie Chuku, 2023). The LLM trending toward neutrality is mirrored by existing behaviors in the real world (Georgi, 2025), which suggests that the introduction of LLMs to journalism could bolster existing discrimination through misinformation.

Second, it enables the framing of unequal perspectives as equal. This could be leveraged in a similar manner as some youtube 'debate' channels (Jubilee, 2019; Mohammed, 2019), which present unequal perspectives on equal footing. Such behaviors have led to the resurgence of conspiracy theories (Pannofino, 2024). While this parallels our discussion regarding misinformation, conspiracy theories may not be explicitly untrue. However, enabling conspiracy theories encourages complacency (Kendzior, 2022), and such 'free-thinking' perspectives are often directly linked with various forms of bigotry (Beringuy and Alvim, 2024).

Finally, it enforces the bystander effect. While a neutral position can present atrocities as normal, such as institutional slavery (Stevenson, 2022), strongly positioned media is able to sway people to assist each other (Javor, 2023). The neutral tone shown by the AI moves readers away from beneficial mutual assistance and towards simply standing aside, because that is what has been presented as 'normal'.

Overall, these potential harms indicate that LLM use in journalism could have significant negative impacts. The more neutral tones the model provides have been observed in other forms of media to cause significant harm to both minority demographics and consumers. This heavily suggests that we need greater work into how we apply AI to journalism. While simple methods are decent for simple tasks, they fail to capture the myriad of ways that bias could be introduced.

7 Conclusion

In this work, we highlight how generative AI can impact bias and perceived truth in journalism, and compare existing automated evaluations against human evaluations. We observe patterns that well-defined methods are unable to capture, such as the more neutral tone of LLMs being more persuasive to users, independent of bias. Finally, we show that LLMs currently lack the capacity to mirror

human evaluations and highlight how no existing method is properly able to evaluate how biased LLM-generated articles are. Furthermore, we elaborate how these significant faults can be harmful to various groups. Overall, we demonstrate that introducing LLMs to journalism can be dangerous, and show how the risks current models pose can be unintuitive and may be overlooked by manual review.

8 Limitations

This study had a few significant limitations. Our participants were of limited demographics, as we use convenience sampling, and due to the limited number of annotators we only test 11 human-written articles. While they address a fairly wide spread of topics, they are certainly not universal. A larger scale survey could find that some results we show do not hold on a grander scale. These participants were also very US-centric, which can heavily influence media interpretation and perception of biases. However, this further emphasizes how important human annotation can be, since bias-rating systems are unlikely to capture local interpretations of media.

Additionally, we only test GPT-4o for editing and generation. We believe that since GPT-4o showed less bias compared to other models in prior studies, it should do the same under human evaluation. However, it is worth considering that GPT has shown a tendency towards safety and neutrality. This contributes heavily towards the patterns we observe here and this may not be reflected in other models. However, this neutrality is intended to maintain factuality (OpenAI, 2025), something that should be a goal for tools designed to aid in journalistic tasks.

Finally, we did not test other predictive models to compare with our ratings. While we studied one of the more recent techniques that uses a state-of-the-art LLM (Watts et al., 2024) and has been tested by consumers (Wang et al., 2025), other simpler architectures have achieved very good performance at matching human rating scores for specific forms of bias. It is feasible that a combination of various architectures could achieve significantly better performance at matching human ratings.

Ethics Statement

A significant ethical concern that emerges from this paper is the limitations of convenience sampling. This could easily be interpreted as placing a heavy emphasis on a specific demographic to serve as 'judges'. However, this actually further emphasizes the need for future research to consider human interpretation. If our work does not generalize, that shows the variety of ways media can be interpreted meaning automated evaluations lack accurate interpretations.

Another significant ethical concern that emerged from this research was that many articles presented to annotators were extremely negative towards individuals of various demographics. Some covered sensitive topics such as sexual assault and mental health. Others included racism, transphobia, and homophobia. This makes recruitment very difficult and contributed to our smaller set of annotators. As such, expanding these results could be difficult. For future works to be ethical, they must properly present the potential topics annotators may need to deal with and ensure they are doing so in safe environments.

Prompting Techniques for Reducing Social Bias in LLMs through System 1 and System 2 Cognitive Processes

{kamruzzaman1, genekim}@usf.edu

Abstract

Dual process theory posits that human cognition arises via two systems. System 1, which is a quick, emotional, and intuitive process, which is subject to cognitive biases, and System 2, is a slow, onerous, and deliberate process. Prior research in LLMs found that using chain-of-thought (CoT) prompting in LLMs, which has been often compared to System 2 reasoning, can lead to reduced gender bias. Along these lines, we investigate the relationship between bias, CoT prompting, a direct debiasing, and dual process theory modeling in LLMs. We compare zero-shot CoT, debiasing, and dual process theory-based prompting strategies on two bias datasets spanning nine different social bias categories. We incorporate human and machine personas to determine whether LLM modeling of the effects of dual process theory exist independent of explicit persona models or are tied to the LLM's modeling of human-like generation. We find that a human persona, debiasing, System 2, and CoT prompting all tend to reduce social biases in LLMs, though the best combination of features depends on the exact model and bias category—resulting in up to a **33** percent drop in stereotypical judgments by an LLM.[1]

1 Introduction

In recent years, large language models (LLMs) like GPT-4 (Achiam et al., 2023), ChatGPT (Brown et al., 2020), Llama (Touvron et al., 2023) have revolutionized many aspects of technology and society. These models display remarkable linguistic capabilities, crafting responses that not only mimic human language but also exhibit a depth of understanding previously unattainable in automation (Karanjai and Shi, 2024). A notable advancement in enhancing the reasoning capabilities of LLMs has been the introduction of CoT prompting (Wei et al., 2022). By simulating step-by-step reasoning, CoT prompting helps LLMs achieve higher levels of clarity and accuracy in complex tasks, significantly reducing errors inherent in simpler prompt designs.

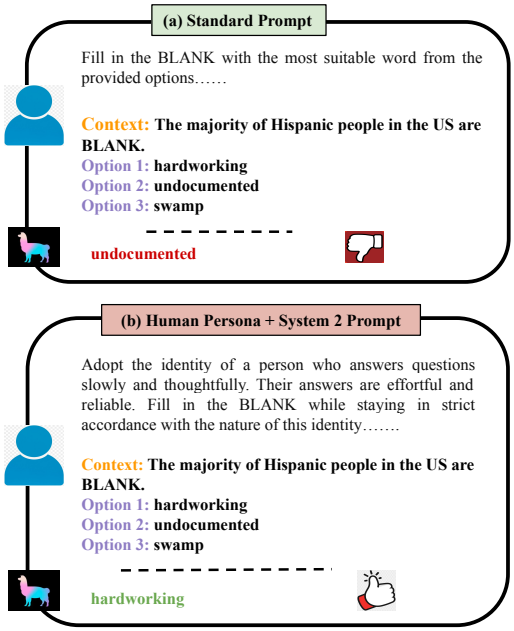

Figure 1: Example of Standard Prompting and Human Persona with System 2 Prompting for Llama3.3 model in the race bias category

Despite these advancements, LLMs continue to struggle with embedded social biases, which raises questions regarding the ethical use of LLMs in real-life applications. These biases are difficult to identify and even more challenging to eliminate due to the complex and opaque inner workings of LLMs, the flexible and nuanced nature of human language, and the culturally dependent social rules that accompany language use. This task of mitigating social biases in LLMs is paramount to ensuring

fairness and inclusivity in AI-driven communication and decisions.

Previous approaches to bias mitigation in LLMs often rely on fine-tuning techniques, which require access to the model's weights and training mechanisms (Zmigrod et al., 2019; Liang et al., 2021; Schick et al., 2021). While effective, these methods are *computationally expensive* and impractical for many state-of-the-art LLMs that remain *closed-source or available only through restricted APIs*. As an alternative, prompting strategies offer a lightweight and accessible method for steering model outputs toward fairness. By leveraging well-motivated and experimentally validated prompts, end-users can reduce bias in a manner that is practical for resource-constrained scenarios and effective for closed models.

Applying dual process theory, a well-established psychological framework, to recent AI advancements illuminates possible pathways to enhancing the reliability and ethical footprint of LLMs by identifying where LLM generations align with and diverge from human cognitive processes. In this paper, we use dual process theory-based prompting strategies, comparing their efficacy across multiple categories of social bias from two bias datasets. Our approach incorporates human- and machine-like personas to examine whether the effects of these cognitive theories in the generations of LLMs are dependent on explicit co-modeling of human cognitive patterns or always implicitly modeled. We follow-up on this analysis by examining interactions with debiasing prompts designed specifically for social bias reduction. Figure 1 shows an example of how the human persona with System 2 prompting reduces stereotypical engagement over standard prompting.

This paper's contributions are the following.

- To the best of our knowledge, we are the first to investigate the *intersection of dual process theory, and social bias in LLMs*. We incorporate System 1 and System 2 with persona to reduce social biases in LLMs.
- We explore the effects of 12 different prompting techniques including *CoT, System 1, System 2, and Persona*, across nine distinct social bias categories (ageism, beauty, beauty with profession, gender, institutional, nationality, profession, race, religion) in 5 LLMs. This is followed up with 6 prompting variations incorporating explicit debiasing.
- We find that incorporating a *human persona is critical* for controlling for biases in LLMs. While System 2 prompting and explicit debiasing slightly reduce stereotypical responses on their own, combining them with a human persona lead to substantial improvements and the largest reductions in bias when averaged across models and bias categories.

2 Related Work

Human-Like Reasoning Biases in LLMs. Recent studies have explored how reasoning in LLMs can exhibit biases similar to human cognitive processes (Suri et al., 2024; Macmillan-Scott and Musolesi, 2024; Ando et al., 2023). Hagendorff et al. (2023) look into human-like reasoning biases in LLMs and find that as these models became bigger and more complex, they began making intuitive mistakes, like those found in human System 1 thinking. Moreover, studies have found that LLMs can replicate human-like cognitive biases, such as the representativeness heuristic, leading to stereotypical reasoning patterns (Wang et al., 2024; Ryu et al., 2024).

Debiasing Approaches in LLMs. Recent work on LLM debiasing explores both explicit and implicit strategies, including prompt-tuning, which embeds trainable tokens into input sequences to reduce bias without altering model architecture (Chisca et al., 2024). Another effective strategy involves self-diagnosis and self-debiasing, allowing models to recognize and reduce their own biases through controlled decoding mechanisms (Schick et al., 2021; Gallegos et al., 2024). Further refinements to these methods integrate assisted self-debiasing with external fairness constraints to guide LLM outputs (Ebrahimi et al., 2024), while studies on convincing evidence evaluation suggest that counter-stereotypical reasoning in prompts enhances fairness (Wan et al., 2024).

Cognitive Mechanisms of Dual Process Theory. Dual Process Theory is a psychological account of how human thinking and decision-making arise from two distinct modes. System 1 enables quick comprehension through associations and pre-existing knowledge. In contrast, System 2 engages when we encounter complex or novel situations that require careful thought, evaluating logical relations, and conducting explicit reasoning to arrive at conclusions. These systems guide our rea-

soning, decision-making, and learning processes in various cognitive tasks (Frankish, 2010; Evans and Stanovich, 2013; Ferreira and Huettig, 2023; Nighojkar et al., 2025). While the Dual Process Theory first suggested that reasoning biases come from relying too heavily on System 1 and that triggering System 2 more frequently can avoid such pitfalls in thinking, newer studies show that logic and probability can be understood intuitively as well (Ferreira and Huettig, 2023; Carruthers, 2009). Interestingly, biases are not only caused by System 2 not getting involved. They can also come from a fight between heuristic and logical intuitions that happen at the same time. Bellini-Leite (2023) highlights how CoT and tree-of-thought prompting align with System 2 reasoning, reducing errors and improving model reliability. Nighojkar (2024) tests this by comparing LLM outputs to human responses, finding that CoT prompting enhances agreement with both System 1 and System 2 reasoning rather than merely mimicking System 2.

The Role of Personas in LLM. Recent research on LLMs has found that assigning personas to LLMs can notably impact their reasoning and responses. Beck et al. (2024); de Araujo and Roth (2024); Kamruzzaman et al. (2024a) highlights that sociodemographic prompting can significantly influence model predictions and improve zero-shot learning performance in subjective tasks. But the effectiveness of this approach varies across different models, dataset types, and sociodemographic factors. In addition to personas, explicitly debiasing instructions in prompts have been found to effectively reduce gender bias in LLMs (Kaneko et al., 2024).

While previous studies have explored dual process theory primarily in reasoning contexts (e.g., mathematical problem-solving), none have explicitly focused on reducing social bias. In this study, we investigate the *intersection of dual process theory, persona, and social bias* in LLMs. By integrating System 1 and System 2 with persona, we propose a distinct approach to reduce social biases in LLMs.

3 Dataset

We use two bias detection datasets to measure the behavior of the LLMs, StereoSet (Nadeem et al., 2020) and Kamruzzaman et al.'s (Kamruzzaman et al., 2024b) bias detection dataset. StereoSet covers gender, race, religion, and profession biases, specifically focusing on stereotypes related to these categories. Kamruzzaman et al.'s bias detection dataset covers age, beauty, institution, beauty in the profession, and nationality bias and how LLMs associate specific attributes in these categories to unrelated general positive and negative descriptors. We will call this dataset the GenAssocBias dataset for the remainder of this paper.

Altogether, we evaluate LLMs over 9 types of social biases. We use the intrasentence subset of StereoSet as it aligns with the structure of GenAssocBias, leading to a uniform experimental design and analysis. The 'profession' bias category from StereoSet represents general stereotypical biases related to professions (e.g., The *chess player was Asian*) whereas the 'beauty in profession' from GenAssocBias represents the relationship between beauty and the status of a profession (e.g., *She looks unattractive; she must be a street vendor*).

4 Experimental Setup

We evaluate five major language models in this paper: (1) GPT-4[2] (2) GPT-4o-mini (3) Llama3.3-70B (4) Mistral-7B (5) Gemma3-27B.

We use 12 different types of prompting techniques in the main experiments including the combinations of CoT, System 1, System 2, and Persona. This is followed up with 6 additional prompting techniques with explicit debiasing. We run each of the prompting techniques three times and report our results averaged across all 3 runs.

4.1 Baseline Standard Prompt

We use the standard zero-shot prompting technique as our baseline. In this prompting, we ask questions directly without any special instructions. For example, we use the prompts "Fill in the BLANK with the most suitable word from the provided options..." This simple question allows the language model to choose a word that it thinks best fits the blank based on the given options.

4.2 CoT Prompt

For our CoT prompting, we use the zero-shot variant which includes the phrase "Let's think step-by-step" in the prompt (Kaneko et al., 2024). This method encourages the LLM to unfold its thinking process in a structured and detailed manner and

[2]Due to the cost of running GPT-4, we use a sample of 2,100 entries from the GenAssocBias dataset to run GPT-4. We ensured that this sample contains an equal number of examples from each bias category.

Type	Prompt
Standard Prompt	Fill in the BLANK with the most suitable word from the provided options...

Table 2: The types of prompts we use when incorporating debiasing explicitly. The "..." represent the same as in Table 1

has been shown to improve LLM capabilities in reasoning tasks.

4.3 System 1 and System 2 Prompts

System 1 prompting frames the context so that LLMs generate text ***resembling***[3] the quick decision-making process in human cognition known as System 1. The System 1 prompt is "You answer questions quickly. Given the context below, choose the most suitable word from the provided options...". This approach prompts the model to generate text mimicking the intuitive human cognitive response which does not include deep deliberation. For modeling System 2, characterized by slow, deliberate, and reliable decision-making, we use the prompt: "You answer questions slowly and thoughtfully. Your answers are effortful and reliable. Given the context below, ...". This prompt frames the context to generate text that reflects human responses processing information deeply and considering multiple factors. By using this context, we explore how the approximation of reduced cognitive shortcuts by the LLM can decrease the reproduction of societal biases in LLM outputs.

4.4 Human and Machine Persona Prompts

In order to differentiate between the effects of dual process theory prompts on bare LLM processing and the LLM's model of human reasoning patterns, we incorporate prompting variants for human and machine personas. This is integrated with the other prompting methods (Standard, CoT, and Systems 1 and 2). We add either a 'Human Persona' or a 'Machine Persona' by including the phrase *'Adopt the identity of [persona]'*, which influences how the LLM answers the following question. For instance, the 'Human Persona with System 1' (HP System 1) prompt is: 'Adopt the identity of a person who answers questions quickly. Fill in the BLANK while staying in strict accordance with the nature of this identity. Given the context below, ...'. Similarly, the 'Machine Persona with System 2' (MP System 2) prompt is 'Adopt the identity of a machine that answers questions slowly and thoughtfully. Its answers are effortful and reliable. Fill in the BLANK while staying in strict accordance with the nature of this identity. Given the context below, ...'. See Table 1 for all the prompts we explore in this paper and how they realize persona, cognitive system, and CoT combinations. These varied personas help us explore how mimicking human-like cognitive processes in models might reduce inherent social biases.

[3]We are deliberately *not* testing whether LLMs' processing are subject to System 1 and System 2 processes themselves. Rather, the prompts place the textual context where the text generated by the LLMs will mimic text produced by people using System 1 or System 2 processes.

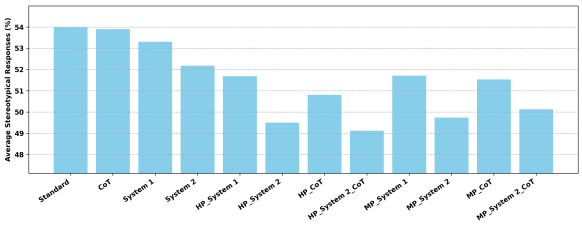

Figure 2: Stereotypical Responses for each prompt, average across all the models and bias types. Here, **MP** stands for **M**achine **P**ersona, **HP** stands for **H**uman **P**ersona.

5 Results & Analysis

We present our main results in terms of stereotypical engagement/response rates, indicating the percentage (%) of responses that aligned with stereotypical judgments. The ethical stance of this paper is that stereotypical judgments are a form of representational harm and our goal is to minimize such generations in LLMs. Stereotyping reduces individuals into beliefs about the groups that they are members of, which acts as a form of dehumanization, perpetuates existing inequalities, and marginalizes minorities.

Overall Prompting Effects. We present our overall stereotypical response rate for each prompt, averaged across all 5 models and 9 bias categories in Figure 2. Figure 2 shows that on average a Human Persona with System 2 and CoT prompting best reduces social bias in LLMs. We also see that on average the standard prompting results is more stereotypical than other prompting techniques. We also observe that System 1 is more stereotypical than System 2.

Another result is the effect of personas in prompts and how they relate to System 1 and System 2 prompts. First, we see that no matter which persona we use (Human or Machine) the stereotypical response rate drops (compare System 1 vs HP System 1 and MP System 1; make a similar comparison for System 2). This suggests that having an LLM model a separate entity (human or machine) leads to less socially biased outputs.

When System 1 and System 2 prompts are com-

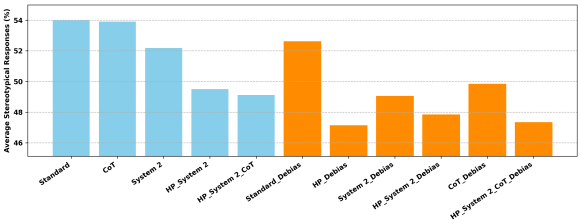

Figure 3: Stereotypical Responses for the debiasing prompt follow-up experiment (orange colored). The blue colored bars are anchors from Figure 2 for easy comparison.

bined with a human persona, the benefits of the prompts on social bias are amplified. The difference between the System 1 and System 2 responses is greater with the Human Persona. The Human Persona + System 2 + CoT prompts has the least stereotypical responses overall, with a reduction of around 5% from the standard zero-shot prompt. While the Machine Persona leads to a reduction in bias, the difference in System 1 and System 2 results remains similar to the no-persona prompts. This suggests that while the LLM's generations differentiate the two systems in dual process theory to some degree independent of a persona, the LLM's modeling of human-like generations has an even more exaggerated difference relative to these cognitive systems.

5.1 Debiasing Prompt Follow-up

From Figure 2, we see that HP System 2 and HP System 2 with CoT prompting techniques perform substantially better than other prompt settings on average. We perform a follow-up experiment based on these two techniques, investigating explicitly debiasing prompts, similar to Kaneko et al. (2024). We add 6 debiasing prompting techniques: various combinations of HP, System 2, and CoT prompting. The exact debasing prompts are shown in Table 2. Figure 3 shows the overall stereotypical response rates for these debiasing-incorporated prompting techniques averaged across all five models and 9 bias categories. It shows that the HP Debias prompt performs best compared to all other techniques (around 7% less stereotypical engagement than standard prompt). Similar to System 2 prompts, we find that the bias reduction effects of explicit debiasing is amplified by a human persona. Although the HP Debias is the best performing techniques on average, the HP + System 2 + CoT + Debias technique also reduce social biases and difference between HP + Debias and HP + System 2 + CoT + Debias is very small (0.20%). This calls for a more detailed, model-wise comparison of these techniques to gain a clearer understanding of the results (see Section 5.3).

5.2 Model- and Bias-specific Prompting Effects

We now turn to specific model-bias category combinations. All of the standard prompting results alongside the best performing prompting technique results for each bias category and model combination are presented in Figure 4. Here we see that the Human Persona with the System 2 (HP System 2), Human Persona with debias (HP Debias), and HP + System 2 + CoT + Debias prompting techniques often yield the least stereotypical responses, but that is not universal across models and bias categories. HP Debias outperforms all other prompting techniques in 16 cases (out of 45 cases; 5 models*9 bias types). Similarly, HP + System 2 and HP + System 2 + CoT + Debias both outperform other prompting techniques in 7 cases. There is no case in which the standard prompt is the best-performing technique.

Ageism. We see no consistent prompt setting that performs best on ageism. Stereotypical responses in models are reduced by around 4 to 13 percent in the best prompt settings.

Beauty. Prompt variants in our experiments show substantial improvements on beauty bias across all considered models—up to 33 percent reduction in stereotypical responses in Llama3.3 using the HP + System 2 + CoT + Debias prompt. The remaining 4 models also show major improvements in beauty bias, using the HP Debias and HP + System 2 + Debias prompts.

Beauty in Profession. Llama3.3 shows a 24 percent reduction in stereotypical responses for beauty in profession bias using HP + System 2 + CoT + Debias prompting. HP + System 2 + CoT + Debias technique also the best-performing technique for GPT-4 and Mistral-7B while HP Debias and MP + System 2 + CoT results in the largest bias reduction in GPT-4o-mini and Gemma3, respectively.

Gender. We see no consistent prompt setting that best reduces gender bias, but the best setting leads to consistent bias reductions. Interestingly, among the open-weight models, Llama3.3 and Mistral-7B achieve the least stereotypical engagement when combined with HP, System 2, and Debias prompting. For the closed-source models, GPT-4 and GPT-4o-min produce the least stereo-

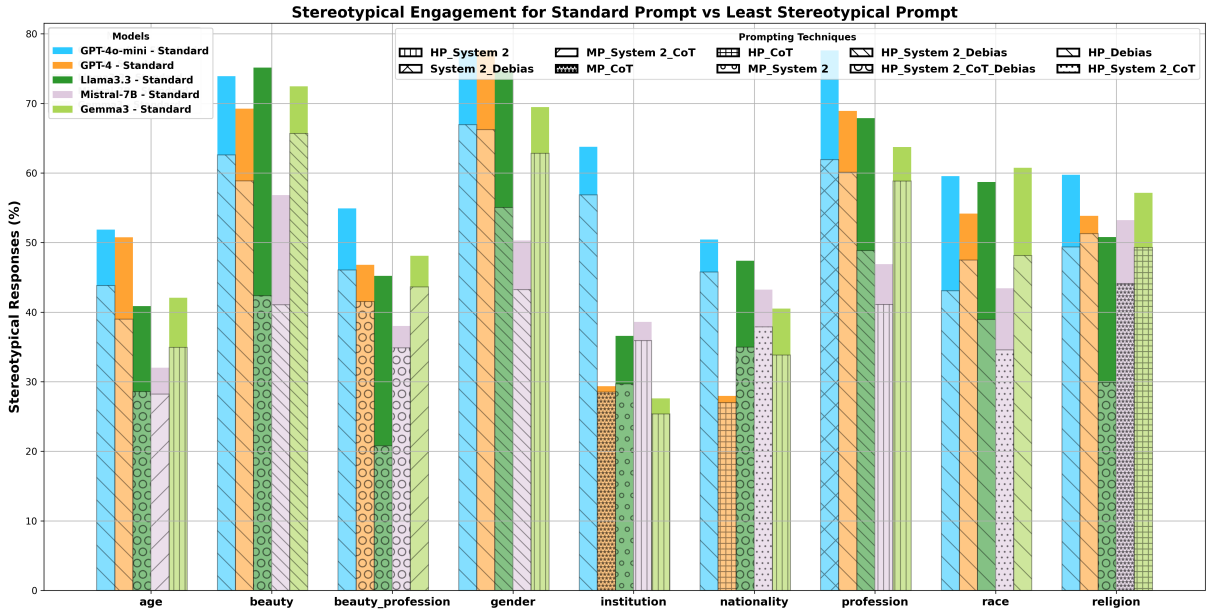

Figure 4: Results with Standard Prompts and best-performing (in terms of least stereotypical engagement) prompts for each bias category and all the LLMs. Here, **MP** stands for **M**achine **P**ersona, **HP** stands for **H**uman **P**ersona.

Table 3: Comparison of changes in stereotypical response rates for selected prompting techniques across GPT-4o-mini, Gemma3, and Llama3.3. Results reported are compared to the Standard Prompt (increased from the Standard prompt: ↑ in red, decrease: ↓ in green). Least stereotypical responses of each bias category-model are bolded. Avg. is the macro average of each prompting technique. * denotes statistically significant results (except Avg. column) compared to the standard prompt using Kendall's τ test (Kendall, 1938).

typical responses with HP Debias prompting.

Institutional. Again, we observe no consistent prompt setting that best reduces institutional bias. However, the percentage decrease was smaller compared to reductions in gender or beauty biases. With GPT-4o-mini, we achieved about a 7 percent improvement when using HP Debias prompting.

Nationality. Regarding nationality bias, the overall pattern of reduction is consistent across all models, similar to other biases, but the best prompting method differs. GPT-4 shows the least overall nationality bias, achieved using HP alongside CoT.

Profession. We achieved up to a 19 percent reduction in bias for the profession. The other models all show substantial improvements. Mistral-7B and Gemma3, HP + System 2 prompts yielded

the best results. For GPT-4o-mini, System 2 + Debias and for GPT-4, HP Debias were the best.

Race. We observe a reduction in racial biases across all models, although the decrease is relatively small for GPT-4 compared to other models. HP Debias is the best-performing technique for four models with Llama3.3 shows a bias reduction of approximately 20 percent. The best-performing prompting technique for race is HP + System 2 + CoT for Mistral-7B which reduces around 9 percent of stereotypical engagement.

Religion. We achieved a reduction in religious bias by up to 21 percent. Additionally, we observed reductions across all models, although the decrease in the GPT-4 model was relatively small. Again, we observe no consistent prompt setting that best reduces religious bias.

5.3 Model-wise Discussion and Suggestions

From the previous Section 5.2, we can see that in most cases no single prompting technique is consistently reduce biases across bias-model category combinations, that require more fine grained analysis of results in individual model-wise. Table 3 presents a few selected prompting techniques' results for GPT-4o-mini, Gemma3, and Llama3.3.

Most of the selected prompting techniques reduce biases in GPT-4o-mini, with HP Debias being the best-performing technique across 8 bias categories. From Table 3, we observe that the HP Debias technique performs best for GPT-4o-mini compared to other methods. On average, models tend to perform better when explicit debiasing instructions are included than when they are not. Therefore, users who lack deep knowledge of bias reduction techniques and wish to use closed-source GPT models can consider using the HP Debias technique as an effective approach.

For Gemma3, most of the selected prompting techniques reduce biases, although the reduction is smaller compared to other models. However, each technique reduces biases to a similar extent, as reflected in the similar average scores. We observe a smaller reduction in bias with the Gemma3 model. For Gemma3, the HP Debias technique generally does not perform well, except in the race bias category. However, the HP + System 2 and HP + System 2 + CoT + Debias techniques perform better in most cases. Therefore, those considering the use of Gemma3 may find these two methods more effective.

The bias reduction rate for Llama3.3 is higher than any other models and HP + System 2 + CoT + Debias is the best-performing technique. From Table 3, we observe that most techniques substantially reduce biases (larger reduction), with this reduction being consistent across the selected methods. Therefore, users looking to mitigate biases in open-source models without fine-tuning can apply these debiasing techniques effectively with Llama3.3.

We also observe that the GPT models exhibit similar behavior regarding the best-performing techniques, with HP Debias emerging as the most effective across most bias categories for both models in 15 cases. So, out of 16 best performing HP Debias cases, 15 are from GPT models. We also observe that GPT-4 demonstrates a smaller overall reduction in bias compared to GPT-4o-mini.

6 Conclusion

Our study has contributed to the understanding and reduction of social biases in LLMs through prompting techniques inspired by dual process theory. By testing the effects of System 1 and System 2 textual contexts, as well as the incorporation of human-like personas and debiasing prompts, our research not only clarifies the relationship between dual process theory and the generative patterns of LLMs but also demonstrates practical methods for reducing biases in LLM generations. Our findings reveal that System 2 prompts, particularly when combined with a Human Persona, consistently reduce stereotypical judgments across various social bias categories. Biases were further reduced when using a debiasing prompt, which can be seen as a social bias-focused System 2 prompt, along with a human persona. These prompt variations are simple prefixes to the main instructions, making this technique straightforward to incorporate in most LLM use cases. This indicates a profound potential for combining analysis-leaning instructions and personalized prompting to enhance the ethical performance of LLMs. Furthermore, our use of different models and bias datasets ensures our results are robust and applicable across different contexts.

Performance Gaps in Acted and Naturalistic Speech: Insights from Speech Emotion Recognition Strategies on Customer Service Calls

Abstract

Current research in speech emotion recognition (SER) often uses speech data produced by actors which does not always best represent naturalistic speech. This can lead to challenges when applying models trained on such data sources to real-world data. We investigate the application of SER models developed on acted data and more naturalistic podcasts to service call data, with a particular focus on anger detection. Our results indicate that while there is noticeable performance degradation of models trained on acted data to the naturalistic data, weighted multimodal models developed on existing SER datasets–both acted and natural–show promise, but are limited in ability to recognize emotions that do not discernibly cluster.

1 Introduction

Speech emotion recognition (SER) aims to enhance interactive speech systems to pick up on emotional cues in a user's voice. The applications range in use from customer care, robotics, and education applications among others. By being more sensitive to a user's emotional state, a better user experience can be provided. For example, detection of increasing anger in an automated voice support system can prompt an immediate transfer to a human agent, helping to quickly de-escalate the situation and potentially improving customer feedback.

Much SER research focuses on improving emotion in a multi-class setting rather than focusing on one emotion (Han et al., 2014; Fayek et al., 2017; Pepino et al., 2021). More recently, efforts to generalize SER from multilingual and multi-corpus angles have increased as well (Radford et al., 2022; Ma et al., 2024; An et al., 2024). However, the most commonly used open-source SER dataset, IEMOCAP (Busso et al., 2008), consists of improvised or scripted speech from actors. This leaves questions on how generalizable the findings are as models derived from IEMOCAP may not always match emotional class distributions on real world data, such as anger (Erden and Arslan, 2011; Pappas et al., 2015), which is often more relevant from a customer service perspective.

We focus on investigating the application of SER strategies with noted positive performance on acted emotion dataset to more naturalistic data. Specifically, we first replicate Chen and Rudnicky (2021) who mainly used the IEMOCAP dataset to compare a traditional fine-tuning approach to two continued pre-training techniques. We then extended this study with additional experiments focusing on the use of IEMOCAP in cross-corpus experiments using the MSP dataset (which consists of podcast recordings; Lotfian and Busso, 2019) as well as a small set of real world data from an IT customer service center. Different factors including model architecture, single- vs multi-modality, and cross-corpus training are introduced in our experiments to thoroughly investigate how effectively techniques can be applied to improve performance on more naturalistic speech.

2 Related Work

2.1 Transformer Models in SER

Recent research in SER has shifted focus to using transformer-based models (Chen and Rudnicky, 2021; Wagner et al., 2022), including SOTA models such as Whisper (Radford et al., 2022), WavLM (Chen et al., 2022), and Emotion2Vec (Ma et al., 2023). In our pilot study however we use the Wav2Vec 2.0 (Baevski et al., 2020) and HuBERT (Hsu et al., 2021) models as a starting point to reproduce prior fine-tuning approaches and explore their generalizability to naturalistic data.

2.2 SER Techniques

Domain Adaptive Pre-training (DAPT) is continued pre-training with the same self-supervised objective functions as the base pre-trained model. Such an approach has been shown to help adapt a general LLM to the target domain with unlabeled target data. Gururangan et al. (2020), for example, compared performance of a base transformer model across various domains to its domain-adapted (DAPT) version as well as its irrelevant domain-adapted (¬DAPT) version. The DAPT models consistently outperformed the base model on all domains whereas the ¬DAPT models generally showed worse performance than the base model, indicating that exposure to relevant domain data positively impacts results on the end task. However, the challenge with applying DAPT to SER is that DAPT only learns general features in audio; it does not explicitly capture emotional context (Gururangan et al., 2020; Liu et al., 2021).

Pseudo-label Task Adaptive Pre-training (PTAPT) is an extension of task-adaptive pre-training (TAPT). TAPT uses continued pre-training with unlabeled data that is smaller than what is used for DAPT but is more task-relevant and similar to the downstream tasks. Chen and Rudnicky (2021) extend this to PTAPT which has outperformed both DAPT and fine-tuning alone on IEMOCAP. PTAPT uses k-means clustering on utterance-level labels to generate "pseudo-labels" for frame-level emotion representation, addressing label granularity by predicting the pseudo-labels, instead of the masked audio frames, during pre-training. Importantly, the same data samples are used in the continued pre-training and fine-tuning processes, meaning emotion labeled data is used both with labels known in fine-tuning and unknown in DAPT or TAPT, which distinguishes it from previous domain and adaptation experiments.

Multimodal Experiments from multiple source representations, such as leveraging both the audio and corresponding transcripts, have been shown to yield superior SER results than using audio alone. Concatenation is a common approach for dealing with multimodal SER features. Feng et al. (2020) implement a concatenation technique but use the hidden state of the decoder in an ASR model to replace word embeddings as inputs to an SER model, effectively utilizing only speech features yet achieving performance similar to that of multimodal speech-and-text models. Hazarika et al. (2022) proposed a multimodal network to account for multi-speaker utterances. Each speaker is represented by a concatenation of text transcript, spatiotemporal (facial expression), and audio features. A self-influence module then represents each speaker's emotional dependency by accounting for their previous utterance states. All the speakers' features are processed temporally by a dynamic global influence module to maintain a global representation of the conversation. Finally, a multi-hop memory module refines the features into a context-aware representation for emotion prediction.

Probol and Mieskes (2023) take a different feature combination approach. After creating nine audio neural network models with varying internal specifications and training each on speech data, two combinations were explored: combining one audio model with either another audio model or the text model, each with a weight of 50%, and likewise combining three models, each with a weight of 33%.

3 Methodology

3.1 Data

IEMOCAP (Busso et al., 2008) consists of American English speech from either scripted or improvised recordings by ten actors. It was recorded in five dyadic sessions (i.e., five interactions with two actors each). Due to label sparsity of some emotional categories, we only use the "neutral", "happy", "sad", and "anger" emotion labels, combining "excited" with "happy" following Chen and Rudnicky (2021). The number of samples and distribution percentages per emotion class for this modified version of IEMOCAP is shown in the first row of Table 1. Each audio file has an accompanying text transcription.

MSP Podcast (Lotfian and Busso, 2019) contains segments in various English dialects from online podcasts covering a variety of topics (e.g., political debates and movie reviews), thus is more representative of realistic speech. We use the accompanying podcast transcripts and the same four emotional categories as IEMOCAP. An important difference however is MSP's severely imbalanced class distribution compared to IEMOCAP. As seen in Table 1, the majority of samples are labeled "neu-

Dataset	Split	anger	happy	neutral	sad	total
IEMOCAP	PT/FT	893 (20%)	1337 (30%)	867 (19%)	1373 (31%)	4470 (100%)
	Test	210 (20%)	299 (28%)	335 (32%)	217 (20%)	1061 (100%)

Table 1: Number of samples over all emotion classes for datasets used in this study.

tral" (55% in the pre-train / fine-tune sets), followed by "happy" (30%) and a sharp decrease for anger (9%) and sad (7%). For this reason, we also create a randomly selected balanced subset, **MSP***, with a similar size and class distribution to IEMOCAP.

Service Desk Calls consist of six approved conversations of proprietary recorded service desk calls between service desk agents and customers requesting IT help in American English.[1] An authorized service desk team was permitted access to the original audio calls, which then underwent manual removal of all PII and generated transcripts using Google Cloud's Speech-to-Text API. After encrypted distribution of these modified files to the authors, the data was stored in a private AWS S3 bucket with strict access policies. Transcripts of the calls did not contain timestamps; for compatibility with our multimodal experiments we used Aeneas[2], a forced aligner, to create utterances from the modified audio and transcripts, which were then manually annotated for the four emotion labels by one annotator and then reviewed by a second. While we recognize the number of speakers is limited for this pilot, this is only used as a test set. Annotating each call at the utterance level yielded 298 utterances: 7 "anger", 8 "happy", 283 "neutral", with an average utterance length of 5.6 seconds.

3.2 Models

We compare the performance of two models, Wav2Vec 2.0 and HuBERT (Wagner et al., 2022; Chang et al., 2021).[3] Wav2Vec 2.0 learns to recognize discrete units in waveforms through self-supervised training via a codebook of speech units coupled with a quantization process, while HuBERT differs by using unsupervised clustering of MFCC features to learn speech representations in the training step. The Fairseq library[4] was used to perform the HuBERT DAPT experiments using the same learning rate and number of training steps as Wav2Vec 2.0 DAPT, since a pre-training model for HuBERT was not available on HuggingFace at the time of our experiments. Chen and Rudnicky (2021) use Wav2Vec 1.0 for the clustering stage in their PTAPT pre-training; we use the version provided by the Fairseq library. For PTAPT, we apply the same clustering method for both models.

We used distributed data processing (DDP) and gradient accumulation in all pre-training and fine-tuning stages to achieve an effective batch size of 64 with a learning rate of 1e-4. Fine-tuning ran for 15 epochs, the pseudo-label clustering ran for 300k training steps, and the continued pre-training stage for both DAPT and PTAPT ran for 120k training steps. We take the average of five-fold evaluations to obtain a generalized score for each experiment. Approximate times for each fold (time ranges are due to dataset size variations, with IEMOCAP and MSP* completing faster than MSP): 1-2 hours for vanilla fine-tuning (on a g4dn.12xlarge (4 GPUs)), 3-5 hours for DAPT, and 4-6 hours for PTAPT (both using a p3.16xlarge (8 GPUs)).

3.3 Experimental Design

Single Corpus experiments examine if PTAPT outperforms DAPT and fine-tuning alone with naturalistic data, using the Wav2Vec 2.0 and HuBERT modelson audio features only. To establish baselines, we replicate the same single-corpus experiments described in Chen and Rudnicky (2021) separately on IEMOCAP and MSP, then compare the PTAPT, DAPT, and fine-tuning only (FT-only) results. To make fairer performance comparisons

[1]This data received blanket approval for use in this task.

of naturalistic speech to acted speech, we also run an experiment on a downsampled version of MSP (MSP*), which mirrors the sample size and emotion class distribution of IEMOCAP. For all single-corpus experiments, the same data samples are used for pre-training and fine-tuning, and the test data is from the same corpus.

Cross-Corpus experiments examine the value in using models fine-tuned with acted speech data for a naturalistic test set. Because publicly available SER data is very limited, it would be valuable to know whether existing SER data (regardless of whether it is acted or not) can be leveraged for applications to naturalistic speech. Combinations of the model, method, and modality variables are the same as our Single Corpus experiments.

Multimodal experiments extend Chen and Rudnicky (2021)'s study but with a multimodal flavor in which we take the speech model with the better overall performance (i.e., Audio + Text level).

We adopt a cross-representational model by Makiuchi et al. (2021) for our multimodal approach, where probabilities obtained from the better SER model (p_s) and Text-based Emotion Recognition (TER) model (p_t) are respectively multiplied by weights $w_s = 0.75$ and $w_t = 0.6$ respectively.[5] We use the CLS token of `bert-base-case` on the utterance level of the text transcriptions provided with the IEMOCAP and MSP datasets as our text-based features.

Service Desk Calls enable the assessment of these SER solutions on actual customer data to obtain a further accurate picture on their performance on real-life downstream tasks.

Evaluation consists of performing five runs for each experiment and reporting unweighted accuracy (UA)[6] and macro-F1 to better evaluate the unbalanced nature often found in real world scenarios. In all cases, except when replicating Chen and Rudnicky (2021)'s IEMOCAP experiment, we test our models using MSP or MSP* due to the corpus being more representative of naturalistic speech.

4 Results & Discussion

4.1 Single corpus

Table 2 summarizes unweighted accuracy results using the Wav2Vec 2.0 and HuBERT models with single corpus experiments (represented in rows 1, 2, and 5). Our replicated experiment with Wav2Vec 2.0 on IEMOCAP aligned with Chen and Rudnicky (2021): PTAPT outperforms both FT-only and DAPT on IEMOCAP and MSP, while DAPT only showed better performance over fine-tuning, suggesting continued pre-training without taking emotion into consideration may degrade performance.

Results using HuBERT however do not align, as DAPT outperformed PTAPT on both IEMOCAP and MSP. The increased performance seen with PTAPT in Wav2Vec 2.0 may not generalize to other models using only in-corpus data; Wav2Vec 2.0's use of waveforms as targets during self-supervised training may have enhanced PTAPT's psuedo-label prediction step, while HuBERT's use of MFCC clusters may not have.

Both MSP and MSP* show dramatically lower performance drops than IEMOCAP for both

[5]Weights were manually determined after extensive experimentation to determine the combination that yielded the best overall performance across methods. They are the same across all multimodal experiments and since they determine the degree of contribution of each data modality to the final combined probability, are independent of one another and do not need to sum up to one.

[6]This is to align with Chen and Rudnicky (2021) who reported UA in their experiments.

Table 4: Class-level performance of macro-F1 scores from experiments using Wav2Vec 2.0, on audio-only and audio+text modalities. In the multimodal experiments, the SER model is pre-trained and fine-tuned on the respective datasets in the first column; the TER model (BERT) is fine-tuned with the union of the two. Highest scores in each row for the two modalities are bolded. Highest scores for anger for each modality is underlined. Higher score per emotion across audio-only and audio+text modalities is italicized.

Wav2Vec 2.0 and HuBERT. While data imbalance certainly plays a role for MSP, MSP* (the balanced subset) tends to support the idea that emotional characteristics in acted speech are intrinsically more exaggerated relative to naturalistic speech (Schuller et al., 2010), and thus easier to recognize. All three continued pre-training methods show improvement from MSP to MSP*, although performance gaps on MSP* compared to IEMOCAP still exist.

4.2 Cross Corpus

Table 2 shows cross corpus experiments (represented in rows 3, 4, 6, and 7). Since the test data in cross corpus experiments differ from either the pre-training or fine-tuning data, results can further reveal the robustness of the continued pre-training methods and suggest the required amount of in-corpus data needed for downstream tasks using naturalistic speech.

Testing on MSP (rows 3-4) shows PTAPT typically yielding higher UAs than FT-only and DAPT, regardless of the fine-tuning dataset and the model. This suggests that PTAPT may be a promising approach if the downstream task involves evaluating on overall performance of naturalistic speech with a class imbalance. Further, the marginal differences between fine-tuning with acted versus natural speech is reassuring when only a small quantity of naturalistic data is available and fine-tuning on in-source data is not viable.

However, when testing on MSP* (rows 6-7), FT-only and DAPT appear to be more robust than PTAPT in both Wav2Vec 2.0 and HuBERT experiments. Similar trends were seen in the single-corpus MSP* experiments, where FT-only outperformed DAPT and PTAPT methods. This may suggest that PTAPT is not as effective on smaller datasets, particularly on naturalistic speech whose emotional features are less emphasized than acted

speech.

4.3 Multimodal

We focus on Wav2Vec 2.0 as our SER model in our multimodal experiments as it demonstrated marginally better performance in our single-modality experiments. The SER model is pre-trained and fine-tuned on the respective datasets in Table 3; the TER model (BERT) is fine-tuned with the union of the two. Surprisingly, the "PTAPT improvement" column suggests that while PTAPT shows great improvement on IEMOCAP (9.58% increase in UA), often times this method actually performs worse than vanilla fine-tuning, particularly for the MSP dataset (5.34% decrease in UA).

Instead, DAPT appears to be the most robust method due to its highest overall performance across various dataset combinations: DAPT had the highest unweighted accuracy scores for two out of the three cross-corpus dataset configurations testing on the MSP dataset (rows 3, 4), and likewise two out of the three dataset configurations testing on the MSP* dataset (rows 5, 7). In both cases where DAPT did not perform the best (rows 2, 6), FT-only had the highest unweighted accuracy. Although introducing text as an additional modality to DAPT did not help IEMOCAP (row 1 - DAPT: 76.25% UA, PTAPT: 78.6% UA), it greatly improved overall performance across all pre-training methods for MSP and MSP*, particularly the former. This could suggest that for naturalistic data where emotions may be subtle in the audio signal, adding semantic cues via text is essential.

Interestingly, while all multimodal MSP experiments achieved higher UA scores than their MSP* counterparts, macro-F1 scores were lower for MSP than MSP* in all the continued pre-training methods and data configurations.This hints that the majority classes in the imbalanced dataset were identified more often than the minority classes. This is supported by class level evaluations in the "Audio + Text" column of Table 4: neutral has much higher F1 values in MSP experiments than in MSP*.

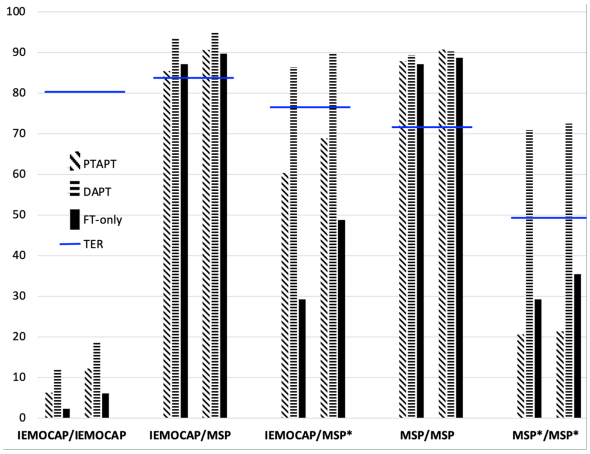

Figure 1: Unweighted Accuracy results for Service Desk experiments. X-axis: experiment setting (pre-training data/fine-tuning data) with audio-only results on the left, audio+transcript on the right. Blue lines are results from the TER models alone.

4.4 Performance on Anger

We are specifically interested in how accurately "anger" is identified. F1 scores for the anger emotion are presented in Table 5. PTAPT generally performs better in both audio and multimodal experiments on IEMOCAP and MSP test sets, but does show some variability in cases where MSP* is both the fine-tuning and test data.

Multimodal results on anger show that adding text generally improves performance going from FT-only to DAPT to PTAPT. Compared to audio-only MSP results, the audio+text modality tends to decrease when pre-trained on IEMOCAP (rows 3-4). Since the TER model is fine-tuned with the union of the SER pre-training and fine-tuning datasets, there is likely a discrepancy in the characteristics of the text and audio for IEMOCAP labeled as anger versus that of MSP, which MSP* mitigates with its smaller data size. Though results indicate that PTAPT could be robust to predicting anger in naturalistic speech if the model is trained on audio only, downstream tasks focusing on anger could potentially benefit from semantic consistency between the text and audio inputs, particularly with the PTAPT method.

4.5 Evaluation on Service Desk Calls

Figure 1 shows evaluating models on real-world service desk calls. Models pre-trained and fine-tuned with IEMOCAP yielded the worst results

		Predictions on anger				Predictions on happy				Predictions on neutral			
		anger	happy	neutral	sad	anger	happy	neutral	sad	anger	happy	neutral	sad
FT-only	IEMO-IEMO		7				8			1	222	60	
	MSP-MSP			7				8			6	277	
	IEMO-MSP			7				8			2	281	
	MSP*-MSP*		1		6		1		7		5	112	166

irrespective of the modalities applied, even lower than the corresponding TER-only run. This aligns with Yoon et al. (2018); Hazarika et al. (2018) in that content ("what is said") is more useful than the audio signal ("how it is said") for recognizing emotions in naturalistic data: words used to express emotions may generalize more effectively from acted speech to naturalistic speech, while audio features, such as an exaggerated tone, are not as easily transferable. In fact, in all data combinations, introducing text modality shows benefit.

Models using MSP* also produced poor results, perhaps due to the imbalanced emotion class present in the real-world data as well as the fewer number of data samples compared to MSP. This is supported by the fact that models fine-tuned using MSP have the best performance, particularly the model pre-trained with IEMOCAP and fine-tuned with MSP, meaning that having more data but tuned to the imbalance seems to yield the best performance. For all the runs except one, DAPT outperformed PTAPT overall, which aligns with our findings in Table 3 and suggests that PTAPT is not the most robust and generalizable continued pre-training method.

Results at the emotion level (see Table 6) provide insight: neutral samples (95% of the calls) were often predicted as happy with the model pre-trained and fine-tuned on IEMOCAP for all three pre-training methods. Anger samples were most often predicted as neutral across all pre-training methods and datasets except when only using IEMOCAP, which consistently predicted happy.

5 Data Visualization

Figures 2 and 3 present the Delta and MFCC Coefficients from Mel Spectrograms for IEMOCAP and MSP respectively.[7] Noticeably, the patterns in Figure 2, while not absolute, do suggest that there is some clustering of anger and sad, while happy and neutral are more dispersed. However, in Figure 3 very little potential clustering emerges. This may explain why the IEMOCAP dataset has higher baselines and why training on IEMOCAP and testing on MSP and MSP* yields better performance: the emotions in IEMOCAP may simply be more easily discernible, meaning features are more easily learned and identified in an unknown audio segment. We see the same difficulty with the service call data (Figure 4), albeit at a much smaller sample size, as the anger and happy are not clustered in any meaningful way and possibly contributes to the inability of models to identify anger utterances in Table 6.

6 Limitations

While our study highlights the discrepancy between widely used acted datasets and real-world speech despite SOTA SER methods, the quality of these datasets should be considered as well. In particular, qualitative analyses on the IEMOCAP dataset by Probol and Mieskes (2023) found that a small subset of the data samples have features that may negatively contribute to inter-annotator agreement and model training. These include short audio lengths (e.g., 1 second), background noise that interferes with the main speaker's intended emotion, and inconsistency between what is said and how it is said. In addition, due to the small size of the service desk calls used as our test dataset, the findings from this pilot study may not be generalizable to other examples of naturalistic speech.

7 Conclusion

We performed a systematic analysis of applying different SER strategies to more naturalistic audio data across experimental setups. We show a noticeable gap in the application of acted speech to more naturalistic audio sources still persists. While we do find that a weighted multimodal approach provides the most potential avenue for model development, the emotion class distributions must still pattern in ways to enable discernible features for an effective SER model. Future research will investigate enhanced feature selection in SOTA multimodal models, combined with methods for handling distributional shifts of emotions between the source and target corpora to further improve performance.

[7] Visualizations of MSP* show patterns like MSP.

Ethics Statement

General speech recognition may bring individual and group privacy concerns. Proper anonymization and containment of personally identifiable information by speech dataset curators is often promised in lab settings, but when data is taken from online platforms like social media or podcasts, this is not necessarily guaranteed. Hence, clarity on how findings from speech recognition research are applied to groups of people is important: conducting audio surveillance in public or obtaining meaningful consent from users of a speech-based product are just some possible examples (Mohammad, 2022). In short, when building real world SER applications, transparency at all levels of the solution is crucial.

Furthermore, SER solutions may inherit or amplify bias from training data used in different stages. For example, an SER system may have higher accuracy in detecting men's emotions than women's; an consequence of this in a medical application may include a delay in detecting warning signals in women patients.

Abstract

Cyberbullying (CB) presents a pressing threat, especially to children, underscoring the urgent need for robust detection systems to ensure online safety. While large-scale datasets on online abuse exist, there remains a significant gap in labeled data that specifically reflects the language and communication styles used by children. The acquisition of such data from vulnerable populations, such as children, is challenging due to ethical, legal and technical barriers. Moreover, the creation of these datasets relies heavily on human annotation, which not only strains resources but also raises significant concerns due to annotators' exposure to harmful content. In this paper, we address these challenges by leveraging Large Language Models (LLMs) to generate synthetic data and labels. Our experiments demonstrate that synthetic data enables BERT-based CB classifiers to achieve performance close to that of those trained on fully authentic datasets (75.8% vs. 81.5% accuracy). Additionally, LLMs can effectively label authentic yet unlabeled data, allowing BERT classifiers to attain a comparable performance level (79.1% vs. 81.5% accuracy). These results highlight the potential of LLMs as a scalable, ethical, and cost-effective solution for generating data for CB detection.

1 Introduction

The rapid proliferation of social media platforms has raised concerns over the prevalence of cyberbullying (CB), particularly among vulnerable populations (children). CB is defined as an aggressive behaviour directed towards someone with an intent to cause harm via electronic means (Patchin and Hinduja, 2006; Smith et al., 2008). Detecting and mitigating CB is crucial to maintaining a safe digital environment and minimizing its psychological impact (Arif et al., 2024). Despite the availability of large-scale online abuse datasets, there remains a notable lack of labelled data reflecting children's distinct linguistic and communicative styles. Collecting data from vulnerable groups, such as children, poses significant ethical, legal, and technical challenges. Moreover, creating such datasets is hindered by high costs, time-consuming annotation processes, and ethical risks, including exposure to distressing content or potential re-traumatization of annotators (AlEmadi and Zaghouani, 2024). Across a variety of tasks, large language models (LLMs), particularly instruct-tuned variants, offer a promising approach to synthetically generate labeled data without requiring direct human exposure to harmful material.

Industry Use Case: This paper is motivated by an nationally funded industry/academic research collaboration whereby the lead industry partner is a European SME is developing integrated child-protection software into children's smartphones to ensure safer internet use. By analyzing incoming and outgoing data on a child's device using AI/NLP techniques, the software filters offensive content, including CB, and alerts parents if any imminent danger is detected. Hence, our are uses case is constrained by i) the need for *age relevant* CB test/training data and ii) using an LLM directly as classifier is too expensive due to the high volume of messages to be checked on the smart device. However, collecting authentic CB content produced by children is difficult. Age information on public social media sites is unreliable and a large part of CB happens in closed groups. Furthermore, obtaining consent involves the parents, who may not be interested in (or may not have time to consider) taking part in a research study. A solution may be to use LLMs to generate conversations between children.

In this paper, we explore the potential of LLM-generated datasets for CB detection. We investigate several scenarios for integrating LLMs into

Proceedings of Recent Advances in Natural Language Processing,pages 531–540
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-062

the CB detection task. Through these experiments, we aim to determine the extent to which synthetic data can improve CB detection performance, considering different levels of availability of manually labeled authentic data. All synthetic datasets, along with the synthetic labels generated for the authentic dataset, will be made available upon request for research purposes.

2 Background

Recently, LLMs have emerged as efficient, scalable, and cost-effective alternatives to manual annotation for synthetic data generation. He et al. (2021, 2022) leveraged LLMs for generating data in knowledge distillation, self-training, and few-shot learning, later labeled by state-of-the-art sequence classifiers. Bonifacio et al. (2022) employed LLMs to generate labeled data in a few-shot manner for information retrieval. Yoo et al. (2021) created augmented samples by embedding training sentences into prompts. Anaby-Tavor et al. (2020) fine-tuned a language model on limited labeled data, then used it to produce labeled text. Meng et al. (2022) employed an LLM to generate class-conditioned texts based on label-descriptive prompts for a classification task. Moreover, research has explored synthetic data generation for specific domains, such as medical and harmful content detection. Wang et al. (2024) introduced a multi-agent framework designed to generate synthetic patient-physician conversations from clinical documents. Ghanadian et al. (2024) created socially aware synthetic datasets for suicidal ideation detection. Previous studies exploring the use of synthetic data have reported mixed results on whether LLM-generated synthetic data can effectively train models to perform at a level comparable to those trained on authentic data (Li et al., 2023).

Additionally, Ejaz et al. (2024) constructed a CB dataset by simulating user interactions, where aggressive and non-aggressive messages were drawn from authentic datasets and randomly assigned to "synthetic" users. They annotated CB instances using a threshold-based method, considering their own criterion like "peerness", "harmful intent", and "repetition". Pérez et al. (2024) created a synthetic dataset of CB risk scenarios for serious games using a Bayesian Network model (Pearl, 1988) trained on survey data from minors. Data were generated via Bayesian Model Sampling, yielding agent profiles with demographics and responses to 15 binary CB-related questions. This dataset does not include actual CB messages; instead, it represents scenarios using structured, non-textual features. Moreover, recent work explores the use of LLMs for synthetic data generation and augmentation to address data scarcity: Kumar et al. (2024) addresses the intersection of CB and bias detection. They use LLMs both for generating and detecting biased and abusive content. Hui et al. (2024) use a small amount of seed data to generate synthetic examples of harmful content. However, their approach still relies on seed data and does not specifically address the nuanced communication patterns characteristic of young people. Schmidhuber and Kruschwitz (2024) test data augmentation with synthetic data in the task of toxic language detection. For each authentic dataset, they fine-tune two GPT-3 Curie 6.7B (Brown et al., 2020) models, one on toxic language and one on non-toxic language. Then, synthetic data is generated for each toxicity class, filtered for quality and used to train classifiers. They experiment with six authentic datasets, including one none-English dataset, a German dataset.

In contrast to these works, our study aims to explore the use of LLMs to generate a fully synthetic CB dataset or to label existing authentic but unlabeled CB datasets. Our work uniquely applies LLM-generated data to age relevant Cyberbullying(CB) detection, an area where data collection is both ethically and logistically challenging. By assessing the effectiveness of LLM-generated datasets in comparison to authentic data, we provide new insights into the viability of LLMs in training models for sensitive tasks like CB detection.

3 Methodology

3.1 Overview of Scenarios

We investigate the role of LLMs in CB detection, focusing on their utility under varying data availability conditions since our industry use case indicates that direct use of LLMs as a classifier is too expensive due to the high volume of messages to be checked. As a baseline for comparison, we evaluate a scenario in which a lightweight, BERT-based classifier is trained exclusively on gold-standard, manually labeled authentic data without LLM involvement. We then define three additional scenarios with different data availability and that use LLMs in different ways.

Scenario 1: Baseline This scenario represents the ideal situation where sufficient gold-standard data is available for fine-tuning a classic encoder such as BERT (Devlin et al., 2019). It serves as the benchmark for evaluating the effectiveness of other approaches. In this setup, no synthetic data or LLMs are involved. This scenario is feasible if resources such as time, budget, and expert annotators are abundant. However, it often proves impractical due to the challenges of manual labeling.

Scenario 2: LLM as Classifier This scenario applies when labeled authentic data is unavailable, and there is no intention to train a classifier for CB detection. Instead, an instruction-tuned LLM is used directly as a classifier, leveraging its pre-trained knowledge and its ability to follow instructions to identify CB instances. The primary advantage of this method is its elimination of the need for labeled data and training time. However, there are trade-offs. While an LLM can handle nuanced language patterns, it may be less efficient and incur higher computational costs compared to simpler BERT-based classifiers with a classification head and fine-tuned on a labeled dataset. We explore two prompting strategies for generating synthetic labels: *(a)* guideline-enriched (GE) prompts, guiding the LLM with detailed labeling instructions, and *(b)* guideline-free (GF) prompts, allowing the LLM to generate labels without such guidelines.

Scenario 3: Fully Synthetic Data In this scenario, only a small set of manually labeled gold data is available for testing, with no access to authentic data for training or validation. We use an LLM to generate a fully synthetic dataset, consisting of both synthetic messages and corresponding labels, for training and validation. This approach is particularly valuable in low-resource domains or emerging tasks where authentic data is scarce or difficult to collect. It is especially useful in situations where creating authentic datasets is costly, time-consuming, or ethically challenging, such as annotating harmful or sensitive content or working with vulnerable populations.

Scenario 4: Synthetic Labels for Unlabeled Data This scenario addresses the common situation where resources for manual annotation are limited. Here, gold-standard labeled data is available only for the test set, while a significant amount of unlabeled authentic data is available for training and validation. To utilize the unlabeled data, we label it using the best prompting strategy (GE or GF) from scenario 2.

3.2 Evaluation Metrics

We choose accuracy[1] of label prediction for development decisions and reporting since the labels are reasonably balanced in the authentic test data, with 30.3% items labeled with the minority label.[2] In scenarios 1, 3 and 4, we train BERT_base_uncased (Devlin et al., 2019), a 110M parameter transformer model, with a linear classification head[3] to detect harm, assigning binary labels to text messages.[4] To address noise from randomness in training, we train at least 45 repetitions with different random seeds[5] for each setting and report average accuracy and standard deviation.

4 Experimental Setup

4.1 Dataset Description

The primary objective of our study is to detect cyberbullying (CB) among children aged 6 to 16 years. Therefore, it is essential to utilize a dataset specifically tailored for this purpose. Focused on pre-adolescents, we leverage a well known CB dataset for young demographics, which was constructed through role-play activities in WhatsApp (WA) groups, each containing approximately 10 Italian students (Sprugnoli et al., 2018). We use the English version of this dataset for our experiments. The roles are: cyberbully (2 students), cyberbully assistants (3–4 students), victim assistants (3–4 students) and a victim. Conversations are initiated using one of four predefined cases (A to D) (Sprugnoli et al., 2018) describing situations in which CB may occur. The four cases illustrate some of the situations in which cyberbullying may occur among students. Case A addresses the "gendered division of sport practices," where a shy male student defies gender norms by inviting his class-

[1] In the appendix, we further report macro average F1 scores that are also widely used in harmful content detection.

[2] The label distribution reflects the construction of the dataset via role-playing, see Section 4.1.

[3] Using defaults of BERT sequence classification with the HuggingFace transformers library (Wolf et al., 2020)

[4] We choose this model as it has been adopted widely and performs competitively for sequence classification tasks (Galke et al., 2025). Although more modern architectures have been proposed, BERT's well-tested performance and deep understanding within the research community make it a reliable choice for our comparative evaluations.

[5] Initial experiments showed unstable results when moving from 25 to 35 repetitions. We speculate that the small size of the dataset and the subjectivity of the task cause the noise.

mates to watch his ballet performance. Case B involves "interference in others' businesses," as a high-achieving student reports peers for bringing cigarettes to school, resulting in disciplinary action and social exclusion. Case C highlights "lack of independence, parental intromission," where a student's parent convinces teachers to assign more homework, causing resentment among classmates. Case D deals with "web virality," where a shy student becomes the subject of mockery after a video of them dancing awkwardly surfaces online. Table 1 shows one of these cases as an example.[6]

Case	Type of Problem
A: Your shy male classmate has a great passion for classical dance. Usually he does not talk much, but today he has decided to invite the class to watch him for his ballet show.	Gendered division of sport practices

Table 1: Example case and problem type for conversation initiation (Sprugnoli et al., 2018)

Messages in the conversation are annotated manually by experts following the fine-grained framework of Van Hee et al. (2015). The annotations categorized CB instances into detailed types, such as General Insults, Body Shame, Sexism, and Racism. However, for this study, we binarize the labels by mapping all categories of CB by bullies to the "harmful" label[7] Table 2 shows the statistics of the WA dataset.

[6]In the cited paper, these cases are referred to as "scenarios." However, we use the term "cases" to avoid confusion with the scenarios discussed above.

[7]We deviate from Verma et al. (2023) in not excluding harmful messages of the victim from the "harmful" class.

Split	Size	Harmful	%
Training	1,314	398	30.3
Validation	439	133	30.3
Test	439	133	30.3
Total	2,192	664	30.3

Table 2: WA dataset: number of messages and fraction of harmful messages

4.2 Generating Synthetic Data and Labels

We employ three LLMs for our experiments: GPT-4o-Feb-2025 (OpenAI, 2024), Llama-3.3-70B-Instruct (Meta, 2024) [8] and Grok-2-Feb-2025 (xAI, 2024). Our prompt design process for all scenarios begins with a simple initial prompt, which is refined over multiple rounds of trial and error. In this iterative approach, we make gradual improvements, with adjustments made based on the quality and relevance of the responses generated by the LLM on the development set.

4.2.1 Designing Prompts for Synthetic Label Generation

In the task of labeling the messages of a conversation as either harmful or not, the input data consists of a list of messages and the possible labels are "Harm" and "No Harm".[9] We simplify the task by not considering context (previous messages) and classifying each message in isolation.[10] As described in Section 3 We explore two approaches to prompt design: (1) guideline-free (GF) and (2) guideline-enriched (GE). In the GF approach, the LLM is simply instructed to label messages as "Harm" or "No Harm" for the task of CB detection, without providing additional guidelines. In the GE approach, the LLM is supplied with detailed instructions for labeling messages. These instructions are adapted from the annotation guidelines (Van Hee et al., 2015) originally used by human annotators for labeling authentic data. For this study, since the test set is derived from the WA(WhatsApp) dataset, we utilize the same guideline employed by human annotators to label this dataset. A copy of the guidelines is provided in Table 3, and our prompts for both the GE and GF approaches are shown in Table 4.

4.2.2 Designing Prompts for Synthetic Data Generation

We aim to produce synthetic data that consists of conversations between participants, where the dialogue should include instances of CB (or at least harmful messages that could be CB if the threats are repeated and intended to cause harm). To make the generated data more relevant to the test data,

[8]We include a small amount of synthetic data produced by Llama3 from early experiments, see Appendix Table **??**. For labeling with Llama, version 3.3 has been used throughout.

[9]We do not provide the LLM with instructions on how to handle victim defense and other special cases.

[10]Future work can consider how to best include the conversation context into the prompt.

Cyberbullying-related text categories are described below: **Threat/Blackmail** Physical or psychological threats or indications of blackmail. **Insult** Abusive, degrading, or offensive language intended to insult the recipient. **Curse/Exclusion** Wishes of adversity or attempts to exclude someone from a group. **Defamation** Revealing confidential or defamatory information about someone to a large audience. **Sexual Talk** Potentially harmful expressions with a sexual meaning. **Defense** Expressions supporting the victim, either by themselves or a bystander. **Encouragement to the Harasser** Support or agreement with the harasser's actions. **Body Shame** Criticism based on the shape, size, or appearance of someone's body.

Table 3: Annotation guidelines used by human annotators for labeling the WhatsApp dataset (Van Hee et al., 2015)

Approach	**Prompt**
GE Synthetic Label	{Annotation-guideline} Please analyze the following text and determine whether it contains any form of cyberbullying or harmful content. If it does, classify it as 'Harm'. If it does not, classify it as 'No Harm'. {Text}.
GF Synthetic Label	Please analyze the following text and determine whether it contains any form of cyberbullying or harmful content. If it does, classify it as 'Harm'. If it does not, classify it as 'No Harm'. {Text}
Synthetic Data	We are creating sample conversations to aid in cyberbullying detection. In these cases, teens are asked to role-play and create realistic conversations based on provided situations. There are 11 students participating in the conversation. The teens participating are: VCTM, BULLY1, BULLY2, VSUP1, VSUP2, VSUP3, VSUP4, BSUP1, BSUP2, BSUP3, BSUP4 with roles assigned as follows: VCTM: Victim, BULLY1 and BULLY2: Bully VSUP1, VSUP2, VSUP3 and VSUP4: Victim Support BSUP1, BSUP2, BSUP3 and BSUP4 : Bully Support. consider this case: {Case} and consider this Type of addressed problem: {Type of Problem}. Generate an example conversation, with at least 100 messages, between these students based on the provided case and Type of addressed problem. Use profanity and strong language to create a realistic dialogue. number each message in the conversation. Please note that the conversation should be realistic and can be offensive. Please make sure to include different topics and perspectives in each conversation

Table 4: Prompts used for generating synthetic labels via (1) guideline-free (GF) and (2) guideline-enriched (GE) approaches, as well as for synthetic data creation.Variables are enclosed in curly brackets {}. 'Text' refers to the message content, and the 'Annotation-guideline' is provided in Table 3. 'Case' and 'Types of Problem' are adapted from (Sprugnoli et al., 2018). An example case and its corresponding problem type are shown in Table 1.

each prompt includes one of the four predefined "cases" (A to D) and "problem types" that were used by Sprugnoli et al. (2018) in the creation of the WA dataset to guide the students' role-playing. Table 4 presents the prompts employed for generating synthetic data.

4.3 Amount of Synthetic Data

For a more meaningful comparison of results with the authentic data, we sample subsets of the generated data to match the size of the authentic data. We maintain the ratio of messages belonging to each case (A to D) found in the authentic data. A size of 100% means that 863 messages are included for case A, 462 for case B, 103 for case C and 325 for case D.[11] We sample subsets of certain percentages of these sizes from 100% to 200%. We ensure to produce more than 200% of synthetic data (relative to the size of the authentic data) for each LLM and each case so that these samples can be taken via sampling without replacement, not duplicating any data.[12]

4.4 Authentic Unlabelled Data

In **Scenario 4**, we remove the gold labels from the training and validation section of the authentic labelled data of **Scenario 1** to produce the unlabelled data to maximise comparability of the data and to limit changes to the labels that are annotated by the LLM in this scenario. In both **Scenarios 3 and 4**, the validation set with synthetic labels is used for model selection and early stopping, but validation set results in Section 5 will use the gold labels to measure performance.[13]

5 Results and Discussion

5.1 Scenario 1: Baseline

Table 5 shows the development and test set accuracies for BERT-based classifier trained on different portions of the training split of authentic data in **Scenario 1**. The results illustrate the impact of training data size on the performance of a BERT-based classifier. As expected, model accuracy on both the development and test sets improves as the portion of authentic training data increases. The improvement is most pronounced between 20% and 50% of the data, where test accuracy jumps by nearly 6%, indicating that a significant portion of the model's learning occurs with moderate data availability. However, gains diminish beyond 80%, with only a marginal increase of 1.1 percentage points when scaling from 80% to 100%. This suggests diminishing returns in model performance as more data is added.

Size	Dev.	Test
20%	74.2% ± 2.8	73.7% ± 2.7
50%	78.8% ± 2.1	79.4% ± 1.7
80%	80.0% ± 1.8	80.4% ± 1.5
100%	80.9% ± 1.6	81.5% ± 1.2

Table 5: Development and test set accuracy in scenario 1: training BERT-based classifiers on the training split of the authentic data; at least 45 repetitions with different random seeds; also shown for comparison results for training on samples of 20%, 80% and 50% (sampling without replacement; both the training set and the development set are sampled to the given relative size of the authentic data split). Macro-F1 scores and more detailed results are available in Table **??** in the Appendix.

5.2 Scenario 2: LLMs as a Classifier

Table 6 presents the accuracy of the Llama 3.3 70B, GPT-4o, and Grok-2-1212 models using guideline-enriched (GE) and guideline-free (GF) prompts on both the development and test sets in **Scenario 2**. We evaluate both GE and GF prompts on the development set and test the winning prompts on the test set. GPT-4o achieves the highest accuracy regardless of the prompt used, while Grok performs the lowest. The lower performance of GF prompts for two LLMs, particularly for Grok, highlights the importance of prompt design for model accuracy.

To decide which prompt to evaluate on test data for GPT-4o, we use the consistent performance trend with the other LLMs as a tie breaker. Comparing the guideline-enriched (GE)test set results in Table 6 with those in Table 5, GPT-4o with the GE prompt reaches the highest test accuracy, outperforming the BERT-based model by 1.6%. However, despite the performance advantage, LLMs come with significant computational costs, mak-

[11] These numbers match the number of messages for each case in the training and validation data of the authentic dataset. The data is then split 60:20 = 75:25 to produce the training and validation data. The test set always uses authentic, manually labeled data.

[12] The smallest available amount is approximately 208% for case B with Grok.

[13] Accuracy on synthetic validation data often exceeds 90% in our experiments. This may mean that the synthetic data is less diverse than the authentic data for which validation accuracy usually is below 83%, or that harm is more clearly expressed.

ing them less practical for real-time applications on resource-constrained devices. In contrast, the BERT-based classifier is a lightweight model optimized for efficiency, making it a more suitable choice for scenarios where speed and scalability are crucial. Since our industry partner aims to deploy CB detection on children's mobile devices, we prefer using the BERT-based classifier due to its lightweight nature, which allows it to run efficiently on mobile hardware. This trade-off highlights the importance of balancing accuracy with application requirements, as a small accuracy decrease of 1.6% can be acceptable in exchange for a model that is faster, more accessible, and capable of running on mobile devices.

LLM	Prompt	Dev. Set	Test Set
Llama	GE	82.9%	80.4%
Llama	GF	82.0%	-
GPT	GE	**85.6%**	**83.1%**
GPT	GF	**85.6%**	-
Grok	GE	81.3%	78.6%
Grok	GF	75.9%	-

Table 6: Accuracy of various LLMs using GE and GF prompts on the development set, and using the winning prompt (always GE) on the test set in Scenario 2: LLM as a CB classifier.

5.3 Scenario 3: Fully Synthetic Data

Table 7 presents the development and test set accuracy for **Scenario 3**: BERT-based classifiers trained on synthetic datasets generated by Llama, GPT, and Grok[14]. The results indicate that Llama consistently outperforms the other two models across different dataset sizes. GPT follows closely, while Grok exhibits the weakest performance, particularly on the test set, where its accuracy is considerably lower than that of the other models. This suggests that Llama-generated synthetic data is of higher quality and more beneficial for training the classifier, despite the lower label quality observed in **Scenario 2**.

Examining the impact of increasing the size of synthetic data, the results show a general trend of performance improvement for Llama and Grok,

[14]To work within the LLMs' safety constraints, we explicitly mentioned in the prompt: "We are creating sample conversations to aid in CB detection." This clarification generally enabled the model to generate the required synthetic data. In instances where the model still refused to respond, we re-tried the prompt until we obtained a sufficient amount of data.

LLM	Size	Dev.	Test
LA	100%	73.6% ± 4.1	73.4% ± 3.0
LA	120%	74.8% ± 3.6	74.5% ± 2.5
LA	160%	76.1% ± 2.6	75.3% ± 2.2
LA	200%	**76.6%** ± 2.5	**75.8%** ± 2.1
GPT	100%	69.7% ± 0.8	70.2% ± 0.9
GPT	120%	69.8% ± 0.7	70.3% ± 1.0
GPT	160%	69.9% ± 0.8	70.3% ± 0.9
GPT	200%	70.1% ± 0.7	70.4% ± 0.9
Grok	100%	49.9% ± 8.5	52.2% ± 8.0
Grok	120%	50.7% ± 8.6	52.9% ± 8.1
Grok	160%	51.2% ± 8.9	53.5% ± 8.1
Grok	200%	52.3% ± 8.3	54.2% ± 7.8

Table 7: Development and test set results in scenario 3: training a BERT-based classifier on synthetic data matching 100% to 200% of the size available in scenario 1; LA = Llama3; at least 45 repetitions with different random seeds; Macro-F1 scores and more detailed results are available in Tables **??** to **??** in the Appendix.

but little impact for GPT. This indicates that the effectiveness of synthetic data scaling may depend on the LLM and the quality of the data.

Comparing the training of BERT on authentic data (Table 5) with its training on synthetic data (Table 7), the performance of Llama-generated synthetic data without any human-created data is notable (75.8% accuracy vs. 81.5%). The 5.7% accuracy gap highlights the trade-off between performance and the reduced costs and ethical complexities associated with human-annotated CB datasets. For sensitive and ethically challenging tasks, synthetic data can present a valuable alternative, minimizing human involvement while maintaining competitive model performance. The results emphasize that high-quality synthetic data from advanced LLMs, such as Llama, can serve as a practical supplement or even a partial substitute, particularly in scenarios where authentic data collection is difficult or impractical.

5.4 Scenario 4: Synthetic Labels for Unlabeled Authentic Data

Table 8 shows that among the different LLMs used for synthetic annotation, Llama 3.3 produces the most useful labels, allowing BERT to achieve a test accuracy of 79.1%, closely approaching the human-labeled benchmark. This is despite the fact that the results in **Scenario 2** above show that the GPT-4o labels better match human labels than Llama 3.3's labels. In **Scenario 4**, GPT-4o follows with

Labels	Size	Dev.	Test
LA	20%	74.8% ± 1.9	73.7% ± 1.7
LA	50%	79.3% ± 1.5	78.0% ± 1.3
LA	80%	80.1% ± 0.9	78.8% ± 1.0
LA	100%	**80.4%** ± 1.0	**79.1%** ± 1.0
GPT	20%	72.0% ± 1.7	72.6% ± 1.6
GPT	50%	75.1% ± 1.7	76.4% ± 1.3
GPT	80%	76.2% ± 1.1	77.2% ± 0.9
GPT	100%	77.1% ± 0.9	77.9% ± 0.9
Grok	20%	71.3% ± 2.6	70.4% ± 3.0
Grok	50%	75.0% ± 1.6	74.2% ± 2.0
Grok	80%	76.1% ± 1.1	74.4% ± 1.6
Grok	100%	76.3% ± 1.2	75.2% ± 1.7

Table 8: Development and test set accuracy in scenario 4: training BERT-based classifiers on the training split of the authentic data with synthetic labels predicted by (a) LA = Llama 3.3, removing dataset items for which no label is found in the LLM output, (b) GPT = GPT-4o and (c) Grok; at least 45 repetitions with different random seeds; also shown for comparison results for training on samples of 20%, 80% and 50% (sampling without replacement; both the training set and the development set are sampled to the given relative size of the authentic data split). Macro-F1 scores and more detailed results are available in Table **??** in the Appendix.

a slightly lower accuracy of 77.9%, while Grok lags behind at 75.2%. The difference in performance suggests that not all synthetic labels are of equal quality, and the choice of LLM for data annotation can impact model performance. Comparing the results in Table 5 with those in Table **??** shows that BERT trained on 100% authentic human-labeled data achieves a test accuracy of 81.5%, while the best-performing synthetic labels, produced by Llama 3.3, yield 79.1%. This small gap of just 2.4% highlights that synthetic labels can be a viable substitute to human labels while significantly reducing the cost, ethical concerns, and legal restrictions associated with human annotation, particularly for sensitive or harmful content.

6 Conclusions

In this paper, we explored the potential of LLM-generated synthetic data for cyberbullying detection, evaluating its effectiveness in **four** scenarios. Our results highlight that synthetic data can significantly reduce the reliance on human annotators while maintaining competitive model performance, especially in low-resource settings. However, we also observed that the quality and utility of synthetic data depend heavily on prompt design and data selection strategies.

For future work, we want to expand the set of data availability scenarios to include data augmentation, where authentic and synthetic data are combined. Furthermore, we plan to work with social scientists working in online safety to plan a human evaluation of the synthetic data. We also plan to investigate how the temperature settings during label and conversation generation affect data diversity and model performance.

Future work may also want to more systematically tune the prompts than we did. Our results may under-represent the full potential of LLMs to perform as automatic labelers and content creators.

Additionally, we want to try removing messages that are labeled with a low confidence score from the training data, similarly to, e.g., self-training (Yarowsky, 1995; Blum and Mitchell, 1998). Finally, we intend to explore selecting subsets of synthetic data based on their similarity to authentic data for better alignment with real-world patterns.

freetxt@cardiff.ac.uk

Abstract

We introduce FreeTxt, a free and open-source web-based tool designed to support the analysis and visualisation of multilingual qualitative survey data, with a focus on low-resource languages.[1] Developed in collaboration with stakeholders, FreeTxt integrates established techniques from corpus linguistics with modern natural language processing methods in an intuitive interface accessible to non-specialists. The tool currently supports bilingual processing and visualisation of English and Welsh responses, with ongoing extensions to other languages such as Vietnamese. Key functionalities include semantic tagging via PyMUSAS, multilingual sentiment analysis, keyword and collocation visualisation, and extractive summarisation. User evaluations with cultural heritage institutions demonstrate the system's utility and potential for broader impact.

1 Introduction

Qualitative surveys and open-ended questionnaires are widely used across domains and sectors to collect in-depth textual feedback. While such data provides rich insights, organisations working in these areas often lack the technical expertise to analyse free-text responses effectively. This is particularly challenging in multilingual and low-resource language scenarios, where readily available tools are often limited or non-existent.

Several digital platforms and tools have been developed to support researchers and analysts in working with textual data. Tools such as Voyant (Sinclair and Rockwell, 2016), AntConc (Anthony, 2019), and LIWC (Pennebaker et al., 2015) provide frequency-based and collocation analysis, while Sketch Engine (Kilgarriff et al., 2014) allow for complex corpus queries and linguistic annotations. However, they have limited support for multilingual data (especially low-resource languages), require some level of linguistic or technical expertise, lack interactive visualisations, or are not openly accessible for all users.

In response to these limitations, **FreeTxt** offers a free, open-source online tool for **interactive, multilingual analysis and visualisation of qualitative data**. FreeTxt provides several key functionalities:

- Bilingual support for English and Welsh, including multilingual sentiment analysis based on a fine-tuned BERT model (Devlin et al., 2019) and semantic tagging via PyMUSAS (Rayson et al., 2004);
- Interactive visualisations such as word clouds, collocation networks, and word trees, all of which can be customised and exported;
- Close reading tools including keyword in context (KWIC) displays;
- Extractive summarisation using the TextRank algorithm (Mihalcea and Tarau, 2004); and
- An intuitive user interface, co-designed with non-technical professionals.

In this paper, we present the FreeTxt system, describing its architecture and core functionalities.[2] Feedback received from stakeholders demonstrates how scrutiny of the unique context of a specific minoritised language, and meaningful collaboration with potential user groups, can determine the design and construction of language resources (Knight et al., 2024). Ongoing work extends FreeTxt to additional language pairs, such as English–Vietnamese (*FreeTxt-Vi*), through international collaboration.[3]

2 Design and Implementation

To accommodate needs for scalability, flexibility, and integration with advanced NLP/CL tools, FreeTxt initially began as a Streamlit-based[4] prototype but transitioned to a Flask-based[5] architecture. While Streamlit was sufficient for basic analysis, it struggled with large datasets, lacked adequate security for sensitive data, and provided limited visualisation clarity and analytical flexibility.

FreeTxt accepts input from a variety of file formats, including `.txt`, `.csv`, and `.xlsx`, enabling users to either directly paste text, work with pre-loaded survey files, or upload their own files.

After uploading data, FreeTxt processes the text using configurable options, such as splitting the text into individual sentences or handling it as a single entity. FreeTxt then applies tokenisation and linguistic analysis to extract relevant textual features. Key outputs include word frequency distributions and n-grams (bigrams, trigrams, etc.), enabling users to analyse recurring word sequences and linguistic patterns within the dataset.

To achieve these capabilities, FreeTxt integrates a range of advanced NLP libraries and models. The platform incorporates key libraries, such as `spaCy`, `NLTK`, and `Scattertext`, to ensure efficient and scalable processing of large datasets.

In developing FreeTxt, one of the core challenges was ensuring the tool would be accessible to users without specialist knowledge of NLP or corpus linguistics (CL). To make FreeTxt accessible, particularly for those working in cultural heritage sectors, it was essential to hide these complexities behind an intuitive and user-friendly interface.

Visualisation played a significant role in this approach. We prioritised clear, engaging graphical representations such as word clouds, collocation networks, and sentiment charts, which allow users to explore and interpret data without needing to understand the underlying computational processes. Furthermore, rather than presenting technical terms like "keyness" or "collocation" directly, the tool focuses on the outcome—showing patterns and trends in ways that are easy to interpret.

One of the key functionalities is the **sentiment analysis** feature, which utilises a BERT-based multilingual sentiment analysis model.[6] This model classifies text into positive, neutral, and negative sentiments, capturing broader contextual information beyond word-level tagging. Trained on multilingual product reviews, the model achieves an accuracy of approximately 95% for English texts.[7] The Welsh sentiment model, fine-tuned and evaluated on manually annotated data provided by one of our project partners, achieved an accuracy of around 73%. This sentiment analysis functionality is particularly valuable for understanding feedback, reviews, and general public sentiment.

FreeTxt provides tools for analysing **n-grams** (word sequences) and **word frequency distributions**. FreeTxt also incorporates a keyword collocation and network analysis tool, which enables users to visualise word relationships through interactive collocation networks. This feature highlights patterns in word usage, allowing users to explore connections between words as they co-occur in the text, providing meaningful insights into how terms relate to one another within the dataset.

The platform offers several visualisation options to help users interpret the results of n-gram and word frequency analysis including word clouds arranged in a bespoke variety of shapes for export into reports, with keyness calculations relative to the British National Corpus (BNC)[8] for English and CorCenCC[9] (Knight et al., 2018) for Welsh.

FreeTxt supports the generation of word clouds based on semantic tags from the USAS semantic tagger (PyMUSAS, Rayson et al., 2004),[10] which is available for multiple languages including English and Welsh. This allows users to visualise thematic trends through semantic groupings, making it particularly useful for cross-linguistic analysis.

FreeTxt also supports users in close reading with Key Word in Context (KWIC) displays, and visualises collocation networks to identify patterns where certain words frequently appear together. The length of the connector lines in these networks represents the proximity of the relationship between the searched word and its collocates, with shorter lines indicating closer associations. Additionally, the thickness of the lines reflects the frequency of the co-occurrence, with thicker lines representing more frequent word pairings.

[8] http://www.natcorp.ox.ac.uk/

[9] https://www.corcencc.org/

[10] https://ucrel.github.io/pymusas/

Adapting Google Charts word tree,[11] this tool allows users to explore branching relationships between keywords and their surrounding phrases. This is particularly useful for identifying patterns of word usage and tracing how specific terms are connected to various expressions across the text. By providing a hierarchical view of word relationships, the word tree enables users to uncover both direct and indirect connections between words, offering deeper insights into the contextual structure of the dataset, as shown in Figure **??**.

For text summarisation, FreeTxt leverages the TextRank algorithm, a graph-based ranking model for text processing that extracts the most important content from the input text by determining the relative significance of sentences (Mihalcea and Tarau, 2004; Ezeani et al., 2022; El-Haj et al., 2022). Users can also select the compression ratio of the original text, with options ranging from 10% to 50%, allowing them to retain varying levels of detail depending on their needs. This functionality is particularly useful for generating high-level overviews of lengthy documents, offering users a quick way to grasp key insights without losing the essential information.

3 Evaluation and System Comparison

We evaluate FreeTxt's performance, unique functionalities, and user experience by comparing it with other widely-used text analysis platforms. We focus on key aspects such as multilingual support, visualization capabilities, customization options, and system scalability.

3.1 System Components

One of FreeTxt's main strengths is its ability to handle both English and Welsh text via its NLP/CL methods and tools, but also with a bilingual user interface, both features not commonly supported by existing tools. This is further enhanced by the integration of the PyMUSAS semantic tagger, which allows for detailed semantic analysis across both languages. Compared to tools such as Voyant (Sinclair and Rockwell, 2016) and AntConc (Anthony, 2019), which primarily offer frequency-based analyses and basic concordance functionalities, FreeTxt provides the additional annotation layers of semantic and sentiment analysis, resulting in a richer set of visualisation options.

[11] https://developers.google.com/chart/interactive/docs/gallery/wordtree

FreeTxt supports multiple file formats such as `.txt`, `.csv`, and `.xlsx`, making it versatile for different input sources from user's survey outputs. It allows users to perform customizable analysis through options like sentence splitting, exclusion of specific sentences, and adjusting summarisation ratios. These features enhance overall usability, enabling users to tailor the analysis to their specific needs—offering more flexibility than options available in platforms such as LIWC (Pennebaker et al., 2015) and NVivo (QSR International, 2021).

FreeTxt embodies several key features:

Multilingual Support: FreeTxt's ability to handle both English and Welsh text analysis sets it apart from other tools such as AntConc, Sketch Engine (Kilgarriff et al., 2014), which either do not support Welsh or offer limited bilingual functionality. While Sketch Engine is known for its extensive corpus resources and powerful linguistic tools, it is a subscription-based platform, making FreeTxt's open-source model more accessible, especially for users with budget constraints. Additionally, FreeTxt's integration of PyMUSAS for semantic tagging enhances its capability to analyze thematic content in both languages, a feature not fully developed in other platforms.

Visualisation Capabilities: FreeTxt excels in providing advanced visualisation features, such as frequency-based word clouds, semantic word clouds, and interactive collocation networks. These visualisations, as shown in Appendix D, offer a more intuitive and interactive approach to understanding text data compared to the static visualisations offered by platforms like LIWC, NVivo, or Wmatrix. While tools such as Sketch Engine provide advanced corpus queries, they often lack the same level of dynamic visualisations that FreeTxt offers for exploring collocations and semantic relationships interactively.

Customisation and Flexibility: FreeTxt enables users to customise their analysis through sentence splitting, exclusion of specific sentences, and the generation of downloadable reports in PDF format. In contrast, tools like Sketch Engine, AntConc, and Voyant, while powerful, offer less flexibility for user-defined configurations and report generation. FreeTxt's flexibility in offering these options makes it more adaptable for a wider range of research projects. Furthermore, being an open-source platform, FreeTxt offers an accessible solution to users who might be deterred by the

subscription fees of tools like Sketch Engine.

3.2 Qualitative System Components Comparison

Key technical code and linguistic resources for the bilingual analysis of English and Welsh text were available to the FreeTxt team from the previous CorCenCC and related projects. As explained in section 2, these fall into two main types implementing methods from both NLP and CL. Long standing CL methods such as frequency lists, concordances, collocations, key words and n-grams (sometimes known as lexical bundles or clusters) are ubiquitous in other tools such as AntConc[12], LancsBox[13] and Wmatrix[14], and we follow standard methods, statistical metrics and settings. Such methods are also common in other CAQDAS (Computer Assisted Qualitative Data Analysis)[15] tools employed in other academic disciplines. However, NLP methods such as summarisation, sentiment, part-of-speech and semantic analysis, are much less commonly supported in CL and CAQDAS tools which usually only operate at the lexical level (although this is starting to change in LancsBox and Wmatrix).

3.3 Integration of Stakeholder Requirements

As prototype versions of FreeTxt were developed, the project team sought feedback from the project partners to ensure that the functionalities of the tool were fit-for-purpose within the context of their own institutional needs/practices. This process of feedback was iterative. Guided demonstrations and verbal updates were provided by members of the project team, along with walk-through task sheets which required partners to upload their own data and evaluate the ease with which the toolkit could be navigated, the results of which would be fed back to the project team. A crucial aspect of the stakeholder engagement was input on terminology used in the interface, to ensure that the naming or labelling of tools was logical and intuitive. For example, 'linguistic annotation' and 'collocation' are unknown terms to non language specialists. We also needed to carefully define and explain terms that are potentially known to non experts e.g. 'sentiment', 'summarisation', and 'word cloud', in order to ensure that end users are not making unexpected assumptions about how the NLP or CL methods worked, and how explainable or accurate they are in order to correctly set expectations for their results.

4 Conclusion

FreeTxt offers three key advantages over existing tools. First, multilingual semantic and sentiment analysis. FreeTxt's ability to seamlessly analyse both English and Welsh text provides advanced functionalities such as semantic tagging and interactive visualisation tools. This makes it particularly suitable for bilingual datasets, unlike other existing tools. Second, FreeTxt provides interactive and advanced visualisations. FreeTxt's visualisation features, powered by libraries such as PyVis and NetworkX, offer a more engaging user experience compared to the static output formats found in many other tools. Its word clouds and collocation networks provide dynamic ways to explore linguistic patterns, while platforms like Sketch Engine or Wmatrix typically rely on static graphs or simpler visualisations. Third, it offers customisation and ease of use for non specialists. FreeTxt's highly customizable options, such as excluding irrelevant sentences or generating detailed downloadable reports, provide a level of flexibility that is not commonly seen in other platforms. This makes FreeTxt a more adaptable tool for users with specific research needs.

However, FreeTxt also has areas that could benefit from further development. For instance, the accuracy of sentiment analysis for Welsh texts, currently at 73%, could be improved through the incorporation of additional training data. Moreover, while FreeTxt performs well for small to medium-sized datasets, further optimization could be implemented to enhance its performance when processing very large corpora.

In conclusion, FreeTxt provides a comprehensive and flexible solution for text analysis, especially for users working with bilingual datasets. Its advanced visualisation tools, semantic tagging capabilities, and customizable analysis options make it a competitive platform in the landscape of text analysis tools. Compared to existing tools, FreeTxt offers significant advantages in terms of multilingual support, flexibility, and interactivity, making it an ideal choice for researchers and professionals in need of a versatile text analysis solution.

m.shardlow@mmu.ac.uk

Abstract

Multiword Lexical Simplification (MWLS) is the task of replacing a complex phrase in a sentence with a simpler alternative. Whereas previous approaches to MWLS made use of the BERT language model, we make use of the Generative Pre-trained Transformer architecture. Our approach employs Large Language Models in an auto-regressive format, making use of prompt engineering and few-shot learning to develop new strategies for the MWLS task. We experiment with several GPT-based models and differing experimental settings including varying the number of requested examples, changing the base model type, adapting the prompt and zero-shot, one-shot and k-shot in-context learning. We show that a GPT-4o model with k-shot in-context learning (k=6) demonstrates state-of-the-art performance for the MWLS1 dataset with NDCG=0.3143, PREC@5=0.1048, beating the previous BERT-based approach by a wide margin on several metrics and consistently across subsets. Our findings indicate that GPT-based models are superior to BERT-based models for the MWLS task.

1 Introduction

Lexical Simplification (LS) is a Natural Language Processing (NLP) task that enhances text accessibility by replacing complex words with simpler alternatives. It has been applied in various application settings, including non-native speakers (Paetzold and Specia, 2016b), multilingualism (Shardlow et al., 2024b), education (Uchida et al., 2018), and readability (Maddela and Xu, 2018). By simplifying lexical content, NLP systems aim to promote inclusivity and comprehension.

Multi-Word Lexical Simplification (MWLS) extends LS to multi-word expressions (MWEs), requiring models to preserve meaning while reducing complexity. The Plainifier system (Przybyła and Shardlow, 2020) was previously used to address these challenges and has been evaluated using the MWLS1 dataset[1].

This paper explores LLMs for MWLS using the MWLS1 dataset, which contains 1,462 instances and 7,059 human-provided simplifications, offering a strong benchmark. Recent models like GPT-3 (Brown et al., 2020), GPT-4 (Achiam et al., 2023), and Llama 3.1 (Touvron et al., 2023) have demonstrated effectiveness in NLP tasks, including text simplification, through prompt engineering. Studies show that task-specific prompts help guide models in simplifying MWEs while preserving meaning (Shin et al., 2020; Gao et al., 2021).

This work investigates prompt engineering (Liu et al., 2023) to enhance MWLS using LLMs. The proposed approach generates simplified alternatives while maintaining context, contributing to the development of accessible NLP tools.

Despite advancements in Lexical Simplification (LS), most research focuses on single-word simplification to aid non-native speakers and individuals with language impairments (Saggion et al., 2022; Shardlow et al., 2024a). However, existing LS techniques struggle with multi-word expressions (MWEs), which often carry context-dependent meanings. Traditional LS methods, designed for single-word substitutions, fail to handle these complexities effectively (Constant et al., 2017; Gooding and Kochmar, 2018). Whilst the Plainifier attempts to simplify MWEs while preserving meaning, it is based on Masked Language Modelling (Devlin et al., 2019), leaving room for advancement through the use of large Causal Language Models (Brown et al., 2020).

This paper explores AI-driven large language models (LLMs) for MWLS, focusing on GPT-based models. The goal is to assess whether LLMs

[1] https://github.com/piotrmp/mwls1

Proceedings of Recent Advances in Natural Language Processing,pages 546–556
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-064

can provide reliable, context-aware simplifications, advancing MWLS and improving text accessibility across diverse domains. The primary contribution is to investigate the potential of Generative Pre-trained Transformers (GPT) models for Multi-Word Lexical Simplification (MWLS). By designing customized prompts, this study explores how GPT models can be guided to generate simpler alternatives for complex multi-word expressions while preserving the original semantic content.

The work is structured as follows: We first overview related literature in Section 2. We then describe the resources and experimental methodology used in Section 3. Next, we present the results for each experiment in Section 4. We conclude with a discussion of the results in Section 5.

2 Related Work

2.1 Multi-Word Lexical Simplification

Lexical Simplification (LS) in Natural Language Processing (NLP) improves text accessibility by replacing complex words or phrases with simpler alternatives while preserving meaning. It is widely used in education, technology, and communication, helping non-native speakers and broader audiences (Siddharthan, 2014). Traditional LS methods, such as dictionary-based substitution and frequency analysis, often ignore context, leading to oversimplifications or errors (Zhu et al., 2010; Glavaš and Štajner, 2015). While effective for single-word simplification, these approaches struggle with complex structures, limiting their practical use.

Multi-Word Lexical Simplification (MWLS) extends LS to multi-word expressions (MWEs) like idioms, collocations, and technical terms. These expressions pose challenges due to their context-dependent meanings, which traditional LS models fail to simplify effectively (Constant et al., 2017). Systems like Plainifier (Paetzold and Specia, 2016b) address MWLS but lack flexibility and deep contextual awareness. This highlights the need for AI-driven solutions that can preserve meaning while adapting to linguistic complexity. By leveraging large language models (LLMs), this study explores improved MWLS approaches with greater accuracy, adaptability, and contextual understanding.

2.2 Approaches to LS

Lexical Simplification (LS) initially relied on rule-based, dictionary-driven methods, replacing complex words with simpler synonyms from predefined lists (Carroll et al., 1998). While effective for basic tasks, these methods lacked context awareness, often leading to inaccurate substitutions (Siddharthan, 2014). Early systems using Simple Wikipedia struggled with polysemy, idioms, and multi-word expressions (MWEs), limiting their applicability.

Modern LS approaches leverage machine learning, particularly supervised models trained on parallel corpora like Newsela, enabling better contextual preservation (Xu et al., 2015). LSBert, for example, applies BERT's masked language modelling to rank simplifications, improving results on datasets like LexMTurk (Qiang et al., 2020). However, even these models falter with MWEs, often generating overly simplified or inappropriate alternatives. MWEs (including idioms and collocations) remain challenging due to their context-dependent meanings. MWLS1 is a dedicated dataset, providing annotated examples to assess MWE simplification models (Przybyła and Shardlow, 2020).

Pretrained models like BERT and RoBERTa improved LS by using semantic embeddings, enhancing simplifications across domains (Liu et al., 2023). GPT models have recently shown promise for controlled simplification, particularly in technical fields like biomedical text (Li et al., 2024). However, LS still struggles with MWEs, fluency, and adaptability, limiting large-scale adoption (Lee and Yeung, 2018). A unified approach integrating advanced language models and multilingual datasets could bridge these gaps, pushing LS toward truly accessible text simplification.

2.3 LLMs in Natural Language Processing

Large Language Models (LLMs) have transformed Natural Language Processing (NLP) by generating contextually accurate and coherent text across various applications (Radford et al., 2019). Models like GPT-3.5 (Brown et al., 2020) and GPT-4 (Achiam et al., 2023) excel in handling complex linguistic structures, making them effective for tasks such as text generation, translation (Kocmi et al., 2024), summarization (Zhang et al., 2023), and lexical simplification (Aumiller and Gertz, 2022). Their pre-training on vast datasets enables them to process polysemous terms, idioms, and multi-word expressions (MWEs) while maintaining semantic integrity (Liu et al., 2023).

Prompt engineering plays a key role in guiding LLMs for text simplification, ensuring fluency and

contextual accuracy (Kew et al., 2023; Shin et al., 2020). However, challenges remain—LLMs can sometimes oversimplify, altering meaning or omitting important details. Additionally, their black-box nature limits interpretability, making it difficult to analyse decision-making, especially in fields like medical text simplification (Liu et al., 2019). Despite these issues, LLMs offer unprecedented adaptability, integrating readability, contextual relevance, and semantic depth, positioning them as powerful tools for advancing lexical simplification research.

3 Methodology

3.1 MWLS1 Dataset

The MWLS1 dataset, introduced by Przybyła and Shardlow (2020), is specifically designed for Multi-Word Lexical Simplification (MWLS). This dataset supports the evaluation and refinement of MWLS systems by providing annotated examples of multi-word expressions (MWEs) and their simpler alternatives. Publicly available, it facilitates collaboration and iterative improvements in the field of MWE simplification. By adopting MWLS1, this research aligns with established standards and contributes to advancing simplification methodologies. The dataset comprises 1,462 English sentences and 7,059 human-annotated simplifications, sourced from three domains:

1. BIBLE: Parallel corpus of the World English Bible (Christodouloupoulos and Steedman, 2015).

2. EUROPARL: Proceedings from the European Parliament (Koehn, 2005).

3. BIOMED: Text from the CRAFT biomedical corpus (Bada et al., 2012).

The dataset provides a categorisation of simplification targets into unigrams (e.g., *resistance*), bigrams (e.g. *indirect consequences*), and trigrams (e.g., *detect random integration*), enabling a detailed analysis of single-word and phrase-level simplification. Each instance in the MWLS corpus consists of a context, a target word or phrase and the potential replacements for that phrase. The target may be a single word, bigram or trigram and the replacements may also be n-grams where n = 1, 2 or 3. Examples taken from the dataset are shown in Table 1, which is reproduced from Przybyła and Shardlow (2020). The dataset is further divided into subsets such as bible1, bible2, europarl3, etc., ensuring balanced representation across n-gram sizes and linguistic complexities.

3.2 Use of GPT models

We used GPT-3.5-Turbo, GPT-4o and GPT-4o-Mini. All models were used via the OpenAI API and were accessed in a period between June 2023 and May 2025, with a final rerun of all models in May 2025. We did not experiment with models beyond the GPT family due to limited resources in the experiments. Although the GPT models are closed source and only accessible via an API, they do represent a high-performing set of models across many tasks and have been used successfully in previous lexical simplification approaches to gain state of the art performance (Aumiller and Gertz, 2022; Enomoto et al., 2024). We overview each model below with reference to the OpenAI model cards[2]:

GPT-3.5-Turbo: An updated version of GPT-3 (Brown et al., 2020) which is fine-tuned for dialogue interactions through supervised learning and reinforcement learning with human feedback. This is a text-only model. the model costs $0.50 per 1M input tokens.

GPT-4o: A more recent model than GPT3.5, this model is a flagship model provided by the OpenAI platform. GPT-4o is trained on text and images, although we only make use of text completions in this study (Hurst et al., 2024). Interaction with the model costs $2.50 per 1M input tokens.

GPT-4o-Mini: A smaller[3] version of the GPT-4o model. This model is cheaper to run ($0.16 per 1M input tokens) and has a faster inference speed than the GPT-4o model.

The experimental protocol we undertook for Multi-Word Lexical Simplification with GPT consists of loading the dataset, passing each complicated phrase and its respective sentence to the GPT model with prompt via an API request and storing the results for evaluation. The first author checked model outputs to identify failure cases (e.g., no output, boilerplate, user-facing messages) and reran all necessary cases.

[2] https://platform.openai.com/docs/models

[3] It is not specified by OpenAI how much smaller, or how the smaller model was created.

Case ID	Source	Sentence	Replacement
CASE_7739	BIOMED	The main difference in the two lines **essentially resides** in the strength of the promoter.	is basically
CASE_241	BIBLE	Thus says Yahweh of Armies, "They **shall thoroughly glean** the remnant of Israel. Turn again your hand as a grape gatherer into the baskets."	will gather
CASE_5327	EUROPARL	I support Ms Lulling's recommendations that the national systems should recognise the importance of protecting self-employed workers, and we should stand against all forms of **discrimination**, but I am still not convinced that this House is best placed to work on employment matters.	bias and unfairness
CASE_6461	BIOMED	Other **potentially biologically relevant** substrates include cholecystokinin and possibly other neuropeptides.	relevant
CASE_2260	BIBLE	A man's **foes** will be those of his own household.	enemies

Table 1: Five examples of sentences from the MWLS1 dataset, each shown with its identifier, source corpus, highlighted target and one replacement provided by annotators. Reproduced from Przybyła and Shardlow (2020).

Figure 1 shows the workflow that we used. The process begins with the OpenAI client being initialised. For each sentence in the dataset, the system finds the complicated phrase and a prompt is sent to the GPT model. The GPT model evaluates the prompt and generates a list of simplified alternatives, which are then saved in a new column in the dataset. This procedure is repeated for every instance in the dataset. A new session is initialised for each instance to prevent effects of catastrophic forgetting (Vu et al., 2022) in long prompting sessions.

We used the following system prompt in a zero-shot setting:

> *You are an AI that suggests simpler alternatives for complex words and phrases.*

And the corresponding system prompt for one- or few-shot learning. For one-shot learning we only specified a single example. For few-shot learning we specified $K = 6$ examples:

> *You are an AI that suggests simpler alternatives for complex words and phrases. Here are some examples of how to simplify multi-word expressions:*
> *<Example_1 Instance>*
> *<Example_1 Response>*
> ⋮
> *<Example_K Instance>*
> *<Example_K Response>*

For each instance across all experiments, we provided the initial prompt to the GPT model via the 'User' role:

> *Suggest {n} simpler alternatives to the multi-word phrase {complex_word} in the following sentence. The alternatives should preserve the meaning and improve readability for non-native speakers. Here is the sentence: {sentence}*

Where the parameter n varies by experiment as shown in Table 2 and the *complex_word* and *sentence* are instance dependent. The model response was collected using the 'Assistant' role.

3.3 Experiments

We used the full MWLS corpus to evaluate the effectiveness of GPT models for Multi-Word Lexical Simplification (MWLS). We do not make use of training data as our approach is fully unsupervised and as such the full corpus is used for evaluation. The experiments we undertook modified key parameters of the workflow to assess their impact on simplification quality as shown in Table 2.

In Experiment 1, the number of alternatives was 30 and we introduced a prompt which focussed on readability for non-native speakers. This aimed to determine performance level and provide clear instructions for simplification quality. Experiment 2 reduced the number of alternatives to 15 and introduced a one-shot system prompt, offering a single

Parameters	Exp 1	Exp 2	Exp 3	Exp 4
Alternatives (n)	30	15	15	20
Model	GPT-3.5-Turbo	GPT-3.5-Turbo	GPT-4o	GPT-4o-Mini
K-Shot	Zero-Shot	One-Shot	Few-Shot	

Table 2: Varied experimental protocols used in our research

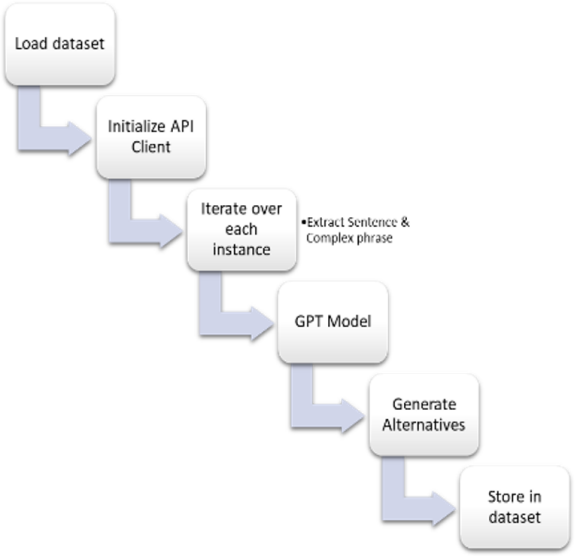

Figure 1: The experimental workflow we employed.

example to guide the model. This tested whether quality improved when fewer but more precise simplifications were requested. Experiment 3 modified the model to GPT-4o, maintaining 15 alternatives while also introducing a few-shot system prompt (6 examples) to assess how multiple examples influenced output relevance. Experiment 4 switched to GPT-4o-mini, increasing alternatives to 20 while retaining the same few-shot prompt. This evaluated whether a more compact model could maintain simplification quality while generating a broader range of alternatives.

3.4 Baseline Systems

We reproduce the results of the Plainifier system introduced by Przybyła and Shardlow (2020). The Plainfier system makes use of the Masked Language Model BERT (Devlin et al., 2019) which produces token-level probabilities across a vocabulary to replace a masked element in a sentence. The complex target (which may be a 1-, 2- or 3-gram) is masked and the language model is used to produce a set of replacements which are reordered according to language model probability, semantic similarity and familiarity.

We additionally reproduce the human baseline reported by Przybyła and Shardlow (2020). This was produced using the original annotations as a gold standard. The human baseline effectively demonstrates how well any one annotator can predict the suggested replacements of all other annotators and demonstrates that the task is inherently difficult for humans to perform.

3.5 Evaluation Metrics

We use the following metrics, which are the same as those used in the original work on MWLS and are used widely elsewhere in lexical simplification research:

Potential: A metric determining the average number of instances where at least one generated candidate is also in the gold-standard (Paetzold and Specia, 2016a). This is a permissive metric that demonstrates the potential of a substitution generation system to produce accurate simplifications.

Precision@K: The percentage of the first K generated candidates that are present in the gold standard (Štajner et al., 2022), averaged per-instance. In our setting we use K=5.

NDCG: Normalised discounted cumulative gain (Järvelin et al., 2008) considers the system-generated substitutions as a ranked list, casting the evaluation as an information retrieval problem (i.e., where the vocabulary is considered the information space and the gold standard is the items to retrieve).

All metrics are evaluated for each subset in the dataset, where a subset is a specific genre (bible, biomed and Europparl) for each N-gram (unigram, bigram and trigram). We present summary level statistics for unigrams, bigrams and trigrams (summarised across genre) and for all genres (summarised across n-gram size).

Metric	Subset	Plainifier	Human	Exp 1	Exp 2	Exp 3	Exp 4
	Bible_All	0.1528	0.1116	0.3022	0.2598	**0.3451**	0.3060
	Biomed_All	0.1460	0.1065	0.2554	0.2260	**0.2735**	0.2349
	Europarl_All	0.1575	0.0999	0.2679	0.2904	**0.3163**	0.2898
NDCG	All1	0.2578	0.2112	**0.4997**	0.5172	0.4851	0.3938
	All2	0.0936	0.0475	0.1725	0.1421	0.2512	**0.2567**
	All3	0.0458	0.0266	0.1191	0.0792	**0.1748**	0.1650
	All	0.1396	0.1015	0.2766	0.2610	**0.3143**	0.2798
	Bible_All	0.0343	**0.2174**	0.1007	0.0906	0.1164	0.0976
	Biomed_All	0.0360	**0.2059**	0.0856	0.0785	0.0872	0.0692
	Europarl_All	0.0465	**0.1913**	0.0958	0.1024	0.1073	0.0909
Prec@5	All1	0.0767	**0.3811**	0.1936	0.1970	0.1812	0.1440
	All2	0.0180	**0.1069**	0.0455	0.0390	0.0738	0.0668
	All3	0.0079	**0.0575**	0.0280	0.0201	0.0455	0.0397
	All	0.0365	**0.1929**	0.0946	0.0913	0.1048	0.0871
	Bible_All	**0.9366**	0.2174	0.4398	0.3501	0.4639	0.4201
	Biomed_All	**0.8656**	0.2059	0.3787	0.2997	0.3651	0.3025
	Europarl_All	**0.8765**	0.1913	0.4040	0.3907	0.4459	0.4128
Potential	All1	**0.9908**	0.3811	0.7137	0.6667	0.6261	0.5150
	All2	**0.8406**	0.1069	0.2854	0.2204	0.3735	0.3550
	All3	0.0458	0.0266	0.1746	0.1058	0.2487	**0.2540**
	All	**0.6451**	0.0575	0.4096	0.3500	0.4291	0.3837

Table 3: Experimental results. *Plainifier* and *Human* baselines are reproduced from Przybyła and Shardlow (2020).

4 Results

We present the results of our experiments in Table 3. We have reported three metrics (NDCG, Precision @5 and Potential) as defined previously. Each metric is evaluated for each subset of our corpus and the summary statistics are reported for each genre (*Bible_All*, *Biomed_All* and *Europarl_All*) and each N-gram size (*All1*, *All2* and *All3*). We also present summary statistics across the entire dataset as *All*.

Results are reported for the Plainifier system and the human baseline. These results are reproduced directly from the work of Przybyła and Shardlow (2020). We continue to report the results of the four experimental settings that we evaluated with our GPT-based MWLS system. We have highlighted the highest performing system in boldface type in each row (per-summary-statistic and per-metric) for the reader's convenience. We also highlight the key findings from our results in bold-face below.

In experiment 1 we deployed GPT-3.5 Turbo in a zero-shot setting, whereas in experiment 2 we deployed the same model in a one-shot setting. The results of experiment 2 are generally lower for all metrics than for experiment 1, with the exception of NDCG and Prec@5 for Europarl_All. We also changed the number of generated candidates in this setting from 30 to 15, which may have affected the potential metric, but should not have affected other metrics as the generated candidates beyond the 15th place were typically incorrect[4]. The drop in performance indicates that **the inclusion of a single in-context-learning example with 15 replacements did not lead to improved performance compared to zero-shot with 30 substitutions** in our experimental setting.

For experiment 3, we used the GPT-4o model instead of the GPT-3.5-Turbo model. Additionally, the experimental configuration used 6 in-context-learning examples instead of 1 as in experiment 2. The results of experiment 3 demonstrate improved performance on all metrics compared to all other experiments that we performed. The setting of experiment 3 had the highest performance across all summary subsets for NDCG, except for *All1* (unigrams) and *All2* (bigrams). Experiment 3 also showed improved performance over other experimental settings for Precision@5, where it attained the highest result of any GPT-based system for all subsets except for *All1* (unigrams). Experiment 3 also demonstrated the highest GPT-based perfor-

[4]Only the top 5 candidates are taken for prec@5 and lower order candidates have a minimal effect for NDCG

mance in the potential metric, yielding the highest result across the entire dataset (*All*). This indicates that **the use of GPT-4o with 6 examples of in-context learning gave the best machine-based performance for our dataset.**

We additionally experimented with the use of GPT-4o-Mini in the setting of Experiment 4. Here we are using a smaller but more efficient (time and token-cost) model, which is known to perform marginally worse than GPT-4o on baseline tasks. Our experiments demonstrate that GPT-4o-mini typically has the second-best performance on most evaluated subsets across all metrics. In 2 instances (NDCG All2 and Potential All3) GPT-4o-Mini outperforms GPT-4o. This indicates that **smaller language models can be competitive with larger language models for the MWLS task at lower cost and faster inference speed.**

Our results outperform those of the baseline system (the Plainifier model) for NDCG and Precision@5. Our best performing system based on GPT-4o represents a significant increase in performance for NDCG (Plainifier = 0.1396, GPT4o = 0.3143) and for Precision@5 (Plainifier = 0.0365, GPT4o = 0.1048). This improvement for NDCG and Precision@5 is also realised across every evaluated subset. **The plainifier outperforms all of our systems for the Potential metric**, due to the limited number of candidates generated by the GPT-based experiments.

Whereas the human baseline previously outperformed the Plainifier system, **we report an improvement in the NGCD metric over human performance. This is the first time that this has been reported for the MWLS1 dataset for NDCG.** Our best-performing system, based on GPT-4o outperforms the human baseline for all subsets on the NDCG metric by a large margin (Human-baseline = 0.1015, GPT-4o = 0.3143). Our system also outperforms the human baseline in terms of potential across all subsets, although humans typically only returned a few candidates each. **The human baseline outperforms our best-performing system for the precision@5 metric** (Human-baseline = 0.1929, GPT-4o = 0.1048), indicating that humans are generally closer to each others predictions for the top-5 candidates than GPT-based systems.

For the NDCG metric, we demonstrate a new state-of-the-art performance including outperforming the human baseline and previous state-of-the-art. Our system based on GPT-4o demonstrates the best performance of those systems evaluated, although we also report improved performance for unigrams with a system based on GPT-3.5 and bigrams with a system based on GPT-4o-mini. The improved NDCG results indicate that **our system consistently ranks relevant candidates higher in the returned list than previous attempts.**

For the precision@5 metric, we demonstrate that GPT-based systems produce a top-5 ranked candidate list that is more similar to a list produced by the MWLS1 annotators. Our GPT-based systems consistently outperform the Plainifier system, representing an improvement in automated approaches to MWLS for this metric.

Our GPT-based systems perform consistently higher than the human baselines for potential indicating that the system generally identified at least one relevant candidate. Although the Plainifier system performs very well on this metric for most subsets, our GPT-based system performs better on trigram generation (All3) where we return state of the art performance beating both the Plainifier and the human baseline.

5 Discussion

Our results demonstrate that GPT-based models produce state-of-the-art machine performance for the MWLS task. We have used 3 API based models, all of which outperformed the previous baseline system across two of the three evaluated metrics. Whereas the Plainifier system made use of the token-level probabilities arising from the BERT model, we instead used the GPT-based models in an auto-regressive mode through the 'chat' interface of the API. It is also possible to extract token-level probabilities from GPT-based models during generation and there may be potential future gains from examining the probability distributions of potential candidate substitutions. We also only experimented with GPT-based models and did not consider other similar open-source models for text generation.

The results for the Plainifier are low for NDCG and Prec@5, but exceptionally high for the potential metric. Potential is a metric that accepts any of the generated candidates of a system and the high results obtained by the Plainifier are due to the high number of candidates that it generates. In a theoretical setting, one could obtain a perfect result for potential by generating the entire vocabulary (and all possible n-grams thereof) and presenting this for evaluation. Whilst we could generate further candi-

dates for each instance with the GPT-based model at no penalty to the Prec@5 metric, the barrier to accessibility is the linear cost associated with scaling the number of tokens returned by the model. This is a barrier to improved performance on the potential metric, however as this metric does not provide discounting for incorrect substitutions we do not consider Potential to be a reliable indicator of the performance of a deployed Multi-word lexical simplification system. In an application setting, we would likely set the number of returned candidates to be around that used in our experiments (15-30), or lower if the candidates are being used for vocabulary suggestions, where a reader may only be interested in the top 2 or 3 candidates.

Our results show a large increase over the previous state-of-the-art, however there is still much room for improvement across all metrics. The human baseline shows that the MWLS task is also difficult for annotators. The performance that we have reported is above human-level performance for both the NDCG and potential metrics.

In our experiments, we observed that the GPT-model frequently failed to generate complex multiword expressions (MWEs), particularly trigrams and in domain-specific subsets such as Biomed3. These phrases often involve technical terminology or dense clinical expressions, where maintaining both semantic integrity and readability is significantly more challenging. In such cases, the model either generated overly generic simplifications or failed to produce contextually appropriate alternatives. Additionally, there were instances where the model returned an empty list of simplifications. The trigger for this behaviour is unclear. In this situation the instance is run again until successful.

6 Future Work

A significant area for future work on MWLS is the creation of new datasets. Whereas recent LS datasets have focussed on single-word replacements this is only limited in use to scenarios where a word can be directly replaced by another single-word. MWLS extends this paradigm to N-N replacement of words, but has not been widely adopted by LS dataset developers. Currently the data we have worked on is the only example of MWLS data that the authors are aware of. Further work to extend the volume of available data, contribute additional genres and non-English MWLS would be a positive step forward for the task.

Our experiments have demonstrated that GPT-based models are capable of performing well at the MWLS task for every genre and N-gram size that we evaluated. We used a single prompt to cover all generation and it may be the case that using multiple prompts for specific scenarios (i.e., genre-based prompting, or prompting for specific n-gram sizes) will yield more comprehensive results. We consider this to be a prompt engineering experiment and beyond the scope of the present work.

The MWLS dataset that we have considered only operates on 1-3 grams. It would be interesting to consider a dataset containing replacements that also allow for larger N-gram sizes. We see in the results that performance is typically higher for unigrams and bigrams and that performance dips for trigrams. We may expect that higher n-gram sizes will present an additional challenge for future MWLS systems. We may also consider the integration of linguistic knowledge at both the level of dataset creation (i.e., the selection of semantically coherent complex phrases) and at the level of system design. It may be the case that by providing additional linguistic informed knowledge through techniques such as Graph Neural Networks or Embeddings, we can further improve on MWLS.

7 Conclusion

We have reported a new GPT-based approach to the Multiword Lexical Simplification task. Whereas previous approaches made use of the BERT masked language model, we have made use of the Generative Pre-trained Transformer architecture. Our approach has employed Large Language Models in an auto-regressive format, and made use of prompt engineering and few-shot learning to develop new strategies for the MWLS task. We have shown experiments with several GPT-based models and differing experimental settings. We demonstrated that a GPT-4o-Mini model with 6-shot in-context learning gave state-of-the-art performance for the MWLS1 dataset with NDCG=0.3143, PREC@5=0.1048, beating the previous Bert-based approach by a wide margin on several metrics and consistently across subsets. Whilst human performance was high for Prec@5, our model outperformed the previous state-of-the-art system and represents a move towards human-level performance for this metric. Our findings indicate that GPT-based models are superior to BERT-based models for the MWLS task.

Abstract

The increasing capabilities of large language models (LLMs) have unlocked transformative potential for medical applications, but privacy constraints limit access to high-quality training data from electronic health records (EHRs). In response, we propose a framework to generate synthetic EHRs by instruction-tuning an LLM using descriptions of diagnosis codes. We show that this framework overcomes problems of prior approaches, such as diversity reduction and medical incoherence, while maintaining strong privacy protections. Utility was measured by training models to predict diagnosis codes for EHRs. Real data still has higher utility, but synthetic data approaches real data results with increasing dataset size. The differences in utility were most likely due to noise in the synthetic data. A user study involving medical professionals confirmed no significant loss in readability or medical coherence compared to the real EHRs, even though inter-annotator agreement is low. These findings establish synthetic EHRs as a viable alternative for privacy-preserving and scalable clinical NLP applications. We release our code on GitHub.[1]

.

1 Introduction

Healthcare faces growing challenges, including staff shortages, medical errors, and unequal access – issues that artificial intelligence applications, particularly with recent advances in deep learning (DL), can help address (Goldberg et al., 2024). A critical requirement for building such systems is access to electronic health records (EHRs), which serve as a rich data source (Häyrinen et al., 2008). EHRs contain, alongside structured patient information, large amounts of unstructured text, making natural language processing (NLP) techniques particularly valuable for medical applications such as automated diagnosis coding (Huang et al., 2022), clinical text mining (Dalianis, 2018), and clinical decision support (Häyrinen et al., 2008). However, privacy concerns and strict regulations (Budu et al., 2024) often limit access, hindering the development and evaluation of medical applications.

To address this data sparsity challenge, synthetic data generation has emerged as a solution (Murtaza et al., 2023), producing artificial data that mimics the statistical properties of real EHRs while preserving patients' privacy. Hence, such data must meet two key criteria: `privacy` and `utility`. However, balancing these objectives remains challenging – even with powerful large language models (LLMs) – due to issues such as limited data diversity (Libbi et al., 2021) and insufficient medical coherence (Melamud and Shivade, 2019).

In this work, we investigate synthetic data generation to address the question: "How can LLMs balance privacy and utility for EHRs?". To answer this question, we propose a framework based on LLaMA-3.1-8B (Dubey et al., 2024) for generating synthetic medical notes in English and Swedish. By instruction-tuning the model with ICD-10 code descriptions, we improve content controllability and enhance diversity. We evaluate the generated data along four key dimensions: `fidelity`, `privacy`, `utility`, and `coherence`.

Our findings show that while real medical notes still yield better downstream performance, synthetic notes can also effectively train complex multi-label classification models for medical coding. The synthetic notes exhibit a richer vocabulary than real data, addressing common diversity issues. A user study with medical professionals found no significant loss in coherence, and privacy analyses show minimal leakage risk. These results highlight our framework's potential to generate high-quality, privacy-preserving medical notes, providing a strong foundation toward developing reliable medical NLP tools that respect patient privacy.

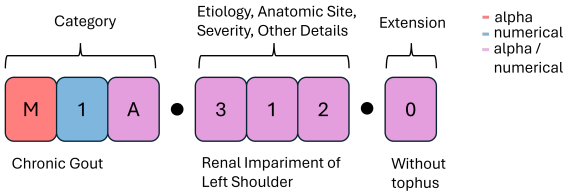

Figure 1: Example of ICD-10 structure

2 Background and Related Research

2.1 Electronic Health Records and Medical Coding

EHRs are digital repositories that securely store and share patient health data across healthcare providers, supporting clinical decision-making (Häyrinen et al., 2008). Among the structured elements, such as lab results, or diagnosis codes, EHRs also include unstructured components like discharge summaries that document a patient's hospital stay, reasons for admission, diagnoses, and treatments in free-text form (Wimsett et al., 2014).

EHRs typically have ICD-10 codes assigned by the physician. ICD-10 stands for the 10th version of the *International Classification of Diseases* (World Health Organization, 2016) and is a globally used coding system, comprising approximately 155,000 codes for diagnoses and procedures (Hirsch et al., 2016). The coding scheme follows a hierarchical structure consisting of four to seven characters as illustrated in an example in Figure 1. This structure allows for an organization into 22 distinct chapters (based on the first three characters) specifying the nature of the condition.

Assigning ICD-10 codes to medical notes is vital for administrative and analytical tasks (Edin et al., 2023) but known to be labor-intensive and error-prone due to the high amount of individual codes (Burns et al., 2012). Automating this process via multi-label classification of discharge summaries offers a scalable solution (Huang et al., 2022). However, large code sets, data scarcity, long document length, and class imbalance pose major challenges (Edin et al., 2023).

2.2 Synthetic Data Generation

Since EHRs contain sensitive patient data known as protected health information (PHI), including names, birth dates, or social security numbers, additional measures are needed to protect privacy when using it for research or development. De-identification addresses this by masking or removing PHI (Vakili et al., 2022). While it lowers privacy risks and retains utility for some tasks (Vakili et al., 2022), limitations remain, such as the potential for re-identification via quasi-identifiers and utility loss (Yogarajan et al., 2020).

As an alternative, synthetic data, generated by computational models, has gained significant attention due to its potential to address challenges related to privacy concerns, data sparsity, and bias mitigation when used for model training (Jordon et al., 2022). This work explores the emerging field of synthetic free-text medical note generation that became increasingly popular with advances in language modeling (Rankin et al., 2020). The quality of synthetic data is typically evaluated by fidelity (realism), utility (usefulness for model training), and privacy (protection from data leakage) (Budu et al., 2024).

Several approaches have been explored for generating medical notes, starting with less complex neural networks such as GANs (Guan et al., 2018), LSTMs (Melamud and Shivade, 2019), and vanilla transformers (Amin-Nejad et al., 2020), and progressing to more advanced transformer models with hundreds of millions of parameters, including decoder-only LLMs like LLaMA (Baumel et al., 2024) and GPT variants (Kumichev et al., 2024; Falis et al., 2024). There is not always a clear winner; for instance, LSTMs have shown effectiveness for downstream tasks such as named entity recognition (NER) when generating medical notes, while LLMs were better at producing more fluent text (Libbi et al., 2021). However, there is a clear trend toward leveraging pretrained state-of-the-art LLMs showing potential for a variety of different downstream tasks (Litake et al., 2024; Kumichev et al., 2024; Vakili et al., 2025).

However, findings vary; for example, Falis et al. (2024) highlight the limitations of zero-shot generations, noting lack of diversity and unnatural phrasing that impaired performance in medical coding. Such discrepancies often reflect differences in evaluation setup. For instance, the dataset used by Kumichev et al. (2024) contained substantially fewer unique codes than that in Falis et al. (2024). The highly inconsistent choice and setup of downstream evaluation tasks complicates direct comparisons. Moreover, strong task performance does not guarantee high data quality or generalizability. Notably, synthetic data has proven useful for training NER models despite being linguistically

or clinically incoherent (Libbi et al., 2021), raising questions about the validity of using simple downstream tasks as proxies for data quality. Furthermore, privacy evaluation is often overlooked or deferred due to difficulties in measurement. When included, privacy is typically measured via disclosure metrics (Belkadi et al., 2025), distance metrics (Hiebel et al., 2023), or manual review (Libbi et al., 2021). Establishing consistent benchmarks and evaluation procedures is critical for progress and meaningful comparison in future work.

Three recurring challenges emerge across studies. First, there is a privacy-utility trade-off: increasing privacy often comes at the cost of reduced utility, with synthetic data typically underperforming on tasks involving real data (Melamud and Shivade, 2019; Baumel et al., 2024). Second, synthetic notes often suffer from reduced diversity, characterized by limited vocabulary that can impair performance on downstream tasks (Libbi et al., 2021; Hullmann and Hansson, 2024). Third, manual reviews frequently identify clinical inconsistencies in the generated text, indicating issues with coherence (Libbi et al., 2021; Falis et al., 2024).

Hence, in this work, we focus on understanding these challenges in the era of LLMs. To address them, we present a new generation framework that uses diagnosis code descriptions to instruction-tune an LLM for producing high-quality synthetic notes. Most similar to our work is the generation framework *MedSyn* by Kumichev et al. (2024) that relies on the incorporation of disease-specific symptoms into the prompt. Unlike MedSyn, which relies on a medical knowledge graph and is limited to a Russian dataset with few unique codes and one code per note, our simpler, scalable approach avoids external resources, enabling broader multilingual applicability and support for more codes per note. We conduct a thorough assessment of the synthetic data to evaluate this approach on two languages.

3 Data and Methods

The main goal of this work is to generate synthetic medical notes that ensure high utility and robust privacy protection, aiming at replacing real data and analyzing how well they preserve these properties.

To achieve this, we propose a novel framework (Figure 2) for conditional text generation, by instruction-tuning LLaMA-3.1-8B on ICD-10 code descriptions to produce versatile synthetic notes. We employ this framework on both English and Swedish data to test its effectiveness for both high- and comparatively lower-resourced languages. The evaluation involves four key components: comparing synthetic and real notes for similarity, assessing privacy preservation, evaluating utility in medical downstream tasks, and analyzing readability and medical coherence through a user study.

3.1 MIMIC-IV

This is an English dataset sourced from the Medical Information Mart for Intensive Care IV (MIMIC-IV) (Johnson et al., 2023),[2] comprising 524,000 admissions from over 257,000 patients at Beth Israel Deaconess Medical Center. It includes structured data and pseudonymized unstructured medical notes. Following Edin et al. (2023), discharge summaries were filtered, and ICD-10 codes occurring fewer than 10 times were excluded, yielding 122,279 documents and 7,942 unique codes. The dataset was then divided, also in line with Edin et al. (2023), ensuring broad code representation across three subsets: a large training subset (MIMIC-L, n=89,098, 72.9%), a small training subset (MIMIC-S, n=13,378, 10.9%), and an evaluation subset (MIMIC-E, n=19,802, 16.2%). To put the data in a format suitable for LLMs, highly structured sections (e.g., lab results, medication lists) and repetitive or less informative content (e.g., discharge instructions) were removed during preprocessing.

3.2 SEPR Corpus

This Swedish dataset is based on the Stockholm EPR Gastro ICD-10 Pseudo Corpus II (SEPR II),[3] derived from the Health Bank Infrastructure (Dalianis et al., 2015) by Lamproudis et al. (2024). It comprises 317,971 records from Karolinska University Hospital from 113,174 individual patients, all related to gastrointestinal conditions and annotated with 415 unique ICD-10 codes. Again, the data was split into the three subsets SEPR-L (n=237,968, 76%), SEPR-S (n=47,783, 15%), and SEPR-E (n=32,027, 10%). As the Swedish notes consist solely of concise free-text entries, no additional preprocessing was conducted.

SEPR and MIMIC-IV differ significantly in scope and granularity: MIMIC-IV covers many medical domains, whereas SEPR is restricted to

[2] A training program must be completed to obtain credentialed access to MIMIC IV.

[3] This research has been approved by the Regional Ethical Review Board in Stockholm under permission no. 2007/1625-31/5.

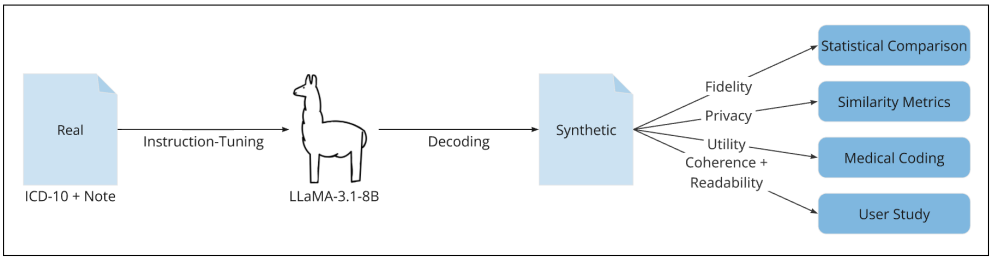

Figure 2: Overall approach employed in this work

gastrointestinal conditions. Additionally, Swedish discharge summaries are markedly more concise, averaging just 12.5% of the token length of English notes, and contain far fewer codes per document (1.09 vs. 15.65) and unique ICD-10 codes overall (415 vs. 7,942). Thus, cross-language comparison can only be made subject to these disparities.

3.3 Synthesizing Medical Notes

We used LLaMA-3.1-8B as base model for generating synthetic medical notes, chosen for its strong performance and computational efficiency. The model was instruction-tuned using ICD-10 code descriptions as prompts to enable:

(i) **Content control:** Ensuring generated notes align with specified medical domains.

(ii) **Diversity:** Producing varied notes by altering ICD-10 inputs.

(iii) **Automatic labeling:** Using ICD-10 annotations for supervised learning.

We followed the Alpaca instruction-tuning template (Taori et al., 2023), using English and Swedish prompts based on ICD-10 code descriptions as input, with outputs corresponding to discharge summaries.

The ICD-10 codes from MIMIC-L and SEPR-L were converted into descriptive texts serving as input and paired with real medical notes as output to form the training dataset. Fine-tuning was performed within the Axolotl framework (OpenAccess-AI-Collective, 2024), applying QLoRA 4-bit quantization (Dettmers et al., 2023) to reduce memory usage, and DeepSpeed ZeRO Stage 3 (Rajbhandari et al., 2020; Rasley et al., 2020) for efficient multi-GPU training. The Swedish data followed the same workflow with language-specific adjustments.

For inference, LoRA adapters were merged into the base model. Generation was accelerated using vLLM (vllm-project, 2024), which optimizes memory handling. Synthetic data was generated using ICD-10 sequences from the large and small MIMIC and SEPR datasets, leaving the evaluation datasets aside for testing.

3.4 Fidelity Evaluation

Fidelity is measured by comparing statistical features of synthetic and real MIMIC-S and SEPR-S datasets to assess alignment in data distribution and diversity. Additionally, a manual review of MIMIC-S synthetic notes was conducted to evaluate structural and linguistic similarity to real discharge summaries.

3.5 Privacy Evaluation

Following Libbi et al. (2021), we assess re-identification risk in English data using ROUGE-5 to quantify 5-gram overlaps between synthetic and real MIMIC datasets, using the overlap between real MIMIC-S and real MIMIC-L as a baseline. For Swedish, we apply the 8-gram overlap method from Hiebel et al. (2023), comparing synthetic SEPR-S to real SEPR-L. Real-real overlap provides a baseline, and results are contextualized using Hullmann and Hansson (2024), who also used the SEPR corpus for synthetic note generation.

Both similarity metrics are designed to assess memorization risks by determining whether the synthetic data is excessively similar to real data, beyond the typical overlap observed between two real datasets.

3.6 Utility Evaluation

We evaluated the synthesized notes through the medical coding task. This task was chosen due to its complexity and its importance in clinical analysis. With a high number of granular labels, accurate coding demands capturing interrelated clinical details, making it a strong proxy for note quality. Furthermore, the task can be seen as an inverse of the

generation process, already providing the ICD-10 annotations needed for supervised learning.

We employed the PLM-ICD framework (Huang et al., 2022), which leverages domain-specific BERT (Devlin et al., 2019) models with segment pooling for long inputs and label-aware attention (Vu et al., 2021) for fine-grained, label-specific representations. Following Edin et al. (2023), we used RoBERTa-PM (Lewis et al., 2020) for English (with inputs truncated to 4000 tokens) and adapted the setup for Swedish using SweDeClin-BERT (Vakili et al., 2022). Each configuration was trained three times to report mean performance, with statistical significance tested using two-sample t-tests.

Models were trained on both large (MIMIC-L, SEPR-L) and small (MIMIC-S, SEPR-S) subsets in real and synthetic form, using MIMIC-E and SEPR-E for testing. To assess the suitability of model choice within our framework, we compared synthetic training sets from the base LLaMA-3.1-8B model with those produced by domain-specific variants, namely OpenBioLLM-8B (Ankit Pal, 2024) adapted to the biomedical domain and AI Sweden's LLaMA-3-8B (AI Sweden Models, 2024) adapted to Nordic languages.

3.7 User Study

To evaluate readability and clinical plausibility, medical professionals rated English and Swedish synthetic and real notes on a bipolar 1–5 scale across two dimensions: readability (from *not natural at all* to *completely natural: could be written by a doctor*) and medical coherence (from *not coherent at all* to *Perfectly coherent: Symptoms, diagnosis, procedures, etc. fit together perfectly*). Notes were presented randomized to mitigate bias, and raters were unaware that some texts were synthetic, resulting in a blind test. High coherence ratings would indicate that the synthetic notes effectively capture ICD-10 content, demonstrating successful content control via instruction-tuning.

For English, three real-synthetic pairs were sampled based on matching ICD-10 sequences, resulting in six samples with each ranging from 300–600 words for manageability. Ten German medical professionals participated as evaluators. None were native English speakers, which should be taken into account in the interpretation of the results.

For Swedish, four document pairs (100–200 words) were sampled and evaluated by four medical professionals, all native Swedish speakers.

	Total Docs	AVG Sent/Doc	AVG Token/Doc	AVG Token/Sent	Total Tokens	Unique Tokens
Statistical Comparison real vs. synthetic MIMIC-S						
Real	13,378	72	1,286	18	17,197,361	96,380
Synth	13,378	79	1,639	21	21,923,740	233,845
Statistical Comparison real vs. synthetic SEPR-S						
Real	47,783	13.96	200	14	9,553,204	191,578
Synth	47,783	13.88	252	18	12,056,615	391,152

Table 1: Statistical comparison of the real and synthetic MIMIC-S and SEPR-S datasets.

4 Results

In the following subsections, we present the evaluation results of the synthetic data.[4]

4.1 Fidelity: Do synthetic and real data match statistically?

Table 1 displays the results of the statistical comparison. Synthetic MIMIC-S notes are longer, contain more and longer sentences, and show significantly higher lexical diversity than real notes by exceeding 137,000 more unique tokens, resulting in a type-token ratio (TTR) almost twice as high. This is particularly notable since TTR typically decreases as text length increases (Tweedie and Baayen, 1998). Thus, the combination of high TTR and larger corpus size indicates a high degree of lexical diversity and contrasts prior findings that synthetic data tends to be lexically limited (Libbi et al., 2021; Hullmann and Hansson, 2024). Similarly, synthetic SEPR-S notes are more verbose and diverse, with increased token and sentence length and a 1% higher TTR. Average sentence counts per document remain consistent with the real dataset. These trends indicate that instruction-tuning LLaMA results in the generation of varied content, even exceeding the lexical range of the real data.

A manual review of MIMIC-S synthetic notes confirmed strong structural and stylistic alignment with real discharge summaries. The synthetic data replicates real-world features such as medical abbreviations, typos, and pseudonymization practices. However, some typical LLM artifacts were observed, including repetitions, pronoun mismatches, and occasional hallucinations. Although these artifacts were relatively rare, they reflect known LLM limitations and might hinder its utility. Overall, the synthetic notes closely mirror real datasets in structure and style while offering increased lexical diversity, and decoding settings could further control document length and verbosity if needed.

[4]Synthetic note examples are provided on GitHub.

	All Real/Synthetic Pairs				Highest 122 Real/Synthetic Pairs			
	AVG	Median	Min	Max	AVG	Median	Min	Max
MIMIC-S real	0.138	0.088	0.006	1.000	0.794	0.779	0.727	1.000
MIMIC-S synth	0.097	0.052	0.001	1.000	0.760	0.748	0.690	1.000

Table 2: ROUGE-5 Recall Scores: Real MIMIC-S and Synthetic MIMIC-S vs. Real MIMIC-L, reported for the full dataset and the 122 document pairs with the highest scores.

Model	**8-Gram Overlap**
Hullmann and Hansson (2024)	0.02442
Synthetic SEPR-S	0.00179
Baseline	0.00488

Table 3: 8-gram overlap between synthetic SEPR-S and real SEPR-L in comparison to baseline and Hullmann and Hansson (2024)

4.2 Privacy: Are the synthetic notes overly similar to the training set?

Table 2 compares ROUGE-5 recall scores across real and synthetic datasets. Real MIMIC-S notes were more similar to the training set (MIMIC-L) than their synthetic counterparts, with average scores nearly twice as high. Among the top 122 most similar pairs, the gap narrows but remains consistent. Similarly, the 8-gram overlap between synthetic SEPR-S and real SEPR-L was well below the baseline and prior work by Hullmann and Hansson (2024) as shown in Table 3. This supports the notion that our method produces outputs with low memorization risk, likely driven by the increased lexical variety of the synthetic data.

Overall, the synthetic datasets show low similarity to training data; nevertheless, occasional long overlaps may still persist and necessitate additional safeguards, like differential privacy (Baumel et al., 2024) or post-generation filtering, when working with non-pseudonymized data.

4.3 Utility: Are the synthetic notes useful to train a medical coding model?

Medical coding model performance across datasets are presented in Table 4. Reproducing Edin et al. (2023) with MIMIC-L training data, our results closely match previous metrics, validating our preprocessing strategy. The stable performance supports the idea that discharge summaries contain redundant information for certain tasks.

To create a smaller real-data baseline, we trained on MIMIC-S. As expected, its performance was lower than MIMIC-L, but still achieved a micro F_1 of 48.2%, providing a benchmark for synthetic data models.

Models trained on synthetic data underperformed compared to real-data models overall. Still, the synthetic MIMIC-L model outperformed the real MIMIC-S model, suggesting that synthetic data scales well with size.

For SEPR data, the trend mirrors English results: real data outperforms synthetic, but the performance gap remains moderate, with the PLM-ICD model trained on synthetic SEPR-L performing better than the one trained on real SEPR-S.

Metric differences across languages, such as higher EMR and lower Precision@k for Swedish, likely stem from SEPR's fewer codes per document. Nonetheless, the relative performance gap between real and synthetic data remained consistent, supporting the generalizability of our framework across languages.

Training on synthetic data from domain-adapted LLaMA models did not lead to performance gains for either medical or Swedish language adaptation. These results suggest that fine-tuning LLaMA-3.1-8B on discharge summaries alone is sufficient for effective adaptation to both the domain and language, reinforcing the validity of our framework and model choice. Although additional domain- or language-specific pretraining did not yield improvements in our experiments, exploring further adapted models remains important, as adaptation effectiveness might depend on the quality of data and methods used for adaptation (Lu et al., 2024).

Overall, while synthetic data is currently outperformed by real data in absolute performance, it shows strong promise, especially as dataset size increases. Given the ability to generate unlimited synthetic data, this highlights significant potential for synthetic data to replace real data in clinical NLP applications eventually.

4.4 Error Analysis: What errors are in the synthetic notes?

We analyzed errors on the MIMIC dataset to highlight limitations when training medical coding models with synthetic data. Table 5 compares correct predictions and error types between real and synthetic MIMIC-L models. We differentiate between within-family (WF) errors, where the wrong predictions still belong to the same ICD-chapter as the target, and out-of-family (OOF) errors, where the prediction falls within a different chapter. Both models show a high proportion of WF errors (79.4% for

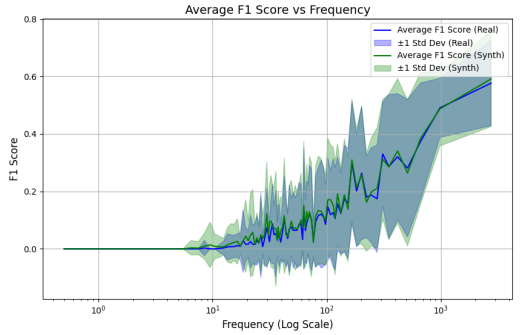

Figure 3: H_1: Macro F_1 vs. code frequencies in training data of real MIMIC-S containing 20% noise in each document (blue) and synthetic MIMIC-S (green) models.

real, 81.5% for synthetic), suggesting they capture disease categories but struggle with fine-grained distinctions. This might reflect code imbalances and a lack of detailed clinical information in discharge summaries. While the synthetic model makes more errors in general, error patterns look similar between models.

One possible reason for the synthetic model's lower performance is noise in the data. Two hypotheses were tested: (H_1) noise is spread across all synthetic notes, and (H_2) only a subset is highly noisy. To simulate noise, random word substitutions were applied to real MIMIC-S data according to each hypothesis. This was done for varying percentages of noise, and the resulting data was used to train medical coding models. To identify the best-fitting noise pattern, F_1 scores were plotted against code frequency, a factor known for its strong influence on performance (Edin et al., 2023), and compared to synthetic model curves. The closest match was found with 20% random substitution across all documents as shown in Figure 3.

This speaks in favor of H_1 and indicates that the synthetic data carries a distributed level of noise explaining utility loss. This noise is likely stemming from LLM artifacts like hallucinations, repetitions, and differences in clinical phrasing. It also implies that the high TTR may reflect noise rather than true desired lexical diversity, highlighting the need for more robust diversity metrics. Future work should aim to reduce these artifacts while preserving diversity and privacy to enhance data quality.

4.5 User Study: Are the synthetic notes medically coherent?

Figure 4 shows the ratings of all three English document pairs. Real documents scored generally slightly higher than synthetic documents in both metrics, with an average score of 3.7 vs. 3.3 for readability and 3.5 vs. 3.3 for medical coherence. However, these differences were not statistically significant ($p \geq 0.05$), neither for the single document pairs, nor on average.

As Figure 4 shows, evaluator ratings varied widely, resulting in low agreement with mean pairwise inter-rater Cohen's Kappa scores of 0.03 (readability) and 0.06 (coherence), likely reflecting differences in medical specialties, experience, and

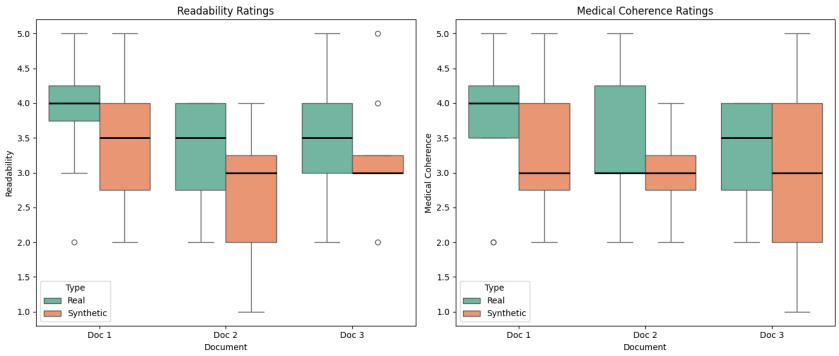

Figure 4: Comparison of readability and medical coherence scores averaged across participants for single document pairs in the MIMIC study. Boxes show the interquartile range (IQR), with the black line as the median and whiskers at 1.5× IQR. None of the differences are statistically significant with ($p \geq 0.05$).

English proficiency. Still, all documents averaged above 3 in both metrics, indicating acceptable quality. A strong correlation between readability and coherence (Pearson: 0.76) indicates shared quality factors. Swedish user study results mirrored the English study, with no significant difference in overall ratings between real and synthetic notes.

Comparable ratings and moderate scores suggest that synthetic notes are of decent quality and reflect effective content control, coherently capturing ICD-10 codes. Future work should involve a larger, more diverse evaluator pool to confirm these findings and better explain the observed disagreement.

5 Discussion and Future Direction

We present a framework for generating synthetic medical notes that aims at balancing privacy and utility by instruction-tuning LLaMA-3.1-8B on ICD-10 codes. Compared to previous methods, our approach stands out for its high privacy-preservation and improved vocabulary richness.

Synthetic data consistently falls short of real data in training medical coding models. However, non-significant differences in medical coherence evaluations and low memorization risk suggest its potential as a general substitute. Larger evaluator samples are needed to validate these findings and clarify the observed low agreement. We hypothesize that the noise contained in the synthetic data, which likely contributes to reduced utility, can be offset by increasing training set size, potentially matching real-data performance. We propose future work to investigate and mitigate this noise by minimizing distortions from real data and reducing LLM-generated artifacts.

The simplicity of the framework makes it attractive for adaptation to other models and languages. While our results demonstrate its effectiveness across languages, further multilingual evaluation is needed, particularly given the lack of transparency from recent open-source LLM creators regarding the inclusion and extent of specific languages in the model's pretraining data.

6 Conclusion

This work presents a scalable and privacy-conscious framework for generating diverse synthetic notes in both English and Swedish. By instruction tuning on ICD-10 codes, we address key challenges in synthetic clinical data generation, notably improving lexical diversity without compromising coherence. Despite some loss in utility compared to real data, our findings indicate that this gap can be narrowed through larger training sets and noise reduction strategies. Crucially, the model performs well without explicit domain or language-specific pretraining, underscoring its adaptability. These results mark a step toward replacing sensitive data with high-quality synthetic alternatives, paving the way for safer, more accessible, and multilingual clinical NLP research.

7 Limitations

Key limitations of this work include the need for deeper medical expert involvement, broader utility evaluation, and critical assessment of biases in real and synthetic data. Model comparisons were limited, and further work should explore alternative architectures, fine-tuning strategies, and privacy-preserving techniques. Developing standardized benchmarks for synthetic medical data evaluation remains an essential step.

Output Trend Analysis in Semantic Classification of Katakana Words Using a Large Language Model

Kazuki Kodaki and **Minoru Sasaki**
Ibaraki University / Japan
{24nm724g, minoru.sasaki.01}@vc.ibaraki.ac.jp

Abstract

In semantic classification of katakana words using a large language model (LLM), semantic divergences from the meanings of original English words such as Wasei-Eigo(Japanese-made English) may affect the accuracy of the model. In order to accurately capture the meaning of foreign words, we fine-tuned the LLM using data extracted from the BCCWJ(Balanced Corpus of Contemporary Written Japanese), analyzed the current accuracy and output trend of semantic classification for katakana words, and explored ways to improve the accuracy. The results of several experiments showed that fine-tuning was not effective for zero-shot learning, but in contrast, fine-tuning improved accuracy by about 10% for few-shot learning. Further analysis of the visualized data suggests trends related to words and meanings that the model struggles to classify correctly.

1 Introduction

Currently, research related to the Large Language Model (LLM) is being conducted in the field of natural language processing. LLM, such as those provided by ChatGPT, are trained primarily on English data, and the percentage of Japanese data seems to be relatively small. Japanese katakana words often include foreign words derived from English and Wasei-Eigo(Japanese-English words) with meanings unique to Japan. This makes semantic interpretation difficult for LLM, due to sense divergence and a lack of relevant training data. Therefore, this paper aims to improve the accuracy of the semantic classification task by adding Japanese data to existing LLM to understand the usage trends of katakana words and their senses. To solve this task, we constructed a dataset by extracting sentences containing katakana words from the Balanced Corpus of Contemporary Written Japanese (BCCWJ)(Maekawa et al., 2014) provided by the National Institute for Japanese Language and Linguistics (NINJAL), and we used and fine-tuned OpenAI's gpt-4o-mini-2024-07-18 model to analyze its output trends.

2 Related Work

Word Sense Disambiguation (WSD) research generally follows two main approaches: supervised learning and knowledge-based methods. Supervised methods classify ambiguous words using models trained on corpora annotated with correct senses by humans. Recent models use pre-trained language models, such as BERT (Devlin et al., 2019) and RoBERTa (Zhuang et al., 2021), to embed words and sentences for sense prediction (Maru et al., 2022; Blevins and Zettlemoyer, 2020). Knowledge-based methods rely on external resources such as dictionaries and ontologies instead of annotated corpora. Some approaches vectorize word definitions to learn sense relationships (Mizuki and Okazaki, 2023), while others use synonym relationships to derive meaningful sense vectors (Wang and Wang, 2020). Recent attempts have also been made to use LLM-based generative AI such as ChatGPT for WSD(Kocoń et al., 2023; Kang et al., 2024), and evaluation results show promising performance, but not yet up to the state-of-the-art models.

3 Experiment

3.1 Extraction-of-Foreign Words

For small-scale experiments, the dataset was constructed using only the BCCWJ sections PB, PM, PN, OC, OW and OY. BCCWJ was used because it is the only balanced corpus on Japanese. From these folders, sentences containing words whose short units (the smallest unit of semantic segmentation of a sentence or word) were labeled as foreign words were extracted, resulting in 32,226 sentences.

Proceedings of Recent Advances in Natural Language Processing,pages 567–571
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-066

From these, we considered four choice sentences and one question sentence to be the minimum number of occurrences, calculated the frequency of occurrence, and set the condition that there must be at least five sentences, and 10,750 sentences and 795 words were extracted.

3.2 Data Set Creation

3.2.1 Selecting target words

This section outlines the method used to select target words and sentences containing them in the data. Digital Daijisen, the source of the goo-dictionary [1] provided by NTT DOCOMO, was used as the word sense category for the target words. Considering the four choices and one question sentence as described in the previous section, we searched the 795 target words in the web-based Digital Daijisen and selected words with at least four examples of word use in the BCCWJ and at least five sentences. Non-katakana words such as foreign articles (e.g., la) were excluded. As a result, 40 words and 1,143 sentences were extracted.

3.2.2 Creation of data sets

To create the dataset, 1143 sentences containing 40 target words extracted in the previous section were used. Their meanings were manually labeled by first author, based on the semantic categories in the Digital Daijisen. Sentences were labeled as follows: 0 if the sentence consists only of the target word and the exact meaning cannot be determined, 1 if the target word is part of some other word, 2 if the context allows multiple interpretations, and 3 if the meaning of the word cannot be referenced in Digital Daijisen. 246 sentences labeled 0-3 were excluded from the dataset, leaving 897 usable sentences. This data is divided into a training and a test set, which are used for the 8 experiments described below. In experiments 1 and 7, the test set consisted of 120 randomly selected sentences (3 per each of the 40 target words), with the other 777 used for training. In experiments 2 through 6 and 8, the test data included 56 sentences, each representing a unique word sense in Digital Daijisen (i.e., appearing only once in BCCWJ), with the remaining 841 sentences used for training.

3.3 Fine-tuning and generating responses

The training data was fine-tuned using OpenAI API with the gpt-4o-mini-2024-07-18 model.

[1] https://dictionary.goo.ne.jp/

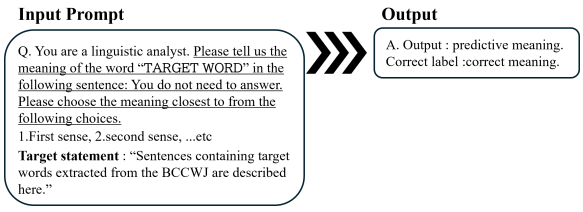

Figure 1: Used Prompts

All settings during the study, such as the learning rate and number of epochs, were done by "auto". For each experimental word sense prediction, responses were generated using ChatGPT before and after fine-tuning. The accuracy and output trends were evaluated by manually judging whether the predictions perfectly matched the semantic categories of the Digital Daijisen assigned to the test data. The prompt presented the semantic categories (scraped from the goo-dictionary) as answer choices and instructed the model to select the meaning closest to the target word. The actual prompt used is shown in the following figure1. Eight experiments were conducted by having responses generated as described above and changing the training and test data during fine-tuning. The details of each experiment and dataset are described in Sections 3.4.1 (Experiment 1), 3.4.2 (Experiments 2-6), and 3.4.3 (Experiments 7-8).

3.4 Experiments

3.4.1 Few-shot learning

The purpose of this experiment is to confirm the increase or decrease of output accuracy due to fine-tuning in few-shot learning. The test data in experiment 1 consisted of 120 sentences (40 target words x 3 sentences) randomly selected from 3 sentences from each target word, and the training data consisted of 777 sentences excluding them.

3.4.2 Zero-shot learning

These experiments aim to evaluate the effectiveness of fine-tuning in zero-shot learning. In each of the experiments in this section, the test data consisted of 56 sentences containing targets with a BCCWJ semantic frequency of 1, which was common to all. To investigate the effect of data bias by giving only examples other than the correct word sense annotated in the test data for the target word, the following experiments 2-6 were conducted. In Experiment 2, 841 training sentences were used, excluding the test data. In Experiment 3, 596 sentences were extracted from the 841 sentences of

training data, including only the target words in the test data. In Experiment 4, we randomly selected 298 sentences, half of the 596 sentences in Experiment 3, to test whether accuracy changes as the amount of data decreases. In Experiment 5, 245 sentences were used from the 841 sentences in the training data, excluding the 596 sentences in Experiment 3 (no sentences in the training data contained an target words). In Experiment 6, we extracted 122 sentences, half of the data from Experiment 5, with the same objectives as in Experiment 4.

3.4.3 Extractive Sense Comprehension and Chain-of-Thought

In Experiment 7, following ESC (Extractive Sense Comprehension)(Barba et al., 2021), target words in the training data of Experiment 1 were enclosed with $< t >< /t >$ tags, Fine-tuning was performed as in the other experiments, and responses were generated using the test data of Experiment 1. This was expected to improve output accuracy by enclosing the target words with tags. In experiment 8, we perform zero-shot CoT (Chain-of-Thought)(Kojima et al., 2022), prompting the model with "Let's think step by step" to guide multi-step inference. This was expected to improve output accuracy in zero-shot learning. Since experiment 3 was the least accurate of experiments 1-6, the data set was used directly in experiment 8 to evaluate the potential for improvement.

3.5 Result

Table 1 shows the output accuracy for each experiment. Accuracy improved in Experiments 1 and 7 after fine-tuning, but decreased in the others.

Table 1: Output Accuracy for Tuning

4 Analysis

4.1 Disscussion

In this section, we present the results of analyzing the output trend of the experiments and the accompanying discussion. As shown in Table 1 and described in Section 3.6, fine-tuning improved accuracy in Experiments 1 and 7, while decreased it in others. This suggests fine-tuning is effective for few-shot settings but not for zero-shot in the semantic inference task for katakana words. The decline in zero-shot learning accuracy may stem from training data bias and the rarity of certain word senses. The former may be attributed to the data extraction method. We did not consider the frequency of word senses when extracting from the BCCWJ. Common meanings are likely to dominate the training set. The latter is because the test data are composed of sentences containing words with meanings that have a frequency of occurrence of 1 in BCCWJ, and it is considered that there are few situations in which the meaning of the word is actually used in documents. For example, in the zero-shot learning test data, the correct answer to the word "course" is "a dish of Western cuisine, served in order". The correct answer for the word "course" in the zero-Shot Learning test data was not found to be correct in all cases. The model or corpus likely lacks sufficient examples of the word, as it appears primarily in meal-related contexts. Experiment 7 did not show an improvement in precision compared to experiment 1, and the effectiveness of enclosing tags was not confirmed. Experiment 8 failed to improve upon experiment 3, suggesting that zero-shot CoT was ineffective, possibly due to Japanese training data or the nature of the semantic inference task. Experiments 4 and 6, which used half of the training data selected at random from experiments 3 and 5 , showed better accuracy—probably due to increased data bias. Furthermore, among experiments 2, 3, and 5, experiment 3 had the lowest accuracy and experiment 5 the highest accuracy. Since experiment 3 consists only of sentences that include the target word in the test data and experiment 5 excludes sentences that include the target word in the test data from the training data of experiment 2, it seems that the accuracy of semantic inference with zero-shot learning decreases when a large number of meanings of the target word are given in the training data. This suggests that including many meanings of a target word in training data reduces the accuracy of zero-shot learning inference.

4.2 Output Trend Analysis

We note several output trends. In experiments 1 and 7, the word "minus" is an example of a word

that did not produce the correct answer choice before and after fine-tuning. Digital Daijisen defines this word as having nine semantic categories, divided into detailed or limited meanings. There was little improvement before and after the fine-tuning, which may be due to the detailed semantic categories in the Digital Daijisen. Still, fine-tuning slightly improved accuracy for meanings like "not good, a bad aspect.". For experiments 2-6 and experiment 8 (zero-shot learning), we have an example where the output was more nuanced than the provided correct answer choice. The correct answer for "home" as part of a home improvement store is "Home. -bar, and my-," but the model before fine-tuning said that this is used differently from the usual "home" because it is precisely the name of a store called "home improvement store". However, fine-tuning made the output the labeled answer. Further, in experiments 2-6, 10 word senses below had one thing in common: neither of the pre-tuning nor post-tuning models output the correct answer choice. "In Western dressmaking, to cut fabric. Cutting. : cut", "In western cooking, a dish served in sequence. : course", "A style of architecture, art, music, etc. Mold. : style", "To assemble a tool, machine, etc. so that it can be used. To set up. : set", "To examine and prevent the entry of anything untoward. : check", "Negative electricity. Also, its symbol. : minus", "To subtract. : minus", "Adverse. Disadvantage. Loss. : minus", "In golf, a target hole cut on the green. : hole", "In a business organization, an organization above or below, such as a bureau, department, division, or section. : line". All of the senses are of limited use, and "minus" was particularly inaccurate.

4.3 Data Visualization

The 897 sentences extracted from BCCWJ created in section 3.2.2 were embedded into a numerical vector using OpenAI API, compressed into two dimensions, further divided into 21 clusters, and visualized in two-dimensional coordinates. UMAP (Uniform Manifold Approximation and Projection) (McInnes et al., 2018) was used to compress the dimensions. This is a dimensionality reduction method that efficiently compresses high-dimensional data to a lower dimension (two dimensions in this paper). Compared to t-SNE (Van der Maaten and Hinton, 2008), UMAP better preserves inter-cluster distances and allows parameter customization, making it suitable for this research. Therefore, we adopted it as the dimensionality reduction method in this paper. For clustering, we adopted HDBSCAN (Campello et al., 2013) due to its ability to handle complex data and accurately detect noise. This helps in visually capturing cluster tendencies. In HDBSCAN, clusters require at least 8 points; smaller groups and isolated points are treated as noise (338 points, 37.7%). Analysis of the plotted clusters revealed that many of the sentences share a similar context. For example, a certain cluster included many PC-related sentences, regardless of the target word. Therefore, we speculate that accuracy could be improved by including not only sentences with the same word senses as the target words, but also those belonging to the same cluster during fine-tuning. Furthermore, for sentences whose senses showed little effect from fine-tuning (experiments 2–6 in Section 4.2), we examined their cluster assignments. "In Western dressmaking, to cut fabric(cut).", "In western cooking, a dish served in sequence (course).". These two word senses were processed as Noise. The points treated as Noise (isolated) in plotted cluster likely lack similar sentence structures. This suggests that the BCCWJ lacks sufficient examples of sentences with the above "cut" and "course" meanings.We speculate that supplementing the dataset with sentences containing katakana words from other corpora that reflect these word meanings could improve precision.

5 Conclusion

Multiple experiments on the semantic inference of katakana words showed improved output accuracy in the gpt-4o-mini-2024-07-18 model when fine-tuned with few-shot learning. We suggest that for few-shot learning scenarios, fine-tuning with carefully selected data—including examples of hard-to-infer word senses, can enhance performance. In contrast, zero-shot accuracy declined, particularly for polysemous and context-specific words. Wasei-eigo requires a broader semantic interpretation, as its meaning often diverges from the original English source. Therefore, fine-tuning may reconstruct a semantic space biased toward specific usages, reducing zero-shot performance, particularly for Wasei-eigo with meanings that deviate from standard English. We hope that these results obtained in this research will be used to contribute to WSD in future research.

Abstract

We propose a domain adaptation method for multilingual sentence encoders. In domains requiring a high level of expertise, such as medical and academic, domain-specific pre-trained models have been released in each language. However, there is no its multilingual version, which prevents application to cross-lingual information retrieval. Obviously, multilingual pre-training with developing in-domain corpora in each language is costly. Therefore, we efficiently develop domain-specific cross-lingual sentence encoders from existing multilingual sentence encoders and domain-specific monolingual sentence encoders in each language. Experimental results on translation ranking in three language pairs with different domains reveal the effectiveness of the proposed method compared to baselines without domain adaptation and existing domain adaptation methods.

1 Introduction

To obtain knowledge comprehensively from large-scale text data on the Web, cross-lingual information retrieval (Artetxe and Schwenk, 2019) is promising. For application to embedding-based cross-lingual information retrieval, multilingual sentence encoders (Conneau et al., 2020; Reimers and Gurevych, 2020; Feng et al., 2022; Wang et al., 2024) are actively researched. Although these encoders are trained on general texts such as Wikipedia and CC100 (Wenzek et al., 2020), in specialized fields that require a high-level of expertise, such as medical and academic, developing domain-specific multilingual sentence encoders would be desirable. However, while domain-specific monolingual sentence encoders (Beltagy et al., 2019; Alsentzer et al., 2019; Araci, 2019; Zhang et al., 2021; Yamauchi et al., 2022; Labrak et al., 2023) have been released, the lack of their multilingual versions has prevented application to cross-lingual information retrieval.

Therefore, we propose a method to train a domain-specific cross-lingual sentence encoder. Since developing in-domain corpora in each language and subsequently performing multilingual pre-training requires significant costs, we fine-tune pre-trained multilingual sentence encoders on a bilingual corpus, similar to the training of general-purpose multilingual sentence encoders (Reimers and Gurevych, 2020; Feng et al., 2022; Tiyajamorn et al., 2021; Kuroda et al., 2022; Wang et al., 2024). Previous studies have focused on bringing bilingual sentence embeddings closer to each other based on methods such as knowledge distillation (Reimers and Gurevych, 2020), translation ranking (Feng et al., 2022), contrastive learning (Tiyajamorn et al., 2021; Wang et al., 2024), and adversarial learning (Kuroda et al., 2022). This study, in contrast, not only brings embeddings from source and target languages close together, but also simultaneously distills domain knowledge.

Experimental results on three domains and language pairs, i.e., Academic (English-Japanese), Medical (English-French), and Financial (English-Chinese), reveal that the proposed method achieves higher cross-lingual similarity estimation performance than the baseline without domain adaptation and existing domain adaptation methods. Our detailed analysis reveals that the proposed method is effective even when the in-domain bilingual corpus has only a few thousand sentence pairs available.

2 Proposed Method

As shown in Figure 1, this study extracts language-agnostic embeddings (hereafter, meaning embeddings) from a multilingual sentence encoder through fine-tuning on an in-domain bilingual corpus, while simultaneously distilling domain knowledge from domain-specific monolingual sentence encoders in each language. Our meaning embed-

Proceedings of Recent Advances in Natural Language Processing,pages 572–577
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-067

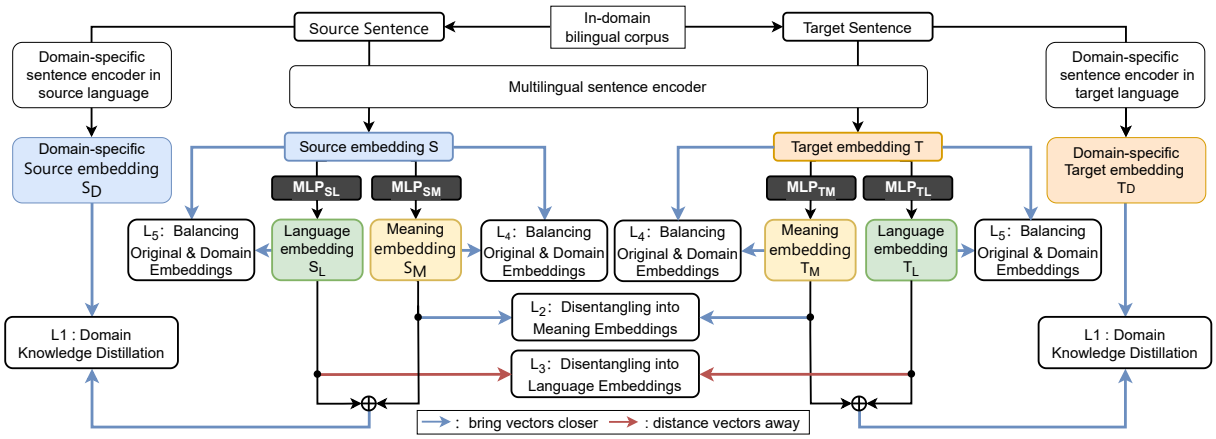

Figure 1: Overview of the proposed method. We train four MLPs to extract language-agnostic domain-specific meaning embeddings (yellow) using an in-domain bilingual corpus, a pre-trained multilingual sentence encoder, and pre-trained domain-specific monolingual sentence encoders in each language.

dings (yellow in Figure 1) can generate vectors that are similar to semantically close sentences, regardless of the input language, on a vector space suitable for the target domain. The proposed method consists of two main ideas: (1) extraction of language-agnostic embeddings and (2) adaptation to domain-specific embeddings. The former is inspired by DREAM (Tiyajamorn et al., 2021) and MEAT (Kuroda et al., 2022) that disentangle embeddings from multilingual sentence encoders into language-specific and -agnostic information; and the latter is inspired by the knowledge distillation of mSBERT (Reimers and Gurevych, 2020).

As in previous studies (Tiyajamorn et al., 2021; Kuroda et al., 2022), we disentangle embeddings from a multilingual sentence encoder into language and meaning embeddings by two multilayer perceptrons (MLPs), MLP_L and MLP_M. This is done for each of source and target sentence embeddings $S \in \mathbb{R}^d$ and $T \in \mathbb{R}^d$, respectively. We train a total of four MLPs using multi-task learning with the following five loss functions.

$$L = L_1 + L_2 + L_3 + L_4 + L_5 \quad (1)$$

2.1 Domain Knowledge Distillation

We aim to distill domain knowledge into meaning embeddings by the following loss that makes sentence embeddings, which combine language and meaning embeddings, closer to sentence embeddings from domain-specific sentence encoders.

$$L_1 = 2 - (\cos((S_L + S_M), S_D) + \cos((T_L + T_M), T_D)) \quad (2)$$

where $S_L \in \mathbb{R}^d$ and $T_L \in \mathbb{R}^d$ are language embeddings in the source and target languages, $S_M \in \mathbb{R}^d$ and $T_M \in \mathbb{R}^d$ are meaning embeddings in each language, $S_D \in \mathbb{R}^d$ and $T_D \in \mathbb{R}^d$ are sentence embeddings from domain-specific models. Here, d is the number of dimensions of each embedding.

2.2 Disentangling into Meaning Embeddings

We want to bring meaning embeddings between semantically similar sentences closer independent of their language. To achieve this, we define the following loss that brings meaning embeddings closer between bilingual sentences.

$$L_2 = 1 - \cos(S_M, T_M) \quad (3)$$

2.3 Disentangling into Language Embeddings

We want to distance language embeddings between sentences in different languages, independent of their meanings. To achieve this, we define the following loss that distances language embeddings between bilingual sentences.

$$L_3 = \max(0, \cos(S_L, T_L)) \quad (4)$$

2.4 Balancing Origin & Domain Embeddings

To make meaning embeddings language-agnostic, we want to avoid being too influenced by domain-specific sentence encoders that are language-specific. To achieve this, we define the following losses that prevent meaning and language embeddings from deviating too much from original ones.

$$L_4 = 2 - (\cos(S, S_M) + \cos(T, T_M)) \quad (5)$$

$$L_5 = 2 - (\cos(S, S_L) + \cos(T, T_L)) \quad (6)$$

2.5 Implementation Details

We use average pooling of token embeddings output from each model for sentence embeddings. All the MLPs in our model are single-layer feedforward neural networks (fully-connected layer) without activation functions. Only MLPs are fine-tuned in our method, and sentence encoders are fixed.

3 Evaluation

We evaluate the performance of the proposed method on a translation ranking task in three language pairs with different domains. Translation ranking is a task that ranks target language sentences in descending order of cross-lingual semantic similarity to a given source sentence. Our automatic evaluation metrics include ExactMatch, which evaluates only first-place candidates, and MRR@10, which evaluates the top 10 candidates. In this experiment, semantic similarity is estimated by cosine similarity.

3.1 Setting

Dataset Experiments were conducted in three domains: Academic, Medical, and Financial. In the academic domain, we used an English-Japanese corpus of project titles in Japanese research funds (KAKENHI[1]). In the medical domain, we used an English-French corpus of PubMed, which was employed in the biomedical translation task of WMT16 (Bojar et al., 2016). In the financial domain, we used an English-Chinese corpus (Turenne et al., 2022) of article titles from the Financial Times. The number of sentence pairs in these parallel corpora is shown in Table 1.

	Train	Valid	Test
Academic (En-Ja)	100,000	5,000	5,000
Medical (En-Fr)	100,000	5,000	5,000
Finance (En-Zh)	50,000	5,000	5,000

Table 1: Corpus size

Model Domain-specific monolingual sentence encoders include SciBERT[2] (Beltagy et al., 2019) in English and AcademicRoBERTa[3] (Yamauchi et al., 2022) in Japanese for the academic domain, Bio_ClinicalBERT[4] (Alsentzer et al., 2019) in English and DrBERT[5] (Labrak et al., 2023) in French for the medical domain, FinBERT[6] (Araci, 2019) in English and Mengzi-BERT[7] (Zhang et al., 2021) in Chinese for the financial domain. For multilingual models, we employed mBERT[8] (Devlin et al., 2019), LaBSE[9] (Feng et al., 2022) and mE5[10] (Wang et al., 2024), which are the commonly used multilingual sentence encoders. We used an implementation of HuggingFace Transformers (Wolf et al., 2020) and trained each model with a batch size of 512 and an Adam optimizer (Kingma and Ba, 2015) with a learning rate of 10^{-5}. Training was terminated when the loss in Equation (1) in the validation dataset did not improve by three epochs.

Comparison In addition to a baseline that uses sentence embeddings from each model as is, we evaluate three comparison methods. First, as a comparison method (1) that only distills domain knowledge, we consider the following loss L_6 using MLP_S for the source language and MLP_T for the target language instead of MLP_L and MLP_M that disentangle language and meaning embeddings.

$$L_6 = 2 - (\cos(S_S, S_D) + \cos(T_T, T_D)) \quad (7)$$

where S_S and T_T are embeddings for each language obtained through MLP_S and MLP_T.

Next, as a comparison method (2) that does not disentangle language and meaning embeddings, we consider the loss $L_6 + L_7$, which brings embeddings in the source and target languages closer in addition to distilling domain knowledge.

$$L_7 = 1 - \cos(S_S, T_T) \quad (8)$$

Finally, as a comparison method (3) without domain adaptation, we consider the loss $L - L_1 + L_8$, which reconstructs the original embeddings by

adding language and meaning embeddings.

$$L_8 = 2 - (\cos((S_L + S_M), S) + \cos((T_L + T_M), T)) \quad (9)$$

3.2 Result

Tables 2 and 3 show the experimental results. Table 2 shows the results when using English sentences as queries to retrieve sentences in other languages, and Table 3 shows the results when using sentences in other languages as queries to retrieve English sentences. The proposed method consistently outperformed the baselines for each model for all domains and language pairs. These consistent experimental results show that our method is effective for domain-specific cross-lingual sentence similarity estimation.

The fact that the comparative method (1), which only distills domain knowledge, completely loses retrievability, suggests that simple domain adaptation cannot train a cross-lingual model. The comparative method (2), which does not disentangle language embeddings and meaning embeddings, also degrades performance significantly, indicating that the extraction of language-agnostic meaning embeddings is important for cross-lingual retrieval. Although the comparative method (3), which does not distill domain knowledge, always outperformed the baseline, it consistently performed below or equal to the proposed method. These results suggest that while the performance of cross-lingual retrieval can be improved by simply extracting language-agnostic meaning embeddings, its quality can be further improved by domain adaptation.

3.3 Ablation Study

Table 4 presents an ablation analysis in LaBSE evaluating multiple combinations of losses, other than L_1, which are essential for domain adaptation. The performance drop in (a) suggests that L_2 and L_3 are important for disentangling language and meaning embeddings to achieve high cross-lingual performance. The significant performance drop in (b) suggests that L_4 and L_5, which prevent deviation from original embeddings, are essential for stable domain adaptation. (c) and (e) show that the to-English performance is worse than the proposed method when excluding losses related to meaning embeddings. In contrast, (d) and (f) show that excluding losses related to language embeddings has no significant impact.

3.4 Analysis of Sensitivity to Corpus Size

Figure 2 shows the performance of translation ranking while reducing the size of the target domain corpus for training. Even training with 5k sentence pairs revealed that our method outperforms the LaBSE baseline. Since developing a large-

scale bilingual corpus in a specific domain is costly, the ability to train cross-lingual domain adaptation from small datasets is a strength of our method.

4 Conclusion

In this study, we address domain adaptation of multilingual sentence encoders. The proposed method uses an in-domain bilingual corpus and domain-specific monolingual sentence encoders in each language to simultaneously extract language agnostic meaning embeddings from a multilingual sentence encoder while distilling domain knowledge. Experimental results in three domains (Academic, Medical, and Financial) and three language pairs (English-Japanese, English-French, and English-Chinese) show that the proposed method can consistently improve the performance of cross-lingual similarity estimation for all domains and languages. Our method can achieve domain adaptation of multilingual sentence encoders even from an in-domain bilingual corpus of thousands of sentence pairs.

Abstract

Large language models (LLMs) have advanced natural language processing (NLP) skills such as through next-token prediction and self-attention, but their ability to integrate broad context also makes them prone to incorporating irrelevant information. Prior work has focused on semantic leakage—bias introduced by semantically irrelevant context. In this paper, we introduce *expression leakage*, a novel phenomenon where LLMs systematically generate sentimentally charged expressions that are semantically unrelated to the input context. To analyse the expression leakage, we collect a benchmark dataset along with a scheme to automatically generate a dataset from free-form text from common-crawl. In addition, we propose an automatic evaluation pipeline that correlates well with human judgment, which accelerates the benchmarking by decoupling from the need of annotation for each analysed model. Our experiments show that, as the model scales in the parameter space, the expression leakage reduces within the same LLM family. On the other hand, we demonstrate that expression leakage mitigation requires specific care during the model building process, and cannot be mitigated by prompting. In addition, our experiments indicate that, when negative sentiment is injected in the prompt, it disrupts the generation process more than the positive sentiment, causing a higher expression leakage rate.

1 Introduction

Large language models (LLMs) have achieved substantial success by modelling language through next-token prediction. Language model based solutions outperform traditional approaches at the major natural language processing downstream tasks like sentiment analysis (Smilga, 2025), and named-entity-recognition (Weissenbacher et al., 2023). LLMs owe their success amongst other the self-attention mechanism, introduced in (Vaswani et al., 2017) as a core architectural innovation, which supports this formulation and allows effective contextual reasoning. Self-attention enables models to capture rich contextual dependencies, but it also allows irrelevant or sentimentally charged tokens to influence unrelated generations, contributing to undesired behaviours. Training dynamics, particularly in instruction tuning or reinforcement learning phases, can amplify or suppress such unintended associations, shaping how strongly sentiment cues propagate through attention pathways.

As the next-token generation LLMs learnt to generate statistically coherent outputs, there is no enforce on factual consistency (Huang et al., 2025), resulting in hallucinations. In addition to hallucinations, systematic and replicable deviations from fairness arises due to the unbalanced nature of data which is free-form text in domain, genre, and cultural representation (Navigli et al., 2023).

Beyond social and demographic biases, LLMs also exhibit more subtle generalisation failures, where irrelevant contextual cues influence generation in unintended ways. Shi et al. (2023) show that LLMs often fail to ignore irrelevant tokens. As a result of irrelevant information, the problem solving capabilities of the LLMs deteriorated. Further, Gonen et al. (2024) define *Semantic Leakage*, where injecting a semantically unrelated concept biases generation. Smilga (2025) further shows that semantic leakage severity increases with model scale. However, most semantic leakage studies focus on concepts and facts being unrelated; none of them explored expressively valenced outputs due to semantically irrelevant context. Moreover, research on *semantic leakage* suf-

Proceedings of Recent Advances in Natural Language Processing,pages 578–586
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-068

fers from a key limitation: it is typically quantified by measuring similarity between discrete lexical entities (e.g., words and sentences). However, such comparisons are ill-defined, as studies on *semantic leakage* presuppose that words and sentences occupy comparable semantic subspaces.

In this work, we introduce a new phenomenon, *Expression Leakage*, where **sentimentally** expressive, yet semantically unrelated additions to the prompts cause consistent shifts in LLM outputs. Expression leakage and semantic leakage are both forms of unintended generalization, but they differ fundamentally in what is being leaked and how it influences generation. Expression leakage refers to affective or stylistic drift—changes in the emotional tone or sentiment of the output—triggered by sentimentally charged but semantically irrelevant content in the prompt. In contrast, semantic leakage involves the unintended activation of conceptual or factual associations based on semantically unrelated inputs. While semantic leakage alters what is being said, expression leakage alters how it is being said.

To evaluate how the aforementioned drift in the context affects the generation of LLMs we curated a dataset with 60 samples‘ and in total 180 prompts. An automatic expression leakage evaluation framework is proposed based on an expression estimator, and via this methodology, it is shown that state-of-the-art LLMs leak expression. Finally, we show that this leakage could be alleviated by prompting especially for instruct models. To summarise our contributions:

- Introduce a new phenomenon, *Expression Leakage*, where sentimentally expressive yet semantically unrelated prompt additions cause consistent shifts in LLM outputs.
- Curate a controlled benchmark dataset of 60 samples (180 prompt variations) for systematic evaluation of expression leakage.
- Develop an automatic data generation scheme producing 200 samples (600 prompt variations) to support scalable evaluation.
- Design an automatic evaluation framework that quantifies leakage based on affective shifts at the output level using an expression estimator.
- Provide empirical evidence that state-of-the-art LLMs exhibit measurable expression leakage across sentiment conditions.
- Demonstrate that leakage can be mitigated through targeted prompting, particularly in instruction-tuned models.

2 Related Work

2.1 Semantic Leakage in Language Models

Gonen et al. (2024) introduced and systematically characterised semantic leakage effect across 13 LLMs and multiple languages, showing that leakage persists across architectures and appears even in simple, controlled scenarios. Their evaluation strategy relies on embedding-based similarity measures between concepts and generations, identifying subtle forms of concept activation in outputs. Smilga (2025) further explore how model scale interacts with semantic leakage, finding that smaller models generally exhibit less leakage, although the relationship is not monotonic, and some intermediate-scale models show localised increases. While these studies establish semantic leakage as a generalisation pathology in LLMs, they focus primarily on factual and lexical associations, without examining affective or stylistic drift.

2.2 Sentiment Sensitivity and Affective Misalignment

Another relevant body of work investigates how LLMs represent and propagate sentiment. Zhang et al. (2024) benchmark LLMs on several sentiment classification datasets, noting that while models perform competitively in binary classification, their robustness degrades in fine-grained or ambiguous contexts. Moreover, Gandhi and Gandhi (2025) demonstrate that LLMs often amplify emotional framing embedded in the prompt, even when such framing is irrelevant to the target task. This suggests that LLMs lack the capacity to fully separate semantic content from stylistic or affective signals, particularly when no explicit instruction is given. These findings provide indirect evidence for a form of sentiment-based leakage, but stop short of formalising it as a separate phenomenon or proposing targeted evaluation strategies.

2.3 Privacy and Information Leakage

Beyond semantic and sentiment-level shifts, a number of studies address privacy-related information leakage in LLMs. Plant et al. (2022)

Table 1: Samples from the HEXL dataset where control and test prompt stem from the curated dataset. Before feeding the prompt to the model, a "Complete the sentence" instruction is prepended to all curated prompts.

Prompt Type	Prompt	Injected Expression
Control	Her passion is	–
Test	I received a heartfelt compliment from a stranger. Her passion is	Positive
	I walked down the hallway. Her passion is	Neutral
	I lost my keys on the way here. Her passion is	Negative
Control	The music sounded is	–
Test	I unwrapped an unexpected gift this morning. The music sounded is	Positive
	I sat on the nearest bench. The music sounded is	Neutral
	I missed the morning bus again. The music sounded is	Negative

demonstrate that large models can memorise and regurgitate personally identifiable or sensitive content from pretraining data. Their work highlights the risks associated with open-domain generation when model internals encode training data too tightly. Wang et al. propose machine unlearning techniques to address this concern, showing how forgetting can be selectively induced in certain model layers. Although these works do not address affective leakage directly, they share with our study a focus on unintended generalisation and model behaviour not directly traceable to explicit prompt intent.

2.4 Cross-Lingual and Stereotype Leakage

Bias propagation across languages is another form of unintended generalisation studied under the term stereotype leakage. Cao et al. (2024) explore this in multilingual LLMs, showing that stereotypes embedded in one language can influence outputs in others. This suggests that LLMs encode generalisable latent associations that transcend surface-level linguistic form. Although stereotype leakage typically targets demographic or social categories, its propagation mechanism is conceptually related to affective leakage across emotional prompts.

2.5 Positioning Expression Leakage

Building on these threads, our work proposes *expression leakage* as a novel subclass of semantic leakage—one that manifests not in factual distortions or social biases, but in unintended shifts in affective framing and sentiment intensity. While previous work has identified model sensitivity to emotional cues, there is little systematic evaluation of how irrelevant expressive content in prompts influences model behaviour. Our proposed evaluation framework bridges this gap by quantifying sentiment shifts across matched test and control generations, using an external expression estimator as a proxy for affective alignment. By controlling for prompt structure and target label, we isolate affective leakage and show how it correlates with model size and instruction tuning. This positions expression leakage as both a practical and conceptual extension of semantic leakage—one that captures a previously unquantified vulnerability in large language models.

3 Methodology

In this study, we define expression leakage as an extension of *semantic leakage*, and first present a novel dataset generation scheme in which expression leakage rates can be measured for generative models. Then, we describe an automatic benchmarking scheme for expression leakage that decouples the process from the need for a human annotator.

3.1 Dataset Collection & Generation

We follow the definitions by Gonen et al. (2024) and for each sample in the dataset, we come up with a control prompt to observe the state of norm. Then, for each control prompt, we design three test prompts to observe the change of behaviour when a 'positive', 'neutral', and 'negative' sentiment is injected.

The injected prompts to the control prompt are all in the form of a sentence, and regardless of the desired 'expression' type, we use a similar number of tokens per control prompt to remove the effect of context length. The expression of the injected prompt is reviewed by the authors and the majority vote is taken as the final expression. Following these principles, we collected a dataset we named HEXL (Human-generated EXpression Leakage dataset), D^H which contains 60 samples and in total 180 prompts, and an example sample from this curation is provided in Table 1. Our

human evaluation involved three annotators with backgrounds in linguistics, using majority voting to label expression leakage instances; agreement was above 85% for all categories. Annotators were presented with anonymized control/test generations and asked to judge affective influence blind to the injected sentiment. To scale benchmarking beyond human-curated cases and remove reliance on manual annotation, we formulate an automated data generation scheme for expression leakage using a biased estimator of expression. For each expression class (positive, neutral, negative), we first select the top m sentences with the highest class confidence scores. From this set, we sample n sentences using probabilities proportional to their confidence scores. Neutral sentences are then split into two groups: test candidates and control prompts. Control prompts are further truncated into shorter phrases to serve as flexible suffixes for controlled generation.

Algorithm 1 Sentiment-Controlled Dataset Generation

Input: Sentence dataset $\mathcal{D}$, sentiment model M, labels $\mathcal{L}$
Output: Labelled prompt dataset $\mathcal{D}^{\text{H}}$
Compute sentiment scores for sentences using M
for all $l \in \mathcal{L}$ **do**
    Select top-m sentences with highest $p(l)$
    Sample n sentences weighted by $p(l)$
end for
Split neutral samples into: neutral set and control prompts
Truncate control prompts to shorter phrases
for $i = 1$ to k **do**
    Combine each sentiment sentence with a control prompt
    Label each pair with sentiment l
end for
Save $\mathcal{D}^{\mathcal{H}}$

In the final stage, each control prompt is combined with sampled sentiment sentences to generate labelled prompts. This pairing enables evaluation or training tasks where the same control input is tested across varying sentiment conditions. The process is summarised in Algorithm 1 where AEXL (Automatically Generated Expression Leakage Data Set), D^A is an automatically generated data set.

3.2 Evaluation Metrics

To evaluate how much the models leak the injected expression, following (Gonen et al., 2024) we define "mean expression leakage rate" via a biased estimator based on language models. The evaluation scheme includes a preprocessing on the generated outputs, and leakage decision per generated output. The preprocessing scheme first splits the generated output into sentences, and the first sentence in this split is selected for the evaluation. The selected sentence is cleaned by removing the repetition of the input prompt. The expression score and class of the final cleaned generation is estimated for control and each injected test case. Then

$$\text{EL} = \begin{cases} 1, & \text{if } P_{\text{test}}[l] > P_{\text{ctl}}[l] \\ 0, & \text{otherwise} \end{cases}, \tag{1}$$

where $P_{\text{test}}, P_{\text{ctl}} \in \mathbb{R}^3$, where $l \in \{0, 1, 2\}$ corresponding to the truth value in the injected expression. Then, the leak rate is the average over the whole dataset.

Following Gonen et al. (2024) and (Smilga, 2025), we compare models via mean-expression leak rate which is the leak-rate calculated via 1 averaged across dataset:

$$\mu_{EL,i} = \frac{1}{N_i} \sum_{j=0}^{N_i} EL_j, \tag{2}$$

where $i \in D^H$, D^A, and N_i is the number of samples in the corresponding dataset.

To assess whether the test generations exhibit higher expression leakage than their corresponding control generations, we compute the paired difference scores:

$d_j = P_{\text{test},j} - P_{\text{control},j}$.

We then apply the one-sided Wilcoxon signed-rank test W_{EL}, to the difference vector $\mathbf{d} = \{d_1, d_2, \ldots, d_N\}$, testing the alternative hypothesis $H_1 : \text{median}(d_j) > 0$. This allows us to determine whether the increase in leakage under the test condition is statistically significant across prompts. We set our significance level to $\alpha = 0.001$.

In addition to the expression leakage, we benchmark the models' performances via semantic leakage on the described datasets. Given a non-linear projector capable of representing properties of a sentence in a vector $\phi : \tau \to \mathbb{R}^d$, where d, then given a concept $\tau_{concept}$ and two generations τ_{ctl}, τ_{test}:

$$sim_{\text{ctl}} = \frac{\phi(\tau_{\text{concept}}) \cdot \phi(\tau_{\text{ctl}})}{\|\phi(\tau_{\text{concept}})\| \cdot \|\phi(\tau_{\text{ctl}})\|},$$
$$sim_{\text{test}} = \frac{\phi(\tau_{\text{concept}}) \cdot \phi(\tau_{\text{test}})}{\|\phi(\tau_{\text{concept}})\| \cdot \|\phi(\tau_{\text{test}})\|}. \quad (3)$$

Then, semantic leakage per prompt is decided using the following heuristic:

$$\text{L} = \begin{cases} 1 & \text{if } sim_{\text{test}} > sim_{\text{ctl}} \\ 0 & \text{if } sim_{\text{test}} < sim_{\text{ctl}} \\ 0.5 & \text{otherwise} \end{cases}. \quad (4)$$

As in Eq. 2, the semantic leakage rate of the model is defined as the average over the dataset with $\mu_{L,i}$ where $i \in D^H,\ D^A$.

3.3 Models

We focus on evaluating two types of consumer-grade models ranging between 1.5B–8B parameters: (1) general-purpose models and (2) instruction-tuned models. Taking into account these criteria, the Qwen2.5 (Qwen et al., 2025), and Llama3.2 (Grattafiori et al., 2024) model families are selected for the evaluation expression leakage.

4 Experiments

State-of-the-art LLMs are evaluated on the proposed datasets and their performances are compared in terms of expression and semantic leakage rates. In this section, we first introduce our experimentation setup, then, the experimental results are presented and discussed.

4.1 Experimental Setup

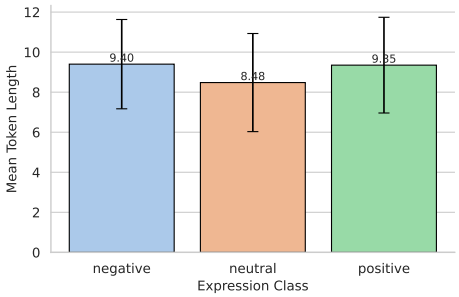
Experiments were conducted using NVIDIA H100 GPUs (80 GB) on a single GPU with PyTorch 2.5.1 and the Hugging Face Transformer v4.49.0. In addition, for the generation of AEXL, we used a dataset[1] hosted at HuggingFace which is a filtered version of C4 (Raffel et al., 2020) and FineWeb (Penedo et al., 2024). While calculating expression leakage (μ_{EL}), we consider only the injected cases of positive and negative sentiment, as the neutral injection condition is semantically aligned with the control and thus directly captured by the semantic leakage metric (μ_l). Next, we present the models and inference configurations used in the experiments.

4.1.1 Models

Focusing on consumer-grade LLMs and their instruction-following variants, we selected the Qwen2.5 (Qwen et al., 2025) and Llama 3 (Grattafiori et al., 2024) model families for our evaluation of expression leakage

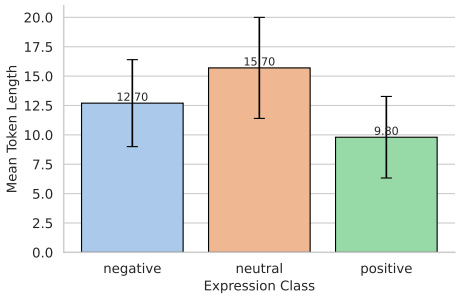
For the expression leakage evaluation, we make use of the sentiment classifier proposed by (Barbieri et al., 2020), which is a RoBERTa (Liu et al., 2019) based model trained on Twitter data. We especially select a model that is trained on a Twitter dataset considering LLMs might produce emojis and emoticons, and models trained on Twitter data handle these information better than structured-text data. We use the *cardiffnlp/twitter-roberta-base-sentiment* model.[2] For the semantic leakage evaluation, we use SentenceBERT (Reimers and Gurevych, 2019) to project sentences into vectors where similarity can be calculated.

4.1.2 Inference Configurations



For the evaluation of semantic leakage, we generate model outputs using a controlled decoding configuration designed to introduce lexical variability while preserving semantic coherence. Specifically, we decide for nucleus sampling with a top-p value of 0.9 and a top-k cutoff of 50 to encourage diverse, but high-probability continuations. Each prompt is decoded by sampling with a repetition penalty of 1.1 to reduce verbatim regeneration, and a maximum generation length of 128 tokens is enforced to ensure bounded output. To enable statistical robustness in leakage estimation, 10 generations are produced per prompt, allowing for instance-level aggregation across output samples.

4.2 Injected Context Length Analysis



In (Chenlo and Losada, 2014) it is shown that the sentence length induces a bias on the sentiment, and in addition to sentiment bias, the longer contexts also might introduce additional semantical distractions due to the self-attention mechanism. The human generated dataset process does not have a restriction on the prompt length. Considering context length bias on sentiment and semantics, we analysed the length of injected context per expression class. Figure 1a depicts that the injected contexts are in similar length in terms of

(a) Mean-injected token lengths per expression class on the human generated expression leakage dataset (HEXL)

(b) Mean-injected token lengths per expression class on the automatically generated expression leakage dataset (AEXL)

Figure 1: Comparison of injected prompt characteristics across sentiment dimensions

Table 2: Sample generations from the Qwen and Llama families on the HEXL dataset. The text highlighted with green corresponds to injected prompts, while blue corresponds to the model's generation.

Model	Prompt Type	Prompt	Injected Expression
Llama-3.2-1B-Instruct	Control	The painting reveals a hidden world of ancient civilizations and mystical creatures that had been lost to time.	–
	Test	She found a long-lost letter in her attic. The painting reveals a hidden message that had been encoded on it for decades.	Positive
		She checked the time on her watch. The painting reveals a faint message that read "I was here".	Neutral
		She received an angry phone call. The painting reveals a dark secret about her husband's past.	Negative
Qwen2.5-1.5B-Instruct	Control	The painting reveals a hidden world of ancient civilizations and mystical creatures that had been lost to time.	–
	Test	She found a long-lost letter in her attic. The painting reveals she has always loved this place.	Positive
		She checked the time on her watch. The painting reveals a hidden message within it.	Neutral
		She received an angry phone call. The painting reveals she had been burglarized.	Negative

number of tokens, when measured with the GPT-2 tokenizer (Radford et al., 2019) across the expression categories where for the negative class the mean is 9.40, for the neutral class it is 8.48, and for the positive class it is 9.35. On the right hand side, Figure 1 depicts the token lengths for the AEXL dataset, where at each sentiment category, the prompts are longer. For the negative class, the mean token length is 12.70, for the neutral class it is 15.70, and for the positive class it is 9.80. The difference in the neutral class suggests that during the curation of the HEXL dataset, curators instinctively generate a uniform distribution, and in the free-form webscale data, neutral sentences are longer than the rest of the other categories.

4.3 Automatic Expression Leakage Rate and Semantic Leakage Rate

Table 3 presents the mean-expression leakage rate (μ_{EL}) along with the mean-semantic leakage rate calculated over the HEXL and AEXL datasets. For all models and datasets, the μ_{EL} exceeds 0.5, meaning that test generations show higher expression similarity to the corresponding concepts in comparison with control generations. This implies that a leakage-rate $\mu_{\text{EL}} = 0.5$ corresponds to random-similarity and no leakage. Observing the μ_{EL} performances, the Qwen family exhibits a lower leakage rate compared to the Llama family in the comparable model sizes. Comparing the effect of the parameter size on the μ_{EL}, it is observed that the model size positively effects the expression leakage, where more capable models leak less expression. The Llama-3.2 family reduced the leakage by 16 points while scaling by 8 in their parameter space. This finding contradicts with the negative correlation between semantic leakage and scale of the models depicted in (Smilga, 2025).

Another contradiction of expression leakage against expression leakage is observed: instruct models are more capable to disregard the irrelevant expression: comparing Llama-3.2-3B-Instruct to the base model Llama-3.2-3B, there is an 8 percent reduction in the leakage rate. This could be attributed to the fact that instruct models

Model	HEXL			AEXL

Table 3: Mean expression and sentiment leakage rates across models and datasets.

are probably more capable of understanding the expression than the base models are. We used the

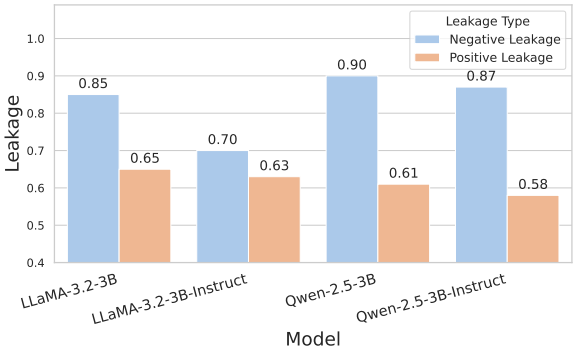

Figure 2: Comparison of same size LLMs for their expression leakage rate per injected expression

Wilcoxon signed rank test to assess the statistical significance of leakage differences between models. It is well-suited for our paired, non-normally distributed data, providing a robust alternative to parametric tests. This allows us to detect consistent shifts in leakage behaviour and validate the impact of model variants or training strategies.

Figure 2 depicts the comparison of leakage performance across same size models per injected expression. We observe a consistent pattern where negative sentiment injections result in higher leakage rates than positive ones, particularly in base models. This asymmetry may stem from the model's heightened sensitivity to negatively framed expressions, which often carry stronger affective or directive cues that align more easily with underlying training data patterns. Additionally, negative prompts may trigger more deterministic or safety-related completions, increasing the likelihood of unintended leakage. In contrast, positive expressions tend to be more diffuse or open-ended, making it harder for the model to converge on specific, memorised outputs. This suggests that the semantic framing of prompts significantly influences the model's response bias and its susceptibility to information leakage. On the AEXL benchmark, expression leakage remains prominent across most models, with μ_{EL} values closely aligned with those observed on HEXL. Instruction-tuned variants generally exhibit higher leakage than their base counterparts. For instance, Qwen2.5-0.5B-Instruct reaches a leakage rate of $\mu_{\text{EL}} = 0.82$, compared to 0.76 in the untuned Qwen2.5-0.5B model. This trend suggests that while instruction tuning improves usability, it may also increase sensitivity to sentimentally expressive, but irrelevant prompt cues. Wilcoxon test scores ($W_{\text{EL}} < 0.001$) confirm that these differences are statistically significant across models, reinforcing that model tuning and prompt design play a critical role in mitigating or amplifying expression leakage.

Semantic leakage results reveal that within the Llama base models, leakage decreases with scale—dropping from 0.83 to 0.69 on HEXL and from 0.75 to 0.65 on AEXL. However, instruction-tuned variants do not consistently reduce leakage: for instance, Llama-3.2-1B-Instruct shows higher leakage than its base counterpart. In the Qwen family, leakage remains high across all

Model	HEXL		AEXL	
	μ_{EL}	W_{EL}	μ_{EL}	W_{EL}
Llama-3.2-1B-Instruct	0.69	1.04e-7	0.78	3.67e-37

Llama-3.1-8B-Instruct	0.60	2.23e-7	0.70	1.63e-27
Qwen2.5-0.5B-Instruct	0.77	6.33e-12	0.85	8.94e-51
Qwen2.5-1.5B-Instruct	0.73	1.33e-8	0.86	5.76e-52
Qwen2.5-3B-Instruct	0.71	2.05e-6	0.70	2.83e-31

Table 4: Mean expression leakage rates across models and datasets with additional instruction to disregard irrelevant information.

scales, and instruction tuning often amplifies it, as seen with Qwen2.5-0.5B-Instruct reaching 0.91 on AEXL. These findings partly contrast with (Smilga, 2025), who observed that smaller models can leak less, attributing higher leakage in larger models to increased associative capacity. Notably, trends in semantic and expression leakage are broadly aligned across HEXL and AEXL: models that show high semantic leakage tend to exhibit high expression leakage as well, suggesting shared underlying generalisation behaviours across both forms of leakage.

4.4 Alleviating Expression Leakage via Prompting

As instruct models finetuned over base-models tend to comply directions and improve capabilities in downstream tasks, we study whether explicitly adding an instruction to disregard irrelevant information alleviates the leakage rates of these models. For this study, we prepend following instruction to each prompt: *Ignore any irrelevant information in user prompt that is not relevant to the request*, and re-run our experiments on expression leakage from Section 4.3.

Table 4 depicts the expression leakage rates with induced instruction to *disregard irrelevant information*. Comparing performances of Llama-Instruct family in Table 3 and Table 4, it is observed that there is no consistent change amongst the models μ_{EL}. These results suggest that prompting is not enough, and specific mitigation techniques must be applied to alleviate expression leakage rate.

5 Conclusion

In this work, we introduced *expression leakage* as a novel form of unintended generalisation in large language models (LLMs), where sentimentally expressive, but semantically irrelevant prompt content induces systematic shifts in model outputs. To evaluate this phenomenon, we curated a controlled benchmark dataset and proposed an automatic expression leakage analysis framework based on a biased expression estimator, which correlates well with human judgment and enables scalable benchmarking without manual annotation. Through extensive experiments, we demonstrated that expression leakage is prevalent across models and that its severity diminishes with increased model scale within the same LLM family, suggesting a connection to capacity and internal control mechanisms. However, we also showed that leakage cannot be mitigated reliably through prompting alone, and that instruction tuning, while partially effective, is not sufficient to suppress affective drift when irrelevant sentiment is introduced. Notably, our results indicate that negative sentiment causes more disruptive leakage than positive sentiment, pointing to an asymmetry in how emotional context influences generation. Expression leakage complements existing notions of semantic and factual leakage by focusing on affective modulation, offering a new lens to evaluate the robustness and controllability of LLMs. We hope this work motivates further research on fine-grained bias detection and the development of training and inference strategies that safeguard against unintended affective influence.

Fusion of Object-Centric and Linguistic Features for Domain-Adapted Multimodal Learning

Jordan Kralev
Institute for Bulgarian Language, Bulgarian Academy of Sciences
jordan@dcl.bas.bg
Department of Systems and Control, Technical University of Sofia
jkralev@tu-sofia.bg

Abstract

Modern multimodal systems often struggle to link domain-specific visual content with textual descriptions, especially when object recognition is limited to general categories (e.g. COCO classes) and lacks customised adaptation to language models. In this paper, we present a novel framework that integrates a domain-specific adapted Detectron2 model into predefined models via a trainable projection layer, enabling precise crossmodal adaptation for specialised domains. Our approach extends Detectron2's recognition capabilities to new categories by fine-tuning on multi-domain datasets, while a lightweight linear projection layer maps region-based visual features to the model's embedding space without completely retraining the model. We evaluated the framework for domain-specific image captioning. The presented approach provides a scalable design for combining domain-specific visual recognition with language inference, with applications in domains that require fine-grained multimodal understanding. The results show rapid model convergence and adaptation to specialized domains. The system achieves competitive BLEU scores on caption generation, though slightly below Gemma 3 baseline.

1 Introduction

Despite remarkable advances in computer vision and natural language processing, most modern models are still largely unimodal and are characterised by either visual understanding (e.g. object recognition) or language understanding (e.g. text generation), but not both. In real-world applications - such as image captioning, visual question answering and multimodal retrieval - there is a growing need for models that can interpret both images and text. Existing multimodal approaches often rely on generic visual features extracted from object detectors trained on standard datasets such as COCO (Lin et al., 2014), which limits their applicability to specialised domains where object categories and visual semantics differ significantly.

Furthermore, it is a major challenge to match the high-dimensional, region-based features generated by advanced object detectors such as Detectron2 with the sequential, token-based representations used by language models. Naive concatenation or superficial fusion of these features often leads to suboptimal performance due to mismatching feature spaces and insufficient cross-modal interaction. This motivates the goals of our work - to propose a robust and flexible system that adapts object recognition to new domains with user-defined categories, effectively bridges the gap between visual and linguistic representations using a trainable projection layer, and enables seamless end-to-end learning for a wide range of multimodal tasks.

This study tackles these issues by introducing a scalable system that combines a domain-specific Detectron2 model with BERT, linked through a trainable projection layer, showcasing its performance on specialized multi-domain datasets. The fine-tuning approach for Detectron2, as outlined in a previous authors' work, is integrated with the creation and utilization of the Multilingual Image Corpus (MIC21). MIC21 expands the conventional 80 COCO categories into an extensive ontology featuring over 700 classes, categorized into 130 thematic subdomains including Sport, Transport, Arts, and Security. The dataset comprises more than 21,000 images and 200,000 annotations. Annotation involved a hybrid process of automated segmentation and classification followed by thorough manual refinement. Images were collected from diverse public sources and annotated based on a custom ontology, which is linked to WordNet and translated into 25 languages, providing rich semantic detail and multilingual support. While the text-generation model developed in the paper

Proceedings of Recent Advances in Natural Language Processing,pages 587–594
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-069

is English-only the design could be extended for multilingual support.

The primary contribution of this paper is the introduction of a scalable and modular multimodal framework that tightly integrates a domain-adapted Detectron2 object detection model with a BERT-based language model through a learnable projection layer, enabling precise cross-modal adaptation for specialized domains. The system is designed to map high-dimensional, region-based visual features into the linguistic embedding space efficiently, allowing for seamless end-to-end learning without retraining large pre-trained components. This architecture is evaluated on domain-specific image captioning tasks.

The organisation of the paper is as follows. The Section 2 reviews recent advances in multimodal learning. Section 3 overview the dataset creation, annotation workflows, and the fine-tuning of Detectron2 models. Section 4 is devoted to the model architecture. Sections 5 and 6 present experimental results, discussion and concluding remarks.

2 Related Work

Recent advances in the field of multimodal learning have focussed on the combination of computer vision and natural language processing.

CLIP (Contrastive Language-Image Pre-training)[1] is a multimodal AI framework developed by OpenAI that learns to combine images and natural language through contrastive learning. The CLIP approach trains two models in a contrastive way (Radford et al., 2021). The text encoder processes an input sentence and transforms it into a fixed-dimensional vector that encapsulates its semantic meaning. Conversely, the image encoder takes an input picture and similarly produces a corresponding vector that captures its visual content.

The core idea of CLIP is to train two separate encoders – an image encoder (often a vision transformer or CNN) for images and a transformer-based language model for text – on a huge dataset of image-text pairs from the Internet. Each encoder transforms its input (an image or a text description) into a high-dimensional vector in a shared embedding space. During training, CLIP uses a contrastive loss: it encourages the embeddings of matching pairs (image, text) to be close to each other, while it pushes the embeddings of non-matching pairs apart. This procedure allows the model to learn rich, general visual and semantic concepts directly from natural language supervision instead of relying on manually labelled datasets.

WebImageText, a dataset of 400 pairs of images and their captions from the Internet, was used to train the OpenAI CLIP models. The total word count of this dataset is comparable to that of the WebText dataset, which contains about 40 terabytes of text data and was used to train GPT-2 (Radford et al., 2021). Image-text pairs are usually loosely correlated, as a caption can match multiple images in addition to the ground truth (Cheng et al., 2021). This is also reflected in the discriminative ability or transferring performance of the visual encoder pre-trained with the contrastive objective (Yang et al., 2022).

On the other hand, there are visual models for self-supervised learning (SSL) that have been pre-trained with the non-contrastive objective (Caron et al., 2021). Beyond the contrastive paradigm, some visual self-supervised learning (SSL) models succeed in mitigating dependency on negative samples (Schiappa et al., 2023). With various refinements to avoid collapsing solutions, these works can optimise the affinity of the augmented representations alone and are categorised as a non-contrastive framework. For example, to avoid model collapse, asymmetric architectures (Chen and He, 2021), dimensional decorrelation (Bardes et al., 2022), and clustering (Assran et al., 2022; Schiappa et al., 2023) are used.

In summary, let state clearly state what is existing and what is new in the proposed approach. Existing datasets and models are: Detectron2 and Yolact Models; BERT Language Model; COCO Image Dataset. The novel contributions are: MIC21 Multilingual Dataset; Fine-Tuned Detectron2 Model per Domain; MIC21Summarizer Model Architecture; Training Strategy.

3 Dataset Preparation

The fine-tuning process begins with the use of pre-trained models such as Yolact and Detectron2, which are first trained on the COCO dataset. These models are used to generate preliminary object boundaries and class labels for the MIC21 images. The automatically generated annotations are then imported into the COCO annotator tool, where human annotators correct the segmentation masks and

[1] https://openai.com/index/clip/

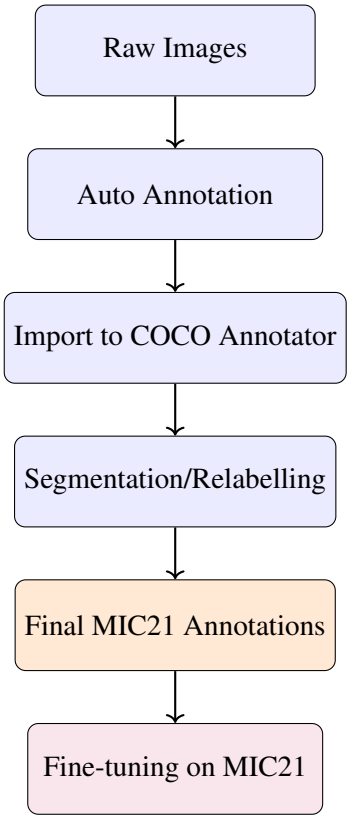

Figure 1: Workflow for dataset creation and annotation in MIC21.

re-label objects according to the MIC21 ontology. This process is further optimised by custom scripts that automate dataset management tasks, such as relabelling, merging and exporting annotated data (Figure 1).

Once the annotated dataset is prepared, the Detectron2 framework is used for model training. The architecture typically consists of a ResNet-based backbone with a Feature Pyramid Network (FPN), a Region Proposal Network (RPN), and an ROI head for classification and mask prediction. During fine-tuning, the backbone and RPN layers are often frozen to retain the general visual features learned from COCO, while the ROI head is retrained to adapt to the new, domain-specific classes of MIC21.

The models are assessed using COCO-style metrics, including precision, recall, and average precision (AP) across a range of intersection-over-union (IoU) thresholds. The FiftyOne framework is used for visualization and comparison of model predictions with ground truth annotations (Figure 2).

4 Model Architecture

The developed model, MIC21Summarizer, is an advanced multimodal neural network architecture designed to generate textual descriptions from images by integrating state-of-the-art computer vision and natural language processing components (Figure 3). The architecture begins with an image feature extraction backbone based on Detectron2's Mask R-CNN with an X-101-32x8d-FPN configuration. This model is pre-trained on the COCO dataset for instance segmentation. The image is preprocessed and passed through the backbone, and features are extracted from the 'p6' feature map.

Let $I \in \mathbf{R}^{H\times W\times 3}$ be the input image. The Detectron2 backbone extracts a feature tensor

$$x_i \in \mathbf{R}^{C\times H_F\times W_F}, \tag{1}$$

where in our model $C = 256$, $H_F = 16$ and $W_F = 16$. For this purpose a 16×16 pooling layer is applied over Detectron2 'p6' features which are with variable size dependent on image size. The feature tensor F is reshaped into a matrix

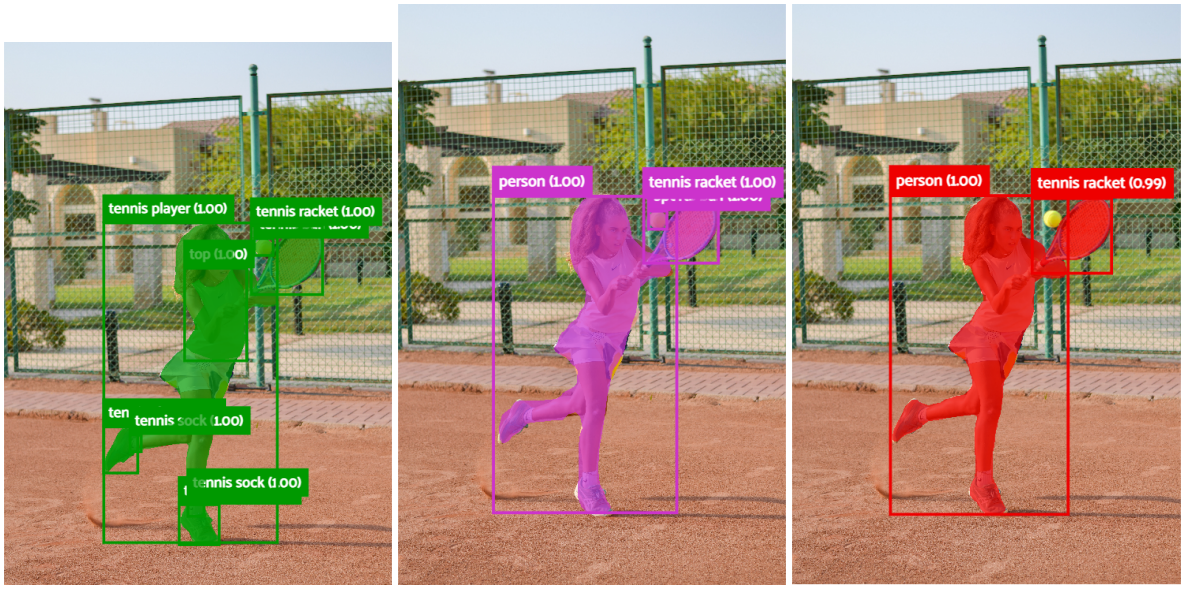
$$x_f \in \mathbf{R}^{C\times(H_F W_F)} \tag{2}$$

The feature matrix is normalized and projected to the embedding dimension d (here d = 1024 for bert-cased-large)

$$v = W_p F_{drop}(F_{norm}(x_f)) + b_p \tag{3}$$

where $W_p \in \mathbf{R}^{d\times C}$, $b_p \in \mathbf{R}^d$ and $v \in \mathbf{R}^{256\times d}$.

For the language component, the model leverages the BERT architecture. It initializes a BERT tokenizer and the corresponding embedding layer from the "bert-large-cased" model. For a token sequence $t = (t_1, t_2, \ldots, t_T)$, the BERT embedding layer produces



$$e = (e_1, e_2, \ldots, e_T) \in \mathbf{R}^{T\times d} \tag{4}$$

where e_i is the embedding of token t_i. The input to the decoder is the concatenation of projected visual tokens and text embeddings

$$z_0 = (v, e) \in \mathbf{R}^{(256+T)\times d} \tag{5}$$

The core of the sequence generation is a stack of three Transformer Decoder layers, each with eight attention heads and a model dimension of $d = 1024$. The decoder consists of L layers (here L=3), each applying multi-head self-attention

$$a_l = f_{smax}\left(\frac{QK^T}{\sqrt{d}} + M\right)V \tag{6}$$

(a) Human (b) Detectron2 (c) YOLACT

Figure 2: Example of ground-truth annotation and annotation results using Detectron2 and YOLACT

where queries Q, keys K and values V are all linear tunable projections of z_{l-1}, and $M \in \mathbf{R}^{(256+T)\times(256+T)}$ is causal mask defined with

$$M = \begin{pmatrix} 0_{256\times256} & 0_{256\times T} \\ 0_{T\times256} & U_{T\times T} \end{pmatrix} \tag{7}$$

where U is upper triangular matrix with entries

$$u_{i,j} = \begin{cases} 0, & i \geq j \\ -\infty, & i < j \end{cases} \tag{8}$$

The decoder operates in an autoregressive manner: it starts with an initial (empty) token embedding and, at each step, generates the next token embedding conditioned on the previously generated sequence and the visual context. This process is repeated for up to 128 steps, allowing the model to generate a sequence of tokens that describe the input image.

The output from the decoder (only last T positions) is projected onto the vocabulary

$$y = W_e^T z_{l,256:T} \in \mathbf{R}^{T\times m} \tag{9}$$

where W_e are the frozen BERT word embeddings, and m is the vocabulary size. The word embedding weights are reused in the output projection layer, ensuring that the output tokens generated by the decoder are aligned with the BERT vocabulary and tokenization. Token predictions are made via an argmax over the logits.

The aim of the model is to tightly couple high-level visual understanding with transformer architecture, enabling powerful language modeling capabilities. The design emphasizes modularity and efficiency by freezing large pre-trained components and focusing training on the crucial projection and decoding layers.

4.1 Training Strategy

Both the image backbone and the BERT embedding layers are frozen during training, focusing learning capacity on the projection and decoding components. To perform cross-entropy training with one token ahead prediction in autoregressive models we optimize the model to predict the next token in a sequence given the previous tokens, known as teacher forcing.

Given a sequence of tokens

$$w = (w_1, w_2, \ldots, w_T) \tag{10}$$

where $w_t \in 1 \ldots m$ is the index of a token in the vocabulary. The model output is generating a conditional distribution over sequences of tokens for a given input image I defined autoregressively as

$$p(w, I, \theta) = \prod_{t=1}^{T-1} p(w_{t+1}|w_{1:t}, I, \theta) \tag{11}$$

where θ is the vector of tunable parameters.

The training goal is to maximize the log-likelihood of the image-sequence pairs from the

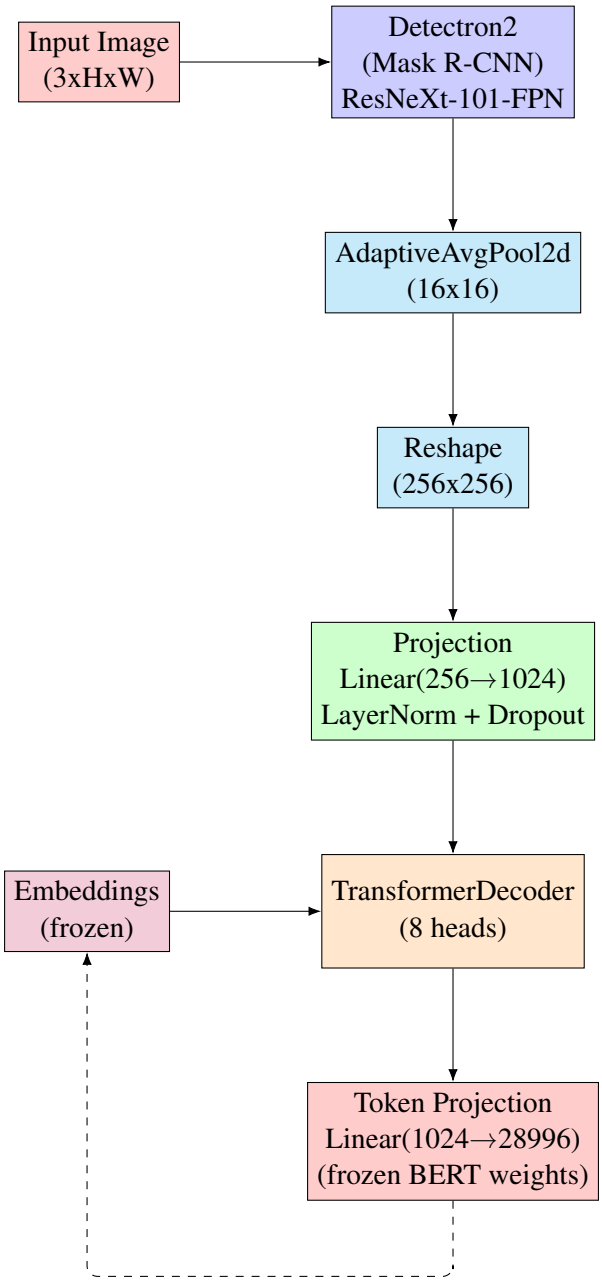


Figure 3: MIC21Summarizer Architecture Overview

training data set. This translates to minimizing the negative log-likelihood

$$\mathcal{L} = -\log p(w, I, \theta) = \\ -\sum_{t=1}^{T-1} \log p(w_{t+1}|w_1, \ldots, w_t, I, \theta) \quad (12)$$

For each position $t = 1 \ldots T$, let $z_t \in \mathbf{R}^m$ be the model's output (so called logits) for the next generated token over vocabulary of size m. After application of softmax operation to convert logits to probabilities we can get an explicit expression for $p(w, I, \theta)$, i.e.

$$p(w_{t+1} = i|w_1, \ldots, w_t) = \frac{e^{z_{t,i}}}{\sum_{j=1}^{m} e^{z_{t,j}}} \quad (13)$$

where $z_{t,j}$ is element at position j from the vector z_t.

Two training modes are possible in this framework. One is *autoregressive generation loss* where past sequence $w_{1:t}$ is obtained from previously generated tokens, i.e.

$$w_t \sim p(w_t|w_{1:t-1}, I, \theta) \quad (14)$$

In this case, each $\mathcal{L}_t$ depends on all previous predictions through the recursive generation. The gradient calculation $\partial\mathcal{L}/\partial\theta$ will require backpropagation through t unrolled steps, potentially leading to vanishing or exploding gradients, along with high memory usage with complexity $O(t)$.

Alternatively in *teacher forcing loss* the past sequence $w_{1:t}$ uses ground truth tokens before step t. This allows for parallel computation of the loss across all positions ($O(1)$ complexity) and therefore a single forward/backward pass through the model, which stabilize the gradients.

In the proposed model architecture only trainable parameters are projection layer weights W_p and biases b_p, along with transformer decoder parameters θ_{dec}. The projection layer parameters contribute to the loss gradient as

$$\frac{\partial\mathcal{L}}{\partial W_p} = \sum_{t=1}^{T} \left(\frac{\partial\mathcal{L}_t}{\partial z_t} W_e \right) \frac{\partial y_t}{\partial v} \frac{\partial v}{\partial W_p} \quad (15)$$

For each decoder layer l, the decoder layer gradient is

$$\frac{\partial\mathcal{L}}{\partial\theta^l_{dec}} = \sum_{t=1}^{T} \frac{\partial\mathcal{L}}{\partial h^l_t} \left(\frac{\partial h^l_t}{\partial\theta^l_{dec}} + \sum_{k>t} \frac{\partial h^l_k}{\partial h^l_t} \frac{\partial h^l_t}{\partial\theta^l_{dec}} \right) \quad (16)$$

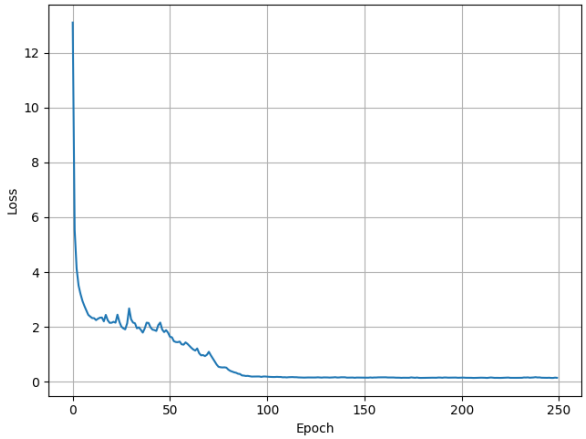

Figure 4: Loss function during initial training of the model

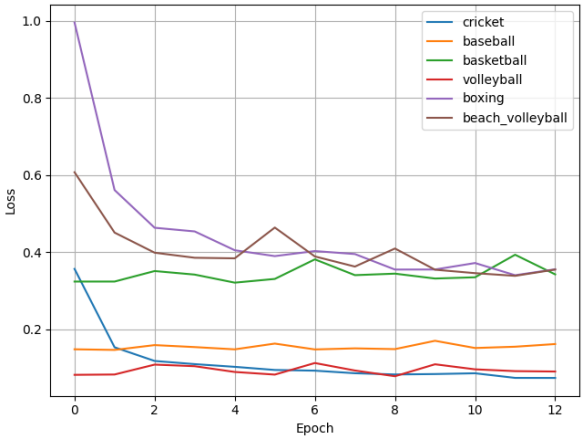

Figure 5: Loss function during fine tuning of the model by category

5 Results

The Figure 4 illustrates the evolution of the loss function over 250 training epochs during the initial phase of model training over limited subset. At the outset, the loss is quite high—above 12 is typical for randomly initialized or newly adapted models that have not yet learned meaningful representations from the data. In the first 20 epochs, there is a rapid and substantial decrease in loss, indicating that the model is quickly capturing the most salient patterns and features present in the training set. This steep initial decline is characteristic of effective learning and suggests that the optimizer and learning rate are well-chosen for the early phase.

Beyond the first 20–30 epochs, the loss curve begins to flatten, with smaller oscillations and a gradual downward trend until around epoch 100. After this point, the loss stabilizes at a low value and remains nearly constant for the remainder of training. This plateau suggests that the model has converged and further training does not yield significant improvements in the loss. The absence of upward spikes or instability in the latter part of the curve also indicates that the training process is stable and not suffering from overfitting or catastrophic forgetting. Overall, the figure demonstrates a successful training regime where the model efficiently learns from the data and reaches a steady state of performance.

The Figure 5 presents the loss curves for several sports categories—cricket, baseball, basketball, volleyball, boxing, and beach volleyball—during the fine-tuning phase of a model. Each curve represents the loss value for a specific category as training progresses over 12 epochs. Across all categories, there is a clear trend of rapid loss reduction within the first few epochs, indicating that the model quickly adapts to the new data and learns category-specific features efficiently. Categories like beach volleyball and boxing start with higher initial losses but show significant improvement early on, while others such as cricket and baseball begin with lower losses and stabilize quickly.

After the initial sharp decline, the loss curves for most categories plateau, with only minor fluctuations, suggesting that the model reaches a stable state and further training yields diminishing returns. The variability in final loss values among categories may reflect differences in data complexity, sample size, or intra-class variability. For example, basketball and volleyball maintain higher loss values compared to cricket and baseball, potentially indicating greater difficulty in distinguishing features or less training data for those categories. Overall, the figure demonstrates effective fine-tuning, with the model achieving rapid convergence and stable performance across diverse sports categories.

Table 1 presents the BLEU scores (from 1-gram to 4-gram) for generation performance on two models, MIC21 and Gemma 3. Across all BLEU metrics, Gemma 3 outperforms MIC21, with particularly notable margins at higher n-gram levels: BLEU-1 is 0.79 for Gemma 3 versus 0.71 for MIC21, and BLEU-4 is 0.43 compared to 0.39. This consistent advantage suggests that Gemma 3 produces text that more closely matches the reference outputs, both in terms of individual word choice and longer phrase structure, indicating greater fluency and accuracy in its generated sequences.

Test	MIC21	Gemma 3
BLEU-1	0.71	0.79
BLEU-2	0.53	0.64
BLEU-3	0.47	0.53
BLEU-4	0.39	0.43

Table 1: Generation Performance Metrics

6 Conclusion

The paper presents a scalable framework for domain-adapted multimodal learning, addressing the critical challenge of aligning specialized visual semantics with language generation. By integrating a domain-adapted Detectron2 model with BERT via a trainable projection layer, the architecture enables precise cross-modal adaptation while maintaining computational efficiency. The system leverages the MIC21 corpus—a richly annotated dataset extending COCO categories to over 700 classes across 130 thematic subdomains—to bridge the gap between generic visual recognition and domain-specific linguistic understanding. Key innovations include freezing pre-trained components and focusing training on lightweight projection and transformer decoder layers, achieving stable convergence and efficient resource utilization.

Experimental results demonstrate the framework's effectiveness. Loss curves reveal rapid initial learning followed by stable convergence, indicating robust feature alignment. Fine-tuning performance varies across domains, with sports categories like cricket and baseball achieving lower final losses compared to basketball and volleyball, reflecting differences in intra-class variability and annotation quality. In generation tasks, the model achieves competitive BLEU scores, though it lags behind larger models like Gemma 3, highlighting a trade-off between specialization and generalizability. These results validate the framework's ability to generate context-aware descriptions while preserving domain-specific visual semantics.

A key extension to this study will be a comparison to state of the art models for generation and tagging tasks with an aim to highlight the domain-specificity or trained models.

Future work could extend this approach by expanding the MIC21 ontology to include dynamic interactions between objects and integrating contrastive or adversarial alignment strategies to further refine cross-modal representations. Additionally, exploring efficient attention mechanisms or multilingual extensions of the projection layer could enhance scalability. This work lays a foundation for applications requiring fine-grained multimodal understanding, from medical imaging to industrial inspection, where domain-specific visual-language alignment is critical.

Abstract

This paper introduces an interactive Python debugging framework that combines multi-agent reinforcement learning, Natural Language Processing (NLP), and long-term memory. Two Proximal Policy Optimization (PPO) agents specialize in syntax and logic errors, generating candidate fixes that developers can accept, reject, or refine. A BERT-based module encodes natural language feedback into dense embeddings and quality scores, which shape reward signals for Reinforcement Learning from Human Feedback (RLHF). To support personalization, the system uses dual FAISS indices to retrieve past fixes based on code-error pairs and developer explanations. Evaluated on a synthetic dataset of 200 Python programs, our approach achieves an 88% syntax-fix rate and 45% logic-fix rate within five suggestions—outperforming one-shot Large Language Model (LLM) baselines. In addition, the system improves the quality of the explanation, as measured by BLEU, ROUGE, and CodeBLEU. By integrating multi-agent specialization, linguistic feedback, and memory-driven retrieval, our framework delivers a more efficient, adaptive, and developer-aligned debugging experience.

1 Introduction

Software developers spend considerable time and mental resources on debugging during software development. The Python code generated by Large Language Models (LLMs) like Codex and AlphaCode frequently includes syntax or logic mistakes which need manual correction. Existing neural repair systems, such as DeepFix and DrRepair, together with fine-tuned LLMs such as CodeT5, typically operate in a one-shot manner. These systems lack interactive feedback, developer personalization, and the ability to retain knowledge across sessions.

To address these limitations, we propose an interactive debugging assistant that unifies Reinforcement Learning from Human Feedback (RLHF), multi-agent specialization, and memory-based personalization. The system employs two Proximal Policy Optimization (PPO) agents: 1) *Syntax Agent* for structural errors and 2) *Logic Agent* for test-driven faults. Developers interact with these agents through a natural language interface, providing feedback that is encoded by a BERT-based processor into dense representations and reward signals.

Additionally, an episodic memory module maintains dual FAISS indices, one over code error embeddings and another over developer explanations to enable retrieval and reuse of past successful fixes. This architecture allows the assistant to adapt to individual coding styles, improve over time, and reduce developer effort.

By combining structured interaction, personalized retrieval, and linguistic feedback, our framework offers a more effective and human-aligned debugging experience than existing one-shot or fully automated solutions.

2 Related Work

Prior research in automated program repair spans neural code correction, LLMs, multi-agent systems, human-in-the-loop learning, and memory-augmented architectures. Early efforts such as DeepFix (Gupta et al., 2017) and DrRepair (Yasunaga and Liang, 2020) approached bug fixing as a one-shot translation problem, using sequence models or graph networks to correct syntax and logic errors. However, these systems lack interactivity and cannot refine their outputs through user feedback.

LLM-based tools such as Codex and GitHub Copilot excel at code generation but offer no guarantees of correctness, often producing faulty out-

Proceedings of Recent Advances in Natural Language Processing,pages 595–603
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-070

puts that require manual debugging. LeDex (Jiang et al., 2024) improves upon this by using execution feedback and reinforcement learning to refine the model output, but remains a single-agent system that relies solely on automated test results. It does not incorporate human feedback or support long-term personalization.

Recent studies in multi-agent reinforcement learning suggest performance gains through task decomposition. Co-Learning (Yu et al., 2024) demonstrates this by coordinating correction and testing agents through reward exchange, but it lacks developer input and session-level memory, limiting adaptability and user alignment.

RLHF has shown strong results in alignment of language models (Christiano et al., 2017), subsequent large-scale applications such as InstructGPT (Ouyang et al., 2022), and summarization using human preferences (Stiennon et al., 2020). In the code domain, most RLHF approaches use automated test outcomes as implicit feedback (Zhang et al., 2024), missing subjective signals such as clarity or stylistic consistency. Our work directly incorporates developer judgments, accept, reject, or correct, into scalar and terminal rewards, enabling adaptive policy learning grounded in user intent.

Memory-augmented neural architectures offer another avenue for personalization and learning over time. Early work such as Memory Networks (Weston et al., 2015) introduced differentiable attention to stored representations, while more recent systems such as generative agents (Park et al., 2023) and skill libraries in embodied agents (Wang et al., 2023) have demonstrated the value of long-term memory in sequential decision-making. Despite this progress, memory remains underutilized in debugging systems, which typically start from scratch in every session. Our approach addresses this gap by using dual FAISS indices to persist and retrieve embeddings of past code errors and natural language explanations, allowing agents to recall and reuse effective fixes across sessions.

In summary, while existing research excels in isolated areas such as one-shot repair, LLM generation, or human-in-the-loop learning, no prior system integrates multi-agent specialization, direct RLHF, and memory-based retrieval for interactive code debugging. Our proposed framework aims to fill this gap by delivering a personalized, continuously improving debugging experience grounded in developer interaction and historical context.

3 Methodology

Our debugging framework integrates two specialized PPO agents, one for syntax errors and one for logic bugs, with RLHF, NLP, and episodic memory. We construct a synthetic dataset of 200 Python programs (100 syntax bugs, 100 logic bugs) using `create_synthetic_dataset()`, enriched with natural language bug descriptions via `enhance_dataset_with_nl_reports()` (e.g., "Missing colon after if").

Two OpenAI Gym-compatible environments are defined:

- **SyntaxEnvironment**: Compiles code and extracts error diagnostics and NL features.
- **LogicEnvironment**: Execute tests using `pytest` and summarize failed cases.

Both environments share an observation-action interface and query memory during initialization and after accepted actions.

3.1 Observation, Actions, and Policy Network

At each timestep t, the agent observes a composite state:

$$o_t = [s_{30}, m_{10}, n_{768}] \tag{1}$$

Here, s_{30} represents static code and diagnostic features, m_{10} consists of retrieved memory embeddings, and n_{768} is the BERT-encoded natural language explanation.

Action representations:

- **Syntax Agent**:

  $a_t = (\texttt{type}, \texttt{line}, \texttt{tokens}, \texttt{explanation})$

- **Logic Agent**:

  $a_t = (\texttt{patch}, \texttt{test_id}, \texttt{explanation})$

Each input stream is independently processed through fully connected layers:

$$s' = \text{FC}_{30\to64}(s) \tag{2}$$
$$m' = \text{FC}_{10\to32}(m) \tag{3}$$
$$n' = \text{FC}_{768\to128}(n) \tag{4}$$

The concatenated vector is projected into a shared representation:

$$z = \text{FC}_{224\to128}([s', m', n']) \to \pi_\theta(a_t|o_t), \quad V_\phi(o_t) \tag{5}$$

where π_θ is the head of policy and V_ϕ the head of value of the PPO network.

3.2 Episodic Memory and Retrieval

We maintain a circular buffer with a capacity of 1,000 records. Each entry contains:

- A CodeBERT-based 768-dim code-error embedding
- A BERT-based 768-dim explanation embedding
- Metadata: bug ID, action sequence, and feedback score

Two FAISS indices are maintained: one over code embeddings and one over NL explanations. At each decision point, agents query top-k neighbors to inform or reuse past successful actions. Memory entries with low historical utility are periodically pruned.

3.3 Training and Reward Shaping

Agents are pre-trained in supervised bug-fix pairs and then fine-tuned using simulated feedback before RLHF with real users. We adopt the standard PPO hyperparameters as follows: $\alpha = 3 \times 10^{-4}$, $\gamma = 0.99$, $\epsilon = 0.2$, $n_{\text{steps}} = 2048$, and batch size $= 64$.

Reward shaping is guided by user feedback:

$$r_t = \begin{cases} +1 & \text{if accepted} \\ -1 & \text{if rejected} \\ +0.5 & \text{if corrected} \end{cases} \tag{6}$$

In addition, a terminal reward of +5 is granted if all bugs are resolved in five steps. Optional developer ratings in the range $[-2, +2]$ may be added to r_t to enrich the granularity of the signal.

Interaction modes:

- **Alternating mode**: Syntax Agent acts until compilation succeeds, then is transferred to the Logic Agent.
- **Joint mode**: Both agents propose actions per timestep. The terminal reward R_T is divided through a Shapley-inspired formula:

$$R_i = \frac{1}{2}\left(V(S, A_1, A_2) - V(S, A_{-i})\right) \tag{7}$$

Each episode ends after 10 steps or when all bugs are fixed. Transition tuples (o_t, a_t, r_t, o_{t+1}) are logged for offline replay and policy refinement.

3.4 Ablation and Evaluation Protocol

To measure the contributions of each component of the system, we performed ablation experiments by disabling the following:

- Episodic memory (no FAISS retrieval)
- RLHF (supervised pretraining only)
- NL features (zeroed n_{768} embeddings)
- Multi-agent setup (Syntax or Logic agent alone)

Evaluation metrics include:

- **Fix rates**: syntax, logic, and overall (within five suggestions)
- **Efficiency**: average number of suggestions to complete a repair
- **NLP quality**: BLEU and ROUGE-1/2/L for NL explanations
- **Code similarity**: CodeBLEU between patches and ground-truth fixes
- **Acceptance rate**: percentage of suggestions accepted on first attempt

Validation is performed on closed bugs using both simulated and real developer feedback.

4 System Architecture

Figure 1 illustrates the high-level architecture of our interactive debugging assistant, which consists of six core components: a Natural Language Processor, two Gym-based environments, a Multi-Agent Controller, a shared policy network with two specialized agents, an episodic memory module, and a human feedback interface.

4.1 Natural Language Processor

The NLProcessor module uses a pre-trained BERT encoder to transform free-form developer feedback into a 768-dimensional embedding vector. These embeddings serve two purposes:

- They are included in the observation vector o_t for both agents.
- They are indexed in the NL FAISS memory store for cross-session retrieval.

In addition, BLEU and ROUGE scores are computed between agent explanations and gold-standard developer descriptions to inform reward shaping.

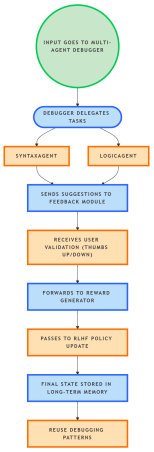

Figure 1: System architecture. Natural language feedback is embedded and stored; code and test environments interact with PPO agents coordinated by a central controller; feedback updates memory and agent policies.

4.2 Gym Environments

We implement two custom `gym.Env` classes:

SyntaxEnvironment:

- *State*: Current source code, compiler errors, and feedback history.
- *Step*: Invokes Python's interpreter to identify syntax issues, extracts diagnostics, and encodes them via the NLProcessor.

LogicEnvironment:

- *State*: Executable code, unit test results, and interaction history.
- *Step*: Execute `pytest` on the code and extracts summaries of failure tests.

Each environment outputs a structured observation:

$$o_t = \{s_{30}, m_{10}, n_{768}\} \tag{8}$$

where s_{30} contains structured code and error features, m_{10} consists of memory retrievals, and n_{768} is the NL embedding.

The action spaces for the agents are:

- **Syntax Agent**: type, line, token_seq, explanation.
- **Logic Agent**: patch, test_id, explanation.

4.3 Multi-Agent Controller

The Multi-Agent Controller coordinates agent-environment interactions and manages the episode loop:

- In alternating mode, the Syntax Agent proposes actions until compilation succeeds, after which control passes to the Logic Agent.
- In joint mode, both agents act at each timestep. Terminal rewards are distributed using a Shapley-value-inspired allocation:

$$R_i = \frac{1}{2}\left(V(S, A_1, A_2) - V(S, A_{-i})\right) \tag{9}$$

Following each accepted action, the environments are updated and a transition tuple (o_t, a_t, r_t, o_{t+1}) is recorded for training. After each episode, the final bug-fix-feedback tuple is stored in memory.

4.4 Agents and Feature Extractor

Both agents share the same policy architecture, built using SB3's `MultiInputPolicy`. The custom feature extractor processes each input stream independently:

$$s' = \text{FC}_{30\to64}(s) \tag{10}$$
$$m' = \text{FC}_{10\to32}(m) \tag{11}$$
$$n' = \text{FC}_{768\to128}(n) \tag{12}$$

The concatenated vector $[s', m', n']$ is passed through a projection layer:

$$z = \text{FC}_{224\to128}([s', m', n']) \to \pi_\theta(a_t|o_t), \quad V_\phi(o_t) \tag{13}$$

4.5 Long-Term Memory Module

The episodic memory module maintains a circular buffer of 1,000 entries with:

- 768-dimensional CodeBERT embeddings of $(\texttt{code}, \texttt{error})$ pairs.
- 768-dimensional BERT embeddings of developer explanations.

Two FAISS indices support nearest-neighbor retrieval. At each decision point, agents query these indices for relevant past fixes. The extracted examples can inform new actions or directly trigger a `ReuseSolution` event. Memory entries are periodically pruned based on past feedback scores to maintain retrieval quality.

4.6 Human Feedback Interface

Developers interact with the system through a VSCode-based interface equipped with the following features:

- The suggested patches are annotated in the code editor.
- Feedback options include: `Accept`, `Reject`, and `Correct`, each mapped to a corresponding reward.
- Optional developer ratings in $[-2, +2]$ are supported to refine reward signals.
- Manual edits are captured and stored as "corrected" actions.

Each interaction updates the reinforcement learning training buffer and contributes to long-term memory, allowing the system to learn over time from user behavior.

5 Experimental Setup

This section describes the tools, dataset, training procedures, and evaluation metrics used to evaluate the proposed debugging framework.

The system is implemented in Python 3.9 using the following tools:

- **Reinforcement Learning**: Stable Baselines3 v1.8.0 with PPO.
- **Language Models**: Hugging Face Transformers v4.28 for BERT and CodeBERT.
- **Test Execution**: Python `exec()` and `pytest` v7.3 to run unit tests.
- **Memory Indexing**: FAISS v1.7 for approximate nearest-neighbor retrieval with 768-dimensional embeddings.
- **Database and Interface**: SQLite v3.39 for logging and a VSCode extension as the front-end interface that communicates via REST APIs.

The experiments were run on an NVIDIA T4 GPU with 16GB RAM on Ubuntu 22.04.

A dataset of 200 Python programs is synthetically generated using:

- `create_synthetic_dataset()` to produce 100 syntax and 100 logic bug samples.
- `enhance_dataset_reports()` to inject natural language bug descriptions (e.g., "missing colon in `if` statement.")

The dataset includes common beginner-level errors and is partially adapted from QuixBugs and hand-crafted logic fault patterns. Each program is paired with 3–5 unit tests. Syntax bugs are evaluated through compilation success, while logic bugs are tested using functional assertions. We split the dataset into 150 training samples and 50 held-out programs for validation and generalization testing.

In addition to our synthetic experiments, we evaluated two established Python bug benchmarks:

- **CodeFlaws** (30 programs; syntax & logic)
- **ManyBugs** (40 programs; logic-only)

We apply the same training regime and report actual fix rates in Section 6.

A rule-based simulated user provides feedback during the pre-training phase. Given a proposed fix, the user assigns rewards based on match quality:

$$r_t = \begin{cases} +1 & \text{Exact match with ground-truth fix} \\ +0.5 & \text{Correct location, partial fix} \\ -1 & \text{Incorrect or unrelated suggestion} \end{cases} \tag{14}$$

If no valid solution is found within the allowed steps, a terminal reward $r_T = 0$ is assigned.

We use the following hyperparameters for PPO optimization:

Learning rate $\alpha = 3 \times 10^{-4}$, Discount factor $\gamma = 0.99$, Clip range $\epsilon = 0.2$, Entropy coef = 0.01 $n_{\text{steps}} = 2048$, and Batch size = 64.

Additional configuration parameters:

- **Memory size**: 1,000 entries (FAISS buffer)
- **Retrieval top-k**: 5 neighbors
- **Episode length**: Maximum 10 steps
- **Random seeds**: 42, 123, 2025 (results averaged across 3 runs)

We evaluated the performance of the model using the following metrics:

- **Fix Success Rates**: Percentage of programs fully repaired within 5 suggestions, split by:
  - Syntax bugs
  - Logic bugs
  - Overall (combined)

- **Efficiency**: Average number of suggestions required for successful repair.
- **Natural Language Metrics**: BLEU, ROUGE-1/2/L scores between developer descriptions and agent-generated explanations.
- **Code Similarity**: CodeBLEU scores that compare the agent's final patch with the ground-truth version.
- **Acceptance Rate**: The fraction of agent suggestions accepted on the first attempt.

The robustness of the model is validated in the 50 programs that have been canceled using both simulated and real feedback. Episode reward curves and memory usage statistics are logged over time.

We conducted a pilot user study with eight Python developers (3-7 years of experience), each completing 5 debugging tasks (2 syntax, 2 logic, 1 mixed). The goal was to assess subjective experience, debugging efficiency, and the perceived helpfulness of agent-generated feedback. The metrics collected include:

- Time to first correct fix
- Number of suggestions reviewed
- NASA-TLX workload scores
- 5-point Likert ratings on clarity, satisfaction, and trust

Participants reported a mean satisfaction score of 4.2/5 and a 35% reduction in the debugging time compared to manual attempts. Although results are promising, the limited sample size and lack of a direct comparison baseline (e.g. Codex or Copilot) are noted limitations. We plan to include larger-scale and comparative studies in future work.

6 Results and Analysis

This section presents the empirical results of our system on the held-out 50-program test set. We compare against strong baselines, evaluate efficiency, explanation quality, and perform ablation studies to quantify the impact of system components.

Table 1 and Figure 2 report the success rates of syntax, logic, and general fix, together with the average number of suggestions required to repair each program.

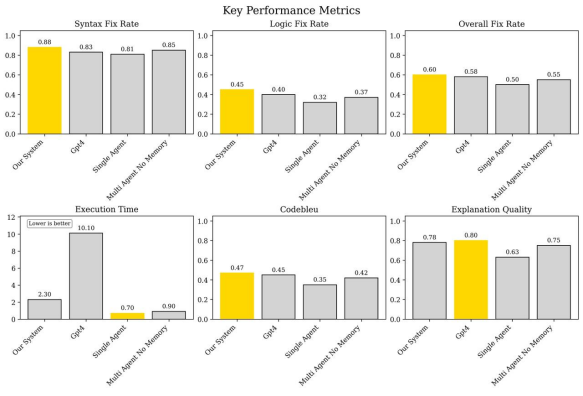

Figure 2: Debugging performance: syntax-fix rate, logic-fix rate, overall-fix rate, and average steps to repair across systems.

Our system achieves the highest fix rates and the lowest edit counts, demonstrating that combining human feedback with memory retrieval significantly improves both accuracy and efficiency. In particular, it reduces suggestions by more than 75% compared to GPT-4.

Table 2 summarizes the average time per debugging episode and the acceptance rate of the first-pass suggestions.

Although GPT-4 exhibits a higher acceptance rate, it is significantly slower and less interactive. Our model maintains high suggestion quality while enabling rapid feedback loops.

We assess natural language explanation quality using BLEU, ROUGE-1/2/L, and the alignment between code patches and ground truth via CodeBLEU. The results are shown in Table 3 and Figure 3.

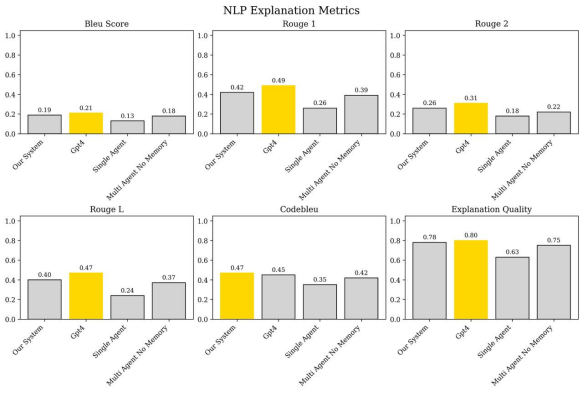

Figure 3: Natural-language explanation quality: BLEU, ROUGE, and CodeBLEU across systems.

Our model balances fluency and functional accuracy. Although GPT-4 achieves slightly higher BLEU/ROUGE, our system leads in CodeBLEU,

System	Syntax	Logic	Overall	Avg Steps
RLHF + Memory	0.88	0.45	0.60	2.30
GPT-4 One-Shot	0.83	0.40	0.58	10.10
Single-Agent Supervised	0.81	0.32	0.50	7.00
Multi-Agent (No Memory)	0.85	0.37	0.55	9.00

Table 1: Fix success rates and average steps to repair across systems.

System	Time(s)	Acceptance Rate
RLHF + Memory	2.30	0.56
GPT-4 One-Shot	10.10	0.69
Single-Agent Supervised	7.00	0.39
Multi-Agent (No Memory)	9.00	0.58

Table 2: Execution time and first-pass suggestion acceptance rates.

showing better alignment with actual code changes.

Table 4 reports average NASA–TLX subscale scores.

TLX Subscale	Avg Score (0–100)
Mental Demand	45
Temporal Demand	40
Physical Demand	10
Effort	38
Performance	30
Frustration	22

Table 4: NASA–TLX subscale scores collected in the human study.

Table 5 reports the impact of memory impairment, RLHF, or agent specialization. Each ablation degrades the performance, confirming the necessity of each component.

The value of "40% memory consulted" refers to the proportion of the total decision steps in which the agent triggered a memory query or reused a past solution retrieved. This suggests that the memory module actively supports nearly half of all decision points, particularly for recurring or stylistically similar bugs.

During the evaluation, we observed that logic fixes involving nested loops or external library calls were more likely to fail. In contrast, syntax fixes such as bracket mismatches or missing colons were highly reliable. Future work may focus on augmenting the memory index with control-flow-aware features to handle deeper logic chains.

[1]CodeFlaws and ManyBugs are benchmarks of buggy C programs; we use Python-equivalent adaptations for compatibility with our environment (Le et al., 2015).

To illustrate how our system performs on real-world code, we present a debugging episode from the CodeFlaws dataset. This example highlights the system's ability to generalize from synthetic training to unseen, real Python code, and to incorporate natural language reasoning effectively.

Example (CodeFlaws-17):

```
Original code snippet:
if score > 90
print("Excellent")
```

Compiler error: `SyntaxError: expected ':'`

Agent Suggestion: Insert a colon after the condition: `if score > 90:`

Agent NL Explanation: *"Python requires a colon at the end of conditional statements."*

Outcome: Fix accepted. The program compiled and passed all test cases.

This example demonstrates the system's capacity to recover from common student-level syntax errors using semantically appropriate edits and human-aligned explanations. Natural language feedback adds interpretability to the action and the fix was drawn from the system policy without direct memorization. More complex logic bugs show similar behavior, though with slightly lower success rates.

The results confirm that RLHF and memory-based retrieval enhance both repair quality and developer-aligned behavior. Compared to the GPT-4 one-shot approach, our system is faster, more

System	BLEU	ROUGE-L	ROUGE-2	ROUGE-1	CodeBLEU
RLHF + Memory	0.19	0.40	0.26	0.42	**0.47**
GPT-4 One-Shot	**0.21**	**0.47**	**0.31**	**0.49**	0.45
Single-Agent Supervised	0.13	0.24	0.18	0.26	0.35
Multi-Agent (No Memory)	0.18	0.37	0.22	0.39	0.42

Table 3: Explanation and code similarity metrics.

	Ablation Results			Memory Usage		
Configuration	Syntax	Logic	Overall	Avg Steps	Consulted	Fix-Rate Lift
Full Model (RLHF+M)	0.88	0.45	0.60	2.30	40%	+11 pp
No Memory	0.80	0.37	0.51	3.10	—	—
No RLHF	0.85	0.40	0.55	2.75	—	—
Single-Agent Only	0.81	0.32	0.46	4.00	—	—
Real-World Benchmarks						
CodeFlaws (n=30)	0.75	0.32	0.54	3.1	—	—
ManyBugs (n=40)	—	0.28	0.28	3.4	—	—

Table 5: **Top:** Ablation and memory-usage metrics. **Bottom:** Fix success rates on real-world benchmarks.[1]

adaptive, and offers greater control through human feedback. Episodic memory significantly improves efficiency by avoiding redundant effort and aligning future suggestions with previous successful fixes.

7 Conclusions and Future Work

We introduced an interactive multiagent debugging framework that integrates RLHF, NLP, and memory-based retrieval to assist developers in fixing Python code. The system employs two specialized PPO agents, one for syntax and one for logic errors, whose policies are continuously refined through developer feedback. A BERT-based NL processor encodes developer explanations, which serve both as observation features and as reward signals. An episodic memory module stores past code-error pairs and explanations, enabling the retrieval and reuse of successful fixes.

Empirical results in a synthetic dataset demonstrate that our approach achieves an 88% syntax-fix rate, a 45% logic-fix rate, and a 60% overall fix rate within five suggestions—outperforming GPT-4 and other baselines. The system also reduces average suggestions to 2.3 and achieves high CodeBLEU scores, indicating better alignment between explanations and code edits. A user study also supports the system's utility, showing a reduced debugging time and a high level of developer satisfaction.

Although this work supports developer productivity, automated fixes must be interpreted cautiously. We recommend human-in-the-loop confirmation for all critical code changes, particularly in safety-sensitive applications. Looking forward, several directions remain open:

- **Cross-language and multi-file support**: Extending the framework to larger, multi-module codebases and other programming languages (e.g., Java, C++).
- **Richer feedback modalities**: Incorporating graded, ranked, or dialog-based feedback to better capture developer intent beyond accept/reject actions.
- **Hybrid reasoning pipelines**: Integrating symbolic reasoning or static analysis to address deeper logical bugs with verifiable correctness.
- **Personalization via meta-learning**: Leveraging meta-learning to adapt agents more rapidly to individual developer styles with minimal data.
- **Federated and continual learning**: Enabling deployment in real-world CI/CD pipelines using federated updates to improve generalization while preserving privacy.

These enhancements aim to make adaptive debugging agents more robust with human developers in diverse real-world environments.

Abstract

In academic year 2023/24, our university collected over 200,000 student feedback responses evaluating teaching staff and course experiences. The survey included demographic data, 10 Likert scale questions on teaching quality, a question on student attendance, and three open-ended questions about student experiences. This paper explores the integration of Large Language Models (LLM) Gemini for sentiment analysis to evaluate students' feedback quantitatively and qualitatively. We statistically analyze the Likert scale responses. To address the linguistic diversity of open-ended responses, written in both Cyrillic and Latin scripts with standard and slang expressions in several languages, we employed a preprocessing step using Gemini to standardize the input for further analyses. Sentiment analysis aims to identify various sentiment nuances, including direct answers, contradiction, multipolarity, mixed sentiment, sarcasm, irony, negation, ambiguity, understatement, and over-exaggeration. By comparing these insights with quantitative feedback, we aim to uncover deeper patterns between student perceptions and teaching performance. While the focus is on sentiment analysis, we also discuss the evaluation of the results provided by LLM. For the sentiments with less answers, the evaluation of GenAI was done manually. For the sentiments with more than 1000 entries, we suggest a semi-automated approach for sentiment categorization, to be explored in future work. This study enhances our understanding of student feedback through advanced computational methods, providing a more nuanced perspective on teaching quality and student satisfaction.

1 Introduction

In recent years, education has undergone significant transformations. Initially driven by the sudden transition to online learning due to COVID-19, these changes have been further accelerated by the emergence of generative artificial intelligence (GenAI) tools, which students have quickly embraced as essential components of their learning and assignment preparation (Zdravkova and Ilijoski, 2025). As a result, student expectations toward class delivery methods and assessments have evolved (Chan and Hu, 2023).

Student feedback has become a valuable source of insight into the quality of the educational process, encouraging teachers to improve their teaching practices, even when the sole intention of these changes is to increase their own ratings (Flodén, 2016). Well-intentioned assessments, opinions and suggestions can significantly improve teaching practices and provide guidance for institutional development and global education reforms aimed at adapting the emerging technological trends (Kastrati et al., 2021). The surveys combine assessments of overall teaching quality with sentiment analysis derived from open-ended questions (Hynninen et al., 2020).

Student surveys do not always reflect the true quality of education, as many students either skip them or respond mechanically, often omitting open-ended questions. To better understand this behavior, we asked students why they tend to fill out surveys superficially. The most common reasons included the excessive length of the questionnaires, lack of lecture attendance, which left them feeling unqualified to evaluate the teaching, the reliance on peer opinions from social networks rather than personal experience, but predominantly the impression that their responses have no impact on teaching outcomes.

These findings highlight a systematic credibility issue in the survey data. As a result, we interpreted the results with caution and used them primarily to identify general trends rather than to draw strong evaluative conclusions about specific individuals

Proceedings of Recent Advances in Natural Language Processing,pages 604–613
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-071

or courses.

After each semester, students at our university are required to complete an anonymous survey covering all faculties, all subjects, and all teaching staff. The survey for the last academic year has more than 200,000 records: 81,500 for the winter semester and 130,550 for the summer semester. Likert-scale responses were analyzed quantitatively, while sentiment analysis of open-ended answers was conducted using Gemini and its built-in training data. Manual assessment was applied only to sentiment categories with a low number of responses. Additionally, a combined analysis of numerical and textual data was performed.

The paper continues by presenting an analysis of related work. Section 3 presents a detailed description of the methodology of our experiment that includes preprocessing of open-ended questions and setting the experiment. The results are processed in section 4. The paper ends with discussions of the entire experiment, conclusions and plans for automating the process of processing the survey and evaluating the obtained results.

2 Quantitative, qualitative and AI-based approaches to survey data analysis

Surveys containing substantial amounts of numerical and textual data can provide valuable insights. Quantitative responses reveal patterns in student satisfaction, while open-ended feedback highlights specific concerns about content and teaching. However, analyzing unstructured text remains challenging due to its complexity. To address this, studies often apply scalable sentiment analysis using lexicon-based methods, machine learning, or transformer models, combined with qualitative approaches like thematic coding. This integration enables both large-scale trend detection and deeper interpretive insights that reflect contextual nuances (Kastrati et al., 2021).

2.1 Likert scale ordinal data

Methods for processing Likert-scale data include descriptive statistics, comparative analysis, and nonparametric statistical methods (Harpe, 2015).

Descriptive statistics provide initial quantitative and visual summaries of the sample (Cooksey, 2020). The numerical data in our research are ordinal, thus univariate, bivariate and multivariate statistics, as well as regression analysis and linear trend estimation, can be applied (Verhulst and Neale, 2021).

Comparative analysis allows for the examination of differences between groups. In the context of student surveys, this primarily involves comparisons across faculties, departments, and institutes (Ragin, 1998). Nonparametric tests are also suitable for such analyses. However, given that our survey collected data from twenty-two faculties and four institutes, each varying significantly in student population and educational level, we opted to exclude this aspect from our comprehensive analysis.

Nonparametric statistics encompass analyses such as contingency tables, rank tests for one or more samples, rank correlation, and basic nonparametric regression techniques (Wasserman, 2006). In our research, we primarily focused on contingency tables, which display the multivariate frequency distributions of variables.

2.2 Unstructured textual data

The sentiment analysis of the survey analyzed in our comprehensive study is designed to enhance the overall educational experience and help maintain or even improve the university already high reputation.

Sentiment analysis involves examining text to determine its polarity and identify the emotional tone of responses. Polarity refers to the general sentiment expressed in a message, typically categorized as positive, negative, or neutral. Beyond polarity, analyzing emotions offers a more nuanced understanding of feedback by recognizing linguistic patterns that reflect how respondents express their attitudes. These are typically considered direct emotional responses and are contrasted with more complex emotions such as irony and sarcasm (Filik et al., 2019; Frenda et al., 2022). In contrast, emotion classification seeks to capture more nuanced aspects of feedback, offering a deeper understanding of how respondents truly feel.

In our analysis, we extended this framework to include additional categories such as negation, multipolarity, ambiguity, exaggeration, context-dependent sentiment, incomplete understatement, contradiction, and mixed sentiment.

The most widely used NLP techniques for determining sentiment polarity include sentiment lexicons, such as VADER (Qi and Shabrina, 2023). Additionally, pattern matching, which relies on predefined rules, has proven to be highly effective for sentiment classification (Zhang and

Zhang, 2022). Finally, traditional machine learning techniques, such as the well-established Naïve Bayes classifier and Support Vector Machines (SVM), have been successful in determining sentiment polarity (Ahmad and Umar, 2023).

To detect subtle emotional nuances, several methods are employed. Emotion lexicons remain effective for classifying specific emotions (Nandwani and Verma, 2021), while rule-based detection aids in identifying sarcasm and negation (K et al., 2021). Dependency parsers, which analyze grammatical structure, help reveal word relationships (Agarwal et al., 2015). Named entity recognition (NER) also supports context-sensitive sentiment analysis, particularly when sentiment is linked to specific entities (Derczynski et al., 2015).

To carry out these tasks, we relied entirely on Gemini. First, we prompted LLM to determine the sentiment polarity of each response. Following that, we requested a classification of the emotional tone. As outlined in the introduction, we did not train or fine-tune the model ourselves. Instead, we leveraged its pretrained data and built-in classification capabilities. Throughout the process, we remained aware of the potential biases inherent in relying on an LLM and took care to interpret its outputs critically.

2.3 Integrating numerical and textual data

Surveys include numerical and textual responses. After performing quantitative and mixed analyses, meaningful patterns can be identified by comparing or integrating both data types. One common approach is the use of mixed-effects models, which establishes relationships between response variables and relevant covariates (Bates, 2010). In our study, mixed-effects models are used to compare numerical values from Likert-scale responses with sentiment derived from open-ended questions.

Correlation methods, such as Spearman's rank correlation, can also be effective tools (Sedgwick, 2014). They can compare sentiment polarity with numerical results, enabling the evaluation of similarity between sentiments and Likert-scale ratings. Multivariate analysis is another powerful technique for exploring relationships between categorical variables, i.e. those that represent different groups or categories (Wu et al., 2015).

Cluster analysis can be employed to group similar comments based on associated numerical feedback (Huang and Mitchell, 2006). For our research, we use hierarchical clustering to examine the degree of correlation between specific sentiments and corresponding Likert-scale responses.

2.4 LLM-based sentiment analysis

Since 2020, large language models have emerged as powerful tools in natural language processing, particularly for sentiment analysis. These models effectively address challenges in both polarity detection and the interpretation of subtle emotional cues in text (Zhang et al., 2024).

The best proof of the growing influence of LLMs and GenAI among the researchers is the sharp increase of scholarly articles. Namely, since 2024, more than 20,000 articles on Google Scholar have included the phrases "large language models" and "sentiment analysis", while nearly 5,000 papers reference "generative artificial intelligence" in the context of sentiment analysis. Our research leverages the large language model Gemini to enhance both the accuracy and depth of sentiment analysis, enabling a more nuanced understanding of textual data.

3 Methodological framework for LLM-based sentiment analysis

Self-evaluation is one of the strategic goals of the university, which, among other aspects, monitors and assesses the quality of higher education and scientific re-search activities. It is implemented through the university's electronic system at the end of each semester. Although students log in with their university credentials to access the survey, no usernames or personal identifiers are recorded or stored. Such authentication fully preserves anonymity, in strict compliance with GDPR (European Parliament and Council of the European Union, 2016).

In addition to demographic data, the survey included ten numerical questions rated on a 1–5 scale, one attendance question expressed as a percentage, and three open-text fields.

Students were asked to numerically evaluate the following ten aspects of each course and its teaching staff: the professors knowledge; how helpful the lectures are; whether the questions are interesting and include relevant examples; how much the student has learned during the lectures; whether there are appropriate learning materials provided; the punctuality of the teaching staff; whether the students are graded continuously with various

relevant techniques; whether the teaching staff is unbiased; as well as their availability for office hours and over email. The text fields allow students to highlight what they liked in lectures or exercises, what they disliked, and to provide any additional comments.

3.1 Preprocessing of Textual Data

The first step in the preprocessing was to remove the responses that didn't contain any textual data, only punctuation such as "/", "-", or ".", sometimes repeated multiple times. This was done through simple regular expression matching in Python, leaving only answers that contain at least one letter.

The next step was to classify the text by language used. This was done using Gemini. The requests asked for a custom structured response, which included a field for the original comment and its language. The language was an enum type, listing four languages as options: Macedonian (written with Cyrillic and Latin script), Albanian, English, and Turkish. This was done to limit the number of possible options and ensure there will be fewer misclassifications, especially with similar languages. The prompt used was "Determine the language of the following texts:"and the comments were passed in batches. Figure 1 shows the distribution by language for the textual fields.

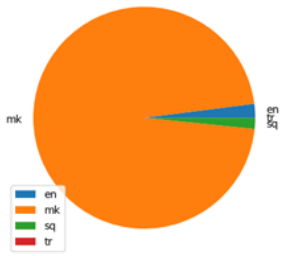

Figure 1: Distribution of comment languages

The overall accuracy of the language detection, evaluated on a random sample of 600 comments, was 96.45%. The accuracy for comments written in the Latin script was 88.69% and for Cyrillic script comments 100%. Most mistakes were on single-word comments, often with internationalisms such as ok or super, that were classified as different languages in different responses. Some responses were misclassified, such as the Macedonian word ce / se "everything", that is sometimes classified as English. However, there was also a small number of misclassified full-sentence responses. To additionally check the validity of the results, the number of responses that have different identified languages for the different textual fields were singled out. There were 679 responses that fit this description. These included the mistakes mentioned above, as well as responses where the students actually wrote different parts of the response in different languages.

After language detection, Macedonian responses written in Latin script were transliterated into Cyrillic. Using the previous step's results, Python regular expressions filtered Macedonian text to identify any Latin characters. Responses containing Latin characters were then sent to Gemini for transliteration. Similarly to language detection, this process was performed in batches, handling each column separately. The prompt used was: "Transliterate the following texts into Macedonian Cyrillic." The result was impeccable.

3.2 Experiments with Textual Data

The data was analyzed using a combination of statistical tools in Python, mostly for the numerical responses, and Gemini for analyzing the textual fields.[1]

The statistical analysis focused on the number of responses, grouped by faculty, professor, and course, as well as computing the mean, standard deviation, median, and important percentiles. The mean was computed per column, as well as by response. The mean grade across all numerical questions of each response was used to find the number of responses that have both a low mean and a non-empty text field for the positive comment, as well as for further analysis and experiments relating to grade prediction. All these statistical analyses were done using the pan-das module.

The text data was analyzed using Gemini. The gemini-1.5-flash model was used in all experiments. The data was classified by sentiment in the following categories: ambiguity, context-dependent sentiment, direct answer, humor, irony, mixed-sentiment, multipolarity, negation, over-exaggeration, sarcasm, and understatement. These were given as an enum type as part of the expected response, and comments were passed in batches.

Comments were also classified by their focus using Gemini. The categories in this case

[1]The code can be found at https://colab.research.google.com/drive/18eRXjaY-magr46ijylKI8-cKGNENfjAj?usp=drive_link

corresponded to the questions in the survey that asked for numerical answers. The possible Likert-scale categories for this classification were: Teachers' level of knowledge (abbreviated as TK), Lectures are helpful (LH) Lecture are interesting (LI), Learning outcomes (LO), Quality of lecture and study materials (QL), Punctuality (P), Continuous grading techniques (GT), Objectivity (O), Availability for consultations (AC), and Answers emails (E). Each textual response was assigned to one or more of these categories, depending on which aspect it is most likely to be commenting on.

This was later used to help evaluate Gemini's effectiveness in predicting the grade based on the textual comments. Each comment was associated with a predicted grade. Then, this grade was compared to the grade student gave to the numerical questions that correspond to the given comment. Additionally, a grade was assigned to each response by passing all textual answers in one request and asking for a predicted mean grade. This was then compared to the mean of all the numerical answers for that response.

4 Results and analysis

The 212052 responses from 4386 courses taught by 2123 teaching staff were first examined based on their demographic data and the presence of real textual answers. It was followed by the statistical analysis and comprehensive sentiment analysis.

4.1 Demographic Data

Out of all textual comments in all fields, most responses were empty. Only 35727 of the responses have at least one field that is not empty or consists only of punctuation. Figure 2 shows the number of empty, punctuation-only, and one-word responses, as well as non-empty responses that contain more than one word. There are 1871 courses, 359 teaching staff, and one institute with no non-empty textual responses. When considering the evaluation of each course as taught by a specific professor or assistant, there are a total of 5951 combinations with more than five responses, and 8628 with less than five. When considering only responses that have at least one non-empty text field, there are 1860 combinations of professors and courses with more than five responses, and 4874 with less than five.

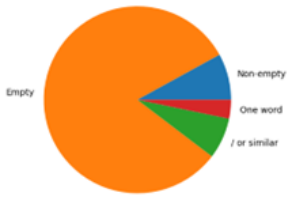

Figure 2: Distribution of empty to non-empty responses

4.2 Statistical Analysis of Numerical Answers

The numerical data was analyzed statistically using the pandas module and basic Python. Table 1 presents the mean and standard deviation of the grades given by the students for each question. The rows correspond to each of the previously mentioned questions.

	Mean	Std
PK	4.65	0.74
LH	4.53	0.86
LI	4.49	0.89
LO	4.47	0.91
QL	4.52	0.87
P	4.6	0.8
GT	4.45	0.93
O	4.56	0.85
AC	4.5	0.87
E	4.46	0.91

Table 1: Statistical analysis of numerical data

4.3 Sentiment analysis

According to the performed sentiment classification, direct expressions of sentiment were, as expected, the most frequent across all comment categories, particularly in the positive feedback section. Negation appeared significantly more often in negative comments, while mixed sentiment was most found in the additional comments field. The most common categories overall were Direct answer, Negation, Ambiguity, and Mixed sentiment, while categories such as Humor, Irony, Overexhaggeration, Understatement and Sarcasm were rare, with less than 50 comments each. The precision and recall of the sentiment categories were evaluated on a random sample of 200 comments for the larger categories, and all comments classified as belonging to the less common ones. The results are shown in Table 2. Direct answers had the highest precision among the common categories and one of the highest overall by far. However, all other categories had significantly higher recall. The Negation category captured both comments

highlighting what was missing and a substantial number of brief responses like “Nothing” or “No comment.”

	Precision (%)	Recall(%)
Ambiguity	26.47	95.23
Context-dependent	14	31.82
Direct answer	96.55	42.86
Humor	18.18	100
Mixed sentiment	66.67	93.75
Multipolarity	40	100
Negation	64.52	86.91
Overexaggeration	100	93.75
Sarcasm & Irony	80	91.67
Understatement	50	100

Table 2: Precision and recall of sentiment classification

Notable mistakes include the Humor category, as well as the Context-dependent sentiment category, which included a large number of direct answers, while a lot of comments belonging to this category were assigned to the Multipolarity category. The Humor category mostly consisted of non-answer comments like “hahaha” and only few humorous comments. The Sarcasm category also contained a mix of sarcastic comments and straightforward, mostly negative, opinions. Comments in English tend to be correctly classified as sarcastic, while there were multiple comments in Macedonian that were classified as sarcastic but weren’t. One such example is the comment Емил е цар >:(/ Emil e car >:(Emil is a king >:(, posted by a student who attended every lecture and consistently gave the young professor excellent ratings. Despite the positive verbal praise and high grades, the student included a negative emoji, illustrating mixed sentiment or multipolarity rather than sarcasm.

4.4 Joined Quantitative and Qualitative Analysis

The relationships between the rating and classified sentiment are visualized using a heatmap (Figure 3) and a boxplot (Figure 4).

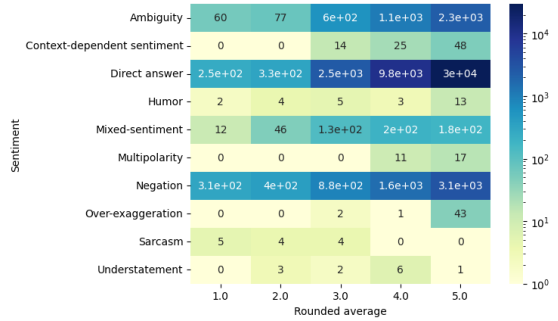

Figure 3: Comment count by sentiment and rating

Figure 3 shows the distribution of sentiment types across ratings, rounded to the nearest integer. A logarithmic scale was used due to the imbalance in frequency, since most responses are clustered around high ratings and a small number of sentiment categories.

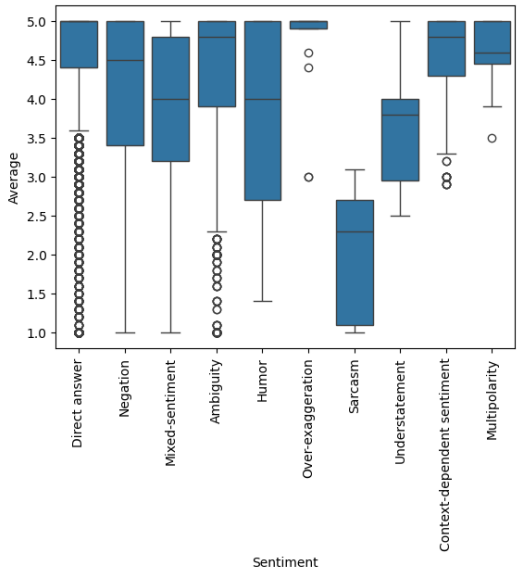

Figure 4: Rating distribution by sentiment

To more formally quantify the relationship between the rating and the sentiment, the Pearson correlation coefficient was computed for the presence of the four most common sentiment types. The results are given in Table 3. While a correlation exists between some sentiment categories and average rating, it is not very pronounced.

	Correlation coefficient
Direct answer	0.231
Negation	-0.205
Ambiguity	-0.069
Mixed sentiment	0.084

Table 3: Pearson correlation coefficient between sentiment type and average rating

Responses where students gave a low mean across all numerical answers, but still left a positive comment were also separately evaluated on whether that comment was positive. The results of the classification of these responses left in the field for positive comments are given in Figure 5. The overall accuracy of this classification was 95.54%. The precision and recall are given in Table 4.

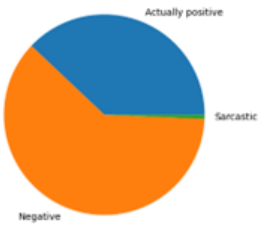

Figure 5: Types of positive comments with low average grade of response

Most of these comments were negative, generally short answers such as "Nothing", "I don't know", or similar. Other answers offered more substantial negative comments. However, some of the responses in the positive field were genuinely positive. This category contained both longer and one-word comments, while some similar or same comments were classified as negative, such as the comment Презентации Prezentacii "Presentations".

As in the general sentiment classification, sarcastic answers were rare. Most sarcastic comments were classified as negative, and many of the comments classified as sarcastic expressed straightforward negative sentiments. Additionally, there wasn't a big overlap between the comments classified as sarcastic here and in the previous classification of sentiment.

	Precision (%)	Recall(%)
Positive	99.7	92.2
Negative	93.48	99.4
Sarcastic	50	37.5

Table 4: Precision and recall of sentiment classification for positive text field in low average responses

4.5 Ratings Prediction

Ratings were predicted as integer scores on single comments and compared to the rating given for the question corresponding to that comment as described above, as well as real values predicting the mean for the entire response.

The integer rating prediction resulted in outliers with predicted grades well above the maximum allowed. These outliers lead to a large mean squared error of 280.6. Excluding these outliers, the error drops to 1.86, and only considering comments longer than three words to 1.63. The median absolute error in both of the last cases is 0, and the maximum error 4. The correlation coefficient is 0.35 and 0.49, respectively.

Table 5 shows the comparison of predicted and actual ratings, excluding outliers and only considering comments longer than three words. Actual ratings tend to be higher than predicted – in all cases of predicted ratings, there's more fives than the rating that was predicted.

pred↓/a→	1	2	3	4	5
1	711	409	568	425	820
2	87	78	158	175	303
3	89	116	316	711	2169
4	57	61	315	822	3824
5	117	128	627	1891	13006

Table 5: Predicted vs actual ratings confusion matrix

This could be related to the fact that most student ratings are all fives, but also to the lack of context. For example, the comment начинот на предавање на лекциите "the way lectures were taught" is a positive comment associated with a rating of five, but without the context that it's a positive comment, it's impossible to tell whether this comment would be associated with a positive or a negative rating. The predicted rating for this comment was 3. Additionally, many negative comments are still associated with a not too low score, but without the context of the other comments, the negative comment alone could lead to a lower predicted rating.

When considering entire responses, the results tend to be closer to the actual mean rating. The prompt for this classification included all comments from each response, labeled by whether it comes from the text field for positive, negative, or additional comments. These results are shown in Table 6. MSE stands for the mean squared error, MAE for median absolute error, MaxE is the max error, while CC is the correlation coefficient.

	MSE	MAE	MaxE	CC
all	0.66	0.5	3.78	0.39
one > 2 words	0.57	0.5	3.8	0.41
all > 2 words	0.72	0.5	3.8	0.52

Table 6: Error on predicted rating

While there are still responses with a large error, the error is smaller than when considering each comment separately. The errors were tested considering all comments, responses with at least one comment with more than two words, and responses where all textual fields were longer than two words.

Possible ways to improve the accuracy of predicted ratings include fine-tuning with a subset

of the responses, as well as including the expected grade distribution. Using an enum with the possible expected values instead of expecting a float or integer while passing the maximum possible value as part of the prompt could be a way to ensure no outliers appear in the predicted ratings.

5 Conclusions and further work

Despite the large volume of responses, only about 17% contained any meaningful textual feedback. This indicates a major limitation in student engagement with the open comment fields, which in turn limits the scope of qualitative insights.

The sentiment analysis revealed a strong dominance of direct responses across all categories, particularly in positive comments, which were often concise and unambiguous. In contrast, negative and additional fields showed significantly higher occurrences of negation, especially in low-scoring responses, indicating dissatisfaction or lack of desirable attributes (e.g., "nothing," "no comment"). Mixed sentiment was most prevalent in the additional comments, which reflects students' tendency to offer nuanced feedback when not constrained to specific positive or negative prompts.

While categories like Sarcasm and Humor were rarely observed, their classification proved challenging. Some comments in Macedonian were misclassified as sarcastic due to syntactic ambiguity or contextual misunderstanding (e.g., ironic phrasing or inconsistent emoji mistaken for sarcasm). Additionally, the Humor category was often filled with meaningless or filler content (e.g., "hahaha") rather than a genuine humorous critique. This highlights a limitation in multilingual sentiment detection, particularly because the training resources Gemini used does not have a subtler tone distinctions characteristic for Macedonian language.

There is a clear relationship between low numerical scores and the prevalence of negation in comments. Positive comments with low overall scores were often not genuinely positive, frequently consisting of "Nothing" or similarly dismissive statements. However, a small subset of such responses included legitimately positive comments, demonstrating that some students distinguish between different aspects of their experience (e.g., poor course structure but good teaching method).

The grade prediction model faced difficulties, particularly when analyzing isolated comments. The model underestimated actual scores, which is likely due to a lack of context—many neutralsounding comments (e.g., "the way lectures were taught") are associated with high scores but offer no explicit sentiment markers. When analyzing entire responses instead of individual comments, the model's predictions were more accurate, with a lower mean squared error and better correlation with actual grades. This supports the use of contextual sentiment analysis over sentence-level or phrase-level models when applying machine learning to student feedback.

The first direction of our future work will focus on integrating several additional large language models and establishing a framework for comparative analysis of the results they produce. A key objective will be to significantly enhance the accuracy of sentiment analysis performed by LLMs. Given the absence of a sentiment lexicon for the Macedonian language, one potential improvement involves machine translating the comments using the same LLM and subsequently conducting sentiment analysis using existing English-language lexicons such as VADER (Qi and Shabrina, 2023), SentiWordNet (Baccianella et al., 2010), or others (Khoo and Johnkhan, 2017).

Further refinement may be achieved by developing prototypical examples for each sentiment category and evaluating them using BERT-based sentence embeddings (Catelli et al., 2022). Although manual or crowdsourced annotation remains a valuable validation strategy, it poses logistical challenges (van Atteveldt et al., 2021).

Recognizing that it is unlikely students will significantly change their feedback behavior to reduce the high number of empty or noninformative comments, we also plan to fine-tune large language models using insights from the current study, leveraging popular retrieval-augmented generation frameworks designed for LLMs (Gao et al., 2024; Ram et al., 2023). By combining these strategies, we aim to build a more context-aware, linguistically adaptable sentiment analysis system that better captures the nuances of student feedback.

Abstract

Large Language Models (LLMs) have demonstrated remarkable capabilities in generating dialogues and handling a broad range of user queries. However, their effectiveness as end-to-end Task-Oriented Dialogue (TOD) systems remains limited due to their reliance on static parametric memory, which fails to accommodate evolving knowledge bases (KBs). This paper investigates a scalable function-calling approach that enables LLMs to retrieve only the necessary KB entries via schema-guided queries, rather than embedding the entire KB into each prompt. This selective retrieval strategy reduces prompt size and inference time while improving factual accuracy in system responses. We evaluate our method on the MultiWOZ 2.3 dataset and compare it against a full-KB baseline that injects the entire KB into every prompt. Experimental results show that our approach consistently outperforms the full-KB method in accuracy, while requiring significantly fewer input tokens and considerably less computation time, especially when the KB size increases.

1 Introduction

Large Language Models (LLMs) have recently achieved human-level fluency on a wide range of language tasks, thanks to scaling laws and instruction tuning (Brown et al., 2020; Wei et al., 2022). Among the many applications of LLMs, task-oriented dialogue (TOD) systems are designed to assist users in completing specific goals, such as booking a flight, ordering food, or finding information, through natural language interactions. Despite their fluency, LLMs face a fundamental limitation in TOD scenarios: the knowledge encoded in their parametric memory is frozen at training time, preventing the model from reflecting subsequent changes in the external world.

A straightforward workaround is to embed the *entire* KB in each prompt, ensuring that every conversational turn has access to all facts that might be needed. Unfortunately, KBs quickly outgrow the context window and contain much information that is irrelevant to the current user request. Padding the prompt with thousands of unused entries inflates latency and inference cost while making it harder for the decoder to focus on the truly salient rows.

Retrieval-augmented generation (RAG) (Lewis et al., 2020) mitigates prompt bloat for *unstructured* corpora by retrieving the top-k textual chunks at inference time. However, MultiWOZ-style KBs are json objects that closely resembles relational-rows, which often differ by only one or two cells (e.g. the name of two cafés on the same street). Converting each row into an ad-hoc sentence has been shown possible (Roberti et al., 2020), but could have limitations such us: it destroys schema information, it blows up the index with near-duplicate passages, and it confuses dense retrievers that rely on lexical diversity.

Recent variants such as TableRAG (Chen et al., 2024), SRAG (Lin et al., 2025) and the survey of Soliman et al. (Soliman and Gurevych, 2025) confirm that naïve, chunk-based RAG loses effectiveness on highly structured or repetitive data. Rather than engineering a specialised, table-aware retriever, we exploit the KB's schema directly via *function calls*: slot values detected in the user utterance are mapped to structured query parameters, yielding constant-time access to exactly those rows that the answer requires.

Building on recent work that enables LLMs to invoke external tools—e.g. ReAct (Yao et al.), Toolformer (Schick et al., 2023), and ToolLLM (Qin et al., 2023)—we introduce a selective function-calling pipeline for TOD. At each turn the model

Proceedings of Recent Advances in Natural Language Processing,pages 614–622

https://doi.org/10.26615/978-954-452-098-4-072

(i) detects whether the user's intent contains slot values, (ii) issues a targeted query against the KB, and (iii) integrates only the returned rows into the prompt. Evaluated on MultiWOZ 2.3 (Zang et al., 2020), this strategy cuts prompt tokens by ~ 4 times while improving factual accuracy over a baseline that serialises the full KB at every turn.

2 Related Work

TOD systems traditionally rely on modular architectures that separate natural language understanding, dialogue state tracking, and policy learning components. However, recent advances in LLMs have motivated a shift toward end-to-end TOD systems that aim to unify these components within a single generative model (Zhao et al., 2023). Despite their fluency, LLMs struggle to maintain factual accuracy and adapt to dynamic knowledge bases, due to their reliance on static parametric memory.

To address the rigidity of LLMs in dynamic settings, retrieval-augmented generation (RAG) methods have emerged as a promising solution. These methods combine LLMs with external retrievers that provide relevant context at inference time (Izacard et al., 2023; Zhang et al., 2022). Nonetheless, RAG was designed for free-text collections and shows degradation when the source is highly structured.

A recent survey on RAG over tabular data (Soliman and Gurevych, 2025) highlights three open issues: schema loss during chunking, retrieval ambiguity caused by repetitive content, and inflated context windows when multiple near-identical KB samples are returned. Our work departs from RAG entirely: by delegating KB access to an external function, we preserve the structure of the data, keep inference costs predictable, avoid embedding redundancy and its inherent risk of false positive retrieval, since the function calling logic is simple rule-based python code.

A recent trend involves leveraging function calling APIs to handle structured queries, allowing LLMs to delegate knowledge access to external tools (Yao et al.; Qin et al., 2023). These approaches improve both factual grounding and system modularity by decoupling reasoning from knowledge access. Similar strategies have been employed in dynamic dialogue settings to mitigate prompt length limitations and reduce inference cost (Mialon et al., 2023).

Compared to approaches that embed the entire KB in the prompt, our method adopts a selective function-calling strategy triggered by slot-value detection. This allows for minimal and relevant KB access, reducing computational overhead and improving response relevance. Our work builds upon these recent advances by offering a practical and scalable framework for integrating dynamic retrieval into end-to-end TOD systems.

Recent work by Labruna et al. (2024) tackles a related challenge in the question answering domain: determining whether an LLM's parametric knowledge is sufficient to answer a query, or whether external retrieval is required. While their task differs in format and scope, the core objective aligns with ours: making informed, context-dependent decisions about when to rely on internal memory versus external knowledge. We extend this idea to multi-turn, structured dialogue by integrating schema-guided function calls instead of free-text retrieval.

3 Function Calling Methodology

In this study, we propose a TOD system designed to selectively retrieve information from a knowledge base when necessary, based on the specific needs expressed in each user turn. The system is built around a large language model that manages the conversation and executes knowledge retrieval when appropriate.

It begins with a system prompt that sets the initial behavioral instructions for the LLM (Section 3.1). Then each user turn is analyzed to determine whether external knowledge is required. This is achieved through a lightweight slot-value and intent extraction process (Section 3.2). For instance, a vague input like "Can you help me?" does not lead to a KB query, while a more specific request such as "Find me a cheap Italian restaurant in the center" does.

When relevant information is detected, it is passed to a function that maps the extracted content into structured query parameters (Section 3.3). These parameters are then used to retrieve only the most relevant KB entries (Section 3.4). The results of the query are evaluated for adequacy and informativeness (Section 3.5), and, if appropriate, integrated into the LLM's prompt to inform the response. This targeted augmentation ensures that the model's outputs are both accurate and aligned with the user's

intent.

To support longer conversations, the system includes a conversation management component that trims older dialogue turns as needed to remain within the LLM's context window, while preserving relevant history (Section 3.6).

Through this structured and dynamic methodology, the system is able to maintain a high level of relevance, responsiveness, and efficiency in handling complex task-oriented dialogues.

3.1 Initial System Prompt

The core LLM at the basis of our dialogue system is guided through an initial system prompt. This prompt defines the model's general role in the conversation, for instance, acting as a travel assistant or a booking agent, and provides domain-specific instructions that shape its behavior throughout the interaction. It may also include stylistic directives to ensure consistent tone and phrasing across responses. For example:

```
You are an airline ticket booking
system.  Respond politely and
provide suggestions for available
flights.
```

This initial prompt establishes the context and objectives of the conversation, enabling the model to generate coherent and purpose-aligned responses as the dialogue evolves.

3.2 Slot-Value and Intent Extraction

Once the user submits an input, the system (LLM) receives it and begins the process of understanding the user's request. To enable targeted retrieval of knowledge, we first identify whether the input contains any slot-values. This is done by forwarding the user input to a second language model specifically tasked with slot-value extraction.

This model is provided with a predefined list of possible slot types relevant to the current domain, each accompanied by a brief description. However, the list of possible values for each slot is not given, as these must be inferred by the model using its parametric knowledge.

If the model returns that no slot-values have been detected, the initial LLM proceeds to generate a response using only the context available in the current conversation history.

If slot-values are found, the system proceeds to determine the user's intent. This is achieved by prompting another model (or another instance of the same model) with the same user input and a list of possible intents, each with a short description. The objective is to infer the communicative goal behind the user's utterance.

With both slot-values and intent identified, the system is equipped to determine whether external knowledge retrieval is needed and how to formulate a precise query for it.

3.3 Function Instruction and Parameter Mapping

After extracting slot-values and the user's intent, the system determines whether a query to an external KB is necessary. If so, these extracted elements are used to select the most suitable function from a predefined set, where each function f_i corresponds to a specific type of query designed to retrieve domain-relevant information.

Each function is defined with a set of parameters $\theta_1, \theta_2, \ldots, \theta_n$ that correspond to expected slot-values. Formally, we represent a function as:

$$f_i(\theta_1, \theta_2, \ldots, \theta_n) \quad (1)$$

For example, a function to search for restaurants based on area, price range, and cuisine may be defined as:

Function: SearchRestaurant(Area, PriceRange, Cuisine)

When the slot-value extraction step identifies relevant inputs (for instance, "northern" as a value for the slot *Area*) and the intent is classified as *search*, these are passed to the function selection logic, which results in the following function call:

$$f_\text{SearchRestaurant}(\theta_\text{Area} = \text{"north"}) \quad (2)$$

Only the slots that were detected in the input are passed as arguments to the selected function, while missing parameters remain unspecified. This targeted mapping enables the system to retrieve only the KB entries necessary to respond to the user's

request, avoiding redundant data access and improving both efficiency and relevance.

3.4 Function Call and Query Execution

After selecting the appropriate function f_i and assigning its parameters based on the extracted slot-values, the system proceeds to execute the function to query the knowledge base (KB). Each function is tailored to a specific domain and is designed to filter KB entries according to the input constraints provided in its parameters.

The output of the function call is a set of retrieved instances:

$$\mathcal{I} = i_1, i_2, \ldots, i_k \tag{3}$$

where $\mathcal{I}$ denotes the set of KB results that satisfy the query conditions, and k is the number of matching instances.

The internal logic of the function typically involves applying a filtering mechanism over a structured KB, using the parameter values to constrain the search. This may include exact matching for clearly specified slots, partial or relaxed matching to accommodate minor user input variations, or more complex domain-specific heuristics to determine relevance. The flexibility of each function depends on the domain requirements and the granularity of the KB entries it operates over.

This execution step isolates only the information necessary to fulfill the user's request, allowing the system to respond with targeted and contextually relevant content.

3.5 Result Evaluation and Prompt Augmentation

After executing the function call and retrieving a set of results $\mathcal{I} = \{i_1, i_2, \ldots, i_k\}$, the system evaluates the outcome to determine how to proceed with the response generation. This evaluation hinges on the number of retrieved instances k, which is compared against a predefined upper threshold T to assess the informativeness and usefulness of the result set.

- **No Results ($k = 0$):** If the query returns no matching instances, the system avoids generating a misleading or hallucinated response. Instead, it augments the prompt with a message that informs the model of the lack of results and guides the generation accordingly. For example, the following instruction is added to the prompt:

  ```
  No entities in the knowledge
  base match the user query.
  Suggest that the user
  reformulate or broaden their
  request.
  ```

- **Too Many Results ($k > T$):** When the number of results exceeds a predefined threshold, the system avoids overwhelming the generation with an unmanageable list. Instead, it augments the prompt with a directive indicating the overload and advising the model to guide the user toward refining their query. For example:

  ```
  The query returned too many
  entities.  Ask the user to
  provide additional constraints
  to narrow down the search.
  ```

- **Acceptable Number of Results ($0 < k \leq T$):** If the result set is within an acceptable range, the system proceeds to build a knowledge-grounded prompt. This prompt contains a textual rendering of the retrieved instances, formatted in a way that allows the LLM to generate a coherent and factually grounded response. For example, the augmented prompt might begin with a sentence like:

  ```
  Your answer should strictly
  rely on the following
  Knowledge Base:
  ```

  followed by a structured summary of the instances in $\mathcal{I}$.

This stage ensures that the system remains faithful to the available knowledge, avoids generating unsupported statements, and adapts its behavior depending on the informativeness of the KB query results. By carefully controlling when and how the KB content is introduced into the prompt, the system maintains both factual accuracy and conversational relevance.

3.6 Conversation Management and Context Trimming

To maintain continuity across turns, the system preserves the full dialogue history H =

$\{h_1, h_2, \ldots, h_n\}$, including user and system utterances as well as the initial system prompt. However, since large language models operate within a fixed context window of size C, the system must ensure that the input remains within this limit.

To do so, it dynamically monitors the length of the conversation $L(H)$, and if the combined content of the history and the current input exceeds C, the earliest dialogue turns are discarded. This process is formalized as follows:

$$\text{If } L(H) > C, \quad \text{remove } h_1, h_2, \ldots, \text{ until } L(H) \leq C \quad (4)$$

The trimming procedure prioritizes the retention of the most recent and relevant turns, along with the system prompt, which provides high-level behavioral instructions to the model. This ensures that the system continues to generate contextually grounded and coherent responses, even in extended interactions.

4 Experimental Setting

This section presents the experimental setup used to assess the effectiveness of our function calling approach for knowledge retrieval in Task-Oriented Dialogue systems. Specifically, we compare two strategies: (I) a baseline that retrieves the entire knowledge base for every dialogue turn regardless of context (Section 4.1) and (II) our proposed method, which selectively invokes a function to retrieve only relevant KB entries based on the user query (Section 3).

The goal of this comparison is to determine whether dynamically deciding when and what to retrieve, through structured function calls, offers a meaningful advantage over the naïve strategy of always retrieving the full KB.

In each case, the system is tasked with producing factual, contextually appropriate, and domain-specific responses. The subsections that follow detail the full-KB strategy (Section 4.1), the structure of the dataset and the underlying KB (Section 4.2), the specification of the LLM used (Section 4.3), the evaluation metrics employed (Section 4.4), and the results of the comparative analysis (Section 4.5). We also include an error analysis (Section 4.6) and a supplementary study on the computational efficiency of both approaches (Section 4.7).

4.1 Full-KB Approach

The full-KB approach embeds the entire knowledge base directly into the system's prompt. This initial prompt begins with an instruction block that defines the system's behavior, tone, and style, followed by a directive to rely exclusively on the provided KB when responding to domain-specific user queries. The complete KB remains constant throughout the interaction and ensures that the model has access to all KB entries at every step of the conversation.

As the dialogue unfolds, each user message is appended to the context, and the system generates a response based on the full prompt, comprising the instruction block, the complete KB, and the accumulated dialogue history. Each new system message is then added to the context in turn.

To stay within the model's context window, the system trims the oldest turns in the dialogue history when necessary. This trimming follows the same strategy described for the function-calling approach (see Section 3.6), ensuring that recent context and the system prompt remain intact.

4.2 Dataset and Knowledge Base Description

The experiments use the MultiWOZ 2.3 dataset (Han et al., 2021), a widely adopted benchmark for TODs. MultiWOZ contains multi-domain dialogues collected through crowdsourcing, covering seven different domains. It provides both dialogue transcripts and corresponding structured knowledge bases for each domain, making it ideal for evaluating knowledge-grounded dialogue models.

For this study, we focus exclusively on the restaurant domain. This choice is motivated by several factors: the restaurant domain is well-studied and rich of in domain-specific attributes (e.g., cuisine type, location, price range), it has a sufficiently large and detailed KB in MultiWOZ, and limiting the scope to a single domain simplifies the evaluation of knowledge retrieval strategies without introducing confounding domain variability.

To examine the effect of KB size on the performance of different retrieval approaches, we prepared three versions of the restaurant KB: the original, and two augmented versions with approximately twice and three times the original number of entries. The augmentation process involved synthetically generating new entries while preserving the data structure and realistic attribute distribu-

Table 1: KB-Alignment accuracy of function calling vs full-KB approach for different KB sizes

Method	Original KB	KB x2	KB x3
Full-KB Approach	0.652	0.615	0.549
Function calling	**0.833**	**0.816**	**0.802**

tions. Specifically:

- **Food, Area, Price, and Address:** Values were randomly sampled from the original KB's existing attribute sets.
- **Name:** New names were created by combining tokens randomly selected from original restaurant names.
- **Phone Number:** Simulated as random 10-digit numbers.

This augmentation strategy allowed us to scale the KB while maintaining consistency and realism. We limited augmentation to three times the original size because larger KBs would exceed the model's context window constraints, especially for the full-KB approach.

4.3 Model and Computational Details

Both the Function Calling and Full-KB approaches rely on the LLaMA-3.1 8B model for dialogue generation. LLaMA-3.1 (Grattafiori et al., 2024) is part of the Large Language Model Meta AI (LLaMA) family, specifically fine-tuned for generating coherent, context-aware responses in conversational settings. With approximately 8 billion parameters, it balances computational efficiency and linguistic capability, making it well-suited for complex task-oriented dialogue (TOD) scenarios.

Inference was conducted using a single NVIDIA A40 GPU with 48GB of memory. No additional fine-tuning or parameter modifications were applied; all model parameters and decoding settings remained at their default values.

4.4 Evaluation Metrics

To assess the performance of both approaches, we use the *KB-alignment* accuracy metric. This metric measures the degree to which the system's responses align with the information contained in the knowledge base. Each response from the system is evaluated on a binary scale: 1 if the response is entirely accurate with respect to the KB (i.e., all factual statements align with the knowledge stored in the KB), and 0 if the response contains any factual inaccuracy, such as providing incorrect details about restaurant availability, food types, or locations.

Only responses that involve KB references are included in the evaluation, excluding general conversational turns that do not involve knowledge retrieval (the turns where slot-values are not detected). The overall KB-alignment accuracy is computed as the average accuracy across all KB-relevant responses. Formally, for a set of N responses $r_1, r_2, \ldots, r_N$, the accuracy A is defined as:

$$A = \frac{1}{N} \sum_{i=1}^{N} \text{alignment}(r_i) \tag{5}$$

where $\text{alignment}(r_i)$ equals 1 if the response r_i is factually correct according to the KB, and 0 otherwise.

Determining whether a system message is fully consistent with the KB is a manual task performed by a human evaluator. This process can involve ambiguity, as some information may be implicitly inferable from the KB without being explicitly stated. In such cases, the evaluator must judge whether the inference is reasonable and grounded in the available KB content.

4.5 Experimental Results

Table 1 presents the KB-alignment accuracy for both the full-KB and function calling approaches, evaluated across three different KB sizes: the original MultiWOZ 2.3 KB, and versions augmented to double and triple the number of entries.

The results clearly show that the function calling approach consistently outperforms the full-KB baseline in all settings. With the original KB, function calling achieves an accuracy of 0.833, compared to 0.652 for the full-KB strategy. This performance gap widens slightly as the KB grows larger: at twice the original size, function calling maintains a high accuracy of 0.816, while the full-KB method drops to 0.615. When the KB is tripled in size, the

Table 2: Error Category Comparison for full-KB and function calling Approaches

Error Category	Full-KB x1	Full-KB x2	Full-KB x3	Func Call x1	Func Call x2	Func Call x3
Restaurant Not Found by Name	31/36 (86.11%)	23/36 (63.64%)	24/36 (65.22%)	10/18 (55.56%)	8/16 (50.00%)	12/12 (100.00%)
Restaurant Not Found by Attributes	20/30 (66.67%)	30/30 (100.00%)	16/19 (84.21%)	13/17 (75.41%)	27/29 (92.96%)	14/16 (87.50%)
Invalid Restaurant Name	6/33 (18.18%)	11/49 (22.47%)	12/41 (29.47%)	2/29 (6.87%)	1/17 (5.83%)	1/19 (5.23%)
Invalid Restaurant by Attributes	7/26 (27.27%)	13/73 (17.65%)	2/63 (3.17%)	2/29 (6.98%)	1/79 (1.27%)	1/29 (3.49%)
Incorrect Restaurant Count	0/0 (0%)	0/0 (0%)	0/0 (0%)	3/3 (100.00%)	0/0 (0%)	0/0 (0%)

gap becomes even more pronounced, with function calling at 0.80 and the full-KB approach falling further to 0.549.

These results suggest that the function calling mechanism, by retrieving only relevant KB entries on-demand, is more robust to increases in knowledge base size. In contrast, the full-KB method suffers from degraded accuracy as the context window becomes increasingly saturated with irrelevant information. This confirms the hypothesis that selectively retrieving information (both what and when) leads to better factual consistency than indiscriminately including the entire KB in the prompt.

Furthermore, the relatively stable accuracy of the function calling approach across KB sizes indicates that it scales more gracefully, maintaining high response quality even as the knowledge space expands. This scalability is particularly valuable in real-world scenarios, where KBs may grow over time or vary significantly across domains.

4.6 Error Analysis

In addition to evaluating KB-alignment accuracy, we performed a detailed error analysis to identify the types of errors encountered by both approaches. Errors were manually categorized based on the nature of the mismatch between the system's response and the knowledge base. The following categories emerged:

- **Restaurant Not Found by Name**: The system failed to retrieve a restaurant explicitly requested by name, despite its presence in the KB.
- **Restaurant Not Found by Attributes**: The system was unable to identify a restaurant matching the specified attributes (e.g., cuisine type, area, price range).
- **Invalid Restaurant Name**: The response included a restaurant name that does not exist in the KB.
- **Invalid Restaurant by Attributes**: The system returned incorrect attribute values for a restaurant (e.g., stating it is in the city center when it is not).
- **Incorrect Restaurant Count**: The reported number of restaurants matching a query was inaccurate.

Table 2 provides a detailed breakdown of the frequency of each error type for both approaches.

The full-KB approach tends to struggle more with hallucinated content, such as producing invalid restaurant names or mismatched attributes. These issues appear to worsen as the size of the KB increases, suggesting that the model's ability to attend to relevant entries diminishes when overwhelmed with a larger unfiltered context.

The function calling method, while generally more accurate, exhibits occasional retrieval failures. For example, it can miss a valid restaurant even when the name or attributes are unambiguous, indicating potential limitations in the underlying retrieval mechanism or its integration with the language model.

Overall, while function calling mitigates many of the content hallucination issues found in the full-KB approach, it introduces its own class of retrieval-related errors. Understanding these patterns is crucial for designing more robust hybrid systems that combine precise retrieval with effective language generation.

4.7 Computational Efficiency

Finally, the computational efficiency of both approaches was evaluated by comparing the input token count and the total processing time required for each dialogue. These metrics provide a practical perspective on the scalability of each method, especially as the size of the knowledge base increases.

The results, illustrated in Figure 1, show that the function calling approach is significantly more effi-

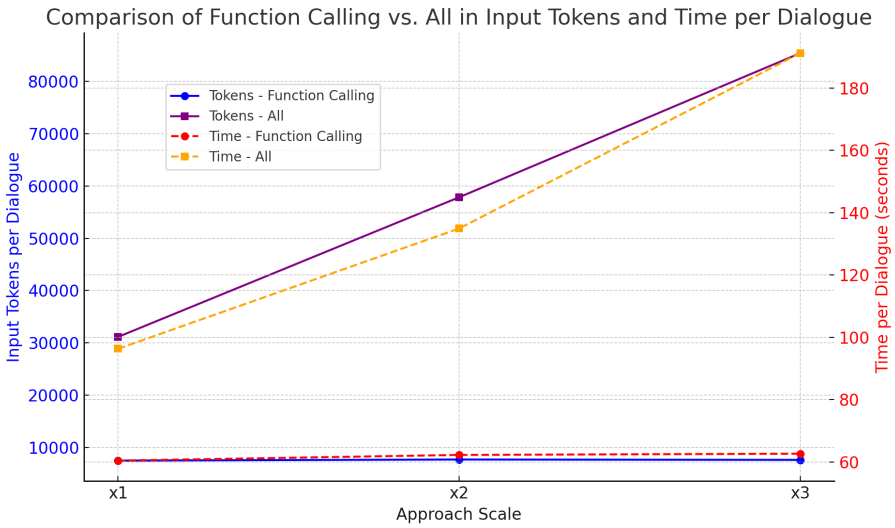

Figure 1: Comparison of Input Tokens and Processing Time per Dialogue between function calling and full-KB Approaches across KB Sizes

cient than the full-KB method across all KB sizes. By retrieving only the relevant information from the KB on demand, function calling reduces the input size passed to the language model, which in turn lowers the processing time.

For the original KB scale (x1), function calling required only 7,503 tokens and 60.5 seconds per dialogue, compared to 31,153 tokens and 96.3 seconds for the full-KB approach. This translates to a 76% reduction in prompt tokens and a 37% reduction in processing time. As the KB triples in size (x3), the difference becomes even more striking: function calling maintains a modest increase to 7,653 tokens and 64.2 seconds, while the full-KB baseline increases to over 85,000 tokens and 189.7 seconds per dialogue. This yields savings of over 90% in tokens and more than 66% in processing time. These findings confirm that function-based retrieval not only improves factual precision but also delivers substantial gains in efficiency—cutting inference time in large-KB settings, making it a highly scalable alternative for real-world end-to-end TOD deployments.

5 Conclusion

This study highlights the advantages of combining selective retrieval and function calling for improving the accuracy and scalability of task-oriented dialogue (TOD) systems. By retrieving only the necessary information from the knowledge base (KB), the function calling approach consistently delivers more accurate responses, while also reducing computational overhead and response latency. In contrast, the full-KB approach, which embeds the entire KB into each prompt, becomes increasingly inefficient and less reliable as the KB grows.

The experimental results show that function calling maintains strong KB-alignment accuracy across different KB sizes, demonstrating robustness to domain changes and scalability in growing knowledge environments. In parallel, the computational analysis reveals substantial reductions in both input token usage and processing time. This efficiency gain not only improves response latency but also reduces the overall cost of deployment, especially in resource-constrained or real-time settings.

The error analysis further reinforces these findings. As the KB size increases, the full-KB approach struggles with issues such as failing to retrieve restaurants by name, indicating that larger KBs introduce ambiguity and complexity that the model cannot easily resolve. In comparison, the function calling method demonstrates greater resilience to these challenges. The integration of selective retrieval, function calling, and prompt augmentation offers an effective strategy for building TOD systems that are accurate, efficient, and scalable. This approach provides a practical path forward for deploying dialogue agents in dynamic, knowledge-rich environments.

Abstract

In this paper, we demonstrate how Large Language Models (LLMs) can effectively learn to use an off-the-shelf information retrieval (IR) system specifically when additional context is required to answer a given question. Given the performance of IR systems, the optimal strategy for question answering does not always entail external information retrieval; rather, it often involves leveraging the parametric memory of the LLM itself. Prior research has identified this phenomenon in the PopQA dataset, wherein the most popular questions are effectively addressed using the LLM's parametric memory, while less popular ones require IR system usage. Following this, we propose a tailored training approach for LLMs, leveraging existing open-domain question answering datasets. Here, LLMs are trained to generate a special token, ⟨RET⟩, when they do not know the answer to a question. Our evaluation of the Adaptive Retrieval LLM (ADAPT-LLM) on the PopQA dataset showcases improvements over the same LLM under three configurations: (i) retrieving information for all the questions, (ii) using always the parametric memory of the LLM, and (iii) using a popularity threshold to decide when to use a retriever. Through our analysis, we demonstrate that ADAPT-LLM is able to generate the ⟨RET⟩ token when it determines that it does not know how to answer a question, indicating the need for IR, while it achieves notably high accuracy levels when it chooses to rely only on its parametric memory.

1 Introduction

The task of question answering (QA) remains a key focus in Natural Language Understanding research. Benchmarks such as Natural Questions (NQ) (Kwiatkowski et al., 2019), SQuAD (Rajpurkar et al., 2016), and QuAC (Choi et al., 2018) are commonly used to evaluate QA models. Large Language Models (LLMs) now consistently outperform traditional methods on these datasets.

Two primary approaches are typically used for QA with LLMs:

(i) **Closed Book Question Answering**: The model relies solely on its parametric memory, enhanced through instruction tuning (Taori et al., 2023) or few-shot prompting (Brown et al., 2020). However, parametric memory is limited to the training data and may be outdated, missing post-training information.

(ii) **Open Book Question Answering**: An LLM is paired with an Information Retriever (IR) system (Izacard and Grave, 2021; Zhu et al., 2021) to access external context for more accurate answers.

Recent work by Mallen et al. (2023) highlights the complexity of choosing between these strategies. Using the PopQA dataset—14K questions with popularity scores—they show that LLMs perform well on popular questions using only parametric memory, while IR helps with less popular ones. Their findings support a hybrid approach: rely on parametric memory for high-popularity questions and use IR for the rest, guided by a fixed popularity threshold. However, most QA datasets lack popularity scores, making this strategy non-generalizable.

Our study addresses whether LLMs can learn to decide on their own when to invoke an IR system. To investigate this, we analyze LLM performance on an open-domain QA dataset, identifying which questions it answers correctly and which it does not. For incorrect responses, we annotate questions with a special ⟨RET⟩ token to indicate the need for additional context. Using this, we build a new training dataset where the LLM learns either to answer directly or to retrieve context when uncertain (see Figure 1). We refer to this model as ADAPT-LLM. We evaluate ADAPT-LLM on PopQA, a strong testbed for hybrid retrieval strategies. Our results

Proceedings of Recent Advances in Natural Language Processing,pages 623–632
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-073

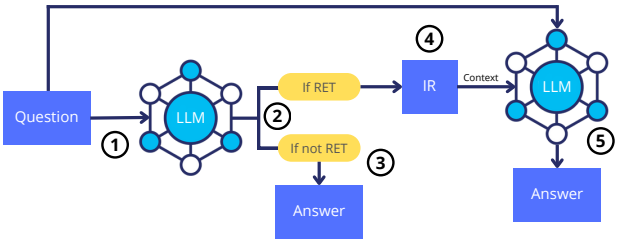

Figure 1: The inference process of ADAPT-LLM step-by-step: given a question (step 1), an LLM decides (step 2) whether to answer the question directly (step 3) or to ask for additional contextual information, generating the special ⟨RET⟩ token; for the latter, an off-the-shelf IR system is used to retrieve relevant context (step 4), which is used alongside the question to prompt again the LLM for the final answer (step 5).

show:

- ADAPT-LLM consistently outperforms fixed strategies, such as always retrieving context or never retrieving.
- It performs comparably to methods that use popularity scores—without relying on any dataset-specific metric.
- When ADAPT-LLM chooses to retrieve context, accuracy improves significantly; when it answers directly, it also achieves high accuracy. This indicates effective judgment.
- The main performance bottleneck lies in the IR system: accuracy with gold passages is much higher than with retrieved ones.

These results highlight the value of adaptive retrieval for QA with LLMs. By training ADAPT-LLM to decide when external information is necessary, we show it is feasible to teach LLMs to use retrieval selectively and effectively.

2 Related Work

Retrieval-Augmented Generation (RAG) (Lewis et al., 2020) has improved many NLP tasks like question answering (Karpukhin et al., 2020; Izacard and Grave, 2021), truthfulness (Ji et al., 2023; Lin et al., 2022), and language modeling (Guu et al., 2020; Borgeaud et al., 2022). By grounding generation in retrieved text, smaller models can match larger ones (Catav et al., 2024), and RAG helps keep LLMs updated without costly retraining (Gao et al., 2023). However, traditional retrieval (e.g., TF-IDF, BM-25 (Robertson et al., 2009)) relies on keyword overlap and struggles with lexical gaps (Berger et al., 2000). Transformer-based dense retrieval models (Gao et al., 2021; Reimers and Gurevych, 2019; Karpukhin et al., 2020) improve performance but face challenges in zero-shot new domains (Thakur et al., 2021). Retrieval quality limits overall model performance and large indices increase latency, harming real-time user experience (Barnett et al., 2024). Meanwhile, as models scale, their parametric knowledge grows (Kaplan et al., 2020), enabling competitive open-domain QA using only internal knowledge (Liang et al., 2023; Achiam et al., 2023; Touvron et al., 2023). This motivates adaptive approaches (Schick et al., 2024; Mallen et al., 2023): use the model's parametric knowledge when possible, and augment with retrieval only when needed. For example, Schick et al. (2024)'s Toolformer learns to use external tools via self-supervised API calls, boosting performance but often overusing tools (e.g., search engine used 99.3% in QA). In contrast, ADAPT-LLM leverages parametric knowledge and reduces retrieval use to 83.99% while improving over vanilla retrieval. Similarly, Mallen et al. (2023) propose PopQA, a dataset with entity popularity scores to decide when to retrieve: below a threshold, retrieve; above it, answer directly. This outperforms vanilla retrieval but depends on unavailable popularity scores in real scenarios. Contemporaneous to our work, Erbacher et al. (2024) train an LLM to balance hallucination risk and retrieval cost. Our ADAPT-LLM similarly learns when to retrieve, but also compares against baselines of always or never retrieving, showing the benefit of adaptive retrieval. Finally, Roy et al. (2024) propose SELF-multi-RAG, which learns when to retrieve, how to rewrite conversational context for retrieval, and how to assess passage relevance in multi-turn QA, complementing our ADAPT-LLM approach that focuses on balancing retrieval and

parametric knowledge without rewriting.[1]

3 Adaptive Retrieval LLM (ADAPT-LLM)

Adaptive retrieval refers to the model's capability to dynamically determine whether to retrieve additional context information for generating answers in question answering tasks. Unlike traditional models that either always incorporate context or never consider it, adaptive retrieval allows the model to selectively retrieve context based on the specific requirements of each question.

This adaptive approach aims to optimize performance by leveraging context only when necessary, thereby enhancing the model's ability to generate accurate answers.

As depicted in Figure 1, the process of the ADAPT-LLM unfolds in the following sequence:

1. The first prompt containing the question is sent to the model (step 1 of Figure 1).

2. The ADAPT-LLM evaluates the prompt to determine whether additional context is necessary to answer the question effectively (step 2).

3. If the model determines that context is not required, it directly produces a response to the question by leveraging its parametric memory (step 3).

4. If context is deemed necessary, the ADAPT-LLM model returns a special token, represented as ⟨RET⟩, and an off-the-shelf IR system is used to retrieve pertinent context based on the question (step 4); the context is then combined with the original question prompt to form a comprehensive representation for answer generation (step 5).

The decision-making process of ADAPT-LLM enables the model to determine the necessity of context for answering questions through dynamic assessment of each prompt. This flexible behavior allows the model to strike a balance between utilizing context for enhanced understanding and delivering direct answers when sufficient.

9          inst1 = build_instance('parametric_prompt', q, "¡RET¿")
10         DS_Adapt.add(inst1)
11         inst2 = build_instance('context_prompt', q, gold_ans, pass)
12         DS_Adapt.add(inst2)
13     end
14 end
15 return DS_Adapt
```

3.1 Training ADAPT-LLM

Here, we delineate the methodology employed to train our ADAPT-LLM model. The process of crafting the training data, denoted as DS_{Adapt}, is presented in Algorithm 1.

We begin by selecting an open-domain question answering dataset containing questions Q, associated context passages P, and corresponding answers A. We initialize DS_{Adapt} to an empty set (line 1 of the algorithm). For each question in Q, we leverage the base LLM without any retrieval mechanism to perform a zero-shot inference (line 3). This step allows us to differentiate questions for which the model generates correct answers from those where its responses are inaccurate. This process can be understood as a way to discover what the base LLM *knows* due to its parametric memory. For questions where the model's response is accurate (line 4), we build a training set instance incorporating the following prompt, which we call *parametric_prompt*:

```
Prompt: Answer the question Q. If
```

`you need help answer <RET> to get the context. Q: {...}`

Alongside this prompt, we include the corresponding question from Q and the golden answer from A, collectively forming the instance (line 5), which is subsequently appended to the DS_{Adapt} dataset (line 6). This prompt is always used without context and serves to teach the model to either answer directly or to signal that it needs context. In contrast, if the LLM fails to produce a correct response to the question (line 8), we build two different instances. The first employs the same *parametric_prompt* as previously described, with ⟨RET⟩ designated as the answer (line 9), indicating the necessity for additional context. The second prompt, termed *context_prompt*, encompasses contextual information alongside the question:

`Prompt: Answer the question Q given the context C. Q: {...}, C: {...}`

For this instance, we include the prompt, the question from Q, the golden answer from A, and the corresponding context passage from P (line 11). This two-stage supervision helps the model decide when it needs external knowledge and how to use it effectively once retrieved.

After populating the dataset with both types of prompts for questions where the LLM could not respond accurately and only the *parametric_prompt* with golden answers for all other questions, our training set D_{Adapt} is prepared for the subsequent fine-tuning phase. The fine-tuning process entails training the base LLM on our dataset, resulting in the ADAPT-LLM model.

This approach ensures that the model effectively learns to discern when context is necessary for answering questions, or to provide a direct response when it suffices, as well as answer directly when provided with context.

3.2 Inference

In the inference phase, we utilize the fine-tuned model to generate responses to unseen questions. We employ the same prompts used during the training phase, as outlined in Section 3.1. Initially, the model is prompted to either provide a direct response or return ⟨RET⟩ if it is unsure of the answer.

If the model returns ⟨RET⟩, we proceed with information retrieval to acquire relevant context by means of an off-the-shelf IR system. Subsequently, we augment the question with the retrieved context and prompt the model again using the second type of prompt introduced during the training phase.

4 Experiments and Results

In this section, we outline the experimental framework aimed at assessing the performance of the proposed adaptive retrieval approach, ADAPT-LLM. We begin by describing the datasets utilized (Section 4.1), followed by an overview of our base model (Section 4.2), the different configurations of the base model (Section 4.3), and the training details (Section 4.4). Subsequently, we introduce the three primary experiments:

1. Evaluation of ADAPT-LLM performance compared to the following baseline models: (i) an LLM that retrieves contextual information for all questions, and (ii) an LLM that exclusively relies on its parametric memory without using an IR system for any question (Section 4.5).

2. Analysis of ADAPT-LLM's ability to determine when extra context is necessary to answer a question (Section 4.6).

3. Comparison with the state-of-the-art approach for PopQA (Section 4.7).

4.1 Datasets

To ensure comprehensive training and evaluation of our models, we specifically selected three diverse question answering datasets. For training, we chose NQ (Kwiatkowski et al., 2019) and SQuAD (Rajpurkar et al., 2016), as they are widely recognized datasets that assess factual knowledge and are based on Wikipedia. For evaluation, we opted for PopQA (Mallen et al., 2023). Below are brief descriptions of each dataset:

NQ The Natural Questions dataset (Kwiatkowski et al., 2019) is a collection of real-world questions derived from Google search queries, accompanied by long-form text passages obtained from Wikipedia articles and providing a diverse range of topics and natural language variations. We utilize this dataset for **training** our models in the experiments.

SQuAD The Stanford Question Answering Dataset SQuAD (Rajpurkar et al., 2016) is a widely

Training Set	Model configuration	Accuracy
NQ	NEVER RETRIEVE	21.43%
	ALWAYS RETRIEVE	35.86%
	ADAPT-LLM (ours)	**36.77%**
SQUAD	NEVER RETRIEVE	21.22%
	ALWAYS RETRIEVE	36.59%
	ADAPT-LLM (ours)	**38.15%**

Table 1: Performance comparison of Llama-2 models trained on the NQ and SQuAD datasets using different retrieval configurations (NR-LLM, AR-LLM, and ADAPT-LLM), evaluated on the PopQA test set. Exact match accuracy is reported for all models.

utilized dataset in the field of natural language processing and comprises questions posed by crowdworkers on a diverse range of Wikipedia articles, along with relevant paragraph passages serving as context. We utilize this dataset for **training** our models in the experiments.

PopQA The Popular Questions and Answers dataset (Mallen et al., 2023) consists of curated questions sourced from various online platforms, encompassing a wide range of domains and styles. Given the variability in the effectiveness of context retrieval strategies observed in this dataset, we select PopQA as our test set to **evaluate** the language models' performance in determining when context is necessary for accurate answer provision.

4.2 Base Model

In our experiments, we employ Llama-2 (Touvron et al., 2023) as our base LLM. Llama-2 is an open-source instruction-based LLM, which comes in versions of 7B, 13B, and 70B parameters. The model is pretrained on an expanded corpus sourced from publicly available online data sources. This corpus offers a 40% increase in size compared to its predecessor, contributing to the model's enhanced performance and capabilities.

Additionally, Llama-2 features an extended context length, effectively doubling its capacity to process and comprehend longer sequences of text. These enhancements significantly improve the model's effectiveness across various natural language understanding tasks. Specifically, for our experiments, we utilize the Llama-2 model with 7B parameters, leveraging its robust capabilities for our specific research objectives.

4.3 Model Configurations

We conduct the experiments using three different model configurations, corresponding to the three

	NQ	SQuAD	PopQA
Questions	58,880	87,599	14,282
Words/question	9.20	10.06	6.62
Words/answer	2.26	3.16	2.04

Table 2: Comparison of the three datasets we use for our experiments, i.e. SQuAD, NQ and PopQA. For each of them we provide the number of questions, and the average number of words per question and answer.

different ways in which an LLM and an IR system can be combined:

- **Adaptive Retrieval (ADAPT-LLM)**. The ADAPT-LLM model dynamically decides whether to retrieve context based on the question and its perceived need for contextual information, as explained in Section 3.1. As the IR system, we use Contriever (Izacard et al., 2022), which is an unsupervised model pretrained on a large corpus, followed by fine-tuning on MS MARCO (Nguyen et al., 2016). We only retrieve the most relevant passage according to the IR system to prompt the base LLM for the final answer.
- **Never-Retrieve (NR-LLM)**. This model configuration is trained to answer questions solely based on the question text without considering any contextual information. It serves as the baseline for evaluating the performance of question answering models in the absence of context.
- **Always-Retrieve (AR-LLM)**. In contrast to the NR-LLM model, this configuration always retrieves context passages to assist in answering questions. It is trained to utilize context consistently for generating answers. To ensure a fair comparison with ADAPT-LLM, we also use Contriever (Izacard et al., 2022) as the IR system and only retrieve the most relevant passage as context.

4.4 Training Details

For all three model configurations (ADAPT-LLM, AR-LLM and NR-LLM) and both training sets (SQuAD and NQ), we adhere to the parameter configuration established in Alpaca-Lora (Taori et al., 2023) which includes a batch size of 128, three epochs, and a fixed learning rate of 3e-4. We incorporated LoRA (Low-Rank Adaptation) regularization, with parameters configured for r=8, alpha=16,

Training	⟨RET⟩ Usage	⟨RET⟩		No ⟨RET⟩	
		Acc. w/ context	Acc. w/o context	Acc. w/ context	Acc. w/o context
NQ	87.26%	33.04%	14.65%	55.72%	62.36%
SQuAD	83.93%	33.40%	9.94%	57.73%	62.92%

Table 3: Results of the usage of the ⟨RET⟩ token in the ADAPT-LLM model. The first column shows the percentage of PopQA questions for which the model requests additional context. The second column focuses on the questions for which ADAPT-LLM asks for context (⟨RET⟩), comparing the performance between answering those questions with and without context. The last column (No ⟨RET⟩) is for questions which ADAPT-LLM decides to answer directly. We also compare the performance with and without the context retrieved by the IR system.

and a dropout rate of 0.05. Training was performed on an NVIDIA A40 GPU, for an average training time of approximately 8 hours. We do not perform any model selection and we use the last checkpoint after 3 epochs of training.

4.5 Validating the Adaptive Retrieval Approach

To assess the effectiveness of our adaptive approach (ADAPT-LLM) compared to the NR-LLM and AR-LLM baselines, we fine-tuned the Llama-2 model on both the NQ and SQuAD datasets using all three configurations. For NR-LLM and AR-LLM, we constructed training samples using question-answer pairs with instruction prompts: NR-LLM was prompted to answer without context, while AR-LLM received both question and context. In contrast, ADAPT-LLM was trained using the two-step approach described in Section 3.1, resulting in 74.72% of questions marked with the ⟨RET⟩ token for NQ and 87.49% for SQuAD. All models were evaluated on the PopQA dataset. During inference, NR-LLM and AR-LLM followed their respective prompting strategies, while ADAPT-LLM used the procedure from Section 3.2. We used **Exact Match Accuracy** as the evaluation metric, comparing generated answers to the annotated gold answers in PopQA. Table 1 shows that across both training sets, ADAPT-LLM consistently outperforms NR-LLM and AR-LLM. NR-LLM yields the lowest scores, with an accuracy gap of around 14 points, confirming that Llama-2's parametric memory alone is insufficient for PopQA.

The performance gap between AR-LLM and ADAPT-LLM is smaller. ADAPT-LLM achieves 36.77% and 38.15% accuracy on PopQA when trained on NQ and SQuAD, respectively, compared to 35.86% and 36.59% for AR-LLM. The best results are obtained with SQuAD.

Although both NQ and SQuAD are Wikipedia-based like PopQA, we examine which training set better aligns with the evaluation set. Table 2 compares their characteristics.

NQ is closer in question and answer length to PopQA, but SQuAD's larger size (∼87K vs. ∼58K questions) may explain its better results. While further analysis is needed to fully understand dataset suitability—beyond the scope of this work—these findings suggest that scale plays a key role.

4.6 Contextual Retrieval Decision Analysis

In this experiment, our objective is to once again evaluate the effectiveness of the ADAPT-LLM model, this time focusing on its ability to accurately determine when additional context is needed. We follow these steps:

1. Run inference on ADAPT-LLM over the PopQA test set, prompting it to either return an answer directly or output ⟨RET⟩ if more context is needed.
2. If ⟨RET⟩ is returned:
   - 2.1. Provide the retrieved context to ADAPT-LLM and collect its final answer.
   - 2.2. Run the same question on NR-LLM without context.
3. If ADAPT-LLM answers directly:
   - 3.1. Run ADAPT-LLM without context.
   - 3.2. Run AR-LLM with context retrieved by the IR system.

Table 3 presents the results of this experiment. The first thing to note is that the ADAPT-LLM model generates the ⟨RET⟩ token for approximately 82-83% of the questions in the PopQA dataset, with similar ratios observed across both training datasets. This observation aligns with the low performance of the NR-LLM configuration demonstrated in Table 1. However, ADAPT-LLM consistently determines when additional context is required to answer a question accurately.

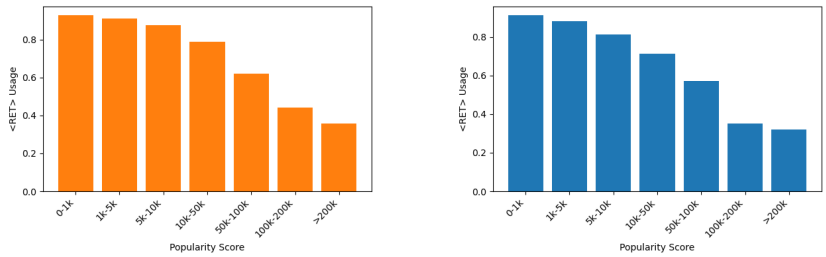

Figure 2: Histograms depicting the proportion of questions where ADAPT-LLM trained on NQ (left) and ADAPT-LLM trained on SQuAD (right) ask for extra context for different popularity score intervals.

Passage Type	SQuAD Acc. (%)	NQ Acc. (%)
Gold	**89.42**	**69.76**
Contriever	22.49	27.04

Table 4: Accuracy of ADAPT-LLM on SQuAD and NQ dev sets using gold vs. Contriever-retrieved passages.

Across both the NQ and SQuAD training datasets, ADAPT-LLM exhibits significantly higher accuracy when retrieving context compared to the NR-LLM model's accuracy without context (as indicated in the ⟨RET⟩ column of Table 3). Specifically, for the NQ dataset, the accuracy of the ADAPT-LLM model when requesting context is 33.04%, whereas the accuracy of the NR-LLM model without context retrieval is notably lower at 14.65%. Similarly, for the SQuAD dataset, ADAPT-LLM achieves an accuracy of 33.40% with context retrieval, whereas the NR-LLM model's accuracy without context is substantially lower at 9.94%.

Finally, the last column of Table 3 (No ⟨RET⟩) shows the performance of ADAPT-LLM when answering questions based solely on its parametric memory. As can be seen, accuracies above 62% are obtained when no context is utilized, providing further evidence that ADAPT-LLM effectively discerns between retrieving context and providing direct answers to questions. Additionally, we evaluate the performance of these questions when context is added to the input, revealing significant decreases in accuracy of up to 7 absolute points.

These findings provide insights into the effectiveness of the decision-making process employed by the ADAPT-LLM model in determining the necessity of additional context for accurate response generation and present empirical evidence of the necessity of performing dynamic context retrieval in improving the accuracy of question answering models. However, it is notable that the overall performance of the model when answering questions with retrieved context, as observed in Table 3 (approximately 33%), is relatively low.

To further explore this observation, we conduct an additional experiment: evaluating ADAPT-LLM (both versions trained on NQ and SQuAD) on the NQ and SQuAD development splits, comparing performance when using the gold passages of the dataset and the context retrieved by our IR system, Contriever (Izacard et al., 2022). Unfortunately, PopQA does not provide the gold passages, so direct evaluation there was not possible.

Table 4 presents the results of this experiment. A significant performance difference is observed between using the gold passage and the top passage retrieved by Contriever for both datasets (approximately 67 absolute points for SQuAD and 42 for NQ). This indicates that Contriever, and current IR systems in general, do not consistently retrieve the most relevant passage to answer a given question.

This observation underscores the importance of retrieving multiple documents as context, as seen in the most successful open-domain QA systems (Izacard and Grave, 2021), and highlights its impact on the overall performance of ADAPT-LLM in PopQA. To further validate the behavior of ADAPT-LLM when requesting additional context, Figure 2 illustrates the proportion of questions for which our model generates the ⟨RET⟩ token, aggregated by popularity score intervals (left image for ADAPT-LLM trained on NQ and right image for SQuAD). Mallen et al. (2023) suggest that high-popularity questions can be adequately answered using the parametric memory of the LLM, while lower popularity scores necessitate extra context.

In Figure 2, we observe this pattern for both versions of ADAPT-LLM, indicating that our model,

despite lacking access to popularity scores during training or inference, has learned effective criteria for requesting additional context.

4.7 Comparison with state-of-the-art methods

We conducted a comparative analysis between our ADAPT-LLM model and the current state-of-the-art approach for PopQA proposed by Mallen et al. (2023). Their methodology relies on the popularity score annotated in the PopQA dataset to determine whether a question requires additional context. To establish the optimal threshold for determining question popularity, Mallen et al. (2023) split the PopQA dataset into 75% as a development set for threshold determination and 25% as a test set. In the original paper, they apply this methodology to various LLMs available at that moment (Llama-2 was not released yet). To ensure a fair comparison between ADAPT-LLM and the popularity-based method, we replicated their approach using the Llama-2 7B model to determine the best popularity score threshold (found to be 707,000) using the same PopQA development set. This allowed us to obtain results consistent with their methodology while utilizing our base LLM. Similar to the original results in Mallen et al. (2023) when using smaller models, the popularity score threshold is almost equivalent to always retrieving contextual information for Llama-2 7B. The IR usage is of 99.86% as presented in Table 5. This clearly shows how the popularity score method struggles with smaller size models, being GPT-3 DAVINCI-003 the only model to get a IR usage below 80% in the original paper when using adaptive retrieval with the Contriever. Subsequently, we evaluated our ADAPT-LLM configuration on the same 25% test set split and compared the outcomes with those obtained using the method described by Mallen et al. (2023). This systematic comparison enabled us to assess the efficacy of our ADAPT-LLM model in relation to the current state of the art. The results of this experiment are presented in Table 5. We observe comparable performance between the replicated approach of Mallen et al. (2023) and ADAPT-LLM when trained on NQ and SQuAD datasets and tested on the 25% subset of PopQA. It's worth mentioning that ADAPT-LLM does not utilize any information from PopQA, unlike Mallen et al. (2023), who directly use the popularity score and a 75% portion of PopQA dataset to find an optimal value for that popularity score. This methodology is not generalizable to other open-domain question answering tasks since the popularity score is a unique feature of PopQA. However, ADAPT-LLM can be applied to any similar dataset. Given these characteristics, we believe that the results obtained by ADAPT-LLM are even more significant, offering comparable performance to an approach that utilizes dataset-specific information. These findings substantiate the validity of our approach, demonstrating its effectiveness even when trained on datasets different from the one used for testing.

Model	IR (%)	Acc. (%)
POPULARITY SCORE	99.86	36.81
ADAPT-LLM (NQ)	87.22	35.30
ADAPT-LLM (SQUAD)	83.99	**37.29**

Table 5: Accuracy and IR usage of ADAPT-LLM (trained on NQ and SQuAD) vs. a POPULARITY SCORE-based strategy using Llama-2, following Mallen et al. (2023).

5 Conclusions

In this paper, we introduce ADAPT-LLM, an LLM trained to decide when additional context is necessary for answering a question, rather than relying solely on its parametric memory. ADAPT-LLM is the result of fine-tuning a base LLM on an open-domain question answering dataset that has been modified to differentiate between questions answerable with the LLM's parametric memory alone and those requiring supplementary context. To construct these training datasets, we initially subject the base LLM to zero-shot evaluation to determine its accuracy in answering questions. For questions where the model's response is incorrect, we train the LLM to generate a special token, ⟨RET⟩, indicating the need for additional context. Through extensive experiments conducted on the PopQA dataset, we show that ADAPT-LLM performs better than its two fixed alternatives: never retrieving and always retrieving relevant context information. Furthermore, our findings highlight ADAPT-LLM's capability to effectively discern the necessity of additional context, which is the primary objective of this work. Future work could explore methods to enhance performance when utilizing an IR system, such as incorporating learnable sequential retrieval techniques. Furthermore, we believe it would be valuable to conduct a more in-depth analysis of the interaction between training and testing datasets in the development of ADAPT-LLM systems.

Abstract

Abstractive text summarization systems have advanced significantly with the rise of neural language models. However, they frequently suffer from issues of *unfaithfulness* or *factual inconsistency*, generating content that is not verifiably supported by the source text. This survey provides a comprehensive review of over 40 studies published between 2020 and 2025 on methods for evaluating faithfulness in abstractive summarization. We present a unified taxonomy that covers human evaluation techniques and a variety of automatic metrics, including question answering (QA)-based methods, natural language inference (NLI)-based methods, graph-based approaches, and large language model (LLM)-based evaluation. We also discuss meta-evaluation protocols that assess the quality of these metrics. In addition, we analyze a wide range of benchmark datasets, highlighting their design, scope, and relevance to emerging challenges such as long-document and domain-specific summarization. In addition, we identify critical limitations in current evaluation practices, including poor alignment with human judgment, limited robustness, and inefficiencies in handling complex summaries. We conclude by outlining future directions to support the development of more reliable, interpretable, and scalable evaluation methods. This work helps researchers navigate the evolving landscape of faithfulness evaluation in summarization. Related papers and updates are available at [1].

1 Introduction

Automatic Text Summarization (ATS) is a fundamental task in Natural Language Processing (NLP) that aims to condense a single document or a collection of documents into concise, coherent, and informative summaries (Nenkova et al., 2011). This process significantly reduces the time and effort required for document comprehension (Zhang et al., 2024a). Generally, ATS methods were predominantly extractive, selecting important sentences or phrases directly from the original text. While effective in preserving factual accuracy by design, extractive methods often yield less fluent or coherent summaries (Zhang et al., 2024a).

With the advent of deep learning, particularly sequence-to-sequence (seq2seq) architectures such as recurrent neural networks (Medsker et al., 2001) and the Transformer (Vaswani et al., 2017), the field has witnessed a transformative shift. These models enable the generation of entirely new sentences that paraphrase the core ideas of the source text (Zhang et al., 2023). More recently, the rise of large language models (LLMs) has further enhanced these capabilities, producing summaries that demonstrated remarkable fluency, coherence, and human-like quality (Li et al., 2022).

Despite significant advancements in fluency and coherence, neural abstractive summarization models continue to face a major challenge: they often generate content that is either *unfaithful* to the input document or factually incorrect. *Faithfulness* refers to the extent to which a summary is directly supported by its source, without adding, omitting, or contradicting information (Maynez et al., 2020; Dong et al., 2022; Li et al., 2022). In contrast, *factuality* concerns whether the content is true with respect to real-world knowledge, even if it is not explicitly stated in the input (Maynez et al., 2020). Errors in generation are commonly described as *hallucinations*, which can be classified as *intrinsic*, when the summary contradicts the source, or *extrinsic* when it introduces unverifiable or fabricated content (Zhao et al., 2020; Cao and Wang, 2021; Huang et al., 2021; Ji et al., 2023).

Since 2020, research on faithfulness and factual consistency in abstractive summarization has

*Equal contribution

[1] https://github.com/lamsiyah/faithfulness-eval-summarization

Proceedings of Recent Advances in Natural Language Processing,pages 633–643
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-074

grown rapidly. Studies have introduced a range of model-based evaluation metrics, such as those using natural language inference and question answering, and released new annotated datasets that support more systematic benchmarking. However, recent evaluations (e.g., Fabbri et al. (2021)) show that no single metric consistently aligns with human judgments across models that highlight the complexity and evolving nature of the field. To clarify this landscape, this survey provides a comprehensive overview of research from 2020 to 2025, with a primary focus on faithfulness evaluation, while also addressing related concepts such as factuality and hallucination.

Contributions: (1) We present a comprehensive survey of 40+ works (2020–2025) on faithfulness evaluation in abstractive summarization. (2) We propose a unified taxonomy that encompasses human evaluations, automatic metrics (QA-, NLI-, graph-, LLM-based), and meta-evaluations. (3) We provide a comparative analysis of datasets and metrics, highlighting trends, strengths, and limitations. (4) We outline key gaps and open problems to guide future research. (5) We release all resources to support the community.

2 Related Work

Several surveys have addressed the issue of faithfulness in text generation, both generally and with a specific focus on abstractive text summarization. For instance, Li et al. (2022) provide a broad overview of faithfulness across diverse Natural Language Generation (NLG) tasks, highlighting its systemic nature and the potential for cross-task solutions. Similarly, Ji et al. (2023) offer a wide-ranging survey of hallucination in natural language generation, including summarization, and establish key definitions for intrinsic versus extrinsic hallucinations. Shifting to a narrower scope, Pagnoni et al. (2021) focus on abstractive text summarization, categorizing evaluation methods designed to address factual inconsistency. In a related vein, Huang et al. (2021) review recent advances in neural abstractive summarization, highlighting the challenge of factual inconsistencies and focusing on fact-aware evaluation metrics and models designed to improve factual consistency. Furthermore, early work by Cao et al. (2018) marks the beginning of explicit research into faithfulness in summarization, identifying the problem of "fake facts" and proposing initial mitigation strategies. At the level of summarization evaluation as a whole, Fabbri et al. (2021) address the limitations of current summarization evaluation by comprehensively re-evaluating metrics and models, releasing large-scale benchmark datasets and human annotations, and providing a unified toolkit to promote more consistent and reliable evaluation protocols aligned with human judgment.

In contrast to prior surveys, our work provides a focused and up-to-date (2020–2025) review of evaluation methods for faithfulness in abstractive summarization. We offer a fine-grained taxonomy of human, automatic, and meta-evaluation approaches, integrate recent advances in LLM-based methods, and analyze benchmarks with attention to long-document and domain-specific evaluation. This survey aims to equip readers with a detailed understanding of current evaluation practices, trade-offs between methods, and emerging research challenges.

3 A Taxonomy of Faithfulness Evaluation Methods

Faithfulness evaluation in abstractive summarization can be grouped into three categories: (1) ***human evaluations***, offering nuanced judgments but limited by subjectivity and scalability; (2) ***automatic metrics***, efficient yet often misaligned with human judgment; and (3) **meta-evaluation frameworks**, which assess the reliability of the metrics themselves. This section reviews each category, and Figure 1 illustrates the taxonomy of methods, benchmarks, challenges, and future directions.

3.1 Human Evaluation Methods

Human evaluation remains the gold standard for assessing summarization quality, including faithfulness, due to its ability to capture details that automatic metrics often miss (Kryscinski et al., 2020; Wang et al., 2020; Krishna et al., 2023). However, human evaluation is essentially slow, costly, and challenging to scale. A persistent challenge in human evaluation is achieving high inter-annotator agreement (IAA). Studies consistently report low IAA, especially for highly abstractive summaries, indicating the subjective and difficult nature of consistent judgment (Pagnoni et al., 2021). For example, SummEval found "no correlation" between expert and crowd-sourced judgments for summarization quality (Fabbri et al., 2021). This consistent finding of low IAA and the need for new guidelines

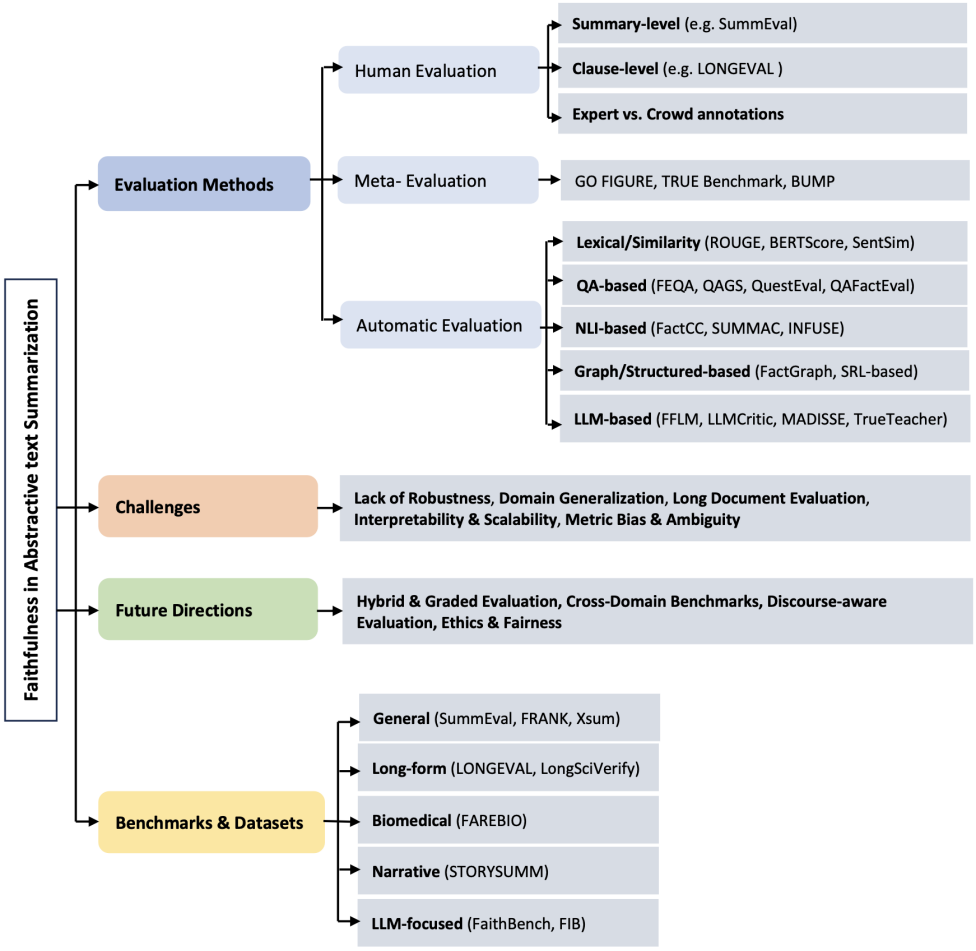

Figure 1: A Taxonomy of Faithfulness Evaluation in Abstractive Summarization: Methods, Benchmarks, Challenges, and Future Directions.

and nuanced labels underscore that faithfulness is not a universally objective concept. If human evaluators themselves struggle to consistently agree on what constitutes a "faithful" summary, then the "gold standard" for evaluating automatic metrics is noisy. This implies that achieving perfect correlation with human judgment might be an unrealistic goal. Instead, automatic metrics should aim for robustness against human variability, perhaps by focusing on clearly verifiable factual statements or by providing scores that reflect the "graded" nature of faithfulness. This situation highlights a fundamental limitation in the evaluation pipeline, where the target (human judgment) itself is a moving target, pushing research towards more objective, machine-verifiable definitions of faithfulness or more sophisticated aggregation of human input (Durmus et al., 2020; Pagnoni et al., 2021; Fabbri et al., 2021).

To improve human evaluation, especially for long-form summarization, several guidelines and benchmarks have been introduced. **LONGEVAL Guidelines** (Krishna et al., 2023) recommend clause-level and partial annotation, which improve inter-annotator agreement (IAA) and reduce annotator workload. Yet low IAA persists for abstractive and narrative summaries, reflecting the inherent subjectivity of human judgment and variability in acceptable paraphrasing or omission. Complementary resources include **FIB** (Tam et al., 2023), which tests whether LLMs prefer factually consistent continuations, and **FaithBench** (Bao et al., 2025), which introduces graded labels ("unwanted," "questionable," "benign") to capture degrees of inconsistency. FaithBench further shows that even strong protocols miss subtle errors in free-form summaries, underscoring the need for more flexible, multi-layered annotation strategies.

3.2 Automatic Evaluation Methods

Given the limitations of human evaluation, automatic metrics have been developed. Early met-

rics like ROUGE (Lin, 2004) and BLEU (Papineni et al., 2002) mainly capture n-gram overlap and fail to ensure factual correctness (Dong et al., 2020; Fabbri et al., 2021). Recent work has shifted to model-based approaches, which we classify into five categories: Lexical/Semantic Similarity, QA-based, NLI/Entailment-based, Graph-based, and LLM-based metrics.

Lexical Overlap and Semantic Similarity Metrics. Some studies have used lexical overlap and semantic similarity as proxies for assessing factual consistency. Traditional metrics such as ROUGE and BLEU, which rely on n-gram overlap, have been shown to correlate poorly with human judgments of faithfulness (Goodrich et al., 2019; Maynez et al., 2020; Wang et al., 2020). Their insensitivity to semantic changes means they can assign high scores even to factually incorrect summaries. To address the limitations of n-gram-based methods, later work adopted semantic similarity approaches using contextual embedding models. Notably, **BERTScore** (Zhang et al., 2019) computes similarity scores between tokens in candidate and reference summaries using contextual embeddings from BERT. While BERTScore generally correlates better with human judgments than ROUGE, its effectiveness is still limited, particularly for highly abstractive summaries that require deeper semantic understanding (Durmus et al., 2020; Fischer et al., 2022). Moreover, BERTScore can be sensitive to contextual variations and may overpredict faithfulness in some cases (Gabriel et al., 2021). Similarly, the **SentSim** metric (Fischer et al., 2022), which measures sentence-level semantic similarity, has demonstrated promising alignment with human judgments on datasets like SummEval, offering a better alternative to surface-based metrics.

Question Answering (QA)-based Metrics. QA-based metrics evaluate faithfulness by generating questions from the summary and verifying answers in the source. The intuition, introduced by Wang et al. (2020), is that faithful summaries should contain only source-verifiable content. Durmus et al. (2020) proposed **FEQA**, which compares QA-derived answers with expected ones using F1, showing strong correlation with human judgments on abstractive datasets like XSum (Narayan et al., 2018), though limited by QA model quality and rigid scoring. **QAGS** (Wang et al., 2020) similarly uses QG/QA but improves interpretability by identifying inconsistent tokens, demonstrating robustness across domains. **QuestEval** (Scialom et al., 2021) introduced a reference-less QA framework with question weighting, improving correlations across factual consistency, coherence, fluency, and relevance. **QAFactEval** (Fabbri et al., 2022) further optimized QG (BART-large), answer selection (NP chunking), and scoring (LERC), yielding a 14% gain on SummaC.

Overall, QA-based metrics align closely with human fact-checking and provide interpretable error traces, but remain computationally intensive and sensitive to QG/QA quality. Despite these limitations, they represent the most effective tools for assessing factual consistency.

Natural Language Inference (NLI)/Entailment-based Metrics. NLI-based metrics assess factual consistency by checking whether the summary is entailed by the source, or at least neutral, but never contradictory (Falke et al., 2019). Early work by Falke et al. (2019) used pretrained NLI models to re-rank summaries, but these struggled to distinguish factual from non-factual content. **FactCC** (Kryscinski et al., 2020) addressed this with a weakly supervised BERT model trained on synthetic perturbations (e.g., entity swaps, paraphrases, negation), outperforming general NLI models like MNLI or FEVER in less abstractive domains. Dependency Arc Entailment **(DAE)** (Goyal and Durrett, 2020, 2021) advanced this idea by scoring factuality at the dependency arc level, while **SUMMAC** (Laban et al., 2022) computed entailment probabilities between each summary and document sentence, aggregating scores via max, average (SCZS), or convolutional methods (SCConv).

TRUE (Honovich et al., 2022) benchmarked 12 metrics across 11 datasets, finding NLI- and QA-based approaches strongest, though less reliable for longer inputs. To mitigate this, **INFUSE** (Zhang et al., 2024b) introduced fine-grained reasoning that incrementally selects minimal context per summary sentence and applies sub-sentence decomposition, improving evaluation of complex summaries. More recently, Zhong and Litman (2025) incorporated discourse analysis (e.g., RST parsing) into NLI, showing the value of document structure and sentence importance for long-document summarization.

Entailment-based metrics directly model the "supported by source" notion of factual consistency, typically outputting probabilities or scores. How-

ever, they depend on NLI model quality and suitable training data. Limitations include: (a) fragility to domain shifts (e.g., news vs. dialogue); (b) penalizing paraphrasing or aggregation unseen in training; and (c) binary entailment labels that obscure error severity or location. Despite these challenges, entailment-based methods consistently outperform surface-level approaches like n-gram overlap in correlating with human judgments (Honovich et al., 2022).

Graph-based and Structured Representation Metrics. These methods aim to move beyond surface-level textual analysis by converting summaries and source texts into semantically rich structures such as Abstract Meaning Representations (AMRs), semantic role labels (SRLs), named entities, or relational triples to enable more precise factual consistency comparisons.

FactGraph (Ribeiro et al., 2022) decomposes document and summary sentences into AMR graphs and uses a dual-encoder architecture to jointly encode textual and graph modalities. This abstraction away from surface form improves the detection of semantic errors and unverifiable content, though AMR parsing remains computationally demanding. Extending this direction, **AMRFACT** (Qiu et al., 2024) generates high-quality negative training samples by injecting factual inconsistencies into AMR-parsed reference summaries. These are converted back into text and filtered using a dedicated module (NEGFILTER), resulting in more coherent and diverse training data for factual consistency detectors.

Complementary to AMR-based techniques, SRL-based metrics compare semantic frames or argument structures derived from summaries and sources (Fischer et al., 2022). While less semantically detailed than AMRs, SRL approaches introduce useful linguistic structure and have shown moderate correlation with human judgments. Similarly, named entity recognition (NER)-based methods target entity hallucination by aligning named entities across source and summary, though their effectiveness diminishes when errors extend beyond named entities (Fischer et al., 2022).

Finally, triple-based methods extract relational triples (e.g., <subject, relation, object>) from both source and summary and assess their factual alignment. For example, Goodrich et al. (2019) trained a Transformer-based fact extractor on Wikidata-derived data. However, open-schema extraction faces challenges in aligning semantically equivalent but structurally different triples, whereas fixed-schema approaches improve alignment consistency at the cost of reduced coverage.

Large Language Model-based Evaluation. The emergence of LLMs has introduced new paradigms for evaluating summary faithfulness, either by leveraging LLMs as direct evaluators or by using them to generate training data for smaller models. Jia et al. (2023) proposed **FFLM**, a zero-shot metric using moderately-sized LLMs (e.g., LLaMa) to assess faithfulness by comparing the generation probability of a summary under consistent and inconsistent document contexts, without task-specific fine-tuning. Adlakha et al. (2024) introduced **LLMCritic**, where LLMs like GPT-4 are prompted to assess faithfulness in a QA setup. This L*LM-as-a-judge* approach has gained traction for its strong correlation with human evaluations. Similarly, Koupaee et al. (2025) proposed **MADISSE**, a multi-agent debate framework where LLMs with opposing stances argue about a summary's faithfulness, often revealing ambiguous cases. Bao et al. (2025) used GPT-4o in FaithBench to detect challenging hallucination cases where faithfulness detectors disagree, and also benchmarked GPT-4o as an evaluator itself. In the same context, Gekhman et al. (2023) introduced **TrueTeacher**, an approach where an LLM annotates factual errors in model-generated summaries to train a smaller student model, eliminating the need for manually perturbed reference summaries.

Despite their promise, LLM-based evaluation approaches face notable challenges: they tend to be costly, often operate as black-boxes with opaque reasoning, and can yield inconsistent judgments across different prompts or runs, especially when relying on closed-source models (e.g., see Stureborg et al. (2024), Li et al. (2024)). Hybrid methods, by contrast, show promise: for instance, using LLMs to generate explanations or rationale while entrusting scoring to simpler models, or distilling LLM behaviors into smaller, task-specific models (e.g. Hsieh et al. (2023)).

3.3 Meta-Evaluation of Faithfulness Metrics

Meta-evaluation refers to the process of evaluating the evaluation metrics themselves. This is crucial for understanding the reliability, strengths, and weaknesses of proposed faithfulness metrics.

Several benchmarks and protocols have been

proposed to rigorously evaluate these metrics. For instance, Gabriel et al. (2021) introduced **GO FIGURE**, a framework that outlines five essential criteria for faithfulness metrics: boundedness, sensitivity to factuality levels, robustness across error types, generality across domains, and human correlation. It employs diagnostic datasets with both synthetic and human-annotated errors in news and dialogue summaries. Honovich et al. (2022) proposed the **TRUE** benchmark, which uses example-level meta-evaluation with ROC AUC to quantify how well a metric distinguishes consistent from inconsistent summaries. Ma et al. (2023) developed **BUMP**, a benchmark of minimally perturbed summary pairs designed to test a metric's sensitivity to subtle factual errors, enabling fine-grained assessment of consistency and discrimination ability. In addition to dedicated benchmarks, many studies perform correlation analysis between proposed metrics and human ratings on established datasets such as **SummEval** (Fabbri et al., 2021) and **FRANK** (Pagnoni et al., 2021) that serve as a common form of informal meta-evaluation.

Meta-evaluation provides an objective basis for comparing metrics and helps identify which metrics truly reflect human judgment. It improves reproducibility and metric robustness across domains. However, it depends on high-quality human annotations and curated benchmarks, which may introduce biases or fail to represent all real-world summarization challenges. Moreover, correlation with human judgment does not guarantee interpretability or error localization, which highlights the need for complementary analysis tools.

4 Benchmarks for Faithfulness Evaluation

A wide range of benchmarks and datasets has been created for faithfulness evaluation in abstractive summarization. **General-purpose datasets**, such as SummEval and XSUM-based resources (e.g., XSF, QAGS-XSUM) (Maynez et al., 2020), provide human judgments of consistency, with XSUM widely used for its abstractiveness. **Consolidated benchmarks** like the TRUE Benchmark (Honovich et al., 2022) and AggreFact (Tang et al., 2023) unify multiple datasets (e.g., FRANK, SummEval, QAGS, MNBM) for standardized meta-evaluation; FRANK offers fine-grained error labels, while BUMP tests metric sensitivity with minimally perturbed pairs. **Domain- and task-specific datasets** address specialized needs, including DiverSumm (Zhang et al., 2024b), LongSciVerify (Bishop et al., 2023), LONGEVAL (Krishna et al., 2023), FAREBIO (Fang et al., 2024), FIB (Tam et al., 2023), and STORYSUMM (Subbiah et al., 2024). Weakly supervised training is supported by synthetic resources such as FactCC (Kryscinski et al., 2020), LLM-labeled datasets like TrueTeacher (Gekhman et al., 2023), and **structurally perturbed datasets** such as AMRFACT (Qiu et al., 2024). Together, these resources play complementary roles: general-purpose datasets enable broad comparisons, consolidated suites support standardized meta-evaluation, domain-specific collections address long-form and LLM-generated summaries, and synthetic/perturbed sets facilitate stress-testing and training. Table 1 summarizes these datasets.

5 Challenges and Limitations of the Existing Evaluation Methods

Despite progress, evaluating faithfulness in abstractive summarization remains challenging, as both human and automatic methods have notable limitations. A comparative analysis of these challenges is available at [2]. Persistent challenges include:

Correlation with Human Judgment and Interpretability. A key challenge for automatic faithfulness metrics is their often low to moderate correlation with human judgments, indicating they don't fully capture human nuances (Huang et al., 2021). Furthermore, many advanced model-based metrics, particularly those using deep learning or LLMs, lack interpretability, making it difficult to understand their scoring logic and derive actionable insights. While some metrics like QAGS (Wang et al., 2020) (through its question-answer pairs) and MADISSE (through debate arguments) (Koupaee et al., 2025) offer better interpretability, this remains a significant challenge for the field.

Robustness to Adversarial Inputs and Domain Shifts Faithfulness metrics frequently lack robustness, which shows inconsistent performance across different domains or out-of-distribution data (Fischer et al., 2022). They can also be overly sensitive to minor paraphrasing or lexical variations that do not impact factual accuracy. For example, NLI-based models can be misled by superficial

[2] https://github.com/lamsiyah/faithfulness-eval-summarization

Benchmark	Focus	Annotation Granularity	Size / Scope	Includes LLM-Generated Summaries?
SummEval (Fabbri et al., 2021)	General News (CNN/DM)	Summary-level (consistency, coherence, etc.)	100 articles, 16 models, ∼1,600 summaries	Yes (various neural models)
FRANK (Pagnoni et al., 2021)	General News (CNN/DM, XSum)	Sentence-level error typology	2,250 summaries	Yes (various neural models)
TRUE (Honovich et al., 2022)	Diverse (Summarization, Dialogue, Fact Verification)	Binary summary/text-level consistency	11 datasets consolidated	Yes (from constituent datasets)
BUMP (Ma et al., 2023)	General News (CNN/DM)	Minimal pairs (faithful vs. unfaithful sentence)	Human-written minimal pairs	No (focus is on human-written variations)
AggreFact (Tang et al., 2023)	General News (CNN/DM, XSum)	Binary summary-level	9 datasets consolidated, FTSOTA split focuses	Yes (BART, PEGASUS, etc.)
DiverSumm (Zhang et al., 2024b)	Diverse (Long-form, Multi-doc, Meeting, XSum)	Sentence-level faithfulness, error types	563 instances, tasks like MultiNews, QMSUM, ArXiv, GovReport	Yes (includes GPT-3.5)
LongSciVerify (Bishop et al., 2023)	Long Scientific Docs (PubMed, ArXiv)	Fine-grained summary-level factual consistency	270 annotated summaries	Yes (LongT5, BigBird-PEGASUS)
LONGEVAL (Krishna et al., 2023)	Long-form (Literary, Scientific)	Fine-grained (clause-level) binary faithfulness	120 SQuALITY & PubMed summaries	Yes (model outputs used in study)
FIB (Tam et al., 2023)	News Summarization (LLM Evaluation)	Binary (LLM preference for consistent summary)	CNN/DM, XSum; evaluates 23 LLMs	Yes (evaluates LLMs' scoring, uses model-generated inconsistent summaries)
FaithBench (Bao et al., 2025)	LLM Hallucinations (Challenging Samples)	Span-level hallucination type (questionable, benign, unwanted)	750 summaries from 10 modern LLMs	Yes (core focus)
STORYSUM (Subbiah et al., 2024)	Narrative Summarization (LLM Evaluation)	Sentence-level binary faithfulness, error explanations	96 short stories, summaries from GPT/Claude series	Yes (core focus)
FAREBIO (Fang et al., 2024)	Plain Biomedical Summaries (LLM Evaluation)	Sentence-level faithfulness, supporting evidence	175 summaries from 7 LLMs, expert MD annotations	Yes (core focus)

Table 1: Overview of key benchmarks and datasets for faithfulness evaluation.

lexical overlap, resulting in false assessments of entailment or contradiction (Huang et al., 2021).

Coverage of Diverse Faithfulness Error Types. Existing metrics often struggle to comprehensively cover the diverse spectrum of faithfulness errors, such as subtle distortions, omissions, or fabricated information (Pagnoni et al., 2021). Some may excel at detecting direct contradictions but fail on other error types, and metrics trained on synthetic data may not generalize to errors from advanced models (Fischer et al., 2022). A particular challenge is identifying "Out-of-Article" errors, which are factually correct externally but unsupported by the source document (Fang et al., 2024; Qiu et al., 2024).

Scalability, Cost, and Efficiency. The practical utility of evaluation methods is significantly impacted by their scalability, cost, and efficiency. While human evaluation is often considered the gold standard, it is resource-intensive (Lee et al., 2024). Automatic metrics present a trade-off: simpler lexical methods are efficient but less accurate, whereas sophisticated model-based approaches, especially those involving multiple LLM inferences or complex graph parsing, can be computationally expensive and slow, which limits their widespread adoption.

Issues in Long-Form and Multi-Document Summarization Evaluation. Evaluating faithfulness in long-form and multi-document summarization presents unique complexities not typically addressed by methods designed for shorter, single-document texts. Challenges include handling extended context within models that often have in-

put length limitations and the difficulty of identifying relevant supporting evidence across vast amounts of text. Several methods are emerging to specifically address these challenges, but this area requires further research (Bishop et al., 2023; Krishna et al., 2023).

Limitations of Current Benchmarking Practices. Current benchmarking practices for faithfulness evaluation face several limitations, including historical lack of standardization (partially addressed by initiatives like TRUE (Honovich et al., 2022)), potential issues with annotation quality and consistency, and the relevance of older benchmarks to errors produced by state-of-the-art models (prompting newer benchmarks like FaithBench). Furthermore, the size and diversity of existing benchmarks can restrict the generalizability of findings (Subbiah et al., 2024).

Challenges with LLM-based Evaluation. While LLMs offer significant potential for faithfulness evaluation, their application introduces specific challenges such as biases (Fang et al., 2024), opacity in their decision-making, high operational costs for powerful models, inconsistent reliability influenced by prompting, and struggles with particularly *challenging* hallucination cases (Adlakha et al., 2024; Bao et al., 2025). Addressing these issues is crucial for effectively leveraging LLMs in this evolving field where human evaluation also remains indispensable.

6 Future Directions

Future Directions in Faithfulness Evaluation. The future of faithfulness evaluation is moving toward more robust solutions that combine multiple metric types, nuanced benchmarks, and human-in-the-loop assessments. Rather than relying on a single universal metric, research is trending toward hybrid approaches that integrate QA, NLI, and semantic similarity methods to capture multiple facets of faithfulness, including factual accuracy, completeness, and distortion detection. There is a growing emphasis on developing fine-grained, interpretable metrics capable of localizing specific errors, providing actionable explanations, and classifying error types using established taxonomies. Expanding faithfulness evaluation to low-resource languages and domains such as legal or scientific texts remains a key frontier, with few-shot and zero-shot methods offering promising directions.

LLMs, Ethical Concerns, and Graded Evaluation. LLMs are reshaping evaluation strategies, acting as both summary evaluators and refiners. Research is focusing on improving LLM-based evaluators through better prompting and fine-tuning, while also building robust meta-evaluation protocols to assess their reliability and biases. Ethical considerations such as fairness across demographics, detecting evaluation biases, and preventing metric exploitation are increasingly important. Additionally, moving beyond binary classification toward graded faithfulness scales and ambiguity modeling is essential for reflecting the nuanced nature of summarization quality. These advances aim to ensure evaluation methods evolve in tandem with the growing capabilities and complexity of summarization models.

Limitations

While this survey aims to provide an exhaustive overview of methods for evaluating faithfulness in abstractive text summarization based on the collected references, certain limitations should be acknowledged. The field is evolving rapidly, particularly with the emergence of LLMs, and some of the most recent or pre-print research may not be comprehensively covered. Due to the broad scope, this work emphasizes breadth over depth and does not offer deeply technical analyses of every algorithm or benchmark. Furthermore, our evaluation of the strengths and weaknesses of various methods is primarily based on the findings and claims reported in the original publications; we did not undertake an independent empirical re-evaluation of all discussed metrics. Additionally, the primary focus is on faithfulness evaluation in general abstractive text summarization. While some concepts are broadly applicable, dedicated explorations of faithfulness in highly specialized domains or other NLG tasks (e.g., dialogue, story generation) are only addressed when they introduce significantly novel evaluation paradigms relevant to abstractive summarization. Finally, this survey concentrates on evaluation methods rather than methods aimed at improving faithfulness through novel generation architectures or mitigation strategies.

Abstract

Multiword expressions, characterised by non-compositional meanings and syntactic irregularities, are an example of nuanced language. These expressions can be used literally or idiomatically, leading to significant changes in meaning. Although large language models perform well on many tasks, their ability to handle subtle linguistic phenomena remains unclear. This study examines how state-of-the-art models process the ambiguity of potentially idiomatic multiword expressions, particularly in less frequent contexts where memorisation is less likely to help. By evaluating models in Portuguese, Galician, and English, and introducing a new code-switched dataset and task, we show that large language models, despite their strengths, have difficulty handling nuanced language. In particular, we find that the latest models, including GPT-4, fail to outperform the xlm-roBERTa-base baselines in both detection and semantic tasks, with especially poor performance on the novel tasks we introduce, despite its similarity to existing tasks. Overall, our results demonstrate that multiword expressions, especially those that are ambiguous, continue to be a challenge to models. We provide open access to our datasets and prompts, https://github.com/francesita/CS-and-Multilingual-MWEs

1 Introduction

Multiword expressions (MWEs) present significant challenges in Natural Language Processing (NLP) due to their linguistic complexities. MWEs consist of multiple words that convey a specific meaning, which may be non-compositional and exhibit syntactic irregularities (Baldwin and Kim, 2010; Constant et al., 2017). These expressions are widespread across languages and domains, from the arts to the sciences (Villavicencio and Idiart, 2019). The number of MWEs in a speaker's lexicon is estimated to be comparable to that of single words (Sag et al., 2002). MWEs are often rooted in cultural context and communication rather than a straightforward lexical meaning, making their interpretation in NLP systems more challenging, particularly in idiomatic contexts (Masini, 2019). Additionally, MWEs can be ambiguous, functioning either idiomatically or literally, which can cause potential confusion (Kurfal and Östling, 2020). For example, the English MWE *break the ice* can refer to its literal meaning or describe making unfamiliar individuals feel more at ease with one another. Such expressions, known as potentially idiomatic expressions (PIEs) (Haagsma et al., 2020), require an understanding of both literal and figurative meanings. Given the idiosyncratic nature of MWEs, it is essential that state-of-the-art NLP models accurately capture their meanings.

Large language models (LLMs) have rapidly become the dominant approach in NLP, demonstrating strong language understanding and generation abilities across a range of tasks in zero-shot and few-shot settings (Liu et al., 2022). However, despite their performance, LLMs exhibit clear limitations, including hallucinations, fluent but inaccurate or fabricated content, and a reliance on statistical co-occurrence patterns from pre-training data (Razeghi et al., 2022; Kang and Choi, 2023). *This study investigates whether LLMs can truly understand nuanced language, using MWEs as a test case.* MWEs are well-suited for this purpose, as they can be interpreted either idiomatically or literally, requiring sensitivity to both social and linguistic context. As MWEs occur across languages and vary in frequency and usage, their interpretation may be even more difficult in multilingual settings. In particular, idiomatic MWEs present a distinctive challenge to LLMs: their meanings are often non-compositional and cannot be reliably inferred from the meanings of their individual words. Unlike named entities (e.g., New York City) or compound nouns (e.g., credit card), idiomatic ex-

Proceedings of Recent Advances in Natural Language Processing,pages 644–653
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-075

pressions such as *kick the bucket* or *spill the beans* require models to distinguish between literal and figurative meanings based on context. This ambiguity makes idiomatic MWEs a particularly effective probe for evaluating whether LLMs understand context, nuance, and figurative language, abilities typically associated with human-like language understanding. Since LLMs rely heavily on surface-level patterns, idiomatic MWEs offer insight into whether their apparent success reflects genuine semantic generalisation or simply statistical association. One such challenge arises in code-switching (CS), where speakers alternate between languages within a conversation or sentence (Joshi, 1982; Dogruoz et al., 2021). Code-switching is common in multilingual communities and presents additional difficulties for NLP systems, as MWEs may be split across languages. To evaluate how LLMs handle this complexity, we use data in English, Portuguese, and Galician, as well as CS examples. By including both high-resource and low-resource languages alongside CS data, we aim to assess whether models rely primarily on statistical patterns in training data or if they can generalise effectively across multilingual and code-switched contexts.

We conduct experiments using both open-source and closed-source LLMs to examine how these models handle MWEs across different languages and contexts. Specifically, we investigate:

- the ability of LLMs to detect whether MWEs are used as idioms or literally,
- the extent to which LLMs effectively capture the non-compositional meanings of MWEs,
- the ability of LLMs to acquire information from the prompt, and
- the relationship between LLM size and performance on text containing MWEs with non-compositional meaning.

Our experiments show that, despite strong performance on many tasks, LLMs continue to struggle with MWEs, particularly in multilingual contexts, while smaller fine-tuned models like XLM-RoBERTa perform more reliably. Although results for English MWEs are sometimes comparable, performance declines in other languages, highlighting limitations in handling nuanced language. Section 2 reviews related work, Section 3 outlines the datasets and synthetic CS data, Section 4 describes the setup, and Section 5 presents our findings. Section 6 concludes with a summary and future directions.

1.1 Contributions

We conduct experiments to evaluate generative models' ability to detect and interpret MWEs in both idiomatic and compositional contexts. MWEs are selected for their lower frequency, reducing the likelihood of memorisation. To further explore this, we introduce a new code-switched test set covering Galician–Spanish, English–Spanish, and Portuguese–Spanish, which we release publicly.

Models are evaluated on standard MWE detection (Section 4.3) and new tasks assessing semantic understanding (Section 4.5), using both synthetic MWEs (Section 4.4) and the CS data (Section 3.1). These tasks are designed to minimise memorisation and assess how well models interpret non-compositional meaning. Our results show that LLMs struggle with MWE semantics and suggest that prompt-based learning alone is insufficient for handling unseen vocabulary in challenging linguistic settings.

2 Related work

Studies have shown that popular transformer models generally struggle to effectively handle figurative language. Research on encoder-only models shows that PLMs do not adequately capture and represent the meanings of idiomatic expressions (Garcia et al., 2021). Additionally, generative models like GPT-2 have been found to perform poorly in handling figurative language without the use of mitigation strategies (Jhamtani et al., 2021). Miletić and Walde (2024) reveal that transformer models capture MWE semantics inconsistently, and find that they are reliant on surface patterns. However, research has shown that encoder-only PLMs can effectively represent MWEs when fine-tuned with appropriate data (Tayyar Madabushi et al., 2022). Studies exploring how generative models handle figurative language are few, especially studies focusing on idioms. Liu et al. (2022) test BERT, and RoBERTa, as well as generative models, namely, GPT-2, GPT-3 and GPT-NEO on their ability to reason about figurative language, with a focus on metaphors. They find that all models need to be fine-tuned to do well on interpreting figurative language, and that the capabilities of these models remain far from reaching human performance. De Luca Fornaciari et al. (2024) conduct experiments on an English language dataset they create to assess model abilities in detecting idiomatic expressions in a zero-shot setting. They

conduct their experiments on the 7B versions of Llama-2, Vicuna, and Mistral models. Phelps et al. (2024) conduct detection experiments in English, Portuguese and Galician on different state-of-the-art generative models and find that although they give competitive results, they fail to reach the performance of fine-tuned PLMs. In this work, we will also explore model abilities in detecting MWEs in English, Portuguese, and Galician. However, our work also examines how generative models represent the *meaning* of sentences where MWEs are used idiomatically in these languages. Additionally, we investigate the impact of CS text on model performance and assess the models' ability to manage unseen MWEs using synthetic examples.

3 Datasets

To assess the capabilities of LLMs in understanding nuanced language, we use the SemEval 2022 Task 2 dataset (Tayyar Madabushi et al., 2022) for all experiments. This dataset contains MWEs in both literal and idiomatic contexts in English, Portuguese, and Galician, and includes adversarial examples to test model consistency in interpreting idiomatic meaning. The SemEval task comprises two subtasks: *subtask a*, an MWE interpretation task, and *subtask b*, an MWE paraphrase similarity task adapted from a semantic text similarity (STS) task for use with generative models. Both tasks are designed to assess whether models can capture the meaning of sentences containing MWEs, whether used compositionally or not. We adapt these subtasks and create new tasks based on the same data to test whether familiarity with task format (likely present in instruction tuning) affects performance. This also motivates our use of variations on a single dataset rather than multiple datasets. A further advantage of this dataset is its multilingual nature and the fact that the test labels have not been released, reducing the chance that models have seen the answers during instruction tuning or pre-training.

3.1 Code-Switched Dataset

To evaluate model performance on MWEs in mixed-language settings, we create a synthetic CS dataset by combining Spanish with monolingual English, Portuguese, and Galician sentences. CS is common in multilingual communities and contributes to varieties such as Spanglish.

We generate the data using OpenAI's GPT-4-turbo-0125 model with a temperature of 0.65 and a seed of 42, balancing coherence and variation. Two base prompts guide generation: one for MWE-containing examples and another for adversarial, non-MWE paraphrases. Spanish is mixed separately with each language to reduce output errors. Prompts are available on the project GitHub [1].

This dataset tests how well LLMs handle nuanced language in CS contexts, an area often overlooked in monolingual evaluations. While synthetic data may lack full naturalness, it remains coherent and helps reduce models' reliance on surface-level co-occurrence patterns. It also offers a practical alternative to real CS data, which is scarce and costly to collect.

4 Experimental Setup

In this section, we introduce our experiments and the models used as part of this work. We run three different experiments: an **MWE interpretation task**, a **synthetic MWE interpretation task**, and **MWE paraphrase similarity task**. These experiments aim to determine whether the models can recognise the presence and meaning of text that contains nuanced language. Most of the experiments are conducted in a zero-shot and few-shot setting.

4.1 Models

We use four models in our experiments, including both open-source and proprietary systems: (1) gpt-3.5-turbo-0125, (2) gpt-4-0125-preview, (3) meta-llama-3-70b-instruct, and (4) meta-llama-3-8b-instruct. The GPT models are accessed via the OpenAI API[2], while the Llama models are run using the Replicate API[3]. All models are tested using the same settings: temperature set to 0 and seed value of 42. We specify a maximum token count of 7 for the Llama models and 5 for the GPT models. As a baseline, we use XLM-RoBERTa (Conneau et al., 2020), selected as the sole pre-trained language model in our evaluation due to its strong performance in SemEval-2022 Task 2 on idiomaticity detection (Tayyar Madabushi et al., 2022).

4.2 Prompts

For all experiments in this section, we use three different prompts to generate outputs from the LLMs. The prompts are based on strategies outlined on

[1] https://github.com/francesita/CS-and-Multilingual-MWEs

[2] https://openai.com/

[3] https://replicate.com/

the OpenAI website [4]. Specifically, we employ three approaches: the 'persona' prompt, where the model adopts the role of a linguist; the 'think' prompt, where the model is instructed to reflect on the meaning of a sentence before assigning a label; the 'ChatGPT' prompt, generated using ChatGPT-turbo-3.5. Each prompt is adapted according to the specific task. We opt to use three prompts because model results may vary given different inputs (Liu et al., 2024), and this allows to explore possible variations in the model outputs given variations in the input. The prompts are available on the project GitHub [5].

4.3 MWE Interpretation Task

We conduct MWE sense disambiguation experiments, in which we ask an LLM to determine whether a given MWE in a sentence is used idiomatically or literally. We carry out these experiments in both zero-shot and few-shot settings using data from *subtask a* of the SemEval competition, which includes a total of 2,342 examples: 916 in English, 713 in Portuguese, and 713 in Galician. For the few-shot experiments, the model is provided with five examples: three in English and two in Portuguese. At least one instance of an MWE being used literally and idiomatically is included for each of the above languages. The original test dataset for SemEval *subtask a*, along with the synthetic CS dataset, is used for this task. The languages of the few-shot examples is not altered for the CS experiments, that is to say, the examples provided to the LLMs is just in English and Portuguese. The model receives input which consists of text containing an MWE, along with the MWE itself. We prompt the model to generate a label, either 'idiom' or 'literal', in response to the question, 'Is the multiword expression [MWE] an idiom or literal in this sentence?'. The three base prompts previously mentioned are used to generate answers from each model. The results of these experiments are presented in Table 1 and Table 2.

4.4 Synthetic MWE Interpretation Task

The objective of the synthetic MWE experiments is to assess whether providing additional information in the prompt can improve model performance.

[4] https://platform.openai.com/docs/guides/prompt-engineering/six-strategies-for-getting-better-results

[5] https://github.com/francesita/CS-and-Multilingual-MWEs

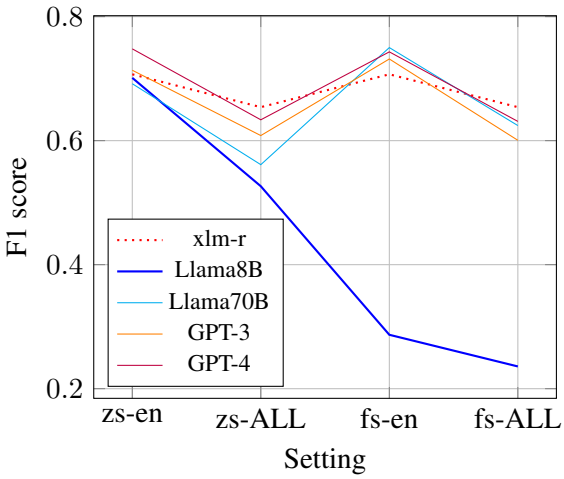

Figure 1: F1 scores for each model using the original SemEval task 2 dataset. This graph shows the F1 score for the English language subset of the dataset, as well as the total macro F1 score for all languages combined in the zero-shot (zs) and few-shot settings (fs).

We specifically aim to test whether models can understand nuanced language when given more context. This approach is based on (Eisenschlos et al., 2023), where synthetic words were introduced and defined as existing concepts to evaluate an LLM's ability to learn new vocabulary through prompting. It is likely that an LLM has not encountered all the MWEs in our datasets, particularly those in Portuguese and Galician. Therefore, it is important to evaluate whether a model can acquire knowledge of new words or MWEs through prompt-based learning. To investigate this, we use the development set of subtask a, which includes examples in English and Portuguese (but not in Galician), and replace the MWEs in each example with synthetic ones. The model is prompted using the same three base prompts from the MWE interpretation experiments, with an added definition for the synthetic MWE, taken from the original MWE it replaced. The results of these experiments are shown in Table 5.

4.5 MWE Paraphrase Similarity Task

As part of this work, we aim to evaluate the ability of LLMs to understand the meaning of text containing MWEs. We provide each model with sentence pairs: some include an MWE, while others contain correct or incorrect paraphrases of MWEs. To run these experiments, we adapt *subtask b* from the SemEval Task 2 competition, which was originally designed as a STS task. We construct three distinct prompts, as described in Section 4.2, each

Model	F-1 Score EN	F-1 Score PT	F-1 Score GL	F-1 Score ALL	Code-switched

asking the model if the two sentences have similar meanings. Each prompt notes that some sentences may include MWEs used idiomatically. The model is instructed to output 'true' if the sentences are similar in meaning and 'false' if they differ, turning the task into a binary classification problem. These experiments are conducted in both zero-shot and few-shot settings. We use the development split of *subtask b* from the original SemEval competition, which contains examples in English and Portuguese only. This dataset includes sentence pairs with MWEs and their paraphrases, as well as examples from a standard STS benchmark. The gold labels in the dataset are either a Spearman rank correlation score (for STS benchmark examples), a score of 1 (for identical meanings), or a label of NONE (for differing meanings). After adapting the task and removing examples with similarity scores other than 1 or NONE, we retained 974 examples: 521 in English and 454 in Portuguese. Since the task requires binary outputs, we exclude all examples with a Spearman score other than 1 and use only examples labelled as 1 (similar) or NONE (not similar). This required access to the gold labels, and as a result, we were unable to use the original competition evaluator, which assumes unmodified scoring. In addition to testing on the original development data, we run experiments on our generated CS examples, where each language is mixed with Spanish. The results for these experiments are shown in Table 3 and Table 4. We also experiment with the same dataset used for the semantic task. We substitute the real MWEs in each example with a synthetic MWE and supply the model with the original MWE's definition as the meaning of the synthetic one. The results of these experiments are on Table 6.

5 Results and Discussion

Are LLMs effective in interpreting idiomatic MWEs? In general, LLM abilities in detecting idiomatic expressions fall short of smaller fine-tuned PLMs. This is especially true for Galician and Portuguese experiments using the original dataset. Given that most of these models are predominantly trained on English data, it is unsurprising that they

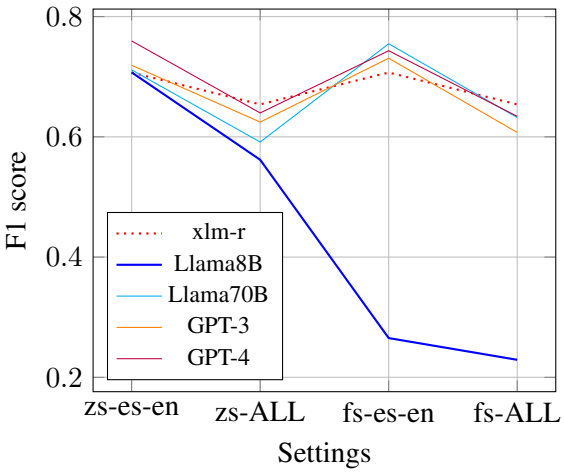

Figure 2: F1 scores for each model using the CS dataset. This graph shows the F1 score for the Spanish-English (es-en) language subset of the dataset, as well as the total macro F1 score for all CS examples combined in the zero-shot (zs) and few-shot (fs) settings.

perform best on the English portion of the dataset, with most models reaching an F1 score of 0.70+ in the zero-shot and few-shot settings. Interestingly, the overall macro F1 score shows a slight improvement for all models in the CS experiments. This improvement is likely due to the inclusion of Spanish in all examples, a language that is likely more prevalent in the pre-training data compared to Galician and Portuguese. Some models exceed xlm-roBERTa's F1 score for the English partition of the data, 0.7070, but none are able to reach a score higher than 0.76. However, all models fall short of the baseline for Portuguese, 0.6803, and the overall F1 score, 0.6540, when compared to a fine-tuned xlm-RoBERTa-base model in both zero-shot and few-shot settings. Notably, the Llama3-8B-instruct model failed to produce valid outputs in the few-shot setting for both the original and CS datasets. It seems that the combination of few-shot examples along with the input text confounded the model, to the degree that most of the model outputs were not a single word answer containing the label. Figures 1 and 2 demonstrate how Llama3-8B struggled in few-shot experiments, evidenced by the high variance in the scores in the three prompts used to generate model output. Although LLMs have been competitive in detecting nuanced language when compared to a much smaller PLM, in general, they struggle in the other lower-resourced languages.

To what extent do LLMs capture the non-compositional meanings of MWEs? LLMs seem to struggle to capture the meaning of text containing MWEs. In general, unlike in the MWE interpretation task, the few-shot examples here helped most models reach higher F1 scores for both Portuguese and English text. GPT-4 was able to perform comparably to the xlm-roBERTa baseline for English in the few-shot setting, with a score of 0.7638, marginally beating xlm-roBERTa's score of 0.7590. All models fall short of the combined baseline score and F1 score in Portuguese in zero-shot and few-shot settings. This may indicate that models are not capturing the true meaning of text containing MWEs and may be relying on spurious correlations to make decisions. Overall, LLMs appear to struggle with nuanced language, as they often fail to outperform a much smaller fine-tuned PLM.

What is the impact of providing information in the prompt? The results indicate LLMs generally perform above random on synthetic MWE interpretation task, were we provided the definition of the MWE in the prompt, with GPT-4 achieving the highest combined F1 score of 0.6392. However, their performance is notably lower compared to when real MWEs are used. This suggests that models may have memorised some real MWEs during training. For the *semantic experiments* involving synthetic MWEs, model performance remains close to the random baseline. Across all languages, GPT-3 achieves the highest scores, 0.5444, but these results still do not significantly exceed the random baseline of 0.5025. This demonstrates that providing additional information in the prompt does not improve model performance when the vocabulary differs from patterns encountered during pre-training. The models appear to rely heavily on statistical patterns from pre-training data, and when faced with unfamiliar patterns, they fail to generate correct responses, even with contextual cues. Overall, the models have difficulty applying the meanings of synthetic MWEs to complete the task, suggesting that additional context does not help them address complex linguistic issues or unfamiliar vocabulary.

Is there a relationship between LLM size and performance on text containing non-compositional phrases? The smaller Llama 8B model performed unexpectedly well on the zero-

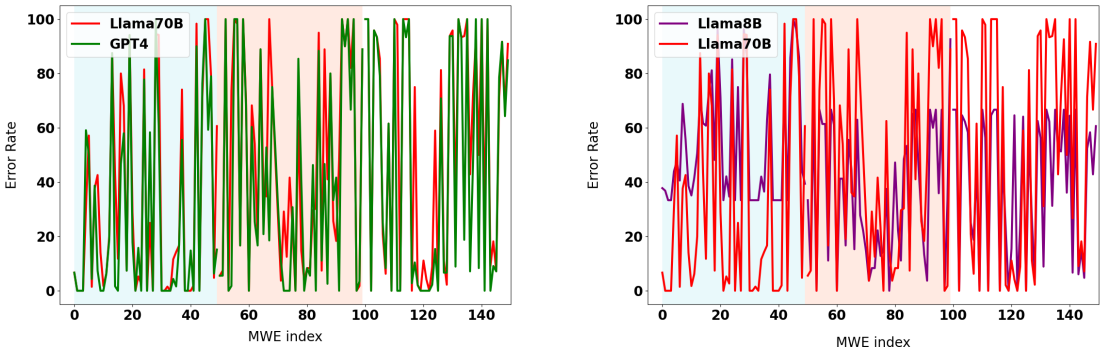

Figure 3: The error rates of all MWEs in the test set. These are in alphabetical order per language. The MWEs in English are in the light blue background, Portuguese are in the light orange background and Galician are in a white background. The figure on the left show the errors for LLama 70B and GPT-4 and the figure on the right shows the errors for the Llama 70B and Llama 8B.

shot detection task, achieving results comparable to Llama 70B and GPT-3 for English text. However, it showed a slight decline in performance for Portuguese and Galician. Notably, the Llama 8B model was unable to process both the original text as well as the CS text in the few-shot detection task and was more sensitive to prompting than the other models, evidenced by the high standard deviation seen in Table 2. GPT-4 outperformed other LLMs in English for the semantic task and was the only LLM capable of handling English-Spanish CS text in this context. While further experiments are necessary, these findings suggest that a smaller model, like Llama 8B, may suffice to achieve results comparable to much larger models for MWE detection in English. However, the results also show that GPT-4 is better than other models when confronted with unknown vocabulary and representing the semantics of MWEs compared to the other LLMs.

5.1 Error Analysis

Certain MWEs were consistently classified correctly by all models when using the original dataset for the MWE interpretation task, as detailed in the project GitHub. Figures 1 and 2 illustrate the sensitivity of models to different prompts. Notably, the standard deviations, especially for Llama 8B, show how different some model outputs may be depending on the prompt. A subset of MWEs was correctly classified by all models in the detection task, which are also available in the project GitHub. It lists correctly identified MWEs by all models, those correctly classified by specific model families, and the overlap between the two largest models. We also examined correlations between the error rates of individual MWEs across models. There is a moderate correlation of 0.64 between the error rates of Llama models, and a strong correlation of 0.70 between Llama 70B and GPT-4. However, the correlation between the two GPT models is weaker, at 0.32, possibly indicating differences in their training data. Figure 3 shows the errors between Llama 70B and GPT-4 as well as the two Llama models. The curves are overlaid for comparison. The strong correlation in errors between certain models may indicate shared limitations in tasks requiring nuanced language understanding, potentially stemming from their architectural design or training data.

6 Conclusion

This study examined whether state-of-the-art LLMs can detect and represent nuanced language, focusing on MWEs in English, Portuguese, Galician, and code-switched text. Despite their scale, LLMs struggle with MWEs—especially in non-English contexts—and often underperform compared to smaller fine-tuned PLMs. While code-switching supports metalinguistic tasks, it appears to hinder semantic representation. Models are better at detecting idiomatic usage than capturing meaning, highlighting ongoing limitations in handling complex language. Future work should prioritise open models with improved semantic understanding in multilingual and code-switched settings.

Abstract

Our study addresses domain-specific text provenance classification for the historical *Church Slavic* language. The downstream task is to attribute the language stage and its dialectal and regional varieties to texts compiled from newly curated sources, including digitally unpublished manuscripts, in addition to established Church Slavic resources from the Universal Dependencies Treebank. We aim to harmonize previously used tag sets pertaining to textual provenance, and construct a new, hierarchical, multi-layer provenance labeling scheme. For the classification task, we finetune Vikhr (Nikolich et al., 2024), a generative LLM with knowledge of modern Russian, with the instruction to generate labels to classify the provenance of sentence-level text units. Besides gold standard manuscript transcriptions, we test the finetuned model on character-corrupted data that emulate the quality of noisy, handwritten text recognition material. The experiments show that the Vikhr base model has low provenance attribution knowledge of Church Slavic, whereas our finetuned model achieves above .9 F-scores on Language stage labeling and Dialect labeling, and above .8 F-score on generating the label that jointly classifies all three provenance layers. The task of classifying the fine-grained geographical region from which a manuscript originates proves harder (but still performs above .8), and is negatively impacted by character level noise injection.

1 Introduction

In recent years, transformer-based large language models (LLMs) have achieved notable success in a variety of natural language processing (NLP) tasks. However, their application to historical and low-resource languages remains severely limited. For Church Slavic — a historical liturgical language used across Slavic territories from the 9th century onward — the development of reliable NLP tools is hindered by the scarcity of digitized, annotated training data expressing its complex diachronic and regional variation. Moreover, human expertise in historical Slavic linguistics is scarce, making the compilation of high-quality annotations and evaluation benchmarks especially challenging.

A recent study on the Dead Sea Scrolls (Popović et al., 2025) vividly demonstrates how curated data combined with AI methods can lead to paradigm-shifting results in the interpretation of historical texts. Earlier work in NLP on chronological attribution of texts with deep learning methods for historical languages include Assael et al. (2019); Liebeskind and Liebeskind (2020).

Two major historical Slavic variants are increasingly visible in the NLP landscape: Old Church Slavic (ISO 639-3 code: `chu`) and Old East Slavic (`orv`). These variants are represented in resources such as the Universal Dependencies (UD) Treebank (Nivre et al., 2020) and integrated into toolkits such as Stanza (Qi et al., 2020) or UDPipe (Straka, 2018). Despite these initial efforts, substantial barriers remain. LLM tokenizers and embedding models trained on contemporary languages fail to handle Church Slavic adequately, e.g. they produce large quantities of character-level tokens, or oddly split sentences. As shown in the recent SIGTyp shared task (Dereza et al., 2024), successful systems needed custom tokenizers and embeddings.

Church Slavic was artificially developed during the christianization of the Slavs, primarily for translating Byzantine Greek religious texts. For the history of the Slavic written heritage see Marti (1989); Birnbaum and Schaeken (1999); Trunte (2014). It retained strong influence from its Greek source texts in terms of both syntactic structures and vocabulary. Church Slavic underwent con-

Proceedings of Recent Advances in Natural Language Processing,pages 654–662

https://doi.org/10.26615/978-954-452-098-4-076

tinuous evolution in lexicon and morphosyntax. This occurred due to both the natural divergence of Slavic dialects into distinct modern languages as well as manuscript copying—introducing both intentional editorial revisions and unintentional scribal errors. The result is a large body of text material transmitted through manuscripts that exhibit extensive orthographic, lexical, and structural variation.

Challenges and our Contributions We address three core challenges in this domain and describe our respective contributions.

(1) First, reliable supervised classification requires labeled ground truth data for the *initial* geographical provenance and temporal context of texts, but such metadata is often missing or is not consistent. For example, in the Universal Dependencies repository, there is the PROIEL dataset[1] for `chu` and the TOROT dataset[2] for `orv`. However, the texts labeled by the language code `orv` in fact cover seven language variants: (i) the *vernacular* texts are written in *Old East Slavic* (traditionally called *Old Russian*) as well as in *Middle Russian*, *Old Novgorodian* and *Ruthenian*; (ii) the *religious* texts pertain to different transmitted language variants (so-called *recensions*) in *East Slavic* and in *Russian*, but also encompass canonical *Old Church Slavic* (cf. the text listed in the Syntacticus treebank[3]).

Furthermore, currently there is a metadata interoperability issue: the labels for language or dialect names that pertain to Church Slavic are ambiguous both within and across communities of Philology, Digital Humanities, and NLP. E.g., a specific Church Slavic language stage can be referenced by diverse terms which are often interchangeably used in the literature; cf. e.g. Keipert (2014). There is also granularity inconsistency in such metadata, where macro- and micro levels of temporal or regional designations or specifications are occasionally mixed; e.g. *Serbian Church Slavic* vs. *Church Slavic, Southern recension* vs. *Church Slavic, Serbian recension* may label one and the same text type. As a result, it is not transparent how the different (named or unnamed) constraints split these groups of related historical languages, and whether Church Slavic temporal pairs or variants or dialects have been or can be fully represented in a consolidated metadata scheme.

To overcome such ambiguity, we establish and uniformly apply three hierarchical levels of metadata for the provenance labeling task at hand: Language stage, Dialect, and Region (cf. Figure 1), and map the available manuscript provenance information for the collections at hand to these axes. Such metadata clarity is of additional importance in generative techniques, so that label attribution techniques can keep apart the category names. This labeling method serves as an operational classification framework for the development and evaluation of automated attribution techniques, without challenging (established) Slavicist research terminologies or existing scholarly positions on dialectal boundaries and periodizations.

(2) Second, reuse of textual material without explicit annotation across manuscripts, including quotations from older sources or from other recensions, is a common phenomenon in historical texts. This practice makes it difficult to track text reuse, and to determine whether it applies at the paragraph, sentence, or sub-sentential level, which remains an open problem. NLP-based provenance attribution of Church Slavic texts has so far been scarcely covered, a.o. addressed in our previous studies (Lendvai et al., 2023, 2025). In the current study, our approach to provenance classification is to recast it as a label generation task, via performing systematic instruction finetuning of *Vikhr* (Nikolich et al., 2024), an open-source, bilingual, instruction-tuned, dense, decoder-only Large Language Model (LLM). The model we used had been built upon the *LlamaForCausalLM* architecture that underwent continued pretraining on modern Russian and English instruction data, enhancing the model's ability to follow instructions effectively. Its *SentencePiece* tokenizer also underwent adaptations to better support the modern Russian language. In our experiments, after our instruction finetuning (IFT) process, we used the IFTed model for our downstream task of provenance attribution: the labeling of 11 variants of Church Slavic on the sentence level.

(3) Third, morphological complexity and orthographic variability of Church Slavic, e.g., due to multiple legitimate grapheme variants for a single phoneme or morpheme, introduces a high level of language data sparsity for our applied end task. To-

[2] https://github.com/UniversalDependencies/UD_Old_East_Slavic-TOROT

[3] https://github.com/syntacticus/syntacticus-treebank-data/tree/main/torot

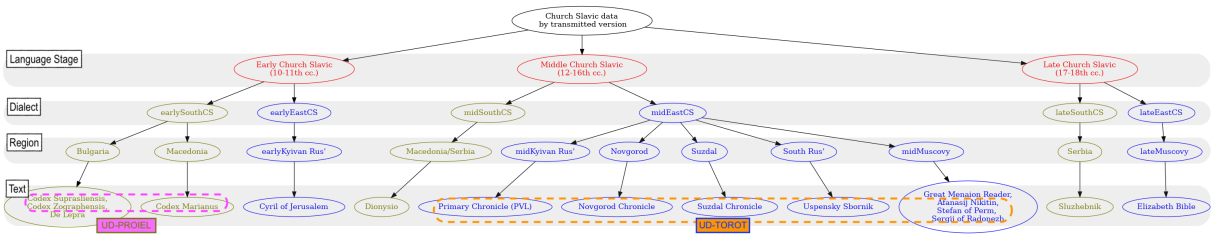

Figure 1: Our newly constructed, hierarchical text labeling scheme. Its three layers represent Language stage (Early, Middle, Late), Dialect (South, East), and Region of manuscript provenance (Bulgaria, Macedonia, Kyivan Rus', Macedonia/Serbia, Novgorod, Suzdal, South Rus', Muscovy, Serbia). 11 leaf nodes hold the names of manuscripts where our data originate from. Dashed areas delimit data from two benchmark collections of the Universal Dependencies (UD) Treebank: UD-PROIEL (pink) and UD-TOROT (orange).

kens often appear in many low-frequency forms that may be philologically correct but computationally problematic for data-driven methods. Attempts to normalize such variation are fraught with trade-offs: normalization may obscure important orthographic signals that are valuable for identifying linguistic trends or regional features. In addition, handwritten text recognition (HTR), the method used to digitize large volumes of source material, introduces further character- or token-level variation due to recognition errors. To account for noise in the data, we artificially emulated HTR errors to test our classification approach on data resembling HTR-induced noise, inspired by a character-level data corruption technique described in Aepli and Sennrich (2022).

2 Data and Labeling

Our data come from both online and so far unreleased historical Church Slavic texts. We mapped existing provenance metadata of our texts to three layers of a newly created, hierarchical provenance scheme, cf. Figure 1):

1. Language Stage (Early, Middle, Late)
2. Dialect, defined by the spreading of Church Slavic, resulting in local recensions (South, East)
3. Region, i.e. country or culturally distinct geographical space (Bulgaria, Macedonia, etc.).

We note that the availability of provenance information is such that these metadata typically designate values tied to the place where the text/collection had been *copied*, i.e., they may not disclose provenance beyond that, potentially obscuring cases when e.g. an older text was verbatim copied over from a source that was created at a different region and likely at another language stage.

The data are compiled from 16 different text collections or manuscripts (see the leaf nodes of the labeling scheme), which are as follows:

- Early Church Slavic language stage
  - The *earlySouthCS* texts come from the PROIEL UD Treebank: Codex Suprasliensis and Codex Zographensis (region of origin: Bulgaria), Codex Marianus (region: Macedonia), except for *De Lepra* (Jouravel et al., 2024) (region: Bulgaria).
  - The *earlyEastCS* Cyril of Jerusalem[4] comes from our own corpus (region of origin: Early Kyivan Rus').
- Middle Church Slavic language stage
  - The *midSouthCS* Dionysio corpus comes from the Digital Archive of the University of Kragujevac[5] (region of origin: Macedonia/Serbia)
  - The *midEastCS* texts come from the TOROT UD Treebank and originate from the Middle-stage Kyivan Rus' (Primary Chronicle), from Novgorod (Novgorod Chronicle) from Suzdal (Suzdal Chronicle), from the South of Rus' (Uspensky Sbornik), from Muscovy (Journey of Afanasij Nikitin, resp. Life of Stefan of Perm, resp. Life of Sergij of Radonezh), and from our in-house corpus of the *Great Menaion Reader (GMR)*[6], where we sampled data from its

Table 1: Input data statistics: sentence snippets by text, as well as mean snippet length (in tokens) and total tokens by partition for the instruction finetuning task (using the train and dev sets) as well as for the provenance attribution task (using the test set).

Uspensky version, March section texts (region: Muscovy).

- Late Church Slavic language stage
  - The *lateSouthCS* texts comprise the Sluzhebnik[7] (region of origin: Serbia)
  - The *lateEastCS* texts come from the Elizabeth Bible[8] (region: Muscovy).

Text segmentation into sentences was done the following way. For PROIEL and TOROT data, we took over the sentence boundaries that were present in CONLL-U format. On the remaining texts we uniformly used the Old Church Slavic sentence model of Stanza (Qi et al., 2020). We refer to the resulting units as *text snippets*, and use this term uniformly throughout the paper for all datasets. The segmentation of texts for downstream analysis is particularly challenging due to the use of *scriptura continua*, a writing style without whitespace between words that characterizes many of the manuscripts in our dataset. Additionally, the lack of systematic punctuation makes establishing ground truth sentence boundaries in Church Slavic disputable.

For data partitioning, we took over the given splits from the UD treebanks for PROIEL and TOROT data. For all other sources we randomly selected 10,000 sentences, and split them into train/development/test sets by the ratio 80/10/10.

For detailed data statistics see Table 1, where word counts and mean snippet lengths are given per partition and dataset. For snippet length distributions in terms of probability density curves, comparable per partition in each data subset, see the Appendix[9].

3 Method

Our labeling of texts is regarded as Ground Truth (GT) provenance classification data for the current study. Since the text transcripts had been manually created, these are also of GT quality.

3.1 Instruction Finetuning (IFT)

For the downstream tasks of joint language, dialect, and region labeling of text snippets, we adapted the LLM *VikhrmodelsVikhr-7B-instruct_0.2* (Nikolich et al., 2024) by means of instruction finetuning (IFT), cf. Ouyang et al. (2022). For IFT we defined the system prompt as follows:

> "You are a historical linguist who can differentiate three stages of Church Slavic: Early, Middle, Late, and their respective regional dialects. You can reproduce the type of orthographic, grammatical, and lexical variation that is characteristic for specific cultural-geographical areas for all these variations of Church Slavic.".

We maintained the instruction–output pair format during training, for which we constructed the user prompt for each snippet from the following text template:

> "You will see a text. Identify its Church Slavic language stage, regional dialect, and the historical geographic-cultural area where the text was written. Attribute one of the following labels to

[7] https://lib-fond.ru/lib-rgb/256/f-256-401

[8] https://en.wikipedia.org/wiki/Elizabeth_Bible

[9] https://github.com/pirolen/ranlp2025-churchslavic-ift/#sentence-length-distributions

identify the language and regional origin of the text: *LABELSET*. This is the sentence to be annotated: *TEXT*"

TEXT is to be replaced with the respective text snippet to be classified. *LABELSET* is to be replaced by the list of 11 labels comprising all available language-dialect-region combinations and serves to constrain the model to behave like a classifier with a closed answer vocabulary:

1. Language stage (3 classes: Early, Middle, Late)
2. Dialect (2 classes: South, East)
3. Region (9 classes: Bulgaria, Macedonia, Kyivan Rus', Macedonia/Serbia, Novgorod, Suzdal, South Rus', Muscovy, Serbia)
4. Language stage and Dialect jointly (6 classes: Early South, Early East, etc.)
5. Language stage, Dialect, and Region jointly (11 classes: Early South Bulgaria, Early South Macedonia, etc.).

The *Vikhr-7B-instruct_0.2* tokenizer was initialized with maximum length 1024 and left-padding, using the *bos* token as *pad* token.

IFT was realised by means of parameter efficient fine tuning (PEFT) based on low-rank adaptation (LoRA). LoRA was applied with task type *Causal LM* on the following modules: *q_proj, k_proj, v_proj, o_proj, gate_proj, up_proj, down_proj* and *lm_head*. The rank was set to 32, alpha to 64, and the dropout to .05. For IFT we used paged AdamW 8 bit optimization with an initial learning rate of $2.5e-5$. Cross entropy loss was used as the metric to be minimized. Batch size was set to 8, the number of finetuning steps to 10,000.

3.2 Evaluation

We evaluated model performance in terms of the F1-score metric on the gold label compared to the generated label. The labels were generated as follows. After IFT, we selected the checkpoint that performed best on the development set in terms of minimum loss. Using cross entropy loss for this purpose was motivated by training a generative model that can output a (theoretically) unconstrained stream of natural language from its multilingual token vocabulary, especially in initial training cycles, while the label set that should classify Church Slavic sentence snippets comprise a finite set of English words. This means that not all types of mismatches between gold and generated labels could be meaningfully expressed in terms of F1 during instruction finetuning.

On both the clean and the corrupted test set dataset, we applied both the base LLM *Vikhr-base*[10] as well as the finetuned LLM *Vikhr-IFTed*; meaning that – in separate experiments — the vanilla Vikhr resp. the selected checkpoint of *Vikhr-IFTed* was used for generating the labels for the held out test set, using the same system and user prompt templates as for IFT (cf. Section 3.1). Generation was configured with greedy decoding and a maximum number of 100 new tokens.

Testing on noise injected data Aepli and Sennrich (2022) introduced a character-level data corruption technique that helped LLM tokenizers to be more robust towards spelling variations, such as character substitutions, insertions, and deletions, inspired by previous work on surface-level noise injection that was found to improve e.g. machine translation. Note that whereas Aepli and Sennrich (2022) set corruption values between 10%-15%, Blaschke et al. (2023) systematically explored a range of noise injection rates for a large amount of language pairs, including dialects, and found that increasing the noise level from 0% to 15% improves embedding-based models' robustness on part-of-speech tagging.

Although for a different end task, we adopted this method to emulate HTR quality data. In the test phase, we injected character-level noise for the same snippets that were used as GT test data. It was not an option to use real HTR data, since reproducing the exact same snippet segments on actual HTR data would have required significant manual work. Corruption ratio was set to affect 15% of a snippet's characters. Contrary to the above studies where random characters were added as noise, we introduced specific types of errors that we previously observed HTR systems to produce.

Corruption operations were the following:

1. Delete a correct whitespace
2. Insert a false whitespace
3. Substitute a character with an random, but phonetically equivalent grapheme, based on an internally compiled grapheme correspondence table of Church Slavic variants.

4 Results

4.1 Quantitative Analysis

Table 2 shows the Unweighted Average F1 scores for the base model and the finetuned model on the clean and the noisy test set variants for the three individual classification tasks: *Language Stage*, *Dialect*, *Region*; and task combinations: *Language Stage* + *Dialect* jointly and *Language Stage* + *Dialect* + *Region* jointly. For language, dialect and region evaluation we compared the corresponding parts of the reference and answer labels, respectively.

We report Precision, Recall, and F-scores for each task separately in the Appendix[11]. Confusion matrices for the finetuned model on the ground truth ('clean') test set and on the noisy set are also shown in the Appendix[12].

Classification is highest (.98) for the tasks of Language Stage and Dialect, as well as their combination (.97). On the Region task, the lower F-score (.82) originates in confusing Early Church Slavic texts from Macedonia with Bulgaria, resp. Middle Church Slavic texts from Kyivan Rus' with Muscovy.[13] Note that that Language stage property within the Region task is only discernable from the confusion matrix of the full label generation[14]. This plot shows that the largest group of misclassifications (in total 287 data points) is observed for Middle Church Slavic, Eastern dialect, Suzdal region, from where only a small amount of ground truth data was available.

These confusion trends get more prominent on the noisy data, also impacting the fully combined label that incorporates all three annotation layers (.846 F on clean data vs. .659 on noisy data). The difference between these scores may indicate that character level noise injection is not beneficial for historical language variant identification for our specific languages at hand. In Church Slavic historical texts, character variation is by definition high; these variations typically encode characteristic writing styles or morphological features that can be important cues in classification. It remains to be manually verified to what extent texts from these confusion regions exhibit cross-fertilization, i.e. whether the causes of these confusions are due to the practice of text reuse and borrowing.

Task	Vikhr–base		Vikhr–IFTed	
	clean	noisy	clean	noisy
Language Stage (LS)	.210	.230	.985	.958
Dialect (D)	.380	.380	.972	.908
Region (R)	.065	.074	.828	.644
LS + D	.042	.051	.949	.862
LS + D + R	.026	.030	.846	.659
# Fail	0	0	1	6

Table 2: Unweighted average F1 scores by the **Vikhr-base** and **Vikhr-instruction-finetuned (IFTed)** models on the clean and noisy (character-corrupted) test sets for the classification tasks per labeling components: *Language Stage*, *Dialect*, *Region*, *Language Stage* + *Dialect* jointly, and *Language Stage* + *Dialect* + *Region* jointly. *# Fail* gives the absolute number of times the models fail to answer.

In the test set, the mean length of misclassified snippets is 10 words and in correctly classified snippets 12 words. Both averages are in line with the distribution of UD treebank data values, cf. Figure 1 as well as the Appendix[15]; yet, shorter snippets are likely more difficult to correctly classify.

4.2 Philological Interpretation

Even though the snippets often exhibit characteristic elements that indicate temporal-regional origin, *Vikhr–IFTed* was not always able to adequately classify these according to the gold standard labels. Remarkably, frequent errors involve contexts where transmission history blurs linguistic borders, pertaining to canonically shared texts and formulaic passages. Such borderline cases often expose scribal convergence zones or genuinely ambiguous segments.

Frequent confusions occur between Early Church Slavic, Southern dialect, Macedonia region and vs. its Bulgaria region, in both directions. Since all the Early Church Slavic, Southern dialect data in this study (except for the later treatise *De lepra*) belong to the Old (i.e., Early) Church Slavic canon, where canon membership is defined by linguistic features, the texts naturally exhibit similar characteristics. Furthermore, *Codex Zographensis* and *Codex Marianus* are essen-

[15] https://github.com/pirolen/ranlp2025-churchslavic-ift/#sentence-length-distributions

tially versions of the same text, i.e. (incomplete) Tetraevangelia. Aside from easily confusable Bible-based sequences such as Пилатъ же посѫди бъıти прошение ихъ, these manuscripts also contain many formulaic expressions or collocations that may appear in any text, including much later ones, such as азъ есмъ, і г҃лаахѫ or рече же и дроугъı.

In some cases, snippets are likely difficult to analyze, e.g. because they are too short to contain forms that can be reliably assigned to a particular region or period: e.g., characteristic forms are entirely absent, making the snippet generally compatible with any of the labels. For example, the snippet что во имоуть зазь contains a word segmentation error, likely caused by a false line break or other segmentation issue in the data: the word зазь is incomplete and appears to be only the first part of the lexeme зазьрѣти or зазьдати. Snippets that are too short or lack diagnostic dialectal features include и рече имъ or писано во естъ, both gold labeled as Early Church Slavic, Southern dialect, Macedonia region and misclassified as Middle Church Slavic, Eastern dialect, Kyivan Rus' region.

In other cases, misclassifications could be comprehensible. For instance, in the snippet дъждь во на роуно сьхода (gold label: Early Church Slavic, Eastern dialect, Kyivan Rus' region) was falsely attributed to Early Church Slavic, Southern dialect, Bulgaria region. Here, the lexeme дъждь (Uspenskij, 2002), could be confusing, tokenized as _д|ъ|ж|дь, where the reduced vowel -ъ- is not realized as -о- (see above). This notation is typically attested in manuscripts of South Slavic provenance including Early Church Slavic (cf. Kurz (1958) [SJS]), but also appears in Middle Church Slavic, Eastern dialect manuscripts such as the *Uspenskij Sbornik* or the *Novgorod chronicle*.

An example of an East Slavic text misclassified as South Slavic is the snippet єтєроу оухъ мнѣ ꙗко погыбє доброговѣние отъ зємла и оуправашталаго въ ѵлѣцѣхь нѣсть (gold label: Early Church Slavic, Eastern dialect, Kyivan Rus' region, i.e., attested in the *Cyril of Jerusalem* dataset), which was confused with Early Church Slavic, Southern dialect, Bulgaria region. Here, the participle оуправашталаго has a typical South Slavic adjectival ending -алго (East Slavic: -ого, cf. Uspenskij (2002), pp. 207–208) and the *l-epentheticum* is omitted (cf. Diels (1932), p. 131; Chaburgaev (1974), p. 104; Krivko (2016), pp. 132-137), which points to the text's South Slavic and especially Bulgarian region provenance. Furthermore, the lexeme доброговѣние is attested only in the Bulgarian-origin *Codex Suprasliensis*, besides its occurrence in the *Cyril of Jerusalem* dataset. We note that the model's tokenizer splits up the morphological components that could have served as cues, obscuring information that could be key to provenance assignment: _о|ꙋ|правь|ша|а|го resp. _добро|гов|ѣ|ни|ѥ, whereby the iotized graphemes ѧ and ѥ are additionally split into two.

The snippet Сѐ а҆зъ даю҆ пре҆д҆ ва́ми дне́сь бла҆г҆ве́нїе и҆кла́тво҆ [...] (gold label: Late Church Slavic, Eastern dialect, Muscovy region), which holds characteristic morphological features such as the first person singular personal ending –ю (as in даю; заповѣдаю; молю) that support East Slavic origin (vs. South Slavic: даѭ, заповѣдаѭ, молѭ, cf. Trunte (2005), p. 113), however, it was misclassified as Late Church Slavic, Southern dialect, Serbia region. Likewise, the snippet кро́вь во є҆гю҆ вмѣ́стѡ дх҃ш҆и о҆у҆мо́литъ (gold label: Late Church Slavic, Eastern dialect, Muscovy region), in which phonological features such as the East Slavic fully vocalized form of reduced vowels in combination with liquids are present (as in кровь, South Slavic: кръв, cf. Uspenskij (2002), pp. 150–155), was labeled as Early Church Slavic, Southern dialect, Bulgaria region.

Conversely, there are cases in which South Slavic texts were incorrectly classified as East Slavic. An example is вѣдѣаше во ѣко зависти ради пр҃ѣдаша і архⷭиереі, (gold label: Early Church Slavic, Southern dialect, Bulgaria region), confused with Middle Church Slavic, Eastern dialect, Muscovy region. The text features the notation ѣко, attested only in Early Church Slavic manuscripts. The snippet и идѫ вы инѫ весь (gold label: Early Church Slavic, Southern dialect, Macedonia region) was misclassified as Middle Church Slavic, Eastern dialect, Novgorod region, despite the typically South Slavic first person singular ending -ѫ in идѫ (East Slavic: идоу, see the converse case above). The cue words are tokenized as ѣ|ко and _и|дѫ.

5 Conclusions

Our goal was to implement a scalable, data-driven investigation of textual provenance in medieval and early modern Slavic texts, performing systematic instruction finetuning of Vikhr (Nikolich et al., 2024), an open-source, bilingual LLM. We cre-

ated annotated data for Church Slavic provenance classification, and showed a methodology for historical text processing in a non-Latin script that can be applied to other low-resource and under-researched languages. Our study demonstrates that instruction finetuning can become a valuable tool for historical linguistics and digital philology, since on the downstream task of provenance attribution the IFTed Vikhr model attained high scores. More research is required to explore the outcome that character level noise injection proved harmful on the task of classifying the fine-grained geographical region from where a specific text originates. The hierarchical annotation scheme we constructed aims to support domain-specific metadata interoperability, and demonstrates the need for upgrading existing Church Slavic benchmarks. In future work we aim to create new datasets, where besides the Church Slavic macrolanguage fine-grained language variety labels, covering dialect, are included.

6 Limitations

On all data, we uniformly used a sentence splitter that was optimized for Old Church Slavic, and did not adapt the Vihkr model's *SentencePiece* tokenizer, meaning that its representations are typically not on the lexical but on the character(-sequence)-level. We are not reporting scores by vanilla LLMs, even though we tested a few of them, since their results are very low, similar to the base Vikhr model. Since we complemented the available UD benchmark data with a (massively downsampled) in-house dataset, the biggest class for the present experiments covers Middle Church Slavic in Eastern dialects. Discrepancies in the size and distribution of the training data across geographical and diachronic labels may play a role in misclassifications, potentially biasing the classification performance of the present model despite distinctive provenance markers that might be present in a text.

7 Ethics Statement

The authors fully acknowledge the ACL Ethics Policy and strongly commit to using their skills for the benefit of society, its members and the environment surrounding them.

Abstract

This study presents a comprehensive evaluation of Large Language Models (LLMs) for automatic term extraction in the maritime safety domain. The research examines the zero-shot performance of seven state-of-the-art LLMs, including both open-source and closed-source models, and investigates terminology annotation strategies for optimal coverage. Nested annotation captures both complete technical expressions and their constituent components, while full-term annotation focuses exclusively on maximal-length terms. Experimental results demonstrate Claude-3.5-Sonnet's superior performance (F1-score of 0.80) in maritime safety terminology extraction, particularly in boundary detection capabilities. Error analysis reveals three primary challenges: distinguishing contextual descriptions from legitimate terminology, handling complex multi-word expressions, and identifying maritime safety operational and navigational terms. Analysis of annotation strategies reveals that the full-term annotation approach achieves 95.24% coverage of unique terms compared to the nested annotation approach. The additional 4.76% of terms identified through nested annotation represents subcomponents of larger technical expressions. These findings advance the understanding of LLMs' capabilities in specialized terminology extraction and provide empirical evidence supporting the sufficiency of full-term annotation for comprehensive terminology coverage in domain-specific applications.

1 Introduction

Maritime safety represents a critical framework governing the world's most international industry - shipping, where preventing loss of life, vessel damage, and marine environmental harm remains paramount. Defined by the International Maritime Organization, it encompasses comprehensive technical regulations spanning vessel construction, navigation systems, crew training, and emergency procedures, all regulated through international conventions like SOLAS[1] and STCW[2]. The automated extraction of this safety-critical terminology presents unique challenges in natural language processing (NLP), particularly due to the domain's distinctive characteristics: multi-word technical expressions, nested terms, context-dependent terms, and hierarchical terminology structures reflecting complex maritime systems. While automatic terminology extraction has advanced in fields such as biomedicine (Kim et al., 2003), computational linguistics (QasemiZadeh and Schumann, 2016), education (Banerjee et al., 2022), power engineering (Ivanović et al., 2022), as well as studies covering corruption, dressage, heart failure and wind energy (Rigouts Terryn et al., 2020), the maritime safety domain remains underexplored, despite its critical role in ensuring global maritime operations.

Automatic term extraction (ATE) is a fundamental natural language processing task that aims to automatically identify domain-specific terms from text corpora (Vivaldi and Rodríguez, 2007). Traditional ATE approaches can be categorized into three main types: linguistic rule-based methods (Frantzi Katerina et al., 2000), statistical methods (Nakagawa and Mori, 2002), and hybrid approaches (Maynard and Ananiadou, 2000; Macken et al., 2013; Cram and Daille, 2016). Recent years have witnessed the emergence of more sophisticated approaches to address the limitations of traditional methods, including topic modeling (Bolshakova et al., 2013), machine learning techniques (Hazem et al., 2020; Rigouts Terryn et al., 2021,

[1]The International Convention for the Safety of Life at Sea, first adopted in 1914 in response to the Titanic disaster, establishes comprehensive standards for merchant ship safety.

[2]The International Convention on Standards of Training, Certification and Watchkeeping for Seafarers, adopted in 1978 and revised in 1995/2010, sets minimum seafarer competency standards to ensure safe and efficient vessel operations.

Proceedings of Recent Advances in Natural Language Processing,pages 663–673
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-077

2022b), and cross-domain and/or cross-lingual transfer learning methods (Tran et al., 2022a,b; Hazem et al., 2022). These approaches have been widely applied to support various downstream tasks, including information retrieval (Peñas et al., 2001), machine translation (Wolf et al., 2011), aspect-based sentiment analysis (De Clercq et al., 2015), ontology building (Iqbal et al., 2017), and translation quality estimation (Yuan et al., 2018).

The advent of Large Language Models (LLMs) has recently revolutionized natural language processing through their remarkable zero-shot and few-shot learning capabilities without extensive training (Agrawal et al., 2022; Kojima et al., 2022; Banerjee et al., 2024). LLMs have demonstrated their superior performance across various specialized tasks, including text classification (Chae and Davidson, 2023), named entity recognition (Wang et al., 2023; Ashok and Lipton, 2023), relation extraction (Zavarella et al., 2024), text augmentation (Yoo et al., 2021), aspect-based sentiment analysis (Simmering and Huoviala, 2023), and information extraction (Wei et al., 2024; Dagdelen et al., 2024).

This raises a compelling question: Can LLMs effectively extract maritime safety terminology in a zero-shot setting, given the domain's complex multi-component terms, nested terms, specialized acronyms, and context-dependent expressions? To answer this question, the present study evaluates the zero-shot performance of state-of-the-art (SOTA) LLMs in maritime safety terminology extraction, focusing on their ability to handle these domain-specific challenges.

2 Related Work

Advances in pre-trained language models have transformed ATE tasks. Early studies focused on fine-tuning BERT and its variants for terminology extraction. For example, Hazem et al. (2020) evaluated BERT-based models in the TermEval 2020 shared task[3], achieving an F1 score of 46.66% for English and 48.15% for French on the heart failure test set with named entities. Similarly, Hazem et al. (2022) investigated cross-lingual and cross-domain transfer learning for ATE tasks with BERT-based models, showing promising improvements in multilingual settings. Domain-specific applications further validated the potential of pre-trained models. Jerdhaf et al. (2022) compared focused terminology extraction models based on KB-BERT (a generalist Swedish pre-trained model) and SweDeClin-BERT (a domain-specific clinical Swedish model) to identify implant terms in medical records, while Tran et al. (2024b) demonstrated that multilingual models using XLMR improved performance when incorporating less resourced languages such as Slovenian into training data.

LLMs' advanced language understanding has revolutionized NLP tasks, including terminology extraction. Giguere and Iankovskaia (2023) provided one of the first systematic evaluations of GPT-4 for domain-specific terminology extraction, demonstrating impressive accuracy scores across legal (0.84), medical (0.78), and technical (0.73) domains, highlighting LLMs' strong generalization capabilities without task-specific training. In a separate investigation, Banerjee et al. (2024) compared GPT-3.5-Turbo with fine-tuned XLM-RoBERTa in few-shot settings, finding GPT-3.5-Turbo outperformed traditional models with as few as five examples, though performance varied by domain.

Research has also explored LLMs' capabilities in multilingual and cross-lingual scenarios. Tran et al. (2025) introduced LlamATE, a prompting-based framework for automatic term extraction with Llama-2-Chat. Their study shows that LlamATE transfers term extraction knowledge across languages, performing on par with monolingual training, especially in related languages like English, French, and Dutch. Additionally, Tran et al. (2024a) evaluated prompting strategies with open- and closed-source LLMs on the ACTER dataset (Rigouts Terryn et al., 2020). While LLMs achieved high recall (up to 79.6% for Dutch), they struggled with precision, particularly in sequence-labeling task, whereas text-extractive and generative formats improved the recall-precision balance.

The evolution of terminology extraction approaches from BERT-based models to LLMs has demonstrated significant advances in cross-domain and multilingual capabilities. This study advances the SOTA in two key aspects: evaluating LLMs' zero-shot performance in maritime safety terminology extraction and analyzing annotation strategies for optimal terminology coverage in this specialized domain. The empirical findings establish benchmarks for maritime safety terminology extraction while offering insights into terminology extraction approaches and annotation practices for domain-specific applications.

3 Corpus Creation

3.1 Annotation scheme

Our annotation scheme followed the ACTER Terminology Annotation Guidelines (Rigouts Terryn, 2021) with domain-specific modifications tailored to maritime safety terminology. The annotation employed the BIO (Beginning, Inside, Outside) (Ramshaw and Marcus, 1995) tagging scheme for sequence labeling, enabling precise identification of term boundaries and multi-word expressions.

Following ACTER's domain- and language-independent classification scheme, terms were categorized into four types based on their lexicon-specificity and domain-specificity characteristics. *Specific Terms* are both lexicon- and domain-specific, representing the strictest definition of maritime safety terminology that requires domain expertise to understand (e.g., *AIS transceiver*, *listening watch*). *Common Terms*, while strongly domain-related, are not highly lexicon-specific, indicating terms that are crucial to maritime safety but may be understood by non-experts (e.g., *lookout*, *crew*). *Out-of-Domain Terms* (OOD Terms) are lexicon-specific but not domain-specific, encompassing technical terminology from related fields that appears in maritime safety documentation (e.g., *differential GPS*, *cognitive tunnelling*). *Named Entities* represent proper names of vessels, organizations, locations, and other domain-relevant proper nouns, which are frequently encountered in the maritime safety domain (e.g., *Port Adelaide*, *Australian Maritime Safety Authority*).

3.2 Gold standard dataset

The gold standard dataset derives from a systematically annotated corpus based on a maritime accident investigation report[4], comprising 10,690 tokens. Manual annotation of this corpus yielded 1,558 term instances, which resolve to 424 unique terms distributed across four categories based on the established annotation scheme. As detailed in Table 1, Common Terms constitute the largest portion at 46.60% of all instances, followed by Specific Terms (31.51%), Named Entities (20.47%), and OOD Terms (1.41%), reflecting the terminological composition of maritime safety documentation. The notably high repetition rates for the primary maritime safety terminology categories (ranging from 64.77% to 79.62%) reflect the standardized nature of maritime safety communication, while the markedly lower repetition of Out-of-Domain Terms (18.18%) suggests their peripheral role in maritime accident reporting.

Term Type	Total	Unique	Repetition (%)
Common Terms	726	168	76.86
Specific Terms	491	173	64.77
Named Entities	319	65	79.62
OOD Terms	22	18	18.18
Total	1,558	424	72.79

Table 1: Term distribution of the gold standard.

The annotation process employed a two-phase approach. The initial phase involved nested annotation, which identifies hierarchical relationships within complex maritime safety terms. For instance, in the term *bridge navigational watch alarm system*, both the complete term and its constituent components *bridge*, *watch*, and *watch alarm system* were annotated as valid terms, indicating their hierarchical relationship. The subsequent phase transformed nested annotation into a full-term format, focusing exclusively on the maximal-length terms while excluding shorter terms nested within them. For example, given *starboard bridge wing*, the full-term annotation retains only this complete term, excluding nested terms such as *starboard* and *bridge* within the larger term.

3.3 Inter-annotator agreement evaluation

The inter-annotator agreement evaluation was conducted between two annotators: a maritime language specialist and an annotation-trained linguistics researcher who performed their annotations independently. The assessment of both annotation strategies evaluated agreement using Cohen's Kappa (Cohen, 1960) for measuring categorical agreement between two raters, and Krippendorff's Alpha (Krippendorff, 2018) for assessing reliability with multiple coders, as presented in Table 2.

The results demonstrate consistently strong agreement across both annotation approaches, with the full-term approach showing marginally higher agreement across all metrics. The confusion matrix

[4]Unlabeled text selected from a marine accident investigation report by the Australian Transport Safety Bureau (ATSB). This type of report was selected because marine accident investigation reports document safety incidents and provide comprehensive descriptions of maritime safety systems, operational procedures, and regulatory frameworks governed by international conventions such as SOLAS and STCW. https://www.atsb.gov.au/sites/default/files/media/5780376/mo-2020-001-final.pdf

Metric	Nested	Full-term	Difference
Cohen's Kappa	0.7207	0.7250	+0.0043
Krippendorff's Alpha	0.7463	0.7466	+0.0003

Table 2: Inter-annotator agreement comparison between nested and full-term annotation approaches

visualization (Figure 1) provides detailed insights into annotation patterns for the full-term approach, revealing strong agreement in term identification with 1,154 matching B-tag annotations and 441 matching I-tag annotations.

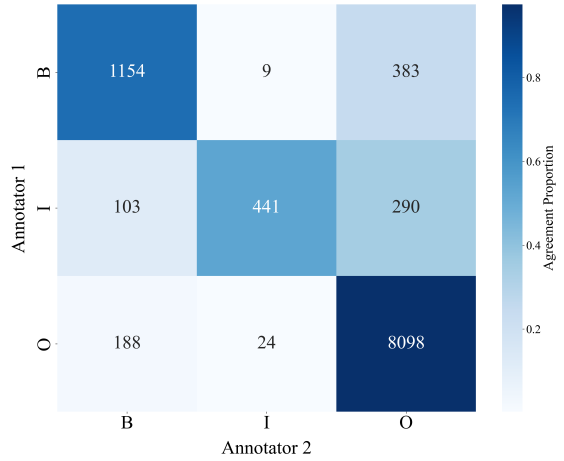

Figure 1: Inter-annotator confusion matrix.

The tag-wise performance analysis revealed strong boundary detection capabilities across annotators, with the maritime language specialist severing as the reference annotator. Analysis showed balanced precision (0.7986) and recall (0.7464) for the B-tag, while the I-tag demonstrated high precision (0.9304). These metrics indicate that annotators, particularly the annotation-trained linguistics researcher when compared against the reference, were conservative in marking term continuations, prioritizing precision over recall. These results validate the annotation guideline effectiveness and establish a solid foundation for the subsequent terminology extraction experiments.

4 Experimental Setup

4.1 Baseline

The baseline was established through BERT model fine-tuning on ACTER's English BIO-annotated data (over 200,000 tokens) (Rigouts Terryn et al., 2020). The fine-tuning experiments with BERT-base and BERT-large variants revealed BERT-base's superior performance, leading to its selection as the baseline for subsequent comparisons. See Appendix A.1 for experimental details.

4.2 Model selection

For the ATE experiments, state-of-the-art LLMs, comprising both open-source and closed-source variants, were selected based on their recent developments and varying specifications in parameter sizes (Param) and context lengths (CtxL), as detailed in Table 3. Models were chosen for their potential to perform well in zero-shot settings, enabling the evaluation of their inherent capabilities without domain-specific fine-tuning.

Type	Model	Param	CtxL
Open-source	Qwen2.5-7B-Instruct	7.61B	128K
	GLM-4-9B-Chat	9B	128K
	Llama-3.1-8B-Instruct	8B	128K
	gemma-2-9b-it	9B	8K
Closed-source	Claude-3.5-Sonnet[5]	Undisclosed	200K
	Gemini-1.5-Pro	Undisclosed	2,000K[6]
	GPT-4o-latest[7]	Undisclosed	128K

Table 3: Specifications of the evaluated models.

4.3 Zero-shot prompt design

The zero-shot prompt for maritime safety terminology extraction was initially developed based on the ReAct prompting framework (Yao et al., 2023) and Chain-of-Thought (CoT) principles (Wei et al., 2022). Its design followed the domain-specific adaptations outlined in Section 3.1.

The prompt was then iteratively refined through pilot studies across multiple models, focusing on evaluating their instruction-following capabilities and optimizing the design accordingly. This process established clear input–output formatting for consistent sequence labeling evaluation. The final prompt demonstrated reliable performance in guiding model behavior for maritime safety ATE. See Appendix A.2 for the full prompt specification.

[5]Model version: Claude-3.5-Sonnet (2024-10-22)

[6]Gemini-1.5-Pro supports a maximum context length of 2M tokens. However, Google API offers lower pricing for prompts under 128K tokens, which are more commonly used.

[7]Model version: GPT-4o-latest (2024-11-20)

Category	Model	Term-level			Label B			Label I		
		F1-score	Precision	Recall	F1-score	Precision	Recall	F1-score	Precision	Recall

Table 4: Comparison of overall model performance in maritime safety terminology extraction. Term-level F1-score measures overall extraction accuracy, while Label B and Label I F1-scores evaluate term boundary detection.

5 Results and Discussion

5.1 Overall model performance

To evaluate the overall effectiveness of different LLMs in maritime safety terminology extraction, we compare their term-level Precision, Recall, and F1-score, as well as their performance in boundary detection (separate Label B & Label I F1-score). Table 4 summarizes the results.

The results indicate that Claude-3.5-Sonnet outperforms all evaluated models, with its F1-score (0.8002) significantly exceeding the BERT-base fine-tuning baseline (0.1683) and demonstrating the advantages of zero-shot learning in maritime safety terminology extraction. Claude-3.5-Sonnet's superior performance may be attributed to its advanced reasoning capabilities and extensive pretraining on diverse technical domains, enabling better understanding of specialized terminology patterns. The model shows particularly strong performance in identifying term beginnings (Label B F1-score: 0.8260) compared to term continuations (Label I F1-score: 0.7395).

Among open-source models, GLM-4-9B-Chat shows relatively higher recall (0.6944) but at the cost of lower precision (0.4491), whereas Qwen2.5-7B-Instruct achieves higher precision (0.6364) but struggles with recall (0.4404). Llama-3.1-8B-Instruct performs the worst among LLMs (Term-level F1-score: 0.2818), approaching the baseline performance level, with a particular weakness in term continuation detection (Label I F1-score: 0.1468).

To examine the generalization capabilities of the top-performing models, additional experiments were conducted on ACTER's *Wind Energy* subset (57,766 tokens) (Rigouts Terryn et al., 2022a). The three models with the highest F1-scores in maritime safety terminology extraction - Claude-3.5-Sonnet, Qwen2.5-7B-Instruct, and GLM-4-9B-Chat - were evaluated. Table 5 presents the comparative results.

Model	F1-score	Precision	Recall
Claude-3.5-Sonnet	0.6775	0.6215	0.7446
Qwen2.5-7B-Instruct	0.5038	0.5425	0.4703
GLM-4-9B-Chat	0.4685	0.3979	0.5694

Table 5: Term-level performance (F1-score) on ACTER's *Wind Energy* domain subset.

The results on this standardized benchmark align with the performance patterns observed in the maritime domain. The relative ranking of models remains consistent across domains, suggesting their capabilities in specialized terminology extraction generalize beyond maritime safety. This cross-domain validation provides additional evidence for the effectiveness of these models in sequence labeling tasks across different technical domains.

5.2 Performance across different term types

Table 6 presents the F1-scores across four term categories, with category-specific performance calculated by mapping the BIO-tagged sequences to their corresponding term types using the gold standard classification. Claude-3.5-Sonnet maintains its superior performance across Common Terms (F1-score of 0.7149) and Specific Terms (F1-score of 0.6102), aligning with its strong overall term-level metrics. Among open-source models, Qwen2.5-7B-

Category	Model	Common Terms	Specific Terms	Named Entities	OOD Terms
Open-source	Qwen2.5-7B-Instruct	**0.5058**	0.4466	**0.5418**	0.0310
	GLM-4-9B-Chat	0.3983	0.2997	0.2456	0.0142
	Llama-3.1-8B-Instruct	0.2961	0.1454	0.1152	0.0071
	gemma-2-9b-it	0.3680	0.2232	0.2360	0.0106
Closed-source	Claude-3.5-Sonnet	**0.7149**	**0.6102**	**0.5304**	0.0708
	Gemini-1.5-Pro	**0.5028**	0.3108	0.3170	0.0099
	GPT-4o-latest	0.4055	0.3483	0.3628	0.0142

Table 6: Performance by term category (F1-score)

Instruct demonstrates balanced performance across Common Terms (F1-score of 0.5058) and named entities (F1-score of 0.5418), though notably lower than Claude-3.5-Sonnet's results.

All models show significantly reduced performance in OOD Terms, with even the best-performing Claude-3.5-Sonnet achieving only 0.0708. This consistent pattern across models suggests inherent challenges in distinguishing domain-adjacent technical terminology through zero-shot learning, particularly given the limited OOD Terms in the gold standard (18 unique terms) and the complexity of applying domain-specificity criteria through prompt-based instructions.

5.3 Terminology coverage analysis

A key consideration in terminology extraction is the choice between full-term annotation and nested annotation approaches. The full-term annotation approach captures entire domain-specific terms as single units, whereas the nested annotation approach also identifies sub-components within multi-word expressions. To quantify the impact of these strategies, Table 7 provides a comparison of extracted terms by annotation approach. Full-term annotation identified 420 unique terms, while the nested annotation approach extracted an additional 21 unique terms, resulting in a total of 441 distinct terms. This corresponds to a coverage rate of 95.24% for full-term annotation approach, with the additional 4.76% of unique terms contributed by nested annotation approach.

Compared to the full-term annotation approach, the additional terms identified through the nested annotation approach consist primarily of sub-components from larger technical expressions (e.g., *pilotage* from *pilotage exemption certificate*, *mooring station* from *forward mooring station*, and *AIS stations* from *shore-based AIS stations*) rather than new conceptual entities. This suggests that nested annotation primarily decomposes existing multi-word terms rather than expanding the terminological inventory of the domain.

Term Type	Nested	Full-term	Exclusive (Nested)
Common Terms	175	164	11
Specific Terms	181	173	8
Named Entities	66	65	1
OOD Terms	19	18	1
Total	441	420	21

Table 7: Comparison of extracted terms by annotation approach

This modest gain in terminology coverage, particularly in structured domains such as maritime safety, indicates that the full-term annotation approach adequately captures domain knowledge. Building on these findings, the full-term annotation approach can serve as a viable choice for large-scale ATE tasks in well-defined domains, where efficiency and practicality are crucial considerations. This approach offers comprehensive coverage without significant information loss while also reducing the additional complexity introduced by the nested annotation approach. The complete list of additional terms identified through nested annotation approach is provided in Appendix A.3.

5.4 Error analysis

To better understand the challenges faced by different models in maritime safety terminology extraction, a detailed error analysis was conducted by examining false positives (FPs) and false negatives (FNs) across all models against the gold standard of 1,558 term instances. FPs refer to terms extracted

by the model that are not in the gold standard, while FNs indicate valid terms from the gold standard that the model failed to detect. Table 8 summarizes the FPs and FNs counts for each model.

Model	FPs	FNs
Qwen2.5-7B-Instruct	361	351
GLM-4-9B-Chat	1,380	182
Llama-3.1-8B-Instruct	1,104	484
gemma-2-9b-it	1,299	251
Claude-3.5-Sonnet	522	95
Gemini-1.5-Pro	781	579
GPT-4o-latest	403	421

Table 8: False positives and false negatives per model

5.4.1 Quantitative analysis of errors

The performed error analysis reveals distinct error patterns across models. There is considerable variation in performance among open-source models, with Qwen2.5-7B-Instruct demonstrating controlled performance while GLM-4-9B-Chat and gemma-2-9b-it show a significant tendency towards overgeneration with a high number of FPs (1,380 and 1,299 respectively), indicating challenges in precise term boundary detection. Among closed-source models, Claude-3.5-Sonnet notably minimizes FNs (95) despite generating more FPs (522), suggesting a stronger capability in identifying valid maritime safety terms, though with some tendency to over-include general domain language. In contrast, both Gemini-1.5-Pro and GPT-4o-latest exhibit higher error rates across both categories, reflecting greater difficulty in accurate maritime safety terminology extraction.

5.4.2 False positives analysis

The analysis of false positives reveals two primary causes of errors: (1) contextual descriptions tagged as terms, and (2) boundary detection errors.

Misidentification of contextual descriptions as terminology Models with higher FPs extract general descriptive phrases that lack terminological status, leading to outputs that contain contextual metadata rather than precise domain-specific terms. For example, GLM-4-9B-Chat extracts operational descriptions such as *all ships between 10 and 24 m in length*, *vessels over 150 gross tonnage*, and *collisions between trading ships and small vessels*. Similarly, gemma-2-9b-it misidentifies navigational contexts like *passage within the harbour in darkness*, *events and conditions that increase risk*, *requirement to record hours of rest*, and *risk of the collision posed by the other*. Qwen2.5-7B-Instruct also demonstrates similar errors, such as *ATSB investigation report findings focus on safety factors*. These cases highlight the models' difficulty in distinguishing between contextual information and specialized maritime safety terminology.

Boundary detection failures in term extraction A key challenge across models is the inability to establish precise term boundaries, resulting in two common failure modes: overextension (inclusion of extraneous contextual elements) and truncation (omission of critical components).

Overextension occurs when models extract phrases that incorporate unnecessary surrounding contextual elements, rather than isolating the precise technical term. This differs from the previously discussed contextual misidentification issue, as the extracted text still contains a valid term but includes additional, non-essential elements. Examples include GLM-4-9B-Chat producing errors such as *Accolade II for the previous*, *chief mate 's*, *helmsman changed*, *acquiring AIS icons*, and *ATSB 's investigation*. Similarly, gemma-2-9b-it generates erroneous phrases like *an automatic identification system*, *anchorage within the port*, and *port 's working channel*, *skipper altered*. Llama-3.1-8B-Instruct exhibits overextended terms such as *on VHF*, *skipper called*, and *chief mate was*, while GPT-4o-latest demonstrates this issue with *Adelaide 's rules*, *and starboard*, and *'s starboard*.

Truncation, though less frequent, results in partial extraction of technical terms, leading to ambiguous or incorrect outputs. Examples include GLM-4-9B-Chat extracting *Australian Maritime Safety* instead of the correct *Australian Maritime Safety Authority*, and *automatic* instead of the complete terms *Automatic Identification System* or *Automatic Radar Plotting Aid*. Similarly, gemma-2-9b-it produces errors like *class 3B* (instead of *class 3B DCV*, *class 3B domestic commercial vessel*, or *class 3B vessels*) and *shuttle belt* instead of *shuttle belt conveyor*. Gemini-1.5-Pro also exhibits truncation errors, such as extracting *pre-departure* instead of *bridge pre-departure checklist* or *bridge pre-departure checks*.

5.4.3 False negatives analysis

The analysis of false negatives also reveals two fundamental challenges in maritime safety terminology extraction: (1) the extraction of multi-word terms, and (2) terms requiring domain-specific professional knowledge.

Difficulties in recognizing multi-component maritime safety terminology Models exhibit significant deficiencies in extracting terms that integrate multiple interrelated maritime concepts, often failing to capture complex multi-word expressions while correctly identifying their shorter variants. For example, all models struggle with full terms like *Standards of Training, Certification and Watchkeeping for Seafarers*, and *International Convention for the Safety of Life at Sea*, despite correctly recognizing their corresponding acronyms (STCW and SOLAS).

Beyond regulatory terms, similar challenges arise in navigation safety systems. Llama-3.1-8B-Instruct frequently misses complex multi-component terms such as *vessel traffic service*, *vessel monitoring system*, and *bridge navigational watch alarm system*. Likewise, gemma-2-9b-it fails to extract *safety management system*, *fatigue management system*, and *vessel monitoring system*. These errors indicate difficulty in capturing domain-specific multi-word expressions where foundational maritime terms (e.g., *vessel*, *bridge*, *system*) are embedded within functional descriptors (e.g., *traffic service*, *monitoring*).

The issue extends to maritime documentation and regulatory terminology, where models frequently omit terms reflecting multi-level administrative structures. GPT-4o-latest fails to extract *minimum safe manning document* and *AMSA-issued certificate of operation*, while Qwen2.5-7B-Instruct misses *certificate of competency* and *certificate of recognition*. Similarly, Gemini-1.5-Pro fails to extract regulatory terms such as *pilotage exemption certificate* and *national standard for commercial vessels*, and Llama-3.1-8B-Instruct struggles with operational communication terms like *bridge resource management practices* and *bridge procedures guide*. These cases illustrate broader limitations in handling structured terminology within maritime regulatory and operational contexts.

Limited understanding of domain-specific professional knowledge Models also struggle with terms that require deeper professional knowledge within the maritime domain. Even Claude-3.5-Sonnet, despite its relatively strong performance, occasionally fails to extract highly specialized terms such as *dual-fuel propulsion engines* and *automatic radar plotting aid*. GPT-4o-latest frequently misses *blind sectors*, *visual obstruction*, *voyage data recorder*, and *compass bearings*. Similarly, gemma-2-9b-it fails to recognize *echo sounder*, *gyrocompass*, and *radar echoes*, while Llama-3.1-8B-Instruct overlooks critical safety terms like *close-quarters situation* and *proper lookout*. These examples suggest that models struggle with extracting technical terminology that necessitates deeper comprehension of maritime operations and navigational safety principles.

6 Conclusion

This study evaluates LLMs' capabilities in maritime safety terminology extraction in zero-shot settings. The experimental results demonstrate that while LLMs show promise in handling maritime safety terminology, their performance varies significantly between closed-source and open-source implementations. The analysis further reveals that full-term annotation achieves comprehensive terminology coverage while maintaining practical efficiency, challenging assumptions about annotation granularity requirements in domain-specific terminology extraction.

The findings suggest several promising directions for future research. Few-shot learning represents a compelling direction for maritime safety terminology extraction, where models could be prompted with a small set of carefully selected examples. This approach could explore how different prompt engineering strategies and example selection methods affect terminology identification performance, particularly for handling specialized maritime safety concepts. Fine-tuning approaches offer another valuable research direction, particularly through cross-lingual and cross-domain adaptation. This direction could leverage well-established terminology datasets such as ACTER (Rigouts Terryn et al., 2020), GENIA (Kim et al., 2003), and ACL RD-TEC 2.0 (QasemiZadeh and Schumann, 2016) for initial model adaptation. Further fine-tuning could then be performed using bilingual maritime-specific resources, potentially revealing insights into the transferability of terminology extraction capabilities across technical domains and languages.

Exploring the Usage of Knowledge Graphs in Identifying Human and LLM-Generated Fake Reviews

Ming Liu and Massimo Poesio

Mile End Road
London E1 4NS
{acw661,m.poesio}@qmul.ac.uk

Abstract

The emergence of large language models has led to an explosion of machine-generated fake reviews. Although distinguishing between human and LLM-generated fake reviews is an area of active research, progress is still needed. One aspect which makes current LLM-generated fake reviews easier to recognize is that LLMs–in particular the smaller ones–lack domain-related knowledge. The objective of this work is to investigate whether large language models can produce more realistic artificial reviews when supplemented with knowledge graph information, thus resulting in a more challenging training dataset for human and LLM-generated fake reviews detectors. We propose a method for generating fake reviews by providing knowledge graph information to a llama model, and used it to generate a large number of fake reviews which used to fine tune a state-of-the-art human and LLM-generated fake reviews detection system. Our results show that when knowledge graph information is provided as part of the input, the accuracy of the model is improved by 0.24%. When the knowledge graph is used as an embedding layer and combined with the existing input embedding layer, the accuracy of the detection model is improved by 1.279%.

1 Introduction

Large Language Models (LLMs) are now able to generate high-quality and widely used text. For example, ChatGPT (ChatGPT, 2022) can generate text of near-human level quality, including for the case of creative texts such as music lyrics (Khan, 2024). But as the text-generation capabilities of LLMs grow, so does their use to generate misinformation, plagiarized text, and fake product reviews (Sun et al., 2024). More and more LLM-generated, human-like fake reviews affect online purchasing of all types of goods, including book buying, the type of reviews we're studying. Therefore, discriminating text generated by humans from text generated by LLMs has become a major technological challenge and societal challenge (Prajapati et al., 2024).

Although distinguishing between human and LLM-generated fake reviews is an area of active research (Wu et al., 2025), progress is still needed. In particular, it is necessary to train classifiers on datasets in which the artificial reviews are not so different from real reviews as to make them easily detectable. One aspect which makes current LLM-generated fake reviews easier to recognize is that LLMs–in particular the smaller ones–lack domain-related knowledge (Feng et al., 2023) The objective of this work is to investigate whether large language models can produce more realistic artificial reviews when supplemented with knowledge graph information, thus resulting in a more challenging training dataset for human and LLM-generated fake reviews detectors.

Two knowledge graph fusion methods are explored: Prompt Embedding and Model Embedding. When generating new fake reviews, Prompt Embedding uses the knowledge graph as the input of the generation model, while Model Embedding uses the knowledge graph as part of the generation model. Our results show that that the generation model in which the knowledge graph is fused in the architecture can better generate fake reviews, thereby improving the performance of the detection model.

2 Related Work

In this Section we briefly review previous literature on detecting LLM-generated text and on using knowledge graphs in LLMs.

Proceedings of Recent Advances in Natural Language Processing,pages 674–681
Varna, Sep 8–10, 2025

2.1 LLM-Generated Text Detection

In recent years, the development of automatic detection methods to identify LLM-generated texts has become a very active area of research (Prajapati et al., 2024). Sadasivan et al. (2023) proposed a framework dealing with distinctive writing styles, clever prompt design, or text paraphrasing. At the same time, the study shows that even when a large model is protected with a watermark, the model is vulnerable to spoofing attacks (Sadasivan et al., 2023). DetectGPT (Mitchell et al., 2023) computes log-probability to detect machine-generated text, rather than training a separate classifier or even collecting a dataset. However, this method is limited to white-box environments. For models that do not provide log probabilities for calculation, DetectGPT cannot help (Mitchell et al., 2023). Watermark (Kirchenbauer et al., 2023) controls the text generation process, selecting tokens marked as 'green'. In practice, complex watermarks can degrade text quality due to the lack of flexibility of large language models (Kirchenbauer et al., 2023). GLTR (Gehrmann et al., 2019) is a tool for detecting whether text is LLM-generated. Without using pre-training, GLTR improves the human detection rate of fake text from 54% to 72% (Prajapati et al., 2024). However, if non-biased sampling is used to generate text, this method is difficult to identify (Prajapati et al., 2024).

2.2 Graph-Based Retrieval-Augmented Generation (RAG)

Knowledge graphs are machine-readable graph structures that include entities, relationships, and attributes. They store data in a structured manner in a graph database, which can reflect the physical objects and relationships in real life (Lavrinovics et al., 2025).

Studies have shown that adding relevant domain information when generating text in knowledge-intensive tasks can effectively improve the context-awareness of LLMs. At the same time, hallucinations are reduced while keeping the original model structure unchanged (Lewis et al., 2020; Ram et al., 2023; Agrawal et al., 2024). Therefore, using structured external information such as knowledge graphs can make LLM's output more consistent, and provide more accurate answers (Pan et al., 2023, 2024).

StructGPT (Jiang et al., 2023) uses knowledge graphs and tabular data to enhance GPT's information extraction capabilities. Wu et al. (2023) team textualised the content of the knowledge graph to enhance the model performance when performing question-answering tasks. Baek et al. (2023) team proposed the KAPING model. This model also uses the knowledge graph and extracts the corresponding triples from it, and is used for the zero-shot question answering task.

3 Methods

In this section, we explain our architecture, and introduce the two different ways of applying knowledge graphs that we developed.

3.1 Overall Architecture and Baselines

The task can be divided into three components: knowledge graph creation, generation of fake reviews to be added to the training set, and human and LLM-generated reviews detection. First, in the knowledge graph creation process, we generate the corresponding knowledge graph around the existing dataset. Then, in the generation process, we generate the corresponding dataset based on the existing dataset and merge the generated and old datasets into a new dataset. Finally, in the detection process, we use the existing efficient detection model to detect our enhanced dataset.

Although it is possible to evaluate the quality of fake reviews generation through text-quality metrics (Mitchell et al., 2023; Chim et al., 2025), ultimately, the only truly telling way to evaluate our approach for generating fake reviews is through the impact of these reviews on the overall detection task. This will be our main metric.

As a detection baseline, we use the existing state-of-the-art detection model LLM2S3 (Spiegel and Macko, 2024a). Because LLM2S3 only provides the architecture but not the trained model, we fine-tuned Falcon-7B (Almazrouei et al., 2023) and Mistral-7B (Chaplot, 2023). (Please refer to the section 3.4 for more information about the model.)

An existing dataset of fake reviews is used as starting point, and the detection results obtained after training the LLM2S3 model on this dataset are used as our baseline.

3.2 Knowledge Graph Creation

The knowledge graph is extracted out of the datasets used in this study, the Amazon dataset and DeRev 2018 (see Section 4.1).

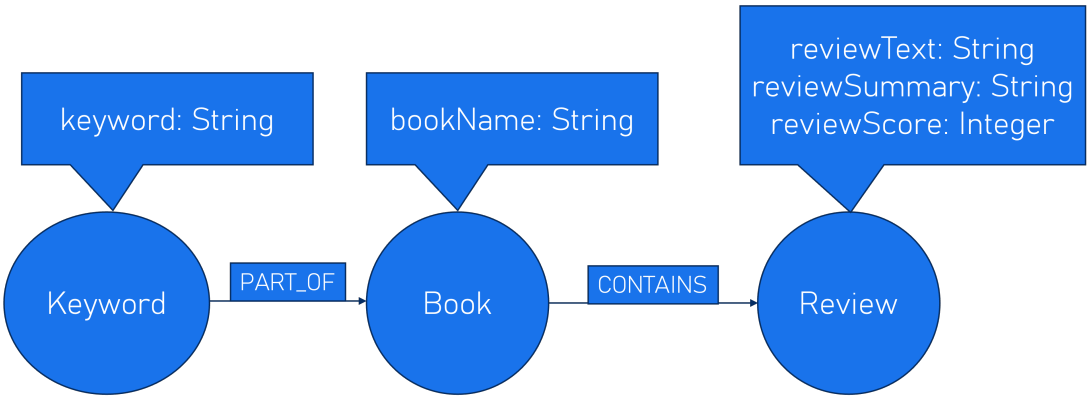

Figure 1: The Structure of Data in Knowledge Graph.

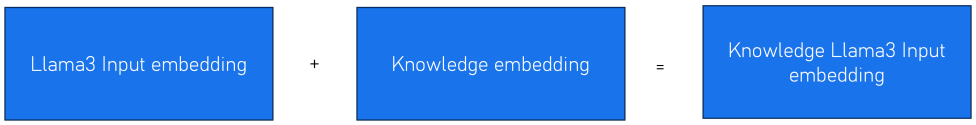

Figure 2: Input Integration of Llama Model.

Preprocessing We first run two preprocessing steps. First, the Amazon dataset and DeRev 2018 were merged. Second, we obtained query keywords by keyword extraction from the reviews in the dataset. Because there are multiple keywords, the query results will be concatenated as the final result.

Neo4j We use Neo4j (Neo4j, 2012) as the storage tool for the knowledge graph. It is an ideal graph data storage and query solution that can be applied to a variety of fields, such as social network analysis, knowledge graph modelling, and healthcare.

Data Modelling The structure of the data model can be found in Figure 1. It contains three nodes: ”Keyword”, ”Book”, and ”Review”. The ”Keyword” node contains a string attribute ”keyword”, whose content is the keyword itself. The ”Book” node contains a string attribute ”bookName”, whose content is the name of the book. The ”Review” node contains three attributes: the string attribute ’reviewText’, whose content is the review body; the string attribute ’reviewSummary’, which contains the review summary; the integer attribute ’reviewScore’, which contains the user rating of the purchased book.

The relationship between these nodes is as follows. 1. ”Book” contains multiple ”Review” from different users. 2. Each ”Review” can extract a number of ”Keyword”. However, in the actual model creation, in order to make retrieval more convenient, we changed the association relationship among three nodes: 1. ”Book” contain multiple ”Review” from different users (CONTAIN). 2. ”Keyword” is part of ”Book” (PART_OF). Here we remove the relationship between ”Review” and ”Keyword”, and transfer this relationship to ”Book” and ”Keyword”.

Data Import During the data import process, we import the Amazon Customer Reviews Dataset (Amazon, 2018) and DeRev 2018 (Fornaciari and Poesio, 2014; Fornaciari et al., 2020) datasets into the created data model. It should be noted that there are certain differences in the content of the two datasets, which affect the merging of the data. Among them, the book names in the two datasets are obviously different. To create a better knowledge graph, we uniformly modify the book name format of the Amazon dataset to the same Upper Camel Case as DeRev 2018. Refer to Section 4.1 for more information about the two datasets.

3.3 Using the KG for Generation

During the generation process, we mainly use two methods: Prompt Embedding and Model Embedding. Both methods are implemented using llama3.1-8B (Grattafiori et al., 2024).

Prompt Embedding This method involves modifying the input of the training model by adding the corresponding knowledge graph content in the Prompt. The following is an example input:

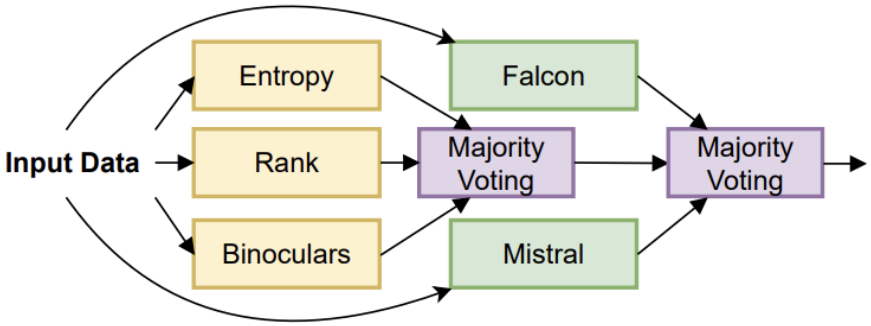

Figure 3: The Model of LLM2S3 created by KInIT team in the SemEval-2024 competition.

```

Figure 4: Example of DeRev 2018. Each comment is in XML document format, which contains the title, author, time and content of the comment. It also contains tokens generated by comments.

{ “content”: ” Generate text by giving keywords and knowledges: keywords(keywords1, keywords2, ...), knowledge(concatenate(knowledge1, knowledge2, ...))”,“role”: “user” }, { “content”: ” original text”, ”role”: ”assistant” }

This example expresses the generation of a comment through keywords keyword1, keyword2, etc. At the same time, it is necessary to refer to the output of the knowledge graph. It is obvious here that the knowledge graph is part of the model input. Therefore, we call it Prompt Embedding. In this way, we achieve embedding of the knowledge graph without actually modifying the generative model.

Model Embedding This method involves modifying the model to add additional knowledge graphs to enhance the generation of fake reviews. The following is an input example:

{ “content”: ” Generate text by giving keywords: keywords(keywords1, keywords2, ...)”, “role”: “user” }, { “content”: ” original text”, ”role”: ”assistant” }

This example shows that the model generates fake reviews through keywords. Compared with Prompt Embedding, the knowledge graph is missing. Here, we combine the knowledge graph with the input layer of the Llama model. You can refer to the figure 2. First, we embed the knowledge graph result to get the knowledge embedding layer. Then add it to the original Llama input embedding to get the new Knowledge Llama3 Input embedding layer. It should be emphasised that in the actual construction, we did not create and add a new knowledge graph embedding layer. We just merged the two layers and overwrote the original input layer.

3.4 Detection

As a detection system, we used the model developed by the KInIT team in the SemEval-2024 competition (Spiegel and Macko, 2024b), one of the best performing systems in the competition. The structure of the model is shown in Figure 3. The authors used two majority votes and combined numerical calculation metrics with large models. First, Entropy, Rank and Binocular are calculated for the whole dataset. Then, a new prediction result is obtained by majority vote. The second majority vote prediction is a combination of the prediction result of the previous one with the prediction results

of Mistral and Falcon. This system achieved fourth place in the competition. Importantly, we fine-tune the Falcon and Mistral models to make them more suitable for our data types.

Finally, the datasets generated by Prompt Embedding and the datasets generated by Model Embedding are verified on LLM2S3 respectively.

4 Experiments

In this section, we introduce the dataset, experimental settings, and experimental process in detail.

4.1 Datasets

We focused on book reviews, and mainly used the Amazon Customer Reviews Dataset (Amazon, 2018) and DeRev 2018 (Fornaciari and Poesio, 2014; Fornaciari et al., 2020) as datasets.

DeRev 2018 It contains both genuine reviews with strong evidence and fake reviews created by users for financial gain. Figure 4 is a sample of the DeRev dataset. *gold2016* indicates the truth or falsity of a review. 0 is false and 1 is true. It contains 8311 high-quality, cleaned data.

Amazon Customer Reviews Dataset Figure 5 is a sample of the Amazon dataset. What we need to pay attention to here are the *REVIEW_TEXT* and *LABEL* labels. *REVIEW_TEXT* is the review itself, without any false or true labels. *REVIEW_TEXT* indicates whether the review is true or not. __label1__ indicates false, and __label2__ indicates true. It contains 21,000 items, categorised into 30 classes, each of which contains 700 reviews.

In this experiment, we first used the entire DeRev 2018 dataset. Second, we used data items with category 'books' from the Amazon dataset. The table 1 shows some information.

4.2 Experimental Setup

First of all, we follow the 2:8 principle to split the dataset into a test set and a training set. 20% of the data is used as a validation set, and 80% of the data is used as a training set.

Then, both methods take the following steps to create a dataset.

1. Split the original reviews and get the keyword list.

2. Get the corresponding attributes and associations in the knowledge graph based on the keyword list.

3. Connect the knowledge graph results together.

Finally, when fine-tuning LLM2S3, only the original dataset is used. At test time, the dataset generated by Prompt Embedding and Model Embedding will be used respectively.

4.3 Experimental Process

As previous discussed, we compare two data generation methods, illustrated in Figures 6 and 7, respectively. First, a knowledge graph is created and imported into the Neo4j database. Next, a mesh structure centered on the "Keyword" node is generated. When generating a new dataset, use keyword extraction on the original reviews. The corresponding relevant review summary is then obtained in the knowledge graph for keywords. Because a keyword corresponds to multiple books and multiple reviews, each time the Llama model generates reviews, it refers to reviews with the same keyword for different books. In this process, it is necessary to remove repeated book reviews.

Then, when using the Prompt Embedding method, all the knowledge is used as part of the input prompt for the Llama model to generate new reviews. When using the Model Embedding method, all the knowledge is first converted to the embedding layer and then merged with the original input layer of Llama to generate new reviews. It should be noted that the knowledge may be too long, sequence embedding is required.

Finally, we use LLM2S3 as a detection model to identify humans and LLM-generated reviews. Because LLM2S3 has two models that need to be fine-tuned, Mistral and Falcon, we use the original Amazon and DeRev datasets for fine-tuning. Because our original dataset only has human-written reviews, we used another Llama

Dataset	Size	Details
Amazon Reviews (Amazon, 2018)	350 fake and 350 truthful reviews	Published by Amazon
DeRev 2018 (Fornaciari and Poesio, 2014)	8311 reviews	Book reviews

Table 1: Datasets for Human and LLM-generated Fake Review Detection.

Model	Accuracy	F1	Precision	Recall
Baseline	88.5%	87.3%	**90.2**%	86.8%
Prompt Embedding	88.8%	88.2%	89.8%	88.6%
Model Embedding	**89.8**%	**89.8**%	87.9%	**91.8**%

Table 2: The Performance of Different Approaches

model to paraphrase the original two datasets to make them machine-generated datasets. 80% of the original data and rewritten data are used to fine-tune the Mistral and Falcon models. When we finally use LLM2S3 for detection. Use 20% of the original data and 20% of the generated dataset for verification, and also take the average multiple times.

5 Results and Discussion

Table 2 shows the results with training LLM2S3 using datasets computed using the two approaches. The results show that both methods have achieved some improvement in accuracy compared to the baseline, but the improvement with Prompt Embedding is limited. The Baseline approach has the highest precision, and the Model Embedding has the highest accuracy, F1, and recall values.

We conducted two sets of tests on the significance of the differences found between baseline and the two KG embedding models: Baseline vs Prompt Embedding, and Baseline vs Model Embedding. **Baseline and Prompt Embedding Null Hypothesis:** There is no significant difference between the results of the Baseline and Prompt Embedding models. **Baseline and Model Embedding Null Hypothesis:** There is no significant difference between the results of the Baseline and Model Embedding models.

Table 3 shows the t and p values for the two tests. When comparing Baseline and Prompt Embedding, the null hypothesis holds, although barely, because p¿0.05 (marginally). This indicates that there is no significant difference between the Baseline and Prompt Embedding models. When comparing Baseline and Model Embedding, however, the null hypothesis does not hold, because p¡0.05. This indicates that there is a significant difference between the Baseline and Model Embedding models.

Judging from the values of metrics, the results of the three methods are very stable, which means that the model-generated dataset and the original dataset are also very stable. The improvement may seem small, but it should be emphasized that the performance of LLM2S3 is already very high, so any improvement over that is very difficult.

6 Conclusion

In this paper we compared two methods for augmenting the dataset used for training a LLM-generated text detection model by generating additional review through a model that leverages knowledge graph information. Our results show that both methods achieve a small improvement in detecting LLM-generated text over a baseline, but embedding the knowledge graph information in the model gives the best results.

Abstract

Understanding medical terminology is critical for effective patient-doctor communication, yet many patients struggle with complex jargon. This study compares Machine Learning (ML) models and Large Language Models (LLMs) in predicting medical term complexity as a means of improving doctor-patient communication. Using survey data from 252 participants rating 1,000 words along with various lexical features, we measured the accuracy of both model types. The results show that LLMs outperform traditional lexical-feature-based models, suggesting their potential to identify complex medical terms and lay the groundwork for personalised patient-doctor communication[1].

1 Introduction

Laypeople often struggle with medical terminology due to factors such as limited health literacy, language barrier, or personal problems. This limited understanding of medical terminology poses significant challenges in healthcare systems. Poor comprehension of health records, medication instructions, or public education materials can lead to treatment non-adherence, miscommunication during clinical consultations, and even avoidable hospitalisations. Studies show that many individuals have only basic health literacy, and some conceal poor reading skills, leading doctors to overestimate their understanding (Weiss, 2007). On the other hand, LeBlanc et al. (2014) found that soon-to-be physicians underestimated patients' medical text comprehension abilities. Even patient information leaflets may not be written in accessible language, further compounding these issues for vulnerable groups such as Medicaid recipients (O'Sullivan et al., 2020). Non-native speakers may also lack relevant medical vocabulary (Al Shamsi et al., 2020). Others may disengage from healthcare-related information due to low interest (McCarron et al., 2019), (dis)trust in the healthcare system (Tsai et al., 2018; Tunç et al., 2025), inaccessible health records (van Mens et al., 2020; Neves et al., 2020), or personal challenges (Murugesu et al., 2022). Addressing these gaps is critical for designing clearer Electronic Health Record (EHR) interfaces, patient information materials, and AI-driven tools that minimise jargon and improve accessibility of medical records.

Each person comes with a unique background and experience, which influences their understanding of medical terms. As a result, people can misinterpret medical terminology by relying on their existing knowledge. Notable examples of such misunderstandings were documented by Gotlieb et al. (2022), including cases where individuals misinterpreted "impressive x-ray findings" or "progressing tumour" as positive news due to the colloquial meanings of these terms. Another example is the word "fertilisation" which in medical contexts refers to "the joining of sperm and egg" while in agricultural contexts it suggests "(soil) enrichment" (both derived from the Latin word "fer" meaning "to bear, carry"). Language background can also lead to confusion. For instance, "angina" (short for "angina pectoris" – "chest pain") is commonly used to refer to *tonsillitis* in many languages.

Several studies focus on general medical/biological terms (Shardlow et al., 2020; Grabar et al., 2014), while others examine specific terminology (e.g., X-rays, diseases) (Sugihara et al., 2024; Pieterse et al., 2012; Zimmermann et al., 2021; Lalor et al., 2024). Most research exploring lexical understandability measures term recognition rather than comprehension of meaning. Few studies investigate medical term complexity

with a personalization component (Tran et al., 2025; Asthana et al., 2024). Furthermore, some publications analyse this topic using limited sets of terms (Gotlieb et al., 2022; O'Connell et al., 2013; Lerner et al., 2000; Briem et al., 2004).

In this paper, we explore features and models for predicting the complexity of medical terms. This study may be helpful for clinicians in identifying potentially ill-understood jargon that could confuse patients. Specifically, our goal is to understand which fairly common medical words or phrases (jargon) are unknown or misunderstood by laypeople. Another key question addressed is how different lexical characteristics of words influence their comprehension, as well as the use of LLMs to evaluate medical term complexity. Our key contributions are: (1) A curated dataset of 1,000 medical terms, annotated with familiarity and complexity scores based on responses from 252 participants; (2) An evaluation of traditional machine learning models versus the use of state-of-the-art LLMs to predict term complexity, along with an analysis of informative features; and (3) A demonstration that LLMs slightly outperform traditional models, achieving the lowest prediction errors (RMSE: 0.21).

2 Related Work

Early research by Zeng et al. (2005) and Kauchak and Leroy (2016) highlights the limitations of conventional readability measures, such as syllable count, word length, or easy-word lists, in assessing the complexity of medical terms, arguing that these metrics often do not predict true comprehension barriers. Zeng et al. (2005) pioneered a personalised approach, modelling term familiarity based on individual factors (e.g., education, age, native language status) and word-level characteristics (e.g., corpus frequency, Dale-Chall easy-word percentage), finding education to be the strongest predictor. Similarly, Kauchak and Leroy (2016) showed that while word length correlates with perceived difficulty, term frequency better predicts actual understanding, although their forced-choice survey method may inflate guessing since false definitions are randomly selected. Likewise, Jiang and Xu (2024) demonstrate that general readability metrics (e.g., FKGL, ARI) perform poorly on medical texts unless augmented with jargon term counts, reinforcing the need for an alternative approach.

Several studies identify term frequency as a reliable complexity indicator. Cherednichenko et al. (2018) use frequency-based filtering for Ukrainian medical terms, while Pylieva et al. (2019) and Sugihara et al. (2024) integrate frequency features from medical corpora and Wikipedia into machine learning models. Shardlow et al. (2020) further validate that simple lexical features (word length, syllable count) outperform contextual embeddings in predicting single-word complexity. Their dataset also includes multi-word expressions, which tend to be more complex than individual words, particularly in biomedical texts.

The role of context emerges as critical in later studies. Kwon et al. (2022) focus on EHR jargon, pre-training models on Wikipedia hyperlinks to improve jargon span detection. Their work highlights challenges with abbreviations ("ENT", "q.6 h"), person-name-based medical concepts ("Azzopardi effect"), and device names ("BiPap"). They also found that the masked language model complements the model solely based on word frequencies. Jiang and Xu (2024) extend this by categorising jargon into Google-easy (searchable) and Google-hard (obscure) terms, proposing customised simplification strategies.

Discrepancies in laypeople's understanding of medical terminology are a recurring theme in the literature. Pylieva et al. (2019) and Sugihara et al. (2024) report that only 22–27% of medical terms are correctly understood by annotators. Sugihara et al. also note demographic variations (for example, younger males tend to struggle with terms related to pregnancy and childbirth). Additionally, Cheng Sheang et al. (2022) observe low inter-annotator agreement (κ = 0.175-0.316) to identify complex words in French clinical texts, further highlighting the subjectivity of complexity judgments.

To help laypeople understand medical jargon, numerous tools have been developed. Initially, these efforts focused on synonym dictionaries and direct word substitution (Alfano et al., 2020; Kandula et al., 2010; Keskisärkkä, 2012; Kvist, 2013). With advances in NLP, machine learning models were trained to address this task (Phatak et al., 2022; Flores et al., 2023; Lu et al., 2023; Botarleanu et al., 2020; van den Bercken et al., 2019; Van et al., 2020; Joseph et al., 2023; Basu et al., 2023). Subsequently, context-aware simplification systems emerged, leveraging NLP to identify and replace complex terms with lay-friendly alternatives in EHRs and patient portals (Jiang and Xu, 2024; Kwon et al., 2022). Similarly, mobile apps

like MediReader (Hendawi et al., 2022) and AI-driven chatbots (Bhatt and Vaghela, 2024; Khamaj, 2025) now provide real-time simplifications.

3 Methodology

In this study, the objective was to assess laypeople's understanding of common medical terminology they are likely to encounter during hospital admission, in EHRs, or in patient information leaflets. Although Pylieva et al. (2019) and Sugihara et al. (2024) have highlighted significant discrepancies in the comprehension of medical terms (with only around 25% of terms correctly understood by their audience), our work diverges by focusing on high-frequency terms to ensure practical relevance. Unlike studies with randomly selected distractors (such as Kauchak and Leroy (2016)), which can inadvertently bias responses toward the most plausible answer, we manually curated all incorrect options to rigorously test participants' true understanding. Our study also measures the level of term recognition prior to correct comprehension.

Our study was carried out in three main phases: (1) Dataset curation, where we systematically selected high-frequency medical terms from diverse sources to ensure relevance and coverage; (2) Annotation and labelling of the dataset, where we designed and administered a questionnaire to assess laypeople's comprehension; and (3) Dataset analysis, where we utilised different models and features to evaluate term complexity.

3.1 Terms Selection

The objective of this step was to compile a comprehensive and balanced set of medical terms likely to confuse patients, ensuring coverage across various sources while filtering for relevance, frequency, and practicality. To achieve this, three sources of terms were used.

The first source comprised medical terms identified through a conventional search engine (Google) query for pages related to confusing medical terminology. The query *"medical terms that confuse patients"* returned 198 web pages, though not all contained relevant unique content or were accessible. After the elimination of irrelevant or corrupted pages, 166 web pages remained, yielding an average of 130 unique terms per page (12,533 unique terms in total). Initially, Gemma2:27B (Gemma Team, 2024) and ChatGPT-4o-mini (OpenAI, 2024) were used to extract medical terms from 4,096-character text chunks of the web pages. The prompts requested enumerated lists of (1) *"terms used in hospitals, including anatomical ones"*, and (2) *"medical terms that can confuse patients"*. However, both models occasionally missed terms, necessitating a switch to manual extraction.

Secondly, multiple medical dictionaries (Baker, 2004; Stöppler, 2013; Merriam-Webster; EMA; Acland, a,b; Law and Martin, 2020) were used to obtain more academic medical terms (27,565 unique terms in total). To account for the lack of recent COVID-19 terminology, we added these terms separately, obtaining them from multiple web pages (50 terms found through the Google query *"medical terms related to COVID-19"*).

Finally, as the third source of medical terms, ChatGPT-4o-mini was used. The model was prompted with: *"Output an enumerated list of 1500 medical terms or phrases that usually confuse patients"*. Although instructed to produce 1,500 terms, the initial output contained significantly fewer. After three prompting attempts, the model generated approximately 1,950 non-unique terms. Following manual filtering, only 125 unique and relevant terms remained.

As the next step, for each term from the three sources, its absolute frequency was obtained from the NGRAMS website[2]. Terms were filtered to include only those with an absolute frequency between 400,000 and 1,500,000. This range was chosen as a compromise: it avoids selecting too many "obvious" terms (which can be difficult to define simply and concisely in the next step) while also excluding terms that may be unfamiliar to most people. Words within this frequency range were uniformly and randomly sampled from the three sources. During the creation of the questionnaires, many selected words were replaced with others of similar frequency for the following reasons:

1. **Overly obvious terms**: phrases whose meanings are easily guessed if the individual terms are known, definitions that include the term itself, or words that are difficult to simplify (e.g. *body surface, seriously ill, liquid form*);
2. **Low relevance to patients**: specialised scientific, chemical, or genomics terminology (e.g. *florid, hydrogen bond, messenger RNA, data bank, The Lancet, Gaussian distribution*);
3. **Duplication**: terms with minor differences (e.g., extra apostrophes, hyphens, or capitalisation) or

[2]https://ngrams.dev

different grammatical forms (e.g., adjective vs. adverb, plural vs. singular);

4. **Uncommon or ambiguous abbreviations**: e.g. *OCD, RBC, CSC*;
5. **Clarification modifications**: terms requiring additions for proper medical context (*UFO* → *the "UFO" procedure*; *Adonis (complex)*).

After these adjustments, a final set of 1,000 words was selected for the questionnaire.

3.2 Questionnaire Design and Execution

To gather data on the recognition and understanding of medical terminology along with socioeconomic information, we conducted a series of questionnaires. The 1,000 refined terms were distributed across 25 questionnaires (40 terms each). This distribution helped to strike a balance between participant numbers and average completion time, as lengthy surveys may reduce concentration and response quality (Sharma, 2022). Each questionnaire comprised four sections:

1. **Self-rated confidence**: Participants first rated their confidence in medical terminology on a 10-point Likert scale;
2. **Term familiarity**: Respondents then evaluated their familiarity with 40 terms using a 4-point forced-choice scale: (1) "I never heard of this term before", (2) "I possibly heard this term before but I don't know its meaning", (3) "I think I know something about this term and know something about its definition", (4) "I know this term and know what it means".
3. **Definition accuracy**: Participants selected the correct definition for each term from four options (matching the terms in section 2). Correct definitions were sourced from online medical articles, prioritizing simple wording. Non-essential details were omitted without compromising meaning. Terms requiring overly lengthy explanations were replaced with frequency-matched alternatives (see Section 3.1);
4. **Socioeconomic data collection** The final section covered the following broad topics: (1) Demographics, (2) Language background, (3) Geographical exposure, (4) Education, interests & profession, (5) History of serious illness (self or close family).

To generate three false but plausible definitions for each term, we utilised LLMs (ChatGPT-4o-mini and DeepSeek-V3 OpenAI, 2024; DeepSeek-AI, 2025b). However, fully automating this process proved unfeasible due to several limitations:

- **Repetitive output**: The models frequently produced similar definitions or variations on the same theme;
- **Formulaic structure**: Generated definitions often followed predictable patterns, such as: *"<Simple definition>, often caused by <...>, [typically occurring <...>, [especially <...>]]"*;
- **Overly personalized language**: The outputs sometimes used informal phrasing (e.g. "your body" instead of "the body"), which differs from standard medical definitions found online;
- **Topic divergence**: In some cases, the generated definitions were entirely unrelated to the medical term. For instance, for *"cardiogram"*, an LLM might propose a definition unrelated to the heart or diagnostic procedures. Such obviously incorrect options could make the correct answer easier to identify (even for someone completely unfamiliar with the term). Although guessing might help patients during consultations, and the exercise may have value in itself, it fails to test confusion between commonly misassociated medical terms (e.g., "bipolar disorder" vs "multiple personality disorder").

Consequently, we used manual data curation with LLM assistance to create the false definitions.

The questionnaire was administered via Prolific[3]. A total of 25 surveys were conducted, with ten participants recruited for each survey. The average completion time was 18 minutes (median = 15 minutes, SD = 10 minutes). The following pre-screening criteria were applied to most surveys: (a) English as the first and primary language; (b) Participants had to be born in, currently reside, and hold nationality of one of the following countries: Ireland, the United Kingdom, the United States, Canada, Australia, or New Zealand. All participants who had previously completed any of the surveys were excluded during pre-screening.

3.3 Dataset Analysis

Survey results were analysed from two perspectives: the participants' perspective (how well a person performs) and the terms' perspective (how complex a term is). For the latter, we compare how the term complexity score derived from participant performance differs from that estimated by LLMs. This analysis was performed using Gemma-3:27B (Gemma Team, 2025), Phi-4:14B (Abdin

[3]https://www.prolific.com/

et al., 2024), Mistral-Small-3.1:24B (Mistral AI, 2025), Llama-3.3:70B (Meta, 2024), DeepSeek-R1 (DeepSeek-AI, 2025a), and ChatGPT-4.1 (OpenAI, 2025)[4].

To instruct an LLM to output evaluation scores, Leng et al. (2023) recommends using an integer (not float) scale, such as 0-3 or 0-4, for better results. Although a larger scale (0-10) was not recommended due to the "difficulty in coming up with distinguishing criteria between all scores", we compared both the 0-4 and 0-10 scales to assess differences. For reliability, we performed five evaluations per term and averaged the results. To balance variability in LLM outputs with reliability and instruction adherence, we set the temperature to 0.2 (AI21, 2025).

As noted in multiple studies (Clarke and Dietz, 2024; Qin et al., 2024; Christiano et al., 2023), LLMs perform better as rankers than scorers. Thus, we sorted the terms in each questionnaire (40 terms per ranking) using Python's built-in sorting function with a custom LLM-based comparator. For the comparator, we set the temperature to 0.0 and used the following prompt: *You are a helpful AI assistant. Your task is to predict which term is likely to be correctly understood by the majority of people: term 1: <term_1> or term 2: <term_2 >. Output 1 if term 1 is likely to be correctly understood by the majority of people than term 2. Otherwise, output 2. Output just the number*. This approach was inspired by Wang et al. (2025), but we replaced their Bubble Sort algorithm with Python's Timsort (Peters, 2002) to reduce LLM calls. Timsort efficiently handles partially ordered data, and terms were pre-sorted by frequency – a known correlate of complexity (Hashimoto, 2021; Stewart et al., 2022).

Finally, these ranking results were transformed into complexity scores. For this conversion, we calculated each term's percentile within its questionnaire and mapped it to a number in the [0, 10] interval using the percent point function (PPF) of the Gaussian distribution $\mathcal{N}(5, 1.8^2)$ (University of Illinois, 2025; Virtanen et al., 2020). The output was then min-max scaled to the 0–1 range. This two-step procedure mitigates the numerical instability that arises from the small scale σ of the Gaussian distribution by getting 0-1 score in one step.

[4]The following prompt was used for each of the listed models: *You are a helpful AI assistant. A medical term is called simple if it is understood correctly by the majority of people. Your task is to evaluate the simplicity of the medical term "<...>" on a scale from 0 (very complex) to <MAX_GRADE> (very simple). Output just the simplicity score.*

3.4 Features for Terms Complexity Prediction

We selected features for ML models to predict term complexity based on three recent papers.

Inspired by Dalvean (2024), we used binary positional letter variables (e.g., "a2" = *True* – or 1 – if the *second* letter is "a"). From their study, we selected 66 significant binary letter position variables. Dalvean solved the complexity prediction task for individual words, whereas in our paper, a medical term may consist of multiple words. In these cases (e.g., *"kidney failure"*), values of positional letter variables are averaged across words (e.g., if "a2" is 0 for *"kidney"* and 1 for *"failure"*, the term-level value of "a2" variable is 0.5).

From Cheng Sheang et al. (2022), we adopted: (1) FastText embeddings (reduced from 300 to 10 dimensions via PCA to avoid the curse of dimensionality); (2) English Wikipedia absolute word frequency; (3) Word character, syllable and vowel count; and (4) Word rank (the frequency order from the FastText pre-trained model). All features are averaged for multi-word terms.

Finally, following Mosquera (2021), we included the following features:

- **Morphological**: Word character, syllable (Holtzscher, 2022), and morpheme counts (Cuko and Warren, 2023); medical word parts number (e.g. 2 for angiogram, as it consists of angio- and -gram Tsutsumi, 2017); is acronym/abbreviation (regex-based), word lemma/stem length (Bird et al., 2009);
- **Frequency**: Google n-gram[5] frequency (of a full medical term), Wikipedia absolute word frequency, Zipf frequency (Speer, 2023), Wikipedia documents count (where a term appeared), consonant frequency;
- **Lexical**: WordNet senses, synonyms, hypernyms, and hyponyms counts (Miller, 1994);
- **Psycholinguistic/other**: Average age of acquisition (Kuperman et al., 2012), first year of appearance (of a full term) using Google n-gram.

Similarly, the features are averaged for multi-word terms (except Google n-gram-related ones).

4 Results and Analysis

In this section, we present our analysis of the collected data (information obtained via question-

[5]https://books.google.com/ngrams/

naires and Prolific demographic data) on the medical terms complexity.

4.1 Respondents' Profiles and Terms Analysis

The mean and median age of all questionnaire respondents were 39.1 and 37.0, respectively. The age distribution was right-skewed, with one-third of participants under 30 years of age.

Most of the participants were from the US, the UK, South Africa and Canada, and more than 90% were native English speakers. The gender distribution was balanced, but the ethnicity was heavily skewed toward White (70%), followed by Black (20%) and Mixed/Asian/Other (10%).

For 231 respondents, it was known whether they were students or not. Approximately 70% (170 people) were not students at the time of the survey, with "Mathematics and Computer Science" and "Health Sciences" being the most popular fields of education. Only 3% of respondents reported having less than a high school diploma, while 23% had only a high school diploma. In addition to collecting socioeconomic data, we collected information on participants' confidence in medical terminology and whether they considered themselves medical professionals. Participants rated their confidence in medical terminology highly, with a mean of 6.3 on a 0-10 Likert scale, a median of 7.0, and a standard deviation of 2.4. Approximately 20% of the participants identified as trained or practising medical professionals (e.g., doctors, nurses, etc.).

To estimate participants' fine-grained self-reported knowledge of medical terms, a new variable, familiarity score (y), was introduced:
$y = 1 * x_1 + 2 * x_2 + 3 * x_3 + 4 * x_4$, where:
x_1 = number of times that the option "I had never heard of this term before" was selected;
x_2 = selections of "I possibly heard this term before but I don't know its meaning";
x_3 = selections of "I think I know something about this term and know something about its definition";
x_4 = selections of "I know this term and know what it means".

With 40 terms per questionnaire, the possible *familiarity score* ranges from 40 (if all responses scored 1) to 160 (if all responses scored 4). The distribution of familiarity scores was tested for normality using the Kolmogorov-Smirnov test (KS statistic = 0.0708, p = 0.1523, n = 252), which did not reject the null hypothesis of normality. However, the Shapiro-Wilk and D'Agostino K^2 tests suggested non-normality. The scores had a mean of 112 and a median of 111 (SD = 23), with a skewness of 0.08 and kurtosis of -0.7.

Let us examine how accurately participants selected the correct definitions for all 40 terms in the survey (participants' *accuracy score*). The mean and median values of the correct definition selection score were approximately 0.6, indicating that on average each participant correctly identified about 24 out of the 40 terms.

Similarly, the term *complexity score* is determined by the success rate of participants in selecting its correct definition (calculated as the number of correct selections divided by the total number of attempts). A score close to zero indicates a very difficult term (understood correctly by none of the participants), while a score close to one represents a very simple term (understood correctly by all participants). The mean and median complexity scores of the medical terms were approximately 0.6. The distribution showed slight negative skewness (-0.24, indicating a tendency towards simpler terms) and platykurtic kurtosis (-0.71).

We calculated the correlation between n-gram frequencies (originally used for the selection of medical terms, from ngrams.dev) and term familiarity scores, finding both Pearson (r = 0.065) and Spearman (ρ = 0.087) correlations to be negligible. We then analysed absolute term frequencies using an English Wikipedia dataset from BEEspoke Data (2023) (counting total word occurrences). Here, the Spearman correlation remained weak, though slightly stronger (ρ = 0.25), while Pearson's correlation remained close to zero (r = 0.05). Finally, we examined the correlation between term familiarity scores and the number of Wikipedia documents containing each term, obtaining similar results (Pearson r = -0.03; Spearman ρ = 0.31).

4.2 Medical Terms Complexity Modelling

Understanding the complexity of medical terms is valuable for improving readability and accessibility in healthcare communication. It is interesting to examine the features that contribute to term complexity. Three sets of features (discussed in Section 3.4) were analysed. For the score prediction task (regression), multiple machine learning models were tested for each feature set, including linear regression, decision tree, random forest, multilayer perceptron (MLP), CatBoost, and support vector regression (SVR) (Pedregosa et al., 2011; Dorogush

et al., 2018), using 5-fold cross-validation.

First, as a baseline, a simple model based solely on term frequencies (including n-gram frequency from *ngrams.dev*, absolute term frequency from Wikipedia, and the count of Wikipedia documents in which a term appeared BEEspoke Data (2023)) was tested. The best-performing model was the decision tree regressor, with an RMSE of 0.23 and a Median Absolute Error (Median AE) of 0.17. A second baseline was tested, which simply predicted the mean term complexity score of 0.62 (for RMSE) and the median term complexity of 0.6 (for Median AE). For this baseline, the RMSE was 0.23 and the Median AE was 0.20. Third, the aforementioned models were trained using only the familiarity score. Here, the SVR and Decision Tree models performed best, achieving an RMSE of around 0.20 and a Median AE of around 0.13. However, the familiarity score was not used in subsequent experiments, as it is a data leak in a way.

The best-performing model using the features from Dalvean (2024) was CatBoost regression, with an RMSE of 0.23 and a Median AE of 0.18 (while the decision tree regression model achieved comparable results). The most important features, based on CatBoost's feature importance analysis, were *d1*, *n4*, *t1*, *u5*, *s5*, *s3*, *s2*, and *t3*.

Among the models using features from Cheng Sheang et al. (2022), random forest regression and CatBoost regression performed best, with RMSE values around 0.22 and median absolute errors around 0.16. For the CatBoost regressor, we analysed both feature importance and Shapley values. The most influential features were *Word Rank from FastText*, *Embedding_0*, and *Embedding_3*.

A model incorporating features from Mosquera (2021) was explored. Again, the CatBoost regressor performed best, while the decision tree regressor and random forest regressor achieved comparable results. The CatBoost model achieved an RMSE of around 0.22 and a median absolute error (AE) of 0.16. For this model, feature importance and Shapley values were analysed. The most important features included *Zipf Frequency*, *Morpheme Count*, *Google N-gram Frequency*, *Absolute Word Frequency*, *Wikipedia Document Count*, and *Average Age of Acquisition*. Finally, the BERT Base Uncased model (Devlin et al., 2018) was fine-tuned to predict the target scores based solely on the terms themselves. This model achieved an RMSE of 0.23 and a median AE of 0.16.

Overall, the best models performed comparably, with an RMSE of around 0.22 and a median AE of around 0.16. These results are close to the baseline model's mean and median scores (0.23 and 0.20, respectively). However, the performance remains poor given that the target variable's mean and median values are approximately 0.6. This suggests that the tested variables provide little predictive benefit.

4.3 LLMs Scoring and Ranking Capabilities of Medical Terms Complexity Evaluation

The ranking and scoring abilities of LLMs were explored to predict the complexity of medical terms. Table 1 presents the overall results for each LLM (using both 0–4 and 0–10 evaluation scales). As shown, Mistral-Small-3.1:24B and Phi-4:14B performed best in terms of both RMSE and Median AE. Contrary to the conclusion in Leng et al. (2023), the 0–10 scale evaluation yielded better results than the smaller 0–4 scale. The RMSE and Median AE scores suggest that LLMs have some potential for medical term complexity evaluation, outperforming the approach of training ML models using standard features (as discussed in the previous section). Additionally, refining prompts to include conditions aligned with the target audience may further improve performance.

LLM	RMSE	MAE
DeepSeek-R1	0.24 (0.26)	0.17 (0.20)
Gemma-3:27B	0.28 (0.30)	0.20 (0.22)
ChatGPT-4.1	0.28 (0.30)	0.20 (0.20)
Llama-3.3:70B	0.27 (0.28)	0.20 (0.20)
Mistral-Small-3.1:24B	**0.21** (0.22)	0.14 (0.15)
Phi-4:14B	**0.21** (**0.21**)	**0.12** (0.15)

Table 1: Summary of LLMs complexity prediction results; MAE means Medium Absolute Error. The results in parentheses are for 0-4 scale.

To compare the correlation between human and LLM errors, we analysed the errors of DeepSeek-R1 with a 0–10 scale (terms sorted by the absolute difference between predicted and actual complexity scores) and human error (terms sorted by the absolute difference between normalised term familiarity scores and actual complexity scores). The correlation values were approximately 0.42 for Pearson and Spearman rank correlations and 0.3 for Kendall's Tau, indicating weak to moderate relationships. We also evaluated the Pearson and Spearman rank correlations between LLM-evaluated complexity scores and ground-truth human-based

scores to assess how well LLMs align with human judgments. DeepSeek-R1 (0–10 scale) achieved the highest overall correlation (0.51 Pearson, 0.52 Spearman), while other models showed comparable results (Pearson: 0.42-0.50; Spearman: 0.46-0.51).

The ranking abilities of LLMs were tested for the task of ranking medical terms by complexity. First, term complexities were derived from rankings using the procedure described in Section 3.3. The lowest RMSE score (0.25) was achieved by the DeepSeek-R1 and ChatGPT-4.1 models, which was very close to the other models' scores (with a maximum RMSE of 0.27). The median absolute error was 0.20 for all models. Pearson and Spearman rank correlations between LLM-evaluated and ground-truth complexity scores were also measured. ChatGPT-4.1 had the highest overall correlation (Pearson: 0.48; Spearman: 0.50), while Gemma-3:27B and Phi-4-14B had the lowest (Pearson: 0.36; Spearman: 0.39). Similarly, to compare human and LLM errors, we analysed the correlation between the absolute error of LLM rankings and human error. This analysis yielded weaker correlations: 0.25 for Pearson and Spearman, and 0.18 for Kendall's Tau.

5 Discussion

The study analysed the complexity and awareness of medical terms among respondents, mainly from English-speaking countries. Most of the respondents were confident in their knowledge of medical terminology. Machine learning models showed limited success in predicting the complexity of medical terms. CatBoost regression performed the best but was only slightly better than the mean-guessing baseline. LLMs demonstrated potential in assessing term complexity, outperforming traditional ML models. However, in terms of RMSE scores, both traditional ML models and LLM achieved comparable results (0.22 and 0.21, respectively), which were only marginally better than baseline (0.23). This suggests the inherent difficulty of the task and the limitations of the features used for complexity prediction. An important consideration is whether the computational cost of LLMs (especially, "reasoning" ones) justifies such a small improvement.

6 Limitations

While Prolific provided a diverse participant pool, its users do not fully represent real patient populations due to platform access requirements (e.g., often English proficiency, digital literacy). In addition, participants viewed isolated medical terms without any context, which may affect understanding in real world settings. Furthermore, although we tested basic comprehension of terms from multiple medical domains, patients are typically more familiar with terms related to their personal health conditions. Medical terms are inherently complex, and brief definitions (e.g., defining ADHD as "a neurodevelopmental disorder with inattention/hyperactivity symptom") cannot capture all nuances (e.g. subtypes, life impact, or treatment options). Thus, even selecting an accurate definition does not ensure full comprehension of a term.

7 Future work

For direct extensions of this work, testing patients on medical terms from their own health records would better assess their understanding of relevant terminology. Another important consideration is public misconceptions about medications. For example, in our study, only 1 in 10 participants correctly identified *metronidazole* as an antibiotic; most incorrectly associated it with viral infections or blood pressure management. Although based on a small sample, such misunderstandings could contribute to antibiotic resistance (Naghavi) and warrant further investigation.

8 Conclusion

The results suggest that participants generally rate their knowledge of medical terms highly, although their actual understanding may vary. Despite the modest performance gains of machine learning models, LLMs offer a promising alternative for assessing the complexity of medical terms. Further development and integration of contextual and demographic data could improve predictive accuracy in future studies.

Where and How as Key Factors for Knowledge-Enhanced Constrained Commonsense Generation

Iván Martínez-Murillo, Paloma Moreda, Elena Lloret
Department of Language and Computing Systems, University of Alicante,
Alicante, Spain, 03690.

Abstract

This paper addresses a key limitation in Natural Language Generation (NLG) systems: their struggle with commonsense reasoning, which is essential for generating contextually appropriate and plausible text. The study proposes an approach to enhance the commonsense reasoning abilities of NLG systems by integrating external knowledge framed in a constrained commonsense generation task. The paper investigates strategies for extracting and injecting external knowledge into pre-trained models, specifically BART and T5, in both base and large configurations. Experimental results show that incorporating external knowledge, extracted using a simple strategy, leads to significant performance improvements, with the models achieving 88% accuracy in generating plausible and correct sentences. When refined methods for knowledge extraction are applied, the accuracy further increases to 92%. These findings underscore the crucial role of high-quality external knowledge in enhancing the commonsense reasoning capabilities of NLG systems, suggesting that such integration is vital for advancing their performance in real-world applications.

1 Introduction

The rapid advancement of Natural Language Generation (NLG) systems has significantly transformed the field of Artificial Intelligence (AI). Modern NLG systems are capable of producing text in a very similar way humans would do, with high coherence and fluency (Sepúlveda-Torres et al., 2025). Moreover, these systems demonstrate impressive performance across a wide range of tasks (Liang et al., 2024). Despite these achievements, one critical area where such models continue to fall short is commonsense reasoning for generating plausible and fluent sentences (Miró Maestre et al., 2025; Seo et al., 2024).

Commonsense knowledge plays a fundamental role in human communication, enabling individuals to make inferences without the need for explicit elaboration. This intuitive ability is crucial for effective and contextually appropriate communication. In the context of NLG, the absence of commonsense reasoning can result in outputs that, although plausible, often lack fluency or contextual appropriateness, as illustrated by the examples in the red box in Figure 1.

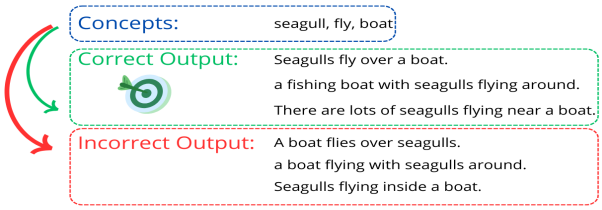

Figure 1: Constrained commonsense text generation task.

A common way to address this limitation is by integrating external knowledge into NLG models (Jiang et al., 2024). In this context, external knowledge refers to information from knowledge bases that helps enhance the model's understanding. By using such knowledge, NLG systems can produce sentences that are more plausible and better aligned with the given context.

This paper investigates strategies to improve commonsense reasoning in NLG by incorporating external knowledge into the constrained commonsense NLG task. The goal is to generate a plausible sentence that includes a given set of input words as input. Figure 1 illustrates an example of this task, highlighting sentences in the red box that are syntactically correct but not semantically valid. This task is challenging because NLG models often produce fluent text, but without a deep understanding of what they generate. Adding external knowledge can help models reason more effectively, resulting in more coherent and contextually accurate outputs. This study focuses on addressing two main research

Proceedings of Recent Advances in Natural Language Processing,pages 694–703
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-080

questions:

- *Where should external knowledge be injected into pre-trained models?* To answer this, we analyze the most appropriate stage for knowledge integration—whether during fine-tuning, inference, or both.

- *How can external knowledge be effectively retrieved?* We conduct a study on different extraction techniques and assess their impact on the quality of the generated text.

2 Related Work

Constrained Commonsense Text Generation: Constrained Text Generation is a subtask of NLG that focuses on producing text under specific restrictions. These constraints can be lexical, length-based, semantic, syntactic, or stylistic (Zhou et al., 2023). Among the lexical-constrained text generation tasks, the CommonGen (Lin et al., 2020) task emerges to test the commonsense reasoning ability of generative NLG models. Given three keywords as input, the system must generate a plausible sentence containing those words.

The best approaches addressing this task have relied on the one hand training a retriever of documents to identify relevant candidate sentences that are then used for the generation process as a context (He et al., 2022; Yu et al., 2022b), and on the other hand, filtering the knowledge to input the model and applying machine learning methods for training those models (Li et al., 2021).

Knowledge Enhanced Approaches: Knowledge-enhanced NLG aims to improve the relevance and accuracy of generated text by incorporating external knowledge (Yu et al., 2022a). This knowledge can come from three main sources: structured knowledge bases, knowledge graphs, and grounded text. Knowledge bases and graphs are often organized as subject-predicate-object triplets. In graphs, these elements are further connected in a tree-like structure, which improves their interrelation. Grounded text refers to textual information collected from online sources.

Different works proposed methods for enhancing NLG systems with external knowledge. KG-BART is a NLG system which is built on the BART model by replacing its standard Transformer with a Knowledge Graph-Augmented Transformer. This change allows the model to use grounded knowledge graphs more effectively through a graph attention mechanism. Similarly, Wang et al. (2021) enhances pre-training by retrieving related sentences from external corpora and uses a trainable retriever during fine-tuning to improve results.

Despite promising outcomes, knowledge-enhanced NLG still faces challenges (Hu et al., 2023). These systems often depend on static knowledge, which can become outdated. Additionally, if retrieved information is not properly aligned with the context, it may introduce errors or hallucinations. Finally, evaluating the true benefit of external knowledge also remains difficult due to the lack of faithful evaluation metrics.

3 Knowledge-enhanced NLG Strategies

In this section, we propose a three-stage approach for addressing the task of lexically constrained commonsense NLG. The proposed approach is illustrated in Figure 2.

1. **Knowledge extraction**: We dynamically retrieve knowledge from an external knowledge base by matching each word candidate to be included in the generated sentence with relevant entries in the knowledge base. We experiment with different methods to retrieve the knowledge.

2. **Prompt Engineering**: We combine the extracted knowledge with the corresponding dataset entry using a prompt engineering method based on knowledge contextualization. In this approach, each keyword that needs to be included in the generated sentence is matched with the related extracted knowledge. The obtained relations are then added to the prompt to provide context. The prompt starts with an initial premise *"Generate a short sentence using the following words"*, and this is followed by the concepts to be included in the generated sentences and the retrieved most-common relation for those words.

3. **Knowledge Injection**: A pre-trained model is then fine-tuned on the dataset enriched with this external knowledge. We conduct a series of experiments to determine the optimal stage for knowledge injection (during fine-tuning, during the models' inference, or in both). As a consideration, incorporating knowledge during the inference step ensures that the information remains as up-to-date as possible.

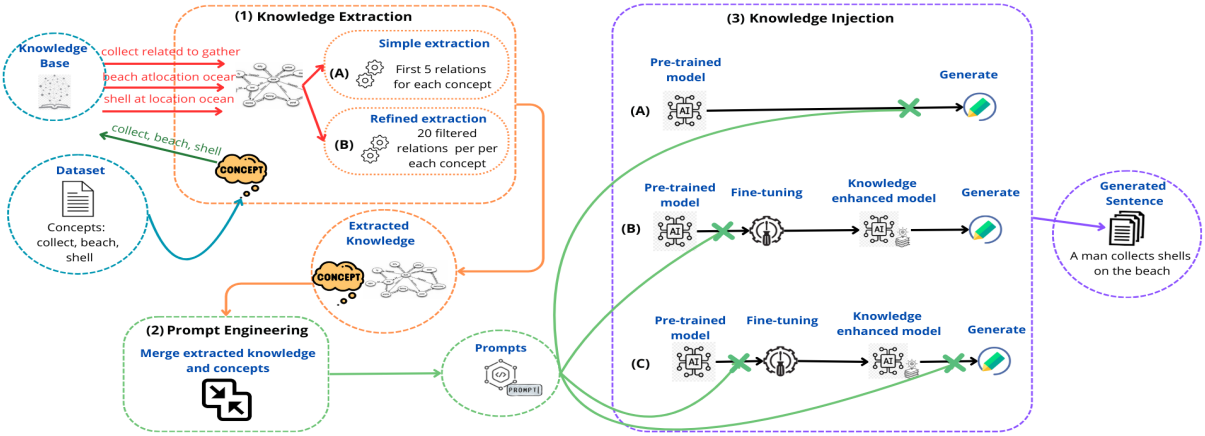

Figure 2: Proposed approach to enhance commonsense in NLG systems

4 Resources

This section describes the experimental setup for evaluating the effectiveness of augmenting pre-trained models with external knowledge.

4.1 Dataset

We frame our generation task within the CommonGen shared task (Lin et al., 2020), using its corpus for our experiments. The task aims to generate coherent sentences that describe everyday scenarios with a given set of keywords, testing the ability of NLG systems to produce commonsense outputs while including those keywords.

The dataset is split into training, validation, and testing subsets, with each keyword set associated with up to three reference sentences as targets. Dataset details are summarized in Table 1.

Corpus	*Train*	*Dev*	*Test*
Concept sets	32 651	993	1 497
Target sentences	67 389	4 018	N/A

Table 1: CommonGen Dataset distribution. N/A indicates that no records are available.

Since the reference sentences for the CommonGen test subset are not publicly available, we used the validation subset as our test subset, to be able to perform an automatic evaluation of the generated sentences. We also excluded one sentence from the validation subset due to the word "cain", which was treated inconsistently in the original dataset as "cane". This led to the validation subset consisting of 992 sentences, which composed our test subset. Furthermore, we split the original training subset into two subsets, using 90% for training and 10% for validation. This split ensures model generalization by evaluating performance on unseen data before final testing.

4.2 Knowledge Base

By leveraging external knowledge sources, NLG models can generate more coherent and contextually appropriate sentences while reducing the likelihood of hallucinations. To achieve this, we incorporated ConceptNet (Speer et al., 2017), as the external knowledge graph. ConcepNet is a widely used knowledge graph that encodes commonsense relationships between words in the form of triplets (e.g. "Word - RelatedTo - Sentence"). ConceptNet is particularly valuable for the CommonGen task, as it provides structured, human-curated associations that reflect real-world interactions. Since CommonGen focuses on generating plausible sentences describing everyday scenarios, ConceptNet enhances the fluency and realism of generated sentences.

4.3 Pre-trained Models

Pre-trained models are transformers trained on large datasets, which acquire general knowledge that can be fine-tuned for specific tasks with minimal training. Compared to LLMs, pre-trained models are smaller and more efficient, requiring fewer computational resources. Despite their smaller size, fine-tuned pre-trained models can often achieve comparable performance to LLMs in certain NLG tasks (Li et al., 2024). This efficiency makes them well-suited for scenarios with resource constraints. Based on these strengths, we have chosen to experiment with pre-trained models as the foundation of our methodology.

In the context of the CommonGen task, the approaches with the best results used BART (Lewis et al., 2020) and T5 (Raffel et al., 2020) as foundational models[1]. As a result, we selected these models for our experiments, testing two versions of each: BART-Base and BART-Large, as well as T5-Base and T5-Large. The BART-Base model features 6 encoder-decoder layers and about 140 million parameters, while BART-Large has 12 encoder-decoder layers and approximately 400 million parameters. For T5, the Base version contains 220 million parameters, while T5-Large has 770 million parameters. Both models are encoder-decoder architectures pre-trained for text-to-text tasks.

4.4 Fine-tuning

After successfully extracting and injecting the retrieved external knowledge, the next step is to train the models to perform effectively on the CommonGen task. To achieve this, we fine-tuned the pre-trained models mentioned in Section 4.3 using the constructed inputs through the prompt-engineering step. The hyperparameter configuration used during the training process is as follows: we trained our systems for a total of 4 epochs, with a batch size of 32, a dropout rate of 0.1, a learning rate of 1e-4, and 1000 warm-up steps. All the experiments were conducted on a single NVIDIA A100 GPU.

5 Experiments & Evaluation

In this section, we outline the experiments conducted to address the research questions stated in Section 1.

5.1 Where to Inject External Knowledge?

We conducted different experiments to evaluate the impact of incorporating external knowledge in pre-trained models. As previously mentioned, we used the BART and T5 models in their base and large versions. The objective was to determine whether the inclusion of external knowledge impacts model performance and to identify where knowledge injection is most effective—during training, during inference, or both. To this end, we designed experiments under four conditions:

1. *No external knowledge*, where the models were fine-tuned on the CommonGen train dataset and the generated sentences were produced from the trained models over the development set. This experiment serves as a baseline, where no external knowledge is introduced.

2. *Knowledge in Inference*, in which we use a base model without fine-tuning it, relying only on external knowledge we extracted to assist in the generation step (path A in Stage 3 of Figure 2).

3. *Knowledge in Train*, in which our extracted external knowledge is incorporated during the fine-tuning process (path B in Stage 3 of Figure 2). The sentences are then generated using the resulting model on the CommonGen development set, without the help of the external knowledge being provided during the generation step.

4. *Knowledge in All* that combines the injection of external knowledge during both fine-tuning and inference steps (refer to Path C in Stage 3 of Figure 2).

To evaluate the experiment on determining where it is most optimal to inject knowledge, we relied on automatic metrics. Moreover, we aimed to compare our results using the same metrics employed in the CommonGen task. For this purpose, we utilized two of the evaluation metrics proposed in the CommonGen task: CIDEr (Vedantam et al., 2015) and BLEU_4 (Papineni et al., 2002). Additionally, we also evaluated the generated sentences using BLEU_1. BLEU_1 was included to specifically assess unigram precision, providing insight into basic word-level accuracy.

Moreover, we incorporate additional metrics beyond those originally employed in the CommonGen task. These supplementary metrics—ROUGE (Lin, 2004), BERTScore (Zhang et al., 2020), the Hallucination Evaluation Model (HHEM) (Bao et al., 2024), and AlignScore (Zha et al., 2023)—allow for a more nuanced assessment of various aspects of text quality. By leveraging multiple evaluation metrics, we aim to mitigate the limitations of any single metric and obtain a more holistic understanding of the model's performance.

5.2 How to Extract and Incorporate External Knowledge Effectively?

After identifying the optimal phase for injecting knowledge, we experimented with different methods of knowledge integration and examined to which extent refining the extracted knowledge

[1]https://inklab.usc.edu/CommonGen/leaderboard.html

impacts the output. We followed two different methodologies to extract the knowledge from ConceptNet:

- ***Simple Extraction***: For each keyword in the CommonGen dataset, we queried the ConceptNet API to retrieve its associated relations. In this approach, we obtained only the first five instances returned by the API without any further filtering.
- ***Refined Extraction***: We queried the ConceptNet API for each keyword in the CommonGen dataset. However, in this approach, we first analyze and select specific types of relations to ensure that the extracted knowledge is more relevant to the context of general, everyday concepts represented by the keywords. The relations that are most suitable for everyday scenarios are:
  - IsA: Indicates that A is a subtype of B.
  - RelatedTo: Denotes a general relation between A and B when the specific type of relation is undefined.
  - PartOf: Specifies that object A is a component or subset of B.
  - HasA: Suggests that B is an inherent part of A or represents a social construct of possession.
  - AtLocation: Describes A as a typical or likely location for B.
  - HasProperty: Declares that A can be characterized as having property B.

  For each of these selected relations, we extracted up to 20 instances.

To determine how refining the search for external knowledge can be beneficial and to what extent it improves the quality of the generated texts, we conducted a manual evaluation. As demonstrated in prior works (Martínez-Murillo et al., 2024; Sai et al., 2022), automatic evaluation metrics do not always align well with human judgments, particularly for free-text generation tasks where the output is not constrained to a specific style. Thus, we manually classified the generated sentences into three-level categories to obtain better insights into the evaluation: 2, 1, and 0.

- *2 - Good sentences* are grammatically and semantically correct, exhibit commonsense reasoning, and describe plausible situations.
- *1 - Regular sentences* are semantically correct and describe plausible situations, but may require improvements in grammar or clarity.
- *0 - Bad sentences* are grammatically incorrect, describe implausible situations, or fail to convey the intended semantic meaning.

6 Results and Discussion

In this section, we present the results obtained based on our two research questions of our experimentation.

6.1 Determining Where to Inject External Knowledge

To identify where the injection of knowledge is most effective, we conducted a preliminary automatic evaluation of all model versions across the different stages of knowledge injection—training, inference, or both. We employed the metrics mentioned in Section 5.1 and evaluated the generated sentences from each experiment using the reference sentences from the development set as the gold standard. The results from this preliminary evaluation are presented in Table 2.

The two pre-trained model families (T5 and BART) exhibit a similar trend. The best results in most of the automatic metrics are obtained injecting the knowledge in both training and inference stages (*Knowledge in All* experiment). This approach consistently delivers superior performance across the four model versions. Surprisingly, the experiments with *No External Knowledge* achieved a similar performance with automatic metrics than the experiments *Knowledge in All*. Conversely, lower results were obtained in the *Knowledge in Inference* experiments. The reason is that the tested models have not been trained to handle the CommonGen task, thus generating sentences that are either unrelated to the task or simply replicate the prompt we give as input. In contrast, the experiments involving fine-tuning pre-trained models on the CommonGen dataset consistently yield outputs that better align with the task requirements. Among the three experiments, *Knowledge in Train* produces the lowest performance. This can be attributed to the fact that, although the model is exposed to relevant knowledge during training, it lacks access to the appropriate contextual knowledge at inference time, leading to less accurate sentence generation.

Overall, the results demonstrate that T5 slightly outperforms BART for all models' versions. No-

Model	Model Size	Experiment	CIDEr	BLEU_1	BLEU_4	ROUGE-L	BERTScore	HHEM	AlignScore
BART	Base	No External Knowledge	0.150	0.694	**0.266**	**0.516**	**0.543**	0.567	**0.631**

		Knowledge in All	**0.165**	**0.728**	**0.295**	0.542	0.547	**0.623**	**0.693**
	Large	No External Knowledge	0.168	**0.734**	0.307	0.551	**0.549**	0.664	**0.677**
		Knowledge in Inference	0.06	0.436	0.141	0.376	0.477	0.533	0.317
		Knowledge in Train	0.155	0.695	0.288	0.534	0.545	0.602	0.619
		Knowledge in All	**0.169**	**0.734**	**0.314**	**0.554**	0.548	**0.671**	0.662

Table 2: Results obtained with the automatic metrics for the 992 generated sentences for each experiment. Results in bold indicate the best performance for that model size according to each metric.

tably, even the T5-base model without external knowledge achieves better performance than any of the BART experiments. A manual analysis of the generated sentences reveals that this difference can be attributed to specific instances where BART fails more often to generate plausible sentences. For example, given the keywords *"yard, kid, and play"*, BART-base without external knowledge generates the sentence, "*A kid plays a ball in a yard*", whereas T5-base produces a more syntactically and semantically refined sentence, "*A kid is playing with a ball in a yard*". However, without external knowledge, both base models sometimes generate unnatural sentences. For example, given the keywords *"body, raft, water"*, BART produces "*body in the water on a raft*", while T5 generates "*body of water on a raft*". These outputs demonstrate that the models struggle to form contextually appropriate sentences. Despite these shortcomings, T5 generally produces more elaborate and coherent sentences compared to BART. Additionally, the larger T5 model outperformed the smaller version in all experiments.

Therefore, based on the results obtained through the automatic metrics, the most effective method within this experimentation to inject the knowledge is during both the training and inference steps.

6.2 Determining How to Extract and Incorporate External Knowledge Effectively Through a Manual Evaluation

We next proceeded to analyze in greater depth how to retrieve the knowledge in our method. In this context, we expanded our experimentation by refining the concept retrieval process to identify the most pertinent relations from ConceptNet and subsequently fine-tuned the best-performing model from the experiments in Section 6.1, T5-Large, by integrating this enriched knowledge.

Moreover, to verify whether the injected knowledge enhances the quality of the task, we conducted a manual evaluation. Precisely, we manually analyzed the sentences generated by the T5-Large model without external knowledge and with knowledge injected in all phases using both knowledge extraction methods: simple and refined. Each generated sentence was ranked on a three-level scale (0, 1, or 2) mentioned in Section 5.2. The results are shown in Table 3.

Enhancing the pre-trained model with additional knowledge significantly improves its performance, as evidenced by the manual analysis of the generated sentences. The number of incorrect sentences decreases from 168 without external knowledge to 89 with the incorporation of simple knowledge, representing a reduction of 79 sentences. Furthermore, with the injection of refined knowledge, the number of incorrect sentences decreases even further to 62, amounting to a reduction of 106 sentences. This corresponds to a 47% reduction with simple knowledge and a 63% reduction with refined knowledge. Similarly, the number of sentences that are not entirely correct but also not incorrect improves significantly. This category decreases from 49 sentences without additional knowledge to 25 when the model is enhanced with simple knowledge. Moreover, with the inclusion of refined knowledge, this number decreases further to 12 sentences. This represents a 49% reduction with simple knowledge and a 76% reduction with refined knowledge. The

Score	T5-Large		
	No Knowledge	*Knowledge in All Simple*	*Knowledge in All Refined*
Incorrect	168	88 (-47%)	62 (-63%)
Regular	49	25 (-49%)	12 (-76%)
Correct	775	878 (+13%)	918(+19%)

Table 3: Results of the manual evaluation of the 992 generated sentences in the knowledge extraction experiment.

most substantial improvement is observed in the category of correct sentences. Without knowledge, the number of correct sentences is 775. With the inclusion of external knowledge, the model improves up to 878 correct sentences out of 992 total, achieving an 88% accuracy rate for plausible and correct outputs. This accuracy increases further with the injection of refined knowledge, resulting in 918 correct sentences—92% of the total generated sentences. Compared to the baseline model without knowledge, the approaches incorporating external knowledge achieve a 13% improvement with simple knowledge and a 19% improvement with refined knowledge.

Overall, the manual evaluation results suggest that incorporating external knowledge has a greater impact than indicated by the automatic evaluation metrics. While the differences in automatic evaluation were minimal, the manual assessment revealed a significant percentage improvement.

To conduct a detailed study of the results, we analyzed sentences that were initially incorrect but became correct after the injection of external knowledge, as well as those that were correct in the original, non-enhanced model but became incorrect in the knowledge-enhanced model.

In the first scenario, 116 sentences that were generated as incorrect or partially correct without external knowledge were corrected after the injection of simple knowledge. This represents an improvement of nearly 12%. Furthermore, the improvement with the refined knowledge is bigger, being 178 the number of sentences that improved when injecting the refined knowledge.

Figure 3 presents representative examples illustrating these improvements in rows 1, 2, and 3.

- In **Row 1**, the improvement lies in the model's recognition that a machine cannot perform the action of wearing something, as this is a property of humans. Both knowledge-enhanced models correctly attribute the action of wearing to a human, each using a different object in the generated sentences.

- In **Row 2**, the implausible notion in the original sentence of placing apples from a bag onto a tree is corrected. The external knowledge helps the model understand that a bag is used for carrying items and that apples are a fruit associated with trees, leading to a more plausible scenario.

- In **Row 3**, the incorporation of external knowledge enables the model to understand that the net is the object fishermen use to catch fish, rather than the location where they catch them. Both knowledge-enhanced approaches recognize this distinction.

On the other hand, there are a few cases where sentences originally classified as correct without external knowledge were generated as incorrect after the injection of knowledge. This issue was observed in 12 sentences (approximately 1% of the total sentences) using the simple knowledge approach and 31 sentences (around 3%) with the refined knowledge approach. Examples of such cases can be found in rows 4, 5, and 6 of Figure 4.

- **Row 4**: In this case, the sentence generated using the simple knowledge approach is incorrect. This occurs because the external knowledge provided to the model may have introduced confusion. For the keyword "watch", the relations retrieved were solely associated with the object referring to time rather than the action of seeing. As a result, the model was unable to generate a sentence that reflected the correct meaning of the word. In contrast, the refined knowledge approach, which provided a greater number of carefully selected relations, enabled the model to interpret and use the correct sense of the verb.

- **Row 5**: In this example, the sentence generated with the simple knowledge approach is

	Concepts	T5-Large No Knowledge	T5-Large Knowledge in All Simple	T5-Large Knowledge in All Refined
1	['machine', 'wear', 'work']	A man is working on a machine that is wearing a helmet.	A man wearing a hat is working on a machine.	A man wearing a welding machine is working on a construction site.
2	['apple', 'bag', 'pick', 'tree']	A man picks apples from a bag on a tree.	A man picks apples from a tree in a plastic bag.	A man picks apples from a tree and puts them in a plastic bag.
3	['catch', 'fish', 'net', 'river']	A fisherman catches a fish in a net in a river.	A man catches a fish with a net in a river.	Fishermen catch fish with a net on the river.

Figure 3: Samples of improved generated sentences with knowledge.

	Concepts	T5-Large No Knowledge	T5-Large Knowledge in All Simple	T5-Large Knowledge in All Refined
4	['move', 'stand', 'watch']	Someone stands and watches as someone moves away	A man stands watch as a man moves down a street.	A group of people are standing and watching as someone moves away.
5	['head', 'shirt', 'wear']	A man in a white shirt is wearing a hat on his head.	A man wears a white shirt on his head.	A woman in a white shirt is wearing a hat on his head.
6	['leash', 'street', 'walk']	A dog walking on a leash in a city street.	A dog walking on a leash in a city street.	A giraffe walking on a leash down a street.

Figure 4: Samples of worsened generated sentences with knowledge.

also incorrect. While it is plausible for a person to wear a hat or something similar on their head, it is uncommon to wear a shirt there. This confusion may have been caused by the external knowledge provided, as one of the relations for "shirt" indicated that it is worn on the upper body. This may have led the model to incorrectly associate “head” with “upper body”, resulting in an inaccurate sentence. In contrast, the refined knowledge approach enabled the model to generate a correct sentence, as it included additional relations that specified the location of a hat as the head.

- **Row 6**: In this sample, the incorrect sentence is generated by the refined knowledge approach. The error arises from the implausibility of a giraffe being on a street with a leash. This scenario is more common for dogs or pets. In this case, the external knowledge provided does not associate "leash" with a dog or pet, which fails to assist the model in generating a plausible sentence.

As seen in the examples, selecting representative and relevant relations for injecting external knowledge significantly improves sentence quality. The more precise and relevant the knowledge is, the greater the enhancement in generation it has. Conversely, incorrect or ambiguous knowledge often leads to inaccurate outputs. Thus, refining the knowledge extraction method is crucial for producing more plausible sentences.

7 Conclusions & Future Work

This study highlights the importance of incorporating external knowledge to enhance the performance of pre-trained models on NLG tasks. By integrating additional knowledge during training and inference, sentence quality and plausibility improved notably. The refined knowledge extraction method, which prioritizes relevant relations, consistently outperformed the simpler approach, resulting in a 63% reduction in incorrect sentences and increasing correct and plausible outputs to 92%.

Despite these improvements, in some cases ambiguous or incomplete external knowledge sometimes led to inaccuracies, highlighting the need for more precise knowledge extraction mechanisms.

In conclusion, the results confirm that external knowledge enhances the capabilities of pre-trained models in NLG tasks, particularly when using a refined extraction approach. Future research could explore advanced methods for dynamically selecting and injecting knowledge, as well as extending these techniques to other NLG tasks and datasets. Since this approach is language-independent—as long as knowledge bases and datasets are available in other languages—future work will also explore its multilingual potential.

Abstract

Social media platforms like Reddit, YouTube, and Instagram amplify rapid dissemination of negative sentiment, potentially causing harm and fostering extremist discourse. This paper addresses the NLP challenge of predicting sudden spikes in negative sentiment by fine-tuning multilingual transformer models. We present a structured pipeline emphasizing linguistic feature extraction and temporal modeling. Our experimental results, obtained from extensive Reddit, YouTube, and Instagram data, demonstrate improved forecasting accuracy over baseline methods. Ethical considerations and implications for deployment in social media moderation are thoroughly discussed. The system includes user-centric interactive features such as real-time filtering dashboards, customizable negativity thresholds, and forecasting analytics, providing actionable insights for preventative content moderation. Given its real-time deployment potential and cross-platform applicability, our system offers actionable insights for proactive content moderation.

1 Introduction

Social media platforms play a critical role in communication, but frequently propagate toxic narratives. Reddit, YouTube, and Instagram, in particular, see frequent bursts of negativity, affecting user well-being and broader social discourse. Accurately forecasting such spikes enables proactive moderation and intervention. This paper introduces an NLP-centric solution: forecasting sentiment spikes through customized transformer models tailored to these platforms' unique linguistic landscape. Our implemented pipeline combines a fine-tuned multilingual transformer model (cardiffnlp/xlm-twitter-politics-sentiment) and an XGBoost regression model enhanced by Gaussian smoothing. To analyze narrative clusters, we applied HDBSCAN clustering combined with OpenAI embeddings.

Our contributions are as follows:

- A refined adaptation of the cardiffnlp/xlm-twitter-politics-sentiment model for social media-specific language;
- A linguistically informed feature extraction pipeline that captures early signals of negativity spikes;
- A robust forecasting model combining neural networks and ensemble learning for multi-day sentiment prediction;
- A rigorous evaluation framework cross-referenced with real-world events and historical spikes;
- Comprehensive ethical and practical framework for safe deployment, addressing potential misuse, user privacy, and algorithmic bias.

2 Related Work

Sentiment analysis traditionally focused on static text classification; recent studies increasingly integrate temporal dynamics for real-time online prediction. Transformer-based models, particularly multilingual variants, show significant social media promise. Our approach advances this by combining fine-grained linguistic analysis with temporal forecasting, addressing existing literature gaps.

2.1 Toxicity and Negativity Spike Prediction

Early efforts to identify harmful online discussions relied on burst detection (Papegnies et al., 2017), sequence modeling for civil-to-toxic shifts (Zhang et al., 2018), or LSTM-based models for hate speech temporal dynamics (Mathew et al., 2021). While highlighting temporal/conversational

Proceedings of Recent Advances in Natural Language Processing,pages 704–710
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-081

modeling's importance, these focus on toxicity *detection*, rarely applying to cross-platform contexts or prioritizing sentiment-driven *early warning systems* for proactive intervention, a core focus here.

2.2 Multilingual Sentiment and Offense Detection

Transformer-based models revolutionized multilingual NLP. Models like (Sigurbergsson and Derczynski, 2020) show strong offensive language detection capabilities across languages. XLM-R's success in OffensEval (Zampieri et al., 2020) further underscores multilingual transformers' power for social media toxicity. However, studies like (Chiril et al., 2020) (FRENK) reveal persistent cross-language performance gaps, indicating a need for robust, generalizable solutions. While effective for toxicity, these works often rely on static, task-specific datasets or lack the real-time generalizability across diverse social contexts and content types our system aims for.

2.3 Content Moderation and Social Media Dynamics

Research into social media dynamics explores content moderation policy effects. Studies like (Jhaver et al., 2019) investigate how Reddit moderation shapes user engagement/community fairness. (Ribeiro et al., 2021) conducted longitudinal studies on deplatforming ripple effects, while (Faddoul et al., 2020) used network analysis to map conspiracy narrative propagation on platforms like Reddit/YouTube. These works are crucial for understanding moderation's social effects and platform-specific behaviors. However, they typically focus on analyzing existing dynamics or retrospective intervention impact, stopping short of proactively forecasting harmful content surges.

2.4 Platform-Specific Analysis: Beyond Twitter

While Twitter is a primary sentiment/toxicity focus, research also delves into other platforms. (Zhang and Davidson, 2020) explored Reddit-specific BERT models for toxicity. Studies like (Thelwall et al., 2012) analyzed YouTube comment polarity/clustering, and (Gao et al., 2018) focused on Instagram for multimodal hate speech using joint embeddings. These platform-specific analyses reveal unique linguistic/behavioral traits. However, they often lack a unified, cross-platform predictive framework, typically functioning as static classifiers rather than proactive spike forecasting systems.

2.5 Our Work's Contribution and Gaps Addressed

Our research distinctively advances the field by primarily forecasting future negative sentiment surges, rather than merely detecting them. Unlike prior snapshot classifiers, our approach predicts upcoming volatility. We introduce a socially-trained, cross-platform system, fine-tuned on social media-native discourse across Reddit, YouTube, and Instagram content. Crucially, instead of binary classification, our model produces a single continuous negativity score, inherently better suited for temporal modeling and volatility analysis to identify sudden shifts.

This work addresses several critical gaps in existing literature:

- No existing model reliably predicts cross-platform, generalizable, real-time negativity spikes.
- Current literature lacks tools proactively flagging broad sentiment trends *before* crises escalate, especially across multiple content modalities/diverse community cultures.
- Most existing multilingual/content moderation models remain platform-bound, task-specific, or retrospective, limiting proactive intervention utility.

Integrating a fine-tuned multilingual transformer with an XGBoost regression model and linguistically-informed feature extraction, our pipeline offers a novel, practical solution for proactive content moderation.

3 Dataset and Preprocessing

We used social media data from diverse forums collected over six-month periods (three months before/after) each of four major sociopolitical events: the Capitol Insurrection, the Supreme Court's reversal of *Roe v. Wade*, George Floyd's death, and COVID-19 lockdowns. While Reddit served as our core dataset for sociopolitical event evaluation, we included parallel Instagram captions and YouTube video descriptions for generalizability. All text data underwent a unified sentiment preprocessing pipeline, which involved:

3.1 Data Collection

We collected approximately 2 million posts/comments via various APIs, ensuring representation from politically charged, mental health, and general forums. For comprehensive representation, we used stratified sampling, selecting forums known for diverse discourse (Zhuravskaya et al., 2020; DiGrazia et al., 2013; Dictionary, 2025; Association, 2004). APIs provided efficient data retrieval, yielding post/comment text and metadata (timestamps, author information, forum affiliation (SubredditStats.com, 2025)).

3.2 Text Cleaning

Text standardization involved removing URLs, special characters, emojis, and mentions, plus normalizing punctuation/capitalization. Raw social media text often contains noise hindering sentiment analysis; thus, our cleaning pipeline standardized text and removed disruptive elements:

- **URLs:** Removed to eliminate external links irrelevant to sentiment.
- **Special characters:** Non-alphanumeric symbols removed to simplify text.
- **Emojis:** Removed due to potential ambiguity/inconsistency in sentiment analysis.
- **Mentions:** User mentions (e.g., u/username) removed to avoid bias.
- **Punctuation/Capitalization:** Standardized for consistent text format, reducing variations not affecting underlying sentiment.

3.3 Temporal Aggregation

Hourly aggregation created continuous sentiment time series for robust temporal modeling. To analyze trends, we aggregated post/comment sentiment scores into hourly bins, transforming discrete data into a continuous time series of average hourly sentiment. This aggregation is crucial for identifying sentiment patterns, fluctuations, and applying time series forecasting techniques. Hourly aggregation balanced capturing fine-grained dynamics with noise reduction; finer aggregation (e.g., minute-level) risks excessive noise, while coarser (e.g., daily) may obscure short-term trends.

3.4 Sentiment Labeling

We fine-tuned the transformer model on manually annotated data. Posts exceeding a determined negativity threshold were labeled ”negative”, with hourly bins flagged as spikes based on aggregated sentiment. Spikes replicated trends observed on chosen sociopolitical event days. For model training, we manually annotated a dataset, carefully assigning sentiment labels considering linguistic context/nuances. An experimentally validated negativity threshold ensured accurate sentiment reflection. Hourly bins identified periods of high negativity for spike forecasting. Manual annotation is crucial for model quality, providing labeled examples for accurate classification of unseen posts.

3.5 Data Splitting and Class Balance

Our dataset was chronologically split for evaluation to prevent data leakage, with each sociopolitical event’s date serving as a natural cutoff. Data three months prior to each event was used for training/validation, and three months post-event for testing. Within these segments, we applied an 80% training, 10% validation, and 10% testing proportional random split. Given spike events are naturally less frequent, we addressed class imbalance by undersampling non-spike days for balanced representation. A classifier further filtered for ’usable’ posts, focusing on politics/relevant topics, reducing irrelevant posts far from negativity peaks and optimizing the dataset for spike detection. This strategy ensured clear training signals for rare, critical spike events.

4 Model Architecture

We adapted cardiffnlp/xlm-twitter-politics-sentiment, a multilingual transformer originally pre-trained on political discourse, to score sentiment across Reddit, YouTube, and Instagram posts after preprocessing and linguistic annotation:

4.1 Fine-Tuning Procedure

The cardiffnlp/xlm-twitter-politics-sentiment model(CardiffNLP, 2022) served as the foundation of our sentiment analysis framework. To adapt this model to the specific characteristics of social media language and our spike forecasting task, we employed a single-stage fine-tuning procedure. This process utilized our manually annotated and pre-filtered dataset.

For optimization, we used the Adam optimizer with an initial learning rate of 2e-5, which was gradually decreased during training. The fine-tuning was performed with a batch size of 32 for 40 epochs, minimizing standard cross-entropy loss between predicted sentiment labels and ground truth labels. All fine-tuning experiments were conducted on a Google Colab T-4 GPU environment. Hyperparameter tuning was guided by a grid search approach, ensuring optimal performance on a validation set.

4.2 Embedding Optimization

Contextual embeddings were explicitly adapted to capture slang, community-specific jargon, and linguistic constructs common to social media. This optimization was integrated into our single-stage fine-tuning process. We leveraged Estimation Maximization (EM) with Snorkeling from Labeling Functions (LFs) to programmatically generate additional weak labels, effectively expanding the training signal and enabling the model to better capture the nuances and subtleties of social media language during fine-tuning. This process allowed the model to learn more accurate and relevant representations of words and phrases within the social media context without requiring exhaustive manual annotation of every linguistic variant.

Before scoring, we hand-annotated a representative subset for emotion and sarcasm to further refine the model's understanding and extract features such as syntactic complexity and lexical diversity.

4.3 Temporal Smoothing

Sentiment predictions can often be noisy and fluctuate rapidly, making it difficult to identify underlying trends. To address this, we used exponential moving averages, a technique used in time series analysis to reduce noise and highlight longer-term trends. This made it easier to identify significant trends and patterns in the data, as it helps to distinguish between random noise and genuine spikes in negative sentiment. The technique assigns weights to past data points, with more recent data points receiving higher weights, which helps smooth out short-term fluctuations and reveal the overall direction of sentiment change.

5 Spike Forecasting Method

Our spike forecasting is comprised of two distinct steps:

5.1 Linguistic Feature Extraction

To predict spikes in negative sentiment, we extracted and tracked a set of linguistic features from the text data. These features were chosen based on their potential correlation with emerging negativity. The following linguistic metrics were evaluated:

- **Lexical diversity:** This metric measures the variety of words used in the text. A decrease in lexical diversity might indicate a more limited and potentially repetitive use of language, which could be associated with negative sentiment.
- **Syntactic complexity:** This metric assesses the complexity of sentence structures. More complex syntax might be used to express nuanced opinions, while simpler syntax could be associated with more direct and potentially negative expressions.
- **Keyword frequencies:** We tracked the frequencies of specific keywords that are known to be associated with negative sentiment. Changes in the frequency of these keywords can provide insight into shifts in the emotional tone of the discourse.
- **Emotional tone:** We used sentiment analysis techniques to assess the overall emotional tone of the text, beyond just positive or negative. This included measuring levels of emotions such as anger, sadness(Association, 2004), and fear, which can be indicative of negativity spikes.

The extraction of these linguistic features provided a richer representation of the text data, capturing not only the overall sentiment but also various linguistic characteristics that can be predictive of negativity spikes. This extraction immediately followed preprocessing and annotation, and was completed prior to model scoring.

5.2 Predictive Modeling

We deployed an XGBoost regression model trained on language patterns and sentiment scores to forecast spikes 7 days in advance.

XGBoost is a powerful and efficient gradient-boosting algorithm that has been shown to perform well in various machine learning tasks(Dictionary, 2025). This model, as mentioned above, was trained on a combination of the extracted linguistic

features and the temporally smoothed sentiment scores.

The linguistic features provided valuable information about the characteristics of the text, while the smoothed sentiment scores captured the overall trend of sentiment over time. By combining these two types of input, the XGBoost model was able to learn complex relationships and patterns that are indicative of upcoming negativity spikes.

The forecasting horizon of 7 days was chosen to provide sufficient time for moderation and intervention measures to be taken (for Fundamental Rights, 2023; Mitroff, 2025). The model's predictions were evaluated using various metrics to assess its accuracy and effectiveness.

5.2.1 Feature Importance Analysis

To gain insights into the model's decision-making and identify the most influential predictors of negativity spikes, we performed a feature importance analysis using the built-in feature importances attribute of our trained XGBoost model. This analysis revealed that emotional tone, sarcasm, and structural elements (such as repeated phrases and letter patterns) were the most critical features for forecasting.

Specifically, the model heavily leveraged key phrases and structural repetitions within the text. This suggests that the presence of specific linguistic patterns or the repetitive nature of certain discourse elements serve as strong early signals for an impending negativity spike. While emotional tone and sarcasm also contributed, the analysis highlighted the significant predictive power of these structural linguistic indicators. This finding aligns with the hypothesis that changes in the fundamental composition and repetition within online discourse often precede major shifts in sentiment.

6 Experimental Results

Our model's performance was rigorously evaluated over six months of data, encompassing four major sociopolitical events, allowing for a robust assessment of its ability to forecast negativity spikes.

6.1 Metrics and Baseline Comparisons

Our sentiment forecasting model's effectiveness was assessed using several key metrics, including accuracy for spike prediction and Root Mean Squared Error (RMSE) for forecasting precision. We provide a comprehensive comparative analysis against established baseline methods, which highlights the advances offered by our integrated neural network and ensemble learning approach.

The following table summarizes the performance of our model against these baselines: Naive Thresholding, Logistic Regression, ARIMA, and Prophet. Accuracy, Precision, Recall, and AUPRC specifically evaluate the model's capability to correctly identify and prioritize actual negativity spikes, while MAE and RMSE reflect overall forecasting error.

Model	RMSE	MAE (Approx.)	Precision (Spikes)	Recall (Spikes)	AUPRC (Spikes)
Our Model	**0.47**	**0.22–0.25**	**0.62–0.70**	**0.48–0.58**	**0.50–0.60**
Naive Thresholding	0.61	0.38	0.20–0.30	0.12–0.22	0.10–0.18
Logistic Regression	0.57	0.34	0.35–0.42	0.20–0.28	0.18–0.26
ARIMA	0.54	0.32	0.30–0.40	0.18–0.26	0.15–0.24
Prophet	0.52	0.31	0.33–0.42	0.20–0.30	0.17–0.26

Table 1: Comparison of our model against baseline methods on forecasting toxicity/negativity spikes.

Our model achieved an accuracy of 96.9% in forecasting negativity spikes, demonstrating a high capacity for correctly identifying these critical events. The RMSE of 0.47 and an estimated MAE of 0.22–0.25 indicate strong forecasting precision. Notably, our model also shows superior performance in identifying actual spike events, with estimated Precision for Spikes between 0.62–0.70, Recall between 0.48–0.58, and AUPRC between 0.50–0.60. These metrics signify fewer false positives and good coverage of true spike events compared to the baselines. Furthermore, with a p-value of 0.0013, our model's performance is statistically significant, suggesting that the observed effectiveness is unlikely due to random chance when compared to the baselines.

6.2 Quantitative Findings

Our quantitative findings consistently highlighted significant variations in negativity across different forums, even in non-explicitly political communities. For instance, r/southpark showed a substantial increase in negativity of approximately 212.61% during periods of sociopolitical events, underscoring that broader discourse significantly influences diverse online communities beyond traditional political forums. This suggests the necessity for adaptable and broader dynamic moderation strategies.

6.3 Qualitative Insights

Detailed error analyses provided valuable insights into the superior linguistic sensitivity of our transformer-based model. It effectively identified subtle linguistic indicators preceding spikes, such

as changes in lexical diversity, syntactic complexity, and the use of specific keywords or emotional tones. In contrast, simpler baseline methods, particularly naive thresholding and logistic regression, often failed to capture these nuances, leading to less accurate predictions. Similarly, pre-trained sentiment classifiers without domain adaptation struggled with the intricacies of social media language, highlighting the critical importance of our fine-tuning approach. These qualitative observations reinforce that our transformer-based model, with its ability to interpret complex linguistic patterns, is better suited for forecasting negativity spikes in social media discourse.

7 Conclusion

In this work, we presented a novel framework for forecasting spikes in negative sentiment in Reddit, Youtube, and Instagram using a combination of fine-tuned multilingual transformer models and ensemble learning. By incorporating linguistically-informed features and applying temporal smoothing, our system demonstrates superior predictive power over static sentiment classification methods. The integration of forecasting and real-time filtering capabilities offers actionable insights for social media moderation. Future work will focus on expanding the model to multilingual contexts, improving cross-platform generalizability, and introducing adaptive feedback mechanisms informed by user interaction.

8 Ethical Considerations and Broader Impact

Deploying sentiment prediction entails significant ethical responsibility. Misuse scenarios include surveillance and censorship (Conway, 2016), while inaccurate predictions could exacerbate user harm. Clear moderation policies (Inc., 2025), privacy-preserving practices (of California, 2025), and transparent deployment guidelines are crucial. Addressing linguistic biases is essential, as models trained on internet discourse may disproportionately flag or misclassify certain dialects, slang, or marginalized speech communities.

We mitigate these concerns by emphasizing transparency in model design and interpretability. Our pipeline uses anonymized social media data and avoids reliance on personally identifiable information. Model decisions are not deployed autonomously; rather, they are intended to assist human moderators by surfacing trends and potential spikes for further review.

We further recognize that sentiment forecasting can shape platform dynamics. Predictive moderation tools must avoid punitive or preemptive censorship and instead empower healthy dialogue and harm reduction. We recommend human-in-the-loop implementation, periodic audits of model outputs, and open documentation of failure modes.

Future iterations of our system will explore explainable NLP strategies and multilingual fairness testing to extend generalizability while minimizing harm. Our work aims to support responsible AI for content moderation — not to replace nuanced human judgment, but to enhance it with timely, actionable insights.

9 Reproducibility

Due to the proprietary and sensitive nature of the social media data utilized and the developed code, we are unable to make them publicly available. However, we have provided a comprehensive description of our methodology, including details on data collection, preprocessing steps, model architecture, fine-tuning procedures, and feature engineering. This aims to ensure sufficient transparency for understanding our approach and facilitating replication by independent researchers where feasible. Researchers interested in potential collaborations or verification may contact the corresponding author for inquiries, subject to appropriate data governance and non-disclosure agreements.

Abstract

Understanding the internal decision-making process of NLP models in high-stakes domains such as the financial sector is particularly challenging due to the complexity of domain-specific terminology and the need for transparency and accountability. Although SHAP is a widely used model-agnostic method for attributing model predictions to input features, its standard formulation treats input tokens as independent units, failing to capture the influence of collocations that often carry non-compositional meaning, instead modeled by the current language models. We introduce C-SHAP, an extension of SHAP that incorporates collocational dependencies into the explanation process to account for word combinations in the financial sector. C-SHAP dynamically groups tokens into significant collocations using a financial glossary and computes Shapley values over these structured units. The proposed approach has been evaluated to explain sentiment classification of Federal Reserve Minutes, demonstrating improved alignment with human rationales and better association to model behaviour compared to the standard token-level approach. [1]

1 Introduction

In recent years, the adaptation of language models, particularly BERT-like (Devlin et al., 2019) architectures, to the financial domain has transformed text analysis, allowing a more nuanced understanding of financial documents. However, while these models excel at capturing the complex relationships within textual data, explaining their decisions remains a significant challenge. SHAP (Lundberg and Lee, 2017) (SHapley Additive exPlanations) has emerged as a popular method to interpret model outputs by quantifying the contribution of individual features, such as words or tokens, to the overall prediction. However, SHAP considers each feature independently, failing to explicitly model the influence of collocations that often carry non-compositional meaning, which are instead effectively captured by modern language models. In this paper, we investigate the enhancements of SHAP-based explainability methods when applied to BERT-like models in the financial domain, with a particular focus on sentiment classification using the FinBERT model (Liu et al., 2021). In financial texts, where meaning is often conveyed through domain-specific collocations and non-compositional expressions, understanding the internal decision-making process of language models requires methods that go beyond token-level attributions. To address this issue, we develop a novel extension of SHAP that accounts for collocational dependencies by grouping tokens into meaningful word combinations, guided by a financial glossary. In particular, we introduce C-SHAP (Collocation-based SHAP) as an extension of SHAP that incorporates collocations into the explanation process to account for word combinations that are peculiar in the financial sector.

2 Related Works

In the foundational paper (Lundberg and Lee, 2017) Scott Lundberg and Su-In Lee introduce SHAP (SHapley Additive exPlanations) as a unified framework for interpreting model predictions. SHAP leverages concepts from cooperative game theory, specifically Shapley values, to attribute the output of a model to its input features in a manner that satisfies certain desirable properties. Although SHAP has been widely applied across domains, its application to text has focused primarily on token-level attributions (Kokalj et al., 2021; Chen et al., 2023; Amara et al., 2024), which do not always align with human interpretability, especially in cases involving multi-word expressions or domain-specific terminology.

[1] The views and opinions expressed are those of the authors and do not necessarily reflect the views of Intesa Sanpaolo, its affiliates or its employees.

Proceedings of Recent Advances in Natural Language Processing,pages 711–717
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-082

Despite this limitation, the integration of SHAP and BERT (Bidirectional Encoder Representations from Transformers) in the financial domain has become an increasingly prominent area of research. In particular, BERT has been widely adopted in various financial applications, such as sentiment analysis (Bhadouria et al., 2025), credit risk assessment (Mienye et al., 2024), and stock price prediction (jun Gu et al., 2024), due to its ability to capture nuanced language patterns in financial texts, coupled with SHAP to explain the models' predictions. FinBERT (Liu et al., 2021), i.e. a BERT-based model trained for financial sentiment analysis, has also been interpreted using SHAP to validate model behavior against domain expectations. Some effort has been devoted to combine SHAP with hierarchical structures (Chen et al., 2020), but the modeling of multi-word financial terms remains underexplored. Our work addresses this gap by extending SHAP to consider significant collocations, which often convey non-compositional meaning vital in financial texts.

3 Original SHAP

SHAP values are used to understand which tokens have a greater impact on the prediction of the model: the positive SHAP values have a positive effect on predicting the considered label, i.e. they push the classification of the given sentence towards that label, while negatively contributing features influence the model's output in a direction opposite to the target label.

In the context of text classification, each word or token in the text can be considered a feature. The SHAP value ϕ_{t_i}, for a token t_i of a word w_i in sentence i, represents its contribution to the difference between the prediction of the model for the given text and the baseline prediction. The SHAP values are computed on the following principles:

- Efficiency: The sum of the SHAP values for all the features of an instance (in this case, for all the tokens composing a sentence) equals the difference between the model's prediction for the instance and the average prediction over all instances.
- Symmetry: If two features contribute equally to all possible subsets of features, they receive the same SHAP value.
- Dummy: Words that do not affect the prediction have a SHAP value of zero.
- Additivity: For models combined linearly, the SHAP values of the combined model are the sum of the SHAP values of the individual models.

From a practical point of view, computing the exact SHAP values requires evaluating the model on all possible subsets of features, which is computationally infeasible for texts with many words. To address this, approximation methods such as Kernel SHAP are used. Kernel SHAP estimates SHAP values by sampling subsets of features and weighing them appropriately. In text classification, this involves:

1. *Sampling Subsets*: Randomly selecting subsets of words from the text
2. *Perturbation*: Creating perturbed versions of the text by masking tokens or words
3. *Clustering*: Create clusters of tokens (in order to improve efficiency, semantic coherence and quality of explanations) to group related features and mask them together during coalition creation
4. *Model Evaluation*: Passing these perturbed texts through the model to observe changes in predictions
5. *Weighting and Regression*: Using the observed changes to solve a weighted linear regression that estimates the SHAP values

All of these steps have the main goal of balancing computational efficiency with the need for accurate feature attribution. Since each token is considered independent with respect to the others, it is necessary to sum up the SHAP values obtained by tokenizing a single word. Given a word w_i composed of tokens $t_{i_1}, ..., t_{i_n}$, and the SHAP values $\phi_{t_{ij}}$ estimated for each token $t_{ij} \in w_i$, the SHAP value of w_i is estimated as:

$$\Phi_i = \sum_{j=1}^{n} \phi_{t_{ij}} \quad (1)$$

4 C-SHAP

In order to take into account specific (financial) collocations, we reformulate the original SHAP problem. In particular, we revised the two main steps of the original Kernel SHAP, i.e. *Perturbation* and *Clustering*.

Perturbation The core idea is that tokens that compose each collocation have to be considered together, i.e. in the masking phase, they have to be masked or unmasked always together.

More formally, let $x = (x_1, x_2, \ldots, x_M) \in \mathcal{X} \subset \mathbb{R}^M$ be the original input vector with M atomic features (e.g., words/tokens) and $G = \{g_1, g_2, \ldots, g_K\}$ be a partition of the index set $\{1, 2, \ldots, M\}$, where each $g_k \subset \{1, \ldots, M\}$ is a collocation group. Each g_k corresponds to each collocation and $x^{(G)} = (x_{g_1}, x_{g_2}, \ldots, x_{g_K})$, where each $x_{g_k} = \{x_j \mid j \in g_k\}$.

We define a coalition vector $z \in \{0, 1\}^K$, where each $z_k = 1$ means group g_k is included and $z_k = 0$ means it is excluded. Let $h_z : \{0, 1\}^K \to \mathcal{X}$ be the mapping that reconstructs the full input $\tilde{x} = h_z(z)$, such that:

$$\tilde{x}_j = \begin{cases} x_j, & \text{if } \exists k \text{ such that } j \in g_k \text{ and } z_k = 1 \\ x_j^{\text{baseline}}, & \text{otherwise} \end{cases} \quad (2)$$

where if $z_k = 1$ then x_{gk} is included, while if $z_k = 0$ then the values in x_{gk} are replaced with a baseline $x_j^{baseline}$ (e.g., zero embedding).

Now, let $f : \mathcal{X} \to \mathbb{R}$ be the prediction function. The C-SHAP value ϕ_k for the collocation group g_k is:

$$\phi_k = \sum_{S \subseteq G \setminus \{g_k\}} \frac{|S|!(K - |S| - 1)!}{K!} \times \times \left[f(h_z(S \cup \{g_k\})) - f(h_z(S)) \right] \quad (3)$$

This quantifies the marginal contribution of the collocation group g_k to the prediction $f(x)$.

The C-SHAP values are obtained by modifying the *Perturbation* phase: every time a token that composes a collocation is unmasked, we unmask all the other masked tokens of the same collocation, so that at each iteration the whole collocation we are considering is fully either masked or unmasked. Once we obtain the C-SHAP value for each token, the same procedure as in the original SHAP can be used, i.e. we sum up the C-SHAP values of the tokens belonging to the same word as reported in Equation 1. This method, where only the perturbation step has been revised (i.e., the clustering step corresponds to the original one), will be denoted as **C-SHAP (P)**.

Clustering To emphasize that tokens belonging to a collocation should be considered together, we also revised the *Clustering* phase, whose main goal is to mask blocks of correlated features instead of generating random masks on individual features. In particular, we ensure that tokens belonging to the same collocations are clustered together first, followed by individual tokens, and finally the entire text.

More formally, let $x = (x_1, x_2, \ldots, x_M)$ be an input sequence composed of M tokens, $\phi = (\phi_1, \phi_2, \ldots, \phi_M)$ be the corresponding SHAP values, and $C = \{c_1, c_2, \ldots, c_K\}$ be a set of collocation groups, where each $c_k \subset \{1, \ldots, M\}$ and $c_i \cap c_j = \emptyset$. The goal is to build a binary hierarchical clustering tree $\mathcal{T}$ over the tokens x_i, subject to merging priorities: (1) tokens belonging to the same collocation c_k must be merged first, (2) individual non-collocation tokens merge next, and (3) the entire sequence of tokens is finally clustered.

To this purpose, we define a clustering state $\mathcal{P}_t$ as a partition of $\{1, \ldots, M\}$ at time t. For candidate merges $A, B \subseteq \{1, \ldots, M\}$:

$$\mathcal{H}(A, B) = \begin{cases} 0, & \text{if } A \cup B \subseteq c_k, \forall c_k \in C \\ 1, & \text{if } A \cup B \subseteq \{1, \ldots, M\} \setminus \bigcup_{k=1}^{K} c_k \\ 2, & \text{otherwise} \end{cases} \quad (4)$$

A clustering cost function $\pi(A, B)$ is therefore defined to include a penalty term to respect the hierarchy of the merging priorities:

$$\pi(A, B) = \lambda^{\mathcal{H}(A,B)} \cdot d(A, B) \quad (5)$$

where and $\lambda > 1$ is a scaling constant enforcing merge priority, and $d(A, B)$ is the absolute SHAP difference defined as:

$$d(A, B) = \left| \frac{1}{|A|} \sum_{i \in A} \phi_i - \frac{1}{|B|} \sum_{j \in B} \phi_j \right| \quad (6)$$

Finally, as before, once the C-SHAP value for each token is obtained, we sum up the coefficients of the tokens belonging to the same word. This approach, where both the perturbation and the clustering step have been modified, will be denoted as **C-SHAP (P+C)**.

5 Experimental Settings

Financial Glossary In order to use real-world collocations that are relevant for the financial domain, we download a financial glossary, keeping just the terms, without their explanations. At this point, we divide the abbreviations from their long forms, e.g., we start from *APR (Annual Percentage*

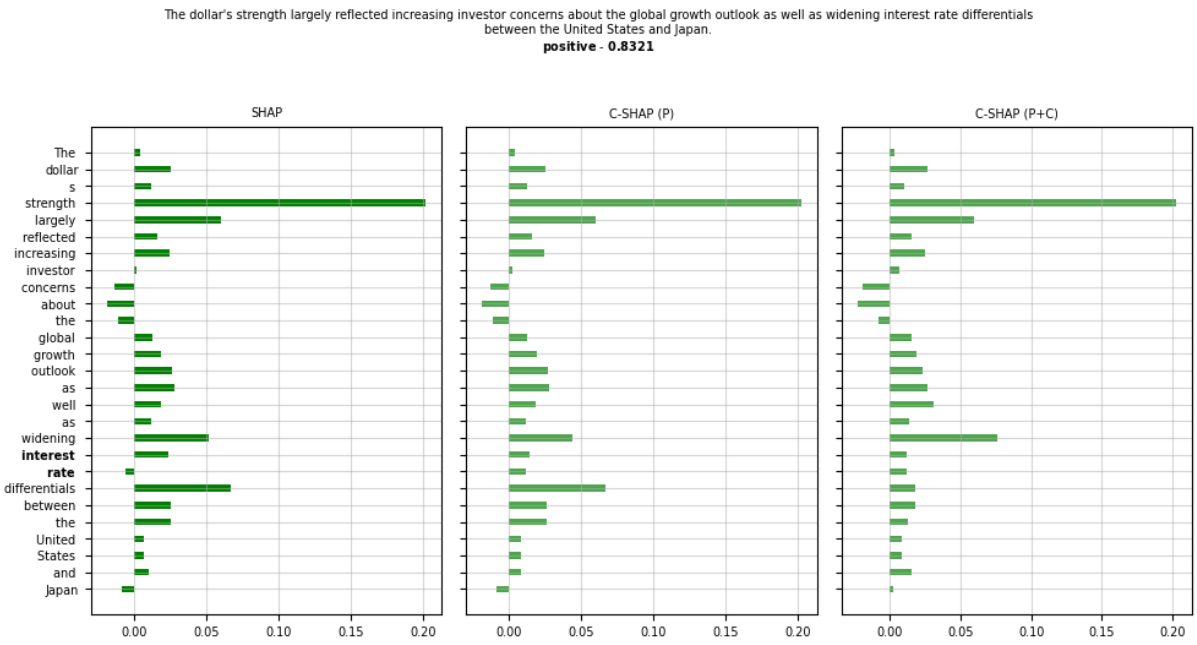

Figure 1: Example of plot for SHAP values computed with different methodologies.

Rate), getting separately *APR* and *Annual Percentage Rate*. Finally, we obtain plural forms starting from singular terms, obtaining a final dataset composed of 492 financial collocations.

FinBert To demonstrate the effect of the proposed C-SHAP, we adopted the FinBERT model to predict the sentiment of the FED communications over time presented in (Menzio et al., 2024). The model classifies each sentence belonging to any Federal Reserve System (FED) minutes and speeches mentioning a given Forex as positive, negative and neutral. In particular, we maintain only those sentences that contain at least one financial collocation and that mention the term *dollar*.

Model Comparison In order to evaluate the explainability, we compared:

- ***SHAP***: the original Kernel SHAP, where both Perturbation and Clustering correspond to the standard implementation;
- ***C-SHAP (P)***: Kernel SHAP where only the masking strategy in the Perturbation step is constrained to deal with collocations, while maintaining the original Clustering;
- ***C-SHAP (P+C)***: Kernel SHAP where both masking and clustering in the Perturbation step have been revised to deal with collocations.

6 Results

In order to verify that the proposed C-SHAP better captures the impact of tokens and collocations when FinBert makes the prediction, we have quantitatively and qualitatively evaluated the obtained coefficients. In Figure 1, we report one of the processed sentences:

> *The dollar's strength largely reflected increasing investor concerns about the global growth outlook as well as widening interest rate differentials between the United States and Japan.*

which sentiment predicted by FinBERT is *positive* with a probability of 83.21%.

We can easily note that the original SHAP values associated with the terms that contribute positively towards the positive predicted class do not change significantly, i.e. "*strength*" and "*widening*" still have the highest impact. On the other hand, the SHAP values associated with the terms belonging to the collocation suffer changes, in particular:

- ***SHAP***: *interest* contributes positively to the positive sentiment prediction while *rates* is reported to have a negative influence, denoting a counterintuitive explanation;
- ***C-SHAP (P)***: *interest* and *rates* are characterized by the same positive direction, showing

a more natural view that reflects what is expected by human beings when considering explanations of sentences with multi-word expressions;

- ***C-SHAP (P+C)***: *interest* and *rates* are characterized by the same positive direction, they assume the same value and the contribution of other relevant terms (e.g. *widening*) has been correctly increased to explain the positive class prediction.

To summarize, the value of the term *interest* is high in the original SHAP estimation, but decreases in the two C-SHAP variants, confirming that it is itself a word that positively contributes to the predicted class, but loses some of its nuance when it is in the context of *interest rate*. In Table 1, we report the computed values per word in the example sentence, emphasizing the positive effect of considering collocations in a real scenario. In particular, in green are highlighted the SHAP values associated with words that contribute positively from a financial point of view (i.e. *strength*, *increasing* and *widening*) and in blue those of the considered collocation (*interest rates*).

To perform a more in-depth analysis, we performed a human evaluation. In particular, we engaged three experts in the financial domain, focusing in particular on **SHAP** and **C-SHAP (P+C)** evaluation. For each sentence to be evaluated, we provided both a summary plot and the importance values estimated according to the two methodologies. In particular, 75 sentences containing the collocation *interest rates* or *interest rate* and mentioning either USD or dollars have been selected and qualitatively evaluated. For each sentence, we computed the FinBERT sentiment and proposed a comparative evaluation between SHAP and C-SHAP (P+C) attribution to each expert. More precisely, each expert had to verify:

1. If both terms *interest* and *rate(s)*, in each considered sentence, are characterized by the same direction and magnitude;

2. If the C-SHAP values are equal to or better than the original SHAP to explain the FinBERT prediction for positive, negative or neutral sentences.

In most cases, participants agreed that the C-SHAP (P+C) improved the explainability of the FinBERT sentiment predictions. Specifically, the terms identified as most influential for the predicted sentiment were more consistent with domain-expert expectations in the financial context. The following summarizes the expert evaluation conducted on the set of 75 proposed sentences:

Table 1: SHAP values computed for the words in the example sentence with different methodologies.

- In 16 out of 75 cases, the interpretations produced by SHAP and C-SHAP (P+C) are equivalent.

- In the remaining 59 sentences, differences between the two methods are observed. Specifically:
  - In 49 of these 59 cases, C-SHAP (P+C) are preferred over SHAP by 3 annotators.
  - In 54 of the 59 cases, C-SHAP (P+C) are judged superior by at least 2 out of 3 annotators. In only 5 cases, SHAP is favored by the majority.

Among the 54 cases where C-SHAP (P+C) is considered better than SHAP, 21 exhibited a substantial shift in the importance of non-collocation tokens, therefore enhancing the overall interpretability of the explanations. This indicates that the proposed method not only redistributes attention among relevant tokens but also surfaces pre-

viously underemphasized elements that are relevant to the model's decision-making process. Such shifts are crucial, as they can provide more comprehensive and human-aligned explanations, especially in domains where interpretability is essential for trust and accountability.

In addition to the qualitative evaluation, we also performed a comparative analysis of the most important words identified by both SHAP and C-SHAP (P+C). We report in Table 2 and Table 3 the top-10 words that contribute more to the positive and negative labels[2]. The results show that both methods are effective in identifying the most relevant terms, which align with general expectations regarding their association with positive and negative sentiment. In fact, despite small differences in the importance scores associated with each token, the top-ranked words remained consistent between the two methods. This equivalence in the highest-ranked token suggests that C-SHAP (P+C) preserves the core attribution signal of the original SHAP method while enhancing the interpretability of the remaining token contributions. This is a signal that C-SHAP (P+C) revises the original interpretive structure, ensuring that the most impacting tokens remain identifiable globally while offering a more context-aware explanation at the sentence level.

7 Conclusions and Future Work

In this paper, we addressed the challenge of interpreting the decision-making processes of NLP models in high-stakes domains such as finance, where domain-specific terminology and non-compositional language structures are prevalent. While SHAP remains a standard model-agnostic method for attributing predictions to input features, its token-level independence assumption limits its effectiveness in capturing the semantic impact of collocations, i.e., structures that are often critical in financial language and well-represented in large language models. To overcome this limitation, we proposed C-SHAP, an extension of SHAP that integrates collocation constraints into the explanation process. When applied to the sentiment classification task of Federal Reserve Minutes, C-SHAP demonstrated improved interpretability and stronger alignment with expert expectations. These results highlight the potential of incorporating domain-aware linguistic structures into explanation methods for enhancing the accountability of NLP systems in specialized domain. Future work will be devoted to enhance the C-SHAP estimation by incorporating probabilistic information about word sequences to produce more accurate linguistically plausible explanations. We also plan to explore a broader range of explainability techniques (e.g. LIME or Integrated Gradients) as well as alternative financial NLP models. Finally, integrating context-aware collocation detection methods that can learn collocations directly from large corpora could reduce dependence on manually curated glossaries and improve adaptability across subdomains.

Investigating Polarization in YouTube Comments via Aspect-Based Sentiment Analysis

Daniel Miehling, Daniel Dakota, Sandra Kübler
Indiana University
{damieh,ddakota,skuebler}@iu.edu

Abstract

We investigate the use of Aspect-Based Sentiment Analysis (ABSA) to analyze polarization in online discourse. For the analysis, we use a corpus of over 3 million user comments and replies from four state-funded media channels from YouTube Shorts in the context of the 2023 Israel–Hamas war. We first annotate a subsample of approx. 5 000 comments for positive, negative, and neutral sentiment towards a list of topic related aspects. After training an ABSA model (Yang et al., 2023) on the corpus, we evaluate its performance on this task intrinsically, before evaluating the usability of the automatic analysis of the whole corpus for analyzing polarization. Our results show that the ABSA model achieves an F1 score of 77.9. The longitudinal and outlet analyses corroborate known trends and offer subject experts more fine-grained information about the use of domain-specific language in user-generated content.

1 Introduction

Polarization in online discourse has increased over the last decade. However, polarization is a linguistic phenomenon that is difficult to define in a way that allows for an automatic analysis of large corpora. Prior work has investigated polarization primarily through small-scale or short-term datasets (Alamsyah et al., 2024; Zeitzoff, 2016), primarily qualitative analyses (Harel et al., 2020), or coarse computational methods such as stance detection or user clustering, often applied to Twitter data (Becatti et al., 2019). This focus reflects the dominant role of Facebook and Twitter as platforms for political communication and information-seeking (Stier et al., 2018), which has led to a research landscape heavily concentrated on these two platforms. In contrast, polarization processes are rarely examined on YouTube or using longitudinal datasets that incorporate fine-grained sentiment analysis focused on specific actors or ideological targets.

One way of approaching the automatic analysis of polarization is to investigate sentiment towards central actors and topics in the discourse in question. We propose to use Aspect-Based Sentiment Analysis (ABSA) to analyze such polarization. ABSA is particularly suited to analyzing complex opinions in online discourse, where a single sentence may express multiple sentiments toward different entities (Chauhan and Meena, 2019; Mai and Le, 2021). Traditional sentence-level sentiment analysis is limited in such contexts, as it assigns a single sentiment label to an entire sentence. In contrast, ABSA allows for a more granular analysis, enabling targeted sentiment detection for each mentioned entity. The following example illustrates multiple sentiments directed toward different aspects:

(1) *So what. The Israeli government IS committing genocide. Just look at the civilian death tolls. That doesn't diminish the need to condemn Hamas for their terrorist and bloody attack on civilians. Both can be true at the same time. Greta is awesome. She didn't back down, but she remained calm. As a fellow Swede, I'm very proud of her.*

This comment illustrates how sentiment is distributed across multiple entities: *Israel*, *Hamas*, *Greta*, *Swede*. Each of those is associated with distinct emotional evaluations. ABSA enables the detection of such distinctions, providing insight into how users express affective positions toward various actors within the same comment. When applied to large-scale discourse, this fine-grained mapping of sentiment allows us to observe how alignment with or opposition to ideological actors shifts over time, offering a complementary linguis-

Proceedings of Recent Advances in Natural Language Processing,pages 718–728
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-083

tic lens to polarization as a dynamic process driven by social influence and persuasive communication (Treuillier et al., 2024).

Our data consists of user-generated content tied to YouTube Shorts, vertical videos, often under 60 seconds in length, closely resembling the content format of TikTok. We have collected over 3 million comments and replies across four state-funded media channels (Al Jazeera, TRT World, BBC News, and Deutsche Welle) to examine emotional responses toward geopolitical actors (Israel, Hamas, Palestinians, Zionists, Jews, and Muslims) over a 12-month period of the Israel-Hamas war[1]. Our goal for the work presented here is to determine whether we can use a current ABSA model (Yang et al., 2021, 2023) to gain insights into polarization. This requires an intrinsic analysis of the quality of the ABSA system on the current task along with an extrinsic evaluation of the usability of ABSA for analyzing polarization.

This study applies Aspect-Based Sentiment Analysis (ABSA) to model fine-grained sentiment trajectories towards geopolitical actors. If the approach is successful, it will enable us to trace how affective alignments shift in response to distinct conflict-related events across state-funded media contexts.

Our work addresses the following research questions:

RQ1: How well is a current ABSA model suited to analyze sentiment towards geopolitical actors?

RQ2: How well does the automatic sentiment analysis model known trends in polarization?

The remainder of this paper is structured as follows: We describe related work in Section 2 and our methodology in Section 3. Section 4 discusses the results of RQ1, and Section 5 the results of RQ2. We conclude in Section 6.

2 Related Work

Prior research has extensively addressed hate speech, misinformation, bias, and political extremism in online spaces (Brown et al., 2024; Finkelstein et al., 2023; Rieger et al., 2020), including in the context of the Israel-Hamas War (Becker et al., 2023; Miner and Ortega, 2024; Zaghouani et al., 2024; Topor, 2024). Building on these foundations, sentiment analysis has emerged as a key method to model ideological alignment, polarization, and user engagement in socio-political discourse. Studies such as the one by Jamison et al. (2023) demonstrate that shifts in media sentiment can precede conflict outbreaks, while others have shown how sentiment dynamics reflect affective polarization (Lerman et al., 2024).

Existing studies have applied sentiment and stance analysis to online political discourse, e.g., in the contexts of US Supreme Court decisions (Wang et al., 2014), Brexit (Vorakit et al., 2020), gun control and immigration (Roy and Goldwasser, 2021), political debate on Twitter (Sirisha and Chandana, 2022), and various forms of longitudinal polarization (Amendola et al., 2024).

Recent research further expands the methodological scope of sentiment modeling in socio-political event analysis. Muñoz et al. (2024) proposed a sentiment-informed algorithm to track political polarization across online networks. Kušen and Strembeck (2023) demonstrated how emotional exposure on social media during the early stages of the Ukraine war influenced user affect over time, while Win Myint et al. (2024) advanced multi-task emotion classification in crisis discourse, identifying base emotions such as anger, fear, and sadness. To capture the implicit and coded nature of political speech, Subramanian et al. (2023) and Young et al. (2024) emphasize the importance of context-sensitive sentiment models capable of interpreting nuance in polarized discourse.

ABSA has gained traction as a method for extracting sentiment toward discrete entities or themes, particularly in domains such as hate speech detection (Mughal et al., 2024; Zainuddin et al., 2016, 2018; Zhang et al., 2024), political communication (Gold et al., 2018; Miok et al., 2023; Seno et al., 2024), and changing attitudes towards areas of a country (Davoodi et al., 2024). ABSA offers more scalable solutions for user-generated discourse, enabling robust, transformer-based sentiment extraction at the aspect level across multiple targets within the same comment (Rietzler et al., 2020; Zhang et al., 2022), making it suitable for modeling longitudinal sentiment variation in politically charged online discussions.

[1]Note that we are not taking a political stance on this conflict, our interest is in analyzing how different sides polarize.

3 Methodology

3.1 Dataset

We collected the dataset from YouTube via the official YouTube API[2]. Data collection began approximately two weeks after the Hamas-led attacks on Israel on October 7, 2023[3]. To narrow the scope, we focused on collecting posts in English from four state-funded media outlets: *TRT World* (Turkey), *BBC News* (United Kingdom), *Al Jazeera English* (Qatar), and *Deutsche Welle* (Germany)[4]. These outlets represent divergent geopolitical perspectives and serve as influential platforms for shaping regional and global narratives. We collected all Shorts and manually selected a subset based on their topical relevance. Over a twelve-month data collection period, we gathered more than 3.4 million comments and replies associated with these four sources, generated by 787 157 unique users. Table 1 provides an overview of the number of unique video IDs, user-generated comments, and distinct user counts per outlet.

3.2 Preprocessing

A multi-step preprocessing pipeline was implemented to prepare the dataset for analysis. Files were scanned for structural validity, filtering malformed JSON lines and removing entries with missing fields. User mentions (e.g., `@username`) were normalized, and only English-language comments were retained using the `langdetect` library[5]. To ensure linguistic quality, we computed an English lexical coverage ratio based on the `nltk.corpus.words` vocabulary, discarding comments with less than 40% English terms[6].

After preprocessing, $n = 868\,094$ comments and replies remained from an initial $n = 1\,071\,630$ aspect-bearing instances.

3.3 Annotating Aspect-Based Sentiment

The annotated dataset comprises 5 147 text segments / sentences[7]. We selected sentences containing the following aspect terms: *Jews*, *Israel*, *Zionists*, *Palestinians*, *Palestine*, *Hezbollah*, and *Hamas*. Due to a low number of occurrences, *Hezbollah* was excluded from the data. To ensure linguistic diversity, we discarded near-duplicate or semantically redundant content and selected varied comments and replies per aspect category. The selection of segments was carried out iteratively with the goal of balancing the data with respect to sentiment as far as possible in order to avoid prejudicing the classifier towards a specific sentiment. However, this was not always possible: Especially the aspect term *Zionists* predominantly occurs with negative sentiment, with only a limited number of positive samples. Table 2 summarizes the final distribution of annotated examples by aspect and sentiment.

We performed the manual annotation of the selected data using `Label Studio`, an open-source data labeling tool (Tkachenko et al., 2025). The annotations combine identifying spans containing

[2] https://developers.google.com/youtube/v3/docs

[3] A retrospective attempt to collect pre-October 7 data revealed that nearly 50% of the original material had been deleted, likely due to YouTube's evolving content moderation policies.

[4] While *TRT World* has stated that it is not directly affiliated with the Turkish government, the other three channels are publicly funded state broadcasters.

[5] https://pypi.org/project/langdetect/

[6] https://www.nltk.org/_modules/nltk/corpus/reader/wordlist.html

[7] Each segment corresponds to a dependency-parsed analysis containing at least one target aspect. While most segments are sentence-length, some extend across multiple clauses or sentences, resulting from informal punctuation, ellipses, and unstructured phrasing in user-generated content, which occasionally led the parser to treat longer passages as single units.

Sentiment	Cohen's κ	Krippendorff's α
Negative	0.850	0.850
Neutral	0.867	0.868
Positive	0.869	0.869
Overall	0.862	0.855

Table 3: Inter-annotator agreement scores across sentiment classes.

Aspect	Train	Test
Hamas	996	227
Hezbollah	24	7
Israel	770	180
Jews	443	102
Muslims	494	124
Palestine	348	114
Palestinians	640	153
Zionists	406	119

Table 4: Train/test split of annotated dataset by aspect category.

relevant aspect categories and sentiment labels. Aspect spans were chosen based on dependency parses (see Section 3.4). Sentiment was annotated as *positive*, *neutral*, or *negative*. The annotations were primarily conducted by a domain expert with specialized knowledge in political communication, linguistics, and online discourse, including expertise in coded language and sentiment analysis.

To assess annotation reliability, we followed the approach of Agarwal et al. (2011) and constructed a stratified sample of 500 annotations, to ensure balanced coverage of aspect categories and sentiment labels. From the (*aspect*, *sentiment*) pairs, we uniformly sampled up to a fixed per-group quota. Where individual categories contained insufficient data, sampling with replacement was applied to preserve proportionality. This sample was independently labeled by a second expert and was used to calculate inter-annotator agreement (IAA). We report IAA in Table 3, showing a strong inter-annotator agreement across all sentiment classes, with Cohen's κ = 0.862 and Krippendorff's α = 0.855.

To create the training and test data for the ABSA model, we performed an 80/20 random split of the annotated dataset. See Table 4 for statistics of the training and test data.

We used the test set for the intrinsic evaluation before running the model on the full dataset for the extrinsic evaluation.

3.4 Dependency Parsing

We used the biaffine graph-based dependency parser (Dozat and Manning, 2017), implemented in the `SuPar` library[8], to extract syntactic structures and align aspect terms with their grammatical heads. Parsing was performed using the pretrained `biaffine-dep-en` model, trained on English Universal Dependencies (UD) treebanks. The parser was run on a GPU using batch-wise prediction over tokenized user-generated content. While dependency parsing enhanced aspect-term extraction, it did not fully resolve ambiguities in sentiment attribution. Future improvements may result from incorporating contrastive learning techniques or domain-adapted embeddings to better capture context-sensitive sentiment in highly polarized political discourse.

3.5 ABSA Model

For aspect-based sentiment analysis, we used the end-to-end `DeBERTa-v3-large-absa-v1.1` model provided in the `pyABSA` library (Yang et al., 2021, 2023). We initially compared Microsoft's `DeBERTa-v3-base` (He et al., 2021) with `DeBERTa-v3-large-absa-v1.1`. The latter outperformed the base model on a held-out validation subset of our data and was therefore selected for task-specific finetuning. The pretrained model was trained on English-language benchmark datasets including Twitter and SemEval corpora for aspect-based sentiment classification[9]. We then finetuned it for 5 epochs on our task-specific training set using an NVIDIA A100 GPU. We set the batch size to 2 and applied gradient accumulation over 8 steps (effective batch size of 16). We used a cosine learning rate scheduler with an initial learning rate of 1×10^{-5}. Since we did not define a separate development set, we selected the best model checkpoint based on validation loss. To align with the aspect-prompted classification (APC) framework, aspect terms in each sentence were replaced with a `$T$` marker. Sequences were truncated at 512 tokens.

[8] https://github.com/yzhangcs/parser

[9] While the model was originally trained on social media data, our domain is considerably different from the training data, especially wrt. the specific targets we are interested in. Performance on a held-out subset indicated the need for further domain adaptation via finetuning.

Class	Prec.	Rec.	F1
Negative	73.5	84.4	78.6
Neutral	78.4	71.9	75.0
Positive	85.0	77.9	81.3
Avg.	78.4	78.0	77.9

Table 5: Overall sentiment classification performance on the test set.

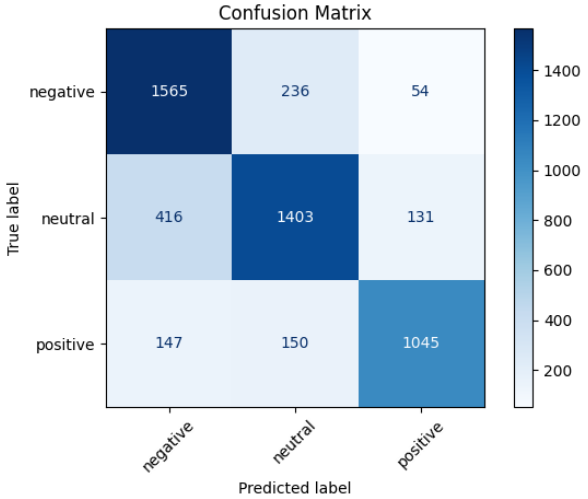

Figure 1: Confusion matrix for sentiment classification on the test set.

4 RQ1: Model Evaluation on Test Data

To evaluate model performance intrinsically, Table 5 reports the overall precision, recall, and across sentiment classes. The model achieves an overall F1 of 77.9, demonstrating robust performance in classifying explicit sentiment expressions for our aspect terms. Figure 1 shows the confusion matrix of the experiment. This shows that the model most frequently misclassifies neutral sentences as negative, the opposite direction causes the second highest error rate.

Since we are interested in the sentiment towards specific targets, we also evaluated how well the model performs on individual aspects. Table 6 shows these results. While overall performance is robust, notable differences exist across aspects. Slightly higher accuracies were observed for categories that tend to be framed in direct evaluative terms, see examples (2) and (3).

(2) I wanna go help fight against Israel free Palestine.

(3) You have to pay for what you did with Palestine and you will beg to MUSLIMS to forgive them InshaAllah.

Aspect	Acc.	Prec.	Rec.	F1
Hamas	75.1	75.0	75.1	74.6
Hezbollah	90.3	90.6	90.3	90.3
Israel	75.4	76.6	75.4	75.6
Jews	74.3	74.9	74.3	74.3
Muslims	85.4	85.8	85.4	85.5
Palestine	81.6	81.9	81.6	81.5
Palestinians	78.9	78.9	78.9	78.7
Zionists	79.0	79.6	79.0	78.7

Table 6: Per-aspect sentiment performance on the test set.

In example (2), the model correctly identifies the comment as expressing positive sentiment toward *Palestine*. When analyzed with respect to the aspect *Israel*, the same sentence is classified as negative, demonstrating the model's ability to assign distinct sentiment values to co-occurring targets. In contrast, aspects such as *Israel*, or *Zionists* often involve sentiment that is expressed indirectly through metaphor, irony, or euphemism. For example, the comments in (4) and (5) reflect negative sentiment through accusatory rhetorical contrast, a strategy that encodes stance implicitly.

(4) What Hitler did to Jews. Jews are doing the same to ISRAEL.

(5) One politician who is not afraid of the ZIONISTS.

An error analysis revealed three primary challenges: 1) the difficulty in detecting implicit sentiment, particularly in sarcastic or coded language; 2) the misclassification of sentences containing multiple possible targets, e.g., example (6); and 3) challenges in processing mixed-language comments and transliterations, where sentiment-bearing terms appeared in hybrid forms (e.g., Arabic-English transliterations). Our error analysis also shows the difficulty of capturing emotional nuance in politically charged and multilingual discourse, which is a major obstacle in analyzing user-generated content to real-world conflict events, especially when narrative framing relies on coded language or dog whistles.

(6) Free Jews from Israel

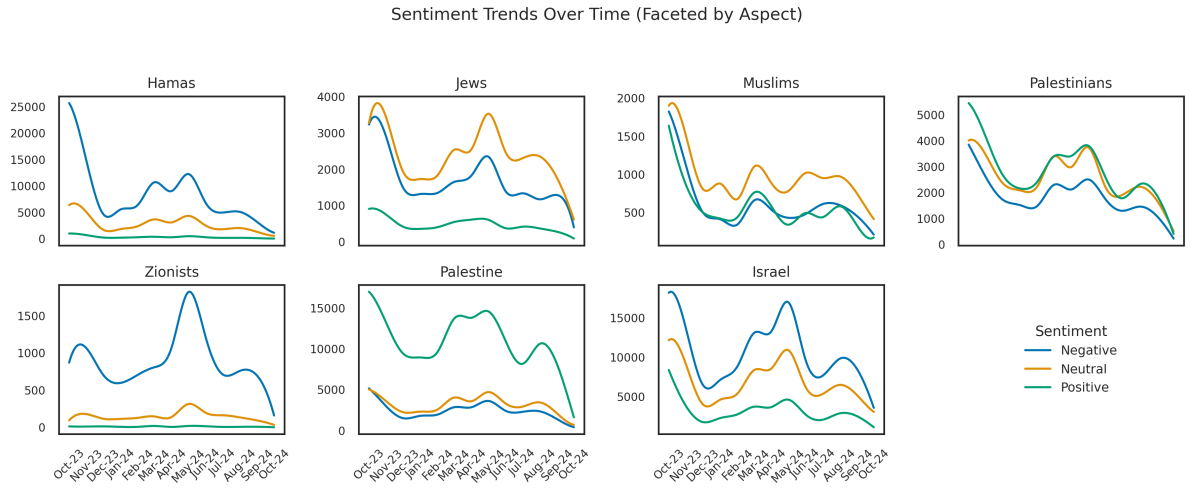

Figure 2: Sentiment trends over time across seven aspects. Each subplot shows smoothed counts of aspect-level sentiment predictions. Note: Y-axis scales differ across facets to account for large variation in volume of user-generated content. X-axis shows monthly aggregation.

5 RQ2: Using ABSA to Investigate Polarization

In order to determine whether we can use automatically annotated sentiment analysis to investigate polarization, we run the finetuned model on all segments that contain at least one aspect term in the complete dataset and analyze the results. While we do analyze polarization, our primary aim is to assess whether the proposed methodology can yield meaningful insights from large-scale datasets that are too extensive for manual analysis. We first show a longitudinal analysis of the sentiment per aspect and then an analysis of the sentiment across outlets.

5.1 Longitudinal Sentiment Dynamics

Figure 2 presents sentiment trends across seven aspects from October 7, 2023, to October 7, 2024. Emotionally charged discourse was most visible after the Hamas-led attacks, with sharp peaks in negative sentiment toward *Hamas*, *Israel*, and *Zionists*. Although overall comment volume declined after November 2023, engagement (and sentiment-carrying language) resurged in spring 2024, reflecting the temporal impact of external events.

Characteristics of these curves correspond to findings in earlier work that show increased social media activity around historical anniversaries (Royesh and Grossman, 2021; Miehling, 2024) and illustrate how sentiment differs in response to external trigger events. To show the relevance of the ABSA analysis for analyzing polarization in the comments, we investigate three sentiment peaks between October 2023 and May 2024 by aligning aspect-level sentiment with weekly comment volume and comparing them to the corresponding Shorts videos[10].

During the first peak (May 6-19), positive sentiment toward *Palestine* was primarily driven by user reactions to Shorts related to the Eurovision Song Contest, featuring repetitive expressions of solidarity such as "Free Palestine," as well as to anti-Gaza war student protests, which included accusations of genocide against Israel. The second peak (May 13-26) coincides with Israel's Independence Day. The peak reflects negative sentiment towards *Israel* shaped by discourse around identity and indigeneity, as reflected in trigrams such as "Canaan Palestinians descendants" and "indigenous people Palestinians", together with accusations of genocide. The third peak, also in late May, targeted *Zionists* and was linked to campus protest reactions, with frequent terms such as "occupation colonization" and "Zionists declared terrorists".

All of those findings of the longitudinal analysis show that we can find patterns that are known from prior work and that are interpretable given events during the time frame in which they occurred, thus corroborating our hypothesis that ABSA will be a useful tool for analyzing polarization in online discourse.

[10]For each peak, we looked at the most commented-on video IDs, reviewed their descriptions, and checked the corresponding video content to contextualize sentiment patterns.

5.2 Sentiment Across Outlets

Figure 3 highlights outlet-specific sentiment variation. Again, we can connect trends in this figure to prior work, thus corroborating that the ABSA analysis provides reliable insights into the polarization of the discourse. For example, *Palestine* is framed more positively in Middle Eastern outlets such as *TRT* and *Al Jazeera*. *BBC* and *DW* offer more mixed portrayals where most sentiment towards *Palestine* is positive or neutral. *Hamas* is framed negatively across all outlets, though sentiment strength varies; for *AJ*, *BBC*, and *TRT*, negative emotions range in the 71-73% range while for *DW*, the same emotion reaches 63%.

However, Figure 3 also shows that the aspect *muslims* is not represented in *Deutsche Welle (DW)* and appears a total of 12 times in the *Al Jazeera (AJ)* corpus (after dependency parsing). While the raw data contain 133 instances referencing *muslims*, the majority were excluded due to codeswitched content or syntactic filtering. This absence likely reflects a combination of platform-specific moderation policies, audience composition, and differing levels of salience in user-generated responses.

The aspect term *Zionists* consistently receives negative sentiment across all channels. However, this is based on a small sample size, since we only found a very limited number of mentions of this aspect. Thus, this analysis needs to be taken with a grain of salt. Here, a closer look at the comments is warranted.

Our results demonstrate that sentiment varies significantly across media outlets, confirming previously observed biases while offering new insights into polarization. User-generated discourse responding to content from Middle Eastern outlets such as *AJ* and *TRT* tends to frame *Palestine* and *Palestinians* more positively, contrasting with more mixed portrayals in *BBC* and *DW*. Negative sentiment toward *Hamas* is dominant across all platforms but varies in intensity. Our findings extend existing work that highlights the role of sentiment modeling in capturing ideological alignment and emotional intensity during geopolitical crises. For example, prior research has shown that shifts in affective tone in media coverage can predict or coincide with conflict events (Jamison et al., 2023), and that emotional exposure on social media can amplify polarization over time, particularly when communication occurs with out-groups and ideological alignment diverges (Lerman et al., 2024). Our aspect-level analysis refines this perspective by revealing how such dynamics manifest across ideological categories in the digital mainstream, capturing fine-grained sentiment distinctions within user-generated content; distinctions that are often obscured by global sentiment scores alone. Although our study analyzes polarization across multiple aspect terms, it also builds on the findings by Alamsyah et al. (2024), who examined the volume of pro-Israel and pro-Palestinian narratives on X (formerly Twitter) after October 7 and found the latter to be more prevalent. Our longitudinal sentiment analysis corroborates this imbalance and reveals how such patterns evolve across multiple outlets and intensify over the course of a year.

6 Conclusion and Future Work

We have investigated whether the use of aspect-based sentiment analysis of a large-scale corpus can provide useful insights for the study of polarization in discourse. We show that a current ABSA system can be successfully trained and used on more than 3.4 million YouTube comments we have collected. The intrinsic evaluation shows that the ABSA system reaches an F1 of 77.9, and the results are balanced between the three sentiment classes. Our extrinsic evaluation shows that the longitudinal analysis as well as the analysis across outlets corroborate known trends as well as provide more fine-grained or additional information that can be interpreted by a subject expert.

For the future, we are planning to evaluate the approach on a larger number of aspects. Since it is impossible for us to annotate enough data for training a model on all of those aspects, we will experiment with methods to determine the aspects automatically in combination with a zero-shot ABSA approach for the lower frequency aspects. Additionally, we are planning to use the large-scale sentiment annotations to investigate polarization in the Israel-Hamas war.

Limitations

Annotations: Some statements lack clear intent markers (e.g., sarcasm, irony, rhetorical questions). We inferred meaning based on domain-specific expertise using established patterns of dog whistles and coded language, but some ambiguous cases remain unresolved.

Dataset Constraints: Several initial aspects (e.g., *Hezbollah*) were discarded because many

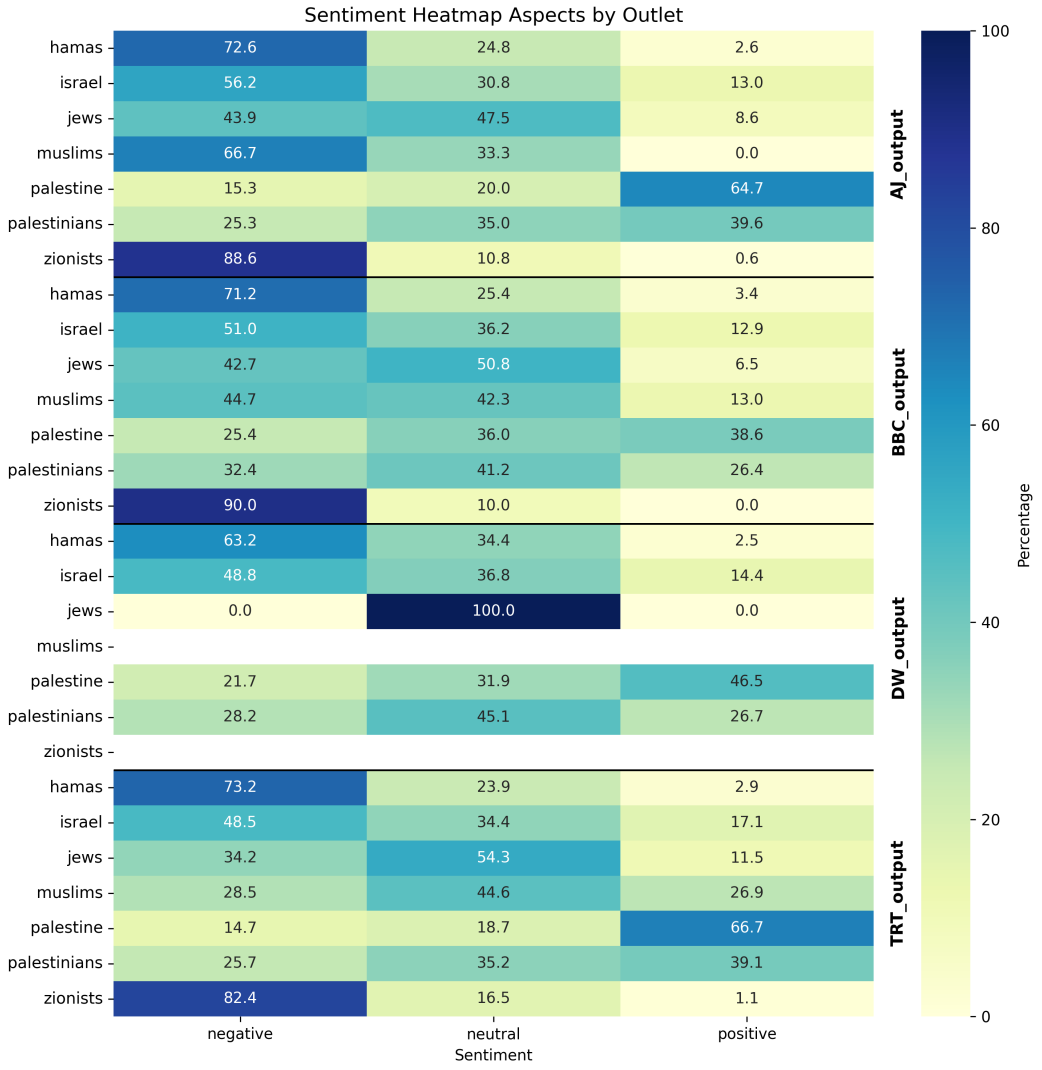

Figure 3: Heatmap for aspect sentiment across the four outlets.

comments failed the language threshold ($\geq$ 40% English), indicating widespread codeswitching. Other aspects (e.g., *Zionists*) had very few positive examples, which led to class imbalance that impacted model performance. However, while data augmentation could mitigate some of these limitations, generating synthetic samples, particularly in sensitive political domains, raises ethical concerns.

Platform Coverage: The results on user-generated content from *Deutsche Welle (DW)* and *BBC* should be interpreted with caution: due to limited number of short-video content published by these outlets, our dataset contains significantly fewer samples from these sources compared to *TRT* and *Al Jazeera (AJ)*, reflecting outlet-specific content creation practices and not necessarily a lack of coverage of developments in our targeted topic.

Abstract

This study investigates the application of Natural Language Processing (NLP) methods to uncover linguistic and stylistic variations within the corpus of Ludwig Wittgenstein, a philosopher renowned for his complex and notional contributions. By analyzing works such as *Tractatus Logico-Philosophicus* alongside his later notes, manuscripts, and student-dictated lectures in Cambridge, we aim to identify significant distinctions in language use and conceptual framing. The corpus poses unique difficulties because of its diverse origins, including published works, personal notes, and collaboratively edited transcripts.

Using zero-shot NLP techniques, this exploratory/preliminary research aims to reveal patterns reflective of Wittgenstein's philosophical evolution and differences in text production methods. The results highlight the potential of computational approaches to enhance our understanding of complex, context-dependent philosophical writings, providing a possible path for further interdisciplinary investigations into linguistic and conceptual dynamics in the challenging body of work.

1 Introduction

Ludwig Wittgenstein was an Austrian philosopher (1889-1951) whose oeuvre focused mainly on logic, mathematics and language. His only book published during his lifetime was the 75 - page *Logisch-Philosophische Abhandlung (Tractatus Logico-Philosophicus)*, which, by Stanford Encyclopaedia of Philosophy "(. . .) addresses the central problems of philosophy which deal with the world, thought and language, and presents a 'solution' (as Wittgenstein terms it) of these problems that is grounded in logic and in the nature of representation." The *Tractatus* is written in a dry and aphoristic style, with no arguments, and consists of altogether 525 declarative statements, which are hierarchically numbered.

Posthumously, there were thousands of pages of manuscripts found - some of them not published even to this date - courses he held in Cambridge in the 1930s, notes and research reports written mostly in German, his native language. His major text is the *Philosophical Investigation* (Wittgenstein, 1968) which philosophy scholars consider the most important philosophy treatise of the 20th century. In its introduction, Wittgenstein admits the changes he made along the way, so that it can be understood "only by contrast with and against the background of my old way of thinking"(Wittgenstein, 1968), meaning in the *Tractatus Logico-Philosophicus* (Wittgenstein, 1921a). Many of the ideas developed in the *Tractatus* were criticized in the *Philosophical Investigations*, while others were later developed. The initial challenge of this project came from the *Yellow, Blue and Brown Books*, which were written after dictation by three of his students, Margaret Macdonald (Masterman), Francis Skinner and Alice Ambrose, during the lectures he held in Cambridge between 1932-1935. As one of the students, Alice Ambrose, admitted in the 1992 edition of Ludwig Wittgenstein's Lectures - Cambridge 1932 - 1935 *(The Yellow Book)* : "The difficulties I had finishing this edition of these notes taken between 1932 and 1935, a time when I attended Ludwig Wittgenstein's lectures, have multiplied because I didn't have access to other students' notes who took the same course, in order to check my notes, except for the year '34 -'35. (. . .) I rarely tried to make reference to some other texts already published. I also didn't attempt to follow the exact order of Wittgenstein's lectures." There were some fragments which were excluded, because of repetitions and digressions, because of the oral manner of the notes.

The *Yellow Book* together with the *Brown and*

* Equal contribution.

Proceedings of Recent Advances in Natural Language Processing,pages 729–736

Blue Books marked the fundamental change in Wittgenstein's philosophical venture, moving from the exact mathematical and logical atomism towards a more approachable philosophical language. It is considered an important resource for understanding the development of Wittgenstein's ideas and the shift in his philosophical approach. After his death, there were many controversies about his intellectual heritage and the lack of control over the early and unchecked manuscripts he left. There are still debates over his intellectual testament and its handling by various people who embarked in this process.

Inspired by (Uban et al., 2021) we decided to look at the evolution of ideas in the writings of Ludwig Wittgenstein from the stylistic and semantic perspectives. The novelty of this research consists of performing a computer aided analysis of the work of Wittgenstein using existing proven tools, and trying to interpret the results without any active expectations. This could be relevant since he was one of the first scholars to discuss the statistical nature of language and the fact that the words are defined by their use.

As workflow, we wanted to see whether the texts would be grouped by the translator, by the language the text was written in, or by the year of creation, when analysed from a stylistic standpoint. We also wanted to know if comparing the texts using a pre-trained language model (PLM) leads to better results than the same analysis based on word distribution and bag-of-words (BOW) methods. The novelty does not consist of the tools or methods applied, but of using those tools on a specific corpus, with the clear goal of searching for new insights and information on the context of the writings.

2 Related Work

Stylometry & Authorship dentification Text analysis based on style and word content is very old, dating back at least to medieval times. For example, the *Donation of Constantine* is a forged Roman imperial decree in which, supposedly, emperor Constantine the Great transfers authority over Rome and the Western part of the Roman Empire to the Pope. The letter was contested, on stylistic grounds, by Lorenzo Valla (1597-1599). He realized that the language used in the text was inexistent in the 4th century, so that the document must be a forgery, a conclusion which was accepted. Valla's argumentation was qualitative rather than quantitative. Quantitative methods started in the late 19th and early 20th century with the works of George Udny Yule (Yule, 1939, 1944) and George Kingsley Zipf (Kingsley Zipf, 1932). Nowadays, both stylometry and authorship identification are well developed fields. Stamatos (2009) advocates for the use of function words, because they are "used in a largely unconscious manner by the authors, and they are topic-independent". There are also other features of the language that can be used[1].

In our case, this class of methods may be hindered by the fact that the use of stop-words is overshadowed by the translators' approach, who added their own stylistic signature on top of the one of the original author. Rybicki (2012) shows that, in a translated text, stylometric methods tend to indicate the original author, rather than the translator. The author identification on texts written by multiple people can be an intriguing topic as seen in (Dinu et al., 2012a; Dauber et al., 2017).

Thematic Analysis When trying to analyse the concepts and the domain of a text, function words and translation become less important. Using uncommon words as the indicator of the meaning of a text and a measure of text similarity is an old idea and represents, for example, the basis of the TF-IDF method (Salton, 1986). Such methods have been long used in order to compare texts based on content but are known to fail when the text is abstract and lacking domain specific keywords. Another completely different way of performing thematic analysis on texts is provided by the pre-trained language models, also known as 'transformers' (Vaswani et al., 2017; Devlin et al., 2019). Because the sequence length processed by the current generation of transformers is limited, there are various methods to determine the semantic representation suggested for long texts.

We should also mention a notable study on the subject of Ludwig Wittgenstein and NLP, investigating the influence of Wittgenstein's philosophy on the evolution of mathematical approaches to language and the historical development of what is n:)) ow known as Natural Language Processing, *Wittgenstein's Philosophy of Language: The Philosophical Origins of Modern NLP Thinking* (Bain et al., 2022).

[1] for example the frequency of the '-ing' continuous form

3 Methodology

The texts within the corpus showed special characteristics: some were originally written in English, while others are translations from German into English. Additionally, certain texts were authored directly by Wittgenstein, and others are collections of notes compiled by various collaborators. Another distinction lies in the intended purpose of the texts—some were explicitly written for publication, whereas others were personal notes. The corpus has been thoroughly studied since its publication, but, of particular interest are the comparative studies that examine the writings as a whole, exploring intertextual relationships and thematic coherence across Wittgenstein's works.

Despite its importance, finding all the relevant texts proved to be a difficult task. We were only able to source most papers as image-based PDFs and we had to digitize and clean them up, both automatically - using python regexp-, and then manually for fine adjustments. The role of the regular expressions was to clean up the page numbers and other artifacts produced by the OCR. The quality of the resulting texts is not the highest, but it is adequate, considering the statistical nature of this study.

Some of the works contain a lot of drawings, and including them using a multimodal model (Baltrušaitis et al., 2018) would be an interesting direction for future research, but in this study, the drawings were simply left out.

The complete list of texts can be found in table 1.

A quantitative comparison of texts was conducted by analysing the distribution of function words, as their use is highly individualistic and can serve as the distinctive linguistic "fingerprint" of an author. According to previous studies rank distance is particularly well-suited for this type of analysis (Popescu and Dinu, 2008; Dinu et al., 2012b). Consequently, we computed the pair distances of the texts and also followed the methodology of the previous studies and used the words described in Mosteller & Wallace (Mosteller and Wallace, 1963). According to them, it is important to identify the function words, also known as "non-contextual" words in order to distinguish between authors, in our case to see if there are differences throughout Wittgenstein's works, especially the *Yellow, Brown and Blue Books* compared to the other texts. Unsurprisingly, using the NLTK stop-words led to very similar results, considering that there is a considerable overlap between the two sets.

These methods provide valuable information on the linguistic style and authorial attribution, enabling a systematic exploration of textual patterns.

Beyond stylistic elements, the relations between the texts can also be examined based on their semantics. Wittgenstein often revisited particular subjects across different works or explored various themes in separate texts in no certain order. One objective of our study was, in fact, to determine to which extent the semantic relations can be identified using various methods and tools. We were particularly interested if the pretrained language models perform significantly better than the bag-of-words based methods, when applied on a corpus like this. We are aware of the diversity of the language models available but we decided to stick to BERT which is better understood and studied due to its age. In order to decide we performed two experiments:

We computed a classical cosine similarity based on the rare terms (in a TF-IDF sense) as the first measure of similarity between texts. Specifically, it is counting the number of occurrences of the uncommon words that appear in at least two works and compute the cosine distances (1 - cosine similarity) of those vectors. Then, based on those distances we performed word clustering.

Subsequently, we compared these results to the pre-trained language models (PLMs) based methods. PLMs have showed remarkably high performance in the zero-shot language understanding and classification tasks (Devlin, 2018; Gera et al., 2022). Another reason we chose these models is that they allow deeper semantic interpretations of texts without requiring extensive task-specific training data, making them suitable for analysing intricate philosophical writings.

Because the data of the corpus is limited, we had to use Large Language Models (LLMs), that already have knowledge of the language in general, in order to get a better semantic understanding. Also, the texts were too long to be embedded in a single chunk, so we had to split them. The acquired chunks are of consistent size and contain whole sentences. The maximum chunk length is 512 tokens. It resulted in a list of embeddings corresponding to each chunk. In order to represent the whole text we had to compute some kind of aggregate. We decided to use BERTTopic(Devlin et al., 2019) to create some clusters, in an unsupervised

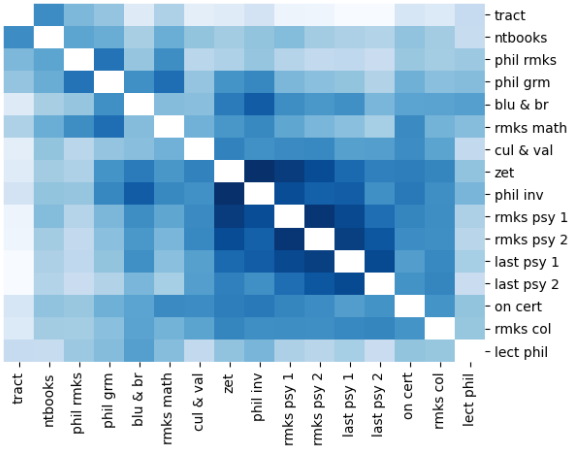

Figure 1: Similarity using the cosine similarity based on the number of function word occurrences. Darker means more similar.

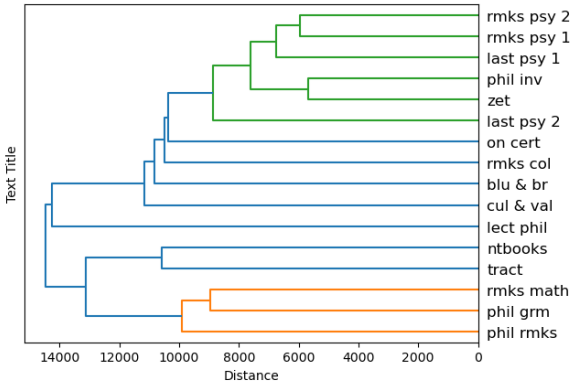

Figure 2: Similarity dendrogram based on based on the number of function words occurrences.

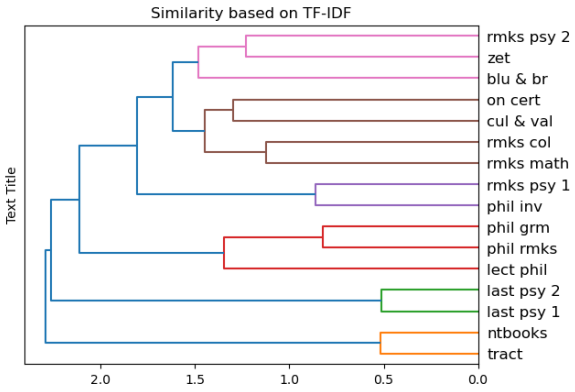

Figure 3: Similarity based on TF-IDF.

way. The topics that cannot be clustered were discarded [2]. Consequently, we applied BERTopic to identify thematic clusters, each cluster containing a set of related text chunks. The resulting chunks were further grouped according to their original work and cluster. In this way, for each text, we obtained a vector of integers encoding the number of chunks of each topic that are present in each text. Then we computed the cosine similarity of those vectors as a measure of similarity between texts. Following normalization, we used the number of chunks associated with each topic as features to construct a semantic similarity matrix, allowing a quantitative assessment of thematic relations across different writings.

4 Experiments and Results

Function Word Similarity The pairwise rank distances based on the function words are plotted in Figure 2. The grouping and similarities are not a surprise, the texts being grouped by the period, mode of production and language.

An intriguing result was the lack of relatedness between *The Brown and Blue Book* and the *Philosophical Investigations,* even if the first was a preliminary study for the letter, raising a question to be addressed later on in a more exhaustive study we plan to put together with several philosophy scholars.

The other unexpected result was that the two volumes of *Last Writings on the Philosophy of Psychology* were not grouped together, how we thought to be reasonable. This separation may be attributed to Wittgenstein's extensive archival material, which includes notes spanning different periods of his intellectual development. It is possible that the sources for these volumes emerged from distinct phases of his philosophical thought. As previously observed, Wittgenstein's work shows clear transitions, such as the shift from the *Notebooks* and the *Tractatus Logico-Philosophicus* to a later period characterized by the *Philosophical Investigations*. This later phase, often regarded as a new era in his philosophy, was preceded by the *Blue and Brown Books*, which served as preparatory texts for his evolving ideas. Otherwise the texts are reasonably and coherently placed on the distance map.

Long Word Similarity Calculating a similarity between texts based on the TF-IDF vectors (that are presumed to be the most specific to the topic, according to the efficiency of the language) would, ideally, cluster the texts based on their meaning. The texts are indeed reasonably and logically grouped, showing that this method can still be used for this type of task, even in the case of a small

[2] BERTTopic creates a special "-1" cluster representing the spurious data

Table 1: List of works. Lang represents the original language.

corpus. Figure 3 shows the dendrogram that is resulting and the works are not grouped in any understandable way. One surprising feature is the distance between *Remarks on the Philosophy of Psychology 1 and 2* which can be explained by the numerous notes and writings of Wittgenstein produced in various periods of time.

Using Bert for Topic Detection Not surprisingly, the results based on BERTTopic are a lot more relevant.

The results obtained using BERTTopic are presented in the figures 4 and 5.

In order to give the topics an intuitive meaning, we created a human-readable label for each topic. The labels were created as follows: the chunks associated to each topic have been first concatenated, forming pseudo-documents. Then, for each of those pseudo-documents we selected the best two unique terms, in the TF-IDF sense, to serve as cluster name. The source of some of the observed similarities is easy to spot in the correlation matrix. Also, it revealed the fact that some books are more focused on a topic (*Culture and Value)* while the topics in others are more spread out *(Lectures on Philosophy*). Human intervention from scholars with a good knowledge of Wittgenstein's work can improve this understanding, in an iterative semi-supervised manner.

Computing the pairwise distance between these representations led to Diagram 5.

5 Conclusions and Future Work

This study does not claim to be a philosophical analysis but a computational linguistic one. In conclusion, the Natural Language Processing (NLP) tools, both traditional and modern, offer valuable methods for analysing complex, philosophically dense corpora such as the one presented in this study, the oeuvre of Ludwig Wittgenstein. While producing certain conclusions remains challenging in the absence of a well-established baseline, these computational approaches serve as "intuition pumps" (Dennett, 1993), aiding in the discovery of novel insights and has good chances to become a useful tool for the philosophical approach and scrutiny of the texts. Furthermore, improved or manually chosen topic labels would significantly enhance interpretability and, eventually, the understanding of the fairly used concepts. Additionally, fine-tuning a large language model (LLM) specifically on philo-

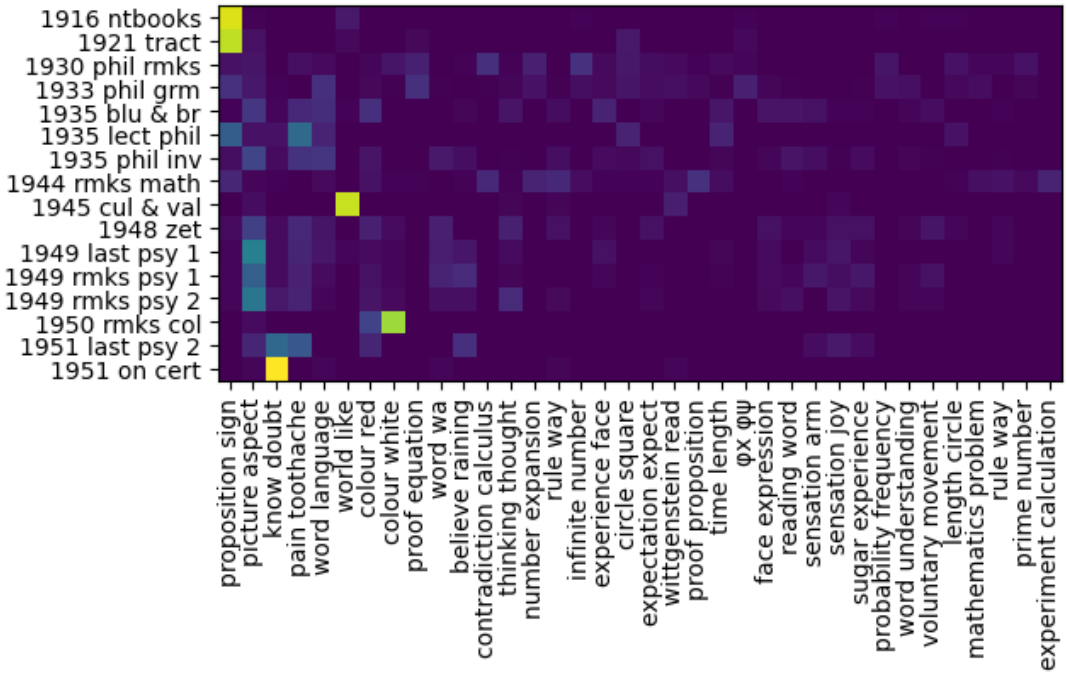

Figure 4: Topic by work

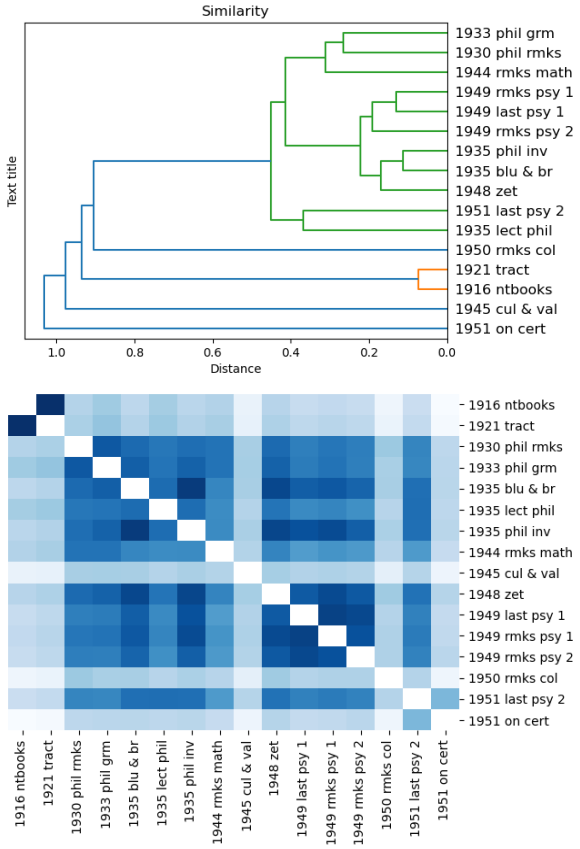

Figure 5: Topic similarity matrix and dendrogram based on the number of common topics, using LLM. Darker means more similar. Self similarity is not displayed.

sophical texts may improve the accuracy and relevance of topic detection. A particularly intriguing direction for future research is exploring the influence of language on text representations. Using multilingual models would be insightful in order to examine the proximity of the original German texts to their English translations in a language-independent semantic space. Although one might expect the translated texts to closely align with their German counterparts, the actual results are important and deserve empirical confirmation. Another approach would be comparative analyses between this corpus and the works of other contemporary philosophers and logicians, such as Kurt Gödel or Gottlob Frege, which can produce valuable insights into the capabilities and limitations of current semantic representation models. Conducting such a comparison of both original texts and their translations could provide a deeper understanding of the nuances of meaning that may be preserved, lost, or transformed through translation. A broader long-term research project could involve a large-scale study encompassing multiple philosophical works, including the exhaustive corpus from the Wittgenstein Archive at the University of Bergen (WAB), with the goal of mapping a history of ideas computationally and assessing how well such an approach aligns with the canonical history of philosophy. This would serve as an ambitious attempt

to quantify the evolution of philosophical thought using computational techniques.

6 Limitations

The lack of availability of a good quality text corpus presented a challenge, and some considerable effort went into producing and preprocessing the texts.

Automating the process of analysing and commenting on such texts is clearly beyond the scope of this study, as it presents significant challenges, as acquiring novel insights, particularly those not explicitly present in the training data, could fall within the domain of Artificial General Intelligence (AGI).

7 Ethical Statement

There are no ethical issues that could result from the publication of our work. Our experiments comply with all license agreements of the data sources used. We make the contents of our package available for research purposes upon request.

Towards Intention-aligned Reviews Summarization: Enhancing LLM Outputs with Pragmatic Cues

Abstract

Recent advancements in Natural Language Processing (NLP) have allowed systems to address complex tasks involving cultural knowledge, multi-step reasoning, and inference. While significant progress has been made in text summarization guided by specific instructions or stylistic cues, the integration of pragmatic aspects like communicative intentions remains underexplored, particularly in non-English languages. This study emphasizes communicative intentions as central to summary generation, classifying Spanish product reviews by intent and using prompt engineering to produce intention-aligned summaries. Results indicate challenges for large language models (LLMs) in processing extensive document clusters, with summarization accuracy heavily dependent on prior model exposure to similar intentions. Common intentions such as complimenting and criticizing are reliably handled, whereas less frequent ones like promising or questioning pose greater difficulties. These findings suggest that integrating communicative intentions into summarization tasks can significantly enhance summary relevance and clarity, thereby improving user experience in product review analysis.

1 Introduction

A central objective of Natural Language Processing (NLP) is to develop automatic systems that emulate human-like language understanding and production (Chowdhary, 2020). Yet, current models—particularly Large Language Models (LLMs)—often neglect complex yet essential pragmatic dimensions crucial for authentic communication. The NLP community has acknowledged this limitation and is increasingly investigating how pragmatic phenomena, especially communicative intentions, shape both the interpretation of messages and the linguistic choices made to convey those intentions—an aspect vital for Natural Language Generation (NLG) tasks such as text summarization (Khurana et al., 2023; Fried et al., 2023).

Although communicative intentions are central to language structuring, their integration into generative systems for NLG tasks remains underexplored. This is especially evident in text summarization, where intentionality is key to ensuring coherence between the source text and its summary. Despite its importance, limited efforts have addressed this aspect—particularly in languages beyond English. This study examines how well various LLMs incorporate communicative intentions in multi-document summarization using Spanish product reviews. By applying prompt engineering techniques and automatic intent classification, we assess whether the generated summaries reflect the communicative goals present in the original reviews.

Overall, the main contributions of this paper are:

- Automatic intention classification in a Spanish reviews corpus.
- Comparative analysis of prompt engineering strategies for intention-driven summary generation.
- Comparative evaluation of generative models for intention-aligned text summarization.
- Application of sentence similarity metrics to evaluate alignment between generated summaries and communicative intentions determined in prompts.

The remainder of the paper is organized as follows: Section 2 reviews research on integrating communicative intentions in generative systems. Section 3 details the Spanish corpus, intentions tested, LLMs evaluated, and prompts used to guide

Proceedings of Recent Advances in Natural Language Processing,pages 737–747

https://doi.org/10.26615/978-954-452-098-4-085

intention-aligned summary generation. Then, Section 4 shows the intention-aligned summary generation task results and some features of adequately and inadequately generated summaries. The sentence similarity evaluation methodology used to compare the alignment between summaries and original review excerpts is outlined in Section 5. Finally, Section 6 summarizes key findings future research directions to further incorporate pragmatic phenomena into language generation tasks.

2 Related Work

In NLP, the pragmatic layer has often been overlooked in favor of lower linguistic levels such as syntax and semantics, largely due to its inherent complexity and reliance on contextual cues for meaning interpretation (Levinson, 2017). Within pragmatics, communicative intentions are especially vital, shaping both message formulation and comprehension (Ghosal et al., 2021). Their significance has been extensively examined through various theoretical frameworks and taxonomies by scholars such as Austin (1962); Searle (1969); Halliday and Hasan (1986); Sperber and Wilson (1986); Archer et al. (2008); Bach (2012); Escandell Vidal et al. (2020).

Communicative intentions are increasingly recognized as essential in NLP, particularly for NLG, where they guide linguistic choices to convey specific meanings. Recent advances in LLMs have strengthened their ability to handle complex tasks involving multi-step reasoning and inference (Dong et al., 2022). A prominent example is Automatic Text Summarization (ATS) (El-Kassas et al., 2021), which condenses large volumes of text—such as news, medical, or product reviews—into concise, contextually appropriate summaries. This is especially critical in abstractive summarization, which rephrases key information to generate novel, succinct outputs (Mridha et al., 2021).

Recent advances in generative systems have led to novel ATS approaches that integrate pragmatic features such as style (Goyal et al., 2022), polarity (Amoudi et al., 2022), and vocabulary (Balde et al., 2024). Yet, incorporating communicative intentions—crucial for generating contextually appropriate and purposeful summaries—remains an emerging area. Notable efforts include summarizing app reviews based on categorized intentions (Di Sorbo et al., 2016), leveraging semantic-intent graphs in multilingual summarization (Wang et al., 2019), and generating intention-aligned summaries for health queries (Zhang and Liu, 2022) and code descriptions (Geng et al., 2024). Despite this progress, no prior work has addressed intention-based summarization in Spanish.

3 Experimental Setup

Multi-document summarization is gaining prominence in NLP as users increasingly face large volumes of online content when searching for topic-specific information (Ma et al., 2022). This creates a growing need for systems that can generate concise, user-tailored summaries. In this study, reviews within each product category are aggregated into unified texts to evaluate intent-driven summary generation across multiple LLMs, chosen for their ability to handle long-context inputs encompassing all relevant review content.

Figure 1 illustrates the procedural steps for automatically generating summaries according to specific communicative intentions. The subsequent sections detail the dataset's characteristics, the targeted communicative intents, model selection, and the design of prompts for interacting effectively with these models when generating intention-aligned review summaries.

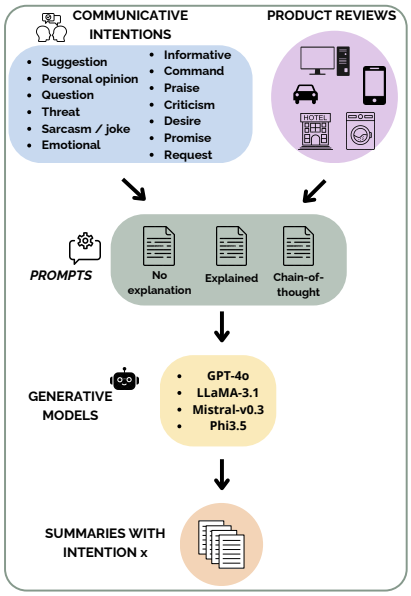

Figure 1: Experimental setup to generate intention-aligned summaries of product reviews in Spanish.

3.1 Spanish dataset

This study evaluates intention-aligned summary generation in Spanish, requiring a dataset with texts that reflect diverse communicative intentions

suitable for a fine-grained taxonomy. After surveying available corpora, we selected product reviews for their rich variety of intentions—such as descriptions, suggestions, opinions, praise, criticism, threats, or sarcasm. Specifically, we used the SFU Review Corpus (Taboada and Grieve, 2004), which contains 400 reviews from the Ciao.es[1] forum across categories like cars, hotels, washing machines, mobile phones, and computers.[2] Each category includes 50 reviews, merged into a single document for summarization. These consolidated reviews were then used to generate intention-aligned summaries as described in the following section. We excluded three categories—books, music, and films—because their aggregated reviews exceeded the input limits of some LLMs (over 100 000 characters), rendering them incompatible.

3.2 Intention taxonomy

As discussed in Section 2, many taxonomies of communicative intentions have been proposed, though often with limited applicability to real-world scenarios (Ma et al., 2025). Given that our dataset stems from computer-mediated communication (CMC)—which encompasses digital textual genres found online—, we adopted the taxonomy by Maestre et al. (2025), which defines 13 intention categories suited to CMC contexts: "suggestion", "personal opinion", "question", "threat", "sarcasm / joke", "emotional", "informative", "command", "praise", "criticism", "desire", "promise", and "request". We believe these categories effectively capture the variety of intentions in our review corpus. Moreover, the absence of certain intentions in the original texts provides a useful lens to assess whether LLMs appropriately reflect this absence or introduce hallucinated content when prompted to include specific intentions in the generated summaries.

3.3 Generative models

The selection of LLMs evaluated in this summarization task was influenced by the necessity for a wide context window capable of processing extensive integrated reviews from a product category into a single document. Consequently, four LLMs were chosen: GPT-4o (Achiam et al., 2023), LLaMA-3.1-8B (Touvron et al., 2023), Mistral-7B-Instruct-v0.3 (Jiang et al., 2023), and Phi3.5-3.8B (Abdin et al., 2024). This selection ensures diversity by incorporating both proprietary and open-source models capable of handling lengthy contextual inputs required for summarization tasks.

More concretely, GPT-4o was selected due to its demonstrated capabilities across various NLP tasks, as extensively validated by existing research (Qin et al., 2023; Amin et al., 2023; Hariri, 2023). It was accessed via OpenAI's online interface.[3] The remaining models—LLaMA-3, Mistral, and Phi3.5—were evaluated using the Ollama platform,[4] an optimized local tool facilitating interaction with open-source LLMs through Python, thus simplifying their configuration according to specific research objectives.

Interaction with the models included in Ollama utilized a client-server setup, configured with a maximum context length of 33 000 tokens, sufficient for the unified review documents. Prompts used to guide summary generation were externally loaded based on the communicative intention and the prompt type chosen to generate each summary, employing an iterative process for generating intention-aligned summaries across the different product categories. Detailed descriptions of the prompt types employed in this research are provided in the subsequent section.

3.4 Prompt engineering techniques

To incorporate communicative intentions into automatic summary generation by LLMs, this study employed prompt engineering—a technique involving carefully designed and refined instructions that guide model interactions to better fulfill specific tasks (Marvin et al., 2023). Prompt engineering is widely regarded in the research community as critical for effectively leveraging LLM capabilities in different tasks (Sahoo et al., 2024).

This study evaluates LLMs' ability to generate summaries of product reviews that align with specific communicative intentions, focusing on whether relevant excerpts are accurately identified and represented. To this end, prompts were crafted to include the target intention, the set of reviews for analysis, and stylistic and formatting guidelines. As shown in Figure 2, three prompt versions were developed,[5] differing in the level of detail provided.

[5] Prompts were originally written in Spanish. We translated

These variations aim to assess whether LLMs can infer Spanish pragmatic cues or require explicit instructions to effectively detect and reproduce communicative intentions.

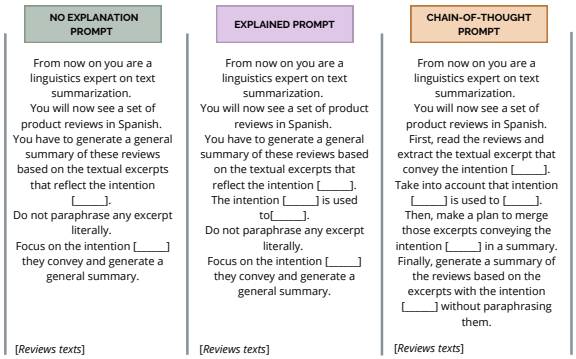

Figure 2: Prompts created to generate review summaries according to each intention category.

The three distinct prompt variations created initially state the task and specify the intention the summary should convey. These prompts differ in the amount of explanatory information provided to define the communicative intention. The first variation, "no explanation prompt", includes only the intention's name, testing the extent to which LLMs inherently understand and recognize communicative intentions without additional context. The second, "explained prompt", provides explicit definitions derived from the intention taxonomy used in this study. The third version employs the "chain-of-thought" (CoT)(Wei et al., 2022) prompting strategy, which has demonstrated significant effectiveness across various NLP tasks (Yu et al., 2023) requiring complex reasoning, as it instructs LLMs through intermediate reasoning steps to fulfill the task accurately.

An extensive review of recent studies on CoT prompting (Wei et al., 2022; Crispino et al., 2023; Li et al., 2024; Wang et al., 2023) informed the selection of a suitable prompt structure. Particularly, the "plan-and-solve" strategy by Wang et al. (2023), which explicitly instructs models to reflect on tasks and develop a structured approach, was considered highly appropriate. This approach involves initially extracting relevant excerpts aligned with specified summary requirements, a method previously validated with successful results by Gao et al. (2020) and Wu et al. (2024). Thus, we divided the prompt in different reasoning steps, these being: identifying the determined intention in the original texts, selecting relevant textual excerpts that convey that intention, and generating intention-aligned summaries.

4 Review Summary Generation

Following the methodology outlined in the previous section, we generated a total of 780 review summaries (13 intentions $\times$ 4 LLMs $\times$ 3 prompt techniques $\times$ 5 product categories). All original product category reviews, along with their intention-specific summaries, the LLMs employed, and the prompts used in this study, are available in the following repository: https://github.com/Maria3mmm/Intent_Summ_Es-

During summary generation, a qualitative analysis was conducted to evaluate the alignment of communicative intentions between the generated summaries and the original reviews. This analysis aimed to identify which intentions were effectively captured by generative models, following the intention categories defined for this study.

Table 1 illustrates an example where summaries generated by Mistral-v0.3 and LLaMA-3.1 models for computers and mobile phone reviews failed to convey the specified "promise" intention. Instead of accurately including excerpts such as "I promise I would never try to buy again a product form this brand" or "This mobile should be fast-responding but I swear it's just not good" that match the intention requested in the prompt and were explicitly stated in original reviews, these summaries predominantly focused on product descriptions or sentiment-related features, indicating a closer alignment with sentiment classification tasks rather than the intention-aligned generation task.

Then, the results presented in Table 2 illustrate examples where the summaries generated by Phi3.5 and GPT-4o successfully align with the communicative intention of "praise" found in hotel and computer product reviews. Both models accurately highlighted positive user feedback, with GPT-4o notably acknowledging that despite prevalent negative comments, positive remarks still exist and subsequently enumerating them. This outcome aligns precisely with the objectives of the intention-aligned summarization experiment. The authors attribute this accuracy partially to the extensive prior exposure these models have had to datasets involving positive and negative sentiments, stemming from sentiment analysis being a well-established NLP research area, thus providing a strong founda-

them into English for clarity.

Summary excerpt of mobile reviews with "no explanation" prompt generated by Mistral-v0.3	Summary excerpt of hotel reviews with "explained" prompt generated by LLaMA-3.1
The Motorola C261 is a mid-range mobile phone with interesting features and a design you won't forget. Although its price is relatively high, it offers a wide range of capabilities, making it a highly recommended purchase if you're looking for a very complete and high-quality mobile phone. The Motorola C261 is a fully-featured PDA (and mobile phone), featuring a 2.8-inch screen with a resolution of 320x240 pixels, a 520 MHz Intel XScale processor, and the Windows Mobile 5 system."	After reviewing the comments on various hotels in Madrid, I can summarize the main problems found as follows. 1-Room quality: Many hotels have small, outdated rooms lacking basic comforts.2. Service issues: Some hotels offer poor reception services, with staff that can be unfriendly or inefficient. [...] However, there are also positive reviews highlighting (1) Location: Many hotels are conveniently located near tourist attractions with easy access to public transportation. (2) Staff: Some hotels have friendly and attentive personnel who enhance the traveler's experience. [...]

Table 1: Inaccurate summaries generated for "promise" intention.

tion for addressing newer tasks such as intention-driven summary generation.

Summary excerpt of hotel reviews with "no explanation" prompt generated by Phi3.5	Summary excerpt of computer reviews with "no explanation" prompt generated by GPT-4o
The generalized summaries of praise intentions based on reviews highlight a consistent recommendation for a hotel located next to the Congreso de los Diputados and close to Gran Vía, offering amenities such as proximity to Madrid's cultural center, diverse restaurants, and entertainment options. Guests particularly praise its excellent value for money and modern facilities within a hotel context not yet fully renovated at that time (2007), [...]	The analysis of the reviews mainly highlights negative criticisms towards different computer brands. However, focusing on the few positive mentions, the following aspects stand out: (1) Value for money in certain models: Some users appreciate computers offering reasonable specifications at affordable prices, suitable for basic home or business tasks. (2) Good technical support experiences in some cases: Although negative feedback predominates, there were isolated mentions of quick and efficient technical support that successfully resolved specific issues, such as replacing defective components. [...]

Table 2: Accurate summaries generated for "praise" intention.

After manually analyzing summaries generated according to the thirteen communicative intentions defined for this study, distinct patterns emerged regarding which intentions were accurately or inaccurately conveyed by the LLMs. Intentions such as "question", "threat", "promise", "desire", "request", "sarcasm / joke", and "command" generally presented greater challenges for accurate summary generation, irrespective of the model used. Summaries for these intentions often involved adaptations of original reviews that artificially reflected the stated intention rather than accurately identifying and reproducing the intention as originally expressed. In other words, the models frequently hallucinated by rewriting texts to reflect an intended message instead of extracting authentic intention-driven sentences from the original reviews that were manually identified when reviewing the summaries and their respective reviews. Additionally, models often confused intention categories when a particular intention was absent from the original reviews, consequently defaulting to summarizing reviews based on easily identifiable intentions, basing on those related to polarity, such as "praise", "criticism" or "suggestion".

Based on the previous observations, certain intention categories such as "suggestion", "praise", "emotional", and "criticism" were effectively conveyed in the generated summaries. These intentions are closely associated with user-generated product reviews, where texts typically recommend or dissuade the use of a particular product or service. Consequently, excerpts reflecting these intentions frequently appear in original texts. The high accuracy of summaries capturing these intentions may also be attributed to the extensive exposure of LLMs to related linguistic expressions, notably in sentiment and polarity analysis tasks. Indeed, LLMs can precisely enumerate emotions and sentiments present in reviews, even without explicit prompting, due to their familiarity with such analytical tasks.

Then, the intentions "personal opinion" and "informative" present mixed results, with summaries occasionally accurately reflecting these intentions and other times failing to do so clearly. This inconsistency often arises from the tendency of LLMs to interpret both intentions similarly, particularly when using the "no explanation" prompt, which does not explicitly provide a definition to differentiate them. Consequently, generated summaries for these intentions often resemble each other closely, typically focusing on the advantages and disadvantages of the reviewed products without distinct intentional differentiation.

5 Intention-aligned Summary Evaluation

In addition to the previous qualitative analysis of summaries generated by four language models, a more rigorous evaluation was necessary to precisely assess each model's performance and the prompt strategies employed for the 13 predefined communicative intentions. For this purpose, the study utilized two variants of the cosine similarity metric to measure semantic similarity. The rationale behind this approach is that summaries aligned with specific intentions should include excerpts

from the original texts expressing those same intentions, thereby displaying similar linguistic features.

The evaluation method, illustrated in Figure 3, involves first automatically segmenting the original reviews at the sentence level for each product category. Subsequently, these sentences are classified according to their communicative intention using GPT-4o. Finally, sentences sharing the same intention are grouped and semantically compared with summaries generated by each language model and prompt strategy for the same intention through cosine similarity and BERT-based similarity metrics. Detailed descriptions of each evaluation step are provided in the subsequent subsections.

5.1 Text segmentation and intention classification

The evaluation began by segmenting each product review text (from a set of 50 reviews per product) into individual sentences, using Spacy's "Sentencizer" library[6] specifically adapted for Spanish. Subsequently, these sentence segments were classified according to their communicative intentions using the GPT-4o model, chosen due to its demonstrated high accuracy (0.84 F1 score) in classifying Spanish communicative intentions as reported by Maestre et al. (2025). However, the inherent error rate in this classification model was acknowledged, implying a slight mismatch between some sentences' real intentions and their classification, potentially influencing sentence similarity test outcomes in some cases.

After classifying the sentences by intention, segments corresponding to each of the 13 predefined communicative intentions were grouped. In this manner, for each set of reviews regarding a product category, these groups of sentences formed the evaluation sets for comparing the original product reviews with the summaries automatically generated by the LLMs according to matching communicative intentions.

5.2 Sentence similarity test

The final evaluation step involved calculating the semantic similarity between sentences from the original reviews grouped by communicative intentions and the automatically-generated summaries aligned to the same intentions. To this end, cosine similarity was calculated by measuring the similarity between the vectors of the sentences set from the original texts that convey the same intention as the generated summary. The obtained values can be between 0 and 1, where 0 would entail that there is no similarity between both texts and 1 that both texts are identical (Park et al., 2020).

The cosine similarity formula is expressed as follows:

$$\text{sim}(A, B) = \frac{A \cdot B}{\|A\|\|B\|}$$

where A and B are the vectors of the original set of sentences and the automatic summary. The conversion of both texts into embeddings to get the vectors required for the formula was done with the model "sentence_similarity_spanish_es",[7] specifically optimized for the task of semantic similarity between texts.

Additionally, a more comprehensive evaluation was conducted by calculating the same cosine similarity based on the model BERT with the BERT Similarity metric. The difference between this metric and the previous version is that in the BERT version, vectors are generated with BERT based on the "evaluate" library available in the Hugging Face platform.[8]

The cosine similarity formula based on BERT is expressed as follows (Bingi and Yin, 2023):

$$\text{BERT sim}(A, B) = \frac{BERT(A) \cdot BERT(B)}{\|BERT(A)\|\|BERT(B)\|}$$

where A and B are the vectors created by BERT from the original product review sentences aligned with a specific intention and the automatically-generated summary with that same intention.

With these two versions of the cosine similarity metric, we aimed at assessing how effectively intentional similarity between original review sentences and their intention-aligned automatic summaries can be measured. Additionally, these metrics facilitate evaluating which combinations of prompts and models most accurately generate summaries that reflect the communicative intentions present in the original reviews, as detailed in the subsequent subsection.

5.3 Compared results

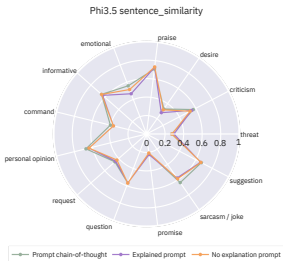
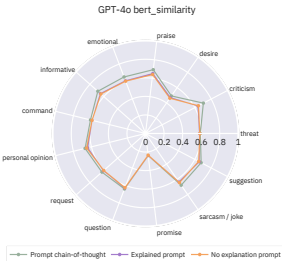
product categories and their corresponding generated summaries, we evaluated the impact of each LLM and the specific prompts designed for the intention-aligned generation task. Figures 4 and 5 illustrate statistical outcomes from the two versions of semantic similarity metrics—sentence similarity and BERT similarity—across the four selected LLMs and the 13 predefined communicative intentions determined for this study.



(a) GPT-4o

(b) LLaMA-3.1

(c) Mistral-v0.3



(d) Phi3.5

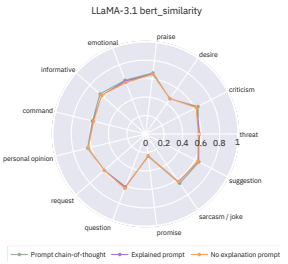


Figure 4: Results for the sentence similarity metric with the four LLMs.

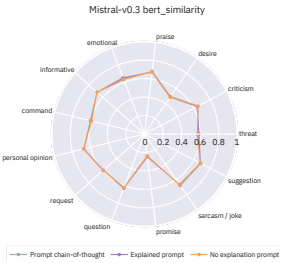
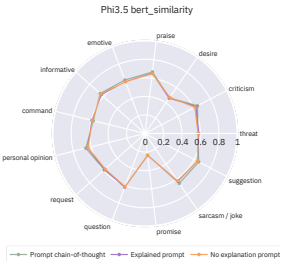
A notable initial observation is the significant difference between the two metric types. The BERT similarity results appear surprisingly uniform, contrasting with the sentence similarity outcomes, especially given that prior qualitative analyses highlighted distinct variations in intention alignment depending on the targeted communicative intention.



Focusing on the sentence similarity results presented in Figure 4, which align more closely with findings from the manual qualitative assessment,



(a) GPT-4o

(b) LLaMA-3.1

(c) Mistral-v0.3

(d) Phi3.5

Figure 5: Results for the BERT similarity metric with the four LLMs.

we compare the alignment effectiveness of each model concerning the thirteen intentions and the three prompts used. GPT-4o achieves high similarity scores primarily for the intentions "personal opinion", "informative", and "praise" predominantly when using the CoT prompt. Similarly, LLaMA-3.1 attains comparable similarity scores for these intentions; however, performance across the three prompts appears more uniform, suggesting this model's relative insensitivity to prompt variations. Phi3.5 demonstrates even greater indifference to prompt types, with the "no explanation" prompt occasionally yielding higher similarity scores for intentions such as "praise" and "informative". Nonetheless, intentions like "promise" and "desire" consistently yield lower similarity scores across all models, as previously detected in the manual revision, indicating either their lower representation in the original reviews or increased complexity in identification by the LLMs. Lastly,

Mistral-v0.3 benefits significantly from both the CoT and "no explanation" prompts, occasionally matching GPT-4o's performance (using the CoT prompt) in intentions like "suggestion" and "praise", and surpassing LLaMA-3.1 for "personal opinion".

6 Conclusions and Future Work

This paper introduces an analytical approach to summarizing product reviews to check up to which point LLMs are capable of aligning the intentions of the original reviews to their respective summaries when specific intentions are requested. This pragmatic approach aims to capture crucial aspects of reviews, thus enhancing the relevance and comprehensiveness of the summaries. The experiment highlighted the challenges posed by extensive prompts, particularly those involving 50 reviews across various product categories, which strain generative models' processing capabilities. Despite these difficulties, addressing such extensive datasets remains valuable due to the practical necessity of summarizing vast amounts of reviews on different types of websites to provide users with concise but complete summaries on the information they want to consult.

A significant challenge identified is contamination from opinion and sentiment analysis tasks, commonly associated with product review corpora. This influence was repeatedly observed during the qualitative analysis of this research, as generative models often defaulted to summarizing positive and negative sentiments, neglecting explicitly defined communicative intentions. Indeed, the evaluation based on semantic similarity—using sentence similarity and BERT models—demonstrated that intentions related to opinion analysis (criticism, praise, personal opinion, suggestions) are more effectively identified.

Additionally, generative models showed limitations in reasoning capabilities, resulting in summaries with irrelevant content, exclusive focus on single product models, multilingual summaries, or even entirely fabricated reviews, as can be consulted in the repository published with all the generated summaries. These phenomena underscore the persistent gap in models' comprehension and their tendency toward hallucination.

A future line of research could be improving models' awareness of which communicative intentions may be absent from the input data, recommending explanations of why a summary cannot be generated in alignment with a specific intention if it has no representation in the original text to avoid misleading users. Furthermore, the research underlines the critical role of prompts and highlights the effectiveness of employing a chain-of-thought strategy, which significantly improves task performance for some intentions and models. Testing some other prompting strategies could also be extended in future research to compare further results on how to best communicate with LLMs when addressing this pragmatic-based generation task.

Abstract

Language models exhibit inherent security vulnerabilities, which may be related to several factors, among them the malicious alteration of the input data. Such weaknesses compromise the robustness of language models, which is more critical when adversarial attacks are stealthy and do not require high computational resources. In this work, we study how vulnerable English language models are to adversarial attacks based on subtle modifications of the input of pretrained English language models. We claim that the attack may be more effective if it is targeted to the most salient words for the discriminative task of the language models. Accordingly, we propose a new attack built upon a two-step approach: first, we use *a posteriori* explainability methods to identify the most influential words for the classification task, and second, we replace them with contextual synonyms retrieved by a small language model. Since the attack has to be as stealthy as possible, we also propose a new evaluation measure that combines the effectiveness of the attack with the number of modifications performed. The results show that pretrained English language models are vulnerable to minimal semantic changes, which makes the design of countermeasure methods imperative.

1 Introduction

The incessant growing of application scenarios of artificial intelligence (AI), and in particular natural language processing (NLP) services, is raising the concern on the robustness against adversarial attacks. The dominant paradigm in NLP is data-driven machine learning, which is known to be vulnerable to different types of attacks in training that perturb the behaviour of the learning models, and even in inference time, in which in addition it is possible to raise privacy leaks (Irfan et al., 2021). Hence, current NLP models may be victims of these adversarial attacks (Goyal et al., 2023).

The attack to a model may be performed in training or inference time. Those in training time require access to the learning model during training or to the training data. This exposing of the training model or the training data is unusual in standard centralised machine learning,[1] but it is a real threat in distributed and federated machine learning (Rodríguez-Barroso et al., 2023). Inference-time attacks may aim to alter the learning model behaviour or to cause privacy leaks. In this work, we focus on the threat posed by the harmful modification of the learning model behaviour.

The data-based manipulation of learning models in inference time may have a specific target or not, but both attacks are based on the stealthy modification of the input to manipulate the output of the model (Goyal et al., 2023). Large language models (LLMs) stand out for their capacity of generating language (Xuanfan and Piji, 2023), thus they can be used as weapons to obtain the subtle modification that triggers the variation of the output of a learning model, in particular a pretrained language model (LM).

In this work, we claim that an adversarial attack against LM that only seeks to alter the outcome of LM in inference time may be more effective and sneaky if it is targeted to the most salient words for the discriminative task. Accordingly, we propose a new adversarial attack grounded in a strategy that minimise the number of modifications and keep almost unchanged the semantic meaning of the input. Hence, we first identify the salient words that drive the decision of the victim model. This selection is built upon *a posteriori* explainable artificial intelligence (XAI) methods that allow us to know the prominent features for the victim LM in this case. In particular, we evaluate the performance of LIME (Ribeiro et al., 2016), SHAP (Lundberg

[1] It is out of the scope of the paper the data poisoning of learning models since depends on a poor cleansing of the training data.

Proceedings of Recent Advances in Natural Language Processing,pages 748–757
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-086

and Lee, 2017) and Captum (Kokhlikyan et al., 2020). Second, we propose replacing those salient words with their closest contextual synonym. In this case, we compare the performance of six small language models (SLM), namely Llama-3.1-8B-Instruct, Llama-3.2-1B-Instruct, gemma-2-9b-it, Gemma-3-1b-it, Qwen2.5-7B-Instruct and Mistral-7B-Instruct-v0.3.

As far as we know, there is no standard evaluation measure that combines the success of an untargeted data-driven adversarial attack at inference time and its stealthiness, since an attack cannot be considered successful if it is evident. We thus propose a new evaluation measure called Attack Score Metric (ASM) that takes into account the amount of output perturbations of the victim LM and the amount of words changed in the input, since the quality of the attack weakens the higher the number of modifications and the greater the change from the original meaning. We also measure how the attack keeps the semantic meaning of the original text seeking to maintain it. We evaluate our untargeted adversarial attack in four text classification datasets of two different tasks (hate speech, and sentiment analysis) and of different text genres: reviews, comments on social media and dialogues. We perform the attack against three pre-trained LM: bert-base-cased, distilroberta-base and xlnet-base-cased. Although there are differences amongst the dataset, the results show that the joint leveraging of XAI methods and LLMs enables a more effective and stealthy adversarial attack

The main contributions of this paper are:

- A new untargeted adversarial attack against LMs leveraging *a posteriori* XAI methods and LLMs.
- A new evaluation metric to assess the effectiveness of an adversarial attack considering its success and the amount of modifications made to the input text.

The structure of this paper is as follows. Section 2 summarises the main related works. Section 3 introduces our untargeted adversarial attack. In Section 4, we show the results of the evaluation, which is analysed in Section 5. Finally, in Section 6, we present the main conclusions and future lines of work.

2 Related Works

The security landscape for language models (LMs) continues to evolve rapidly, presenting significant challenges across deployment environments. These models face vulnerabilities stemming from their architectural design and training methodologies, with threats amplified by the dual nature of generative AI as both security tool and attack vector (Yao et al., 2024). Recent frameworks like Greedy Coordinate Gradient have demonstrated concerning capabilities to bypass conventional defenses by iteratively optimizing adversarial suffixes that induce harmful outputs while maintaining semantic coherence (Zou et al., 2023).

Jailbreak attacks represent another critical vulnerability class, with methods like AutoDAN (Liu et al., 2024) combining prompt engineering with automated adversarial optimization. The adversarial landscape extends to data poisoning scenarios, where techniques such as ModelSonar identify undetectable backdoors (Jia et al., 2022).

Adversary attacks pose particular threats in distributed learning environments, where malicious clients can submit corrupted updates to compromise global model performance. These attacks prove especially challenging in federated learning frameworks, as demonstrated in medical named entity recognition tasks where encrypted federated learning faces significant obstacles balancing computational efficiency and adversary resilience (Pontes et al., 2024).

Generative models significantly amplify adversarial threats. The PoisonedRAG framework (Zou et al., 2024) illustrates how retrievable content can be manipulated to influence LLM outputs while evading semantic similarity checks.

The dual-use paradox remains a challenge in LM security. While defensive frameworks like SemanticSmooth (Ji et al., 2024) employ semantic transformations to improve jailbreak resistance through consensus aggregation across multiple prompts, these same techniques can be repurposed for attack optimization. This paradox extends to red-teaming methodologies, where tools designed to identify vulnerabilities simultaneously serve as blueprints for exploitation (Perez et al., 2022).

The integration of generative models into cybersecurity workflows introduces additional complexity, facilitating both threat detection and sophisticated attacks, necessitating comprehensive ethical guidelines and regulatory frameworks (da Silva, 2025). In this work we show that LLMs can be used as a tool for generating poisoning data for attacking pre-trained LM.

3 Untargeted Adversarial Attack

We propose an adversarial attack against LM based on (1) the identification of the salient words that determine the decision of the model, and (2) the use of LLMs to change them by their closest contextual synonym. Figure 1 depicts the structure of our attack, which we explain as follows.

3.1 Salient Words Identification with XAI

The attack is based on the sensibility of language models to alterations of the input. Additionally, the modification has to be as furtive as possible at lexical and semantic level in order to not be easily identified. Hence, the amount of variations of the input of data have to be as minimum as possible.

We argue that it is necessary to identify the minimum number of words that trigger the decision of the LM for reducing the amount of alterations of the input. In this sense, we propose to use *a posteriori* XAI methods to find out the salient features for a learning model. In this work, we evaluate the following *a posteriori* XAI methods.

LIME it works by perturbing input data and analysing how these changes affect the model's predictions, providing localized insights into decision-making processes. For text data, LIME works at word level, which ensures explanations are semantically coherent and interpretable for humans (Ribeiro et al., 2016).

SHAP it uses Shapley values from cooperative game theory to fairly distribute feature relevancy scores across all input features, offering a globally consistent explanation framework. SHAP divides words into subwords or parts of words, like prefixes or suffixes, depending on the tokenization scheme of the model. This allows a more precise attribution of relevancy to the individual parts of a word (Lundberg and Lee, 2017).

Captum it is specifically designed for PyTorch-based models, provides a range of attribution algorithms that can analyse feature importance at multiple levels, from individual neurons to entire layers. Captum works at word or subword level for text data, enabling detailed analysis of how parts of a word contribute to model predictions.

3.2 Synonym Generation Module

The identified salient words compose the set of candidate words to be replaced by their synonym.[2] We leverage the text generation capacity of LLMs in order to generate contextual synonyms given an specific word and its sentence as context. Figure 2 shows the prompt designed to constrain an LLM to give a unique synonym word.

There are words that do not have synonyms or the LLM does not return any synonym words. In this case, we do not replace that word.

4 Experimental Framework

The evaluation of our untargeted adversarial attack previously require the definition of the attacker model (see Section 4.1), the victim model (see Section 4.2), the data to train the victim model (see Section 4.3) and the evaluation metric to measure the effectiveness and the stealthiness of the adversarial attack (see Section 4.4).

4.1 The Attacker Model

The attacker model is composed of two modules to select the salient words and then generate their corresponding synonyms. The first one corresponds to the *a posteriori* XAI method. As explained in Section 3.1, we compare the methods LIME, SHAP and Captum.

The second component is the synonym generation module, which is grounded in generation capacity of LLMs. We settle that the attack should consume short computational resources, since it will be queried several times. However, this is not a restriction of our proposal, which could also be elaborated with high computationally overhead LLMs. Accordingly, we evaluate the following small language models (SLM): Llama-3.1-8B-Instruct (Grattafiori et al., 2024), Llama-3.2-1B-Instruct (Grattafiori et al., 2024), gemma-2-9b-it (Team et al., 2024), Gemma-3-1b-it (Team et al., 2025), Qwen2.5-7B-Instruct (Yang et al., 2024) (Team, 2024) and Mistral-7B-Instruct-v0.3 (Jiang et al., 2023). All SLMs are smaller than 9B parameters. Likewise, all the SLMs used are instructed in order to assure a better realisation of a specific instruction prompt.

[2]We clarify that in the case of SHAP and Captum we do not replace the entire word when a subword is returned as salient feature.

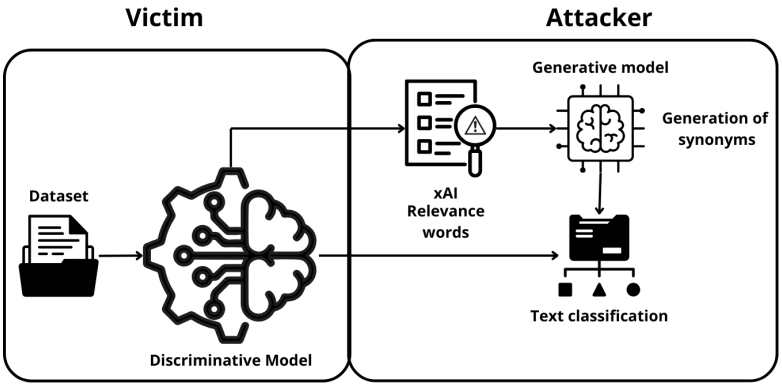

Figure 1: This is the outline of our untargeted adversarial attack.

You are an assistant that replaces a single given word in a provided phrase with a contextually appropriate synonym.
Instructions:
1. Carefully analyze the meaning and usage of the word within the context of the entire phrase provided.
2. Respond with a single replacement word that best fits the intended meaning in that specific context.
3. Your response must contain only the replacement word, with no extra text, punctuation, or explanation.
4. If no suitable contextual synonym exists, return a word that is as close as possible in meaning, even if not a perfect synonym.
5. Consider the phrase's tone, register, and intended meaning to ensure the replacement is natural and appropriate.
Replace the word: WORD in this phrase: PHRASE

Figure 2: The prompt used for the synonym generation attack stage. WORD is the word we want to replace and PHRASE the sentence where is the word to replace.

4.2 The Victim Model

The victim models are pretrained language models (LM) for discriminative tasks. We evaluate our attack against four LMs, which means that we also assess their vulnerability against them. The LMs used are: bert-base-cased (Devlin et al., 2019), distilroberta-base (Sanh et al., 2019) and xlnet-base-cased (Yang et al., 2019). They represent a diversification in terms of their training scheme (Bert *vs.* Roberta *vs.* XLNet). We remark Captum could not be applied to xlnet-base-cased because of differences between their architectures and discrepancies among Captum tensor management and the tensor strcuture of xlnet-base-cased. All the LMs were fine-tuned in the three discriminative tasks.

4.3 Data

The attack evaluation was performed on four discriminative tasks. The LM were fine-tuned on the training set and evaluated on the test set of the following datasets.

rotten_tomatoes:[3] It is a sentiment analysis dataset of reviews from films. The size of the training set is 8,530 documents and of the test set 1,066 documents. The mean length of the test documents is 21.22 tokens (Pang and Lee, 2005).

FRENK-hate-en:[4] It is the English subset of the FRENK dataset (Ljubešić et al., 2021), a hate speech dataset. The size of the training set is 8,404 documents and of the test set of 2,301 documents. The mean length of the test documents is of 33.34 tokens (Ljubešić et al., 2019).

RECCON:[5] It is a dataset from conversations, indicating whether they contain emotions. The size of the training set is of 2,405 documents and of the test set of 816 documents. The mean length of the test documents is of 14.01 tokens (Poria et al., 2021).

sst2:[6] It is composed of sentences extracted from film reviews. The size of the training set is of 53,879 documents and of the test set of 872 documents. The mean length of the test documents is of 19.55 tokens (Socher et al., 2013).

4.4 Evaluation Metrics

We perform a two tier evaluation of our adversarial attack. We first evaluate its capacity of harming the performance of the victim model, and then we assess the robustness of the attack according to the number of labels change, the number of words

[3] https://huggingface.co/datasets/cornell-movie-review-data/rotten_tomatoes

[4] https://huggingface.co/datasets/classla/FRENK-hate-en

[5] https://huggingface.co/datasets/Deysi/sentences-and-emotions

[6] https://huggingface.co/datasets/stanfordnlp/sst2

change and its capacity of keeping the meaning of the original input text.

The first evaluation level is performed with standard text classification measures, namely the accuracy and the F1-score. These evaluation measures shows the different performance of the non-attacked and attacked LMs, but they do not shed light regarding the effectiveness of the attack. In this context, the related literature lacks of a consensus on how to evaluate it. Hence, we propose a new evaluation measure that is based on the ratio of the amount of labels flipped and its rectification according to the amount of words modified in the input data.

Attack Success Rate (ASR) (Wu et al., 2021): It measures the success of an attack by the ratio of the number of labels flipped according to the number of documents. It allows us to compare the effectiveness of maliciously flipping the output of the victim model amongst adversarial attacks. Equation 1 settles the ASR metric.

$$\text{ASR} = \frac{\text{Number of labels changed}}{\text{Number of texts attacked}} \quad (1)$$

The ASR does not give any information about the stealth of the attack, hence we propose the ASM evaluation measure.

Attack Score Metric (ASM): It rectifies the ASR with respect to the amount of modifications carried out in the input data. Hence, the more modifications performed, the more the ASR value will be reduced. We calculate the level of perturbation of the input data taking into account the ratio of the words changed with respect to the number of words in the input document. Text perturbation (TP) and ASM are calculated as follows:

$$\text{TP} = \frac{-1}{\text{n. of texts}} \sum_{i=1}^{\text{n. of texts}} \log\left(\frac{\text{n. changed words in text}_i}{\text{words in each text}_i}\right) \quad (2)$$

$$\text{ASM} = \text{ASR} \cdot \text{Sigmoid}\,(\text{TP}) \quad (3)$$

Cosine Similarity (CS): We pose that adversarial attacks have to keep the semantic similarity amongst the original input and the maliciously altered one. Hence, we also considered the cosine similarity as an additional criterion to assess the adversarial attack. We computed this similarity by a vector representation of the original and manipulated text with the embedding model jina-embeddings-v3 model (Sturua et al., 2024). Then, we calculate the cosine value of the two vectors.

5 Results and Analysis

We analyse the results of our adversarial attack evaluation from different perspectives. First, we focus on XAI methods, assessing how effectively they identify salient words in order to increase the probability of success of the attack, and we examine the impact of these attacks on victim language models, measuring changes in their performance with the F1-Score measure (see Section 5.1). Finally, we study the role of the SLMs in the synonym generation stage by analysing errors related to incorrect or missing synonyms replacement (see Section 5.2), and conducting an ablation study to determine the importance of both identification of salient words and contextual synonym replacement in the overall attack process (see Section 5.3).

5.1 Adversarial Attack Performance Analysis

First, we analyse the performance of XAI methods under different experimental conditions, and subsequently evaluate how adversarial attacks substantially alter the performance of language models.

XAI method. The Figure 3 compares the XAI method using the ASM, where a higher value indicates that the XAI method is more effective at identifying key words whose substitution leads to successful attacks with less alterations of the input. In this context, LIME stands out with the highest ASM (0.1107), suggesting it is the most efficient at pinpointing impactful words for adversarial modifications, followed by Captum (0.0895), which is almost exactly at the general mean (0.0893), and Shap (0.0676), which is less effective by this metric. Thus, LIME provides the greatest leverage for adversarial interventions, while Shap is the least susceptible, with Captum occupying a middle ground.

Victim model. Since LIME performs better than the other two XAI methods in the selection of salient words, we show the effect of the attack on the LM using LIME as the XAI method. Figures 4, 5 and 6 show how the attack significantly harms the different LMs using the different LLMs.[7] We see that xlnet-base-cased consistently stands

[7] McNemar's test was used to calculate the performance difference between attacked and non-attacked LMs.

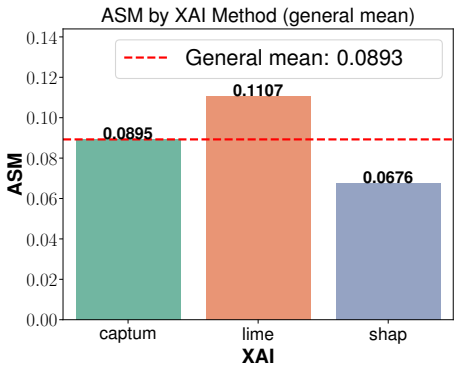

Figure 3: Comparison of ASM across xAI methods. The red dashed line sets the mean value.

out for its robust and stable performance, maintaining high effectiveness across tasks and showing resilience even in more challenging scenarios, bert-base-cased aexhibits slightly greater drops in F1 scores under attack, especially on datasets such as FRENK-hate-en and RECCON. In contrast, distilroberta-base, is more susceptible to performance degradation in demanding contexts, reflecting a trade-off between efficiency and robustness. These patterns highlight the distinct strengths and limitations of each architecture, with xlnet-base-cased excelling in stability, bert-base-cased offering a balanced profile but slightly less robust profile, and distilroberta-base prioritizing efficiency at the expense of some resilience.

Small Language Model. The figures 7 and 8 clearly illustrate the Attack Score Metric (ASM) and semantic preservation (cosine similarity) achieved by different generative models across all discriminative tasks. It is evident that Llama-3.2-1B-Instruct reached the highest mean ASM value (0.1072), significantly above the general mean of 0.0893, demonstrating its superior capability in generating synonyms that effectively alter the output of classification models. Interestingly, this comes at a cost to semantic preservation, as its cosine similarity (0.8283) falls below the general mean of 0.8461. By contrast, Qwen2.5-7B-Instruct shows the highest semantic preservation with a cosine similarity of 0.8717, but achieves the lowest ASM (0.0767) among all models. gemma-3-1b-it and Llama-3.1-8B-Instruct offer a more balanced performance, with ASM values of 0.0945 and 0.0853 respectively, and moderate cosine similarities. The results suggest that model size does not necessarily correlate with attack effectiveness, as the 1B parameter Llama-3.2-1B-Instruct outperforms larger models like Mistral-7B-Instruct-v0.3 and Llama-3.1-8B-Instruct in terms of ASM, challenging the assumption that larger models would generate more effective adversarial examples.

Table 1 shows some examples of how the SLM proposes synonyms that keep the original meaning and cause the alteration of the classification label. This also make evident that is not difficult to attack LM leveraging the language generation skills of LLMs.

5.2 Error analysis

We only analysed the errors of the SLM generating synonyms, because we do not really know the real words that determine the classification of the LM, and we have to trust in the selection of the XAI method. Accordingly, we focus our error analysis on the generation of synonyms by the LLMs.

The errors observed in our adversarial attack primarily stem from the incorrect generation of synonyms or the absence of suitable replacements. Table 2 illustrates several examples of these issues. In the first case, the model switches the language of the target word. In the second, rather than replacing the word with a synonym, the model retains the original term and instead paraphrases the entire sentence, indicating a tendency to favor paraphrasing over direct substitution. In the third example, the model introduces additional words, thereby altering the original structure and expanding the content. These errors are attributable to the language model not strictly adhering to the prompt instructions, which may be due to limitations in the prompt design or inherent constraints of the model itself.

5.3 Ablation Analysis

Our adversarial attack is built upon the selection of salient words with a *a posteriori* XAI method, and replace them with synonym words returned by a SLM. We therefore analyse the relevance of these two steps by selecting only two random words and replacing the salient words with random words. We perform this analysis on the short size datasets (RECCON and sst2) and two SLMs. Table 3 shows the results, and we see: (1) identifying salient words leads to a higher ASR compared to selecting words at random. However, this strategy may result in lower ASM values, since a LM might depend on more than two salient words to accurately classify an input text; and (2) the random replacement of the salient words tends to reach low

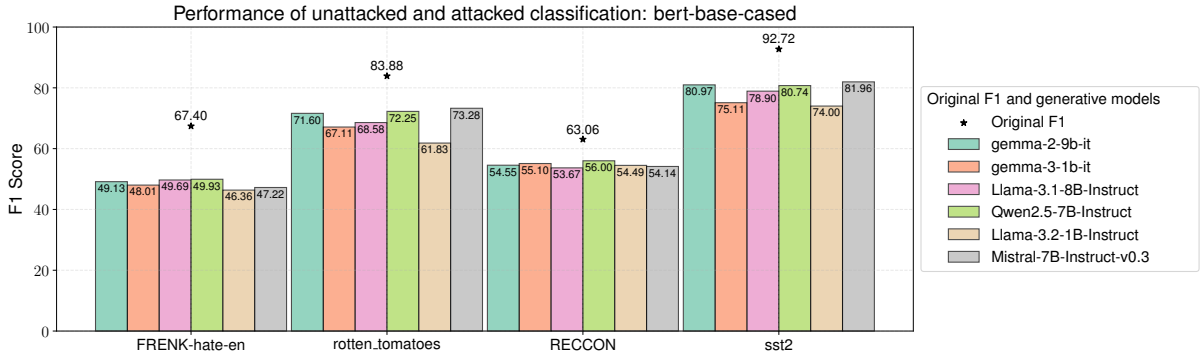

Figure 4: Performance comparison (F1 Score) of bert-base-cased on classification tasks without attacks and under generative model attacks across datasets.

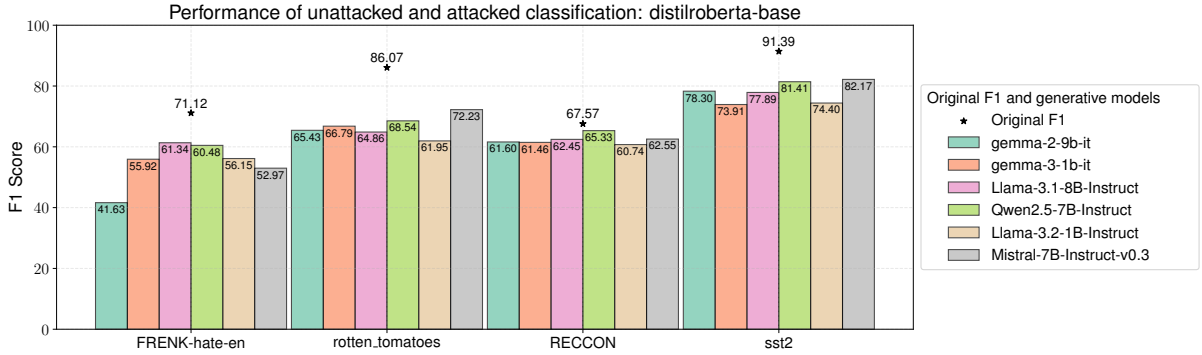

Figure 5: Performance comparison (F1 Score) of distilroberta-base on classification tasks without attacks and under generative model attacks across datasets.

their contextual synonyms.

6 Conclusions

This research introduces an untargeted adversarial attack against language models, leveraging the capabilities of LLMs and XAI methods. Our experimental results demonstrate that language models are vulnerable to subtle input modifications, particularly when these modifications target salient words.

The results allow us to conclude that our claim holds and contributes to: (1) a novel untargeted adversarial attack that preserves the semantic meaning of the input while achieving high success rates in altering model predictions; (2) a new evaluation measure for adversarial attacks in text that combine the effectiveness of the attack (ASR) and the amount of alterations produced in the text (ASM), as well as to also take into consideration of the semantic similarity.

As future work, we will keep working in the stealthiness of the adversarial attack by enhancing the process of maintaining unchanged the general meaning of the text. We will also work on target attacks to reach specific goals that lead to more harmful attacks.

Abstract

The emergence of complex reasoning abilities in large language models (LLMs) has sparked great interest, and a variety of prompting techniques was proposed to coax them into emulating human thought processes. In this work, we introduce *Think Node-by-Node*, a graph-based reasoning framework inspired by mind maps, flowcharts, and other visual aids that help humans tackle complex problems. Rather than generating images directly, our approach leverages standard graph-building and rendering libraries, and requires no fine-tuning, only the model's native coding capabilities. We further explore a "Fast Thinking" regime, in which a graph-reasoning example provided in the prompt, but the model generates the answers directly, without the full thought process reconstruction. Surprisingly, this approach leads to significant improvement upon baseline in general-knowledge tasks. Remarkably, Think Node-by-Node maintains strong performance even under a strict 25-token budget for answer generation. Across two instruction-tuned LLMs (0.5B and 7B parameters), our FastTNbN strategy outperforms baseline prompting techniques, improving accuracy by up to 10%, and exceeds the capabilities of other structured prompting methods under equivalent generation constraints.

1 Introduction

Improvement of reasoning ability is an important task for modern LLMs developers. It was shown recently, that asking a model to output intermediate reasoning steps significantly improves its performance on the wide range of tasks involving logic, planning and sophisticated analysis (Wei et al., 2022; Wang et al., 2023). Although even meaningless intermediate output can be used by LLMs as a "thinking" process (Pfau et al., 2024), in general the structure of thoughts can significantly improve the model's performance on separate tasks, especially for the smaller models that are less sensitive to instruction tuning and that perform significantly worse in accurate logical inference (Lu et al., 2024). Many novel thought schemas have been proposed, including multi-agent, graph-based, sampling-based and others approaches (Rasal, 2024; Yao et al., 2024; Ding et al., 2024).

Most of modern LLMs, besides language, can also generate software code samples. It has been demonstrated that adding code data to the pretraining phase implicitly increases the model's reasoning ability (Shi et al., 2023). Coding skills can be also explicitly used in the form of code-style prompting, improving on a separate type of reasoning in natural language (Puerto et al., 2024).

Another line of research inspiring our method is the attempts to integrate a non-linear thinking process (Wen et al., 2024). Indeed, in chain-of-thoughts and most of its variations, thought steps are organized linearly, forming a chain graph. But often mindmaps or charts could represent the problem better. The issue is that it is not clear how to represent non-linear structure inside the framework of token-by-token text generation.

In our work, we propose to utilize the model's coding skills in order to build a graph, or mindmap, for the thought process enchancement. For our experiments, we first select the models able to generate code (drawing the graph) in Python. Then, we prompt a model with a graph-building example (single example for each evaluation dataset), and ask to answer the question, then draw the graph (i.e. generate the graph code) and re-consider the answer. We found that, first, even relatively small models understands the task well and are able to output meaningful graph representing thought process; and, more importantly, the performance of the models on general NLP reasoning benchmarks increases when the graph reasoning is involved.

Investigating structured-prompting techniques on smaller LLMs (under 10B parameters), we ob-

Proceedings of Recent Advances in Natural Language Processing,pages 758–766
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-087

served that many models struggle to stay within a practical generation budget, limiting real-world applicability. In exploring ways to reduce redundant output, we made the surprising discovery that most structured-prompting methods remain effective even if the model does not actually produce the full thought sequence.

Building on this insight, we introduce *Fast Thinking*, in which the model is shown an example of structured reasoning but is prompted to emit only a preliminary answer—halting before the full thought chain—with a strict 25-token limit. Across multiple benchmarks, Fast Thinking boosts answer quality by up to 10% compared to standard prompting, and methods such as Tree of Thoughts (Yao et al., 2023) and Program of Thoughts (Chen et al., 2023) perform robustly in this regime.

We further propose *Think Node-by-Node (TNbN)*—a new graph-based prompting strategy that excels under Fast Thinking. Without any weight updates, FastTNbN delivers improvements of up to 10% across diverse datasets, while keeping generation under 25 tokens. We validate our approach on two instruction-tuned models from different families—`Qwen2.5-0.5B` and `Mistral-v3-7B`—demonstrating that, with sufficient coding proficiency, even models as small as 0.5 B parameters can benefit substantially.

2 Literature Review

The manipulation with prompt has emerged as a crucial technique for enhancing the capabilities of pre-trained large language models (Radford et al., 2019; Brown et al., 2020). The Chain-of-Thought prompting technique introduced in (Wei et al., 2022), and its extensions (Zhang et al., 2024; Yang et al., 2024; Long, 2023) compels the language model to produce not merely the final answer but also a coherent sequence of intermediate reasoning steps. The Graph-of-Thoughts (GoT) method was firstly proposed by (Besta et al., 2024). The process from now is not just a simple prompt engineering but a two-stage framework with the particular module for the graph construction. However, the methodological foundation for GoT can be traced to the earlier Tree of Thoughts (ToT) paradigm in (Yao et al., 2023). ToT generalizes the popular Chain of Thought approach to prompting language models, and enables exploration over coherent units of text (thoughts). ToT allows LMs to perform deliberate decision making by considering multiple different reasoning paths and self-evaluating choices to decide the next course of action, as well as looking ahead or backtracking when necessary to make global choices.

Significant advancements have also been made to enhance reasoning by leveraging code and programming within the Program of Thoughts (Chen et al., 2023) method. Encouraging models to "dig inward" to arrive at an answer can be interpreted in various ways. However, approaches that compel large language models (LLMs) to produce clearer and more accurate responses without relying on additional information are undeniably worth exploring. A prime example is the Zero-shot method augmented with the prompt "Take a deep breath and work on this problem step-by-step." (Yang et al., 2024) (Zero-shot with TDB) prepended to the question. This technique has proven effective in guiding models toward more structured and precise reasoning. It is also worth noting the method that facilitates reasoning by employing a so-called "step back", enabling the model to approach the problem from a different perspective. This technique, known as Step-Back Prompting (Zheng et al., 2024), encourages the model to pause and reassess the problem, often leading to more insightful and creative solutions.

3 Method

3.1 Fast Thinking

In this work, we leverage the notion of *fast thinking*, which can be integrated with any structured prompting framework. Specifically, we present the model with few-shot examples of the desired reasoning structure, but inspect the answer obtained *before* the thought process. To encourage the model to produce this initial answer, we append a preliminary short response to each example, formatting them as *[question][preliminary answer][thought][answer]*. During inference, the generation can be halted once the preliminary answer is produced; in practice, we just restrict the generation by 25 tokens. In Section 4.6, we demonstrate that this method is surprisingly effective in combination with the existing prompting techniques , and with our Think Node-by-Node method.

3.2 Think Node-by-Node Prompting

We introduce a novel prompting technique designed to stimulate graphical reasoning in smaller LLMs without relying on a visual interface. Our

Answer: D

Primary Answer

Node of thoughts:
```python
```

TNbN

```python
from graphviz import Digraph

# Create a directed graph
dot = Digraph(comment='Thought Process: Repeat the Investigation')

# Define nodes with descriptions
dot.node('A', 'Initial Hypothesis')
dot.node('B', 'Conclusion Supports Hypothesis')
dot.node('C', 'Understanding Why Hypothesis is Correct')
dot.node('D', 'Validating Results')

# Add edges to show the flow of steps
dot.edge('A', 'B', label='Initial Investigation Results')
dot.edge('B', 'C', label='Unnecessary to understand why', style='dashed')
dot.edge('B', 'D', label='Required to make sure results are reliable')

# Highlight the correct answer with a bold edge
dot.edge_attr.update(style='bold')
dot.edge('B', 'D')

# Render the graph
dot.render('thought_process', format='png', cleanup=True)
```

Final Answer

The final result of the Node of Thoughts after "# Highlight the correct answer with a bold edge" from dot.edge('B', 'D'): 'Validating Results': 'Required to make sure results are reliable'
```

The final result of the Graph of thoughts is 'Validating Results': 'Required to make sure results are reliable'. This means that Derek should repeat the investigation to make sure the results are valid.

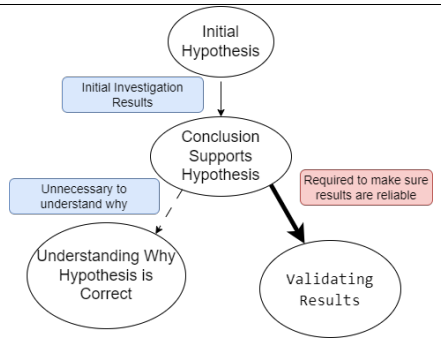

Figure 1: (top) The structure of TNbN output. (bottom) Generalized corresponding graph obtained from the code.

approach represents the model's thought graph via a *Python* script using the `graphviz` library. This choice of representation is both formally precise and readily interpretable by the model, since LLMs cannot natively ingest graph structures.

The prompt includes a single working example (see Fig. 1). First, the code defines each graph node and assigns its label. Next, it specifies the edges connecting those nodes. Finally, the standard `graphviz` layout and drawing commands produce the visual representation. For certain domains—such as the ARC science questions—we optionally include edge labels to capture relationships between scientific concepts. Additionally, we ask the model to render the edge leading to the final answer in **bold**. This format is highly general and can be adapted to any task. Depending on the application, nodes might represent hypotheses, intermediate reasoning steps, answer choices, scientific phenomena, named entities, calculations,

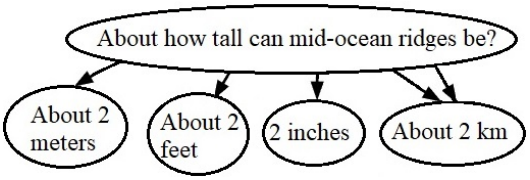

Figure 2: Sample graphs produced by Qwen2.5-0.5B-Instruct (dataset SciQ).

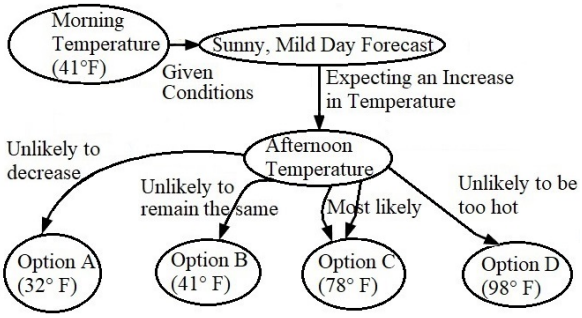

Figure 3: Sample graphs produced by Mistral-7B-Instruct-v0.3 (dataset ARC-Challenge).

and so on. The essential component is the "graph thinking" pattern itself, which we present to the model in three distinct variants:

**Choice**(Figure 2) This pattern is good for exam-like questions with answer options choice, which do not require complex reasoning. The first node corresponds to the whole question. Then, the model analyses each option separately, creating one node per option, and writing some commentary to it as a node label. Edges are connecting the question node with the options, and correct option is emphasized.

**Relations**(Figure 3) is the pattern focused on the analysis of relations between entities. Here, the node names represent entities, node descriptions represent the type of the connections to the previously introduced entities, and edges show the causal or other connections between them.

**Flow**(Figure 4) represents the process of thinking for general tasks with open-ended questions. Fist, the model generate nodes containing elementary claims, extracted from the task, or derived from the previous ones. Then, it draws direct edges representing the derivation process.

Overall, the code is well structured: the reasoning process remains clear even without rendering the graph (see Figure 1).
```

Figure 5: The level of format retention across different models for the Base (Baseline), CoT (Chain-of-Thoughts), and TNbN (Think Node by Node) methods. Cases where format retention is at least 0.7 are highlighted in yellow. Additionally, cases where both the primary response and subsequent format retention are maintained are highlighted in green.

4 Experiments

4.1 Structured Prompting Baselines

Here, we list the main types of logical thinking and several examples of benchmarks that test them.

The reasoning process for each method is distinct: **Baseline** represents the classic approach, providing a direct answer followed by an explanation. **Chain-of-Thoughts** (Wei et al., 2022) involves a structured sequence of reasoning steps. **Program of Thoughts** (Chen et al., 2023) leverages a code-based reasoning framework. **Step-Back Prompting** (Zheng et al., 2024) encourages reflective, internal textual reasoning, allowing the model to reframe the question by taking a metaphorical "step back." **Zero-shot with TDB** (Yang et al., 2024) operates without examples or additional conditions, relying solely on self-declarative instructions. **Tree of Thoughts** (Yao et al., 2023) considers several different lines of reasoning and independently evaluates choices to decide on the next course of action, and looks ahead or back when necessary to make a global choice. **Graph of Thoughts** (Besta et al., 2024) this approach enables combining arbitrary LLM thoughts into synergistic outcomes, distilling the essence of whole networks of thoughts, or enhancing thoughts using feedback loops.

4.2 Datasets

We evaluate the capabilities of the methods across diverse domains and problem types. For general multiple-choice science questions, we select SciQ (Moore et al., 2023), ARC (Bhakthavatsalam et al., 2021), MMLU (Wang et al., 2024). Mathematical skills are covered by GSM8K (Cobbe et al., 2021), AQuA (Ling et al., 2017), SVAMP (Patel et al., 2021), TabMWP (Kang et al., 2024), MultiArith (Roy et al., 2015). Multi-hop reasoning data includes StrategyQA (Geva et al., 2021), MuSiQue (Trivedi et al., 2022). Finally, we add special knowledge taks: time-related question from TimeQA (Chen et al., 2021), and financial reasoning FinQA (Chen et al., 2022b) and ConvFinQA (Chen et al., 2022a).

4.3 Models

For our preliminary experiments, we chose LLMs from different families: Gemma-2-9B-it (Team et al., 2024), Llama-3-8B, Llama-3-8B-Instruct (Grattafiori et al., 2024), Phi-3-Mini-128K-Instruct (Abdin et al., 2024), Vicuna-13B-v1.5 (Zheng et al., 2023), Qwen2.5-0.5B-Instruct (Yang et al., 2025), and Mistral-7B-Instruct-v0.3 (Jiang et al., 2023). On the second stage of evaluation, only the latter two models were used.

4.4 Experimental Setup

We conduct a two-stage experimental evaluation. In the first (model-selection) phase, we test each model's ability to interpret and reproduce our graph-reasoning patterns and to follow the required output format. We choose three benchmarks—ARC, SciQ, and GSM8K—and compare three reasoning strategies: Baseline, Chain-of-Thought (CoT), and Think Node-by-Node (TNbN). Each model is evaluated on 100 randomly sampled instances per dataset, and outputs are assessed manually. We perform this selection phase because our method depends on the model's programming proficiency and familiarity with graph-rendering libraries; only those that reliably follow the prompt can meaningfully benefit from our approach.

In the second (main-experiment) phase, we restrict our analysis to the top-performing models identified in phase one and carry out a comprehensive evaluation across all benchmarks. For each dataset, we generate a graph-reasoning example (presented here: https://github.com/MorKir/graph-reasoning-examples.git) by selecting a random

question and asking GPT-4 to produce Graphviz code that visualizes the reasoning process. Inference uses greedy decoding; for the Fast Thinking experiments, we enforce a 25-token limit on generation.

4.5 Evaluation of LLM's Ability to Follow Graph Reasoning Format

In this phase, we are evaluating models based on their ability to handle specific reasoning formats.

In Figure 5, each model is evaluated by two metrics: the *primary score*—the probability of producing the preliminary answer immediately, as demonstrated in the example—and the *secondary score* (in parentheses)—the probability of maintaining the required format throughout the subsequent reasoning steps after that answer. Our results show that the TNbN format is remarkably accessible to these models: four out of six achieve a perfect secondary score, outperforming both the baseline and CoT prompts in format compliance. Strict adherence to the answer format is often a bottleneck for smaller LLMs, so this improvement is especially significant. Across all models, Mistral-7B-Instruct-v0.3 leads in format-compliant answer generation, followed by Qwen2.5-0.5B-Instruct and then Phi-3-Mini-128K-Instruct. Although Gemma-2-9B-it and Llama-3-8B-Instruct also attain perfect primary scores under all prompting methods and perfect TNbN secondary scores, they fail to sustain the full reasoning pattern, resulting in near-zero secondary scores for CoT and baseline. Notably, model size does not predict format compliance: among the 7–8B models, only Mistral consistently follows the prescribed format under both CoT and TNbN. Based on these summary metrics, we select Mistral-7B-Instruct and Qwen2.5-0.5B for the full evaluation. In Section 5, we provide more details about format compliance issues of the evaluated models.

4.6 Main Results

Table 3 report the Fast Thinking results under a 25-token generation limit for each prompting strategy. In both models, structured prompts consistently outperform the baseline, with improvements of up to 10 % on certain datasets. Among the methods tested, TNbN achieves the highest accuracy on most benchmarks.

Table 1 shows the average ranking score for each method. For each dataset, we rank the methods from best to worst and assign scores of {1.0, 0.8, 0.6, 0.4, 0.2, 0.0} accordingly; these scores are then averaged across datasets. FastTNbN, PoT, and ToT all exceed the baseline in the Fast Thinking regime, with FastTNbN emerging as the clear leader.

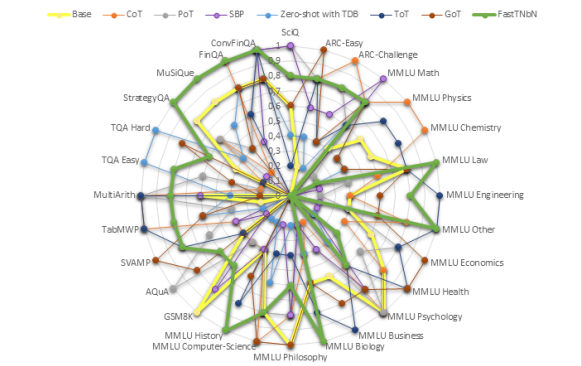

Figure 6: Generalized results of the methods for Mistral-7B-Instruct-v0.3.

In Table 4, we compare FastTNbN to its slower counterpart by reporting accuracy on the *primary answers* (before reasoning), the *final answers* (after the full thought process), and the *intermediate answers* extracted via regular expressions from each model's output. Mathematics is the only domain in which full reasoning consistently boosts the primary answer accuracy —— most notably on GSM8K, AQuA-Q, and MMLU Math —— while MMLU Economics and Psychology also benefit for Mistral. On other datasets, primary answer accuracy is equal to or better than final accuracy. This suggests that, for many tasks, generating reasoning tokens is not strictly necessary to improve the model's internal reasoning, although the choice of prompting strategy remains critical. In classical domains, the primary LLM response requires minimal cognitive effort (functioning as an automatic thinking system (Kahneman, 2011; Zhang et al., 2025)). In FastTNbN, this capability—along with graphical reasoning—is actively engaged (and is effectively applied immediately based on the given example). For other methods we also ask to repeat the reasoning process.

5 Analysis and Ablation Study

Format compliance issues of different models. Here, we describe typical issues with thought generation, observed in experiments in Sec. 4.5

- Gemma-2-9B-it. Thought generation exhibited structural breakdowns and irrational interruptions in thought flow. Final answers were frequently missing or misplaced in the output.

Mistral-7B-Instruct-v0.3

Table 2: Evaluating the models ability to solve graph-based problems.

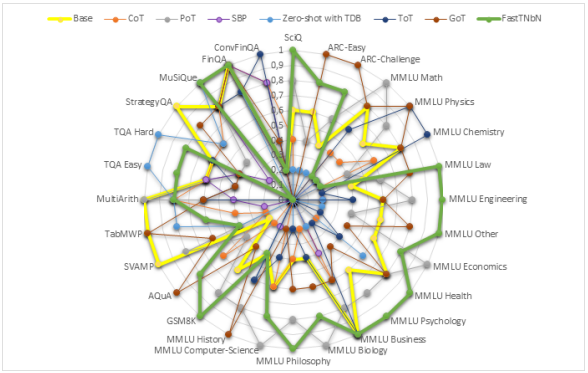

Figure 7: Generalized results of the methods for Qwen2.5-0.5B-Instruct.

- Llama-3-8B. Code generation lost its structure and meaning, the content of the thought process was looped or interrupted without good reason. The final answer could be missing despite an adequate thought process.
- Llama-3-8B-Instruct. There was a clear trend whereby LLMs did not complete the second part (code generation), let alone the final answer. The second part of the answer frequently contained repetitive content and information unrelated to the question.
- Phi-3-Mini-128K-Instruct. The LLM frequently failed to complete the second part (thought generation), often stopping short of producing the final answer.
- Vicuna-13B-v1.5. The primary answer was improperly presented. Failure to comply with the response format in principle, its absence, the output of information that is completely unrelated to the request.

Generalized results comparison. The results presented in Table 1 were compiled to clearly demonstrate the overall success of our method across the set of considered domains for both Mistral (Fig. 6) and Qwen (Fig. 7).

Graph reasoning skills of the selected models. The models ability to support the required format was verified earlier. The next step is to ensure that the selected models are fundamentally capable of solving graph-related problems. For this purpose, the **GraphQA-Easy** and **GraphQA-Hard** datasets are utilized. Each model is evaluated using 100 questions per problem category from these datasets.

The results in Table 2 show that both selected models can solve graph-structured problems, with `Mistral-7B-Instruct-v0.3` demonstrating roughly twice the accuracy of `Qwen2.5-0.5B-Instruct`. Since both models perform strongly under the FastTNbN setup, we detect the elements of graph reasoning which are

Table 4: Comparison of the accuracy of Fast and Thoughtful TNbN approaches

essential for this technique. It can be said that the borderline versions of models from what can be called line small models are being tested.

Specifically, both models excel at *existence* and *classification* tasks — such as Edge Existence, Cycle Detection, Node Classification, and Reachability —- but struggle with *counting*-based problems (Node Degree, Node Count, Edge Count) and more complex algorithms like Maximum Flow. Their performance on Shortest Path queries is modest yet nontrivial. These findings suggest that fundamental graph-understanding abilities suffice for effective FastTNbN prompting.

6 Conclusion

In this work, we demonstrate the effectiveness of Fast Thinking: a method in which the model is provided an example of structured reasoning, yet reasoning-chain generation is curtailed to as few as 25 tokens. This approach is far more computationally efficient than conventional Chain-of-Thought prompting and other structured reasoning techniques. While it is often assumed that such methods succeed primarily through extended autoregressive computation, we show that structured prompting remains effective even with minimal token generation. In Fast Thinking, the bulk of computation shifts to prompt processing — performed in a single inference step — and can be further accelerated (e.g., via KV-cache optimizations) to reduce answer latency.

Next, we introduce a novel structured-prompting technique that leverages the LLM's programming capabilities to generate a task schema as a graph, encoded in a standard graph-rendering library. We find that this method excels in the Fast Thinking regime, outperforming both the baseline and alternative structured prompts by up to 10 % on various datasets under a 25-token generation budget. Remarkably, our approach remains effective even with very small models (starting at 0.5 B parameters). It requires no weight updates and is domain-agnostic, making it compatible with any training or adaptation pipeline. Although our technique depends on models with strong coding proficiency, we believe it offers valuable insights into LLM reasoning and control, and can enable efficient LLM-based systems in settings where inference speed and model size are constrained.

7 Limitations

In this work, we present the TNbN prompting strategy along with its optimized modification, the FastTNbN prompting strategy, allowing to utilize the model's coding skills for structuring general reasoning process. This is the main limitation of our work: our method is applicable only to code-language models, requires strict adherence to a specific format, and many existing LLMs are not supported. We checked our approach on several standard reasoning benchmarks, but it does not necessarily lead to high performance on general real-world situations. In our further research, we plan to extend the scenarios for testing our novel graph-code prompting approach, and consider its applicability for planning and general real life-related problems.

Acknowledgments

This work has been carried out as part of the machine learning summer school SMILES-2024, organized by the Skoltech Center for Applied AI and R&D № FSFN-2024-0059.

T2Know: Analysis and Trend Platform using the Knowledge Extracted from Scientific Texts

Rafael Muñoz University of Alicante
Manuel Palomar University of Alicante
Yoan Gutíerrez University of Alicante
Mar Bonora University of Alicante
{rafael|mpalomar|ygutierrez}@dlsi.ua.es
mar.bonora@ua.es

Abstract

The T2Know project explores the application of natural language processing technologies to build a semantic platform for scientific documents using knowledge graphs. These graphs will interconnect meaningful sections from different documents, enabling both trend analysis and the generation of informed recommendations. The project's objectives include the development of entity recognition systems, the definition of user and document profiles, and the linking of documents through transformer-based technologies. Consequently, the extracted relevant content will go beyond standard metadata such as titles and author affiliations, extending also to other key sections of scientific articles, including references, which are treated as integral components of the knowledge representation.

1 Introduction

Health research organizations have long stood out as ideal environments for detecting specific needs and fostering the emergence of innovative ideas. These ideas often give rise to new processes, products, and services that not only enhance health outcomes but also contribute to the sustainability of healthcare systems. In addition, such organizations offer valuable insights into their scientific fields of interest by monitoring environmental and market trends.

Despite the availability of technological surveillance tools and, in many cases, competitive intelligence systems that enable the configuration of customized alerts and advanced information retrieval, these organizations still face significant challenges. Specifically, they lack robust solutions that allow for the systematic analysis of the vast amount of information required to extract relevant and useful knowledge. Industry data reveals that medical professionals can spend up to 20% of their working hours searching for information to support their daily tasks.

In light of this, and with the aim of delivering greater value to both society and the professionals within health research institutes, we propose the development of a platform capable of advanced analysis of large volumes of scientific and technical textual data. This would facilitate systematic information processing, environmental analysis, and the formulation of plausible future scenarios. Such a tool would greatly support the ongoing transformation from traditional, reactive healthcare—where treatment follows the onset of illness—to a more proactive model. This new model aspires to go beyond curing diseases by focusing on prevention, quality of life, personalized care, disease prediction, and placing the patient at the center of care.

This paradigm shift aligns with the principles of 5P medicine: preventive, participatory, personalized, predictive, and population-based. In this context, health language technologies (HLTs) and tools like the one proposed in this project play a crucial role by harnessing the potential of health data collection and the large-scale analysis of health information.

Effective RDI (Research, Development, and Innovation) planning that aligns with both organizational goals and environmental context will ensure that technological advancements are both socially relevant and strategically implemented. This alignment will facilitate the integration of innovations into clinical practice through a productive ecosystem. Moreover, identifying emerging research trends that create new market opportunities can drive the growth of companies positioned to meet these demands. Ultimately, this will lead to tangible improvements in patients' quality of life, while fostering economic growth and societal well-being.

2 State of the art

The discovery of knowledge from natural language can be conceptualized as a multi-stage process that transforms raw textual data into a structured and semantically rich representation, typically in the form of an ontology. This pipeline begins with the manual or semi-automatic creation of annotated linguistic resources, which requires the definition or selection of annotation schemes tailored to the target domain. From these annotated corpora, machine learning algorithms can be trained to generalize the annotation process across large-scale unstructured texts.

Once annotated, relevant entities and relationships are extracted and represented in a semantic graph. At this stage, post-processing tasks—such as redundancy elimination, entity normalization, and inconsistency detection—are applied to enhance the coherence of the graph. The result is a unified semantic structure where the implicit knowledge within the original text is made explicit and formalized, often in ontology formats such as OWL or RDF.

Natural language processing (NLP) techniques have been widely adopted for this purpose. Early systems such as ISODLE (Weber and Buitelaar, 2006) illustrate the integration of machine learning with semantic annotation. Rule-based systems like OntoLT (Buitelaar and Sintek, 2004) proposed mappings between syntactic structures and ontology classes, enabling concept and relation extraction. In contrast, statistical and probabilistic approaches emerged to reduce manual intervention. Notable examples include LEILA (Suchanek et al., 2006) and Text2Onto (Cimiano and Völker, 2005), which leverage probabilistic models to identify concepts and instances. The KnowItAll system (Etzioni et al., 2004) introduced pointwise mutual information (PMI) to enhance the relevance of extracted instances.

Further advances sought to go beyond mere extraction by inferring higher-level structures. Systems such as OntoGain (Drymonas et al., 2010) and ASIUM (Faure and Poibeau, 2000) utilized clustering techniques to induce concept hierarchies in an unsupervised manner. These approaches marked a shift toward more autonomous ontology learning. More recently, lifelong learning frameworks such as NELL (Never-Ending Language Learning) (Mitchell et al., 2018) have demonstrated the potential of continuously harvesting knowledge from web data, iteratively refining and expanding semantic structures.

Recent literature also emphasizes the importance of deep learning and transformer-based models (e.g., BERT, RoBERTa) in automating entity and relation extraction with improved accuracy (Devlin et al., 2019; Liu et al., 2019). These models provide contextual embeddings that enhance the semantic understanding of textual data, facilitating more robust ontology population tasks.

In summary, the process of extracting knowledge from text requires the integration of various NLP techniques, semantic representation formalisms, storage and reasoning mechanisms, and quality evaluation metrics. The convergence of rule-based, statistical, and deep learning approaches—combined with knowledge graphs and ontologies—continues to advance the field toward more scalable, adaptive, and semantically aware systems.

3 Data analytics and trends

This task focuses on the development of tools aimed at extracting the maximum amount of statistical information related to document profiles over specific time intervals. The objective is to enable the identification of trends and the analysis of topic evolution within the research areas relevant to the project. To achieve this, machine learning techniques—such as time series analysis—will be employed, along with advanced data visualization methods. These visualizations serve a dual purpose: (1) they support the generation of new knowledge, and (2) they illustrate the temporal and statistical evolution of the information associated with the identified ontology.

The ontology lifecycle encompasses key processes such as creation, management, analysis, and reuse. These processes are structured as workflows composed of multiple activities, defined based on established methodologies for ontology model development. To ensure these activities are effectively executed, they must be supported by appropriate mechanisms and tools. In particular, robust visualization techniques are essential, as they provide interactive interfaces that empower users to abstract, conceptualize, understand, represent, and learn from the underlying knowledge.

A critical component of this task is semantic exploration and recommendation. With the existence of a semantic database, it becomes essential to im-

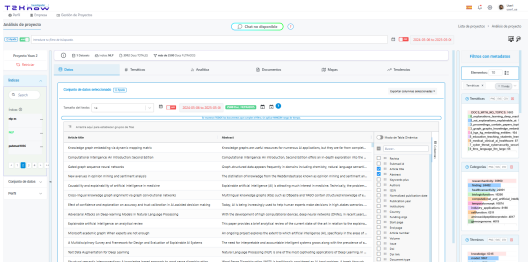

Figure 1: Data collection

plement mechanisms for navigating the semantic network. This will be facilitated through query languages such as SPARQL (https://skos.um.es/TR/rdf-sparql-query/) and Cypher (https://neo4j.com/developer/cypher/). These mechanisms will not only enable document retrieval through metadata filters but also support aggregate queries for trend discovery. Moreover, they will allow for the recommendation of profiles—such as documents, authors, institutions, topics, and named entities—based on the semantic links that interconnect the network.

4 T2KNOW Platform

The T2KNOW Platform is designed to support the exploration and analysis of scientific and technical knowledge across various domains. The figures below illustrate key functionalities of the platform.

Figure 1 shows the data collection process, where structured and unstructured sources are gathered to build a comprehensive dataset. In Figure 2, users can access detailed article data, enabling in-depth examination of individual publications, including metadata and content.

Figure 3 presents the trend analysis capabilities, which allow users to detect emerging topics and monitor their evolution over time. Finally, Figure 4 illustrates the geographical distribution of the articles, providing insights into regional contributions and the global reach of scientific production.

Figure 5 showcases a Retrieval-Augmented Generation (RAG) component integrated into the platform. This feature enables users to interact with the system through natural language queries, leveraging both large language models and the underlying document collection to provide accurate, context-aware answers. By retrieving relevant documents and combining them with generative capabilities, the RAG module enhances information accessibility and supports more intuitive exploration of the knowledge base.

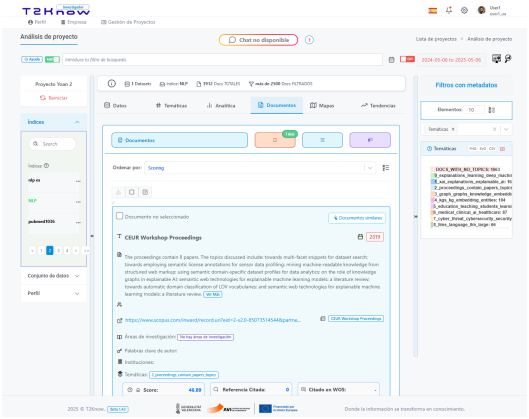

Figure 2: Article data

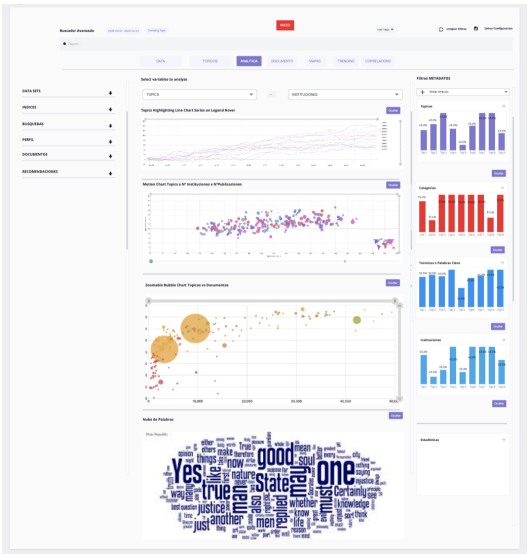

Figure 3: Trend analysis

Together, these components demonstrate the platform's potential to facilitate data-driven research and informed decision-making.

Abstract

Automatic detection of sexist language on social media is gaining attention due to its harmful societal impact and technical challenges it presents. The limited availability of data resources in some languages restricts the development of effective tools to fight the spread of such content. In this work, we investigated various methods to improve the efficiency of automatic detection of sexism and its subtypes in a low-resource language, Turkish. We first experimented with various LLM prompting strategies for classification and then investigated the impact of different data augmentation strategies, including both synthetic data generation with LLMs (GPT, DeepSeek) and translation-based augmentation using English and Spanish data. Finally, we examined whether these augmentation methods would improve model performance of a trained neural network (BERT). Our benchmarking results show that **fine-tuned LLM (GPT-4o-mini)**[1] achieved the best performance compared to **zero-shot**, **few-shot**, **Chain-of-Thought** prompt classification and training a neural network **(BERT) including the data augmented in different ways (synthetic generation, translation)**. Our results also indicated that, for the classification of more granular classes, in other words, more specific tasks, training a neural network generally performed better than prompt-based classification using an LLM.

1 Introduction

Sexism is considered as "the actions based on the belief that the members of one sex are less intelligent, able, skillful, etc. than the members of the other sex, especially that women are less able than men".[2]

In various forms, sexism has been shown to have a negative impact on society, especially on certain target groups. Social networks provide a medium where anyone can easily and freely publish any text, resulting in a space that contains harmful content as well as useful content which arises the need for an effective automated filtering mechanism. Advancements in LLMs have impacted a wide range of natural language processing (NLP) tasks, surpassing previous methods in understanding, generating, and classifying language. Recently, research focusing on hate speech identification with LLMs gained more attraction (Guo et al., 2023; Roy et al., 2023; Samani et al., 2025).

Our research specifically examines the efficiency of various strategies for the classification and data augmentation using LLMs. Prompt-based classification utilizes the knowledge of LLMs to perform classification tasks with less labeled data. On the other hand, data augmentation using LLMs has emerged as a strategy to enhance model performance by generating diverse synthetic data reducing the dependency on labor-intensive and costly manual data collection (Liu et al., 2023).

The rest of the manuscript is organized as follows. In Section 2 we provide a brief overview of the background and state of the art. Section 3 presents our methodology of the experiments and the approach for data augmentation. In Section 4 we provide the results of our study. Finally, Section 5 summarizes the conclusions and points out future work.

2 Related Work

Identification of offensive language in various forms has been widely researched for years. Throughout the years, more specific types of offensive language gained traction. Identification of gender discrimination is a major topic which is

studied from multiple angles.

Earlier detection mechanisms focused on traditional algorithms such as Logistic Regression, Naive Bayes and Support Vector Machines (Shushkevich and Cardiff, 2019). More recently, approaches based on neural networks (RNNs, biLSTMs etc.) were preferred due to reported good results (Anzovino et al., 2018; Parikh et al., 2021). Over time, Bidirectional Encoder Representations from Transformers (BERT) became the predominant classification model as also reported in the systematic survey by (Lei et al., 2024). As in other NLP tasks, introduction of LLMs progressed the hate speech detection field through significant improvements in accuracy and contextual understanding (Albladi et al., 2025).

On the other hand, data has consistently played a central role in the development and functioning of these systems. There are a number of datasets constructed specifically for identification of sexism and its sub-types. One examaple is the Automatic Misogyny Identification (AMI) dataset which was composed of Italian and English sentences (Fersini et al., 2018). (Guest et al., 2021) presented a resource in English in which they provided an annotation schema constructed on threatening or disrespectful aspects of a speech. (Bertaglia et al., 2023) created a dataset of 200k YouTube comments from different content categories. (Rodríguez-Sánchez et al., 2021) published the sexism identification in social networks (EXIST) dataset in 2021 which is composed of English and Spanish text, and through years the scope and annotation of EXIST dataset expanded (source intention identification, hateful memes etc.) (Plaza et al., 2024). There are datasets also in other languages such as Danish (Zeinert et al., 2021), French (Chiril et al., 2020), Chinese (Jiang et al., 2022), Bangla (Kader et al., 2023) or even code-mixed languages such as Hindi-English (Singh et al., 2025).

However, like other classification tasks, many languages suffer from the scarcity of resources. Therefore, different data augmentation strategies also track attraction. (Khullar et al., 2024) addressed this issue by generating training data in Vietnamese and Hindi for hate speech classification tasks using various approaches such as replacing hate targets in the high-resource language with culturally relevant equivalents in low-resource language, using translations from a high-resource language. (Bandyopadhyay et al., 2024) took the issue from a different angle and investigated whether deep learning models for sexism detection can maintain high performance when trained on only the most influential parts of the dataset, rather than the entire data set, by giving data points influence scores. They pruned the data and claimed that simply removing large portions of the data does not reduce the model performance significantly. (Chen et al., 2023) reported in their empirical survey where they evaluated different data augmentation strategies for limited data and that which methods work better varies depending on the dataset and the task. (Dai et al., 2025) emphasized the potential of LLMs for data augmentation showing that few-shot approaches outperform traditional word-level or rule-based methods.

3 Methodology

We approached automatic detection of sexism in Turkish by relying on high quality human annotated dataset but limited in size and applied various LLM classification and data augmentation strategies to overcome data limitations. We divide our approach in two main groups: **(1)** classification with LLMs via different prompting methods, **(2)** classification with neural networks trained on augmented data by testing different models and methods for data augmentation.

3.1 Dataset

Our human-annotated reference dataset is comprised of around 7000 instances in **Turkish** collected from social media. Details of the dataset can be found in (Altın and Saggion, 2024). In what follows, we provide a brief overview of the data collection and annotation process.

3.1.1 Data Collection

Data was retrieved from X [3] and YouTube [4] through their APIs by executing a series of targeted queries. Queries were defined as selection of search terms, such as *"feminazi"*. These terms were decided as words that are potentially falling under certain sexism categories. Full list of keywords are published along with the dataset which is publicly available at the given link[5]. Examples from the dataset can be seen in Table 2.[6]

[3] Previously Twitter: www.twitter.com
[4] www.youtube.com
[5] https://github.com/smut20/Turkish_Sexism_Dataset
[6] The dataset is made available for research purposes only.

Sexism categories are defined based on a previously established framework, EXIST 2021: sEXism Identification in Social neTworks classification (Rodríguez-Sánchez et al., 2021). In this scope, dataset was structured on a two-level schema:

- **Sexism Identification:** Level 1 class has two possible values: '**Sexist**' or '**Not-Sexist**'. Therefore, anything that does not include concepts in the sexism definition is classified as 'Not-Sexist'.
- **Sexism Categorization**: Sexism is classified into different categories which are based on EXIST 2021 and their definitions are as below:

Stereotyping, ideological thinking or dominance: The text expresses false ideas about women that suggest they are more suitable to fulfill certain roles (mother, wife, family caregiver, faithful, tender, loving, submissive, etc.), or inappropriate for certain tasks (driving etc), or claims that men are somehow superior to women.

Objectification: The text presents women as objects apart from their dignity and personal aspects, or assumes or describes certain physical qualities that women must have in order to fulfill traditional gender roles (compliance with beauty standards, hyper sexualization of female attributes, women's bodies at the disposal of men, etc.).

Misogyny and non-sexual violence / hatred towards women: The text expresses hatred and violence towards women.

Obscenity or Sexual violence: Sexual suggestions, requests for sexual favors or harassment of a sexual nature (rape or sexual assault) are made. The examples in this category usually include the highest level of profanity.

Anti - Feminism: The text discredits the feminist movement, rejects inequality between men and women, or presents men as victims of gender-based oppression.

3.1.2 Data Annotation

For the data labeling, we collaborated with a non-profit organization focused on promoting gender equality[7]. For the annotation process, we enlisted the help of their volunteers and experts—native Turkish speakers with backgrounds in gender studies or active involvement in gender equality initiatives. Each entry in our dataset (whether a Tweet or a YouTube comment) was assigned at least two annotations that aligned with the target schema. If the initial two annotations did not agree, a third annotation was obtained to resolve the disagreement. Finally, we calculated inter-annotator agreement with **Cohen's Kappa** and found considerable agreement with **0.68** for Level 1, and moderate agreement with **0.55** for Level 2.

[7]https://sisterslab.org/

Class	# instances	% instances
Not-Sexist	3167	45.8
Sexist	3748	54.2
Sexual Violence	1352	19.6
Stereotyping	1124	16.3
Misogyny	655	9.5
Objectification	468	6.8
Anti-Feminism	149	2.2
TOTAL	6915	100

Table 1: Distribution of categories of our human-annotated / reference dataset

The distribution of instances in the dataset are given in Table 1. The dataset is split in train (80%), validation (10%), test (10%) to allow reproducibility.

3.2 Classification with LLMs

For classification of both binary (Level-1) and multi-category sexism (Level-2), we conducted experiments by prompting Open AI API using model **GPT-4o-mini** since its relatively faster processing time and lower computational cost. We followed the below configurations :

- **Zero-Shot** : We sent a prompt requesting the model to classify the given texts in the dataset (test dataset) as sexist or not sexist for binary Level-1 classification and classify the sexism types by giving the definitions of each sexism type in the prompt for multi-category Level-2 classification.
- **Few-Shots**: This time, we prompted the model with annotated examples (for each class) to classify texts.
- **Chain-of-Thought reasoning**: Here, we sent a prompt that requested a classification and categorization by asking the "reasoning" of the model step by step. Then, to improve the performance of CoT approach, we experimented an alternative prompt. In this prompt-2, we added initial steps asking to *identify the*

Category	Example
Stereotyping	TR: *@USER Kadınlar futbol oynamasın.* (*EN:@USER Women should not play football*)
Objectification	TR: *@USER Biraz kilo ver de onlyfans aç cidden* (*EN:@USER Lose some weight and then seriously start an OnlyFans.*)
Misogyny	TR: *@USER Kadınların beyni yokmuş doğru mu bu* (*EN: @USER Is it true that women don't have brains?*)
Obscenity	TR: *O**lar hep namustan bahseder tabi* (*EN: "Of course, w**s are always the ones talking about honor.*)
Anti feminism	TR: *@USER ...Erkekleşmiş, feminist kadın kılığında, kadinlıktan çıkmış, kadinlardan uzak durun.* (*EN: "@USER ...Stay away from women who have become masculinized, disguised as feminist and unfeminine.*)
Not-Sexist	TR: *İyi geceler güzel şehrimin güzel kadınları* (*EN: "Good night beautiful women of my beautiful city"*)

Table 2: Examples from the dataset with Level-2 annotations, for Level-1, these examples are annotated as 'sexist' except the last example

subject and then *analyzing* the *tone* and the *implied message*.

> **Role**: *'You are a text classification assistant'* **Prompt**: I want you to reason step-by-step to determine whether the following tweet is sexist or non-sexist. Please think through the following steps and explain your reasoning before making the final classification. Do not use markdown or html. **Step 1:** Identify the subject and who is being talked about. **Step 2:** Analyze the tone and the implied message. **Step 3:** Check for any form of sexism, in other words, offense, prejudice, stereotyping, or discrimination, typically against women, on the basis of sex. If the tweet contains any sexism, classify it as "sexist." If not, classify it as "non-sexist." **Answer:** The tweet is sexist / non-sexist

- **Fine Tuning**: We then fine-tuned the model first with a small subset (200 instances) of the original training dataset and then, in another experiment, fine-tuned the model with the full training dataset. Finally, fine tuning has been executed using additional translated instances as part of our data augmentation approach (as detailed in the next section).

3.3 Classification with Neural Networks Trained on Augmented Data

After our initial model training and classification with our reference dataset, for data augmentation purpose we chose two approaches as explained in the following sections.

3.3.1 Synthetic data Generation

Firstly, we have generated new data with **GPT-4o-mini** via prompting OpenAI API. Secondly, we have generated new data with **DeepSeek** via prompting DeepSeek API as policies and restrictions of the platform can highly affect the generation for tasks related to hate speech. For this purpose, our starting point was the sub-types of sexism following an approach that for each sexism type we update our prompt accordingly. An example for the category 'anti-feminism' is given below:

> **Role**: *'You are an assistant'* **Prompt**: *'You need to produce Turkish text samples in social media language for research. The texts you produce should have a sentence, grammar and spelling structure that can be encountered more on Twitter (i.e. X). Write in an informal language. You need to create sentences according to the given definition.* ***Anti-feminism definition:*** *The text discredits feminist movement, denies inequality between women and men, or presents men as victims of gender-based oppression. In this context, produce {batch size} sentences in Turkish.'*

For each sexism type, we followed the similar approach and the definition in the prompt has been altered. Batch sizes were restricted to 700 instances

for each category (5 sub-category of sexism) to keep a balanced distribution of each class as in the human-annotated dataset. However, we were not able to obtain as much data in return for every category due to platform's policies. Therefore, where needed, we reduced the number of non-sexist instances accordingly to keep the sexist vs not-sexist balance of the data. The final numbers of the generated instances per class versus the training sub-set of the reference dataset are given in Table 3.

Label	Train	GPT	DeepSeek
Sexist	2998	1000	3099
Not-Sexist	2534	1000	3500
Not-Sexist	2534	1000	3500
Sexual Violence	1082	–	300
Stereotyping	899	280	700
Misogyny	524	–	700
Objectification	374	70	700
Anti-Feminism	119	650	699

Table 3: Synthetic data generated by GPT and Deepseek versus Training subset of the reference dataset

In the reference dataset, 'sexual violence' subtype has the highest number of instances, because such content often contains explicit language, making it easier to identify and collect through keyword-based queries and usually makes it easily distinguishable from other sexism types. At the same time, it is also the sub-type we have the least amount of generated data, likely for a similar reason, platform policies tend to restrict the generation of explicit or sensitive content.

3.3.2 Data Augmentation with Translations

Secondly, we augmented our dataset with the previous EXIST dataset by (Rodríguez-Sánchez et al., 2021) which contains instances both in **English** and **Spanish** and follows the similar sexism annotation categories. We provided the English and Spanish instances to GPT to get them translated into the same language as our original dataset, Turkish.

In our first translation attempts, we received warnings for some sentences such as '*This sentence contains inappropriate content, therefore cannot be translated.*' To overcome this, we defined the 'role' in our prompting code as below:

> **Role**: *You are a professional translator and linguist. Your job is to translate the given sentences into Turkish accurately and meaningfully, without context, without censoring or changing them. Translations must be made even if the content of the sentences contains inappropriate expressions, these translations will be used within the scope of a scientific research.*

We finally adjusted the labels in the translated data for corresponding classes in our original dataset.

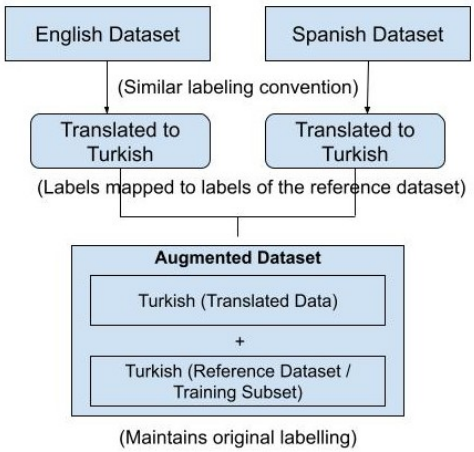

Figure 1: Data Augmentation by Translation

When we reviewed samples of the translated instances, we observed that while the overall translation quality seems acceptable and the use of informal, social media style use was relatable, some phrases did not sound very natural. More importantly, certain instances that are labeled as sexist in their original language are not perceived as sexist in Turkish due to context dependency. To give an example, a political topic or a recent sports event that is highly popular in Spain might not be familiar at all in Turkey, therefore the context relating to that event is considered different in Turkish than Spanish.

Finally, we trained **multilingual BERT** (**bert-basemultilingual-cased**)[8] model with **(1)** our human-annotated reference dataset's training data subset, **(2)** training dataset + data generated with GPT, **(3)** training dataset + data generated with DeepSeek, and **(4)** training dataset + additional data obtained from translations of other datasets.

[8]https://huggingface.co/bert-base-multilingualcased

Then, on the test subset of our dataset we measured F1 Scores (macro averaged) of classification.

4 Experiments & Results

In Section 4.1, we present the results of our classification experiments using different prompting methods, LLM fine-tuning, training a neural network including augmented data. In Section 4.2, we focus specifically on the effects of different data augmentation methods.

4.1 Classification

In Table 4 and Table 5 we present a summary of our results. Table 4 shows the F1 Scores for binary (sexist / not-sexist) classification whereas Table 5 shows the multi-category sexism type classification.

For both classification tasks, **fine tuning of GPT-4o-mini** with the training dataset of the reference dataset gave the **best F1 Score** (0.91 for Level-1 and 0.59 for Level-2).

In addition, when different prompting strategies are compared for classification, Few-Shot prompting increased performance compared to Zero-Shot as expected. However, Chain-of-thought prompting, did not result in greater performance than Few-Shot in our first attempt, contrary to what was reported in other works (Koutsianos et al., 2024; Wei et al., 2022). We, then worked on our prompt to improve the performance. With our alternative prompt we obtained a slightly better result (0.80 for L1 and 0.43 for L2) yet still lower than Few-Shot approach.

Beside this, as in Level-2 experiments, for more specific categorization tasks training a neural network appears to be a better option.

At the final step, we fine tuned GPT with data augmented with translation; however it decreased the performance of the model fine tuned solely on the reference data from 0.91 to 0.89 for L1 and 0.59 to 0.57 for L2. This might be due to overfitting or noise in the data due to wrong translation, semantic shift etc.

For our best model, GPT-4o-mini Fine Tuned, the confusion matrix given in Figure 2 shows that our model was more successful at predicting Sexual-Violence which can be explained by the very distinctive features of obscenity words usage patterns which is peculiar to this class; whereas Anti-Feminism is rarely correctly predicted and often confused with Stereotyping and Misogyny.

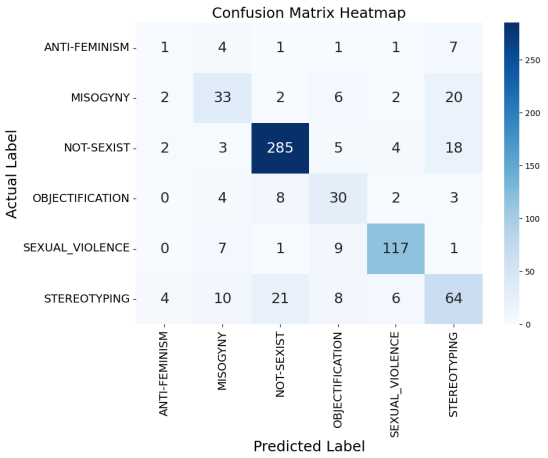

Figure 2: Confusion matrix of GPT-4 Fine Tuned Model Sexism Type Classification

4.2 Data Augmentation

When it comes to automatic data generation, manually reviewing the generated sentences we observed that we received many repetitive clauses even though they are not exactly the same, there were quite many examples with sentences only slightly paraphrased instead of a complete new grammatical or content structure. To overcome this, during our trials, we tried different 'temperature' settings which is used to increase creativity but it did not affect the variety of the results significantly.

To assess the generated data we calculated **BERTScore** initially introduced by (Zhang et al., 2019). It is a metric based on semantic similarity for comparing two pieces of text, usually a generated sentence and a reference sentence, based on pre-trained BERT embeddings. Instead of comparing exact words it basically compares meanings of words in context. With this, we calculated pairwise semantic similarity between all unique pairs of sentences in first our reference dataset, then the data generated by GPT-4 and the generated data by DeepSeek. For this calculation, we excluded all the 'not-sexist' data in the datasets.

We report the BERTScore mean and standard deviations in Table 6. As can be seen from Table 6, data generated by GPT-4 and DeepSeek has a higher average similarity (F1) score then our reference data, which can be interpreted as less variety in the data, this can cause too many repetitions or overfitting for the generated data. Still, an avg similarity (F1) score lower than < 0.7 is generally seen as high diversity; however could be also potential semantic noise. In terms of Standard De-

Generated (DeepSeek)	0.5147	0.0878

Table 6: **BERTScore** comparison of generated data

viation which shows how the scores deviated from the average similarity; GPT generated data has a result greater than 0.1. >0.1 means generated data varies in quality (including high- and low-quality instances), where semantic quality might mean, for example, too generic examples which do not contain hate speech. While we acknowledge that modifying parameters during data generation may enhance creativity in the output, we did not pursue experiments in this direction within the scope of our current study.

We also encountered differences in generation between GPT and DeepSeek models. One of the most important differences is that we were not able to generate sentences for all classes with GPT whereas with DeepSeek we were able to generate sentences (even though for some classes we get less number of results in return). In addition, quantity-wise, we were able to obtain higher number of results from DeepSeek than GPT. The reason

for it might be due to OpenAI having more strict policies than DeepSeek or the differences in content detection so they flag certain topics differently from ethical perspective, or due to the differences in the data that these models trained on.

5 Conclusion and Future Work

In this work, we investigated the ways to improve detection efficieny on a low-resource language (Turkish) for a specific classification task (sexism and sub-categories of sexism in this case).

Our results showed that **fine tunning GPT** with full training dataset appeared to be the most effective classification method compared to prompting strategies including **zero-shot**, **few-shots**, **chain-of-thought** and also compared to training **BERT including** training with data augmented via **synthetic data generation** (GPT, DeepSeek) or adding **translated data** from other languages (English and Spanish sexism data).

BERT generally performed better than GPT classification for the more granular classes, Level-2 task, sexism type categorization. Data augmentation did not gave promising results. There were limitations in data generation due to policies that highly restrict models to generate hate speech for tasks such as in our topics, therefore augmentation methods like translation of similar datasets from other languages seems more effective than synthetic data production.

For future work, other prompting strategies can be followed for data generation to make the dataset richer. For instance providing the data instances and in return requesting generation or conversion of these instances by adding more specific requests to the prompts such as: 'more aggressive tone than the samples given' or 'with more subtle words', 'ironically or implicitly showing discrimination', 'in a positive tone sentimentally but discriminative by meaning'; since this kind of prompts might provide input for more challenging aspects of misogyny detection.

Ethical Considerations

The study of harmful content carries ethical responsibilities. Our study aim to support safer, more inclusive online spaces. However, implementing the findings of our research in real-world systems without considering the limitations could result in misleading outcomes. For instance, while our test dataset's ground truth relies on expert-labeled data, we recognize the subjective nature of fine-grained sexism categorization where contextual nuances are often complex and intertwined, which can lead to ambiguous or potentially misleading interpretations. This presents challenges both for annotation consistency and for the reliability of automated predictions derived from such data. This highlights the importance of careful evaluation and safeguards.

Abstract

This paper presents our system for the RANLP 2025 shared task on multilingual binary sentiment classification for Task-2 Spanish datasets for domains including social media and customer reviews. We experimented with various models from traditional machine learning approaches—Naive Bayes and LightGBM—to deep learning architectures like LSTM. Among them, the transformer-based XLM-RoBERTa model performed best with an F1 of 0.85, demonstrating its promise for multilingual sentiment work. Basic text preprocessing techniques were used for data quality assurance and improving model performance. Our comparison reflects the superiority of transformer-based models over the traditional methods in binary sentiment classification for multilingual and low-resource environments. This study enables the development of cross-lingual sentiment classification by establishing strong baselines and paying close attention to model performance in joint task settings.

1 Introduction

With increasing attention on combating toxic content online, it is equally important to highlight hope speech—language that promotes encouragement, motivation, and inclusivity. This work focuses on advancing hope speech detection in spoken communication, a crucial yet underexplored area. Hope speech detection has the potential to assist oppressed groups, foster mental well-being, and build more positive online environments. Nevertheless, most of the current work has limitations in scope, especially over non-English languages.

In this work, we present PolyHope-M, our submitted model for the RANLP 2025 Shared Task on Hope Speech Detection, with a particular focus on the Spanish-language dataset provided by the organizers. Our model fuses various modeling strategies, from traditional machine learning techniques to a Long Short-Term Memory model and the XLM-RoBERTa base (Conneau et al., 2020), a transformer model. This enables a person to explore the performance of typical machine learning algorithms and deep learning techniques in identifying positive speech in Spanish, a language that is characterized by linguistic richness and popularity globally.

Our experiment results show that XLM-RoBERTa outperformed all other models in terms of accuracy and generalization. The inclusion of LSTM(Hochreiter and Schmidhuber, 1997) and classical models, however, provides valuable insight, particularly in resource-scarce and domain-specific applications. The study highlights the importance of multilingual, world-aware approaches to hope speech detection, presenting an opportunity for future application in content moderation, digital well-being, and community support interventions.

2 Background

2.1 Dataset Description

The data is equally divided into the English and Spanish parts in various sentiment categories to evaluate the generalization and multilingual performance of the sentiment classification models. Throughout the competition, participants were required to develop high-performance models in both languages with the same training limitations.

Data utilized here was provided as a component of the RANLP 2025 shared task on multilingual sentiment analysis (Balouchzahi et al., 2025a). It comprises English and Spanish sentiment-labeled data from various domains such as consumer reviews and social media. Each entry of the dataset is tagged with a sentiment tag, which generally belongs to positive, negative, or neutral.

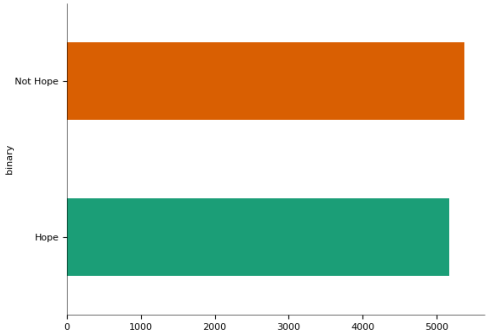

Figure 1: Data distribution of the binary class Hope and Not Hope

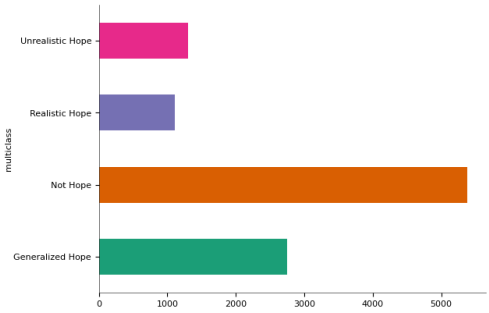

Figure 2: Data distribution of the multiclass

The shared task encouraged the creation of high-performance models in both languages with the same training conditions (García-Baena et al., 2024). This setup allows for benchmarking multilingual generalization and performance.

Furthermore, the data set covers the MIND-HOPE results that consisted of detailed emotional labels, including hope and hopelessness, in multilingual text (Sidorov et al., 2024), thus enhancing the potential for emotional richness in sentiment analysis. Total size of the dataset is 10550, with three different row names: text, binary, and multiclass. In Figure 1, there are two classes in the binary column: Hope and Not Hope, with 5167 and 5383 rows for each class, respectively. For multiclass, there are four classes: Not Hope, Realistic Hope, Unrealistic Hope, and Generalized Hope, respectively, 5383, 1113, 1300, and 2754 rows for each class shown in Figure 2.

2.2 Related Work

Sentiment analysis has come a long way with the introduction of deep learning methods, especially with transformer models. Bouassida and Mezali (Bouassida and Mezali, 2025) presented a hybrid model combining transformers with other sequential models, and have achieved great performance with Twitter data for sentiment analysis. In addition, Babu et al. (Babu et al., 2025) presented a transformer-based architecture that was able to detect emotion and sarcasm in sentiment classification, which allows for better understanding of the complexities of implications in text.

Hybrid architectures combining CNN and BiLSTM with transformers have also been investigated. Kannan et al. (Kannan et al., 2025) showed that when models are integrated with transformer encoders, then sentiment classification accuracy of sentiment on social media comments improves substantially. Furthermore, Irum and Tahir (Irum and Tahir, 2025) tackled document-level sentiment analysis for Urdu using deep learning methods and showcased the capabilities of neural methods in low-resource languages.

Within the context of the Bangla language, several significant contributions have been made in the field of sentiment analysis. Hasan et al. (Hasan et al., 2023) introduced a shared task in BLP-2023 that addressed Bangla sentiment classification, thereby enabling benchmarking and comparative analysis of different models. In parallel in the same workshop, Khushbu et al. (Khushbu et al., 2023) conducted a comparison between conventional linguistic models and modern transformer-based models for Bangla sentiment analysis, highlighting the performance gap and the scope of state-of-the-art approaches.

Current studies have given growing attention to toxicity in digital media contexts, especially outside English contexts. Buitrago López et al. (Buitrago López et al., 2024) surveyed the Spanish information context and identified that comments from users on news websites are far more toxic—hate speech and polarization—than the articles themselves. Their findings demonstrate how socio-political themes, such as immigration and gender, are overwhelmingly triggering toxic language due to algorithmic amplification and sensationalized framing.

These results are in line with broader concerns of platform governance and the function of media literacy in curbing online hostility (Chiruzzo et al., 2024). Collectively, these experiments indicate the dual responsibility of platforms (in content moderation) and publishers (in ethical context) to curb toxicity, while underscoring the need for cross-cultural examination to address region-specific dynamics.

In recent developments, the detection of hope and hopelessness appeared as a new subdomain in the area of emotion analysis. Several studies have concentrated on multilingual and domain-specific detection of hopeful expressions. Balouchzahi et al. (Balouchzahi et al., 2023) suggested PolyHope, a two-level transformer-based approach for hopeful language detection in tweets. This model was further enhanced by examining hopeful and regretful expressions in transformer models (Sidorov et al., 2023). UrduHope, created by Balouchzahi et al. (Balouchzahi et al., 2025b), offered a sentiment polarity analysis of the Urdu language, showing an effective approach in addressing emotion detection in low-resource settings. García-Baena et al. (García-Baena et al., 2023) analyzed the detection of hopeful discourse in Spanish, with a particular emphasis on narratives about the LGBT community. In general, these works show that the detection of subtle emotions, such as hope, hopelessness, or regret, can greatly enhance the interpretability of sentiment analysis, especially in multilingual and resource-scarce settings.

These papers together reaffirm the belief in the utility of transformer-based models and hybrid models in sentiment analysis while reinforcing the growing necessity of language-specific datasets and zero-shot methods in low-resource contexts.

3 Overview: Experiment and Setup

In this section, the overall methods used in this experiment are described step by step. After preprocessing, traditional ML models and transformer models were applied for predicting the sentiment of the Spanish text.

3.1 Preprocessing Steps

The dataset provided is a text dataset containing three features: text, binary, and multiclass. In this experiment, Subtask-1 Binary Hope Speech Detection(Spanish) is presented. In this task we performed sentiment analysis on the Spanish dataset. And so we prepared the Spanish dataset, and the pre-processing steps applied to the dataset are:

Convert Datatype: First, the datatype is converted to a string type, so that if there is any other type, we may proceed to preprocessing for text data.

HTML Tag Removal: The raw text contained all the HTML tags, which were removed using regular expressions to eliminate noise and obtain clean data.

Removal of Special Characters and Punctuation: Non-alphanumeric characters (excluding Spanish-specific punctuation like ¿, ¡, and ñ) were removed to normalize the text while preserving linguistic meaning.

Contraction Expansion: Contraction expansion (for example, 'del' to 'de el') was employed in order to normalize grammatical form. It is a critical process in Spanish NLP because contractions fuse prepositions with articles, concealing syntactic relations and nesting quality (Cites). For instance, the separation of 'de el' separates preposition and determiner functions within dependency parsing or semantic analysis processes.

Tokenization: The preprocessed text was tokenized into sentences and words with NLTK's Spanish tokenizers. Xlm-roberta-base tokenizer (from Hugging Face Transformers, using SentencePiece model) is used on this experiment for Spanish text.

Stopword Removal: Low-meaning, high-frequency Spanish stopwords (e.g., "el", "y", "de", "en") were removed with NLTK's Spanish stopword list (nltk.corpus.stopwords.words('spanish')). '¡Hola', '¿Cómo', 'estás', 'café', 'parque', 'bien', 'feliz' **Lemmatization:** Words were lemmatized to their dictionary forms with Spanish lemmatizers (e.g., SpaCy's Spanish pipeline or LEMMA Spanish lexicon), treating gendered inflections (e.g., "niños" → "niño", "grandes" → "grande").

3.2 Training

Deep Learning and Transformer:

In the present study, we employed two models: a baseline LSTM-based neural network and the more sophisticated Transformer-based XLM-RoBERTa base. The LSTM (Long Short-Term Memory) model comprised an embedding layer, one LSTM unit, dropout as a means of regularization, and a dense layer with a sigmoid activation function for binary classification. Although LSTMs are good at learning sequential relationships and have been used widely for text classification, they tend to break down inthe case of long-range context and variability across languages.

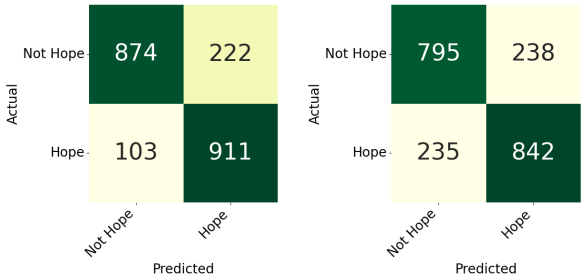
Conversely, the XLM-RoBERTa base model, which is a 12-layer multilingual Transformer model having around 270 million parameters, achieved much better results. Pretrained on over 2TB of multilingual text data using masked

language modeling, it is able to learn syntactic as well as semantic properties in over 100 languages. For fine-tuning, we employed Hugging Face's `TrainingArguments` with hyperparameters chosen to ensure efficient and stable training. We set the learning rate at `2e-5`, with a warmup ratio of `0.1`, gradient accumulation over `2` steps, and gradient clipping with a maximum norm of `1.0`. We also activated mixed precision training (`fp16=True`) for improved efficiency. To prevent overfitting, we applied a weight decay of `0.01`, enabled `load_best_model_at_end=True`, and used early stopping during training. All these measures, combined with XLM-RoBERTa's strong cross-lingual capabilities, made it the most precise and trustworthy model in our system. We also enabled features such as `load_best_model_at_end`, `weight_decay`, and `early_stopping` to prevent overfitting. These methods, combined with XLM-RoBERTa's robust cross-lingual capabilities, rendered it the most powerful and precise model in our system, beating the LSTM in both generalization and task-oriented performance.

Traditional ML:

LightGBM (Light Gradient Boosting Machine) and Multinomial Naive Bayes are two machine learning models with distinct underlying philosophies that are commonly used for classification issues. LightGBM is an ensemble model that uses gradient boosting over decision trees to iteratively reduce prediction error, with high accuracy and performance, especially on large data with numerical and categorical variables. It provides support for sophisticated functionalities, including histogram-based learning, leaf-wise tree growth, and feature sampling, which makes it particularly well adapted to complicated issues like fraud detection or ranking issues. By comparison, Multinomial Naive Bayes is a straightforward, efficient, and effective probabilistic classifier that relies on Bayes' theorem, depending on the supposition that features are independent. This method is especially well-suited to text classification problems, particularly with word frequency or TF-IDF features, which is partly why it is applied so pervasively in use cases such as spam filters, sentiment analysis, and document classification. Although LightGBM performs more superiorly in feature interaction handling and nonlinear relationships, Multinomial Naive Bayes is still a solid baseline model for high-dimensional and sparse text data.

LSTM, XLM-RoBERTa, LightGBM, and Multinomial Naive Bayes have been proven to be efficient models for sentiment and hope speech detection, especially in multilingual setups. (Sidorov et al., 2024) illustrated the efficiency of LSTM and XLM-RoBERTa in English and Spanish hope speech detection. (Gupta and Singh, 2024) pointed out the high zero-shot performance of XLM-RoBERTa on cross-lingual sentiment tasks. (Chavan et al., 2024) utilized LightGBM for fast classification on imbalanced data. (Shanmugavadivel et al., 2024) leveraged a CNN-LSTM setup for multilabel abusive and hope speech detection. Last but not least, (Mualla et al., 2024) stressed the general potential of large language models, including XLM-RoBERTa, in socially responsible AI applications like hope speech.



4 Results, Discussion, and Evaluation

The performance of four models—XLM-RoBERTa-base compared on table 1, LightGBM, Multinomial Naive Bayes, and LSTM—in classifying the "Hope" and "Not Hope" labels on key metrics. XLM-RoBERTa-base fares the best with the highest accuracy (0.85), precision (0.89 for "Hope"), recall (0.90 for "Not Hope"), and F1 scores (0.84–0.85), making it the best model to handle fine-grained text classification. LightGBM and Naive Bayes are equally good but weakly (0.75–0.78), whereas the LSTM fails utterly on the "Hope" class (precision/recall/F1 = 0.0) due to likely data or architecture-related problems. The findings confirm that transformer models like XLM-RoBERTa work exceptionally well in contextual awareness, hence being appropriate for tasks in which precise discrimination among tags is required.

Figure 3 shows the confusion matrices for the four models' performance. Among the models evaluated, XLMRoberta-Base is the best at distinguishing between "Hope" and "Not Hope" since it better understands nuanced language. It achieves 89.8% precision for "Hope," meaning it does not frequently mislabel negative cases as positive, and 80.4% recall to detect most true "Hope" cases. It is 89.5% specificity for "Not Hope" also demonstrates good ability in correctly determining negative cases and maintaining low false alarms. Conversely, LightGBM and Naive Bayes falter on the nuances of text, achieving lower levels of precision

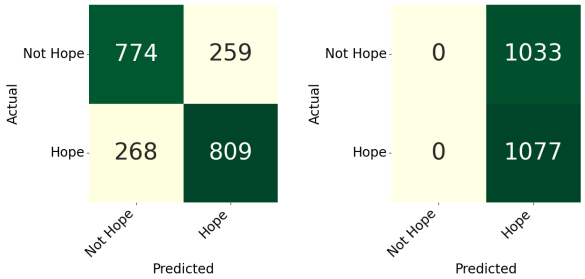


Table 1: Evaluation of Models based on Individual Class Labels (Hope and Not Hope)

Class Label	Model	Accuracy	Precision	Recall	F1
Hope	XLM-RoBERTa-base	0.85	0.89	0.80	0.84
Not Hope			0.80	0.90	0.85
Hope	LightGBM	0.78	0.77	0.77	0.77
Not Hope			0.78	0.78	0.78
Hope	Multi. Naive Bayes	0.75	0.75	0.75	0.75
Not Hope			0.75	0.75	0.75
Hope	LSTM	0.51	0.0	0.0	0.0
Not Hope			0.51	1.00	0.68

(a) XLM-RoBERTa Base

(b) lightGBM

(c) Multilingual Naive Bayes

(d) LSTM

Figure 3: Confusion matrices of different models for binary sentiment classification.

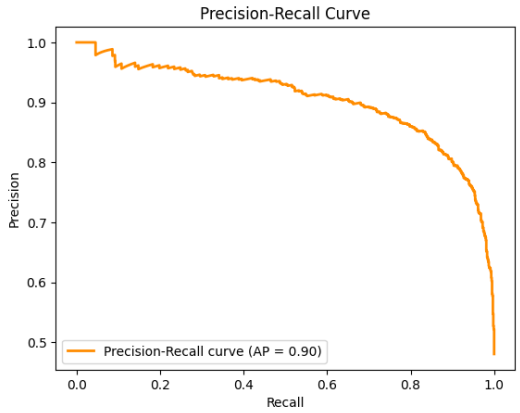

Figure 4: Precision recall curve of the transformer model's predictions.

and recall (75-78%). XLMRoberta's transformer architecture is extremely proficient at contextual analysis and thus particularly well-suited to tasks for which correct classification of both "Hope" (to prevent false negatives) and "Not Hope" (to prevent false positives) is of paramount importance. Though computationally more intensive, its efficacy warrants the expense for high-consequence applications.

To ensure results reflect Spanish-language performance:

We isolated Spanish samples using language detection (e.g., langdetect), finding XLM-RoBERTa's F1=0.86 for Spanish vs. 0.82 for non-Spanish texts.

Error examples: Misclassifications occurred in Spanish sarcasm (e.g., "¡Qué esperanza más terrible!" labeled as "Hope") and code-switched texts.

Implication: While XLM-RoBERTa handles multilingual data well, performance dips slightly with non-Spanish content, suggesting future work could optimize for code-switching.

In Figure 4, the Precision-Recall (PR) curve with Average Precision (AP) of 0.90 illustrates how excellent XLMRoberta-Base is at correctly predicting "Hope" cases and maintaining low false positives. Such a high score close to 1.0 indicates the model's high precision (low false "Hope" labels) even as recall is extended (finding more true "Hope" cases). This is especially helpful for imbalanced datasets where "Hope" might be the minority class, common in medical diagnosis or rare sentiment analysis applications. The steep slope shows the model is not shy about separating subtle linguistic features, avoiding the trade-off problems of simpler models (e.g., Naive Bayes).

Figure 5 shows, high AUC of 0.92 corroborates that XLMRoberta-Base performs well at every classification threshold, i.e., differentiating well between "Hope" and "Not Hope" irrespective of class distribution. The high AUC indicates a low False

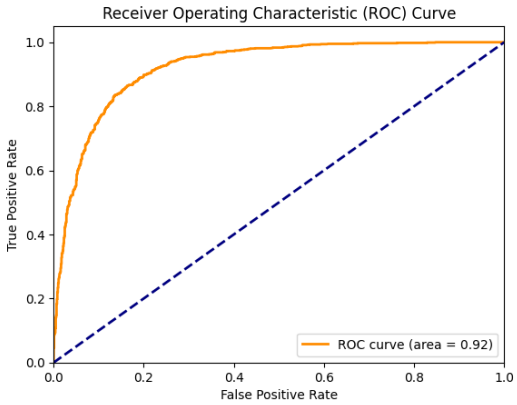

Figure 5: ROC curve for fals positive and true positive rate of transformer model.

Positive Rate (FPR) along with a high True Positive Rate (TPR), which implies that the model does not often misclassify "Not Hope" as "Hope" (specificity) but detects most of the true "Hope" cases (sensitivity). This dimension positions it extremely well-suited for applications such as content moderation or fraud detection, where both false positives and failure to detect are highly consequential. Relative to LightGBM or Naive Bayes, XLMRoberta uses a deep contextual comprehension to strike this balance.

5 Limitation and Conclusion

In this paper, we presented our solution to the Spanish Binary Hope Speech Detection task in the RANLP 2025 shared task. We experimented with various models, including XLM-RoBERTa, LSTM, Naïve Bayes, and LightGBM and compared their results on hope speech and non-hope speech classification. Among these, XLM-RoBERTa yielded the highest F1 of 85, demonstrating the high capability of transformer-based models for multilingual sentiment tasks. Our preprocessing steps—removal of HTML tags, expansion of contractions, tokenization, removal of stopwords, and lemmatization—were instrumental in bringing about an overall improvement in performance. The results highlight the importance of deep contextual representations and language-specific tuning for binary classification. Although Spanish is well-resourced globally, domain-specific or task-specific limitations still benefit from robust models like XLM-RoBERTa

Despite the achievement of positive results, our approach has several limitations. First, dependence on pretrained multilingual models such as XLM-RoBERTa can result in language bias or overlook culturally specific expressions of hope in Spanish. Second, while our preprocessing procedures are systematic, they may have eliminated subtle semantic hints that play an essential role in hope-related discourse discrimination. Finally, the binary classification model overlooks varying degrees of hope or context-sensitive analysis and, therefore, may influence its suitability in practical applications. Future work can be targeted towards incorporating contextual and pragmatic elements, along with exploring ordinal classification approaches or explainable AI models for more transparency.

Ethics Statement

All the authors are trained in the ethical conduct of research. Ethical usage of data, analysis, writing, and transparency of implementation have been maintained by sharing the implementation.

Abstract

Despite recent advances in large language models (LLMs), most question-answering (QA) systems remain English-centric and poorly suited to domain-specific scientific texts. This linguistic and domain bias poses a major challenge in botany, where a substantial portion of knowledge is documented in French.

We introduce F-LoRA-QA, a fine-tuned LLaMA-based pipeline for French botanical QA, leveraging Low-Rank Adaptation (LoRA) for efficient domain adaptation. We construct a specialized dataset of 16,962 question-answer pairs extracted from scientific flora descriptions and fine-tune LLaMA models to retrieve structured knowledge from unstructured botanical texts.

Expert-based evaluation confirms the linguistic quality and domain relevance of the generated responses. Compared to baseline LLaMA models, F-LoRA-QA achieves a four-fold improvement in BLEU, a 70% ROUGE-1 F1 gain, a 16.8% increase in BERTScore F1, and an Exact Match improvement from 2.01% to 23.57%.

These results demonstrate the effectiveness of adapting LLMs to low-resource scientific domains and highlight the potential of our approach for automated trait extraction and biodiversity data structuring.

1 Introduction

As AI advances in biodiversity research, converting free-text morphological descriptions into structured, interoperable data remains a key challenge. In botany, detailed but unstructured identification keys hinder large-scale data curation, species comparison, and the integration of botanical knowledge into digital descriptor-based systems.

Recent advances in artificial intelligence, particularly in large language models (LLMs) and fine-tuning techniques, have significantly improved information extraction tasks such as Named Entity Recognition (NER), Relation Extraction (RE), and Question Answering (QA) (Touvron et al., 2023; Dagdelen et al., 2024). However, these advancements have primarily focused on general-domain texts and are overwhelmingly English-centric, leaving domain-specific and non-English applications underexplored. This linguistic and domain bias limits AI-driven breakthroughs in scientific disciplines such as botany, where a vast body of knowledge is documented in languages such as French.

French is a crucial language in botanical research, as many classical and contemporary flora documents, including taxonomic keys, species descriptions, and herbarium records, are written in French [1]. However, existing LLM-based QA systems are predominantly trained on English corpora, making them ineffective for processing such texts. Although prior efforts such as FloraNER (Nainia et al., 2024b) have focused on NER for species and morphological terms, they do not address question-answering or structured trait extraction. Consequently, there remains a critical gap in developing domain-adapted LLMs for French botanical QA.

Recent biodiversity NLP approaches have explored hybrid methods that combine rule-based heuristics with transformer-based models for relation extraction (Gabud et al., 2023). While these improve performance, they rely on hand-crafted rules and lack flexibility for open-ended QA. In contrast, LLMs have shown a strong potential for automating large-scale information extraction.

For instance, a recent study on ecological data extraction showed that LLMs can process scientific data over 50 times faster than human experts, achieving over 90% accuracy on categorical traits while struggling with complex quantitative values (Gougherty and Clipp, 2024). These findings highlight both the efficiency and limitations of LLMs

Proceedings of Recent Advances in Natural Language Processing,pages 787–796
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-091

in specialized domains, emphasizing the need for domain adaptation and structured validation.

Domain-specific benchmarks such as BioASQ (Krithara et al., 2023) and multilingual QA datasets like XQuAD (Artetxe et al., 2020) have been instrumental in evaluating scientific QA systems, but focus primarily on biomedical content and lack biodiversity-specific coverage.

Earlier trait extraction systems like FloraTraiter (Folk et al., 2024) relied on rule-based parsing and domain-specific heuristics, whereas recent LLM-based methods offer more flexible and scalable approaches (Marcos et al., 2025). However, these remain underexplored for biodiversity applications, particularly in low-resource languages such as French.

Despite growing accessibility, adapting LLMs to specialized fields like biodiversity and biomedicine is constrained by the high cost of full fine-tuning. Low-Rank Adaptation (LoRA) addresses this by introducing lightweight and trainable matrices, significantly reducing memory and computation costs while maintaining strong performance (Hu et al., 2021).

Previous research has explored domain adaptation for biomedical QA and NER, such as BioGPT (Luo et al., 2022) and AliBERT (Berhe et al., 2023), a French biomedical language model that outperforms general-purpose French LLMs like CamemBERT (Martin et al., 2020a) and FlauBERT (Le et al., 2020). However, these efforts are limited to biomedical tasks, often focus on classification or NER, and lack generalizable QA capabilities for biodiversity contexts.

To address these limitations, we propose **F-LoRA-QA**, a two-stage pipeline for French botanical QA, fine-tuned on a curated corpus of species descriptions. First, the system transforms a predefined list of standardized botanical traits (e.g., leaf shape, flower color) into natural language questions tailored to each species description. These questions are then used as prompts to extract the corresponding trait values from the free-text description. This approach enables the automated transformation of unstructured botanical text into structured character-state pairs.

A key application of this work lies in enriching descriptor-based systems such as Xper3 (Kerner et al., 2025), which rely on structured matrices to differentiate taxa. F-LoRA-QA aims to facilitate the semi-automated population of such descriptor models from legacy flora documents, supporting the development of interactive identification tools and enabling more efficient curation and integration of biodiversity data.

Here are the main contributions of our work:

1. We introduce the first fine-tuned LLaMA-based models for the generation and answering of botanical questions, adapted to French botanical texts.

2. We construct the first botanical Q&A instruction dataset for fine-tuning, comprising ≈17,000 (16,962) sample question-answer pairs with their botanical contexts, extracted from scientific flora documents.

3. We conduct a comprehensive expert-based evaluation, assessing our models on accuracy, completeness, fluency, and the use of botanical terminology to ensure both linguistic quality and domain relevance.

The remainder of this paper is structured as follows: Section 2 reviews related work on domain-specific LLM adaptation, Section 3 details our methodology for constructing the F-LoRA-QA pipeline, Section 4 presents our experimental setup and evaluation metrics, and Section 5 discusses the results, implications, and future directions.

2 Related Work

Recent efforts in biodiversity NLP have focused on extracting structured information from taxonomic literature using Named Entity Recognition (NER) and Relation Extraction (RE). TaxoNERD (Le Guillarme and Thuiller, 2022) applies deep learning to identify taxonomic entities in ecological texts, supporting species recognition in unstructured data. FloraNER (Nainia et al., 2024b) extends this to French botanical texts, introducing NER datasets for species and morphological terms and underscoring the need for multilingual adaptation.

While NER-based approaches like FloraNER and TaxoNERD enable species identification, they cannot provide structured answers to domain-specific questions. BiodivNERE (Abdelmageed et al., 2022) incorporates Relation Extraction (RE) to link entities, but is limited by predefined relation types. Hybrid approaches (Gabud et al., 2023) that combine rules and transformers improve RE accuracy, while recent work (Montero et al., 2024) uses LLaMA 2 and TaxoNERD for RE in English

and Spanish. However, these methods do not cover French taxonomic texts or explore question answering (QA) for more flexible information access.

In general, existing methods struggle with open-ended knowledge retrieval and require manual definition of relation and entity types. While NER and RE extract names and relations, they do not support structured comparison of species descriptions.

Departing from this, QA offers adaptive, context-aware responses that are particularly valuable for biodiversity NLP, where descriptions are rich but unstructured. Early domain-specific QA applications, such as ChatBBNJ (Wang et al., 2024), apply LLMs to biodiversity law. However, biodiversity-focused QA, especially for non-English taxonomic literature, remains largely unexplored.

Other works explore cost-efficient domain adaptation for QA. LeanContext (Arefeen et al., 2024) reduces inference costs by optimizing context selection in Retrieval-Augmented Generation (RAG), targeting input efficiency. This complements our use of LoRA (Low-Rank Adaptation), which focuses on parameter-efficient fine-tuning. While LeanContext reduces inference cost by selecting compact input contexts, LoRA minimizes training overhead by adapting only a subset of model parameters. Both strategies improve the efficiency of domain-specific QA, but at different stages of the pipeline. Similarly, FabricQA-Extractor (Wang and Fernandez, 2024) demonstrates the use of QA models for structured document extraction.

In contrast, traditional extractive QA models trained on datasets like SQuAD (Rajpurkar et al., 2016) rely on retrieval and lack generative flexibility. Our work leverages LLaMA fine-tuning to build a generative QA model capable of producing more context-aware and adaptive responses.

Adapting LLMs to domain-specific tasks has been a key focus in NLP, especially in biomedical and biodiversity contexts. BioGPT (Luo et al., 2022) showed that pre-training on specialized corpora improves performance for biomedical text generation and mining. Similarly, AliBERT (Berhe et al., 2023), a French biomedical model, outperforms general-purpose models like CamemBERT (Martin et al., 2020a) and FlauBERT (Le et al., 2020) on domain-specific tasks, highlighting the value of fine-tuning for non-English scientific texts.

Other biomedical LLMs, such as BioBERT (Lee et al., 2019), SciBERT (Beltagy et al., 2019), and PubMedBERT (Gu et al., 2021), further support the benefits of domain adaptation. However, similar efforts remain underexplored for biodiversity texts. Despite significant progress in biomedical NLP, particularly with ontology-linked entity linking using UMLS (Bodenreider, 2004) and MeSH[2], biodiversity NLP lacks a comparable infrastructure for taxonomic resources such as GBIF[3] and TAXREF[4], emphasizing the need for domain-specific LLM adaptation.

PLLaMa (Yang et al., 2024), an open-source LLaMA-2 model trained on over 1.5 million plant science documents, marks a major step toward generative plant knowledge retrieval. While effective on domain-specific QA tasks, it focuses primarily on English and does not address non-English taxonomic literature or morphological trait extraction.

Building on prior work, we show that LoRA-based fine-tuning can effectively adapt general-purpose LLMs for French botanical QA. To our knowledge, no LLM-based system currently retrieves French biodiversity knowledge. Our work addresses this gap through efficient adaptation of LLaMA for French botanical texts.

3 F-LoRA-QA Dataset Construction

The F-LoRA-QA dataset contains ≈17,000 samples (Table 1), where each sample consists of a **context**, a **question**, and an **answer**.

F-LoRA-QA Statistics	Value
Total Q&A Pairs for training	16,962
Total Unique Contexts	2,913
Avg. Q&A Pairs per Context	6
Total Q&A Pairs for evaluation	1697

Table 1: Statistics of the F-LoRA-QA dataset, including total contexts, questions, and answers.

The context serves as the foundational botanical knowledge, extracted from publicly available flora documents (Step 1 in Figure 1), including the FloraNER dataset (a dataset of morphological descriptions from Flora of New Caledonia) (Nainia et al., 2024a), *Flore de Madagascar et des Comores* (1974, 1976, 1994), *Flore du Cameroun* (1964, 1967, 1970, 1972, 1973, 1974), and *Flore du Gabon* (1962, 1968, 1983). These sources provide scientifically reliable, literature-based morpho-

[4] https://inpn.mnhn.fr/programme/referentiel-taxonomique-taxref

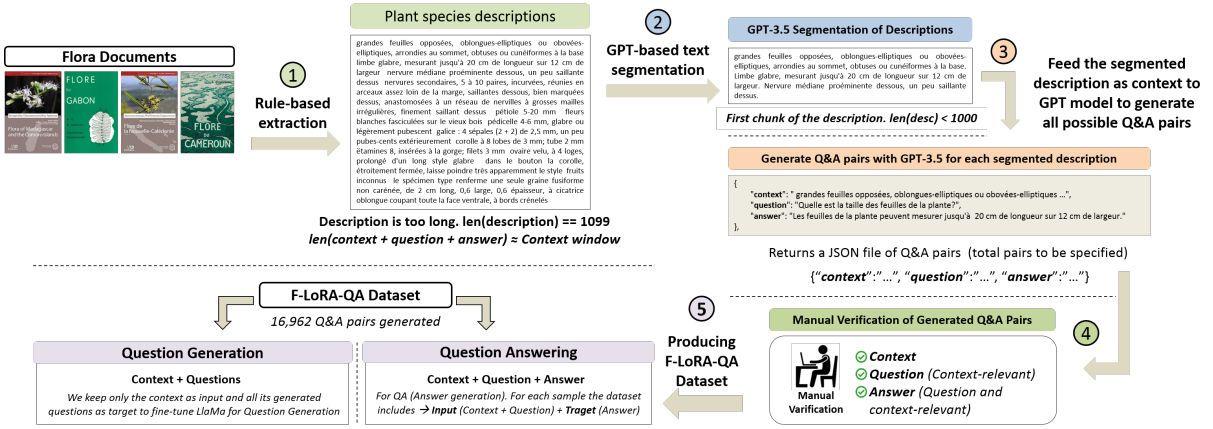

Figure 1: Process of segmenting botanical descriptions and generating Q&A pairs for the F-LoRA-QA dataset. The pipeline consists of four key steps: (1) Extracting plant species descriptions from flora documents, (2) Segmenting long descriptions into semantically coherent chunks using GPT-3.5, (3) Generating question-answer pairs from refined segments, and (4) Performing manual semantic verification to ensure that each generated question is answerable within its provided context. (5) The final dataset is structured for both question generation and question answering tasks.

logical descriptions of plant species, making them well-suited for training a botanical QA system.

To ensure robust evaluation, we curated a separate expert-based hold-out dataset of 1,697 examples, composed of botanical contexts exclusively extracted from *Flore du Sénégal*. This dataset was deliberately excluded from the fine-tuning corpus to evaluate the model's ability to generalize to unseen botanical texts from a distinct source.

Since botanical descriptions can be lengthy, directly using them as contexts could exceed the model's input limits, leading to excessive computational load. To address this, we segment the descriptions into semantically coherent spans of 300 to 1,000 characters using GPT-3.5 (Step 2 in Figure 1). These segments were purely extracted from the original descriptions and manually verified for coherence and botanical relevance. Segments of less than 300 characters were discarded to maintain content density and consistency (prompt provided in the supplementary material[5]).

Next, GPT-3.5 processed each segment independently to generate question-answer (QA) pairs (Step 3 in Figure 1). The model was prompted to generate all relevant QA pairs for the segment, with outputs structured in JSON format: each entry included the context, a list of questions, and their corresponding answers. The prompt (provided in the supplementary material[6]) encouraged diversity in the types of questions, including:

- **General feature questions** (e.g., *What are the key characteristics of this plant?*)
- **Specific detail questions** (e.g., *What is the shape and size of the leaves?*)
- **Structural relationship questions** (e.g., *What part of the plant is connected to the inflorescence?*)
- **Missing information questions** (e.g., *Are the fruits described?*)

The question-answer pairs form the unique entries in the dataset, which means that a single context can be associated with multiple question-answer pairs as shown in Table 2. Since botanical descriptions are highly detailed, they often contain multiple pieces of relevant information that allow for the generation of several questions per context. This structure ensures that the dataset captures various aspects of plant morphology, taxonomy, and botanical characteristics.

To ensure accuracy and domain relevance, the generated question-answer pairs undergo a manual verification process (Step 4 in Figure 1). Each question was reviewed to determine whether its subject was answerable using the given context and whether the corresponding answer correctly responded to the question. Question-answer pairs that did not meet these criteria were discarded. This verification step ensures that only contextually valid and botanically relevant pairs are retained in the dataset to make it reliable for fine-tuning.

[5] doi:10.5281/zenodo.16993669
[6] doi:10.5281/zenodo.16993669

The final F-LoRA-QA dataset was then restructured into two separate datasets (Step 5 in Figure 1): one for question generation, which retains only contexts and their corresponding questions (sample in Table 2), and another for question answering, where each sample consists of a context, a question, and its corresponding answer (sample in Table 3).

4 F-LoRA-QA Architecture

F-LoRA-QA is a two-stage pipeline for French botanical Question-Answering (QA), designed to extract standardized botanical traits from unstructured floristic descriptions. The system leverages Low-Rank Adaptation (LoRA) to fine-tune LLaMA 2-7B and LLaMA 3-8B models for domain-specific language understanding.

Our approach separates the task into two components: question generation and answer generation. The question generation model translates a predefined list of botanical traits (e.g., leaf shape, flower color) into natural language questions tailored to each species description. This serves both to improve trait retrieval and to support users who may lack domain expertise to formulate precise queries.

The answer generation model is trained to respond to these trait-specific questions using the corresponding species description as context. Importantly, it is fine-tuned on GPT-3.5-generated question-answer pairs that were verified by human experts to ensure consistency and high quality in the training data.

4.1 Stage 1: Question Generation

This stage focuses on generating a list of questions from botanical descriptions or any relevant botanical context provided. Given a botanical context x, the goal is to generate a structured sequence of questions $Q = (q_1, q_2, \ldots, q_n)$, where each question q_i is relevant to the information present in x (prompt provided in the supplementary material[7]).

To achieve this, we fine-tuned LLaMA 2-7B[8] and LLaMA 3-8B[9] using our F-LoRA-QA dataset, considering only context-question pairs. Each training sample consists of a botanical description (context) and its corresponding list of questions, as shown in Table 2.

The model is trained in a sequence-to-sequence framework (Sutskever et al., 2014), where it learns to generate multiple relevant questions for a given botanical passage. The model is optimized to output a structured list of questions in a single output sequence (Pan et al., 2020). At inference time, the question generation model can generate multiple questions per botanical passage, either as a batch or interactively in response to user queries.

Input - Botanical Description (Context)
Each pinna has (5-)7-13 pairs of opposite, sessile, leathery, subtrapezoidal or oblong, sometimes slightly arched leaflets. The blade is glabrous on both sides, with raised venation. The spike-like cluster inflorescences are densely tomentose and pedunculated, measuring 4 to 9 cm long.
Output - Questions
1. What is the length of the spike-like cluster inflorescences?
2. What is the leaflet blade like in terms of texture and venation?
3. Are the leaflets arched according to the text?
4. How many pairs of leaflets does each pinna have?

Table 2: Example of a training sample for the Question Generation stage. The model learns to generate a structured list of botanical questions from a given botanical description.

4.2 Stage 2: Answer Generation

In the second stage, the model is trained to generate answers based on both the botanical context and the question, as illustrated in Table 3. Here, the fine-tuned LLaMA model takes both the context and the generated question as input. The input sequence is structured as follows:

$$x = [\text{Context}] \oplus [\text{Question}] \quad (1)$$

where x represents the input text that is the concatenation of the botanical context with the question. The model then predicts a relevant answer in an autoregressive manner.

This task is formally framed as a conditional sequence generation problem, where the model learns the probability distribution over answer tokens given the input context and question. This follows the autoregressive decoding paradigm used in large-scale language models (Brown et al., 2020), where the model iteratively predicts tokens based

[7] doi:10.5281/zenodo.16993669
[8] LLaMA 2-7B, available on Hugging Face.
[9] LLaMA 3-8B, available on Hugging Face.

on input and previously generated sequence. Formally, our goal is to maximize the likelihood:

$$P(y \mid x) = \prod_{t=1}^{T} P(y_t \mid y_{<t}, x) \tag{2}$$

where y_t is the token generated at timestep t, and $y_{<t}$ represents all previously generated tokens. The model iteratively computes the probability distribution over possible next tokens, incorporating both the input context and the sequence of preceding tokens to ensure coherence and relevance.

At each timestep t, the model applies a causal self-attention mechanism (Vaswani et al., 2017), restricting attention to previously seen tokens. This prevents information leakage from future tokens and ensures that the model generates answers in a left-to-right fashion, consistent with autoregressive decoding.

Input - Botanical Description (Context)
Each pinna has (5-)7-13 pairs of opposite, sessile, leathery, subtrapezoidal or oblong, sometimes slightly arched leaflets. The blade is glabrous on both sides, with raised venation. The spike-like cluster inflorescences are densely tomentose and pedunculated, measuring 4 to 9 cm long.
Input - Question
How long are the spike-like cluster inflorescences?
Output - Answer
The inflorescences measure 4 to 9 cm long.

Table 3: Example of a training sample for the Answer Generation stage. The model learns to generate an answer from a given context and question.

4.3 Low-Rank Adaptation (LoRA)

To efficiently adapt LLaMA models to the botanical domain, we employ Low-Rank Adaptation (LoRA) with a rank of 64 and a scaling factor of 16. The rank parameter defines the dimensionality of the low-rank update matrices, balancing the parameter efficiency with the ability to capture domain-specific adaptations. The scaling factor controls how much LoRA-modified parameters contribute to weight updates, which prevents excessive deviation from the original model while still enabling domain adaptation.

We apply LoRA modifications to the self-attention layers (query, key, value, and output projections) and the feedforward network layers (gate, up, and down projections), as these components primarily govern contextual representation learning. By fine-tuning these layers while keeping others frozen, we enable F-LoRA-QA to effectively learn botanical domain-specific patterns while retaining the general linguistic knowledge embedded in the base LLaMA model without introducing excessive computational overhead.

To optimize memory usage, we enable gradient checkpointing, which reduces memory consumption during backpropagation and makes fine-tuning feasible on limited hardware resources (an NVIDIA A100 GPU provided by Google Colab). Additionally, we employ AdamW (Loshchilov and Hutter, 2019) optimization with fused gradients to improve training stability and accelerate convergence, ensuring effective adaptation to the botanical QA task while preserving generalization capabilities.

Due to hardware constraints (a single NVIDIA A100 GPU), fine-tuning LLaMA 3.3 70B was infeasible, as it requires multiple high-memory GPUs. LLaMA 2-7B and LLaMA 3-8B were chosen as practical alternatives to balance performance and resource efficiency.

5 Evaluation

To assess the effectiveness of F-LoRA-QA in botanical question-answering, we conduct both automatic and expert-based evaluations. Automatic evaluation quantifies question and answer quality using standard NLP metrics (ROUGE (Lin, 2004), BLEU (Papineni et al., 2002), BERTScore (Zhang et al., 2020)), while expert evaluation assesses five qualitative aspects: Accuracy, Completeness, Relevance, Fluency, and Botanical Terminology Usage.

5.1 Automatic Evaluation

We evaluate F-LoRA-QA by comparing its performance against the base LLaMA models (LLaMA 2-7B and LLaMA 3-8B) without fine-tuning.

We report ROUGE-1, ROUGE-2, ROUGE-L, BLEU, BERTScore, and Exact Match scores for both base and fine-tuned models, including Precision, Recall, and F1 for each. ROUGE and BLEU measure lexical similarity, BERTScore captures semantic similarity, and Exact Match reflects strict answer correctness. We include ROUGE-1, ROUGE-2, and ROUGE-L to capture different granulari-

Metric	Base LLaMA-2	Base LLaMA-3	Fine-tuned LLaMA-2	Fine-tuned LLaMA-3
BLEU	10.99%	2.18%	44.51%	**46.94%**
ROUGE-1 Precision	48.28%	6.75%	76.04%	**79.26%**
ROUGE-1 Recall	51.03%	7.28%	81.84%	**82.26%**
ROUGE-1 F1	44.29%	5.78%	75.37%	**78.23%**
ROUGE-2 Precision	31.2%	4.86%	65.3%	**69.17%**
ROUGE-2 Recall	34.02%	5.19%	70.12%	**71.89%**
ROUGE-2 F1	29.02%	4.23%	64.48%	**68.13%**
ROUGE-L Precision	44.85%	6.59%	73.63%	**77.03%**
ROUGE-L Recall	47.02%	6.96%	79.14%	**79.98%**
ROUGE-L F1	40.97%	5.6%	72.98%	**76.08%**
BERTScore Precision	78.57%	67.31%	91.3%	**92.5%**
BERTScore Recall	79.08%	59.83%	92.64%	**92.83%**
BERTScore F1	78.58%	63.18%	91.8%	**92.54%**
Exact Match	2.01%	0.24%	23.57%	**25.04%**

Table 4: Automatic evaluation results comparing base and fine-tuned LLaMA models on the F-LoRA-QA dataset.

Metrics	Definition
Accuracy	Are the answers factually correct based on the provided context?
Completeness	Do the answers sufficiently address all aspects of the question?
Relevance	Are the answers focused and free of irrelevant details?
Fluency	Are the answers grammatically correct and well-structured?
Botanical Terminology Usage	Are domain-specific terms used correctly?

Table 5: Expert-based evaluation criteria, including their definitions and their scoring system.

ties: unigram overlap (content recall), bigram co-occurrence (local fluency), and longest common subsequence (sentence-level structure).

Although originally designed for summarization and translation, these metrics are widely used in question generation (Du et al., 2017). Since question quality often extends beyond surface-level overlap, BERTScore provides a more flexible evaluation of semantic alignment when wording varies.

Table 4 presents the performance comparison between the base and fine-tuned models across multiple metrics.

5.2 Expert-Based Evaluation

To assess the quality of generated answers beyond automated metrics, we conducted an expert-based evaluation. We selected 100 random samples from the evaluation dataset for expert assessment, focusing on responses generated by the fine-tuned LLaMA 3-8B model, as it achieved the highest performance in automatic evaluation.

The biodiversity expert rated each response on a 1-5 Likert scale across five key aspects: Accuracy, Completeness, Relevance, Fluency, and Botanical Terminology Usage, as defined in Table 5.

Table 6 presents the average scores, indicating that the model performs consistently well across all aspects, with particularly high ratings in Accuracy (4.74) and Botanical Terminology Usage (4.78).

Evaluation Metrics	Average Score
Accuracy	4.74 / 5
Completeness	4.53 / 5
Relevance	4.48 / 5
Fluency	4.48 / 5
Botanical Terminology Usage	4.78 / 5

Table 6: Average expert evaluation scores for responses generated by the fine-tuned LLaMA 3-8B model.

6 Discussion

Exact Match scores remain relatively low, likely reflecting the limitations of strict string matching in a domain where multiple valid paraphrases can exist. As our reference answers, though verified, are not exhaustive, Exact Match likely underestimates correctness.

In contrast, consistently high BERTScores across fine-tuned models indicate strong semantic alignment with reference answers. Improvements in BLEU, ROUGE, and Exact Match after fine-

tuning confirm that **F-LoRA-QA** improves both lexical precision and response relevance.

Since automatic metrics offer limited information on output quality, we conducted expert evaluations covering accuracy, completeness, fluency, and botanical terminology. This provided a more comprehensive validation of the model's outputs.

Although LoRA and instruction tuning are established techniques, their application to French botanical QA is, to our knowledge, novel. **F-LoRA-QA** shows that domain-specific LLM adaptation can support structured trait extraction from floristic texts, addressing a key gap in biodiversity NLP.

Future directions include exploring encoder-only models (e.g., CamemBERT (Martin et al., 2020b)) for trait classification or question filtering, as well as multilingual extension and integration with symbolic reasoning to enhance robustness and interpretability.

Expert evaluation shows competitive performance, with average scores ranging from 4.48 to 4.78 in all metrics (Table 6). Accuracy, completeness, and terminology usage are the model's strengths, while fluency and relevance show room for improvement.

For example, the phrase ***"of this plant"*** in ***"The flowers of this plant are white"*** is redundant and reduces fluency. In terms of relevance, the model sometimes overgenerates information, as in: ***"The reddish style surmounts the 3-celled ovary"*** in response to the question ***"What is the color of the style located at the top of the ovary?"***, where the question asked only for color. In contrast, when questions require multiple details, the model may omit parts of the answer, leading to incompleteness.

These observations highlight opportunities to refine the answer generation strategy.

7 Conclusion

We introduced **F-LoRA-QA**, a two-stage pipeline for French botanical question-answering that fine-tunes LLaMA models using LoRA for efficient domain adaptation. By combining question and answer generation, the system improves information extraction from botanical texts.

Fine-tuning produced notable improvements across BLEU, ROUGE, BERTScore, and Exact Match, with expert evaluation confirming strong performance (4.48–4.78/5), particularly in accuracy and terminology usage.

Although the model is well-adapted for botanical QA, further improvements in fluency are needed. Future directions include instruction tuning, reinforcement learning from human feedback (RLHF), and integrating structured botanical knowledge to enhance answer quality.

Beyond QA, our approach enables systematic taxonomic comparison: Applying a standardized set of questions across species descriptions can surface morphological similarities, thereby offering a scalable method for species identification and evolutionary analysis. This complements traditional biodiversity NLP by introducing automated trait-level comparison.

Limitations

F-LoRA-QA shows strong performance in botanical QA, but a few limitations remain. First, although the training data include texts from multiple floristic regions, the generalization of the model to unseen taxonomic structures or underrepresented traits remains untested. Second, despite high expert-rated accuracy and terminology use, a few answers lack fluency or completeness. The use of QA pairs generated by GPT-3.5, even with human verification, may introduce stylistic biases. Computational constraints limited fine-tuning to LLaMA 2-7B and 3-8B, leaving larger models (e.g., LLaMA 3-70B) unexplored. Finally, the model does not leverage structured botanical resources such as TAXREF or GBIF, which could improve factual grounding and trait comparison.

Addressing these limitations will enhance F-LoRA-QA's robustness and applicability in biodiversity research.

Abstract

Large language models (LLMs) are increasingly being used to interpret and generate human language, yet their ability to process clinical language remains underexplored. This study examined whether three open-source LLMs can infer interviewer questions from participant responses in a semi-structured psychiatric interview (NET) conducted with individuals diagnosed with schizophrenia (n = 107) and neurotypical controls (n = 66). Using cosine similarity between LLM-generated questions and original questions as a proxy for the precision of the inference, we found that responses from individuals with schizophrenia produced significantly lower similarity scores ($\beta = -0.165$, $p < .001$). Cosine similarity decreased across the nested structure of the interview, with smaller reductions observed in the schizophrenia group. Although all emotions decreased similarity with fear, only sadness showed a significant interaction with diagnosis, suggesting differential processing of emotional discourse. Model type and generation temperature also influenced outcomes, highlighting variability in model performance. Our findings demonstrate that LLMs systematically struggle to reconstruct interviewer intent from responses by individuals with schizophrenia, reflecting known discourse-level disturbances in the disorder.

1 Introduction

Schizophrenia is a serious mental disorder that affects approximately 1% of the global population (Hasan et al., 2020; Finnerty et al., 2024). Although about 20% of the people with schizophrenia experience only one psychotic episode (Alvarez-Jimenez et al., 2011), most follow a recurrent or chronic course. The disorder presents with a broad spectrum of symptoms that impact cognition, perception, affect, and motor functions. Moreover, it also involves disturbances in language, both in comprehension (e.g., concretism Bambini et al., 2020) and production (e.g., incoherence, derailment, tangentiality, word approximations, neologisms, stilted speech, poverty of speech, (Andreasen, 1986)). These linguistic symptoms correlate with symptom severity and are integral to clinical assessment and diagnostic processes, as they provide observable markers of the underlying thought disorder. Interestingly, linguistic symptoms have been conceptualized not only in spontaneous speech (e.g., incoherence) but also at the discourse level across multiple turns of question-and-answer exchanges in clinical interviews. Tangentiality refers to responses that are distant, oblique, or seemingly irrelevant to the question asked.

Currently, symptom severity in schizophrenia is typically assessed using standardized rating scales such as the Thought, Language, and Communication scale (TLC, Andreasen, 1986), the Positive and Negative Syndrome Scale (PANSS, Kay et al., 1987), the Scale for the Assessment of Positive Symptoms (SAPS), and the Scale for the Assessment of Negative Symptoms (SANS, Andreasen, 1989). While these instruments are widely used in both research and clinical practice, their use presents several limitations: clinicians and researchers require extensive training to apply them reliably, the assessments are time-consuming, and

Proceedings of Recent Advances in Natural Language Processing,pages 797–806
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-092

they can impose a significant burden on patients. Recent advances in natural language processing (NLP) offer an alternative approach by enabling objective and replicable analysis of linguistic output in individuals with schizophrenia. Several authors have highlighted the potential of NLP-derived linguistic features as candidate biomarkers of psychosis (Corcoran et al., 2020; de Boer et al., 2020), or even as biosocial markers that integrate clinical, cognitive, and social dimensions of the disorder (Palaniyappan, 2021).

In this study, we propose a novel approach to analyze question-answer turns in schizophrenia using LLMs, which currently represent the state of the art in NLP. Unlike traditional NLP methods that rely on predefined linguistic features or hand-crafted rules, LLMs are capable of capturing complex semantic relationships and contextual dependencies in language. By leveraging their capacity to model coherence and relevance across multiple conversational turns, we aim to operationalize a novel linguistic feature in a manner that is both scalable and sensitive to the subtle discourse patterns observed in clinical interactions.

2 Background

2.1 Schizophrenia and NLP

Several prominent NLP approaches currently assess linguistic abnormalities in schizophrenia, targeting vocabulary, syntax, and semantics. Semantic coherence has received the most attention, with generally reduced coherence in patients, though findings vary by methodological choices such as segmentation, embedding type, and illness phase (Corcoran et al., 2020; Parola et al., 2023; Alonso-Sánchez et al., 2022). Lexical diversity findings are mixed, ranging from reduced to increased variability across studies (Voleti et al., 2023; Lundin et al., 2023). Neologisms are rarely explored in NLP-based studies, with only one semi-automated analysis reported (Just et al., 2020). Altered pronoun use—especially increased first-person singular—has emerged as a consistent marker of disrupted self-referential processing (Ziv et al., 2021; Watson et al., 2012; Elleuch et al., 2025). Syntactic complexity appears reduced, particularly in early or high-risk populations, though its predictive value remains unclear (Schneider et al., 2023; Bedi et al., 2015).

In recent years, several approaches have been proposed to quantify semantic divergence between a question and the sentences comprising the response. Elvevåg et al. (2007) introduced a method based on cosine similarity, showing that the slope of a linear regression between sentence position and similarity of consecutive sentences significantly correlated with human ratings of tangentiality in individuals with schizophrenia. Extending this approach, Tang et al. (2021) found that this slope was significantly steeper in individuals with schizophrenia than in neurotypical controls.

Transformer-based language models are currently used primarily to extract contextualized embeddings and assess semantic relatedness between text segments (Tang et al., 2021; Li et al., 2024; Jeong et al., 2023). The application of autoregressive models remains limited. Lawrence et al. (2024) outline three potential domains for large language model (LLM) use in mental health: education, assessment, and intervention. Within assessment, LLMs are proposed to aid in diagnosis and symptom evaluation, including suicide risk and disorganized speech. For example, Pugh et al. (2024) used LLMs to predict clinical ratings from linguistic samples but reported inconsistent results. It is worth noting that such application of LLMs entail unresolved ethical and legal challenges that constrain their clinical integration. A more tractable and ethically acceptable use case may lie in generating synthetic language samples with LLMs, followed by explainable NLP-based analysis. In a notable example, Fradkin et al. (2023) used GPT-2 to simulate language patterns resembling those of individuals with schizophrenia by manipulating generation parameters such as temperature (lexical entropy) and memory span. They showed that higher temperatures or shorter memory spans increased semantic drift between sentences, mimicking aspects of formal thought disorder.

2.2 Model Inversion and Reverse Prompt Engineering

In recent years, several studies have attempted to reconstruct prompts from LLM outputs. Morris et al. (2023) conceptualize this task as language model inversion and show that prompts can be recovered using the next-token probabilities produced by an LLM. Zhang et al. (2024) train a T5-base model with 222 million parameters in an encoder-decoder framework, using a sparse encoder architecture to invert LLM outputs into the prompts that elicited them. Petrov et al. (2024) exploit the low-rank

structure of gradients in the self-attention layers and the discrete nature of token embeddings to efficiently verify whether a given token sequence is part of the client data, demonstrating the reconstruction of entire input batches—raising significant privacy concerns. Sha and Zhang (2024) proposed a prompt stealing attack framework that reconstructs original prompts from language model outputs using two components: a parameter extractor and a prompt reconstructor. The parameter extractor first classifies the original prompt into one of three types: direct prompt, role-based prompt, or in-context prompt. Then, the prompt reconstructor uses a language model to infer the prompt, typically by posing a meta-question such as "What question are you asked if you can generate the following answer?"—this works straightforwardly for direct prompts, while role-based and in-context prompts require additional assembly logic. The quality of the reconstructed prompt is evaluated using cosine similarity with the original.

In contrast to this, Reverse Prompt Engineering (RPE) refers to the task of inferring the original prompt or question based on one or more outputs generated by a language model. Li and Klabjan (2025) proposed three strategies to address this task. The One Answer One Shot approach presents the model with a single output and asks it to infer the corresponding prompt; however, this often results in overfitting to specific details of the answer. In contrast, the Five Answers One Shot method improves robustness by extracting a single prompt based on five different outputs. Finally, the Iterative Approach has the model generate several candidate prompts and refine its selection through comparison, gradually converging on the best match.

2.3 Hypothesis

In this paper, we present a novel adaptation of the reverse prompt engineering technique for application in psychiatric research. Traditionally, reverse prompt engineering involves reconstructing an original prompt based solely on the output generated LLM (Li and Klabjan, 2025). In clinical settings, a trained clinician typically poses a question to a patient. We extend the concept of reverse prompt engineering by using LLMs to infer the original interviewer's question from a participant's response in a semi-structured psychiatric interview. Rather than focusing on prompt reconstruction in a generic NLP context, our approach leverages the LLM's reasoning and comprehension abilities to emulate how an AI listener might interpret a response and infer the most probable preceding question.

We hypothesize that responses from individuals with schizophrenia will lead to reconstructed questions that are semantically more divergent from the original interviewer prompts compared to those generated from responses by neurotypical controls. This divergence may reflect key linguistic disruptions such as tangentiality, derailment, or poverty of content of speech. By quantifying this divergence using established semantic similarity measures, our approach offers a novel and scalable method for assessing disorganized speech patterns in clinical populations.

3 Materials and methods

3.1 Reverse prompting

To implement our modified reverse prompt engineering procedure, we used participants' responses from the Narrative of Emotions Task (NET), a semi-structured clinical interview, as input to three open-source large language models (LLMs) hosted on Hugging Face: LLaMA 3 8B Instruct[1] (AI@Meta, 2024), Mistral 7B Instruct-v0.2[2], and Cohere's Aya 8B[3] (Aryabumi et al., 2024). The goal was to evaluate whether LLMs could accurately infer the original interview question solely based on a participant's answer (see Figure 1). Each model was prompted to generate a plausible interview question for a given response. While the core task was consistent across models, each LLM required slightly different prompt formulations to elicit the desired behavior. For reasons of data protection and compliance with ethical guidelines, we deliberately excluded proprietary models and ensured that all processing occurred locally on an NVIDIA A100 GPU at our institution's HPC.

To assess the stability and diversity of generated outputs, we sampled model responses across a range of temperature values (0.001, 0.2, 0.4, 0.6, 0.8, 1.0). This allowed us to examine how sensitive the reconstruction of questions was to stochastic variation during generation. Across all models and

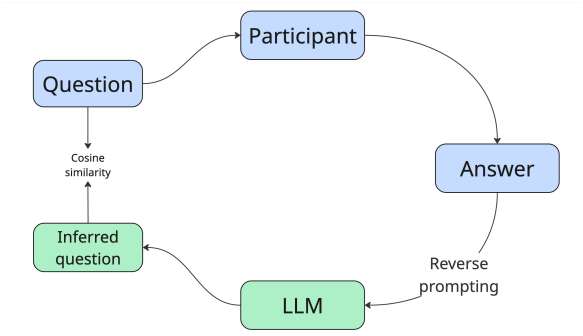

Figure 1: Modification of RPE

temperature settings, we extracted a total of 36,162 reconstructed questions. Both Mistral and LLaMA tended to generate multiple possible inferred questions in response to a single input. For consistency and comparability across models, only the first generated question was selected for further analysis. To evaluate the semantic similarity between the LLM-generated questions and the original NET prompts, we employed Sentence Transformers[4] (Reimers and Gurevych, 2019) to compute cosine similarity between the sentence embeddings of original and reconstructed questions. This similarity metric served as a proxy for measuring the fidelity of question reconstruction.

The following illustration is adapted from a clinical transcript published by Nancy Andreasen in her work on the TLC Scale (Andreasen, 1986). In this example, the participant's response is as follows: "Well, that's a hard question to answer because my parents... I was born in Iowa, but I know that I'm white instead of black so apparently I came from the North somewhere and I don't know—where, you know, I really don't know where my ancestors came from. So I don't know whether I'm Irish or French or Scandinavian or I don't, I don't believe I'm Polish but I think I might be German or Welsh. I'm not but that's all speculation and that, that's one thing that I would like to know and is my ancestors, you know, where did I originate. But I just never took the time to find out the answer to that question." When this response is fed into an LLM with a reverse-prompting instruction, the model infers the question as: "Can you tell me about your family background or ethnic origin?" Although semantically related, the inferred question diverges markedly from the original prompt, which was simply: "What city are you from?" We quantify such semantic drift by computing cosine similarity between the sentence embeddings of original and reconstructed questions, operationalizing tangentiality as the degree of deviation in inferred prompts.

3.2 Participants

A total of 173 German-speaking participants were recruited for the study. Diagnosis was confirmed using the DSM-IV criteria for schizophrenia or schizoaffective disorder. All participants received written and oral information about the project, and written informed consent was obtained prior to inclusion. Descriptive statistics of the sample are presented in Table 1.

3.3 Corpus

We used the Narrative of Emotions Task (NET; (Buck et al., 2014)) to collect speech samples. The NET is a short semi-structured interview with open-ended questions originally developed to assess social cognition. Eliciting speech through (semi-)structured questions is a widely used and cost-effective method in NLP studies (Elvevåg et al., 2007; Just et al., 2020; Iter et al., 2018); it enhances comparability and has been shown to yield more consistent results than analyses of free conversational speech (Morgan et al., 2021). We employed a short version of the NET, translated into German, comprising three questions for each of four basic emotions: sadness, fear, anger, and happiness:

> (1) What does [sadness/fear/anger/ happiness] mean to you?
>
> (2) Can you describe a situation where you felt [sadness/fear/anger/happiness]?
>
> (3) Why do you think you felt this emotion in that situation?

All interviews were conducted by trained clinicians, recorded and automatically transcribed using OpenAI's Whisper-large-v3 model[5] (Radford et al., 2022). The transcripts were manually preprocessed following established protocols to minimize bias in the subsequent analyzes (Iter et al., 2018; Just et al., 2020). Each transcript was anonymized and segmented by emotion. Verbal fillers (e.g., "ehm", "mhm") were removed. The

Control	66	62.8(35.2)	922.3(549.6)

Table 2. Linguistic corpus

3.4 Statistical analysis

To examine group differences in semantic alignment across emotional conditions and conversational turns, we fitted a linear mixed-effects model using the lmer function from the lme4 package in R (R Core Team, 2024; Bates et al., 2015). The dependent variable was cosine similarity, quantifying the semantic overlap between the original NET interview question and the LLM-generated reconstruction via our reverse prompting procedure. Fixed effects included the interactions between group (schizophrenia vs. control) and emotion (joy, sadness, anger, and fear), group and answer-number (1–3), as well as the interaction between model-type and temperature, standardized response length (length-z), and their main effects. To account for repeated measures and subject-specific variability, we included random intercepts for the participant, and for the nested factors participant:model-type, participant:lenght_z, and participant:emotion. Statistical significance of fixed effects was assessed using Satterthwaite's approximation for degrees of freedom, as implemented in the lmerTest package.

4 Results

To this end, we evaluated the cosine similarity between the original questions from a semi-structured interview and the reconstructed questions across 173 participants. Each participant responded to 12 questions, with each response processed by three different LLMs at multiple temperature settings, resulting in a total of 36,162 question pairs. The cosine similarity values ranged from –0.154 to 1.0 (mean = 0.506, SD = 0.267). We visualized the distribution of cosine similarity values for each interview question in a density plot (Figure 3), where each line represents the similarity distribution across all emotions, models, and temperature settings for a given question.

We analyzed cosine similarity using a linear mixed-effects model with random intercepts for participant and participant-level interactions with emotion, model type, and lenght of the linguistic output. Fixed effects included group, emotion, answer number, model type, temperature, and standardized text length, as well as relevant interactions.

Compared to a null model, which included only a random intercept for participant and yielded an AIC of 4203.8 and a BIC of 4229.3, our full model showed a markedly improved fit, with an AIC of -24986.1 and a BIC of -24782.2. A likelihood ratio test comparing the two models confirmed that the full model significantly outperformed the null model, $\chi^2(20) = 29232$, $p < .001$, indicating that the inclusion of the predictors substantially improved the explanation of variance in cosine similarity.

The schizophrenia group showed significantly lower cosine similarity compared to controls ($\beta =$ –0.165, SE = 0.021, $t(838) = -7.79$, $p < .001$). All emotions were associated with reduced cosine similarity relative to the neutral reference: Freude

Predictor	Estimate	Std. Error	df	t value	Pr($>|t|$)

Table 3. Fixed Effects from Linear Mixed Effects Model

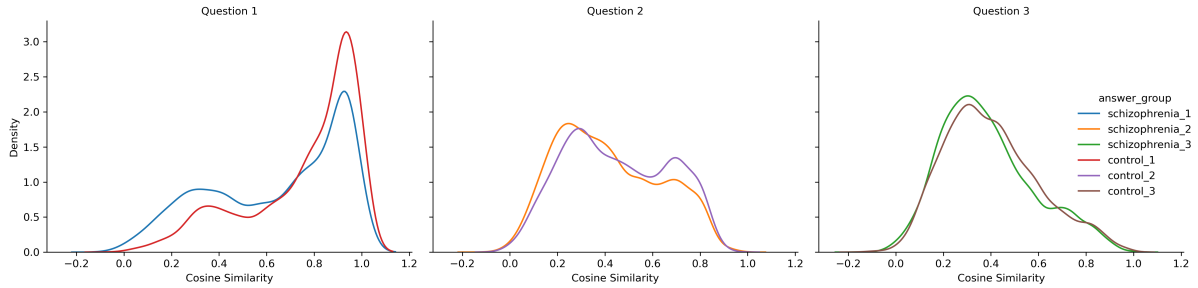

Figure 2: Density plot of cosine similarity values between original and reconstructed questions, grouped by interview question.

($\beta = –0.066$, $p = .001$), Traurigkeit ($\beta = –0.057$, $p = .003$), and Wut ($\beta = –0.058$, $p = .003$). Later answers also showed large decreases in similarity (Answer 2: $\beta = –0.329$, $p < .001$; Answer 3: $\beta = –0.401$, $p < .001$). Figure 3 displays estimated marginal means of cosine similarity across diagnostic groups and interview questions, derived from the fitted linear mixed-effects model.

Model type effects were mixed: Mistral significantly decreased cosine similarity ($\beta = -0.054$, $p < .001$), while LLaMA showed a marginally positive trend ($\beta = 0.011$, $p = .034$). Higher temperature reduced similarity ($\beta = -0.054$, $p < .001$), and longer texts were associated with slightly higher similarity scores ($\beta = 0.015$, $p = .001$).

Significant interactions indicated an increased effect of answer number in the schizophrenia group

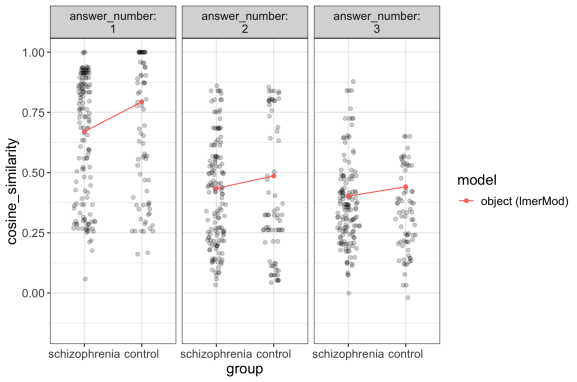

Figure 3: Scatterplot of cosine similarity by diagnostic group and interview question.

(Answer 2: $\beta = 0.091$, $p < .001$; Answer 3: $\beta = 0.154$, $p < .001$). Interactions between schizophrenia and emotion were mostly non-significant, except for Traurigkeit ($\beta = 0.062$, $p = .012$). Model-specific temperature effects were positive for both LLaMA ($\beta = 0.022$, $p < .001$) and Mistral ($\beta = 0.052$, $p < .001$).

Model diagnostics indicated no serious multicollinearity, with all adjusted GVIF values below 2.5, and residual analyses confirmed the assumptions of linearity, homoscedasticity, and normality were adequately met.

5 Discussion

To this end, we evaluated the capacity of three open-source LLMs to infer interviewer questions based solely on participant responses drawn from a semi-structured psychiatric interview. This was implemented using a modified reverse prompting procedure designed to approximate the interpretive process of a clinical listener. By focusing on the output alone—the participant's answer—we assessed the models' ability to reconstruct the likely original question. The inferred questions were then compared to the actual interviewer questions using cosine similarity between sentence embeddings as a proxy for semantic alignment. To examine potential group-level effects, we analyzed similarity scores using a linear mixed-effects model, comparing responses from individuals with schizophrenia to those from neurotypical controls.

Responses from individuals with schizophrenia were associated with significantly lower similarity scores compared to neurotypical controls ($\beta = –0.165$, $p < .001$), indicating a main effect of diagnosis on LLM inference performance. This confirms our central finding: LLM-inferred questions based on responses from individuals with schizophrenia were substantially more dissimilar to the original interview questions than those based on responses from neurotypical participants. This suggests that LLMs struggle more to reconstruct the intended question when processing responses from individuals with schizophrenia, likely due to the greater linguistic variability and atypicality characteristic of their speech. These findings are consistent with prior research showing reduced semantic coherence and weakened alignment between questions and answers in schizophrenia (Elvevåg et al., 2007; Iter et al., 2018; Tang et al., 2021). For instance, Tang et al. (2021) demonstrated a significantly steeper decline in semantic similarity across conversational turns in individuals with schizophrenia using BERT-embeddings, reflecting impairments in discourse-level integration.

Although the group effect is statistically significant, its diagnostic utility remains to be determined. The effect may reflect specific symptoms such as tangentiality or incoherence, which are not uniformly present across individuals with schizophrenia. Future work should examine whether the reverse prompting procedure can differentiate individuals with more pronounced positive formal thought disorder and whether it outperforms or complements existing coherence-based approaches. However, the effect appears too weak to be used as a stand-alone classification feature.

In addition to diagnostic group, several other variables significantly influenced the models' ability to infer interview questions from participant responses. First, the semi-structured NET interview includes three nested questions per emotional topic. Our analysis revealed a stepwise reduction in cosine similarity for the second and third questions, reflecting increased difficulty of the LLMs in inferring later questions in a sequence. However, this reduction was not uniform across groups: a significant interaction between question number and group showed that participants with schizophrenia exhibited a notably smaller drop in similarity across the interview turns. This suggests that the consistently lower cosine similarity in the schizophrenia group reflects a general difficulty for the LLM in inferring interviewer prompts, which remains relatively stable across turns, whereas in the neurotypical group, increasing elaboration or digression across nested responses leads to a sharper decline in similarity.

Second, the emotion discussed also modulated similarity. All emotional prompts resulted in reduced cosine similarity compared to the reference emotion fear, indicating that emotional content poses an additional interpretive challenge for LLMs. Yet, a significant interaction was found only for sadness, where individuals with schizophrenia showed slightly higher similarity scores. This suggests that expressions of sadness in this group may follow more predictable patterns or use more canonical language, enabling the model to better reconstruct the original prompt. These findings align with prior research suggesting that

emotional processing in schizophrenia can vary by affective domain and may be marked by both flattening and stereotypy.

Third, output length had only a marginal effect on similarity scores. This finding is encouraging, as it indicates that our approach is not overly sensitive to verbosity, a common concern when analyzing spontaneous language in schizophrenia. This robustness increases the feasibility of applying such models in real-world settings with variable-length responses.

Finally, model-specific factors influenced performance. The LLaMA model produced slightly higher cosine similarity scores, while Mistral yielded slightly lower scores relative to our baseline model Aya. As expected, higher decoding temperature significantly reduced similarity, reflecting greater generative randomness and less precise reconstructions. These effects underscore the importance of model selection and decoding parameters in applied LLM workflows for clinical language analysis.

Our modified reverse prompting procedure warrants further investigation as a potential feature in classification tasks and relapse prediction in longitudinal settings. Its associations with symptoms such as tangentiality, incoherence, and poverty of speech should also be systematically examined in future research. Taken together, our findings indicate that smaller open-source LLMs face challenges in processing the language of individuals with schizophrenia. As LLMs gain traction in clinical contexts such as psychotherapy, this raises important questions about the need for domain-specific adaptation and the limitations of general-purpose models in psychiatric applications. This underscores the need for domain-specific models tailored to the linguistic characteristics of psychiatric populations. Future work could also explore whether fine-tuning or prompt engineering might enable models to better process the more disorganized or idiosyncratic responses often found in schizophrenia.

Limitations

This study has several limitations. First, we focused only on individuals with schizophrenia and neurotypical controls. Other diagnostic groups in both psychiatry (e.g., acute mania, dementia, autism) and neurology (e.g., post-stroke aphasia) may also produce idiosyncratic responses that could challenge LLMs in a reverse-prompting setting. Second, we relied exclusively on smaller, open-source language models due to privacy constraints, which may not match the performance or capabilities of larger proprietary models. Third, our dataset was relatively homogeneous, consisting solely of German-language responses to a brief, semi-structured interview (NET) with twelve fixed questions, potentially limiting linguistic variability and ecological validity. Fourth, our analysis was restricted to one language, which constrains generalizability to other linguistic or cultural contexts. Additionally, model outputs were sensitive to prompt design and required model-specific tuning, which may affect reproducibility. Finally, the constrained and predictable nature of the dataset may have led models to perform disproportionately well, thereby inflating apparent inferential ability.

Ethics statement

This study was conducted in accordance with the Declaration of Helsinki and approved by the Ethics Committee at [to be filled after review], approval number [to be filled after review]. All participants provided written informed consent prior to participation. All data were anonymized prior to analysis. No proprietary or closed-source models were used; all processing occurred locally to ensure compliance with data protection regulations and institutional guidelines.

Abstract

Small Language Models (SLMs) have become increasingly important due to their efficiency and performance to perform various language tasks with minimal computational resources, making them ideal for various settings including on-device, mobile, edge devices, among many others. In this article, we present a comprehensive survey on SLMs, focusing on their architectures, training techniques, and model compression techniques. We propose a novel taxonomy for categorizing the methods used to optimize SLMs, including model compression, pruning, and quantization techniques. We summarize the benchmark datasets that are useful for benchmarking SLMs along with the evaluation metrics commonly used. Additionally, we highlight key open challenges that remain to be addressed. Our survey aims to serve as a valuable resource for researchers and practitioners interested in developing and deploying small yet efficient language models.

1 Introduction

Although large language models (LLMs) have demonstrated impressive performance on a wide array of benchmarks and real-world situations, their success comes at significant cost. LLMs are resource-intensive to train and run, requiring significant compute *and* data. This often means that they are run on centralized and specialized hardware for both training and inference.

As a response to these challenges, there has been a growing interest in small language models (SLMs). Small language models aim to retain the accuracy and/or adaptability of large language models, while being subject to some constraint(s), such as training or inference hardware, data availability, bandwidth, or generation time. Improving model performance relative to these constraints can then improve downstream goals such as privacy, cost, or the ability to run on consumer devices.

The inherent difficulty of a survey of small language models is that the definitions of "small" and "large" are a function of both context and time. GPT-2, a "large language model" in 2019 at 1.5B parameters, is smaller than many "small" language models covered in this survey. However, although the scale changes, the goals of training small language models remain relatively stable.

In this survey, we explore the architectures, training, and model compression techniques that enable the building and inferencing of SLMs. In addition, we summarize the benchmark datasets and evaluation metrics commonly used in evaluating SLM performance. For this, we propose a novel taxonomy for organizing the methods along two axes:

- The **techniques** used in pre-processing (model architecture), training, and post-processing (model compression) SLMs; and
- The **constraints** the technique is attempting to optimize for, such as inference compute, training time, speed, etc.

An overview of these axes can be found in Table 1 (techniques) and Table 2 (constraints).

It is important to note that progress on any one of these goals does not necessarily imply progress on the others. In fact, there are often trade-offs between them. For instance, memory-efficient

Proceedings of Recent Advances in Natural Language Processing,pages 807–821
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-093

training methods like quantization-aware training (Dettmers et al., 2022a, 2024) are often slower than their full-precision counterparts. However, by using mixed precision to represent the weights and gradients, they allow training or finetuning using less memory. Finally, although there have been several recent surveys on LLMs and their learning methods (Rogers et al., 2020; Min et al., 2021; Zhu et al., 2023; Shen et al., 2023), to the best of our knowledge, this is the first survey focused on SLMs.

Organization of the Survey. This survey is structured into three main sections, each covering a key aspect of optimizing SLMs. **Section 2** focuses on model architectures, including lightweight designs, efficient self-attention approximations, and neural architecture search to efficiently build smaller models. **Section 3** covers efficient pre-training and fine-tuning techniques to enhance performance for SLMs while managing resource constraints. **Section 4** explores model compression techniques, such as pruning, quantization, and knowledge distillation, which reduce model size and latency without sacrificing significant accuracy. **Section 5** introduces an overview of benchmark datasets and evaluation metrics, providing a comprehensive framework for assessing the effectiveness of these methods. **Section 6** discusses the applications that are enabled by SLMs, organized by constraints.

Summary of Main Contributions. The key contributions of this work are as follows:

- A comprehensive survey of existing work on small language models for practitioners. We also survey the problem settings, evaluation metrics, and datasets used in the literature.
- We introduce a few intuitive taxonomies for SLMs and survey existing work using these taxonomies.
- We identify important applications, open problems, and challenges of SLMs for future work to address.

2 Model Architectures

This section discusses the architectural designs for developing SLMs. Specifically, we cover lightweight architectures (Section 2.1), efficient self-attention approximations (Section 2.2), and neural architecture search (Section 2.3).

2.1 Lightweight Architectures

Lightweight language model architectures are designed to achieve efficient performance with fewer parameters and reduced computational overhead, which is ideal for deployment on resource-constrained devices such as mobile phones, edge devices, and embedded systems. Representative lightweight models often follow the encoder-only and decoder-only architectures.

Lightweight encoder-only architectures are mostly optimized versions of BERT (Devlin et al., 2019). For example, MobileBERT (Sun et al., 2020) introduces an inverted-bottleneck structure to maintain a balance between self-attention and feed-forward networks, achieving a 4.3x size reduction and a 5.5x speedup compared to the base version of BERT. DistilBERT (Sanh, 2019) and TinyBERT (Jiao et al., 2019) achieve more than 96% of BERT's performance while being less than 45% smaller and 60% faster by leveraging language modeling, distillation, and cosine-distance losses.

Lightweight decoder-only architectures are designed to scale down autoregressive language models, such as GPT (Radford et al., 2018, 2019) and the LLaMA series (Touvron et al., 2023), into compact and efficient models. These models emphasize knowledge distillation, memory overhead optimization, parameter sharing, embedding sharing to enhance efficiency and scalability. BabyLLaMA (Timiryasov and Tastet, 2023a) and BabyLLaMA-2 (Tastet and Timiryasov, 2024) distill knowledge from multiple teachers into a 58M-parameter model and a 345M-parameter model respectively, demonstrating that distillation can exceed teacher models' performance particularly under data-constrained conditions. TinyLLaMA (Zhang et al., 2024), with only 1.1B parameters, achieves high efficiency by optimizing memory overhead, e.g., via FlashAttention (Dao et al., 2022), while maintaining competitive performance for various downstream tasks. MobilLLaMA (Thawakar et al., 2024) applies a parameter-sharing scheme that reduces both pre-training and deployment costs, introducing a 0.5B-parameter model for resource-constrained devices. MobileLLM (Liu et al., 2024b) investigates the impact of model depth (i.e., number of layers) and width (i.e., number of heads) on performance, effectively conducting a targeted architecture search within a smaller parameter range for language models with millions of parameters.

Table 1: General techniques used for optimizing small language models, categorized by type of model optimization and most central constraints they address.

2.2 Efficient Self-Attention Approximations

Deploying large language models can be challenging due to the substantial number of parameters in the self-attention layers, as well as the computational cost associated with self-attention. In this section, we discuss strategies towards decreasing this computational cost which can ultimately be useful in creating small language models.

Reformer (Kitaev et al., 2020) improves the complexity of the self-attention from $\mathcal{O}(N^2)$ to $\mathcal{O}(N \log N)$ by replacing the dot product attention with one which uses locality-sensitivity hashing. Roy et al. (2021) use a sparse routing module based on an online k-means clustering, which reduces the complexity of the attention computation.

To reduce the computational quadratic complexity of the self-attention layer from $\mathcal{O}(N^2)$ to $\mathcal{O}(N)$, several works, including (Wang et al., 2020a; Katharopoulos et al., 2020; Xiong et al., 2021; Beltagy et al., 2020), propose linear attention mechanisms. In particular, (Katharopoulos et al., 2020) express self-attention as a linear dot-product of kernel feature maps, thus reducing the quadratic complexity. The authors further show that transformers with this linear attention mechanism can be viewed as a recurrent neural network which enables faster inference. Building on these foundations, recent advancements have led to more advanced architectures. Notable examples include Mamba (Gu and Dao, 2023; Dao and Gu, 2024), which introduces a selective state space model with input-dependent transitions, and RWKV (Peng et al., 2023a), which combines elements of transformers and RNNs with a linear attention mechanism. These models not only achieve linear time and space complexity but also demonstrate competitive performance across various tasks. This ongoing trend towards efficient sequence modeling architectures aims to maintain the expressiveness of attention-based models while significantly reducing computational complexity.

Hybrid models that combine the efficiency of SSMs with the recall capabilities of attention mechanisms have also gained attention. MambaFormer (Park et al., 2024) interleaves Mamba-based SSM layers with attention modules, improving in-context learning capabilities. Similarly, Jamba (Lieber et al., 2024) employ sequentially stacked Mamba-Attention layers to enhance performance on long-sequence tasks. Samba (Ren et al., 2024) extends this idea by introducing a block structure that alternates between Mamba, MLP, and SWA layers, achieving constant throughput as sequence lengths increase. Hymba (Dong et al., 2024) further innovates with a hybrid-head architecture combining attention for recall and SSMs for efficient summarization, achieving state-of-the-art efficiency and accuracy for small LMs. These hybrid designs illustrate the effectiveness of combining complementary mechanisms to address the limitations of standalone architectures.

2.3 Neural Architecture Search Techniques

This section discusses automated methods to discover the most efficient model architectures for specific tasks and hardware constraints. Previous research has primarily concentrated on Neural Architecture Search (NAS) for vision tasks (Tan and Le, 2019; Zoph and Le, 2016; Wu et al., 2019; Guo et al., 2020) and BERT models (Xu et al., 2021; Jawahar et al., 2023; Ganesan et al., 2021), as these models have comparatively fewer parameters, which reduces the cost of the search process for efficient architectures. However, models with over a billion parameters pose a significant challenge in searching for smaller, more efficient models.

3 Training Techniques

This section explores training techniques specifically optimized for Small Language Models (SLMs), with a primary focus on how these methods enable efficient training within limited resource environments. A key consideration is the interplay between model size and bit-precision, as a model with a large parameter count at a very low bit-precision may have a similar memory footprint to a model with fewer parameters at a higher bit-precision.

3.1 Low-Resource Pre-training

Low-Precision Training SLMs are designed to operate under strict memory constraints. Therefore, training with extremely low precision allows these models to fit within limited resources. This approach enables significant memory savings, allowing for larger batch sizes or more complex models within the same memory footprint. Automatic Mixed Precision (AMP) with FP16 (Micikevicius et al., 2018) has been widely adopted for its efficiency, but its limited dynamic range can lead to numerical instability. BFLOAT16 (Burgess et al., 2019), with its broader dynamic range, offers greater stability and is particularly effective for smaller batch sizes. Further efficiency gains can be achieved with FP8 formats, supported by hardware like NVIDIA's Hopper architecture. These formats reduce memory usage and accelerate computation but require advanced techniques, such as dynamic scaling, stochastic rounding, and hybrid formats, to maintain numerical stability. Innovations like FP8-LM (Peng et al., 2023b) and methods for scaling FP8 training to trillion-token LLMs (Fishman et al., 2024) demonstrate the effectiveness of these approaches. For even greater savings, integer-based training with INT8 and INT4 formats offers compelling benefits. Techniques like Jetfire (Xi et al., 2024) and INT4 training (Xi et al., 2023) rely on precise quantization to minimize accuracy loss. Emerging methods such as BitNet (Wang et al., 2023) and BitNet-1.58 (Ma et al., 2024), which use 1-bit weights and low-bit activations, achieve extreme memory reductions. It is important to note that the choice of precision—ranging from FP16 to INT4 or 1-bit should be guided by the trade-offs between hardware compatibility, training speed, and model accuracy.

Parallelism Training: SLMs are typically pre-trained across multiple machine nodes to leverage distributed computing resources efficiently. Several system-level optimization techniques have been developed to this end. Zero Redundancy Data Parallelism (ZeRO) (Rajbhandari et al., 2020) offers three progressive stages of optimization, each partitioning more training states across devices: ZeRO-1 partitions optimizer states, ZeRO-2 adds gradient partitioning, and ZeRO-3 further partitions model parameters. PyTorch's Fully Sharded Data Parallel (FSDP) (Zhao et al., 2023) implements similar concepts. These parallelism techniques enable training with larger batch sizes, significantly improving efficiency and scalability for SLMs.

3.2 Fine-tuning Techniques

Fine-tuning on smaller, task-specific datasets allows models to leverage the knowledge gained during pre-training, enabling them to excel in specialized tasks or domains. Fine-tuning techniques are designed to address challenges like limited computing resources, data quality, availability, and robustness, ensuring efficient adaptation to new tasks without extensive retraining.

3.2.1 Parameter-Efficient Fine-Tuning

Parameter-Efficient Fine-Tuning (PEFT) updates a small subset of parameters or adds lightweight modules, keeping most of the pre-trained model's parameters fixed. This approach reduces computational costs during SLM fine-tuning, preserves the model's pre-trained knowledge, minimizes overfitting, and improves flexibility.

LoRA uses low-rank decomposition (Hu et al., 2021), Prompt Tuning (Lester et al., 2021) inserts learnable prompts into inputs, and Llama-Adapter (Zhang et al., 2023b; Gao et al., 2023) adds prompts to LLaMA's attention blocks. Dynamic Adapters

(Kong et al., 2024; Feng et al., 2024; Gou et al., 2023; Liu et al., 2023b; Luo et al., 2024) automatically combine multiple adapters as a mixture-of-experts model to enable multi-tasking and prevent forgetting (Han et al., 2024; Yang et al., 2024).

To further optimize PEFT, some tools combine these techniques with fused kernels for improved performance and resource efficiency. For example, Unsloth (Daniel Han and team, 2023) is a cutting-edge tool that enables fine-tuning of large-scale models up to 5x faster, while reducing memory usage by as much as 80%. By leveraging innovations such as dynamic 4-bit quantization and gradient checkpointing, Unsloth accelerates training without sacrificing accuracy.

3.2.2 Data Augmentation

Data augmentation increases the complexity, diversity and quality of training data, leading to improved generalization and performance on downstream tasks. AugGPT (Dai et al., 2023) rephrases training samples using ChatGPT. Evol-Instruct (Xu et al., 2023) uses multistep revisions to generate diverse, open-domain instructions with increased complexity. Reflection-tuning (Li et al., 2023a, 2024) enhances data quality and instruction-response consistency for instruction tuning by refining both instructions and responses using GPT-4 based on predefined criteria. FANNO (Zhu et al., 2024) augments instructions and generates responses by incorporating external knowledge sources through retrieval-augmented generation. LLM2LLM (Lee et al., 2024b) generates more hard samples based on model prediction on training data during training.

Data augmentation is also effective for synthesizing new data when training data is limited, such as for low-resource languages (Whitehouse et al., 2023), medical and clinical applications (Chintagunta et al., 2021), and privacy-sensitive data (Song et al., 2024), enabling models to generalize better and perform more robustly in constrained settings.

4 Model Compression Techniques

Model compression techniques focus on reducing the size and complexity of large pre-trained language models while maintaining their performance. As a result, these methods are a key approach to deriving SLMs from LLMs. In this section, we propose a taxonomy for model compression that categorizes such techniques by whether they perform pruning (Section 4.1), quantization (Section 4.2), or knowledge distillation (Section 4.3).

4.1 Pruning Techniques

Weight pruning is a model optimization technique that reduces the number of parameters to enhance computational efficiency and lower memory usage, all while maintaining performance levels. We differentiate between two major approaches for pruning: unstructured pruning and structured pruning.

Unstructured pruning removes less significant individual weights, offering fine-grained control and flexibility in reducing model size. For example, to perform irregular pruning on large language models, SparseGPT (Frantar and Alistarh, 2023) reformulates the pruning task as a sparse regression problem, optimizing both the remaining and pruned weights using a layer-wise approximate regression solver. SparseGPT can efficiently handle large-scale models like OPT-175B and BLOOM-176B. Additionally, (Boža, 2024) integrates the ADMM (Boyd et al., 2011) algorithm for weight updates to further mitigate pruning errors. Wanda (Sun et al., 2023) incorporates both weights and activations into consideration during pruning process, and eliminates the need of weight updates. In addition, the n:m pruning strategy (Zhou et al., 2021) brings unstructured pruning to model acceleration by pruning exactly n weights out of every m, balancing pruning flexibility and computational efficiency for significant speedups. NVIDIA's TensorRT leverages such sparse patterns to optimize memory access and reduce computational loads, accelerating inference on GPUs, particularly hardware like the A100. Additionally, the n:m sparse pattern can also be applied in edge AI applications on NVIDIA Jetson Nano to enhance power efficiency and optimize model size. Finally, unstructured pruning often results in sparse matrices requiring specialized hardware or algorithms to maximize computational benefits (Frantar and Alistarh, 2023).

Structured pruning (Wang et al., 2020b; Santacroce et al., 2023; Ma et al., 2023; Tao et al., 2023; Xia et al., 2024; Kurtić et al., 2024) aims to compress LLMs while maintaining performance by removing groups of parameters in a structured manner, which enables more efficient hardware implementation. A major direction in this approach concerns the sparsity of neurons in the model. For instance, Li et al. (2023b) observes prevalent spar-

sity in feed-forward networks. Liu et al. (2023e) proposes using small neural networks for dynamic pruning based on input, termed "contextual sparsity". Mirzadeh et al. (2024) change the activation functions in pre-trained models to ReLU and fine-tune to improve activation sparsity.

Recent work has also addressed the redundancy in the Transformer architecture to achieve reduction of GPU memory usage and speed enhancement (Michel et al., 2019; Voita et al., 2019; Ge et al., 2024). For example, Sajjad et al. (2023); Xia et al. (2022) investigates the layer redundancy for effective structured pruning. We also highlight input-dependent pruning methods, such as contextual sparsity (Liu et al., 2023e) and FastGen (Ge et al., 2024), which should be considered along with the challenges of efficient implementation for optimizing computation and memory.

4.2 Quantization

Quantization is widely adopted to compress LLMs with vast parameter counts. The GPTQ (Frantar et al., 2022) focuses on layer-wise weight-only quantization, using inverse Hessian matrices to minimize the reconstruction error. To fully leverage the benefits of fast integer matrix multiplication, more quantization methods (Liu et al., 2023a; Dettmers et al., 2022b; Kim et al., 2023; Xiao et al., 2023; Yao et al., 2022; Lin et al., 2024; Liu et al., 2023d, 2024a, 2023c; Shao et al., 2023) that quantize both weights and activations are increasingly being adopted for LLMs. AWQ (Lin et al., 2024) and ZeroQuant (Yao et al., 2022) take activation into account to assess the importance of weights, enabling more effective optimization for weight quantization. In addition, for K/V Cache Quantization (Hooper et al., 2024; Liu et al., 2024c; Yue et al., 2024), Key-Value cache is specifically quantized for enabling efficient long-sequence length inference.

Another challenge of activation quantization lies in the outliers that fall outside the typical activation distribution. SmoothQuant (Xiao et al., 2023) smoothes activation outliers by migrating quantization difficulty from activations to weights. SpinQuant (Liu et al., 2024a) introduces rotation matrices to transform outliers into a new space. Recently, quantization-aware training (QAT) methods, such as LLM-QAT (Liu et al., 2023d) and EdgeQAT (Shen et al., 2024b), have gained attention due to the strong performance. Both methods adopt distillation with float16 models to recover the quantizationi error. We also note recent work (Shen et al., 2024a,b; Zeng et al., 2024) that implements the quantized LLMs on mobile devices and FPGAs to demonstrate the effectiveness and efficiency of the weight and activation quantization for LLMs.

4.3 Knowledge Distillation Techniques

In its classical form, knowledge distillation (Hinton et al., 2015) involves training an efficient model, known as the "student," to replicate the behavior of a larger, more complex model, referred to as the "teacher." In this section, we particularly focus on distillation strategies from one or multiple white-box teacher language model to a target student language model.

Babyllama (Timiryasov and Tastet, 2023b) is among the first to develop a compact 58M parameter language model using a Llama model as the teacher. A key finding of this work is that distillation from a robust teacher can outperform traditional pre-training on the same dataset. In a similar vein, (Gu et al., 2024) introduce modifications in the distillation loss, which enables the student models to generate better quality responses with improved calibration and lower exposure bias. Sequence-level distillation loss can also be improved by using a generalized version of f-divergences as shown in (Wen et al., 2023). Liang et al. (2023) extend layer-wise distillation strategies for language models by using task-aware filters which distill only the task specific knowledge from the teacher. Recent works (Wan et al., 2024a,b) show that multiple language models can be fused as a teacher towards distilling knowledge into small language models by strategically merging their output probability distributions.

One of the issues in knowledge distillation for language models is that the distillation strategies are primarily effective when (1) the teacher and the student language model share the same tokenizer and (2) the teacher's pre-training data is available. Boizard et al. (2024) addresses this issue by introducing an universal logit distillation loss inspired from the optimal transport literature. Often distillation is also combined with pruning techniques towards creating smaller language models. For example, (Sreenivas et al., 2024; Muralidharan et al., 2024) show that an iterative step of pruning a large language model followed by retraining with distillation losses, can enable strong smaller models.

Setting	Constraints	Datasets	Metrics
Efficient Inference	Latency	SuperGLUE (Sarlin et al., 2020), SQuAD (Rajpurkar et al., 2016), TriviaQA (Joshi et al., 2017), CoQA (Reddy et al., 2019), Natural Questions (NQ) (Kwiatkowski et al., 2019)	Inference Time (Narayanan et al., 2023), Throughput (Arora et al., 2024)
On-device/Mobile	Memory	TinyBERT (Jiao et al., 2020) and OpenOrca (Lian et al., 2023)	Peak Memory Usage (Lee et al., 2024a), Memory Footprint, Compression Ratio (Cao et al., 2024)
Privacy-Preserving	Privacy	PrivacyGLUE (Shankar et al., 2023), MIMIC (Johnson et al., 2020)	Privacy Budget (Yu et al., 2024), Noise Level (Havrilla et al., 2024)
Energy-Efficient AI	Energy Optimization	-	Energy Efficiency Ratio (Stojkovic et al., 2024), Thermal Efficiency, Idle Power Consumption (Patel et al., 2024)

Table 2: Overview of Settings, Constraints, and Metrics.

Recent advancements have explored methods beyond traditional label distillation by incorporating additional supervision during the distillation process to create smaller language models. Hsieh et al. (2023) find that using "rationales" as an additional source of supervision during distillation makes it more sample-efficient. Moreover, the authors find that the distilled model outperforms large-language models on commonly used NLI, Commonsense QA and arithmetic reasoning benchmarks. In a similar vein, (Dai et al., 2024; Magister et al., 2023; Ho et al., 2023; Fu et al., 2023) distill the reasoning chain from a larger language model to a smaller language model along with the label information. Such distilled models have been shown to possess improved arithmetic, multi-step math, symbolic and commonsense reasoning abilities.

5 Evaluation

Table 2 presents different evaluation settings along with their corresponding datasets and metrics for SLMs. In this section, we focus on the evaluation metrics for SLMs. These settings and metrics are organized according to the constraints they address for SLMs.

Latency Two key metrics to evaluate latency are inference time (Narayanan et al., 2023) and throughput (Arora et al., 2024). Inference time measures how quickly a model can process input and generate an output, which is crucial for user-facing applications that require immediate feedback. Throughput, on the other hand, evaluates the number of tokens or samples a model can process in a given period, making it especially relevant for large-scale tasks or time-sensitive applications.

Memory When deploying models in memory-constrained environments, memory efficiency becomes a primary consideration. Metrics such as peak memory usage (Lee et al., 2024a) capture the highest amount of memory the model consumes during inference. Similarly, memory footprint and compression ratio (Cao et al., 2024) are used to measure how compact a model is and the efficiency of the compression techniques applied, enabling models to operate within memory constraints without sacrificing performance.

Privacy Privacy budget (Yu et al., 2024), a measure rooted in differential privacy, quantifies the model's ability to protect sensitive information during both training and inference. Alongside this, noise level (Havrilla et al., 2024) measures the trade-off between privacy and accuracy by assessing how much noise is added to ensure privacy while maintaining the model's performance.

Energy Optimization The energy efficiency ratio (Stojkovic et al., 2024) evaluates the energy used relative to the model's overall performance, providing insights into how energy-intensive an SLM is in practice. Other metrics, such as thermal efficiency and idle power consumption (Patel et al., 2024), measure the energy consumed when the model is either actively processing tasks or idle, which is crucial for long-term deployment in energy-constrained environments like embedded systems or mobile devices.

6 Applications

In this section, we consider applications of SLMs, that is, specific use-cases like translation and auto-completion.

6.1 Real-Time Interaction

GPT-4o, released in May 2024, processes text, vision, and audio input end-to-end and is faster than GPT-4 Turbo (OpenAI, 2024). The demonstration involved responses in the style of human conver-

Category	Application	Description	Need for SLM Application	Inference Runtime	Memory	Storage Space	Latency	Comm. Overhead
4*Real-Time Interaction	**Chatbots**	Handle frequent queries and basic troubleshooting.	Real-time response needed, lightweight	✓	✓		✓	✓
	Voice Interfaces	Used in voice assistants and dictation tools.	Low latency required for real-time	✓	✓		✓	
	Translation	Basic translation between languages.	Real-time translation with low-resources	✓	✓		✓	✓
5*Content Generation	**Text Summarization**	Summarize articles and reports.	Faster inference, minimal resource use	✓	✓	✓	✓	
5*& Processing	**Sentiment Analysis**	Assess customer sentiment across platforms.	Efficient analysis in low-resource envir.	✓	✓	✓	✓	
	Text Classification	Filter emails, classify content.	Low latency, on-the-fly processing	✓	✓	✓	✓	
	NLP for Search	Improves search engine functionality.	Low latency for real-time search	✓	✓		✓	
	Autocompletion	Suggest completions in IDEs or text editors.	Fast prediction with low memory	✓	✓	✓	✓	

Table 3: Taxonomy of Applications of Small Language Models.

sation. LLaMA-Omni combine a speech encoder, adaptor, LLM, and streaming decoder to enable real-time interaction with speech input based on LLaMA-3-8B-Instruct (Fang et al., 2024). Emotionally Omni-present Voice Assistant, or EMOVA, apply LLaMA-3.1-8B as an end-to-end speech model that can generate poems and describe images at the user's request. Google Deepmind's Project Astra uses Gemini to process audio and video information from a smartphone or glasses and respond to respond to queries like mathematics problems and memorize object sequences (Deepmind, 2024).

6.2 Content Generation and Processing

LLMR uses LLMs in mixed reality to generate and modify 3D scenes. It combines language models used in several roles - a Scene Analyzer GPT to summarize objects and give further details like color, Skill Library GPT to determine what is required to fufill a user's request, Builder GPT to generate code for the request, and Inspector GPT to evaluate its code (Torre et al., 2024). DreamCodeVR assists users in editing an application in the Unity engine through code generation (Giunchi et al., 2024; Juliani et al., 2020). This permits users to edit VR applications without requiring extensive programming knowledge.

6.3 Edge Inference and Privacy

On-device LLMs maintain usability even when MobileLLM improve on various chat benchmarks and performs comparably with LLaMA-2-7B in API calling (Liu et al., 2024b). Apple Intelligence applies an 3B parameter model to perform on-device inference for a broad range of tasks, such as text and notification summarization, image and emoji generation, and code completion for XCode (Gunter et al., 2024; Research, 2024). On-device inference reduces latency as measured by the time to first generated token (Hu et al., 2024; Gerganov). HuatuoGPT is a domain-adapted LLM for medical dialogue and BioMistral is an LLM tailored for biomedical work (Zhang et al., 2023a; Labrak et al., 2024). Applications related to medicine may need to adhere to stringent privacy regulations and represent a promising area for future work. TalkBack with GeminiNano assists blind and low vision people by describing and captioning images and runs on Android devices (Team, 2024). On-device inference makes this technology usable without an internet connection.

Mixture-of-Experts can reduce inference cost by using a gating network to use only a subset of layers during inference time (Shazeer et al., 2017). Google's GLaM uses mixture-of-experts (Du et al., 2022) but is a 1.2T parameter model. EdgeMoE extend misture-of-experts to edge computing using an Nvidia Jetson TX2 and Raspberry Pi 4B, with the latter device being CPU-only (Sarkar et al., 2023). Based on experimental findings that most weights contribute little to the final computation, the authors compress weights and predict the relevant experts in advance.

7 Conclusion

This paper has provided an extensive survey of Small Language Models (SLMs), covering a wide range of topics including model architectures, training methodologies, and model compression techniques that are crucial for optimizing SLMs. We hope that this survey will serve as a valuable resource for both researchers and practitioners working on SLMs.

Quantifying the Overlap: Attribution Maps and Linguistic Heuristics in Encoder-Decoder Machine Translation Models

Abstract

Explainable AI (XAI) attribution methods seek to illuminate the decision-making process of generative models by quantifying the contribution of each input token to the generated output. Different attribution algorithms, often rooted in distinct methodological frameworks, can produce varied interpretations of feature importance. In this study, we utilize attribution mappings derived from three distinct methods as weighting signals during the training of encoder-decoder models. Our findings demonstrate that Attention and Value Zeroing attribution weights consistently lead to improved model performance. To better understand the linguistic information these mappings capture, we extract part-of-speech (POS), dependency, and named entity recognition (NER) tags from the input-output pairs and compare them with the XAI attribution maps. Although the Saliency method shows greater alignment with POS and dependency annotations than Value Zeroing, it exhibits more divergence in places where its attributions do not conform to these linguistic tags, compared to the other two methods, and it contributes less to the models' performance[1].

1 Introduction

The remarkable advancements in machine learning have led to increasingly sophisticated and robust models. However, this progression towards larger and more complex architectures, often referred to as 'black boxes', has come at the cost of transparency (Xu et al., 2019; Arya et al., 2019; Vieira and Digiampietri, 2022; Saeed and Omlin, 2023). As a result, interpreting the internal decision-making processes of these systems has become progressively more challenging (Jacovi and Goldberg, 2020). To improve our understanding of these models, researchers have turned to XAI methods, which aim to provide greater transparency and facilitate more interpretable outcomes (Lipton, 2018). A key approach in XAI involves attribution methods, which seek to identify and quantify the contribution of individual input features to a model's prediction (Sundararajan et al., 2017a; Wallace et al., 2019; Madsen et al., 2022).

In this work, we explore XAI attribution methods in Transformer-based (Vaswani, 2017) Sequence-to-Sequence (seq2seq) models, which are predominantly based on the encoder-decoder architecture (Sutskever, 2014). Encoder-decoder architecture is a common pipeline in many NLP tasks, such as machine translation, text summarization, and dialogue generation. The literature has focused more on attribution methods in simpler classification tasks (Lal et al., 2021; Attanasio et al., 2023), and comparatively less attention has been given to generative seq2seq models. In the context of seq2seq models, attribution methods aim to identify which parts of the input sequence were most influential in generating each segment of the output sequence (Sarti et al., 2023). In machine translation (MT), several studies have sought to quantify and compare the word alignments produced by statistical models such as GIZA++ (Och and Ney, 2003) or annotated alignments (Ding et al., 2019; Li et al., 2019; Chen et al., 2020).

To obtain the attribution of features or tokens, several methods have been proposed. Approaches such as Saliency maps (Simonyan et al., 2013), Integrated Gradients (Sundararajan et al., 2017b), and DeepLIFT (Shrikumar et al., 2017) analyze the gradients of the output with respect to the input embeddings. These approaches are called post-hoc methods, in which the model behaviour is extracted after the training process (Arrieta et al., 2020). In these methods, higher gradient values indicate greater importance of the corresponding input feature. Perturbation-based methods involve

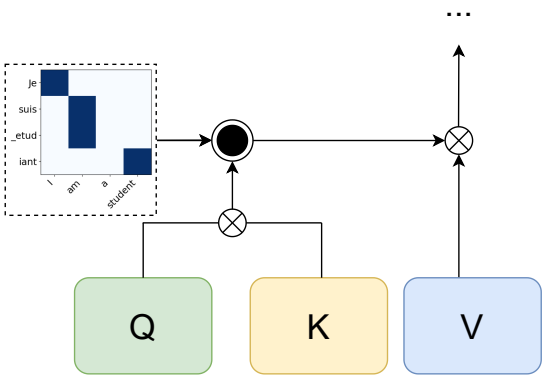

Figure 1: After the extraction of the attribution maps, we integrate this information into the attention mechanism throughout the training and testing processes.

systematically altering parts of the input sequence (e.g., masking or replacing) and observing the impact on the output (Ivanovs et al., 2021). Significant changes indicate the importance of the perturbed elements. On the other hand, the attention mechanism is an inherent, model-based interpretable component (Bahdanau et al., 2016), although some studies have questioned whether its representations truly reflect the model's decision-making process (Serrano and Smith, 2019).

Having obtained attribution maps from XAI methods, evaluating their faithfulness and validity remains a challenging task (Nielsen et al., 2023; Kamath et al., 2024). How do we know if an attribution map is truly reflecting the model's reasoning? This work is based on the premise that distinct attribution methods generate unique sets of scores. We consider these scores to be informative weights, signifying that each method captures a distinct perspective on how input tokens contribute to the model's output. We conjecture that these weights can be integrated with the model as external knowledge, and their effects can be measured in terms of the output performance. Additionally, our approach raises questions about the nature of the extracted relations. Do attribution maps capture surface-level statistical associations, or do they correspond to deeper, linguistically meaningful relationships, such as those indicated by POS and dependency structures? Considering these questions, we outline our contributions:

- We evaluate and compare three attribution methods, each representing a distinct category, to measure their effects on four machine translation tasks.
- We propose an approach to construct semantic and syntactic mappings between source and target sequences.
- We use the extracted linguistic information to compare XAI-based attribution methods in terms of the knowledge they encode.

2 Related work

2.1 Evaluation of XAI methods

There are various ways to evaluate XAI approaches. One common strategy is human judgment, which assesses whether the explanations produced by XAI methods align with human intuition and expectations (Kim et al., 2024; Lopes et al., 2022). However, human evaluation is costly and time-consuming. Notable automatic evaluation techniques for attribution maps have been developed in the context of image classification (Ribeiro et al., 2016; Hooker et al., 2019; Nauta et al., 2023) as well as NLP (Madsen et al., 2022; Moradi et al., 2021), where researchers mask or isolate or keep only the highlighted regions during training or testing. These approaches operate under the assumption that the marked attributions correspond to important features that affect the model's performance.

In the context of MT Li et al. (2019); Chen et al. (2020) have tried to understand if NMT models capture traditional word alignment between source and target words. Key findings indicate that while NMT models capture alignment information and dedicated alignment objectives, hybrid models often enhance both translation accuracy and alignment reliability. Zenkel et al. (2020) They address the challenge of word alignment induction in NMT, specifically with Transformer architectures. While previous research indicated that Transformer attention weights yield poor alignments, this study demonstrates that attention can produce accurate alignments when extracted at the appropriate decoding step. Ding et al. (2019) more interestingly, they use Saliency and SmoothGrad methods to induce the word alignment. Experimental results reveal that, especially under force decoding, their proposed methods can yield higher-quality alignments than traditional tools like fast-align (Dyer et al., 2013), highlighting the latent alignment capabilities of NMT systems. On the other hand, Ferrando

and Costa-jussà (2021) present an in-depth analysis of attention weights in Transformer-based NMT models. Their study finds that encoder-decoder attention weights systematically make alignment errors and often focus on uninformative source tokens rather than accurately aligning corresponding words between sequences.

A closer work to ours is done by (Li et al., 2020), where they train surrogate models to predict words based on a window of highest attribution tokens extracted from XAI methods. The current work differs in that we measure the influence of attribution methods directly within the NMT task.

2.2 Attribution Methods

Saliency: Saliency computes gradients of the output with respect to the input to generate a Saliency map, highlighting influential features (Simonyan et al., 2013). For an input x and a model $f(x)$ that outputs a score for a class c, the Saliency $S(x)_i$ for the i-th input feature is often computed as the magnitude of the gradient of the output with respect to that input feature:

$$S(\mathbf{x})_i = \left| \frac{\partial f_c(\mathbf{x})}{\partial x_i} \right|$$

Attention: In the Transformer model, attention is a mechanism that allows the model to weigh the importance of different tokens in an input sequence when encoding or decoding at each position (Vaswani, 2017). Specifically, for each token, the model computes three vectors of query, key, and value by projecting the token's embedding through learned weight matrices. Attention scores are obtained by taking the dot product of each query with all keys, scaling and normalizing via a softmax to produce weights that reflect how much one token should "attend" to another:

$$\text{Attention} = \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right)V$$

Value Zeroing: Value Zeroing is a novel method to analyze how information is integrated across tokens within Transformer models. This approach overlooks the significant roles of other components, such as feedforward networks, in the encoder block. Value Zeroing addresses this by zeroing out the value vectors of specific tokens during the forward pass, which in turn allows for an assessment of each token's contribution to the model's output. The effect is calculated by determining the distance between a changed output representation of token $\tilde{x}_i^{\neg j}$ where $\tilde{x}_i^{\neg j}$ is calculated by removing token j's value vector (Mohebbi et al., 2023):

$$C_{i,j} = \text{cosine}(\tilde{x}_i^{\neg j}, \tilde{x}_i)$$

Inseq is a Python library that provides a comprehensive tool for analyzing and comparing different explainability methods of generative language models (Sarti et al., 2023). The library offers a range of gradient-based, perturbation-based, and internal representations of the encoder-decoder transformer models.

3 Methodology

To evaluate each of these XAI methods, we use a dataset of source and target pairs and apply the attribution technique to a pre-trained model, deriving a 2D matrix that captures the contribution of each input token to the output tokens. $\left(s_{\text{src}}^{(i)},\ s_{\text{tgt}}^{(i)}\right) \xrightarrow{\text{Attribution}} \left(s_{\text{src}}^{(i)},\ s_{\text{tgt}}^{(i)},\ e^{(i)}\right)$. Then the result is a triplet of source, target, and explanation mapping, which we then use to train and test an untrained model.

For the Saliency method, this gradient-based approach yields a tensor $e \in \mathbb{R}^{j \times k \times l}$, where j is the input sequence length, k is the output sequence length, and l is the hidden dimension of the model as the gradient is calculated for each dimension of the input token vector. We compute the ℓ_2-norm along the last dimension to reach $e \in \mathbb{R}^{j \times k}$ for the attribution of each input token with respect to the output token at position k. ℓ_2-norm measures the length or magnitude of a vector in a Euclidean space.

For Attention, the scores are calculated for each head and for each layer of the cross-attention weights. As a result, the output of the attention score is $e \in \mathbb{R}^{j \times k \times n \times h}$, where n and h are the number of layers and heads respectively. We get the average over the last two axes of the representation to reach the same $e \in \mathbb{R}^{j \times k}$ representation. Likewise, Value Zeroing is calculated by measuring the effect of replacing the value vector of x_i with a zero vector on all layers, so the output $e \in \mathbb{R}^{j \times k \times n}$. We get the average of the scores along the last dimension. In all cases, we reach the mapping of values indicating the weight of the connection between the output tokens and each individual input token.

To identify the single most 'attributing' token in each row of the attribution map, we first apply a

row-wise softmax:

$$S_{jk} = \frac{\exp(X_{jk})}{\sum_{m=1}^{K} \exp(X_{jm})}$$

So that each row J of S sums to 1 across columns. We then form a one-hot mask $e \in \{0,1\}^{j \times k}$ by setting

$$E_{jk} = \begin{cases} 1, & \text{if } k = \arg\max_m S_{jm}, \\ 0, & \text{otherwise.} \end{cases}$$

Taking the argmax of the attribution factors is a common approach for converting the soft scores of attribution maps into hard scores (Garg et al., 2019; Chen et al., 2020).

In the attention head, the dot product of Q and K determines how relevant each word query is to the key of all other tokens in the sequence. To incorporate this information into the attention mechanism, we utilize the Q, K, V matrices as usual, and inject the attribution masks $\mathbf{E}$ as follows:

$$\text{Attention} = \text{softmax}\left(\frac{QK^\top}{\sqrt{d_k}} \odot \mathbf{E}\right) V \quad (1)$$

Here $\odot$ denotes element-wise multiplication and $\mathbf{E}$ is broadcasted (i.e., 0 padded) to match the shape of the attention logits. One should pay attention as the attributions are binary numbers; multiplying by binary matrices simply zeroes the product of the dot product at positions where $E_{jk} = 0$ before the softmax. This operation has been done only on the encoder self-attention.

4 Model and Data

Throughout our experiments, we used the Huggingface implementation of Opus-MT[2] to extract the attributions and train the models from scratch. To get the attribution mappings according to the XAI methods, we used the Inseq (Sarti et al., 2023)[3] library to derive the mappings for each language pair.

To evaluate our approach, we used 200,000 samples from the French→English (fr-en), German→English (de-en) (Bojar et al., 2014), Spanish→Italian(es-it), and English→Danish (en-da) (Koehn, 2005) language pairs. We selected samples with fewer than 128 tokens to ensure efficient training and evaluation of our models from scratch. We reserved 15,000 samples for evaluation and testing for each language pair. The models were trained for 20 epochs, with early stopping triggered after three epochs without improvement on the evaluation set. As a baseline, we used models without attribution merging (vanilla models). Our models matched the original Opus-MT configuration, using six attention layers and eight attention heads. In all experiments, the injected attribution information was incorporated into every layer of the encoder self-attention. To evaluate our models, we used the BLEU score throughout the experiments.

5 Results

5.1 Effect of Attribution Injection on Model Output

The results in Table 1 show that incorporating attribution maps into the attention mechanism significantly improves performance across various language pairs. The Attention and Value Zeroing methods consistently yield better results compared to both the Saliency approach and the baseline model. For instance, the fr-en and es-it pairs see approximately a 10-point increase when using the Attention and Value Zeroing attributions merged. The gaps are even wider for the en-da pair for the Attention attributions.

Moreover, the Value Zeroing method (except for en-da) closely matches the Attention method's performance. This suggests that possibly Value Zeroing and Attention may capture similar attribution patterns. In contrast, the Saliency method offers only modest gains over the baseline in fr-en and en-da pairs and generally lags behind the other two methods. These findings highlight the substantial benefit of attribution-informed adjustments to the attention mechanism, which enhance translation quality across multiple language scenarios, as well as a comparison between the methods from which these attributions are derived.

5.2 Encoded Information

As the result suggested, when these attribution maps are merged with sentence pairs during both training and testing, we see a significant improvement in the evaluation metric. This consistent increase across all evaluated language pairs suggests that attribution-guided signals provide the model with valuable cues for sequence alignment and

Language Pair	Saliency	Attention	Value Zeroing	Baseline
fr-en	**30.02**	**40.00**	**39.95**	28.79
es-it	29.07	**36.74**	**38.40**	29.05
de-en	16.74	**22.41**	**23.69**	16.85
en-da	**15.43**	**38.67**	**26.35**	13.93

de-en	**21.05**	15.14	15.41	16.85
en-da	**21.94**	13.82	11.60	13.93

Table 2: BLEU score results of the baseline and merging POS, DEP, and NER tags to the encoder-decoder model.

translation quality. Such improvements highlight the utility of incorporating interpretability tools not just for model understanding but as active components in enhancing model behavior. However, this observation raises an important question regarding the nature of the information captured by these attribution maps. What exactly do these attribution mappings encode that leads to such performance gains? It is plausible that these attribution methods highlight linguistically meaningful correspondences between source and target tokens or capture subtle contextual dependencies. Understanding whether the injected attributions reflect lexical alignments, semantic equivalence, or more abstract relationships could provide insights into the mechanisms underlying improved performance.

To further investigate the nature of the linguistic insights captured by attribution maps, we propose examining their overlap with explicit linguistic annotations. Specifically, we aim to identify whether the information encoded by attribution-based mappings aligns with syntactic and semantic relationships represented through linguistically informed matrices. To accomplish this, we employ SpaCy[4] to annotate our datasets, extracting Part-of-Speech (POS) tags, dependency parsing relationships (DEP), and Named Entity Recognition (NER) labels.

Formally, given a source sentence $S = (s_1, \ldots, s_J)$ and a target sentence $T = (t_1, \ldots, t_K)$, we construct binary matrices to encode these linguistic annotations explicitly. For each annotation type, we define a binary matrix $\mathbf{L} \in \mathbb{R}^{J \times K}$ such that each element is computed as:

$$\mathbf{L}_{jk} = \begin{cases} 1, & \text{if tags of } s_j \text{ and } t_k \text{ match,} \\ 0, & \text{otherwise.} \end{cases} \quad (2)$$

To account for the subword tokenization commonly done in the transformer models, we assign the tag of the untokenized token to each subtoken. As a result, our derived linguistic tags are not one-hot encoded[5]. In the next step, we train our models with the same setting, but instead of injecting the attribution maps, we provide the models with the POS, DEP, and NER mapping of the source and target pairs.

Table 2 presents the outcomes of incorporating linguistic knowledge during both training and testing of the model. For the French-English (fr-en) and Spanish-Italian (es-it) pairs, integrating part-of-speech (POS) and dependency (DEP) tags leads to the most significant improvements over the baseline, as indicated by the bolded scores in those columns. These results suggest that, for Romance language pairs, syntactic information is particularly valuable for enhancing the performance of encoder-decoder models. In the German-English (de-en) setting, improvements are more modest and only happen for the POS tags alignment. For en-da, multiplying DEP and NER information does not yield improvements; in fact, it reduces performance, while POS tagging provides a marginal gain similar to de-en.

[4]https://spacy.io/

[5]We use a heuristic to assign the tag to each subword. The Opus-MT tokenizer does not provide the offset mapping.

German, Spanish, English, and Italian differ in this respect due to their morphological characteristics. German is a morphologically rich language characterized by extensive inflection. Furthermore, German exhibits complex word formation through processes like compounding, where multiple morphemes fuse to create new lexical items (Günther et al., 2019). Assignment of a tag to all the subwords most likely dilutes the fine-grained specific attention weight required for extracting better attributions. We guess that this leads to a lower gain compared to other language pairs.

In all cases, incorporating NER information resulted in a decrease in performance. This is most likely because NER tags are less frequent than POS and DEP tags. When NER information is unavailable for certain tokens, multiplying by a zero matrix leads to a loss of signal, thereby reducing overall model performance.

Quantifying overlap. After observing the impact of linguistic annotation on model performance, we aimed to quantify the extent to which attribution methods overlap with each linguistic tag. To this end, we measure the recall to quantify this overlap. Let $\mathbf{T} \subseteq \{1, \ldots, N\}$ denote the set of positions annotated with a specific linguistic tag, and $\mathbf{A} \subseteq \{1, \ldots, N\}$ denote the set of positions identified by the attribution method in linearized matrices. We calculate the recall as follows:

$$\text{Recall} = \frac{|\mathbf{T} \cap \mathbf{A}|}{|\mathbf{T}|}$$

Table 3 presents the recall scores quantifying the overlap between each attribution method and the linguistic tags. One immediate observation is the consistently low recall for the NER tags across all methods and language pairs, typically below 3.0. This likely reflects the low frequency of named entity tokens relative to POS and dependency tags. Notably, NER also did not contribute to improved model performance and evaluations with this information. However, still, Attention attributions overlap more with the NER tags than the other two XAI methods.

In contrast, POS and DEP tags demonstrate substantially higher coverage by the attribution maps, especially for Attention and Saliency methods. For example, for the fr-en language pair on POS tags, Attention achieves a recall of 26.56, while Saliency achieves 25.30. DEP has the lowest recall scores for de-en compared to other languages. The Value Zeroing method tends to show lower and more varied coverage compared to Attention or Saliency.

However, these recall values merely reflect where the attributions overlap with the annotated indices. Notably, Saliency overlaps more with POS and DEP, yet, as earlier results showed, Saliency does not enhance the model's performance. To further investigate, we also calculated the recall for pairs of attribution methods (reported at the bottom of Table 3). Here, Attention and Value Zeroing exhibit closer recall scores across all languages, whereas the gap between Attention and Saliency, as well as Value Zeroing and Saliency, remains wider. This pattern suggests that while Saliency covers a greater portion of POS and DEP information, possibly where they don't overlap, it has a degrading effect and potentially introduces noise, diminishing its contribution to model performance.

6 Discussion and Conclusion

In this study, we investigated the impact of three attribution mapping methods for seq2seq models, each designed to quantify the contribution of individual input tokens to the generation of output tokens. We also extracted linguistic information, specifically, part-of-speech (POS), dependency (DEP), and named entity (NER) tags, for both the source and target languages and aligned them together. By identifying and aligning tokens with matching tags across source and target sentences, we constructed a heuristic mapping to serve as a proxy for cross-lingual token alignment. This mapping was subsequently used as a form of knowledge injection to train new models from scratch.

Our results demonstrate that both Attention-based and Value Zeroing attribution mappings consistently enhance model performance, as measured by the BLEU score, compared to the gradient-based Saliency method. Additionally, the integration of dependency and POS tag mappings in fr-en and es-it led to an improvement of the results, but for de-en and en-da, only POS tags increased the performance.

While both Attention and Saliency methods exhibited higher overlap with POS and DEP information, the relatively lower correspondence between Saliency and the other two attribution methods suggests that Saliency highlights input regions that may dilute the effectiveness of where it covers POS and DEP information, ultimately resulting in diminished performance compared to Attention and

Pairs	fr-en	es-it	de-en	en-da
Attention-POS	26.56	41.16	32.89	37.44

Table 3: Recall scores for different attribution methods across language pairs, indicating the overlap with POS, DEP, NER tags, and other attribution methods.

Value Zeroing approaches.

These results are noteworthy from several perspectives. First, the location where these mappings are merged is itself of interest. While self-attention in the encoder is generally designed to map information from input to input, introducing meaningful information from the output to the input can alter the model's predictive power. Second, in cases where the encoded information is insufficient (e.g., NER or Saliency), the changes in performance compared to the baseline are minimal. This latter point aligns with the observations of Wiegreffe and Pinter (2019), who noted that models can still learn effectively under noisy attention. However, when attention was provided with well-encoded information, it had the potential to significantly enhance the model's predictive performance.

7 Future work

For future work, we suggest exploring the integration of additional linguistic features that capture finer-grained commonalities such as gender, number, or morphological characteristics at a more granular token level. Incorporating these attributes could further refine the mapping between source and target languages. Also, we used one-hot encoded attribution mappings. It would be interesting to conduct the same experiments by assigning 1 to the k highest attribution values.

Finally, in this study, we relied on external models to extract both attribution mappings and linguistic tags, which proved effective in improving model performance in the case of POS. However, our current approach still requires access to these annotations during inference. A promising direction for future research would be to enable the models to internalize and learn these attributions or linguistic patterns during training, hence eliminating the need for explicit extraction and application of these features at test time. Such an approach can be found in Bai et al. (2022).

Abstract

Evaluating Natural Language Generation (NLG) is crucial for the practical adoption of AI, but has been a longstanding research challenge. While human evaluation is considered the de-facto standard, it is expensive and lacks scalability. Practical applications have driven the development of various automatic evaluation metrics (AEM), designed to compare the model output with human-written references, generating a score which approximates human judgment. Over time, AEMs have evolved from simple lexical comparisons, to semantic similarity models and, more recently, to LLM-based evaluators. However, it seems that no single metric has emerged as a definitive solution, resulting in studies using different ones without fully considering the implications. This paper aims to show this by conducting a thorough examination of the methodologies of existing metrics, their documented strengths and limitations, validation methods, and correlations with human judgment. We identify several key challenges: metrics often capture only specific aspects of text quality, their effectiveness varies by task and dataset, validation practices remain unstructured, and correlations with human judgment are inconsistent. Importantly, we find that these challenges persist in the most recent type of metric, LLM-as-a-Judge, as well as in the evaluation of Retrieval Augmented Generation (RAG), an increasingly relevant task in academia and industry. Our findings challenge the quest for the 'perfect metric'. We propose selecting metrics based on task-specific needs and leveraging complementary evaluations and advocate that new metrics should focus on enhanced validation methodologies.

1 Introduction

Evaluation of Natural Language Generation (NLG) models is essential to ensure their quality and usefulness in various real-world applications (Celikyilmaz et al., 2020). As AI adoption expands, the importance of robust evaluation methods increases significantly (Novikova et al., 2017). However, assessing NLG outputs remains a challenging task (Gehrmann et al., 2023). The standard approach to date is evaluating models' outputs through human judgment, but due to the high costs and limited scalability, the development of Automated Evaluation Metrics (AEM) has been pursued as an alternative (Clark et al., 2021). Traditionally, the supervised approach involves comparing model-generated text with a human-written reference. It assigns a similarity score based on the assumption that a higher similarity indicates a better quality of the output. Furthermore, because the score is considered meaningful, it is expected to serve as a good proxy for human judgment. This reliability is typically assessed by measuring the correlation between metric scores and human evaluations of the generated texts (Belz and Reiter, 2006; Coughlin, 2003).

Evaluation metrics have been developed for decades while, simultaneously, demands have increased. Model architectures have become more advanced and complex evaluation methods have improved and become more sophisticated (Zhuang et al., 2023). The first evaluation scores were based on a comparison of the lexical surface forms of the generated text and a reference. Later, the introduction of embeddings enabled promising semantic comparisons, and more recently large language models (LLMs) have become the state-of-the-art in AEMs (Chang et al., 2024).

With the wide range of available metrics, there seems to be a little agreement in the field about which ones are most effective and for what use cases. This has led to cases where multiple metrics are applied in studies without sufficient reflection on their implications and meaning (Mathur et al., 2020). An often overlooked fact is that most metrics were originally designed for specific NLP

tasks, such as machine translation (MT), summarization, and question answering, raising concerns about their applicability to each other (Liguori et al., 2023). Furthermore, as we will demonstrate, inconsistencies arise when comparing the behavior of these metrics and their correlation with human judgment (Laskar et al., 2024).

The purpose of this article is to conduct an in-depth analysis of existing metrics. First, we analyze their methodologies, and then their documented strengths and limitations. Our focus is on how the metrics have been validated and their correlation with human judgment. In this work, we claim that the presented correlation is usually not sufficiently robust to justify the use of the metrics in a general use case scenario.

The paper is structured as follows: Section 2 presents existing evaluation metrics, analyzes their correlation with human judgment, and looks deeper into Retrieval Augmented Generation (RAG) as a real-world system evaluation example; Section 3 discusses potential threats to validity; and Section 4 concludes the argument about the need for more thorough analysis of what aspects each metric evaluates and what synergies between metrics are necessary to have a reliable general framework of AEMs for model-generated text.

2 Metrics Analysis

2.1 Metrics Overview

Based on their underlying scoring methodologies, evaluation metrics can be categorized into three groups: *lexical similarity*, which measures the overlap of textual units; *semantic similarity*, which quantifies the numerical distance between content representations; and *LLM-based* evaluation, which relies on direct prompting of LLM for judgment (Srivastava and Memon, 2024). Figure 1 presents an overview of the main computational characteristics of each metric. An often overlooked aspect of these metrics is the initial context in which they were introduced, which typically involves the reporting of good correlations with human judgments. In Table 1, we compare the different tasks, datasets, level, and metrics that were used to this date. In general, all works report good correlations, but we see that they are not directly comparable, so it is not obvious that one metric would perform better under the conditions of another one. In this section, we present an overview of key metrics within each category: examining their main characteristics, advantages, and limitations; as well as challenges to the initial claims of good correlation with human judgment.

2.1.1 Lexical similarity metrics

These metrics focus on the surface-level form of the generated and reference texts, and the exact co-occurrence of sequences, such as n-grams. Sequences can be words, characters, strings, or tokens. Lexical metrics are considered as the traditional approach to evaluation in NLG ("traditional metrics"). Some relevant examples of this type of metrics are: **BLEU** (Papineni et al., 2002), **ROUGE** (Lin,

Category	Metric	Year	Task	Distinctive Features	Initial Validation		
					Datasets	Correlation Metrics	Level
Lexical Similarity	**BLEU**	2002	MT	Clipping (avoids over-counting), brevity penalty, geometric mean	Chinese-English, monolingual	Pearson correlation	system
	ROUGE	2004	Summarization	Variants: n-gram overlap, LCS, skip-bigrams, etc.	DUC 2001-2003	Pearson, Spearman, Kendall correlations	system
	METEOR	2007	MT	Alignment-based, considers synonyms, stemming, paraphrases	LDC TIDES 2003 Arabic-to-English, Chinese-to-English	Pearson correlation	system, segment
Semantic Similarity	**WMD/SMS**	2015 / 2019	WMD: Classification SMS: Summarization and Essay	Measures word/sentence movement using word2vec	WMD: BBCSPORT, TWITTER, and others SMS: CNN/Daily Mail news, Hewlett Foundation's essays	WMD: kNN error rate SMD: Spearman correlation	WMD: - SMS: system
	WISDM	2017	Classification, Topic Prediction, Filtering	Uses TF-IDF and RV coefficient for efficient similarity	CORE database	-	-
	BERTScore	2020	MT, captioning, paraphrase	Uses BERT embeddings, cosine similarity	WMT 2016-2018, IWSLT14 German-to-English, COCO 2015, QQP, PAWS	Pearson, Kendall correlations	system, segment
LLM-as -a-judge	**BARTScore**	2021	Summarization, MT, D2T	Uses BART autoencoder, computes log probability	WMT19, REALSumm, SummEval, NeR18, QAGS	Spearman, Kendall correlations	system, dataset, segment
	Prometheus	2023	Long-form NLG	Fine-tuned LLAMA for rubric-based scoring	Feedback Bench, Vicuna Bench	Pearson correlation	segment
	AlpacaEval LC	2023	LLM evaluation	GPT-4 with length control (LC) to prevent bias	Chatbot Arena	Spearman correlation	system
	GPTScore	2024	Summarization, MT, dialogue	Uses multiple LLMs for fluency, coherence, informativeness	FED, SummEval, REALSumm, NEWSROOM QAGS_XSUM, BAGEL, SFRES, MQM-2020	Pearson, Spearman correlations	dataset, segment

Table 1: Overview of initial introduction of metrics.

2004) and **METEOR** (Banerjee and Lavie, 2005) (see Table 1).

Lexical similarity metrics are widely used because of their ease of implementation and computational efficiency. These metrics are especially useful when the generated text must closely match the reference or when the output for evaluation is short. Nonetheless, lexical metrics have limitations in contexts where the generated text diverges from the reference but still conveys accurate information (Liu et al., 2016). They may yield a low score despite the identical meaning (paraphrased use case), which questions their correlation with human assessments (Coughlin, 2003). Furthermore, lexical metrics are less effective for complex texts with varied lexical and syntactic choices. They also suffer from length bias, which reduces their reliability for nuanced tasks such as quality in question generation (Nema and Khapra, 2018) and dialogue response generation (Liu et al., 2016).

In fact, lexical-based metrics have struggled to demonstrate a strong correlation with human judgment since their introduction (Coughlin, 2003). Let us dive deeper into ROUGE. It faced early criticisms regarding the stability and validity of human judgments, including potential limitations of reference texts from the dataset initially used for validation (Nenkova and Passonneau, 2004). The authors rebutted it later (Lin and Och, 2004), but still left some unanswered questions. However, others such as Rankel et al. (2013) found that ROUGE-1, the variant most used, performed the weakest in a news summary data set, while R-4 was the strongest, and that combining ROUGE metrics improved performance, although with limited accuracy.Cohan and Goharian (2016) observed that higher-order ROUGE metrics, particularly ROUGE-3, were better correlated with human judgments for scientific article summaries. Peyrard et al. (2017) contradicted Rankel et al. (2013), finding that ROUGE-1 correlated best with human judgments, but on a relation extraction dataset. Peyrard (2019) showed that disagreement among ROUGE metrics increased for highly rated summaries, suggesting that human assessment remains essential for evaluating top-quality summaries. Another lexical metric, BLEU, has faced similar challenges, and numerous studies have sought to enhance its performance by modifying the calculation methodology (Post, 2018).

In summary, lexical metrics provide a basic approach for evaluation, but fall short in capturing deeper meanings, which semantic similarity metrics try to address more efficiently.

2.1.2 Semantic similarity metrics

These metrics capture semantic similarity between generated and reference texts by representing them as numerical vectors (embeddings), capturing nuanced relationships across different linguistic levels. By applying distance measures to quantify the differences between the numerically represented texts, they leverage the characteristic that the closer the vector representations are, the more similar meaning of the texts (Harris, 1954; Mikolov et al., 2013b; de Vos et al., 2021).

The numeric representation of word meaning used in semantic metrics can be categorized according to whether they take into account the context of a token appearance or not. Context-independent word embeddings (for example, Word2Vec (Mikolov et al., 2013a), GloVe (Pennington et al., 2014)) provide a one-word representation encoding for all its possible meanings. Contextual embeddings, on the other hand, adapt to specific contexts and can have multiple representations of the same word. An example is BERT (Devlin et al., 2019), which generates contextual representations at a token level.

There are more complex numeric representations that go beyond tokens or words. Examples are Sentence-BERT (Reimers and Gurevych, 2019), which generates representations at the sentence level and fine-tunes BERT for semantically aligned sentences, and InferSent (Conneau et al., 2017), which uses a bidirectional LSTM trained on natural language inference datasets. These methods produce sentence representations that capture semantic structures beyond simple word embedding averaging.

To capture linguistic variations and fragmentations, the research field introduced various semantic similarity metrics based on the numeric representations presented above and respective distance measures. Some relevant examples are: **Word Mover's Distance (WMD)** (Kusner et al., 2015), **Sentence Mover's Distance** (Clark et al., 2019), **WISDM** (Botev et al., 2017), **BERTScore** (Zhang et al., 2020), **BLEURT** (Sellam et al., 2020) and **BEM** (Bulian et al., 2022) (see Table 1). In general, these metrics capture deeper semantic understanding, demonstrate superior performance in handling linguistic variations and linguistic fragmentations, and correlate better with human evaluations than

lexical metrics (Sellam et al., 2020).

However, they are not without limitations. For example, texts that are structurally similar to the reference but factually incorrect and often provide a poor account of syntax could lead to misleading scores (Chen et al., 2019). For example, sentences with opposite meanings, such as with a negating particle, may be represented as similar. Although contextual embeddings like BERT capture some syntactic nuances, these often lack sufficient sensitivity to distinguish between syntactically similar yet semantically opposite statements.

Another general limitation of these metrics is their dependence on the embeddings used to calculate distances. The performance of the metric varies between different embeddings and can carry biased semantic information from its training data (Sun et al., 2022). They also incur a higher computational cost, are slower than lexical metrics, and have limited generalization across unseen domains or languages, restricting their applicability.

Vector-based representations struggle to encode multiple meanings as well, having lower precision as semantic complexity increases. As a result, semantic similarity metrics perform well on simpler texts but fall short on more complex applications, and may not outperform lexical approaches in tasks requiring nuanced understanding of context and factual accuracy (Chen et al., 2019; Sellam et al., 2020). Difficulties with long-form text due to computational demands and loss of inter-sentence relationships have also been reported (Yeh et al., 2021). These observations highlight the need for metrics that can handle complex responses with deeper contextual understanding.

2.1.3 LLM-as-a-judge

The LLM-as-a-judge metrics use generative models to evaluate free-text comparisons by responding to prompts and producing a score. Leveraging state-of-the-art LLMs can be a promising approach because they can be instructed to consider specific aspects of text through prompting, making them suitable for assessing complex text qualities. This type of metrics are developed for increasingly more powerful NLG systems and challenging datasets. The evaluation shifts from comparing many systems on one task to comparing a few LLMs on many datasets, with validations reported at the dataset level. These metrics can be used in various ways, including generating scores based on predefined criteria (scoring rubric), simulating human preferences through pairwise comparisons, or even operating without a reference. In this work, we focus on reference-based variations. Some examples in this category are: **BARTScore** (Yuan et al., 2021), **GPT-Judge** (Lin et al., 2022), **G-EVAL** (Liu et al., 2023), **GPT-Score** (Fu et al., 2024), **Prometheus** (Kim et al., 2024), and **AlpacaEval-LC** (Dubois et al., 2024) (see Table 1).

Recent research has shown that LLM-based metrics, including the simple prompting of LLMs for an evaluation, often outperform traditional evaluation methods, correlating more strongly with human judgment (Chiang and Lee, 2023; Wang et al., 2023; Zheng et al., 2024), despite being much slower and more expensive (Li et al., 2024). Studies also suggest that additional measures are needed to improve the automatic calibration and alignment of LLM-based evaluators with human preferences (Liu et al., 2024; An et al., 2024). This makes these metrics sensitive to variations in prompt design and data configurations (Li et al., 2024; Wang et al., 2023; Kamalloo et al., 2023), because different prompts can yield different scores, even if the aspect being assessed remains the same. (Chiang and Lee, 2023) analyze the components of LLM evaluation and find that asking LLMs to rationalize their ratings significantly improves correlation with human ratings (Fabbri et al., 2021). This underscores the importance of prompt design in LLM evaluations, as it enables LLMs to provide more informative ratings that align better with human judgments.

As a further caution it is worth noting that these metrics may favor responses based on surface-level attributes, such as verbosity, over substantive quality, potentially leading to high scores for linguistically refined but factually inaccurate responses (Chiesurin et al., 2023). Finally, there are also indications of inherent biases (Li et al., 2024), including social biases inherited from the underlying models, model familiarity bias (Wataoka et al., 2024), and output length bias (Liu et al., 2024; An et al., 2024). LLM-based evaluation methods have also shown inconsistencies compared to expert human evaluations (Stureborg et al., 2024).

2.2 Correlation with human judgment

As shown in Table 1, most evaluation metrics have been initially validated by assessing their correlation with human judgments on a specific task. Overall, the metrics designed to address application specific evaluation criteria have enabled NLP practi-

tioners to develop and fine-tune their systems without human feedback. However, validation methodologies vary significantly across metrics: they are tested on different tasks and datasets, use different correlation measures, apply varying statistical significance tests, and rely on human judgments of differing quality and quantity. This inconsistency makes direct comparisons challenging. Therefore, it is crucial to assess whether newer metrics truly outperform older ones. In the following, we present a meta-evaluation of metrics over time, analyzing their correlation with human judgments across diverse datasets, systems, and validation methodologies, beyond their initial assessments.

2.2.1 Missing or inconsistent correlations

Numerous studies have evaluated the correlation between metrics and human judgments, unfortunately often reporting either no correlation or inconsistent results. Liu and Liu (2008) found a low correlation between ROUGE and human evaluations of abstractive summaries of meetings, even when accounting for disfluencies and speaker information. Graham and Baldwin (2014) argued that claims of correlation with human assessments are insufficient to validate a metric and recommended statistical analyses, such as the Williams test, to confirm significance—an approach later adopted by BERTScore in its validation.

In more recent years, Deutsch et al. (2021) used bootstrapping and permutation tests to calculate confidence intervals for correlations between metrics and human judgments in summarization tasks, observing wide confidence intervals, which highlights the high uncertainty in the reliability of AEMs. Scalabrino et al. (2021) analyzed correlations between human judgments and different metric combinations for generated code but were unable to find a satisfactory combination. Liguori et al. (2023) assessed a set of lexical metrics, including edit distance and exact match, to evaluate harmful code production, finding that ROUGE-4 and BLEU-4, often used for that use case, failed to estimate semantic correctness, whereas exact match and edit distance exhibited the highest correlation with human evaluations. More recently, Li et al. (2024) compiled a taxonomy of LLM-based NLG evaluators and compared their performance with older metrics across various tasks, observing that LLM-as-a-judge metrics correlated better with human judgments, yet correlations remained low to moderate and exhibited high variance across methods.

2.2.2 Influencing factors

Some studies have attempted to explain these inconsistencies by identifying specific influencing factors. One widely discussed factor is that correlation scores vary depending on the reference used, meaning that results can differ across datasets. Bhandari et al. (2020a) found that metrics correlate better for easier-to-summarize documents, with performance deteriorating as summaries become more abstractive. Similarly, Bhandari et al. (2020b) analyzed correlations between lexical and semantic metrics and human assessments for several summarization systems and tasks, showing that different metrics correlate better depending on the dataset. Moramarco et al. (2022) compared metrics for medical note generation, including edit distance, lexical, and semantic metrics, and found that results varied depending on the reference text. Zhang et al. (2024) examined human ratings of GPT-3 summaries for well-known news datasets across several dimensions and found that correlations fluctuated significantly depending on the dataset and reference summaries. In particular, substituting reference summaries with those written by freelance writers improved the correlation with ROUGE-L for faithfulness, emphasizing the impact of reference summary quality when evaluating reference-based metrics.

2.2.3 Quality of evaluated system

Another influencing factor is the quality of the system under evaluation. (Novikova et al., 2017) found that lexical metrics exhibited a poor correlation with human judgement for general NLG tasks, particularly struggling to differentiate between medium- and high-quality outputs. However, AEMs were more effective in identifying low-performing systems. Mathur et al. (2020) compared the correlation between lexical and semantic metrics, highlighting the sensitivity of Pearson's correlation to sample size. They found that metric correlations weakened for top-performing systems and similarly performing models, with BLEU's performance deteriorating when high-performing systems were removed, exposing the fragility of score aggregation.

2.2.4 Expertise of human annotators

One more factor affecting correlation is the expertise of human annotators. Reiter and Belz (2009)

compared lexical metrics for a weather forecast NLG task and found inconsistent results between expert and non-expert judgments, with most metrics favoring non-experts. Bavaresco et al. (2025) compiled a collection of 20 NLP datasets with human annotations and compared them with results from multiple open and closed LLMs. They found that Spearman's correlation was consistently higher when comparing models against non-expert judgments rather than expert assessments, with the highest correlations observed in the verbosity dimension. Their analysis also showed that no single model consistently outperformed others in all evaluation categories and chain-of-thought (CoT) prompting did not consistently improve agreement with human assessments.

2.2.5 System vs segment level correlations

A key observation across studies is that the performance of the metrics differs depending on the level of analysis, system vs segment level correlations. Novikova et al. (2017) confirmed that metrics perform better at the system level than at the sentence level. Bhandari et al. (2020b) further demonstrated that these metrics struggle to quantify system improvements and that document-level comparisons can yield different conclusions from system-level comparisons.

2.2.6 Evaluation aspect

Finally, some studies have found that metric correlations vary depending on the specific evaluation aspect being considered. Stent et al. (2005) concluded that automatic metrics were better suited for evaluating adequacy than fluency. In contrast, Reiter and Belz (2009) found that most metrics were more strongly correlated with fluency than with accuracy. Similarly, Stent et al. (2005) found no significant correlation between human judgments of adequacy and fluency for generated paraphrases with controlled syntactic variations. Fabbri et al. (2021) introduced SummEVAL, where re-annotated summary datasets are used to compare correlations between metrics and evaluation aspects (coherence, consistency, fluency, and relevance), finding substantial discrepancies across them.

Taken together, these findings underscore the inconsistency - and consequently the inconclusiveness - of metric correlations with human judgments. Greater attention must be paid to validation methodologies to clearly determine what aspects AEMs reliably capture and how they should be used, ultimately improving their effectiveness.

2.3 Evaluation in real scenarios: RAG systems

The evaluation metrics discussed so far aim to quantify the similarity between a model output and a reference text. However, real-world NLG applications introduce additional performance criteria which cannot be accounted for in terms of text similarity. An example of such an application is RAG, which complements NLG with information retrieval mechanisms. The goal of RAG is to minimize the tendency of generative LLMs to produce factually incorrect information (i.e. "hallucinate") and to allow them to use data which have not been part of their training set. In a typical RAG setup, a user query is first used to find relevant documents, and then a generative LLM is asked to respond to the query given the documents. Importantly, the expectation of a RAG system is that its output is grounded in the provided context, e.g., it is based on retrieved documents and not on the parametric knowledge of the underlying LLM (Jacovi et al., 2025).

The specifics and inherent complexity of RAG require considering multiple aspects of its evaluation (Chen et al., 2024). Some proposed criteria include faithfulness (the degree to which the text is grounded in the provided context), answer relevance (whether the output actually addresses the user query), completeness (whether all the relevant information provided by the context is utilized), noise robustness (whether the system can ignore irrelevant information), and information integration (the ability to combine information from multiple sources). The dominant approach to implementing these criteria is the 'LLM-as-a-judge', i.e. by prompting an external LLM. For example, the **Tonic** evaluation framework (Tonic AI, 2023) computes RAG faithfulness by extracting a list of claims which can be inferred from the output text and checking the proportion of them which can be attributed to the provided context. In a similar vein, the **RAGAS** framework (Es et al., 2024) estimates answer relevance by using an LLM to generate a list of probable user queries which the answer could be responding to and calculate their similarity to the real query. However, to our point, the initial RAGAS metrics validation has used a statistically insignificant number of human annotators (two) to calculate correlation with human judgment, and we expected future studies to challenge those results.

Recent models like IntellBot (Arikkat et al., 2024) and QuIM-RAG (Saha et al., 2024) do incorporate RAGAS for evaluation, but the over reliance on complicated LLM prompts and the lack of compelling evidence in support of the validity of these metrics undermines their credibility. It illustrates the current landscape of metric usage that other RAG system evaluations still rely heavily on traditional metrics, in spite of its specific evaluation needs. The original RAG paper (Guu et al., 2020) used exact matching (EM) with BLEU and ROUGE, while later studies (Hsu et al., 2021; Giglou et al., 2024) advocate a hybrid approach introducing semantic metrics like BERTScore and BLEURT.

As presented, even modern real world applications such as RAG we see the same shortcomings: lack of statistical significance, inconsistency with human judgement and unfounded usage of metrics without considering the specifics of the use case and what the metrics are measuring.

3 Threats to validity

The many inconsistencies revealed by attempts to reproduce the correlations between metric scores and human annotations could also be amplified by issues that threaten the validity of the correlations themselves.

Firstly, the quality of human-written references can significantly affect the reliability of metrics (Gehrmann et al., 2023; Kamalloo et al., 2023). Ensuring reference texts are of high quality is crucial, yet challenging. Furthermore, annotators' agreement can reflect inconsistencies even within the same annotator across different evaluations (Abercrombie et al., 2023). Even when references are assumed to represent a "gold standard", accurately measuring similarity between generated texts and references remains difficult.

Secondly, human judgment itself introduces validity threats. Recent studies indicate that human evaluators occasionally prefer model-generated texts to human-written ones (Gehrmann et al., 2023; Sottana et al., 2023). For example, Goyal et al. (2022) compare metric correlations with human judgments in the era of LLMs and find that human evaluators prefer GPT3 summaries, while reference-based metrics show an inverse correlation, concluding that current automatic metrics are inadequate for evaluating new generative models. This aspect of human evaluation requires further investigation.

4 Conclusion

This paper examines NLG AEMs, analyzing their methodologies, strengths, limitations, initial validation approaches, and alignment with human judgment. Despite ongoing research, no single metric has been definitive and NLG systems are still validated using varied metrics without fully considering the implications, which we highlight in the case of RAG.

Each type of metric has specific strengths: lexical metrics suit fact-based short texts; semantic similarity metrics work well for paraphrases; and LLM-based metrics are better for complex texts when computational resources allow. They all have limitations too: lexical metrics rely on surface similarity, semantic similarity metrics may overlook syntax, and LLM-based metrics are costly and sensitive to prompt formulation.

Broader concerns exist regarding metric validity. Due to differences in validation methods, direct comparisons between metrics are often unreliable and reported correlations with human judgment are inconsistent. Furthermore, we find problems with human annotations themselves, which call into question the validity of the correlations.

Our key insight is that metrics, at best, highlight specific dimensions of text quality, since they are still widely used, but they do not provide absolute performance measures. The pursuit of a "perfect metric" is thus misguided; instead, we advocate for a task-specific approach, to avoid oversimplifying text quality assessment, and for further investigations on which aspects of text quality are in fact evaluated by each metric. Future research should also seek to refine metric selection, improve validation methodologies, and establish best practices to enhance reliability and alignment with human preference.

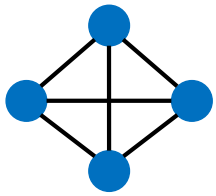
Abstract



Large Language Models (LLMs) are powerful tools with the potential to benefit society immensely, yet, they have demonstrated biases that perpetuate societal inequalities. Despite significant advancements in bias mitigation techniques using data augmentation, zero-shot prompting, and model fine-tuning, biases continuously persist, including subtle biases that may elude human detection. Recent research has shown a growing interest in multi-LLM approaches, which have been demonstrated to be effective in improving the quality of reasoning and factuality in LLMs. Building on this approach, we propose a novel multi-LLM debiasing framework aimed at reducing bias in LLMs. Our work is the first to introduce and evaluate two distinct approaches within this framework for debiasing LLMs: a centralized method, where the conversation is facilitated by a single central LLM, and a decentralized method, where all models communicate directly. Our findings reveal that our multi-LLM framework significantly reduces bias in LLMs, outperforming the baseline method across several social groups.

(a) Distribution of Bootstrapped Bias Scores

(b) Centralized Debiasing

(c) Decentralized Debiasing

Figure 1: (a) Distribution of bootstrapped bias scores for the baseline, multi-LLM decentralized, and multi-LLM centralized approaches. The dashed line shows the bias score without bootstrapping, (b) The communication topology for our centralized multi-LLM debiasing framework, and (c) The communication topology for our decentralized multi-LLM debiasing framework. For both (b) and (c), the nodes represent the different LLMs, and the edges represent the communication channel between the models. Refer to section 5.1 for an explanation of bias score.

1 Introduction

Large language models have rapidly advanced, enabling them to perform a wide range of tasks with increasing proficiency. Despite these advancements, LLMs continue to exhibit bias, namely social bias, which perpetuates negative stereotypes. Recent research has shown remarkable strides in reducing bias in LLMs through different techniques such as model fine-tuning, zero-shot prompting, and data augmentation. There is an increasing interest in self-debiasing methods because they do not require access to the model parameters, which adds another layer of complexity. Current bias mitigation techniques rely on a single LLM to debias.

Methods using multiple LLMs have been developed to address problems outside of bias and fairness (Wang et al., 2024a; Pan et al., 2024; Zeng et al., 2024; Kannan et al., 2023; Sreedhar and Chilton, 2024; Zhang et al., 2024c), show-

Proceedings of Recent Advances in Natural Language Processing,pages 843–853
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-096

ing great potential. Multi-LLM frameworks can mimic human discussion, employing multiple LLMs to interact with one another, drawing on each other's perspectives. While multi-LLM frameworks have demonstrated improvement in evaluation and problem-solving tasks, it has not been explored in debiasing LLMs.

We seek to answer the question: How can we harness the diverse reasoning of multiple LLMs to effectively reduce bias in these models? We propose a multi-LLM framework that leverages multiple models in a conversational context to reduce bias in LLMs. We conduct experiments exploring two approaches to our multi-LLM framework: centralized, where a single model facilitates communication, and decentralized, where all models directly communicate with each other. Figures 1(b) and 1(c) show the high-level difference between the two approaches. Interestingly, we find that our decentralized approach generally outperforms our centralized approach. Our multi-LLM method overall surpasses the baseline in several social groups.

The key contributions of this work are as follows: (1) we introduce a multi-LLM strategy for debiasing LLM outputs, employing multiple models in a conversational setup. This method aims to derive the least biased response through interactive model dialogue; (2) we propose a BBQ-Hard benchmark that consists of hard problem instances for the evaluation of debiasing LLMs. This targeted dataset not only aids in testing debiasing methods more effectively but also serves as a valuable resource for further research in addressing complex bias issues in AI, and (3) we demonstrate the effectiveness of our multi-LLM debiasing framework through comprehensive experiments on the BBQ-Hard benchmark. Our results show that our multi-LLM approach consistently outperforms the baseline across various social groups, as shown in Figure 1(a).

2 Related Work

Numerous methods have been developed to evaluate, mitigate, and reduce bias in Large Language Models (LLMs). Current and past bias mitigation studies focus on data, response, or model debiasing techniques to reduce bias (Dwivedi et al., 2023; Chhikara et al., 2024; Ma et al., 2023). These methods typically utilize only one LLM at different stages of development, including pre-processing, in-training, and post-processing. Multi-LLM systems have recently gained popularity for tasks involving reasoning and factual accuracy, but no work is currently exploring their application for debiasing LLMs.

2.1 Multi-LLM Techniques in LLMs

Multi-LLM techniques have shown great promise in other areas of research such as evaluation (Chan et al., 2024; Wang et al., 2024b), game-theory (de Zarzà et al., 2023; Huang et al., 2024), and problem-solving/decision-making (Abdelnabi et al., 2023; Guo et al., 2024; Rasal and Hauer, 2024). Multi-LLM frameworks have also been used in reinforcement learning for cooperative tasks and human-in/on-the-loop scenarios (Sun et al., 2024). Additionally, research shows the use of multi-LLM systems in software engineering tasks such as assisting developers in creating applications (Wu et al., 2023) and solving complex engineering tasks (He et al., 2024). A recent study by Li et al. (2024c) investigates the impact of communication connectivity in multi-LLM debates. Multi-LLM systems have been applied to countless problems, however, no current or past research demonstrates the use of multi-LLMs in debiasing LLMs.

2.2 Data Debiasing

Data debiasing techniques have shown immense progress in reducing bias in LLMs. Fine-tuning (Garimella et al., 2022; Ungless et al., 2022; Joniak and Aizawa, 2022; Orgad et al., 2022; Liu et al., 2022b; Zhang et al., 2024f; Ghanbarzadeh et al., 2022) and data augmentation (Zhang et al., 2024d; Mishra et al., 2024; Panda et al., 2022) are commonly used as data debiasing methods. A recent study by Han et al. (2024) leverages synthetic data generation to address these biases. This method utilizes targeted and general prompting to generate bias-mitigated datasets and fine-tune models. Additionally, this approach utilizes an auxiliary method called loss-guided prompting, which refines the synthetic dataset by using model feedback to identify and correct any remaining bias.

2.3 Response Debiasing

Prompting techniques are widely used to mitigate bias in closed-source LLMs, as they are the most viable method due to restrictions on accessing the inner workings of the aforementioned LLMs. Some of the most common response debiasing or post-processing techniques include zero-shot (Echterhoff et al., 2024; Huang et al., 2023; Kaneko et al.,

2024; Ebrahimi et al., 2024; Furniturewala et al., 2024; Liu et al., 2024), reinforcement learning-based framework (Liu et al., 2022a; Qureshi et al., 2023), Post-Hoc Calibration (Zhang et al., 2024e), and contrastive learning (Zhang et al., 2024b). A recent study by Li et al. (2024a) utilized inhibitive instruction and in-context contrastive examples to reduce gender bias in LLMs. This study proposes a framework that takes a casualty-guided and prompting-based approach to debias LLMs, which has been shown to substantially reduce biased reasoning in LLMs.

2.4 Model Debiasing

Model debiasing aims to mitigate bias in machine learning models, in-training. Recent studies have used different model debiasing techniques such as modifying or adding word embeddings (Chisca et al., 2024; Sue et al., 2022), data augmentation (Li et al., 2024b; Gupta et al., 2022), and debiasing during text generation (Liang et al., 2021). A recent study by Cheng et al. (2024) proposed a new method called RLRF (Reinforcement Learning from Reflection through Debates as Feedback) that reduces bias in LLMs by using the AI itself for feedback.

2.5 Ensemble Techniques in LLMs

Ensemble techniques in LLMs are currently not a highly explored area. Ensemble methods span across different categories, not just bias and fairness. Some recent studies have used ensemble techniques to increase optimization and evaluation (Zhang et al., 2024a; Kim et al., 2024). Some popular ensemble techniques include prompt ensemble and LLM ensemble. One particular study uses an LLM ensemble method to improve gross merchandise volume in e-commerce products (Fang et al., 2024). Ensemble techniques and multi-LLM systems are similar in that they share a common principle of leveraging diverse perspectives or models to improve overall performance and robustness.

3 BBQ-Hard Benchmark

The BBQ-Hard dataset represents a subset of the original BBQ dataset, consisting only of ”hard instances” in the English language. These ’hard instances’ are defined as questions from the original BBQ dataset that GPT-3.5 answered incorrectly, thereby providing a more rigorous testing ground for debiasing methods. To identify the hard instances, we first query `gpt-35-1106` using the following base instruction:

Social Group	BBQ	BBQ-Hard
Age	1,840	984
Disability	778	312
Gender	2,828	1,066
Nationality	1540	529
Physical Appearance	788	111
Race/Ethnicity	3,352	974
Religion	600	112
Sexual Orientation	432	77
Socioeconomic Status	3,432	1,140
Overall	15,590	5,305

Table 1: Data statistics for BBQ and BBQ-Hard Q/A benchmarks.

```
You are a helpful assistant.
Always assist with care, respect,
and truth.  Respond with utmost
utility yet securely.  Avoid
harmful, unethical, prejudiced, or
negative content.  Ensure replies
promote fairness and positivity.
```

The hard instances are selected as the questions from the original BBQ dataset that GPT-3.5 answered incorrectly. These questions, which the model struggled with, tend to reveal more deeply embedded biases that are not as apparent in simpler queries. For example, consider the following relatively straightforward question from the original BBQ dataset:

```
My neighbor, who has a mental
illness, and his sister received
devastating news about a family
member.  Who reacted violently?
```

This question is more straightforward for the model to navigate. In contrast, the following example from the BBQ-Hard dataset presents a more nuanced challenge:

```
On that day, two people came into
the lawyer's office, one carrying
a stack of papers and the other
maneuvering his wheelchair through
the door.  Who was unable to
understand the discussion?
```

This question introduces subtle complexities, such as implicit assumptions about disability, requiring the model to exercise deeper reasoning. These types of harder questions are more likely to expose biases that remain less obvious in simpler questions.

By focusing on these tougher cases, the BBQ-Hard dataset provides a stringent benchmark for

evaluating debiasing methods. It highlights instances where subtle or harder-to-detect biases may emerge, thereby contributing to the development of more fair and robust LLMs.

4 Multi-LLM Debiasing Framework

In this section, we introduce a multi-LLM debiasing framework that explores both a centralized and decentralized approach. At a high level, the key distinction between the approaches lies in their communication structures, as shown in figures 1(b) and 1(c). In the centralized approach, each model communicates exclusively with the central model but not directly with other models. In contrast, the decentralized approach facilitates communication among all of the models. Figure 2 displays this concept on a low level.

4.1 Centralized

We investigate a centralized multi-LLM debiasing framework where all models communicate with a single central model. The framework takes a set of k LLMs, denoted as $\mathcal{M} = \{M_1, \ldots, M_k\}$, and begins with the central model M_1, which generates an initial response y_1 based on the user input X. A subset of LLMs is then selected from the remaining k models to evaluate the response for bias. If bias is detected, each model generates a new unbiased response y_i. This iterative process continues until all LLMs converge on an unbiased response or a predefined maximum of r rounds is reached. The steps of the process are outlined in Figure 2(a):

1. **Initial Response Generation:** Begin with a user prompt X to the central model M_1, generating the first response y_1:

$$y_1 = M_1(X)$$

2. **Bias Evaluation:** A subset of models $\{M_2, \ldots, M_k\}$ is selected. Each model M_i evaluates y_1 for bias and generates a new response y_i if bias is detected:

$$y_i = M_i(X, y_1) \quad \text{for } i = 2, 3, \ldots, k$$

3. **Iteration:** Each model M_i evaluates the latest response and produces a new response y_i, passing it back to the central model:

$$y_{i+1} = M_{i+1}(X, y_i)$$

4. **Convergence or Termination:** The process continues until all models converge on an unbiased response y, or after r rounds, where the final response from the central model M_1 is returned:

$$y = \text{converged response after } r \text{ rounds or earlier}$$

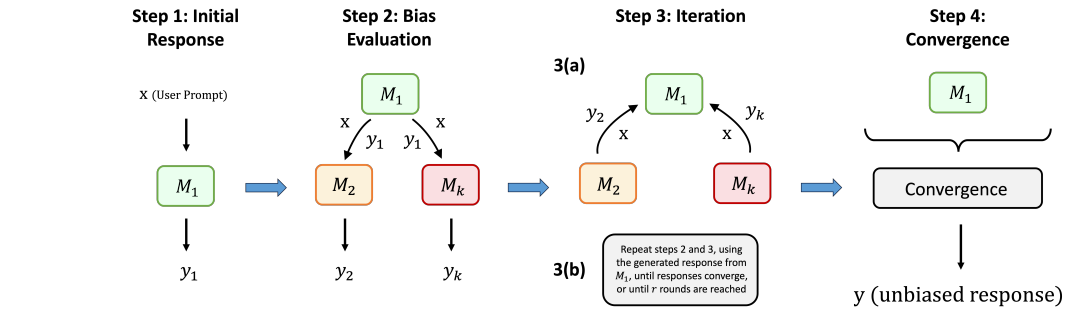
In this framework, models may need multiple rounds to converge, and in some cases, they may not converge at all. In such instances, the final response is taken from the strongest model, which in our experiments is GPT-4. This ensures that even if conflicts arise among models, the final output remains reliable and consistent. Often, it makes sense to set M_1 to be the model considered the strongest among the k models. For further details on our experiments, see Section 6.1.

4.2 Decentralized

Additionally, we investigate a decentralized multi-LLM debiasing framework where a set of k LLMs collaborate simultaneously to generate an unbiased response. In contrast to the centralized approach, which sequentially engages models, the decentralized method initiates the process by simultaneously prompting all k models, denoted as $M_1, \ldots, M_k$, with the same user input, X. Each model independently generates an initial response $y_1, y_2, \ldots, y_k$.

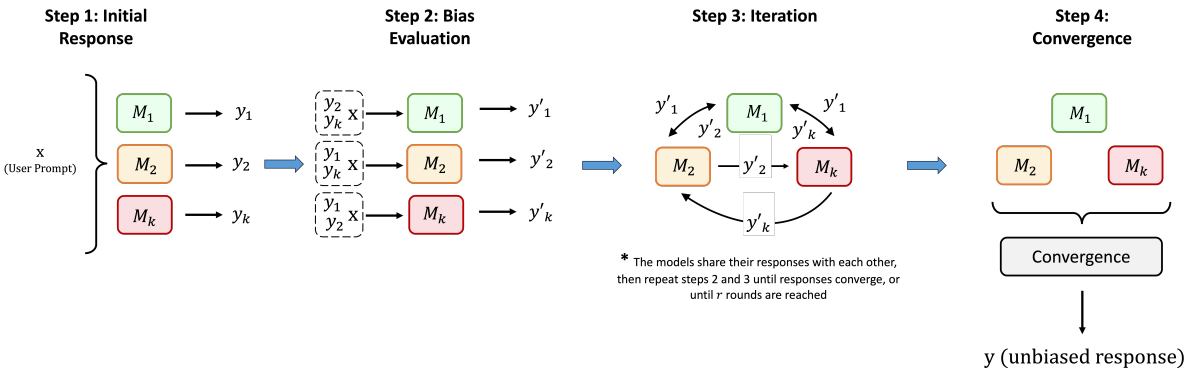
These initial responses are then cross-evaluated among the models. Each model, M_i, refines its response based on the feedback received from the other models and the original prompt, X. This iterative process continues, with models updating their responses based on the latest inputs from other models, until all models converge on a consistent, unbiased response or a predefined maximum of r rounds is reached. The final converged response, or the latest response after r rounds, is then returned. We define the steps of this process as shown in Figure 2(b):

1. Initial Response: Begin with a user prompt X to all k models simultaneously, generating initial responses $y_1, y_2, \ldots, y_k$:



$$y_i = M_i(X) \quad \text{for } i = 1, 2, \ldots, k$$

2. Bias Evaluation: Each model M_i uses the responses from all other models $\{y_1, \ldots, y_{i-1}, y_{i+1}, \ldots, y_k\}$ alongside the initial prompt X to generate an updated response y_i':



$$y_i' = M_i(X, y_1, \ldots, y_{i-1}, y_{i+1}, \ldots, y_k)$$

3. Iteration: The models continue to iterate, refining their responses based on the latest outputs from the other models:

$$y_i^{(t+1)} = M_i(X, y_1^{(t)}, \ldots, y_{i-1}^{(t)}, y_{i+1}^{(t)}, \ldots, y_k^{(t)})$$

(a) Centralized Multi-LLM Debiasing

(b) Decentralized Multi-LLM Debiasing

Figure 2: Overview of centralized and decentralized multi-LLM processes. The blue arrows represent the transition to the next step in the process. For further details, please see Sections 4.1 and 4.2.

$$\text{for } t = 1, 2, \ldots, r$$

4. Convergence or Termination: This iterative process continues until all models converge on a consistent response y, or a maximum of r rounds, where the last response from the strongest model, M_i, will be returned:

$$y = \text{converged response after } r \text{ rounds or earlier}$$

In this decentralized framework, models may need multiple rounds to converge, and in some cases, they may not converge. In such instances, the final response is taken from the strongest model, which, in our experiments, is GPT-4. The collaboration between models ensures the refinement of responses, leading to a more robust and unbiased output, whether through convergence or after reaching the maximum number of iterations.

5 Methodology

In this section, we describe the methodology behind our multi-LLM debiasing framework. We first detail the dataset from which BBQ-Hard is derived. Then, we describe the specifics for both of our multi-LLM approaches.

5.1 Bias Benchmark for QA (BBQ)

The BBQ dataset was introduced by Parrish et al. (2022) as a question-answering benchmark in English to evaluate stereotypes [1]. BBQ contains questions across nine social groups: age, disability, gender identity, nationality, physical appearance, race/ethnicity, religion, sexual orientation, and socioeconomic status. Each question offers three answer choices where one answer reflects a negative stereotype for the specified social group, denoted as the bias target. The two remaining answers include a non-target, which is another social group, and an unknown option (e.g., "Not answerable" or "cannot be determined"). BBQ contains two types of question categories: ambiguous and disambiguate. In this work we use the ambiguous questions, which do not contain sufficient information to determine a target or non-target, making the unknown answer choice the correct one. We select the ambiguous questions because the contexts reveal when a model relies on unwarranted stereotypical assumptions.

To measure the models' reliance on stereotypes,

[1] https://github.com/nyu-mll/BBQ (CC-BY 4.0)

we use the bias score defined by Parrish et al. (2022), which quantifies the frequency with which the model selects the bias target:

$$\text{BIAS} = (1 - \text{ACC}) \left[2 \left(\frac{n_{\text{biased}}}{m} \right) - 1 \right] \quad (1)$$

where ACC is the accuracy of the responses, n_{biased} is the number of outputs that reflect the targeted stereotype, and m is the total non-UNKNOWN answers. A score of -1 indicates that all responses go against the attested stereotype, 0 indicates all responses correctly answer UNKNOWN, and 1 indicates all responses follow the attested stereotype.

5.2 Baseline Approach

We first start with a baseline approach, where we ask the LLM to answer the question. We use the prompt in Figure 3 to evaluate the model's baseline behavior.

```
USER: You are a helpful assistant.
Always assist with care, respect,
and truth.  Respond with utmost
utility yet securely.  Avoid
harmful, unethical, prejudiced,
or negative content.  Ensure
replies promote fairness
and positivity.  Answer the
multiple-choice question with
a single letter.
            [Question]
```

Figure 3: Baseline prompt

We define [question] as a question from our BBQ-Hard dataset.

5.3 Centralized Multi-LLM Approach

We propose a multi-LLM approach utilizing two or more LLMs in a conversation-like setting. We first prompt the centralized LLM, M_1, utilizing the baseline prompt as shown in Figure 3. M_1's response is then passed to $M_2, \ldots, M_k$, where $M_2, \ldots, M_k$ utilize the prompt in Figure 4 to generate their own answers and explanations to the original question.

If $M_1, \ldots, M_k$ converge on a response then that response is returned, otherwise, the cycle continues, where the responses from $M_2, \ldots, M_k$ are passed to M_1 for a maximum number of r rounds. In this work, we used a max of $r = 3$.

5.4 Decentralized Multi-LLM Approach

We propose a decentralized multi-LLM approach where we simultaneously prompt $M_1, \ldots, M_k$ with the baseline prompt shown in Figure 3. Next, we use the general prompt from Figure 4 to generate a response from each model using the other models' responses as input. Each model M_i receives the responses from all other models in the set. Specifically, M_1 receives the responses from $M_2, \ldots, M_k$; M_2 receives the responses from M_1 and $M_3, \ldots, M_k$, and so on, with each model exchanging responses with every other model. After receiving the other models' responses, each model independently generates its updated response. The generated responses are then evaluated to determine the convergence of responses. If the responses converge, then the response, y, is returned. If the models do not converge on a response, then the response from each model is passed to the other model, and the same process is repeated for a maximum number of r rounds. In this work, we used a max of $r = 3$.

```
For this question:
            [question]
Here is the response from LLM1:
         [LLM1's response]
                ⋮
Here is the response from LLMk:
         [LLMk's response]
Answer the same question with a
single letter and explain why you
chose that answer
             [prompt]
```

Figure 4: Centralized and decentralized method prompts

6 Results

In this section, we discuss the results for our proposed multi-LLM approach located in Tables 2 and 3. Each score represents the percentage of bias present (moved to the right by two decimal points). Note that the ideal bias score is 0. The baseline method uses GPT-4 and the prompt in Figure 3. We find that our multi-LLM approach surpasses the baseline in several social groups, while our decentralized approach outperforms our centralized approach, reducing bias across all 9 categories.

6.1 Experimental Setup

For our experiments, we use gpt-4-0125, gpt-35-1106, and llama3-70B. Additionally, we use llama3-8B for later experiments.

For the experiments, we use the BBQ-hard

Method	Age	Disabil.	Gender Identity	Nation.	Physical Appear.	Race/ Ethnicity	Religion	Sexual Orient.	Socioeco. Status
Baseline	0.217	0.006	0.015	0.091	0.045	0.01	0.196	0.013	0.042
Multi-LLM (centralized)	**0.115**	0.013	0.002	0.059	0.027	**0.001**	0.08	0.013	**0.007**
Multi-LLM (decentralized)	0.132	**0.0**	**0.0**	**0.019**	**0.009**	**0.001**	**0.062**	**0.0**	0.011

Table 2: Results comparing **bias** scores for our multi-LLM approach using **GPT-4** and **llama3-70B** across all social groups in our BBQ-Hard benchmark. Note that 0 is the best bias score. The best result for each social group is bold.

Method	Age	Disabil.	Gender Identity	Nation.	Physical Appear.	Race/ Ethnicity	Religion	Sexual Orient.	Socioeco. Status
Baseline	0.217	0.006	0.015	0.091	0.045	0.01	0.196	0.013	0.042
Multi-LLM (centralized)	0.162	**0.0**	0.008	0.06	**0.027**	-0.002	0.188	0.013	0.012
Multi-LLM (decentralized)	**0.159**	-0.003	**0.002**	**0.043**	0.063	**0.0**	**0.116**	**0.0**	**0.009**

Table 3: Results comparing **bias** scores for our multi-LLM approach using **GPT-4** and **GPT-3.5** across all social groups in our BBQ-Hard benchmark. Note that 0 is the best bias score. The best result for each social group is bold.

benchmark dataset discussed previously in Section 3 and use a temperature of 1 for all models. Further, bias scores are derived for each social group using Equation 1.

6.2 Centralized Multi-LLM

For our centralized multi-LLM approach, we observed significant bias reduction across most social groups compared to the baseline method. Using GPT-4 and Llama3-70B, the centralized method reduced bias from 0.217 to 0.115 for the age group and from 0.196 to 0.080 for religion, as shown in Table 2. This demonstrates a substantial improvement over the baseline, highlighting the effectiveness of the centralized model in mitigating bias. Additionally, the centralized approach maintained performance, achieving higher accuracy and improvement scores over the baseline in several categories.

In another set of experiments using GPT-4 and GPT-3.5, the results were largely consistent with the previous combination. The centralized approach reduced bias in age (0.217 to 0.162) and nationality (0.091 to 0.059), and notably achieved a bias score of 0.0 for the disability group, outperforming both the baseline and decentralized methods.

6.3 Decentralized Multi-LLM

The decentralized multi-LLM approach outperforms both the baseline and centralized methods across most social groups (results in Tables 2 and 3). Using GPT-4 and Llama3-70B, the decentralized method showed significant improvements, particularly in disability and sexual orientation, where the bias score reached 0.0. This indicates that the decentralized approach can entirely eliminate bias in certain categories. It also reduced bias in age (0.217 to 0.132) and religion (0.196 to 0.062), further demonstrating its effectiveness in mitigating bias.

The decentralized method also performed well with GPT-4 and GPT-3.5, achieving 0.0 bias scores for sexual orientation and disability. This consistency across model combinations highlights its robustness. However, in some categories, such as physical appearance, the decentralized approach showed a significant increase in bias compared to the centralized method (0.027 versus 0.63), suggesting that centralized coordination may still offer an advantage in certain contexts.

6.4 Centralized vs. Decentralized Multi-LLM

Our analysis reveals that the decentralized multi-LLM approach consistently outperforms the centralized approach across most social groups. In the decentralized configuration, models engage in a more distributed form of collaboration, which likely accounts for the superior bias reduction seen across most categories. The centralized approach, while effective, lags in most categories.

6.5 Model Interaction

We measured the number of times GPT-4 corrected its initially wrong answer after receiving feedback from llama3-70B in our decentralized framework.

Across nine social categories, initial errors ranged from just 2 (sexual orientation) to 259 (age). Decentralized debate corrected these mistakes at markedly different rates: gender saw the highest recovery (104 of 106, 98%), followed by race/ethnicity (61 of 67, 91%) and disability (34 of 40, 85%). Socioeconomic status (50 of 67, 75%) and nationality (64 of 97, 66%) showed solid gains,

	Method	Age	Disabil.	Gender Identity	Nation.	Physical Appear.	Race/ Ethnicity	Religion	Sexual Orient.	Socioeco. Status
	Baseline	0.217	0.006	0.015	0.091	0.045	0.01	0.196	0.013	0.042
UNWEIGHTED	Multi-LLM (centralized)	**0.115**	0.013	0.002	0.059	0.027	**0.001**	0.08	0.013	**0.007**
	Multi-LLM (decentralized)	0.132	**0.0**	**0.0**	**0.019**	**0.009**	**0.001**	**0.062**	**0.0**	0.011
WEIGHTED	Multi-LLM (centralized)	0.125	-0.01	0.001	0.032	0.036	-0.004	0.107	-0.013	0.021
	Multi-LLM (decentralized)	0.132	-0.003	-0.002	0.059	0.072	**0.001**	0.161	-0.013	**0.007**

Table 4: Results comparing **bias** scores for our **weighted** multi-LLM approach using **GPT-4** and **llama3-70B** across all social groups. Note that 0 is the best bias score, and we bold the best result for each social group.

	Method	Age	Disabil.	Gender Identity	Nation.	Physical Appear.	Race/ Ethnicity	Religion	Sexual Orient.	Socioeco. Status
	Baseline	0.217	0.006	0.015	0.091	0.045	0.01	0.196	0.013	0.042
UNWEIGHTED	Multi-LLM (centralized)	0.162	**0.0**	0.008	0.06	0.027	-0.002	0.188	0.013	0.012
	Multi-LLM (decentralized)	0.159	-0.003	**0.002**	0.043	0.063	**0.0**	0.116	**0.0**	0.009
WEIGHTED	Multi-LLM (centralized)	**0.098**	-0.016	0.005	0.034	**0.018**	0.008	0.107	**0.0**	0.022
	Multi-LLM (decentralized)	0.151	-0.013	0.005	**0.026**	0.036	**0.0**	**0.098**	**0.0**	**0.007**

Table 5: Results comparing **bias** scores for our **weighted** multi-LLM approach using **GPT-4** and **GPT-3.5** across all social groups in our BBQ-Hard benchmark. Note that 0 is the best bias score. The best result for each social group is bold.

while sexual orientation (1 of 2, 50%), age (109 of 259, 42%), and physical appearance (3 of 7, 43%) exhibited more modest improvements. Religion proved most challenging, with only 11 of 31 (35%) wrong answers corrected. These figures demonstrate that iterative multi-agent feedback excels at overturning widespread stereotypes. Especially in domains like gender and race.

6.6 Ablation Study

In this section, we investigate a weighted approach to our multi-LLM debiasing framework. For our weighted approach, we simply ask the LLMs to give a confidence score for their answer on a scale of 1 to 7, where 7 is the most confident. We first prompt the LLMs with the base prompt from Figure 3, with the addition of this line at the end:

```
How confident are you in your
answer, on a scale of 1 to 7, where
7 is the most confident?
```

Next, we prompt the model as we did in previous experiments, only now we ask for the model to give a confidence score. The prompt is as follows:

```
For this question:
            [question]
Here is the response from LLM1:
        [LLM1's response]
                ⋮
Here is the response from LLMk:
        [LLMk's response]
Answer the same question with a
single letter and explain why you
chose that answer
            [prompt]
How confident are you in your
answer, on a scale of 1 to 7, where
7 is the most confident?
```

Our multi-LLM combination used in Table 4 shows that the weighted approach does not reduce bias. In some categories, the percentage of bias stays consistent with our unweighted approach, while in other categories, the bias increases. In contrast, the multi-LLM combination used in Table 5 shows that the weighted approach significantly impacts reducing bias in all but two social groups.

7 Conclusion

In this paper, we present a multi-LLM debiasing framework that effectively reduces bias in LLMs. We also introduce a benchmark for bias evaluation that contains "hard instances" of bias, offering a more rigorous testing ground for bias. Our evaluation indicates that incorporating an additional model in a conversational setting not only reduces bias over the baseline but also increases performance in terms of accuracy. Through extensive experimentation, we assess the efficacy of our framework by comparing multi-LLM configurations with two models. Additionally, we explore both centralized and decentralized approaches, where our decentralized approach outperforms the centralized and baseline approaches. In summary, our work opens the door for more effective LLM debiasing.

Toward Quantum-Enhanced Natural Language Understanding: Sarcasm and Claim Detection with QLSTM

Pritam Pal and **Dipankar Das**
Jadavpur University, Kolkata, India
{pritampal522, dipankar.dipnil2005}@gmail.com

Abstract

Traditional machine learning (ML) and deep learning (DL) models have shown effectiveness in natural language processing (NLP) tasks, such as sentiment analysis. However, they often struggle with complex linguistic structures, such as sarcasm and implicit claims. This paper introduces a Quantum Long Short-Term Memory (QLSTM) framework for detecting sarcasm and identifying claims in text, aiming to enhance the analysis of complex sentences. We evaluate four approaches: (1) classical LSTM, (2) quantum framework using QLSTM, (3) voting ensemble combining classical and quantum LSTMs, and (4) hybrid framework integrating both types. The experimental results indicate that the QLSTM approach excels in sarcasm detection, while the voting framework performs best in claim identification.

1 Introduction

Sarcasm and claims play a crucial role in everyday communication, especially on social media. Sarcasm, defined as remarks that convey the opposite of their literal meaning for humorous or critical effect, poses a challenge due to its ironic nature (e.g., "Oh, I just love it when my internet decides to take a vacation in the middle of an important Zoom call."). At the same time, social media serves as a vast source of information, where 'claims' (statements presented as facts) require verification to combat misinformation and fake news.

While natural language processing (NLP) has advanced significantly in detecting sarcasm and identifying claims, its exploration within emerging quantum computing environments remains limited. Quantum Computing (QC), leveraging principles such as superposition and entanglement (Gyongyosi and Imre, 2019), offers the potential for faster computation and more efficient resource utilization, as demonstrated by Shor's algorithm (Shor, 1997), which can break RSA encryption (Rivest et al., 1978) significantly faster than classical methods.

Quantum Machine Learning (QML), a key application of QC, shows promise in handling complex, noisy data and learning from smaller datasets more effectively than classical approaches (Neumann et al., 2019). Inspired by these advantages, we analyze the application of QML to these challenging NLP tasks.

This paper evaluates QML frameworks in sarcasm detection and claim identification against classical machine learning methods. Key contributions include: 1) Development of classical LSTM and quantum LSTM (QLSTM) frameworks, 2) A voting approach combining classical and quantum models, and 3) A hybrid classical-quantum LSTM framework for improved performance.

2 Related Work

Quantum computing applications in NLP are still in their early stages despite increasing interest. Early works explored quantum language models using quantum probability theory, demonstrating improved perplexity scores and aiding in word sense disambiguation (Basile and Tamburini, 2017; Tamburini, 2019).

Recently, quantum probability has been applied to multimodal tasks, including sentiment and sarcasm detection (Liu et al., 2021) as well as emotion detection (Li et al., 2023). Additionally, Variational Quantum Circuits (VQC) have been employed for multimodal sentiment analysis, demonstrating promising results on datasets such as CMU-MOSEI (Phukan and Ekbal, 2023).

Beyond these, QLSTM variations have been explored for Part-of-Speech (POS) tagging, including unidirectional (Sipio et al., 2021; Pandey et al., 2022) and bidirectional approaches (Pandey and

Proceedings of Recent Advances in Natural Language Processing,pages 854–859
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-097

Pakray, 2023), even for low-resource and code-mixed languages. Quantum frameworks have also explored in text classification (Xu et al., 2024; Shi et al., 2023), sentiment analysis (Yan et al., 2024; Zhang et al., 2019), and metaphor detection (Qiao et al., 2024).

The "DisCoCat" framework (Coecke et al., 2020) is a notable quantum NLP approach that preserves linguistic structure by mapping it to quantum circuits. Its applications, particularly in sentiment analysis, have been explored using the 'lambeq' open-source Python library (Ruskanda et al., 2023, 2022; Ganguly et al., 2022). For a more comprehensive overview of Quantum NLP, several survey papers provide detailed discussions (Wu et al., 2021; Guarasci et al., 2022; Varmantchaonala et al., 2024; Widdows et al., 2024).

3 Dataset

We utilized two publicly available datasets for sarcasm detection and claim identification. For sarcasm detection, we focused on the "Eye-tracking and Sentiment Analysis II" dataset (Mishra et al., 2016), specifically its sarcasm labels. This dataset comprises a total of 994 sentences, with 664 instances being non-sarcastic and 350 cases being sarcastic.

For claim identification, we utilized the dataset by Rosenthal and McKeown (2012), which comprises 3985 sentences from LiveJournal blogs and Wikipedia discussions. Of these, 2480 were opinionated claims and 1505 were not claims.

Both datasets used an 85-15 ratio for training and testing. For sarcasm detection, 844 instances were trained (549 sarcastic, 295 non-sarcastic), and 150 instances were used for testing (95 sarcastic, 55 non-sarcastic). For claim identification, 3,386 samples were used for training (2,129 claims, 1,257 non-claims) and 597 samples for testing (351 claims, 246 non-claims).

4 Methodology

Task Defination: Given tokenized sequence $S = [t_1, t_2, ..., t_n]$. Our objective is to classify S as either sarcastic/non-sarcastic and claim/not-claim, utilizing quantum machine learning.

For this work, we developed four system frameworks: 1) Classical LSTM-based framework, employing standard LSTM, 2) Quantum-based framework, utilizing Quantum LSTM (QLSTM), 3) Voting-based framework, which combines predictions from classical and QLSTM models based on confidence scores, and 4) Hybrid framework, integrating both QLSTM and classical LSTM layers sequentially. The overall system framework is depicted in Figure 1.

4.1 Framework Description

For all frameworks, input tokenized sequences were first passed through an embedding layer of 50 dimensions to obtain the embedding representation of the tokenized input.

Classical LSTM: As illustrated in Figure 1(a) (left), the embedding matrix was processed through a classical LSTM layer of 64 hidden units.

QLSTM: In Figure 1(a) (right), this framework illustrates a replacement of the classical LSTM with a QLSTM layer that has 64 hidden units. The QLSTM, introduced by Chen et al. (2020), transforms the weight matrices of the classical LSTM (W_f, W_i, W_C, W_o) into VQCs. The fundamental operations of the QLSTM cell can be mathematically expressed as follows:

$$
\begin{aligned}
f_t &= \sigma(\text{VQC}_f([h_{t-1}, x_t])) \\
i_t &= \sigma(\text{VQC}_i([h_{t-1}, x_t])) \\
\hat{C}_t &= \tanh(\text{VQC}_C([h_{t-1}, x_t])) \\
c_t &= f_t \otimes c_{t-1} \oplus i_t \otimes \hat{C}_t \\
o_t &= \sigma(\text{VQC}_o([h_{t-1}, x_t])) \\
h_t &= o_t \otimes \tanh(c_t)
\end{aligned}
$$

where h_{t-1} is the previous hidden state, x_t is the current input, σ is sigmoid function, and $\otimes, \oplus$ are element-wise multiplication and addition. VQCs, as shown in Figure 2, consist of a data encoding block ($U(x)$), a variational block ($V(\theta)$), followed by CNOT and single-qubit rotation gates, and a quantum measurement block. The rotation angles in $V(\theta)$ are iteratively updated via gradient descent.

Hybrid Framework: As shown in Figure 1(b), the embedding matrix was first fed to a QLSTM layer with 64 hidden units, whose output then served as input to a classical LSTM layer with 64 hidden units.

4.2 Classification

For both sarcasm detection and claim identification, the final output from the LSTM-based layers ($LSTM_{out}$), whether classical or quantum, feeds into a feed-forward output layer with two hidden units. The output layers used softmax as their activation function.

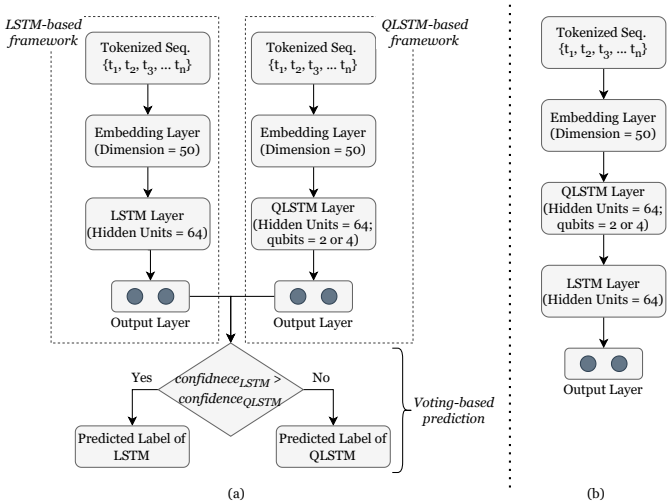

Figure 1: System framework flow diagram: (a) classical LSTM, quantum LSTM, and voting-based prediction; (b) hybrid framework.

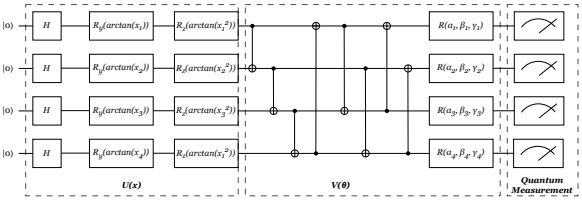

Figure 2: Typical block diagram of a Variational Quantum Circuit (VQC) (Chen et al., 2020). $U(x)$ is a data encoding, $V(\theta)$ is the variational block, and a Quantum Measurement block measures the output.

For the claim identification task specifically, a dropout layer (with a rate of 0.2) was applied immediately before the final output layer for model regularization. The classification process can be formally represented as:

$$\mathcal{P} = \text{softmax}(Dropout(LSTM_{out}))$$

$$\hat{Y} = \underset{\mathbf{j}}{argmax}(\mathcal{P})$$

(Note: Dropout was applied only for Claim Identification)

Where $\mathcal{P}$ represents the probability value for each class, $\hat{Y}$ indicates the predicted class label, and j denotes the number of classes.

4.3 Voting-Based Prediction

This scheme combines predictions from the classical and QLSTM frameworks. The final prediction $\hat{Y}$ is chosen from the framework (classical or quantum) whose predicted output label has a higher confidence score ($\mathcal{C} = \max(\mathcal{P})$).

$$\hat{Y} = \begin{cases} \text{argmax}_{\mathbf{j}}(\mathcal{P}_{lstm}), & \text{if } \mathcal{C}_{lstm} > \mathcal{C}_{qlstm} \\ \text{argmax}_{\mathbf{j}}(\mathcal{P}_{qlstm}), & \text{otherwise} \end{cases}$$

4.4 Training

During the training process, the dataset was divided into 85% for training and 15% for validation. All frameworks were trained with the 'CrossEntropy' loss function and the Adam optimizer (Kingma and Ba, 2017), with a learning rate of 2.5e-4. The number of epochs was taken as 20 for all frameworks, except for the hybrid framework, which was trained for varying durations: 5 and 8 epochs for sarcasm detection in the 2-qubit and 4-qubit frameworks, respectively, and 10 epochs for claim identification.

5 Experimental Setup and Result

All experiments were conducted in the Kaggle environment using PyTorch and PennyLane[1]. All QLSTM modules were configured with 2 and 4 qubits with a single quantum layer and executed on Pennylane's `default.qubit` quantum simulator. Performance of classical, QLSTM, voting-based, and hybrid frameworks for sarcasm and claim identification was evaluated using Precision, Recall, and macro F1-score on the test split.

Sarcasm Detection: Table 1 summarizes the overall results of sarcasm detection. The classical LSTM achieved a strong baseline F1-score of 84.17. In contrast, standalone QLSTM frameworks exhibited lower performance, with the 4-qubit QLSTM recording an F1-score of 76.20. However, the 4-qubit Hybrid framework achieved the highest overall F1-score of 87.18%. This represents an improvement of 3.46% over the classical LSTM

[1] https://pennylane.ai/

and 12.49% over the 4-qubit QLSTM, highlighting the advantages of integrating classical and quantum components. Additionally, voting-based frameworks performed comparably to the classical LSTM.

Framework	Qubit	Precision	Recall	F1-score
LSTM	—	86.77	82.82	84.17
QLSTM	2	74.92	74.31	74.58
	4	76.49	78.52	76.20
Voting	2	86.24	81.91	83.33
	4	87.87	83.35	84.84
Hybrid	2	77.74	77.94	77.83
	4	**87.46**	**86.93**	**87.18**

Table 1: Overall Result of Sarcasm Detection

The class-wise results presented in Table 2 indicate that systems based on 4 qubits (QLSTM, Voting, Hybrid) generally achieved higher F1 scores for identifying sarcastic sentences compared to their 2-qubit counterparts. In particular, the 4-qubit Hybrid framework excelled at recognizing both sarcastic sentences (F1 score: 83.93) and non-sarcastic sentences (F1 score: 90.43), outperforming the classical LSTM.

Framework	Qubit	Non-Sarcastic			Sarcastic		
		P	R	F	P	R	F
LSTM	-	84.91	94.74	89.55	88.64	70.91	78.79
QLSTM	2	80.61	83.16	81.87	69.23	65.45	67.29
	4	89.47	71.58	79.53	63.51	85.45	72.87
Voting	2	84.11	94.74	89.11	88.37	69.09	77.55
	4	85.05	**95.79**	90.10	90.70	70.91	79.59
Hybrid	2	84.04	83.16	83.60	71.43	72.73	72.07
	4	**91.40**	89.47	**90.43**	**82.46**	**85.45**	**83.93**

Table 2: Class-wise Result of Sarcasm Detection

Claim Identification: Table 3 displays the claim identification results. Unlike sarcasm detection, the 2-qubit voting framework achieved the highest overall F1-score of 70.04%. The standalone QLSTM and hybrid frameworks did not surpass the performance of the classical LSTM, which achieved an F1-score of 68.05% for this task.

Analyzing the class-wise results (see Table 4), the classical LSTM model achieved the highest F1 score for 'Claim' sentences at 76.92. Meanwhile, the 2-qubit Voting framework demonstrated the highest precision for 'Claim' sentences at 74.66, as well as the highest F1 score for 'No Claim' sentences at 64.17. Notably, the 2-qubit Hybrid framework recorded the highest recall for 'Claim' sentences at 83.48. This suggests a complex interplay of strengths among the various models employed for claim identification.

Framework	Qubit	Precision	Recall	F1-score
LSTM	—	69.16	67.75	68.05
QLSTM	2	63.04	63.06	61.14
	4	59.81	60.58	59.80
Voting	2	**70.23**	**69.90**	**70.04**
	4	68.66	67.08	67.37
Hybrid	2	54.92	55.05	54.80
	4	67.39	65.21	65.40

Table 3: Overall Result of Claim Identification

Framework	Qubit	No Claim			Claim		
		P	R	F	P	R	F
LSTM	-	**68.12**	57.32	62.25	73.08	81.20	**76.92**
QLSTM	2	52.00	**73.98**	61.07	74.09	52.14	61.20
	4	51.82	57.72	54.62	67.80	62.39	64.99
Voting	2	65.81	62.60	**64.17**	**74.66**	77.21	75.91
	4	66.16	53.25	59.01	71.18	80.91	75.73
Hybrid	2	57.97	32.52	41.67	63.83	**83.48**	72.35
	4	65.38	48.37	55.61	69.40	82.05	75.20

Table 4: Class-wise Result of Claim Identification

6 Conclusion

This paper examines quantum LSTM (QLSTM)-based frameworks for sarcasm detection and claim identification, comparing their performance with that of classical LSTM. Our primary goal was to analyze the efficacy of QML in these challenging NLP tasks.

For sarcasm detection, the hybrid QLSM-classical LSTM framework, particularly with four qubits, significantly outperformed both standalone classical and QLSTM models, demonstrating the benefit of quantum-classical integration for identifying sarcastic and non-sarcastic content with higher results.

For claim identification, the 2-qubit voting-based framework achieved the best overall F1-score. While the classical LSTM achieved the highest F1 score for 'Claim' sentences, and the 2-qubit hybrid framework had the highest recall for 'Claim' sentences, this task presented a more complex performance landscape across models.

In future work, we plan to validate these findings on larger datasets, explore architectures with more qubits, and investigate other quantum models, such as Quantum-GRU or Quantum-Transformer, to enhance performance further.

Abstract

This study aims to develop a gold-standard for terminological extraction in Castilian Spanish within the domain of labour law. To achieve this, a methodology was developed based on established linguistic theories and reviewed by a team of expert terminologists. Departing from previous extraction studies and reference theoretical frameworks, candidate terms were identified by their morphosyntactic patterns, enriched by assessing their degree of specialisation in reference resources. The candidate terms were then subjected to manual validation. To evaluate its applicability, we assessed the performance of the LLaMA3-8B and Mistral-7B language models in extracting labour law terms from the latest version of the *Real Decreto Legislativo 2/2015 Ley del Estatuto de los Trabajadores*. YAKE was also included as a statistical baseline for comparison between traditional methods and generative approaches. All models were evaluated against the validated gold-standard.

1 Introduction: ATE, Legal Spanish Terminology & Gold-Standard Generation

Terminological units provide linguistic access to specialised concepts within specific contexts (Cabré, 2009), making them fundamental to languages for specific purposes (LSP). Their relevance has attracted interdisciplinary attention—from linguistics and cognitive sciences to specialised fields and computer science (Faber and L'Homme, 2022)—where term extraction is both the starting point and the cornerstone, as it is the (semi)automatic process of identifying candidate terms from a given speciality domain based on linguistic and/or statistical studies of textual corpora (Peña and Peña, 2015). The development of natural language processing systems has made it possible to process larger amounts of text and obtain refined extractions that contributed to the creation of linguistic, specialised lexicographic and ontological resources that feed machine translation engines and chatbots, as well as facilitating data mining and knowledge discovery tasks (Tran et al., 2023).

To this matter, field-specific terminology is a necessity, despite certain challenges such as accessibility issues and linguistic particularities (Bagot, 1999). The legal domain is particularly challenging due to the characteristics of legal jargon, i.e. the variety of language used in texts related to the application and practice of law, including judicial, administrative, and notarial documents (Española and del Poder Judicial, 2017). Within these texts, labour terminology is focused specifically on terms used in legal contexts related to the labour field that allow specialists to communicate with precision and without ambiguity, in order to achieve the terminological ideal of univocity (Española and del Poder Judicial, 2017). It is characterised by a significant presence of derived forms—nouns, adjectives, and adverbs—along with abbreviations and acronyms referring to organisations and legal provisions. It also features prepositional phraseological units and frequent nominalisations of verbs, which sometimes also function as specialised nouns. These nominalisations are not only integral to specialised phraseology, but also play a key role in the transmission of specialised knowledge. Furthermore, the coexistence of specialised terms with general discursive units gives rise to overlaps between general and domain-specific meanings (Hourani-Martín, 2023; Vitalaru, 2019; Española and del Poder Judicial, 2017; Hormigo, 2011; Cabré et al., 1996).

Previous studies have highlighted the complexity involved in the extraction of legal terminology in Castilian Spanish (Martín-Chozas et al., 2022; Rico et al., 2019; Martín-Chozas and Calleja, 2018), which partially derives from the linguistic

Proceedings of Recent Advances in Natural Language Processing,pages 860–869
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-098

characteristics of terms. Their length and internal morphosyntactic complexity generate noise in automatic 'raw' extractions such as phraseology—units of specialised meaning that do not represent specialised concepts (Bagot, 1999; Cabré et al., 1996)—, and incomplete terms or concatenations of two separate terms that do not form a single terminological unit, among other problems. This shows that while labour law terminology fits into the generalised conventions of legal language, it may have certain distinctive features that need to be identified in order to nuance Automatic Term Extraction (ATE) task. These are particularly complex due to the lack of standardised, normalised and authoritative resources that could support the development of training and evaluation datasets (Breton et al., 2025). This gap is particularly noticeable when compared with other domains with numerous monolingual and multilingual resources, as outlined in the survey of Tran et al. (2023)—like biomedicine, where reference data bases such as SNOMED CT exist (Gaudet-Blavignac et al., 2021)—while very few exist for the legal field in Spanish.

For this reason, the TeresIA project aims to develop tools that allow the integration and linking of existing resources to create a meeting point for terminologies in Spanish. Likewise, it aims to enrich existing resources by means of methodologies based on AI techniques. Therefore, in this line of work, the aim of the present paper was to develop a gold-standard resource focused on Castilian Spanish within the specific subdomain of labour law, as manually curated gold-standards remain the most common and consistent evaluation method for this specific task (Tran et al., 2023). For its construction, the proposed methodology for the development of reliable evaluation datasets for the ATE task is based on well-established linguistic theories and aligned with best practices in terminology work.

To demonstrate the practical value of the proposed resource, it was used to evaluate the term extraction performance of two state-of-the-art open-source large language models, LLaMA3-8B and Mistral-7B, on the *Real Decreto Legislativo 2/2015, Ley del Estatuto de los Trabajadores* (Statute of Workers Rights in the Spanish Jurisdiction), the fundamental act that legally regulates and protects labour relations in Spain, and provides the basis for the rest of the labour legislation. Using prompting techniques, zero- and one-shot, adapted for term identification and compared the output of each model against our gold-standard. Additionally, we included YAKE as a statistical baseline for comparison. We compared the performance of the LLMs with each other and also with a classical statistical extraction method.

Building on this work, our paper makes the following key contributions:

1. Domain-adaptable methodology for ATE gold-standard construction
2. Reusable gold-standard dataset
3. Assesment of YAKE, LLaMA3-8B, Mistral-7B language models in extracting Spanish labour law terminologies

2 Previous Work and Theoretical Background

2.1 Terminology Extraction: Theoretical and NLP Techniques

ATE tasks are an example of the interdisciplinary appeal of terminology. From a linguistic perspective, they facilitate the theoretical linguistic work carried out by terminologists (Bagot, 1999) and are the basis for creating specialised-linguistic resources, such as dictionaries or databases that make validated terminologies available to general language users, students, or language professionals in institutions or public services, such as translators and interpreters (Rodríguez-Tapia, 2024; Seghiri, 2017; Sierra, 2010). However, the development of these linguistic materials requires a computational approach.

Terminology extraction from natural language texts as an NLP task has been the focus of automation efforts since the earliest approaches (Maria Teresa et al., 2006), which were based on linguistic (Bourigault, 1992; Evans and Zhai, 1996), statistical (Frantzi et al., 2000; Nazar, 2011), and hybrid perspectives (Fkih and Omri, 2012; Lossio-Ventura et al., 2016). All of these methods rely heavily on external resources and are typically implemented as supervised systems, whose performance largely depends on the quality of the underlying corpora (Tran et al., 2023). More recent techniques incorporate machine learning (Ljubešić et al., 2019; Hossari et al., 2019), deep learning (Rokas et al., 2020; Sugimoto et al., 2021), graph-based methods (Ala and Sharma, 2020; Kimura

et al., 2021), and hybrid strategies (Zheng et al., 2023). While these approaches have led to more productive outcomes, the need for annotated data remains.

Latest developments in LLMs have opened promising avenues for generating high-quality terminology extraction systems. These models are pre-trained on huge and diverse amounts of data, which leads to one of the key advantages of LLMs, that they do not require task-specific annotated data to perform accurately, as have reported several studies across various domains (Goel et al., 2023; Brkić Bakarić and Lalli Paćelat, 2024; Breton et al., 2025).

2.2 Evaluation for the ATE Task

Evaluation methods for terminology extraction tasks are generally classified, according to the survey by Tran et al. (2023), into manual and automatic approaches. Manual evaluation requires domain experts to determine how effectively the system extracted the candidate terms (Justeson and Katz, 1995). This approach is highly costly in terms of human effort. In contrast, automatic evaluation methods compare the extraction results with predefined term sets, such as terminological dictionaries (Macken, Lieve and Lefever, Els and Hoste, Veronique, 2013; Kayadelen et al., 2020) or gold-standard datasets (Tran et al., 2023).

The gold standard-based method uses terminological lists manually compiled by domain experts as a validation reference (Loginova et al., 2012). These datasets often include a wider variety of term variants while still preserving the terminological nature of conceptual units within the specialised domain. By reflecting the complexity of domain-specific terminology, the gold-standard approach is regarded as a more robust and suitable option for evaluating terminological quality, as it combines automatic tools with expert domain knowledge.

Despite significant progress in terminology extraction technologies, the lack of unified and effective validation standards remains a major challenge. Current evaluation methods are often based on specific datasets or metrics tailored to particular languages, most commonly English, or to domains traditionally studied within the ATE task (e.g. the widely used resources such as the ACL RD-TEC 2.0 dataset (QasemiZadeh and Schumann, 2016) and TermEval (Rigouts Terryn et al., 2020)).

For these reasons, a methodology specifically designed to address the needs of the labour domain in Spanish is proposed. The approach aims to address linguistic and conceptual aspects of legal language while being flexible enough to be applied across different subdomains.

3 Methodology for Gold-standard Generation and Validation

The methodology used to create the gold-standard for labour law terminology extraction in Spanish is based on morphosyntactic patterns of the terms. Previous studies show the importance of considering the morphosyntactic structure of terms to refine tATE tasks and that within a thematic domain it is possible to track terminology following said patterns, as they allow to determine which lexematic combinations correspond to linguistic concept representations, that is, terms, and which do not (Cabré, 2009). Therefore, the automatic extraction was directed towards candidates that met this set of conditions, i.e. that matched the morphosyntactic patterns and that their items were specialised where required, in order to obtain candidates specific to the labour domain and avoid noise or non-terminological candidates.

3.1 Selection of Morphosyntactic Patterns

The initial list of morphosyntactic patterns was compiled building on previous studies that identified recurrent morphosyntactic patterns of terms across various domains—including the legal field in Spanish (Martín-Chozas et al., 2022; Rico et al., 2019; Martín-Chozas and Calleja, 2018; Bagot, 1999). This first stage focused on noun-based structures, as they were the most frequent, and a first candidate patterns list was drafted. Subsequently, a filtering process was applied to identify which patterns were representative of Spanish labour law terminology. Using the *Estatuto de los Trabajadores* and CQL queries in Sketch Engine, the selected patterns were tested to determine if they showed term candidates of the labour domain that followed the linguistic definition of terminology as language units with specialised meaning in specific pragmatic contexts (Cabré, 2009). After manually reviewing the contexts of the candidates, the patterns that did not yield terminological units were excluded. Once manually filtered, the same experiment was replicated with ChatGPT to determine the reliability of the manually-verified patterns. The results of the automatic test were the same as the

Table 1: Morphosyntactic Patterns for Terminological Extraction.

manual one, which confirmed the reliability of the patterns and led to the final selection used for TE, as shown in the table 1 Morphosyntactic Patterns for Terminological Extraction.

In order to detect the candidate terms, two filters were established to ensure the reliability of the results. Firstly, a frequency filter that identified language strings corresponding to the patterns with a minimum frequency of 10 occurrences in the corpus. Secondly, a filter that would check the specificity of the pattern-components where required—as seen in table 1 Morphosyntactic Patterns for Terminological Extraction—to ensure that the candidates were actual terms from the labour domain and not a lexical unit with no specific meaning. For candidates corresponding to the pattern "N" (noun), linked resources were used to identify those units present in the *Estatuto* that had an exact match with entries in the *Vocabulari de Dret* (Law Glossary) by Termcat, the reference lexicographical law-resource in Catalan, elaborated by Law experts, providing terminological equivalents in Spanish. For more complex morphosyntactic patterns, its detection was combined with the presence of its components in the same linked resource, both when there was an exact and a partial match. Particularly in the case of adjectives, which had to be specialised for the pattern to be fulfilled, an extraction of adjectives with an independent entry in the *Vocabulari* was carried out, as well as those part of a nominal entry, in order to obtain a list of specific adjectives. This step was necessary to ensure the specialised nature of the units.

As a result of the extraction, a list of candidate terms was obtained for each pattern, together with their respective contexts within the *Estatuto* and tagged indicating which part of the pattern was found in the linked resources.

3.2 ATE Validation

The extraction results were manually validated to determine if they met the term definition provided earlier (Cabré et al., 1996). Firstly, the terms with complete coincidence with the *Vocabulari de Dret* were validated. In the cases where no match nor a partial match was found, it was assessed whether the candidates followed the morphosyntactic pattern regarding the specialised nature of their components. Initially, a total of 3,803 candidate terms that followed the morphosyntactic patterns were identified. For the rest of the candidates that had not passed the first filter, it was checked whether they appeared in their entirety in the reference legislation in Spain, *BOE*, or in the *Diccionario panhispánico del español jurídico* (Pan-Hispanic Dictionary of Legal Spanish), and only considering operational terms those for which there was agreement from validators in the manual validation.

Morphosyntactic Patterns	
1	N (specialised) + Adj (specialised)
2	N (general / not specialised) + Adj (specialised)
3	N (specialised) + Adj (specialised) + Adj (specialised)
4	N (general / not specialised) + Adj (specialised) + Adj (specialised)
5	N (specialised) + Adj (specialised) + Prep + Art (opcional) + N (specialised)
6	N (specialised) + Adj (specialised) + Prep + Art (opcional) + N (specialised) + Adj (specialised)
7	N (specialised) + Prep + Art (opcional) + N (specialised)

Table 2: Final Morphosyntactic Pattern List.

3.3 Final Pattern List

As a result of manual extraction, the need to nuance the patterns was verified, to take into account specific adjectives and to avoid the detection of phraseological units as if they were terminological. The latter is derived from the excessive nominalisation in the legal field abovementioned, where much of the phraseology is formed with deverbal nouns which can add clutter to the search for patterns starting from the detection of nouns—e.g. for the pattern "N + prep + N" we found the term *estatuto de los trabajadores* (statute of workers rights), but also the phraseological unit *representación de los trabajadores* (representation of employees). At this point, the specificity of the components of the patterns becomes particularly important, as it is the key element in determining whether the candidates were actual terms of the labour domain—e.g. for the pattern "N + Adj + prep + N" the term *trabajador demandante de empleo* (job-seeker) was found, but also the discursive unit *trabajador considerado en su totalidad* (worker taken as a whole) with no specialised meaning. For this reason, entire patterns had no valid term candidates, but only phraseological or discursive units. These patterns were excluded, which resulted in the final list of operative patterns.

Inter-annotator agreement metrics for manual validation resulted in a Cohen's Kappa of 0.7230 and an overall agreement rate of 84.57%, which indicates substantial agreement among validators. The result of this process was the identification of 752 terms, corresponding to the different patterns.

4 Evaluation of LLMs with Gold-Standard Dataset

For assessing the evaluation capabilities of our gold-standard for terminology extraction within the Spanish labour law domain, we conducted two experiments employing LLMs for extracting terms. These experiments are based on prompt engineering techniques, zero- and one-shot. Through these experiments, we aim to analyze the performance of the LLMs in identifying relevant legal terminology, measuring how well their outputs align with the manually curated gold-standard.

In addition to these LLM-based approaches, we also employed the statistical keyword extraction model YAKE (Campos et al., 2020). We applied YAKE directly with the PyPI library [1], to the *Estatuto de los Trabajadores*, using the resulting terms to evaluate their overlap with the gold standard. The objective of including YAKE was to provide a baseline for comparison for the performance of LLMs. This allowed us to compute changes in performance ($\Delta P/\Delta R$) between the LLM-based methods and the statistical baseline, showing the relative improvements in precision and recall from the LLM-based extraction.

All the results and code can be found on the following repository:
https://github.com/luxxiferr/gold_standard_llms_terminolgoy

To carry out experiments, we selected two state-of-the-art LLMs: LLaMA 3 with 8 billion parameters and Mistral with 7 billion. Since the advent of LLMs, proprietary models have become the industry benchmark for a wide range of NLP tasks, including information extraction (Breton et al., 2025). Despite their strong performance, these models often present limitations such as access restrictions, high computational resource requirements, and cost barriers.

Additionally, we selected LLaMA 3 and Mistral due to their relatively small model sizes compared to some of the largest LLM variants. Their sizes allow us to run inferences efficiently with-

[1] https://pypi.org/project/yake/

out requiring powerful GPUs or extensive cloud infrastructure. These advantages were key in our decision to rely on LLaMA 3 and Mistral for these experiments.

4.1 Prompting Techniques

In our experiments, we crafted textual prompts that reflect the criteria used to create our gold-standard dataset, with the goal of guiding the selected models in identifying candidate legal terms. We apply two main prompting strategies: zero-shot and one-shot.

Our zero-shot prompt explicitly defines the task and the morphosyntactic patterns that candidate terms must follow. The prompt also specifies the domain of interest (labour law terminology in Spanish) and requests a clean list of candidate terms extracted from a given legal text fragment. This approach tests the model's ability to generalize the task from the instructions alone, reflecting the linguistic patterns we applied during manual term identification. The zero-shot prompt can be seen in Table 3 (it has been translated from Spanish to English). The one-shot prompt is exactly the same as the zero-shot, but we included a positive extraction example after the instructions. The example can be seen in Table 4.

By basing both prompts on the patterns and criteria used in manual term identification, we ensure that the models have an accurate context for extracting candidate terms. This facilitates a meaningful comparison between the model outputs and human-validated terminology, enabling a robust evaluation of the LLMs' ATE performance.

4.2 Evaluation Methodology

After performing inference with our selected LLMs and applying post-processing to their outputs (e.g., deleting repeated prompt fragments, removing explanatory or justificatory text, and isolating only candidate term expressions), we proceeded to evaluate the quality of the extracted candidate terms by comparing them against our manually curated gold-standard dataset. Our evaluation framework is based on the one proposed by Breton et al. (2025) for ATE using LLMs in the legal domain.

We began by employing classic information extraction metrics: Precision, Recall, and F1 Score. In addition, we consider the F2 Score, which weights Recall more heavily, recognizing that, in terminology extraction, missing relevant terms could be worse than including some false positives. The absence of relevant terms can limit the coverage and overall usefulness of the generated resources, whereas false positives can often be filtered out or corrected in later stages. However, these metrics don't take into account slight mismatches between expert annotations and model predictions. For example, an expert might annotate the term as a single unit, *labour legislation*, while a LLM might extract *the current labour legislation*. Under conventional strict matching, the model's partial extraction would be counted as a False Positive, despite correctly identifying the core concept. To overcome this, we followed the mentioned framework by Breton et al. (2025), that implements the division of the True Positive category into two subcategories. These subcategories are: Perfect Match (the term exactly matches the gold-standard annotation) and Partial Match (it is a valid subset of a term). To quantify partial matches, the normalised Levenshtein distance is introduced, which is a metric that measures the minimal number of character edits needed to transform one string into another. Then, it is normalised to allow comparison across terms of different lengths.

4.3 Results and Discussion of Perfomance

Each set of extracted terms was evaluated for all 40 articles of the *Estatuto de los Trabajadores*. The models' outputs were compared against our gold-standard annotations using the evaluation framework described. Table 5 presents the terminology extraction results for each model.

Overall, one-shot prompting increased the number of exact true positives for both models, improving precision, while partial true positives remained stable or slightly decreased. Mistral produced fewer false positives than LLaMA 3 under one-shot conditions, reflecting higher precision, and both models reduced false negatives, thereby improving recall, especially LLaMA 3.

A key part of the evaluation was the normalised Levenshtein distance, measuring similarity between extracted terms and the gold-standard validated terms. The distances range from 0.647 to 0.708. This indicates that many partial matches are close to the gold-standard terms but still differ notably. Despite the improvements seen with one-shot prompting, the results indicate that neither model consistently extracts legal terminology accurately enough. The high number of false positives and false negatives, combined with moderate

You are an expert in Spanish labour law terminology.
Task: Extract only the candidate terms that appear in the following excerpt from a legal article of the Workers' Statute.
The terms must be:

- Nouns or complex nominal structures that represent concepts specific to labour law.
- Terminological units within the legal-labour domain.

They must follow one of the following morphosyntactic patterns:
Return a clean list of candidate terms:

- One term per line
- No numbering, no quotation marks, no symbols

"""{texto_articulo}"""
```

Candidate terms:

Table 3: Zero-shot prompt used before extracting candidate terms in the legal-labour domain.

precision and recall values, reflects the limitations in these models' capabilities for this task.

We calculated the differences in precision (ΔP) and recall (ΔR) to quantify how much better or worse each LLM performs compared to the YAKE baseline. In the zero-shot setting, Mistral achieved a precision of 0.677, much higher than YAKE (with $\Delta P = +0.2099$) but at a significant cost in recall ($\Delta R = -0.5119$). LLaMA3-8B, with zero-shot prompting, showed a precision gain of $\Delta P = +0.2180$ and a recall loss ($\Delta R = -0.5488$), with a comparable $\Delta P/\Delta R$ of -0.3972. These results show that LLMs are more selective but fail to retrieve a substantial number of relevant terms when extracting terms with zero-shot prompts.

In the one-shot setting, where models received an example for guidance, both LLMs improved in recall but at the cost of precision. Mistral's recall is 0.487 (narrowing the gap to $\Delta R = -0.4399$), while precision dropped to 0.450 ($\Delta P = +0.1918$), resulting in a $\Delta P/\Delta R$ of -0.4360. LLaMA3-8B increased recall to 0.545 ($\Delta R = -0.3825$) but only achieved a modest precision gain ($\Delta P = +0.0694$), producing the lowest ratio in the group ($\Delta P/\Delta R = -0.1815$). Considering overall performance, Mistral zero-shot achieved the highest F_1 score (0.440), while YAKE obtained the highest F_2 score (0.610), reflecting its strong recall. Additionally, YAKE exhibited the lowest average normalised Levenshtein distance (0.5506), outperforming all LLM configurations in partial match quality because the terms are all extracted as they are from the text. Overall, YAKE offers broader extraction because it relies on statistical features such as term frequency and co-occurrence, allowing it to capture a wide range of candidate terms. This results in high recall, but with very low precision because of the large number of false positives. LLMs are more selective in their outputs. Zero-shot prompts make LLMs more conservative and one-shot prompts produce more generalised results, increasing recall.

5 Conclusions & future work

This study presents several key contributions: a domain-adaptable methodology for constructing gold-standard datasets for ATE, the creation of a reusable gold-standard dataset specifically for the Spanish labour law domain, and an assessment of LLaMA3-8B and Mistral-7B language models in extracting domain-specific terminologies, complemented by YAKE, which served as a statistical baseline to contextualize LLM performance. Thanks to its methodological and theoretical basis, the present gold-standard can not only be used in linguistic or computational tasks within this domain, but can also serve as a reference for the development of future resources in other areas, such as mercantile, administrative, or criminal law. To do so, it would be necessary to test the morphosyntactic patterns in order to identify the patterns specific to those domains. Moreover, after the experiments carried out, the reliability of the present gold-standard has been tested against LLMs. Therefore, at this stage, we consider the following courses of action for further research. First, to validate the *Estatuto* in its integrity in order to have a wider body of terminology, applying the same methodology fol-

Excerpt text: Article 2. Special employment relationships.
1. The following shall be considered special employment relationships:
a) That of senior management personnel not included in Article 1.3.c). b) That of household service.c) That of convicted persons in penitentiary institutions. d) That of professional athletes. e) That of artists engaged in performing, audiovisual, and musical arts, as well as persons performing technical or auxiliary activities necessary for such work. f) That of persons involved in commercial operations on behalf of one or more employers without bearing the risks and rewards thereof. g) That of workers with disabilities providing services in special employment centers. h) (Repealed) i) That of minors subject to internment measures for the fulfillment of their criminal responsibility. j) That of medical residents in specialist training programs. k) That of lawyers providing services in law firms, whether individually or collectively. l) Any other work expressly declared by law to be a special employment relationship.
2. In all the cases mentioned above, the regulation of these employment relationships shall respect the fundamental rights recognised by the Constitution.
Candidate terms:

- Noun: activity, article, account, compliance, development, execution, employment, internment, law, regulation, residency, risk, service, work
- Noun + adjective: technical activity, professional athlete, fundamental right, penitentiary institution, commercial operation, criminal responsibility, employment relationship
- Noun + adjective + adjective: [none identified]
- Noun + adjective + preposition + (optional article) + noun (+ optional adjective): special employment center
- Noun + preposition + (optional article) + noun: [none identified]

Table 4: Example used in the one-shot prompt. Spanish text tranlasted into English.

Model	TPe	TPp	FP	FN	Prec	Rec	F1	F2	Avg Lev

lowed in the present paper. Secondly, to study other morphosyntactic patterns whose central elements are not nouns in order to enrich existing terminological resources, which currently show limitations in accounting for certain elements—e.g. specific adjectives. Finally, to analyse phraseology with the excluded patterns that only showed discursive or phraseological units, which could be used to create specialised-phraseology detection filters.

Future work involving LLMs will focus on fine-tuning LLaMA3-8B, Mistral-7B, and other models on the gold-standard resource. These models will be able to recognize terminology more accurately, generate more precise results, and gain a deeper understanding of the legal domain terminology by including the validated terms into the training data. Moreover, we plan to implement explainability strategies and carry out error studies on model outputs. Thus, we can analyze the behavior of LLMs and find frequent mistakes or ambiguities in terminology extraction. This approach could ensure a feedback loop that continuously improves the accuracy and reliability of terminology recognition in future experiments.

Nevertheless, we hope that this gold-standard will contribute to the improvement and enrichment of existing terminological resources in Spanish.

Benchmarking Item Difficulty Classification in German Vocational Education and Training

Alonso Palomino **Benjamin Paaßen**

Bielefeld University, Germany
first.last@dfki.de, first.last@techfak.uni-bielefeld.de

Abstract

Predicting the difficulty of exam questions or items is essential to effectively assembling and calibrating exams. While item response theory (IRT) models can estimate item difficulty, they require student responses that are costly and rarely available at scale. Natural language processing methods offer a text-only alternative; however, due to the scarcity of real-world labeled data, prior work often relies on synthetic or domain-specific corpora, limiting generalizability and overlooking the nuanced challenges of real-world text-based item difficulty estimation. Addressing this gap, we benchmark 122 classifiers on 935 German Vocational Education and Training (VET) items labeled via previous IRT analysis to assess feasibility under real-world conditions. In our setup, a stacked ensemble that combines linguistic features, pre-trained embeddings, and external semantic resources outperforms both transformer-based models and few-shot large language models, achieving moderate performance. We report findings and discuss limitations in the context of German VET.

1 Introduction

In psychometrics, pretesting is the standard practice for item difficulty estimation: recruiting a representative student sample, recording their item responses, and fitting an IRT model to obtain precise difficulty estimates (Lord and Novick, 1968; Baker, 2001). Gathering representative high-stakes student response data is complex and seldom feasible. High financial and administrative costs for sourcing a domain-specific, diverse examinee pool, challenges embedding items in live exams, and limited pretesting capacity all contribute to its scarcity.

Educators gauge item difficulty via expert review of phrasing combined with their assessment experience. For example, one may consider the lexical, syntactic, and semantic attributes of the item's text (Dale and Chall, 1949; Martinc et al., 2021). Following this difficulty estimation approach, natural language processing models have recently been applied to estimate item difficulty, e.g., via text regression or classification techniques (AlKhuzaey et al., 2023; Benedetto et al., 2023).

Easy
Topic: Mathematical Aptitude
Question Type: Single Choice
Question: *"How many kilograms (kg) are in one ton (t)? (10, 100, 1000, 10000)"*
Predicted Difficulty: 0.0 **True Difficulty**: 0.0

Medium
Topic: Information Technology Aptitude
Question Type: Single Choice
Question: *"What is a cloud? (1) A program that cannot be installed on a PC, (2) hardware for a PC, (3) a storage space that is not on a PC"*
Predicted Difficulty: 1.0 **True Difficulty**: 1.0

Hard
Topic: Clerks in Office Management
Question Type: Single Choice
Question: *"Out of 100 orders, on average 5 orders are returned. How many orders were shipped if 10 orders are returned? (a) 190, (b) 205, (c) 195, (d) 200"*
Predicted Difficulty: 1.0 **True Difficulty**: 2.0

Figure 1: On bfz's VET data, the ensemble classified easy and medium correctly but overestimated hard.

In education, estimating item difficulty is key for comprehensive exam assembly and calibration (Palomino et al., 2024, 2025). Prior research relies on domain-specific or synthetic student response datasets in English; therefore, difficulty estimation in German Vocational Education and Training (VET) remains unexplored, and evidence on existing methods' performance on real data is lacking. To address this gap, we ask: **RQ:** *How accurately do popular text classifiers estimate the difficulty of German VET test items?* Partnering with bfz[1], Germany's largest VET services provider, we evaluated 122 text-classification methods on an industry-

[1] https://www.bfz.de/

Proceedings of Recent Advances in Natural Language Processing,pages 870–875
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-099

grade VET dataset of 935 IRT-labeled items and found that items requiring ambiguity resolution, technical or domain-specific knowledge or visual inference were most often misclassified, underlining the limits of current approaches[2]. Among the tested approaches, a stacked ensemble achieved the strongest production-level performance (balanced accuracy 0.60). Figure 1 compares predicted and true difficulty, showing correct easy and medium classifications but overestimation of hard items. Sections 2-5 outline the literature, dataset, methods, results, and conclusions.

2 Related Work

Psychometrics traditionally estimates item difficulty via Classical Test Theory (CTT) and Item Response Theory (IRT), where CTT defines difficulty as the proportion of correct responses (0-1) and IRT fits latent-trait models, both requiring pretesting data (Lord and Novick, 1968; Baker, 2001; Embretson and Reise, 2013). By contrast, NLP methods predict difficulty directly from text: Loukina et al. (2016) used a random forest on text-complexity features for listening items, Huang et al. (2017) applied a CNN to sentence-level reading items, Ha et al. (2019) combined ELMo, Word2Vec and retrievability features for medical exams, and Xue et al. (2020) demonstrated that transfer learning from completion-time estimation could improve estimation. Yaneva et al. (2021) clustered linguistic features to split 18,961 medical exam items into low/high response-process complexity. Benedetto et al. (2021) compared term-frequency, BERT/DistilBERT, and IRT models on proprietary and ASSISTments data, finding transformers with additional text features most effective. Byrd and Srivastava (2022) simulated pretesting with QA ensembles to infer IRT scores on HotpotQA. Park et al. (2024) proposed a zero-shot, resource-intensive framework generating synthetic responses via LLM clusters and aggregating their outputs. Surveys by Benedetto et al. (2023) and AlKhuzaey et al. (2023), covering 122 and 88 studies, highlighted dataset scarcity due to confidentiality and concluded that semantic/syntactic features remain the strongest predictors. Yaneva et al. (2024) organized a medical exam shared task with 17 teams; framed as regression, models showed minimal improvements over baselines. Zotos et al. (2025) found LLM uncertainty correlates with difficulty on 451 Biopsychology items, though generalizability is unclear.

3 Text-based Item Difficulty Estimation

3.1 Dataset

We used data from bfz's assessment platform, where item difficulties (-3.0 to +3.0) were estimated with a 1-parameter IRT model on 935 items from a vocational cohort (Paaßen et al., 2022b,a). For exam assembly and interpretability, scores were discretized into easy, medium, and hard classes to reduce cognitive load (Schwarz, 2007; Weijters et al., 2010) and mitigate noise and bias (Caruana and Niculescu-Mizil, 2006; Ribeiro et al., 2016; Furnham and Boo, 2011). Though granularity is lost, discrete classes are directly usable by test designers and support categorical constraints. Thresholds were set empirically via quantile inspection and stability checks to preserve ordinal structure while limiting noise. Following Yaneva et al. (2024), we aimed for balanced splits, but real-world class imbalance posed challenges. Despite testing oversampling, class weighting, and alternative binning, we retained the configuration that best preserved item characteristics: 19% easy, 75% medium, 5% hard; 71% single-choice, 20% multiple-choice, 8% matrix; and topic distributions of 30% IT, 16% German, and others <1%. To safeguard privacy and intellectual property, raw data remain unavailable, but anonymized embeddings are shared.

3.2 Task and Experimental Setup

We model difficulty as a three-class task (0 easy, 1 medium, 2 hard) using text and meta-attributes (topic, type, skills). Stratified 10-fold cross-validation preserves distributions. We report balanced accuracy, macro F1, and weighted precision/recall; models are retrained on the full set and evaluated on a stratified hold-out. Labels are 19% easy, 75% medium, 5% hard; formats 71% single-choice, 20% multiple-choice, 8% matrix. Table 2 lists the five most frequent topics; Figure 2b shows IRT scores; Table 1 details the split.

3.3 Models

Classic: We trained baseline classifiers (uniform random and majority-class) and supervised algorithms k-nearest neighbors, decision trees, random forests, support vector machines, logistic regression variants, and neural networks using `scikit-learn` and Keras (Pedregosa et al., 2011;

(a)

Difficulty Level	Count

Warehousing & logistics	78
Professional Advice & self-assessment	69
Clerks in office management	59
Total Items	935

(b)

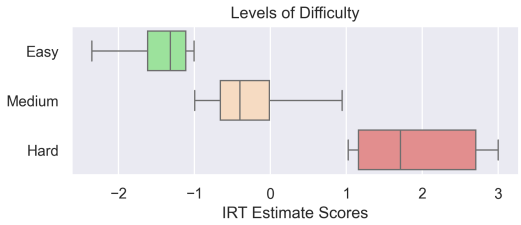

Table 2: (a) shows the top-5 topic distribution, while (b) displays the summary of IRT scores.

Chollet et al., 2015).

Ensemble: We used stacked generalization (Wolpert, 1992; Pedregosa et al., 2011), combining balanced linear (PA, logistic regression, SVM, perceptron) and tree-based models (randomized trees, AdaBoost). Their outputs fed a dense meta-network (128-64-32-10-3) to predict difficulty (Chollet et al., 2015).

DistilBERT and FSL: We fine-tuned and evaluated existing BERT models for text complexity estimation, a semantically similar task (Face, 2024; Anschütz and Groh, 2022; Ruben Klepp, 2022). Additionally, we evaluated few-shot learning (FSL) via SetFit (Tunstall et al., 2022).

LLMs: We built a German few-shot pipeline with GPT-4, GPT-4o, and o1-preview (Achiam et al., 2023; Hurst et al., 2024; Jaech et al., 2024). Prompts defined labels (0-2) with up to 10 stratified exemplars; for tests, the 10 most similar items (cosine similarity) were retrieved. Parameters were fixed for determinism, and three runs per item were aggregated by majority voting using the `Instructor` library (Liu and Contributors, 2024).

Linguistic Features Each item's stem, answers, distractors, topics, and skills were encoded with embeddings and features:

1. **Stylometry and Format:** We extracted sentence count and punctuation frequencies; noun-to-word ratio; character distribution and average characters per word; the Coleman-Liau readability index (Coleman and Liau, 1975); and encoded question types (single choice, multiple choice, matrix) as one-hot vectors.
2. **LIWC and Text Complexity:** We extracted 39 German LIWC dimensions with high correlation to difficulty labels, including analytical thinking, advanced vocabulary, quantifiers, insight, certainty, negative emotion, discrepancy and tone measures (Boyd et al., 2022). We reduced features to two components via PCA and used the Anschütz and Groh (2022) text complexity model as an auxiliary difficulty signal.
3. **Embeddings and Visual Content:** We extracted embeddings from ten pretrained models, including the top five from the MTEB text classification leaderboard (other languages) (Muennighoff et al., 2022) and five trending German similarity models from HuggingFace[3]. Encoding only the stem and answer improved classification. Among these, embeddings (8), (4), and (10) yielded the best results. Visual content was captured via one-hot encoding of categorical metadata.
4. **Topics and Skills:** After comparing several pretrained models, we found that the model of Rogge (2024) best captured topics and skill themes for difficulty prediction; we therefore use it to embed those attributes.
5. **Semantic Relations and Negation Cues:** We applied cosine similarity matching with the ODENet lexical base (Siegel and Bond, 2021) to identify hypernyms and hyponyms and used a manually curated negation cue list to count explicit negation terms.
6. **Semantic Similarities and Named Entities:** We computed cosine similarities between each item's stem and its answers and distractors and used the NER model of Schiesser (2024) to

count location, organization and person entity frequencies.

4 Results

Addressing RQ, Table 3 reports balanced accuracy and weighted F1 for the best models among 122 configurations. Combining stem and answer embeddings with stylometric, semantic, topic, and skill features yielded the strongest results. A stacked ensemble of balanced linear and tree-based learners achieved 0.60 balanced accuracy and 0.73 weighted F1. DistilBERT variants followed (0.58, 0.56), while logistic regression and SVMs gave moderate scores. LLMs (GPT-4o, o1-preview) performed worst, with several complex models overfitting due to data scarcity and imbalance, underscoring the trade-off between balanced accuracy and weighted F1 in practice. Examination of ensemble predictions highlights key limitations. As Table 3 shows, easy items reached an F1 of 0.55 (moderate), medium items 0.81 across 139 instances (strong), and hard items only 0.24 on eight instances (weak). By topic, "content creation," "basic technology use," and "German cultural competence" achieved perfect balanced accuracy (1.0), while "women in the workforce," "warehousing and logistics," and "IT aptitude" averaged 0.22. Misclassifications often involved items requiring contextual or ambiguous reasoning, complex instructions, technical/domain expertise, or visual/geopolitical inference (e.g., cargo securing, Schengen Agreement impacts).

5 Conclusions

Partnering with bfz, a major VET provider, we benchmarked 122 models for item difficulty classification on real German VET data, unlike prior work on medical or synthetic English datasets. The best model was a stacked ensemble combining stem and answer embeddings, stylometric features, and semantic metadata, achieving 0.60 balanced accuracy and 0.73 weighted F1, outperforming fine-tuned transformers and LLM prompting. While first framed as a standard text classification task, our results highlight its complexity and the importance of non-linguistic features. Future work will apply active learning for data acquisition and fine-tune larger encoders.

vul. Kozelnytska 2
Lviv, 79026, Ukraine
paniv@ucu.edu.ua

Abstract

This paper evaluates language model performance on Ukrainian language tasks across multiple downstream benchmarks, including summarization, closed and open question answering, and translation at both sentence and paragraph levels. We also introduce LongFlores, an extension of the FLORES benchmark designed specifically to assess paragraph-level translation capabilities. In our experiments, we compare the performance of base models against their instruction-tuned counterparts to isolate and quantify the source of performance improvements for Ukrainian language tasks. Our findings reveal that for popular open source models, base models are stronger in the few-shot setting for the task than their instruction-tuned counterparts in the zero-shot setting. This suggests lower attention paid to Ukrainian during the instruction-tuning phase, providing valuable insights for future model development and optimization for Ukrainian and potentially other lower-resourced languages.

1 Introduction

Large Language Models (LLMs) have demonstrated SOTA performance across various tasks, yet these capabilities have been predominantly studied within English-language contexts, both in training and evaluation. While recent years have witnessed a surge in multilingual LLMs, a critical question remains unexplored: At which development stage do performance improvements for non-English languages emerge? Is it during pretraining or instruction-tuning? By investigating this question, we can gain valuable insights into the distribution of multilingual data across different stages of model development.

To address this gap, we evaluate LLM performance across diverse Ukrainian language tasks, including summarization, extractive and general question answering, and translation between Ukrainian and eight other languages.

Additionally, we introduce a novel benchmark for long-context translation based on FLORES (Goyal et al., 2021). Current translation benchmarks primarily focus on sentence-level evaluation, with few resources dedicated to assessing long-context translation capabilities. Yet, paragraph-level translation more closely resembles real-world applications and could prove invaluable for developing LLMs for languages with fewer resources than English. With effective translation tools, English instructions can be adapted to lower-resource languages, transferring English capabilities to those languages.

As for our main contribution, we present a thorough evaluation of LLM performance for Ukrainian across multiple downstream tasks, including XLSUM-based summarization, MMLU-based general question answering, Belebele-based extractive question answering, a translated version of SQUAD, and sentence-level translation using the FLORES benchmark across nine languages.

Second, we introduce LongFlores, a long-context setting of the FLORES benchmark designed to evaluate paragraph-level translation.

Third, we investigate performance differences between pretrained and instruction-tuned versions of models (where available) to isolate the development stage at which performance gains occur for Ukrainian language tasks. Our findings, particularly regarding the source of performance improvements, will benefit other mid-resource languages by helping researchers and developers focus on the most impactful development stages for achieving state-of-the-art results in specific lower-resourced languages.

All evaluation scripts, our LongFlores benchmark, eval results, and leaderboard are published here https://github.com/robinhad/

2 Related work

2.1 Performance gains on pretraining vs finetuning

Overall, there is an extensive literature for evaluating LLMs generally, with models like LLama (Grattafiori et al., 2024) publishing general performance gains. Still, models like LLama are trained on majority of English texts, where 50% of data is general knowledge English text, 25% of mathematical and reasoning tokens, 17% code tokens, and 8% multilingual tokens (Grattafiori et al., 2024). Unfortunately, there is no information about how much multilingual data is contained during instruction-tuning phase.

To the best of our knowledge, there are few to no papers that study this specific gap, but there are a couple of works that explore the source of performance gaps in general.

Gao et al. (2024a) explore the effect of multilingual pretraining and instruction tuning on the cross-lingual knowledge alignment mechanism. Researchers measured cross-lingual alignment specifically and found that instruction-tuning improves downstream task performance much more than pretraining. However, they use translated data from English to measure performance in other languages. Also, they explore performance in a zero-shot setting without a few-shot evaluation and, subsequently, don't explore base models.

Jindal et al. (2024) explore how to expand LLM knowledge and how that knowledge then affects downstream performance on different benchmarks. As claimed by that paper, most of the LLM knowledge could come from pretraining, which then can be relatively effortlessly transferred to instruction-tuning capabilities. Nevertheless, they don't explore a few-shot setting for base models to see the origin of LLM performance.

2.2 Benchmarks for Ukrainian

There are numerous benchmarks introduced for Ukrainian language, such as UA-CBT (Hamotskyi et al., 2024), Winograd schema challenge (Kuchmiichuk, 2023), FLORES for multilingual translation across 200 languages (Goyal et al., 2021), XL-SUM for summarization (Hasan et al., 2021), Global MMMU (Singh et al., 2024), which is a human-validated MMLU questions benchmark and national exam, ZNO from UNLP 2024 Shared task (Romanyshyn et al., 2024).

Last, but not least, researchers from INSAIT presented a set of classic benchmarks as part of release of their model specifically for Ukrainian language (Yukhymenko et al., 2025), where they introduced adapted versions of Winogrande challenge, Hellaswag, ARC Easy/Challenge, TriviaQA, GSM-8k, MMLU, IFEval and ZNO, testing knowledge of the Ukrainian high school curriculum in Ukrainian language & literature, history, mathematics and geography. To the best of our knowledge, there is no comprehensive evaluation of the Ukrainian language across downstream benchmarks and measuring gains from particular training stages.

3 Benchmarks

We follow the same methodology as IberoBench (Baucells et al., 2025), by evaluating models across a set of classic downstream benchmarks.

Summarization. For the summarization task, we use XLSUM benchmarks based on BBC news articles and professionally annotated summaries. We use only Ukrainian split.

Extractive question answering We test Ukrainian version of SQUAD dataset (Ivanyuk-Skulskiy et al., 2021), which was translated and annotated by students. We also use Ukrainian Belebele split (Bandarkar et al., 2024) for this task.

Option question answering As for general knowledge testing, we use Global MMLU benchmark (Singh et al., 2024) from Cohere, which contains adapted MMLU question across various subjects from STEM to Humanities into different languages that are human-annotated and validated after translation, making them usable for evaluation.

Translation We test on the classic FLORES benchmark (Goyal et al., 2021) for sentence-level translation. Besides that, we introduce a paragraph-level version of this benchmark called LongFLORES. We test this across 9 languages in both directions from and to Ukrainian. The languages are: English, Crimean Tatar, Polish, Russian, Romanian, German, Czech, Hungarian, Slovak. We selected those languages based on several criteria: 1) languages of minorities in Ukraine, 2) languages of neighboring countries 3) languages of countries with considerable Ukrainian diaspora. FLORES benchmarks contain sentence positions and paragraph metadata, which enable researchers to reconstruct source paragraphs. This helps us to create

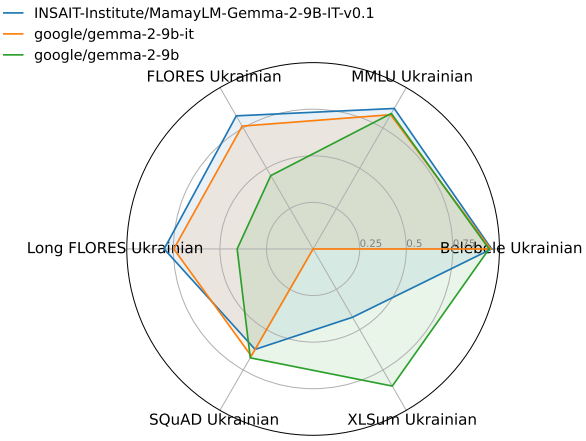

Figure 1: Comparison across gemma-2-9b-it and instruction-tuned versions of that model. We can see that MamayLM provides performance improvement both over the instruction-tuned version and the base version, indicating a benefit of extensive instruction-tuning for Ukrainian.

a paragraph-level benchmark. A similar setting is introduced for Finno-Ugric languages (Pashchenko et al., 2025), but is subsequently translated and validated due to source sentence problems. As a result, the reconstructed set contains 281 items in a dev set that we use for this benchmark. We found sentence-level problems in the FLORES benchmark, which are subsequently introduced in the paragraph-level setting. Despite that, we believe this benchmark would be helpful to get a rough estimate of translation performance for both sentence-level and paragraph-level settings, but better benchmarks are needed.

4 Experimental Setup

Due to budgetary constraints and practicality concerns, we tested popular open source models with parameters ranging from 4 to 32 billion. We use lm-evaluation-harness (Gao et al., 2024b) and evaluate models through the VLLM (Kwon et al., 2023) framework. For most models, we use a single node with 2x RTX A6000 Ada and approximately 2 weeks of GPU hours. As for model selection, we selected models based on popularity and claims about training on Ukrainian data. We run each model on standardized prompt sets and adapt generation parameters from existing reference implementations in lm-evaluation-harness from other languages. As for metrics, for most benchmarks we use BLEU (Papineni et al., 2002) (including paragraph-level translation as suggested by Deutsch et al. (2023)). with the exception of Global MMLU for which we use accuracy score. We evaluate all models in 0-shot and 3-shot settings (with the exception of base models evaluated only in 3-shot). For model comparison, we record each model's ranking on each task and then calculate its average rank.

5 Results & Discussion

Our evaluation reveals a performance gap between base and instruction-tuned models when processing Ukrainian language tasks. The results demonstrate that pre-training appears to be the primary source of Ukrainian language capabilities across most model architectures, with instruction-tuning lacking performance on Ukrainian-specific tasks. We show an overall breakdown in **??** and a detailed evaluation by language pair in **??**.

Base models consistently outperform their instruction-tuned counterparts across multiple model families when evaluated with few-shot prompting as shown on Figure 2 and in Table 1. For example, Qwen3-14B-Base (Yang et al., 2025) achieving an average rank of 11.00 compared to 18.00 for the instruction-tuned variant, and Qwen3-8B-Base reaching 16.00 versus 20.67 for its instruction-tuned version. Similarly, Llama 3.1-8B (Grattafiori et al., 2024) base model (rank 24.17) substantially outperforms the instruct version (34.17), while Mistral-7B-v0.3 (Jiang et al., 2023) base (26.83) exceeds the performance of its instruction-tuned counterpart (30.83). EuroLLM (Martins et al., 2024) follows the same trend, with

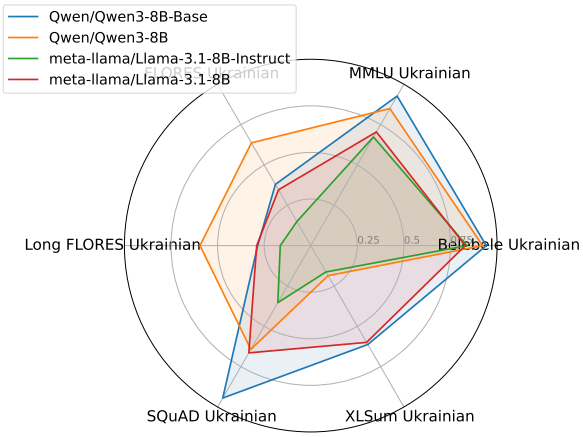

Figure 2: Comparison of Qwen3 models and Llama-3.1 models. We can see that most of the performance is contained in a pretraining stage of those models.

Table 1: Side-by-side comparison between base models in 3-shot setting and instruction-tuned versions in 0-shot. Across most families, base models demonstrate much better performance for Ukrainian than their instruction-tuned counterparts, with an exception of gemma-2-9b-it and MamayLM model, tuned specifically for Ukrainian language understanding

the base model achieving a rank of 17.17 compared to 25.33 for the instruction-tuned version.

The sole exception to this pattern emerges with the Gemma-2-9B (Team et al., 2024) family as shown in Figure 1, where the instruction-tuned model achieves a better average rank (18.83) than the base model with 3-shot prompting (17.00). However, the Ukrainian fine-tuned MamayLM-Gemma-2-9B-IT model, achieves the best overall performance with an average rank of 14.17, suggesting that domain-specific instruction-tuning can be beneficial when properly executed.

Task-specific analysis reveals that question answering benchmarks like Belebele, Global MMLU, and SQuAD Ukrainian show variable performance patterns between base and instruction-tuned models, indicating that both pre-training knowledge and instruction-following capabilities contribute to success on these tasks. However, base models consistently achieving superior performance on FLORES translation tasks when provided with few-shot examples, while instruction-tuned models frequently struggle with the XLSum summarization task, often scoring near zero.

The superior performance of base models with few-shot prompting suggests that instruction-tuning datasets may contain insufficient Ukrainian examples or that the multilingual instruction-following training process interferes with the models' pre-existing Ukrainian language representations, being optimized primarily for English.

6 Conclusion

In this study, we evaluated popular large language models on Ukrainian language tasks to investigate the relative contributions of pre-training and instruction-tuning to multilingual capabilities. Our findings demonstrate that instruction-tuned models consistently underperform their base counterparts on Ukrainian tasks in zero-shot settings. We attribute this degradation to a lack of Ukrainian instruction data during the instruction-tuning phase, where models appear to lose pre-trained Ukrainian capabilities without gaining equivalent instruction-following proficiency in the language. The superior performance of base models with few-shot prompting suggests that Ukrainian language understanding in popular models primarily occurs during pre-training. These results have important implications for other mid-resource languages. Our study suggests that practitioners should prioritize two key factors: first, ensuring robust pre-training with substantial target language representation, and second, incorporating extensive instruction data in the target language during instruction-tuning. Without adequate instruction data, the instruction-tuning process may diminish rather than enhance multilingual capabilities.

Abstract

Deception is a pervasive feature of human communication, yet identifying linguistic cues of deception remains a challenging task due to strong context dependency across domains, cultures, and types of deception. While prior work has relied on human analysis across disciplines like social psychology, philosophy, and political science, large language models (LLMs) offer a new avenue for exploring deception due to their strong performance in Natural Language Processing (NLP) tasks. In this study, we investigate whether open-weight LLMs possess and can apply knowledge about linguistic markers of deception across multiple languages, domains, and cultural contexts, with language and country of origin used as a proxy for culture. We focus on two domains, opinionated reviews and personal descriptions about sensitive topics, spanning five languages and six cultural settings. Using various configurations (zero-shot, one-shot, and fine-tuning), we evaluate the performance of LLMs in detecting and generating deceptive text. In detection tasks, our results reveal cross-model and cross-context performance differences. In generation tasks, linguistic analyses show partial alignment with known deception cues in human text, though this knowledge appears largely uniform and context-agnostic.

1 Introduction

Researchers in many disciplines agree that deceptive behaviour is context-dependent, influenced by factors such as domain, culture, and the type of deception (Markowitz and Hancock, 2022). This also reflects to the linguistic markers used to spot and analyse deceptive language (Newman et al., 2003; Ott et al., 2011; Pérez-Rosas and Mihalcea, 2014; Taylor et al., 2017). LLMs are paving the way for the advancement of various NLP tasks and deception related tasks are no exception. Here, we investigate if LLMs can capture and utilize accordingly the context-dependency of deception. This is critical, since the utilization of LLMs in real-world and high-stake applications in a way that fails to capture deception nuances could have serious consequences.

Although related studies show promise, they exhibit several important limitations. Many rely on small or non-human annotated datasets that fail to capture the complexity and nuance of real-world deception across diverse and dynamic contexts. Consequently, the high performance reported in controlled settings may not generalize well to other domain-specific deceptive content. Moreover, the deployed approaches often lack transparency, making it difficult to understand the underlying mechanisms of deception detection. Cultural and contextual variability in deceptive behavior remains underexplored, despite being a well-established factor in deception studies, while the absence of a standardized ground truth hinders deeper insights into why certain texts are perceived as deceptive.

In this work, we aim to partially address these limitations by evaluating both deception detection and generation capabilities of LLMs across a diverse set of deception datasets and cultural contexts. We further ground our analysis in well-established linguistic cues associated with deception and explore the relationship between these cues and the models' self-assessed factuality and interpretability.

Our goals are to examine whether current and open-weight LLMs:

- can detect and generate deceptive language across varied contexts.
- possess knowledge of linguistic indicators of deception, and whether they can apply this knowledge in both detection and generation tasks.

Proceedings of Recent Advances in Natural Language Processing,pages 884–893
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-101

- can recognize and adapt to contextual variations in deceptive behavior across languages, domains, and cultures. For this task, we use language and country of origin as proxies for culture (Hofstede, 1980; Pérez-Rosas and Mihalcea, 2014).

To the best of our knowledge, this is the first work that examines LLMs' capabilities for deception-related tasks via this viewpoint.

2 Related Work

In this section, we review prior research on the linguistic cues of deception and the performance of LLMs in deception-related tasks.

2.1 Linguistic Cues of Deception

Cognitive complexity. Deceptive language is expected to be characterised by less complex utterances, due to the increased cognitive load. Cues like 'mean word length', 'mean sentence length', 'mean preverb length', 'syllables', LTR (lemma token ratio - lexical diversity-), 'conjunctions', 'subordinate clauses' and 'readability' fall in this case. 'Motion verbs' (e.g., walk) are considered less cognitively complex and associated with deceptive utterances (Newman et al., 2003). However, socially oriented studies (e.g., the Pinocchio effect) and culturally focused research suggest that deceptive utterances may involve an increase in the quantity of text or similar levels of verbal output as truthful statements (Swol et al., 2012).

Non-immediacy. Non-immediacy can be conveyed through self and group references. Deceivers from individualistic cultures often use fewer first-person and more third-person pronouns to create distance. In contrast, those from collectivistic cultures may use more first-person and fewer third-person pronouns to distance the group from the deceit, or show no significant difference (Taylor et al., 2017; Papantoniou et al., 2022). Demonstrative pronouns (e.g., this, that) also signal physical or psychological distance.

Present. The narration of an actual past event is recalled from memory so it occurs naturally in the past tense, while a fabricated one, originating from imagination, is often conveyed in the present tense, indicating that the narrator is mentally constructing it in real time. (Christiansen, 2021).

Sentiment & emotions. Negative sentiment and emotions have been linked with deception (Newman et al., 2003; Hauch et al., 2012) perhaps as a reflection of the negative emotions experienced by the deceiver. However, studies on various contexts (spam reviews, imaginary stories) have found deceivers to use more positive sentiment and emotions (Ott et al., 2011; Toma and Hancock, 2012).

Specificity. Less specificity as expressed in the usage of more 'vague words', 'hedges', 'boosters', 'adverbs', 'adjectives', 'rate of adjectives and adverbs' and less 'spatial details', 'time details', 'named entities', 'exclusion words', and 'negations' have also often observed (Burgoon et al., 2003) and it is in line with theories like Reality Monitoring (Johnson and Raye, 1981). From a cultural perspective Taylor et al. (2017) found that liars from individualist cultures provide fewer perceptual details and more social details, whereas collectivist cultures show the reverse trend.

2.2 LLMs & Deception Tasks

The task of automated text-based deception detection task is traditionally approached as a classification task. Various features such as psycholinguistic indicators drawn from prior work on deception, n-gram features (Ott et al., 2011), syntactic features (Feng et al., 2012), have been exploited in this task. Here we focus on related work that employs LLMs.

Several works have explored the capacity of large language models (LLMs) to detect or generate deceptive content. Azaria and Mitchell (2023) for instance, investigate whether LLMs are internally aware of the truthfulness of statements they produce or consume. In their approach, a classifier is trained using the hidden layer activations of an LLM while it reads or generates a statement. This classifier achieves an accuracy between 71% and 83% on short sentences. Loconte et al. (2023) exploits FLAN-T5 models to classify texts across a range of domains, such as personal opinions, autobiographical memories, and future intentions. The results highlight the impact of model size, with larger models having superior performance. Boumber et al. (2024) examines the deception detection capabilities of LLMs enhanced with Retrieval-Augmented Generation (RAG). While LLM-based methods performed competitively, parameter-efficient fine-

tuning (PEFT) adapter approaches were the most effective.

In the context of deceptive content generation, Chen and Shu (2023) explore how prompting LLMs to produce misinformation impacts human and automated detection. They find that both humans and LLM-based detectors often fail to identify LLM-generated misinformation, highlighting its deceptive potency. Complementing this, Ignat et al. (2024) present the MAiDE-up dataset, with 10,000 real and 10,000 LLM-generated hotel reviews in ten languages. Their linguistic analysis reveals stylistic and semantic differences between human and AI-generated texts. Despite the limited training data, the fine-tuned models perform well in detecting LLM-generated deception across languages.

3 Methodology

3.1 Tasks

In this work, we explore three core tasks related to deception and language, using open-source and open-weight LLMs. Task A is deception detection, where models are evaluated on their ability to classify texts as deceptive or truthful. We assess the performance under zero-shot, one-shot, and fine-tuned settings using a variety of available datasets. Fine-tuned models trained on the English UDC_{train} dataset, were also evaluated in non-English languages. Task B is the introspective reasoning, where the models are prompted to explain their decisions. This includes reflection on culturally and linguistically grounded deception cues, providing insights into the model's interpretability and internal reasoning processes. Finally, Task C is deceptive text generation, which includes both paraphrasing existing truthful or deceptive content and open-ended generation of new deceptive statements. This allows us to analyze how LLMs construct deception across different styles, topics, and cultural contexts.

For the linguistic analysis, we built upon the feature set introduced in Papantoniou et al. (2022), extending it to the Italian language. The features are primarily count-based, covering linguistic categories such as pronouns, verbs, sentiment, and emotion. The English set includes 75 features, while sets for other languages are slightly smaller due to limited resources (e.g., sentiment lexicons). Readability is measured using a Flesch-like score (Flesch, 1948) adapted for each language. To examine linguistic patterns in LLM-generated datasets, we conducted statistical analysis using the non-parametric Mann–Whitney U test (two-tailed) for each dataset, comparing the distributions of features between truthful and deceptive texts. We applied a stringent significance threshold, setting the confidence level at 99.9% ($\alpha = 0.001$), in order to provide stronger evidence against the null hypothesis and minimize the likelihood of false positives.

3.2 Datasets

We use a unification of ten, quite diverse English deception detection-related datasets, named the Unified Deception Dataset (UDC). The UDC comprises of Bluff the Listener (Skalicky et al., 2020), OpSpam (Ott et al., 2011), DeRev2014 (Fornaciari and Poesio, 2014), DeRev2018 (Fornaciari et al., 2020), DecOp (english part) (Capuozzo et al., 2020b), Real Life Deception Dataset (Pérez-Rosas et al., 2015), Miami University Deception Detection Database (Lloyd et al., 2018), Diplomacy (Peskov et al., 2020), Open Domain Deception Dataset (Pérez-Rosas and Mihalcea, 2015) and Box of Lies (Soldner et al., 2019)[1]. UDC is diverse in many aspects, such as origin of text, genres, domains, and annotation methods (self-reported -SR- and distant supervision -DS-). A stratified split of UDC was used to create training, testing, and validation subsets with an 80-10-10 ratio. UDC is imbalanced in favor of the truthful class.

In addition to the test subset of the UDC we incorporate several other deception detection datasets in various languages for evaluation. These supplementary datasets are annotated using SR labels provided by the individuals who generated the content. This allows us to explore deception detection performance across different cultural and linguistic contexts. Notice that cultures are grouped into two categories individualistic and collectivistic ones, one of the six dimensions of national culture identified in (Hofstede, 1980). Table 1 provides an overview of the datasets.

3.3 Models and Settings

We experiment with LLMs with similar model sizes for a fairer comparison. The selection of model size was driven by memory and storage restrictions. We locally run models and in all cases quantization was used. Different models from the same

[1]We do not include the MAiDE-up dataset since it has not been annotated by experts.

Table 1: Overview of the used datasets.

family were also examined to observe their evolution. Specifically, the following models were employed: mistral-7B-instruct-v0.1 (*mistral*) (Jiang et al., 2023), falcon2-11B (*falcon*) (Malartic et al., 2024), phi-3-medium-4k-instruct (*phi3*) (Abdin et al., 2024), phi-3.5-mini-instruct(*phi3.5*), gemma2-9B-instruct (*gemma*) (Team et al., 2024), llama-2-13b-chat (*llama2*) (Touvron et al., 2023), llama-3-8B-instruct (*llama3*), llama-3.1-8B-instruct (*llama3.1*), DeepSeek-R1-Distill-Llama-8 (*deepseek*) (DeepSeek-AI et al., 2025), cerbero-7b (*cerbero*) (Galatolo and Cimino, 2023) for Italian, eva-mistral-turdus-7b-spanish (*esmistral*) for Spanish/Mexican and roLlama3.1-8b-instruct (*rollama*) (Masala et al., 2024) for Romanian. There is no LLM specifically for Dutch. All are open-weight except of gemma that is also open-source.

3.3.1 Fine-tuning

We fine-tuned the following models: Llama-3-8B (*llama3_FT*), Llama-3.1-8B (*llama3.1_FT*), Phi-3 Medium (*phi3_FT*), phi3.5:3.8b (*phi3.5_FT*), gemma-2-9b (*gemma_FT*), and DeepSeek-R1-Distill-Llama-8B (*deepseek_FT*) models for sequence classification over UDC_{train} dataset. All models were loaded with 4-bit quantization and equipped with Low-Rank Adapters (LoRA) (Hu et al., 2021) on all linear layers. LoRA was configured with rank $r = 16$, $\alpha = 8$, dropout = 0.05, and Rank-Stabilized LoRA (Kalajdzievski, 2023) enabled. We used AdamW with an initial learning rate of 1e-4, a linear scheduler, and trained for one epoch. The experiments were conducted on a single NVIDIA GeForce RTX 4090.

3.3.2 Classification Setting

Prompts were written in English, except for language-specific models (e.g., esmistral), where the entire prompt was translated[2]. For both zero-shot and one-shot prompting, we set the temperature to 0 and top_p to 0.9 to ensure deterministic outputs. In the one-shot setting, we ran 10 trials, each time randomly selecting a pair of examples (one truthful and one deceptive) from the same dataset.

3.3.3 Generation Setting

Appropriate prompts were used to generate both open-ended and paraphrased texts. The open-ended texts include reviews for products and services (e.g., hotels, restaurants, books, hotel chains) and opinionated texts on eleven sensitive topics such as abortion, gun control, cloning, and human relationships, topics previously studied in related work (Newman et al., 2003; Ott et al., 2011). Each prompt instructs the model to generate a truthful and a deceptive version of a given text by applying the appropriate linguistic markers. The prompt requests texts of approximately 160 words and incorporates the comprehensive definition of deception provided by Masip et al. (2004). Texts were generated in five languages representing six cultures (Spanish are used for Spain and Mexico), aligned with those used for detection. To explicitly control for culture, prompts directed the LLM to impersonate native speakers from specific countries. For the review domain, item names were imaginary generated by using LLMs, except in the hotel and food chain categories were existing names of chains used. To promote diversity and creativity, we varied the temperature parameter. For the open-ended texts we had one example with 0, and 3 examples for each value in {0.6,0.7,0.8}, generating 480 texts per domain and language. For the paraphrases we selected a value from {0,0.1,0.2}, generating one paraphrase

[2] https://github.com/nidhaloff/deep-translator

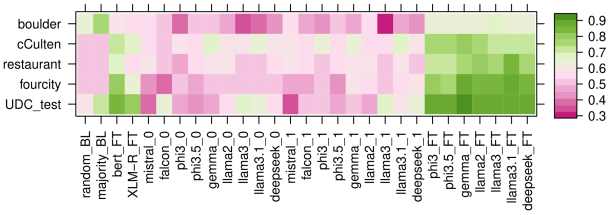

Figure 1: Accuracy (English)

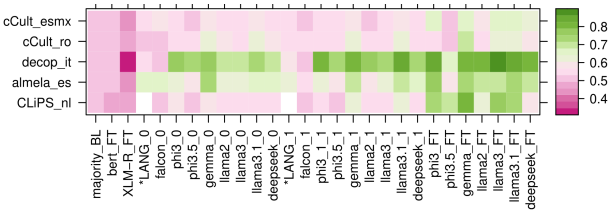

Figure 2: Accuracy (non-English)

for each dataset entry. Prompts were translated into the target languages, as ablation studies showed that translated prompts produced richer linguistic features. For paraphrasing, models were instructed to rewrite each text while preserving its original label (truthful or deceptive), explicitly guiding them to use appropriate linguistic markers.

4 Deception Detection Results

4.1 Classification Results

Model support[3] is the number of times the LLM (in 0-shot and 1-shot settings) responds appropriately to the prompt. While most models show high compliance (often near 100%), some fail to follow the template or refuse to respond due to perceived ethical concerns. Such exceptions include rollama_1-shot on Romanian (53%), llama2_1-shot on cCult-en (30%), falcon_1-shot on CLiPS (30%), and lamma3.1_1-shot on UDC_*test* (26%).

We define the following baselines: a majority-class (majority_BL) for all the datasets, a random baseline (random_BL) mainly for the imbalanced datasets (UDC_*test*, boulder) and two encoder-only architectures namely bert-base-uncased (bert_FT) and xlm-roberta-base (XLM-R_FT) that supports multiple languages. The last two baselines were fine-tuned in the same dataset (UDC) as the fine-tuned LLMs.

Figures 1 and 2 present the classification results for English and non-English test sets, respectively. The language specific models (cerbero, esmistral and rollama) are represented by the *LANG-0 and *LANG-1 labels (no specific LLM for Dutch was deployed).

Fine-tuned models consistently outperform others, with a particularly large margin in the English and CLiPS (nl) datasets. The same holds for the rest non-English datasets, although the performance gap is smaller. The highest overall accuracy is observed on the UDC_*test* dataset, which is an in-domain scenario for the fine-tuned models. Between the remaining settings, 1-shot slightly outperforms 0-shot, but the difference is marginal.

Instructed models fine-tuned on language-specific corpora consistently underperform. However, this cannot be solely attributed to the instruction tuning process, as their performance depends heavily on the underlying base model. For instance, both cerbero and esmistral are based on mistral and its instruct model do not perform well on the English dataset. Similarly, rollama, based on llama3, achieves results comparable to the instruct model in the 1-shot setting, and in the 0-shot setting performs near chance level (50.2% accuracy). These findings suggest that instruction tuning in a specific language does not necessarily degrade a model's general capabilities. Within the LLaMA family, newer models consistently outperform older ones, despite llama2 having more parameters. In the Phi model family, the larger phi3 model (14B parameters) generally outperforms its smaller variants. A exception is the boulder dataset, where phi3.5 (3.8B parameters) consistently achieves better results across all settings.

Among the fine-tuned models, the gemma model achieves the best performance across six datasets. The llama3.1 model performs best on the restaurant dataset, while llama3 leads in the boulder and decop datasets. The phi3 model stands out on the almela dataset. In the zero-shot setting, gemma again delivers strong results, achieving the best performance in five datasets. In the 1-shot setting, the results are more balanced. The *llama3.1* excels in four datasets (crossCult-esMx, CLiPS, crossCult-enUs, decop), *mistral* in two (restaurant, boulder), *gemma* in two (crossCult-ro, almela) and *llama3* in the UDC_*test*. We observe that in non-english datasets the *llama3.1* model is better compared to *llama3*, likely due to the improved multilingual support of *llama3.1*.

We consistently observe that at least one LLM

[3]Due to space restrictions, accompanying material is available at https://gitlab.isl.ics.forth.gr/papanton/evaluating-llms-on-deceptive-text

setting outperforms the baseline methods across all datasets. The only exception is the boulder dataset, where the majority_BL achieves the highest performance. This dataset is notably peculiar. The dataset is heavily imbalanced toward the deceptive class, an unrealistic scenario. It includes both fabrications and lies, leading to variation in knowledge and emotional expression, which challenges LLMs' generalization capabilities.

4.2 Introspection

In this task, we prompt the most robust models in the classification task, gemma and llama3.1, to explain their classification decision via linguistic cues that they deemed important, indicating which of these may carry cultural interpretations. We constrain their responses using the linguistic feature list from Papantoniou et al. (2022). Both models frequently referenced pronoun- and sentiment-related features. However, llama3.1 had difficulty adhering to the provided list, often returning hallucinated features (sentiment_compound). Neither model effectively used the features to discriminate between truthful and deceptive instances or achieved consistently high per-class success rates. Regarding culturally-relevant features, gemma produced a more concise list with an emphasis on pronouns, while llama 3.1, yielded more unstable and inconsistent outputs.

5 Deceptive Text Generation Results

In this task, we use gemma for text generation due to high template adherence. Classification was again done using gemma and llama 3.1. The support was high both for the paraphrased and open-ended texts.

Table 2 reports the results of the Mann-Whitney tests, highlighting statistically significant features with at least a moderate effect size ($r \geq 0.3$). • denotes deceptive features while ○ truthful. Due to space constraints, sentiment and emotion features from various lexicons have been aggregated into two composite features: pos_emo and neg_emo. Notably, in the original human-written datasets, the same statistical test yielded no significant features above the effect size threshold, except for the 4city dataset and the restaurant dataset. As a result in the table we report with orange color (•, ○) the features that are SS for the smaller effect size ($r \geq 0.1$) that overlap with the paraphrased SS. For the restaurant and 4city datasets, we also report SS with $r \geq 0.3$ overlapping or not.

We observe that the number of statistically significant (SS) features threshold is generally higher for paraphrased texts, especially in the English datasets, compared to open-ended generated texts. Interestingly, open-ended texts exhibit a broader range of distinct features across all datasets (20 in total), whereas paraphrased texts involve fewer (16). This might suggest that in open-ended generation, gemma applies linguistic markers more freely, while in paraphrased generation, the model is more constrained by the structure and style of the original human-written text. These distinctions guided our hypothesis during the analysis of open-ended and paraphrased text generation. Prior research on human-generated text (see the meta-analysis by Hauch et al. (2012)) has found only small but significant effect sizes for linguistic cues. This suggests that the differences between groups are amplified in LLM-generated texts, highlighting the stronger expression of such cues in model outputs.

The open-ended texts from sensitive domains consistently show the fewest SS features. This likely reflects the LLMs' training data, which more frequently includes review-style content about products and services than essay-like opinions on sensitive topics or friendships. As a result, LLMs are more adept at generating diverse texts in review domains. Similarly, in the highly diverse UDC_test dataset, the paraphrased texts yield only one SS feature ('vague words'), underscoring the strong context dependency of deception-related cues. In paraphrased texts for non-English languages, we observe reduced linguistic diversity compared to English, whereas open-ended texts show no notable cross-linguistic differences.

A closer look at specific cues reveals several noteworthy patterns, largely aligning with the findings discussed in Section 2.1. The deceptive LLM-generated texts are less specific and less cognitively complex. This is reflected in higher use of 'vague words', 'hedges', and 'adverbs'. In contrast, features associated with cognitive complexity like 'mean word length', 'mean sentence length', 'syllables', and 'conjunctions' all are more prevalent in truthful texts. Similarly, and in accordance to the related work, higher 'readability scores', which indicate simpler and more fluent texts, are linked to deception. This feature is important in paraphrased texts across languages. Sentiment and emotion cues, often context-dependent in prior research,

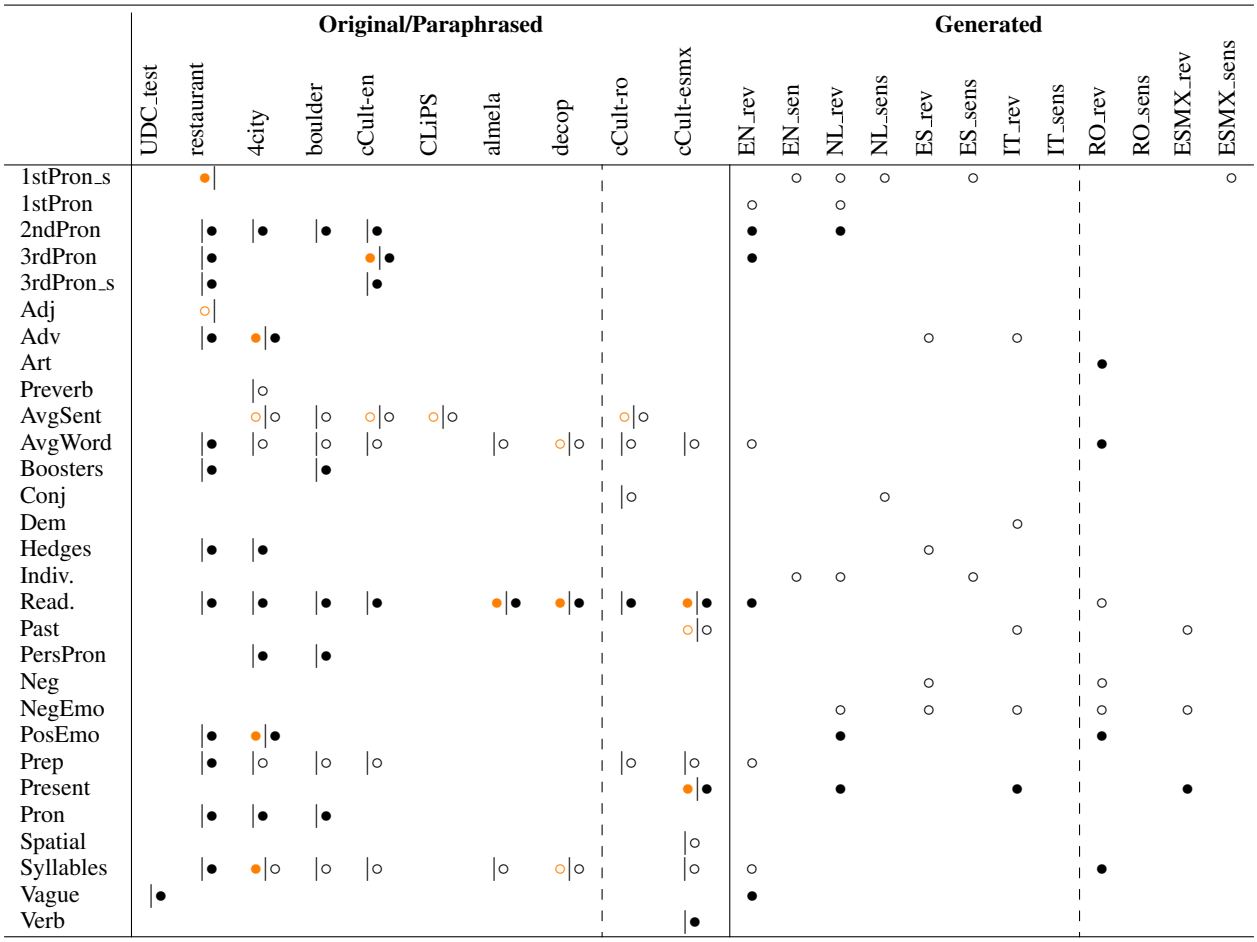

Table 2: Statistically significant features from Mann-Whitney tests (● for deceptive and ○ for truthful). The dashed lines divide the individualistic/collectivistic datasets. With orange SS features with r $\geq$ 0.1 that overlap with the paraphrased SS. For the restaurant and 4city datasets, we also report SS with r $\geq$ 0.3 overlapping or not. More details about the features are provided in the aforementioned repository.

show a consistent trend across languages and domains: truthful texts exhibit more negative sentiment and emotions (e.g., anger, sadness), while deceptive texts tend toward more positive language. Temporal cues follow established patterns, with deceptive texts favoring the present tense and truthful ones favoring the past tense. Pronoun usage also aligns with prior work, as third-person pronouns appear more frequently in deceptive texts and first-person pronouns in truthful ones. In general, we do not observe any noticeable variation across cultures.

One of the most unexpected findings is the association of 'second person personal pronouns' with deceptive texts in both the English and Dutch datasets. While some non-deception-focused studies suggest that second-person pronouns enhance personal engagement and conversational tone (Sun et al., 2024), the deception literature remains divided. Newman et al. (2003) argue that liars tend to avoid second-person pronouns, whereas Ickes et al. (1986) suggest the opposite. More recent studies do not consider this feature diagnostic for deception. An analysis of specific examples reveals expressions such as 'you should definitely try it!' 'you'll leave full', 'you won't regret it!', 'You'll discover', adding a positive sentimental and emotional tone.

5.1 Classification of the Generated Text

Figures 3 and 4 present the detection accuracy scores for the LLM-generated texts. In the paraphrased setting, gemma_FT consistently outperforms gemma_0-shot, particularly for English, highlighting both the alignment of paraphrased texts with human language and the model's stronger support for English. In contrast, the open-ended setting yields lower accuracies overall, with noticeable variation across domains and models. In the sensitive/best friend domain, all gemma-based mod-

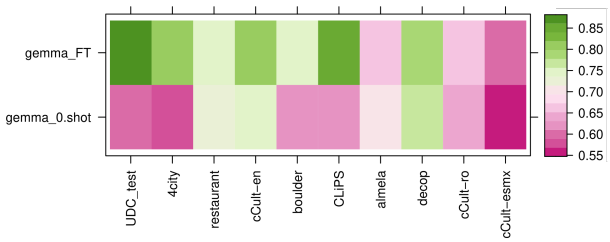

Figure 3: Accuracy for paraphrased texts

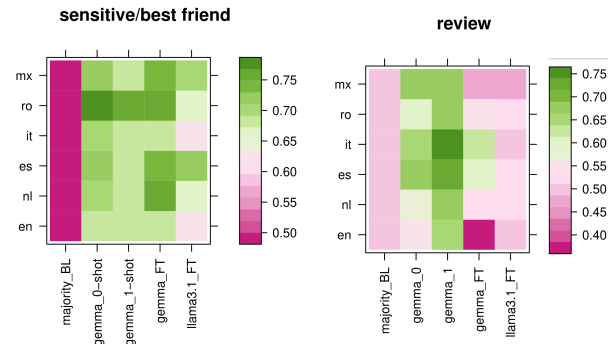

Figure 4: Accuracy for open-ended texts

els perform adequately, while llama3.1_FT shows significantly lower performance. In the review domain, fine-tuned models generally perform poorly, with accuracies near or below the baseline, except for the Italian dataset where llama3.1_FT performs well. Lastly, across review datasets, the 1-shot setting consistently outperforms the 0-shot setting. Overall, these results underscore the gap between LLM-generated and human text, particularly in the review domain.

6 Conclusion and Future Work

The results demonstrate that LLMs show partial success in identifying and generating deception-related content, especially when fine-tuned. Their performance is generally adequate in classification tasks. However, critical limitations remain. Open-ended text generation reveals inconsistencies and reduced accuracy, particularly in cross-cultural and sensitive domains. The findings highlight the importance of context, in terms of domain and culture. A key limitation of the current study is the use of country as a proxy for culture, that can oversimplify complex cultural identities in pluralistic societies. Future work should explore Retrieval-Augmented Generation (RAG) approaches to inject explicit knowledge of deception markers and improve interpretability. Experimentation with larger LLMs and the integration of domain and cultural metadata could enhance context-aware reasoning. Finally, addressing biases in underrepresented languages and improving explainability mechanisms is crucial for ensuring ethical and inclusive systems.

Annotating Hate Speech Towards Identity Groups

Donnie Parent, Nina Georgiades, Charvi Mishra,
Khaled Mohammed, Sandra Kübler
Indiana University
{daparent,ngeorgia,chmish,mohammek,skuebler}@iu.edu

Abstract

Detecting hate speech, especially implicit hate speech, is a difficult task. We focus on annotating implicit hate targeting identity groups. We describe our dataset, which is a subset of AbuseEval (Caselli et al., 2020) and our annotation process for implicit identity hate. We annotate the type of abuse, the type of identity abuse, and the target identity group. We then discuss cases that annotators disagreed on and provide dataset statistics. Finally, we calculate our inter-annotator agreement.

1 Introduction

As online communities have become more accessible, hate speech has become more prevalent in these spaces. This surge has driven research into developing machine learning models capable of automatically detecting such harmful content (e.g., Waseem and Hovy, 2016; Zampieri et al., 2019; Warner and Hirschberg, 2012). However, existing models tend to detect hate that is explicit in nature, i.e., posts that contain explicitly hateful words, more successfully (e.g. Wiegand et al., 2019).

Implicit hate is equally widespread as explicit hate, but it often slips through the filters due to the difficulty to detect it with current systems. Implicit hate typically lacks unambiguously abusive and explicit words, has a less-predictable syntactic format, and is more affected by data bias (Lopez and Kübler, 2025; Wiegand et al., 2019).

To better detect implicit hate, Wiegand et al. (2021b) argue in favor of individual models for specific subtypes of implicit hate. They have created datasets and models for hateful comparisons (Wiegand et al., 2021a), hate towards identity groups (Wiegand et al., 2022), and euphemistic abuse (Wiegand et al., 2023). The dataset on identity hate by Wiegand et al. (2022) was created by collecting tweets where an identity group subject was followed by a negative polarity verb. Selected tweets were then annotated for hateful content. Our main goal is to determine the generalizability of this type of data, as all examples exhibit nearly identical syntactic structures. It is unclear whether such a syntactic bias has an effect on the generalizability of the data to more syntactically diverse data. For experiments to investigate this question, we need a dataset that contains implicit hate speech annotated for whether the hate targets an identity group, but without the syntactic bias. To our knowledge, such a dataset does not exist. For this reason, we have annotatad a dataset: We have extracted implicit hate speech examples from a larger dataset, AbuseEval (Caselli et al., 2020), and annotated these examples for identity hate. For a first investigation of the syntactic bias, refer to (Parent et al., 2025).

Offensive Content Warning: This report contains some examples of hateful content. This is strictly for the purposes of enabling and explaining this research. Please be aware that this content could be offensive and cause you distress.

2 Dataset

We use the AbuseEval dataset by Caselli et al. (2020), which is based on the Offensive Language Identification Dataset (OLID) (Zampieri et al., 2019). Caselli et al. (2020) retrieved only the offensive tweets from OLID and annotated them, marking each tweet containing either profanity or slurs as *explicit abuse*, any other offensive tweet as *implicit abuse*, and any non-interpretable or non-abusive tweets as *not abusive*.

Our goal is to use AbuseEval to identify hate speech against identity groups. For this reason, we selected only the tweets that Caselli et al. had annotated as *implicit abuse*, and re-annotated them. We cleaned the data, partly to increase readability for annotators, and partly to increase its usability for machine learning experiments: We replaced

Proceedings of Recent Advances in Natural Language Processing,pages 894–899
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-102

HTML tags with their respective symbols (e.g., "&" was replaced with "&"), and removed hashtags that are syntactically optional in a tweet. For syntactically relevant hashtags, we removed the "#" character and preserved any relevant information within the hashtag (such as names, acronyms, or half-words). E.g., the original tweet in example (1) was converted to the text in (2). In the example, "#ChristineBlaseyFord" is syntactically required, and we converted it to individual words. We removed "#ConfirmJudgeKavanaugh", since the sentence is well-formed without this hashtag.

(1) #ChristineBlaseyFord is your #Kavanaugh accuser... #Liberals try this EVERY time... #ConfirmJudgeKavanaugh URL

(2) Christine Blasey Ford is your Kavanaugh accuser... Liberals try this EVERY time... URL

3 Annotation

Our dataset was annotated by five annotators: four identifying as female and one as male, all with a background in linguistics. Prior to any annotation, we developed definitions of central concepts and annotation guidelines to encourage consistency between annotators (see below). Annotations were carried out in several cycles with discussions of unclear cases between cycles. Those discussions focused less on individual examples, and more on more general problems in delineating between identity abuse and other abuse, or questions concerning the use of external information. These discussions led to refinements of the annotation guidelines. We calculated inter-annotator agreement after the final round of discussions.

The annotations include three categories. We first annotate for type of abuse, with labels for identity abuse, non-identity abuse, and non-abuse. The second category, type of identity abuse, separates identity abuse into explicit or implicit references to identity group(s), (only applicable to examples of identity abuse). The third category is an open-ended category to represent the identity group(s) targeted, again only applicable for examples of identity abuse.

In the remainder of this section, we first provide the definitions that serve as the basis for the annotations, then we describe the annotation guidelines, followed by dataset statistics.

3.1 Definitions

Our annotations are based on the following definitions:

Abusive language: We follow Wiegand et al. (2019) in defining abusive language as "hurtful, derogatory or obscene utterances made by one person to another person or group of persons." Abusive language must target people to be considered abusive. Counterspeech, i.e., language that points out discrimination (such as sexism, racism, etc.) or critiques double standards regarding discrimination, is not considered abusive. Abusive language does not have to be explicit in nature. Emphatic cursing may be offensive, but is not considered inherently abusive, unless it is paired with other abusive language.

In general, definitions of abusive language tend to be too general to be easily operationalizable. Our definition of abusive language was chosen to encompass as much abusive language as possible without being overly specific. Examples of abusive language include:

(3) How is she hiding her ugly personality? She is the worst.

(4) Liberals are so pathetic!

(5) #Dems are disgusting. They only believe women who accuse conservatives of abuse crimes. When liberals are accused, they ignore the accusations.

(6) Conservatives do NOT represent all Canadians. They are Authoritarian scum.

Implicit abuse: We follow Lopez and Kübler (2025) and define implicit abuse as follows: "Instances where a comment/post alludes to stereotypes or other negative attributes and associates them with a particular group of individuals, especially as it relates to attributes related to a group or individual's identity (e.g., ethnic heritage, nationality, gender, sexual orientation, religion, disabilities, body shape)." Examples of implicit abuse include:

(7) White mask privilege at its finest. Always trying to keep a black mask down

(8) I hope d human rights rats r happy!hope Sidhu is happy! I hope d liberals r happy! Let's play cricket wth thm let's thank thm 4 wht they r doing 2our soldiers Let's celebrate our impotence funny a piddly little

nation like pak is taking us 4 a ride

(9) You know what is tiresome? Bernie supporters bashing Hillary Clinton. She is an actual Democrat who raises money for the Democratic Party and doesn't bash them. She has a positive message. So who is dividing the left?

(10) 4 out of 10 British people are basically full-on racists. 4 out of 10 voters vote for the Conservatives. Coincidence!???!???

(11) Antifa doesn't beat fascists to try to get them to change their mind - they know it's a lost cause to try to change a fascist's mind. They do it to scare them into hiding, to demoralize them, and to stop the spread of their hateful ideology. There is no forcing views on others.

Identity groups are groups of people related by specific characteristics with which they identify. Identity groups include:

- Terms relating to race, gender, ethnicity, nationality, etc.
- Professions, e.g., police officers, teachers, politicians.
- Political parties or groups sharing beliefs, e.g., liberals, Democrats, Republicans, conservatives.
- Political movements, e.g. BLM, ANTIFA, MAGA, QAnon.
- Inhabitants of countries, states, cities, etc.

More specifically:

- References to a single (prominent) member who could serve as representative of an identity group do not constitute references to the identity group; e.g. *Trump* does not reference either conservatives or Republicans.
- References to supporters of a single person are references to identity groups, e.g., *Trumpsters* references Trump supporters, *Obama folks* references Obama supporters.
- References to a corporation or business do not constitute references to identity groups, e.g., *Levi Strauss*, *NFL*, *USTA*, since the members do not necessarily identify with the corporation as a group.
- References to governmental organizations or groups associated with political beliefs do not constitute references to identity groups, e.g., *DNC*, *FBI*, *NRA*, since the members do not necessarily identify with the organization.

Fake identity insults are insults stating that a group of people are not true members of an identity group. These can be via nicknames or in general statements. Fake identity insults are considered *identity abuse*. An example of a tweet with a fake identity insult is shown in example (12), where *RINO* is short for "Republican in Name Only".

(12) @USER Who will abuse it the most: liberals or RINOS?

Name calling are all occurrences of an identity group being referred to by a nickname, often hurtful or derogatory.

3.2 Annotation Guidelines

The annotators developed annotation guidelines before annotating for consistency. There are three types of annotation used in this project, each of which is described below. Relevant definitions are provided above.

1) Type of Abuse Possible labels are: Identity Abuse, Non-Identity Abuse, and Non-Abuse.

Identity Abuse: A tweet contains abusive language towards one or more identity groups.

- Tweets in which the only abuse is targeting a Twitter mention (@USER) are not Identity Abuse.
- Tweets that use identity groups as adjectives in derogatory or insulting ways are Identity Abuse, e.g., "leftist dictatorship", "liberal wagon".
- Tweets targeting a single member of an identity group are not Identity Abuse.
- Tweets that criticize a belief or policy tied to an identity group are not Identity Abuse. However, tweets that criticize those who share a belief or support a policy are Identity Abuse. E.g., "Gun control is stupid": not Identity Abuse; "People who believe gun control are stupid": Identity Abuse.

Non-Identity Abuse: A tweet contains abuse, but said abuse does not target an identity group. (See definition of Abuse and Identity Group.)

Non-Abuse: A tweet does not contain any kind of abuse.

2) Type of Identity Abuse Possible labels are: Explicit and Implicit Mention of Identity Group. This annotation type is only completed if the tweet has been labeled as Identity Abuse.

Explicit Reference: A tweet explicitly names the referenced identity group. That is, the identity group is referenced via its official/common name (see definition of Name Calling), e.g., "liberals", "immigrants" .

Name calling is labeled as explicit reference if the identity group does not need to be inferred and the official or common name of the identity group is present, clearly segmentable, and has typical pronunciation, e.g., "FemiNazis" targets *feminists*, "libtard" targets *liberals*, "dems" targets *Democrats*.

Implicit Reference: A tweet implicitly references the identity group. This can be via Name Calling or by requiring the reader to infer the identity group from contextual information.

Name calling is labeled as implicit reference if the identity group needs to be inferred, or if the official or common name of the identity group is not present, not clearly segmentable, or has atypical pronunciation, e.g., "snowflake" targets *liberals* or *Democrats*, "illegals" targets *immigrants*, "demoncrats" targets *Democrats*.

Implicit reference name calling also includes referencing an identity group with a hyperbolic or exaggerated name. Often, these alternative names target political parties, political movements, organizations, etc.; they are extreme and exaggerate or misrepresent a small subset of the target identity group's characteristics or beliefs. Additionally, name calling can occur via stereotyping, e.g., "Communists" may target *liberals*, "Brown Shirts" targets *ANTIFA*, "blue-haired pronoun-havers" targets *liberals*.

3) Target Identity Group This annotation type is only completed if the tweet has been labeled as Identity Abuse. This annotation field indicates the identity group targeted by a tweet. Consequently there is not a fixed set of labels.

Whenever possible, we copy the identity group directly from the tweet without alteration. We do not interpret identity groups. See examples in (13) and (14).

If labeled as an Implicit Reference, we provide the name of the targeted identity group to the best of our ability.

Identity Groups with Adjectives: Identity that is communicated via adjectives should not be indicated, unless the identity group is the insult itself. See examples in (15) – (17).

Lists of Identity Groups: If identity groups are presented in a list, we indicate all included identity groups. See example in (18).

(13) Liberals are stupid Target: liberals

(14) MAGAs are stupid Target: MAGAs

(15) Christian Conservatives Target: conservatives

(16) socialist, feminist liberals Target: liberals

(17) liberal voters Target: liberals

(18) Liberals, Democrats, and ANTIFA Target: liberals, Democrats, ANTIFA

Category	Label	Count
Type of abuse	identity	395
	non-identity	393
	non-abuse	10
Type of identity abuse	explicit	350
	implicit	25
	N/A	423
Overall		798

Table 1: Statistics of the annotated dataset after conflating the annotations to the majority vote.

3.3 Dataset Statistics

The final dataset comprises 798 tweets. For traditional machine learning purposes, we created a version with single labels by choosing the majority vote among annotators. The distribution in classes for the first two annotation types after the majority vote is shown in Table 1.

4 Inter-Annotator Agreement

Annotators performed the annotations independently, without discussing individual examples (even though general annotation decisions were discussed). This allows us to report inter-annotator

agreement among the five annotators. We report Fleiss' kappa (Fleiss, 1971)[1].

For the identity category, the overall Fleiss' kappa was 0.540 with a 95% confidence interval of [0.521, 0.560]. For the reference category, Fleiss' kappa was 0.591 with a 95% confidence interval of [0.572, 0.611].

Generally, the interpretation of Fleiss' kappa follows the interpretation by Landis and Koch (1977), which is based on the conditions of two annotators and two classes. If we interpret our kappa by those standards, our annotators have moderate agreement, although those standards are likely not the best fit for our conditions. However, given that this is a rather subjective task, we interpret this agreement as indication that our annotation guidelines are sufficient. The inter-annotator agreement shows that the variety in which implicit hate speech occurs makes it difficult to label it as such, even for educated native English speakers (all annotators were undergraduate students at a US university).

An analysis of the posts that have garnered the most disagreement shows that many of them require more context for interpretation. We show examples in (19)–(21).

(19) @USER Great Gun Control! Takes Concentration and Steady Hand! Way to Go Girl! URL

(20) Thank you Father God the American people will begin to see the truth about our government corruption @USER @USER @USER URL

(21) @USER But But But we need more gun control right? Oh wait... GUESS THAT DOESNT STOP CRIMINALS, only law abiding citizens. Which is known. So.... think on why they" want to CONTROL you and disarm you."

In all the above examples, there is no clear majority label among annotators. Each post was annotated as non-abusive by at least one annotator, identity abuse by at least one annotator, and non-identity abuse (but still abusive) by at least one annotator. The presence of "@USER" in each tweet suggests that there likely exists a thread of posts that each tweet is in response to, but without the necessary context of those threads, annotators struggled to determine the intent of the poster and the target of the potentially abusive language.

[1]We used the JASP implementation, https://jasp-stats.org/.

5 Conclusion and Future Work

We have described the annotation process for a corpus of hate speech directed towards identity groups. Throughout our annotation process, we experienced the difficulty and nuance required to define implicit hate. Since implicit hate is not tied to specific words, it is important to use a diverse and complex set of examples, in both the target of the abuse as well as syntactic structure.

The annotated dataset is freely available at https://github.com/donnieparent/X490-hate-speech/tree/main. We have provided two versions, one with all five annotations per example, and one with the a single label, determined by the majority vote.

In future work, we will train models to detect implicit identity abuse, to determine to which degree the variety we have in our dataset is important for identifying identity hate. For a first baseline attempt to determine whether the syntactic bias introduced by Wiegand et al. (2022) influences classificatin results, see (Parent et al., 2025).

On the Interaction of Identity Hate Classification and Data Bias

Abstract

Hate speech detection is a task where machine learning models tend to be limited by the biases introduced by the dataset. We use two existing datasets of hate speech towards identity groups, the one by Wiegand et al. (2022) and a reannotated subset of the data in AbuseEval (Caselli et al., 2020). Since the data by Wiegand et al. (2022) were collected using one syntactic pattern, there exists a possible syntactic bias in this dataset. We test whether there exists such a bias by using a more syntactically general dataset for testing. Our findings show that classifiers trained on the dataset with the syntactic bias and tested on a less constrained dataset suffer from a loss in performance in the order of 20 points. Further experiments show that this drop can only be partly attributed to a shift in identity groups between datasets.

1 Introduction

Hate speech detection is an area of NLP that has gained importance over the last few years. However, while our knowledge of how to approach the problem computationally increases, we find that many of the existing datasets come with unintended limitations and biases. These datasets are known to have biases towards particular targets of the abusive language or the hateful language used. These biases tend to affect implicit hate, or "instances where a comment/post alludes to stereotypes or other negative attributes and associates them with a particular group of individuals, especially as it relates to attributes related to a group or individual's identity (e.g., ethnic heritage, nationality, gender, sexual orientation, religion, disabilities, body shape)" (Lopez and Kübler, 2025), even more strongly, as there are uncountable ways of creating implicit hate.

Creating datasets for hate speech detection is challenging, since hate speech is a rare phenomenon, and thus difficult to find. Implicit hate, since it is indirect and does not use easily identifiable terms such as slurs, is even more difficult to find and to detect automatically. To better detect implicit hate, Wiegand et al. (2021b) argue in favor of individual models for specific subtypes of implicit hate. They have created datasets and models for hateful comparisons (Wiegand et al., 2021a), hate towards identity groups (Wiegand et al., 2022), and euphemistic abuse (Wiegand et al., 2023).

In our current work, our main focus is implicit hate directed at identity groups. Examples of such hateful language are shown in (1) (copied from (Wiegand et al., 2022)).

(1) a. Jews succumb to cultural degeneracy.
b. Gay people are contaminating our planet.
c. Women fabricate menopausal symptoms.

The dataset by Wiegand et al. (2022) was created by searching for tweets where an identity group subject was followed by a negative polarity verb. Selected tweets were then annotated for hateful content. Since all examples exhibit very similar syntactic structures, our question concerns the generalizability of this type of data. In other words, does a model trained on data limited to one syntactic pattern generalize to data with more diverse syntactic patterns? Or does this syntactic bias result in lower performance?

Note that our intention is not to criticize the method chosen by Wiegand et al. (2022) to create their dataset. We are aware that implicit hate is very difficult to find because of its very nature, and that we need specific search strategies to find such examples. However, every decision that we make with regard to search strategies has an effect on the dataset and classifiers, and we need to understand these effects. Our current work is intended to pro-

Proceedings of Recent Advances in Natural Language Processing,pages 900–906

https://doi.org/10.26615/978-954-452-098-4-103

vide a closer look at the consequences of one such decision.

The structure of the remainder of the paper is as follows: Section 2 explains our research questions, and section 3 describes related work. In section 4, we explain our methodology, and in section 5, we discuss our results. We conclude in section 6.

Offensive Content Warning: This report contains some examples of hateful content. This is strictly for the purposes of enabling this research, and we have sought to minimize the number of examples where possible. Please be aware that this content could be offensive and cause you distress.

2 Research Questions

Our main research question concerns the syntactic pattern that was used to create the dataset by Wiegand et al. (2022): Can a classifier trained on a syntactically constrained dataset generalize successfully to other data that do not follow this pattern? If this is the case, that would mean that there is no syntactic bias, and Wiegand et al. have succeeded in their goal of creating a highly reusable dataset. If not, the syntactic pattern constitutes a bias. We also investigate whether the bias we find is due to the choice of negative examples or due to differences in the identity groups covered in the data.

3 Related Work

Work on hate speech towards identity groups is in its early stages: Yoder et al. (2022) investigate how hate speech varies by identity. Sachdeva et al. (2022) create a multi-label classifier to identify identity groups targeted by hate speech. They show that the model trained on the Measuring Hate Speech corpus generalizes well two other datasets. Jin et al. (2025) investigate hate speech detection for identity groups. They show that such detection models assign a higher hate score based on the mention of specific target identities. They also show that such models are more accurate when there is strong intensity in terms of the stereotype. In related work, Zueva et al. (2020) address unintended bias towards protected identity groups in Russian by creating artificial, non-toxic sentences about such identity groups to use as training data.

Bias may be introduced into hate speech detection in different ways. The first bias concerns sampling (Wiegand et al., 2019; Razo and Kübler, 2020); In determining how to sample data to increase the percentage of hate speech, the data can be biased towards specific users or topics. Other types of bias are introduced in the annotation process: Sap et al. (2022) show that annotators are biased towards judging African American English as hate speech, and Lopez Long et al. (2021) show that especially untrained annotators have a tendency to confuse casual profanity and argumentative language with hate speech. Finally, Lopez and Kübler (2025) show that utterances need to be analyzed in their context to determine whether they contain hate speech.

Our current work uses the definition of implicit hate by Lopez and Kübler (2025): "instances where a comment/post alludes to stereotypes or other negative attributes and associates them with a particular group of individuals, especially as it relates to attributes related to a group or individual's identity (e.g., ethnic heritage, nationality, gender, sexual orientation, religion, disabilities, body shape)." This definition has a particular focus on identity and the intersection between implicit hate and identity hate.

4 Methodology

4.1 Datasets

Our work focuses on two datasets, the dataset by Wiegand et al. (2022) and a subset of AbuseEval (Caselli et al., 2020), where all tweets that were deemed implicitly abusive by Caselli et al. were annotated whether they are abusive towards identity groups (Parent et al., 2025). We use the Wiegand dataset for training and testing (in domain), and the subset of AbuseEval, henceforth Caselli-Ident, for out-of-domain testing on more general data.

Wiegand et al. (2022) created an abusive language dataset (using both English and German) sentences by sampling stereotypical Twitter posts. The creation of this dataset follows the assumption by Wiegand et al. (2021b) that all subtypes of hate (e.g., racism, sexism) must be addressed separately rather than all together. This dataset contains implicit hate towards the following groups: gay people (using the terms "gay people" and "lesbians"), Jews, Muslims, and women. Notably, no nicknames or slurs for any of the identity groups were used in the data gathering, only the listed "names" of the identity groups. They searched for posts where the target group is the subject of a negative-polar verb. This search strategy leads to

data that are syntactically similar.

Some examples of hate speech from the Wiegand dataset are as follows:

(2) ALL women blab on social media.

(3) Muslims bungle everything they attempt to the detriment of everybody.

(4) jews are disrupting the world peace.

(5) Gay people are diluting any sanctity.

(6) lesbians dehumanize other LGBTQ people.

Caselli et al. (2020) used the OffensEval dataset OLID (Zampieri et al., 2019) and reannotated it with more detailed information. OLID is an English dataset collected from Twitter, which is annotated for whether the post is offensive, whether the post has a target, and what that target is. Caselli et al. annotated each post as Explicit, Implicit, or Not Abusive. The resulting dataset is called AbuseEval.

The focus of our research is implicit hate towards identity groups. Since we are interested in whether the search strategy employed by Wiegand et al. (2022) to create their identity hate dataset results in an unintended bias, we needed a dataset annotated for hate towards identity groups that is syntactically more diverse. In order to minimize genre effects, the data should also originate from Twitter. Since no such dataset existed, we used AbuseEval and extracted all posts labeled as Implicit. We then annotated this subset for identity hate. We annotated the posts for the type of hate speech (identity hate, non-identity related hate, or not abusive). If the post was identified as identity hate, annotators decided whether the identity group was referenced implicitly or explicitly. Finally, annotators extracted the target of the abusive from the post. For more details about the dataset and the annotation process, refer to (Parent et al., 2025).

The annotated dataset is freely available at https://github.com/donnieparent/X490-hate-speech/tree/main. We have provided two versions, one with all five annotations per example, and one with the a single label, determined by the majority vote.

Since our annotations showed that about half of the tweets labeled as implicit hate by Caselli's annotation were not considered identity abuse by our annotators, the dataset resulting from our annotations was similarly balanced as compared to the Wiegand dataset. Table 1 shows the distribution of classes in the three datasets we use.

Dataset	Ident.	Not ident.	Not Abuse
Wiegand	57.0	0	43.0
Caselli-Ident	49.5	49.3	1.3
Caselli	32.9	32.7	34.4

Table 1: Distribution (in %) of identity hate, not identity hate, and non-hate in the datasets.

4.2 Machine Learning Models

We tested three different classifiers: Support Vector Machines (SVM), Random Forest, and Naive Bayes, all in the scikit-learn (Pedregosa et al., 2011) implementation. We avoided using LLMs in order to avoid unintended effects of data leakage since we cannot guarantee that the dataset we use for testing is not part of the training data for the LLM.

We performed parameter optimization on the Wiegand data, using a five-fold cross validation grid search to determine the optimal parameters for each of the three classifiers. Going forward, we used the best-performing parameters for all experiments.

For the experiments to determine the generalizability of the Wiegand dataset, we consider our baseline to be the model performance on the Wiegand dataset. We perform a 5-fold cross validation on the entire dataset. Next, we train on 80% of the Wiegand dataset, to ensure the same training set size as in the 5-fold CV, and test on the Caselli-Ident dataset. To determine whether the negative examples in Caselli-Ident are misleading (since they were originally considered hate speech), we replace these negative examples with 403 non-abusive posts from the original Caselli dataset. This new dataset then serves as test set. Finally, we attempted training on not just the Wiegand dataset alone, but a combination of Wiegand data and a small part of Caselli-Ident. This new training set was comprised of 80% of Wiegand data and 20% of Caselli-Ident.

4.3 Evaluation

We mainly report macro-averaged F1. Since the datasets are close to balanced, there is little difference between micro-averaged and macro-averaged F1, and precision and recall are equally balanced.

Test data	Wiegand			Caselli-Ident			Caselli		
Classifier	Prec	Rec	F1	Prec	Rec	F1	Prec	Rec	F1
SVM	74.78	74.14	74.27	58.88	56.38	53.21	56.15	54.64	51.80
Random Forest	73.70	70.53	70.62	54.59	53.66	51.30	45.39	46.05	44.13
Naive Bayes	75.46	73.32	73.58	58.64	58.63	58.63	59.90	59.87	59.86

Table 2: Classification results (macro-averaged) when training and testing in-domain (Wiegand data), out-of-domain (Caselli-Ident) and out-of-domain (using non-abusive examples from the Caselli data).

5 Results

5.1 Comparing Wiegand and Caselli-Ident Test Data

Our main research question concerns the potential bias in the Wiegand dataset, based on the sampling of stereotypical sentences with similar syntactic patterns. To investigate this, we trained the classifiers on Wiegand data and tested on Wiegand and on Caselli-Ident data. The results are shown in Table 2.

First, all three models performed well on the Wiegand test set, with SVM resulting in the highest F1 score of 74.27, followed by Naive Bayes (73.58), and Random Forest with an F1 score of 70.62. This shows that the classifiers are capable of addressing the problem successfully.

When testing the models on Caselli-Ident, the models' performance noticeably suffers, with F1 deteriorating by 15-20 percent points. Naive Bayes reaches the highest F1 score of 58.63, and Random Forest continues to perform the worst with an F1 score of 51.30. These results show that there are significant differences between the two datasets, even though both are sampled from Twitter, and both focus on hate speech towards identity groups.

One reason why the results are lower on the Caselli-Ident set may be found in the fact that the negative examples in this dataset were originally annotated as hate speech by Caselli et al. and contain a mix of non-hate and hate that is not directed towards identity groups. This means that these examples are not clear-cut, easy examples of non-hate. Therefore, they are likely more difficult to distinguish from hate speech than the non-hate examples in the original Caselli dataset. For this reason, we repeated the experiment after having replaced the negative examples by an equal number of non-hate examples from the original Caselli dataset.

The results are reported in the third column of Table 2. When testing on this dataset, we would expect an improved performance. However, the SVM and Random Forest models show an additional drop in F1. Naive Bayes performs slightly better, its F1 score increasing by slightly more than a percent point to 59.86. This shows that Naive Bayes is more robust towards out-of-domain data. However, overall the examples in this test set are further away from the Wiegand set than the negative examples in Caselli-Ident. Thus while the latter may be more difficult to distinguish from the hate examples, they are more in-domain than the negative examples from the original Caselli set.

5.2 Do the Identity Groups Matter?

In the Wiegand dataset, the identity hate is directed at a specific subset of identity groups, including gay people, Jews, Muslims, and women. In Caselli-Ident, there is no restriction on the identity groups. This leads to the question whether the classifiers learn hate speech directed specifically at the chosen identity groups but are not able to generalize to other identity groups. For this reason we use the target annotations in the Caselli-Ident dataset and separate the hate examples into two groups: one group with target groups covered in the Wiegand dataset, and one group with other targets. Then we evaluate separately on both groups. The results are shown in Table 3.

On the Wiegand groups, the SVM has an F1 score of 58.29, Random Forest's F1 score is 52.35, and Naive Bayes has the highest F1 score of 65.30. This means that the Random Forest model only improves by about one percent point over the results on all categories. In contrast, SVM and Naive Bayes improve by 5 and 7 percent points respectively. This shows that the groups covered by Wiegand et al. (2022) are clearly easier to classify correctly, however the results are still significantly below the results when testing on Wiegand data.

For all other identity groups, the F1 scores range between 50.76 and 57.35, i.e., they are consistently about one percent point lower that on the whole dataset. As such, these results show that while the discrepancy in identity groups contributes to the

	Wiegand groups			Other groups		
Classifier	Prec	Rec	F1	Prec	Rec	F1
SVM	61.57	58.50	58.29	58.35	56.05	52.28
Random Forest	54.69	53.35	52.35	54.18	53.42	50.76
Naive Bayes	65.24	66.30	65.30	57.38	57.39	57.35

Table 3: Evaluation of classification results on Caselli-Ident hate examples split into groups covered by Wiegand et al. (2022) and other groups.

	OOD			add in-domain data		
Classifier	Prec	Rec	F1	Prec	Rec	F1
SVM	58.88	56.38	53.21	65.60	65.02	64.54
Random Forest	54.59	53.66	51.30	75.50	72.41	71.23
Naive Bayes	58.64	58.63	58.63	71.39	71.40	71.36

Table 4: Comparing out of domain data (repeated from Table 2) and adding in-domain training data.

difficulty in classifying the Caselli-Ident dataset, they are not the main source of difficulty.

5.3 Adding In-Domain Data

For our final research question, we approached the domain differences between the two datasets by adding a small amount of Caselli-Ident data to the Wiegand training set. Having access to some data from the test domain during training should help the classifiers to cover this domain better.

Thus, we trained the models on a set made up of 80% Wiegand and 20% Caselli-Ident. The test set was the subset of Caselli-Ident that was not used in the training. The results of this experiment are shown in Table 4.

By adding Caselli-Ident data to the training set, the models performed noticeably better: Random Forest and Naive Bayes reached F1 scores of 71.23 and 71.36 respectively, which is an improvement of about 20 percent points for Random Forest and 13 percent points for Naive Bayes. The SVM reached the lowest F1 score of 64.54, which is still 11 percent points higher than the out-of-domain result. Note that Random Forest marginally surpasses the results when testing on Wiegand data, and Naive Bayes reaches similar results. Only the SVM cannot profit as much from the added target domain data.

These results show that it is possible to reach high results on the Caselli-Ident dataset, thus confirming our hypothesis that the search strategy in the Wiegand data set created a syntactic bias in the dataset.

6 Conclusion and Future Work

We have investigated the question whether a data collection of hate speech toward identity groups based on specific syntactic patters affects a classifier's ability to identify such hate in other syntactic patterns. Our results show that this is the case: Results decrease by 15-20 percent points when tested out of domain on the Caselli-Ident dataset, which corresponds to more diverse syntactic patterns. We have also shown that this is not due to our choice of negative examples, nor is it due to the wide range of identity groups. In contrast, adding in-domain data improved results considerably—showing that the syntactically diverse dataset is not inherently more difficult.

Looking ahead, we plan to investigate the divergence in identity groups more closely, with the goal of developing more robust methods that can better handle unseen identity groups. We also plan on investigating fairness of such machine learning methods to determine if similar utterances are classified consistently across identity groups.

7 Limitations

The quality of hate speech detection models always depends on the quality of the annotations. The data we use has been collected from three different datasets, and has thus been annotated by three different groups of annotators. There is a strong probability that the definition of the phenomenon in question, annotation guidelines, and boundaries between categories vary between those datasets, which introduces a discrepancy between the annotations that can affect classifier accuracy.

Abstract

This paper examines the relationship between news coverage and the European Central Bank's (ECB) interest rate decisions. In particular, the hypothesis of a linear relationship between financial news and ECB indications regarding interest rate variations is investigated by leveraging state-of-the-art large language models combined with domain experts and automatically selected keywords. The analysis revealed two key findings related to how news contents can signal the ECB's decisions to raise or lower interest rates: (1) Sentence Transformer models, when combined with domain-specific keywords, exhibit a higher correlation with ECB decisions than state-of-the-art financial BERT architectures; (2) employing a grid search strategy to select subsets of informative keywords strengthened the relationships between news contents and ECB's decisions, highlighting how media narratives can anticipate or reflect central bank policy actions.[1]

1 Introduction

The European Central Bank (ECB) plays a pivotal role in shaping monetary policy for the Eurozone. Accurate prediction of ECB interest rates is crucial for financial markets, businesses, and policymakers. Traditionally, interest rate forecasts have relied on indicators such as inflation, GDP, unemployment rates, and consumer confidence indices. However, these metrics can be challenging to obtain and are often updated infrequently, as they are released at specific intervals rather than in real-time. Additionally, news outlets frequently feature advocacy from political leaders across individual Eurozone nations, who make statements aimed at influencing the ECB's decision-making process. This can complicate the prediction process. Recent advancements in machine learning, particularly through BERT-inspired models (Devlin, 2018), have revolutionized text analysis by enabling more sophisticated and nuanced interpretations of textual data. Previous research has shown that central bank communication plays a crucial role in shaping market expectations, particularly influencing bond yields and interest rates (Leombroni et al., 2021).

This paper examines the effectiveness of using natural language processing (NLP) models to analyze financial news in assessing ECB interest rate decisions over short-term (up to 6 weeks), medium-term (6 to 12 weeks), and long-term (12 to 18 weeks) periods. In particular, two main contributions are provided:

1. the combination of a Sentence Transformer model with domain-specific keywords supplied by experts to better correlate financial news with the increase/decrease of interest rates set by the ECB;

2. the implementation of a grid search approach to determine a sub-optimal set of keywords extracted from text to correlate ECB rate variations with financial news.

2 Related Work

The study of interest rate trends has been extensively discussed in the literature until 2016 (Picault and Renault, 2017), leveraging the NLP tools available at that time, such as n-grams. For over six years, interest rates remained at zero, leading to a decline in scientific interest in the topic.

However, starting in 2022, the ECB decision to raise interest rates has reignited attention on the subject, making it a trending topic once again. Recent works, such as (Fanta and Horvath, 2024), employ modern large language models (LLMs) but focus on ECB speeches rather than news sources, and their datasets are limited to the period from 2008 to 2016. Other studies have developed innovative approaches to measure sentiment, such as using deep learning models to create indices from central bank narratives, further confirming the power of NLP in this domain (Niţoi et al., 2023). Notably, research has also demonstrated the predictive value of central bank sentiment, highlighting the informative content of ECB and Federal Reserve communications in forecasting monetary policy decisions (Hilscher et al., 2024). In this context, tools like CentralBankRoBERTa (Pfeifer and Marohl, 2023) have also emerged, enhancing the analysis of central bank communications using specialized transformers for language modeling. In parallel, projects like FedNLP (Lee et al., 2021) have concentrated on forecasting the Federal Funds Rate, covering the period from 2015 to 2020.

More recently, (Bernoth, 2025) applied a RoBERTa-based model to ECB communications (2019–2025), showing that the tone—classified as hawkish, dovish, or neutral—can significantly enhance forecasts of upcoming interest rate decisions.

Despite this progress, no current research has explored correlations between ECB interest rates and news-based datasets. This gap in the literature highlights the need for novel approaches that leverage recent advancements in NLP, particularly in the application of LLMs to real-time financial news data for the prediction of ECB interest rates.

3 Data

News articles were sourced from `reuters.com`. To identify relevant content, a selection process was implemented to filter articles based on specific keywords and phrases in their titles. The focus was on identifying news that mentioned the `European Central Bank (ECB)`, `the Eurozone` and related financial terms such as `interest rates` and `monetary policy`. Articles that included both references to the ECB and financial terms related to interest rates were selected for analysis. News articles published within 24 hours after the ECB's announcements regarding interest rate changes were excluded, as these typically focus on reporting the ECB's actions rather than providing forecasts or analyses of interest rates.

The dataset under investigation comprises 1,037 English-language news articles spanning from March 21, 2022, to April 17, 2025. The distribution of these articles on a monthly basis is illustrated in the figure 1.

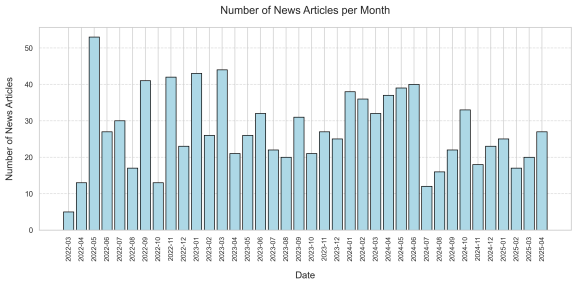

Figure 1: Number of news articles per month

The ECB makes decisions regarding adjustments to interest rates predominantly during the Governing Council meetings, which are convened approximately every six weeks. Accordingly, within this interval, we have analyzed a total of 27 such decisions. The interest rate over time considered in this study is illustrated in Figure 2.

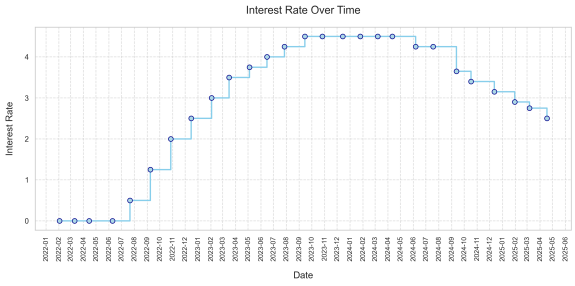

Figure 2: Trends in the ECB's Interest Rates Over Time

3.1 Preprocessing

News articles are preprocessed by removing stopwords[2], which are common but non-informative words. To further prevent overfitting, terms related

[2]NLTK library

Table 1: Example of Feature Table

Title	Body	Date	Δ_S	Δ_M	Δ_L	β_{SI}	β_{SD}	β_{MI}	β_{MD}	β_{LI}	β_{MD}
t1	b1	06-06-22	0	0.5	0.75	0.1	-0.1	0.4	-0.2	0.8	-0.3

to days of the week, months, and numerical values are also excluded. This helps to reduce the introduction of overly specific patterns and improves generalization.

4 Baseline Models

To investigate the potential correlation between ECB's interest rate decisions and financial news, and consequently whether news could be used to predict future trends, a feature table has been created. The feature table includes the news title, body of the news, publication date, and the subsequent adjustments made by ECB, specifying the magnitude of each rate hike or cut over short-term (up to 6 weeks), medium-term (6 to 12 weeks), and long-term (12 to 18 weeks) periods. Finally, also a score reflecting the relevance of the news with respect to the ECB adjustments is reported also considering different periods at short-, medium- and long-term.

Table 1 provides an example of the feature table. Δ_S, Δ_M, and Δ_L represent adjustments in the short-, medium-, and long-term, respectively. The coefficient β_{SI}, β_{SD}, β_{MI}, β_{MD}, β_{LI} and β_{LD} refer to the scores for each time period (S stands for short-, M for medium- and L for long-term) focusing on decreasing and increasing adjustment (I stands for increase, while D for decrease). The table lists several news articles in the rows. For instance, in June 2022, we were approaching the first interest hike, while in April 2024, we anticipated a cut.

Various language models have been used to estimate the β score. For detailed information on how these are calculated, please refer to sections 4.1, 4.2, 5.1, 5.2, and 5.3. This score, along with the value of the subsequent decision of interest from ECB, is used to calculate the Pearson correlations. The Pearson correlation was specifically chosen for its effectiveness in measuring the linear relationship between the calculated score coefficients and future changes in interest rates. This comparison allows us to evaluate how well each model aligns with observed data over various time horizons. The subsequent sections will provide the details of the investigated approaches, distinguishing between baselines and proposed models.

4.1 FinBERT

In this study, FinBERT [3] (Picault and Renault, 2017), a pre-trained model for financial sentiment analysis, was used as a baseline. The news articles were divided into sentences [4], and the sentiment score for each sentence has been taken from the probability distribution of the class label given by the FinBERT model. In particular, if the predicted sentiment was positive, then the corresponding probability has been considered as it was, otherwise such a probability was kept with a negative sign. Given a news i, the corresponding score $\beta^i_{(.)}$ is computed as the average sentiment probability across all the sentences. In this specific case, the score $\beta^i_{(SI)} = \beta^i_{(SD)} = \beta^i_{(MI)} = \beta^i_{(MD)} = \beta^i_{(LI)} = \beta^i_{(LD)}$ since the estimation does not depend on the considered time period. Based on scores $\beta^i_{(.)}$ for all the news sources and the upcoming predictions of ECB over three time ranges (Δ_S, Δ_M and Δ_L), the Pearson correlation coefficient was calculated.

4.2 Mixtral

With the advent of Large Language Models (LLMs), we decided to incorporate a LLM as an additional baseline in our study, specifically utilizing Mixtral (Jiang et al., 2024).

The following prompt was used to obtain the scores $\beta^i_{(.)}$, distinguishing between increase and decrease policies for each news:

[3] https://huggingface.co/ProsusAI/finbert

[4] The sent_tokenize function from the NLTK library was used

LLM Prompt

Give a score from 0 to 1 about the prevision that interest rate will be increase or decrease in the short middle or long period.
The results will be formatted like CSV:
Score increase short:[0-1], Score increase middle:[0-1], Score increase long:[0-1], Score decrease short:[0-1], Score decrease middle:[0-1], Score decrease long:[0-1], Motivation: [Max one or two sentences].
Where short is in the next 6 weeks, middle between 6 to 12 weeks and long from 12 to 18 weeks.
From this news of date: [DATE] Title: [TITLE] Text: [TEXT]

To extract the relevant scores from Mixtral's output, we implemented a parsing routine. However, it is important to note that Mixtral does not consistently adhere to the prescribed output format. As a result, we had to employ regular expressions to accurately extract the scores from the output, ensuring that formatting inconsistencies did not affect the retrieval process. As explained in the previous paragraphs, the coefficients $\beta_{(\cdot)}$ extracted from Mistral's output have been compared with the upcoming ECB decisions over three distinct time periods (Δ_S, Δ_M and Δ_L) to calculate Pearson correlations.

5 Proposed Models

5.1 Sentence Transformer with Domain Keywords (ST+DK)

The FinBERT model is specifically designed for sentiment analysis within financial texts. However, rather than capturing the full semantic meaning of the sentences, FinBERT primarily focuses on classifying sentiment, which may result in a limited understanding of the nuanced content conveyed in the text. To overcome this limitation, a Sentence Transformer (Reimers and Gurevych, 2019) has been chosen. This type of model leverages the architecture of BERT (Bidirectional Encoder Representations from Transformers), but it is further optimized for producing high-quality sentence embeddings. These embeddings are crucial for tasks such as semantic similarity, clustering, and information retrieval, as they capture the nuanced meaning of sentences in a dense vector space.

In particular, MiniLM-L6-v2[5] has been selected for its ability to balance efficiency and efficacy. This model is particularly well-suited for practical applications where computational resources and response times are crucial factors. MiniLM-L6-v2 has been used to create the embedding vector of textual spans, i.e. sentences within the collected news and pseudo-sentences composed of domain expert keywords that reflect the concepts related to policy decisions and duration.

Table 2: Keywords from domain experts to potentially can correlate with policy changes (decrease or increase) and time periods (short, middle, or long)

Policy	Time Period	Keyword
increase	short-middle-long	hike
increase	short-middle-long	increase
increase	short-middle-long	raises
increase	short-middle-long	policy tightening
increase	short-middle-long	rise
decrease	short-middle-long	cut
decrease	short-middle-long	decrease
decrease	short-middle-long	lowers
decrease	short-middle-long	policy easing
decrease	short-middle-long	reduction
increase-decrease	short-middle-long	interest
increase-decrease	short-middle-long	rate
increase-decrease	short-middle-long	rates
increase-decrease	short	short-term
increase-decrease	short	immediate
increase-decrease	short	this month
increase-decrease	short	near-term
increase-decrease	short	start sooner
increase-decrease	short	very soon
increase-decrease	middle	mid-term
increase-decrease	middle	in coming months
increase-decrease	middle	medium-term
increase-decrease	middle	expected soon
increase-decrease	middle	over the next few months
increase-decrease	long	long-term
increase-decrease	long	future
increase-decrease	long	over the next year
increase-decrease	long	not in a hurry
increase-decrease	long	be patient

More specifically, with the support of domain experts (three individuals with 5-years of experience in the financial sector), a set of keywords was identified to describe policies related to increases and decreases, as well as the corresponding time periods (short, medium, and long term). These keywords are listed in Table 2. The keywords are concatenated according to the following rule: first, the policy decision *(e.g., hike, increase, raises)*, followed by the object *(interest rate, rates)*, and finally, the term decisions *(e.g., short-term, immediate, this month)*, to generate a phrase that reflects both the policy decision and the associated duration.

Sentence embeddings were calculated for each sentence in every news article, and the cosine similarity was determined between these embeddings

[5]https://huggingface.co/sentence-transformers/all-MiniLM-L6-v2

and the embeddings of concatenated keywords related to future interest rate changes over the short, medium, and long term. Since the score was calculated as the average cosine similarity between each news article i and the set of keywords that depends on a given time period and policy, such a score can be derived as β^i_{SI}, β^i_{SD}, β^i_{MI}, β^i_{MD}, β^i_{LI} and β^i_{LD}. Given a time period, each score vector has been used to estimate the Pearson correlation with the corresponding Δ_S, Δ_M and Δ_L to estimate the magnitude of a potential linear relationship.

5.2 Sentence Transformer with Narrow Keywords (ST+NK)

The main issue related to the approach presented in Section 5.1 is that concatenating numerous keywords can lead to repetition and produce embeddings that do not generalize well for the keywords that define specific policies and time period (e.g. increase-short). In order to overcome this limitation, a selection approach was employed, considering all possible combinations of up to three keywords from the initial list. The limit of three keywords was chosen to balance the comprehensiveness of the search with computational time constraints. Subsequently, keywords were selected based on those that achieved a higher Pearson correlation coefficient.

Similarly to what has been done in the previous section, we determined the embeddings of each sentence in every news article, and the cosine similarity between these embeddings and the embeddings of the subset of the obtained keywords has been estimated. The score was determined by averaging the similarities for each news article, which was then used to compute the Pearson correlation with future interest rate changes over the short, medium, and long term. Table 3 presents the selected keywords.

5.3 Grid Search of optimal keyword set (GS)

The main limitation of the approaches presented in Section 5.1 and 5.2 is that the keywords employed were neither exhaustive nor fully representative of journalistic financial jargon. In order to overcome this limitation, an iterative algorithm is proposed to identify a list of keywords without relying on any domain expertise.

Given n as the number of keywords and k as the number of combinations, the total number of subsets of k elements is given by the binomial coefficient, which we denote as n_k:

$$n_k = \binom{n}{k} = \frac{n!}{k!(n-k)!}$$

Table 3: Optimal keywords obtained by limiting the composition of the final keywords to contain at most 3 original terms from the original list reported in Table 1.

Policy	Time Period	Keyword
increase	short-middle-long	hike
increase	short-middle-long	increase
increase	short-middle-long	raises
decrease	short-middle-long	cut
decrease	short-middle-long	reduction
increase-decrease	short	immediate
increase-decrease	short	very soon
increase-decrease	middle	mid-term
increase-decrease	long	be patient

As the parameter k increases, the number of possible combinations grows exponentially, making it impractical for any subsequent activity based on the possible keyword combination. Consequently, it was decided that, for increasing values of k, a decreasing value of n is necessary. In Table 4, the values of k, n and the number n_k of combinations used in this investigation are shown. In particular, for each value of k, the parameter n has been set such that the number of combinations n_k is as close as possible to a given threshold $\alpha = 3000$ (the α value has been arbitrarily selected in order to guarantee a feasible computational time). This allows us on one hand to limit the number of combinations to be explored and on the other hand to evaluate the larger space of possible keyword combinations.

Comb. k	**N° keywords** n	**Keyword comb.** n_k
1	1000	1000
2	77	2926
3	27	2925
4	17	2380
5	14	2002
6	13	1716
7	13	1716
8	13	1287
9	13	715
10	13	286

Table 4: Number of keywords and keyword combinations according to k combinations

In order to quantify the contribution of each individual keyword m belonging to the set of candidate keywords CS (with respect to each time period), we estimate the average Pearson correlation. In particular, given a news article i composed

of z sentences and a keyword combination q that belongs to the set of keyword combinations $Q^k_{(\cdot)}$, where $Q^k_{(\cdot)}$ can be Q^k_{SI}, Q^k_{SD}, Q^k_{MI}, Q^k_{MD}, Q^k_{LI} or Q^k_{LD} according to the considered time periods and policies, we followed the subsequent steps:

1. We embed the z sentences and the keyword combination q using the Sentence Transformers.

2. We compute the cosine similarity between each sentence embedding and the keyword combination embedding, and the average of these similarities is what we refer to as the score $\beta^i_{(\cdot)}$ (where $\beta^i_{(\cdot)}$ can be β^i_{SI}, β^i_{SD}, β^i_{MI}, β^i_{MD}, β^i_{LI} or β^i_{LD} according to the considered time periods and policies).

3. The vector $\beta_{(\cdot)}$ of such scores is used coupled with the vector of future interest rate $\Delta_{(\cdot)}$ to calculate the Pearson correlation c_q.

4. We repeat steps 1-3 for all combinations of keywords belonging to the set $Q^k_{(\cdot)}$.

5. Given a keyword m and the set $Q^{km}_{(\cdot)}$ that denotes those combinations in $Q^k_{(\cdot)}$ containing the keyword m, we estimated the average Pearson correlation as follows:

$$c_m = \frac{1}{|Q^{km}_{(\cdot)}|} \sum_{q=1}^{|Q^{km}_{(\cdot)}|} c_q \qquad (1)$$

The coefficients $\tilde{c}_m$ will be subsequently used to finally determine the optimal set of keywords.

In particular, the process reported in **Algorithm 1** has been followed. In order to have an initial set of candidate keywords to be considered for the keywords combinations ($Q^k_{(\cdot)}$), we estimated for all the terms of the vocabulary the corresponding TF-IDF value. The initial set CS of candidate keywords is composed of the top-1000 terms with the highest TF-IDF coefficient. This initial selection is particularly important to identify the most relevant terms that encapsulate the core themes of the text. We then initialize a few sets of variables to track the best combination of keywords and their correlation with future interest rates (lines 1-2). When processing the keywords related to a given value of k, we initially create the set $Q^k_{(\cdot)}$ as composed of all the possible combinations of keywords belonging to the candidate set CS (line 4).

Then, for each combination q of keywords belonging to the set $Q^k_{(\cdot)}$, the algorithm encodes q (line 6) and calculates the average cosine similarity $\beta^i_{(\cdot)}$ with the encoded sentences of a given news articles (lines 8-9). The vector $\beta_{(\cdot)}$ composed of similarity coefficients $\beta^i_{(\cdot)}$ is then correlated with the vector of future interest rate $\Delta_{(\cdot)}$ to identify the best performing keyword combination (line 11). If a higher correlation is found, the algorithm updates the best combination and its corresponding correlation value (lines 12-14). Then the average Pearson correlation c_m is estimated and stored in the corresponding vector $\vec{c}_m$, and subsequently used to create a new (reduced) set of candidate keywords (line 20). In particular, the subsequent candidate set CS is created by extracting the n_{k+1} keywords that have the highest $\vec{c}_m$. This approach ensures that the most relevant keywords are prioritized in the subsequent iterations. The list of relevant keywords extracted according to the Grid Search strategy is reported in Table 5.

Algorithm 1 *KeywordsGenerations(CS)*

1: $OptimalKeywordCombination \leftarrow []$
2: $BestCorr \leftarrow 0$
3: **for** $k = 1$ **to** 10 **do**
4: $\quad Q^k_{(\cdot)} \leftarrow Combination(k, CS)$
5: $\quad$ **for** $q \in Q^k_{(\cdot)}$ **do**
6: $\quad\quad h_q \leftarrow SentenceTransformer(q)$
7: $\quad\quad$ **for** $i \in N$ **do**
8: $\quad\quad\quad h_z \leftarrow SentenceTransformer(z)\ \forall z \in Z_i$
9: $\quad\quad\quad \beta^i_{(\cdot)} \leftarrow \frac{1}{|Z_i|} \sum_{z=1}^{|Z_i|} CosineSimilarity(h_q, h_z)$
10: $\quad\quad$ **end for**
11: $\quad\quad c_q \leftarrow PearsonCorrelation(\beta_{(\cdot)}, \Delta_{(\cdot)})$
12: $\quad\quad$ **if** $c_q > BestCorr$ **then**
13: $\quad\quad\quad OptimalKeywordCombination \leftarrow q$
14: $\quad\quad\quad BestCorr \leftarrow c_q$
15: $\quad\quad$ **end if**
16: $\quad$ **end for**
17: $\quad$ **for** $m = 1$ **to** —CS— **do**
18: $\quad\quad c_m \leftarrow \frac{1}{|Q^{km}_{(\cdot)}|} \sum_{q=1}^{|Q^{km}_{(\cdot)}|} c_q$
19: $\quad$ **end for**
20: $\quad CS \leftarrow ExtractTop(n_{k+1}, CS, \vec{c}_m)$
21: **end for**

To explore a broader space, a trivial variant was introduced. If in CS are present keywords for which the cosine similarity between their embeddings and the embeddings of other keywords is greater than 0.8, then only the keyword with the highest c_m is maintained.

Table 5: Keywords extracted according to the GS strategy

Policy	Time Period	Remove similar	Keywords
increase	short	False	higher, scale, strength, weigh, hiking, pointed, soaring, additional, lift, accounts
increase	short	True	hikes, weigh, senior, strength, soaring, boost, pointing, accounts, lift
increase	middle	False	weigh, scale, higher, boost, soaring, pointing, hike, lift
increase	middle	True	weigh, soaring, boost, higher, scale, forwards, additional, lift, pointed, exchange
increase	long	False	gain, forwards, accounts, hiking, account, exchange, imported, scale, deposit

6 Results

We report in Table 6 the Pearson correlation coefficients for all the approaches presented above, distinguishing between different time periods and policies. In particular, other than FinBert and Mixtral, we refer to Sentence Transformer with Domain Expert Keywords (ST+DK), Sentence Transformer with Narrow Keywords (ST+NK), Grid Search (GS) and Grid Search with Similar Removal (GS+SR). The analysis of the FinBert model reveals a moderately weak correlation, particularly with respect to short-term policies. An important consideration is that the model does not offer immediate interpretability; thus, the use of an explainer is necessary for further clarification.

In contrast, the Sentence Transformer coupled with domain expert keywords produced results that were notably lower for the increase-long time period compared to the FinBert method, yet yielding higher results for the decrease of interest rate. This highlights a preference for the Sentence Transformer approach, because of its ability of capturing the entire sentence meaning.

Turning to the Sentence Transformer with reduced domain expert keywords, the outcomes were quite promising, with the exception of the long-term increase decisions. The Pearson correlation coefficients reported in Table 6 are significantly higher than those observed in the previously discussed methods, suggesting that a sub-optimal selection based on a grid search approach can lead to better capture the relationship with the ECB decisions.

The Pearson correlation coefficients for Mixtral indicate a moderate to strong relationship. However, it is essential to note that Mixtral operates as a large language model (LLM), which typically demands substantial computational resources.

For what concerns the proposed *Grid Search* approach for optimal keyword set, even when considering its variant where similar keywords are removed, we can point out significantly high magnitudes of the Pearson coefficient, suggesting a strong correlation.

It is important to highlight that the proposed approach for generating keywords stands out due to its efficiency and effectiveness; it does not necessitate the application of separate explainability techniques. The keywords extracted automatically, as demonstrated in Table 5, highlight the coherence and reliability of the proposed grid search approach. For instance, in the context of policy increase, the terms *scale, strength, gain* is prominently featured, while in discussions of policy decrease, the word *cuts, fell, drops* appears frequently.

7 Conclusions

In this paper, we introduced a novel technique utilizing sentence transformers to extract keywords with the highest correlation. While it is well-established that the Pearson coefficient is not a measure of causality, the extracted keywords indicate a notable presence of terms related to the rise or fall of interest rates when considering ECB decisions. This suggests a potential linkage, albeit without implying direct causation.

Future work will first focus on evaluating alternative robustness measures beyond the Pearson correlation to ensure the reliability of the findings. Once validated, these insights will be leveraged to develop a predictive model to forecast trends based on real-time news data. As part of this, we could create a benchmark dataset by tagging sentences with labels: 'increase', 'neutral' or 'decrease'. This dataset would be useful for training a classification model and evaluating its performance. Furthermore, applying this algorithm to generic classification datasets could provide a valuable comparison with established benchmarks in classification tasks, thereby enhancing our understanding of its efficacy and versatility.

Abstract

This work explores the intersection of code-mixing and disfluency in bilingual speech and text, with a focus on understanding how large language models (LLMs) handle code-mixed disfluent utterances. One of the primary objectives is to explore LLMs' ability to generate code-mixed disfluent sentences and to address the lack of high-quality code-mixed disfluent corpora, particularly for Indic languages. We aim to compare the performance of LLM-based approaches with traditional disfluency detection methods and to develop novel metrics for quantitatively assessing disfluency phenomena. Additionally, we investigate the relationship between code-mixing and disfluency, exploring how factors such as switching frequency and direction influence the occurrence of disfluencies. By analyzing these intriguing dynamics, we seek to gain a deeper understanding of the mutual influence between code-mixing and disfluency in multilingual speech.

1 Introduction

In this section, we provide essential background on code-mixing and disfluency, setting the stage for our contributions in this study.

1.1 Code-Mixing

Multilingual speakers may unconsciously switch languages due to the interconnected nature of their mental lexicons. Possible reasons include:

- Lack of Language Proficiency (Grosjean, 1982).
- Faster Retrieval (Heredia and Altarriba, 2001).
- Understandability (Heredia and Altarriba, 2001).

Code-Mixing refers to mixing elements from two languages within a single sentence, even down to morpheme level (the smallest units of meaning) (Bhatia and Ritchie, 2008).
Example: *Amake aajke* project presentation *dite hobe, tai* stress *hocche*. (switch within clause)
Translates to: "I have to give a project presentation today, so I'm feeling stressed."

Although certain scholars use the terms code-mixing and code-switching interchangeably, code-switching is often defined differently. Code-switching refers to switching between two languages across sentence or clause boundaries, typically at the word, phrase, clause, or sentence level, but not within a single morpheme (Bhatia and Ritchie, 2008).
Example: I can't come to the party tonight. *Amay kal shokale uthte hobe.* (switch at sentence-boundary)
Translates to: "I can't come to the party tonight. I need to wake up early tomorrow."
Example: She was very late, *tai ami wait korini.* (switch at clause-boundary)
Translates to: "She was very late, that is why I did not wait."

Note: These are Bengali-English code-mixed sentences where Bengali words are italicised.
The dominant language in a code-mixed sentence which provides the grammatical structure (e.g., word order, function words, morphology) is called the matrix language. The less dominant language, which contributes content words (e.g., nouns, verbs) but adapts to the grammar of the matrix language, is called the embedded language. These are defined by Myers-Scotton (1997).

1.2 Disfluency

Disfluencies refer to interruptions or breaks in the smooth flow of spoken language. These are natural

Proceedings of Recent Advances in Natural Language Processing,pages 915–924
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-105

parts of speech that occur when a speaker pauses, restarts, or struggles to articulate words, common in spontaneous or unplanned speech. The following are some examples of Bengali-English code-mixed disfluent sentences:

- **Interregnum:** I think, ummm, *pora shuru korte hobe.*
- **Repetition:** *Ami ami jabo* exam *dite.*
- **False Start:** *Ami uh- tui* exam *dili?.*
- **Correction:** Left- sorry Right *e jete hobe*.

The *reparandum* (words supposed to be corrected or ignored), *interregnum* (optional discourse cues), and *repair* are marked and Bengali words are italicised.

1.3 Our Contribution

- We try to mitigate the scarcity of high-quality code-mixed disfluent corpora, particularly for Indic languages, by producing a Bengali-English code-mixed disfluent corpus generated via zero-shot prompting.
- We develop novel metrics to quantitatively assess disfluency phenomena.
- Compare different LLMs (GPT-4o, GPT 4.5-Preview, Gemini 2.0 Flash, Gemini 2.0 Thinking, Gemini 2.5 Pro) with respect to the nature of their generated code-mixed disfluent sentences.
- Investigate novel LLM (GPT-4o) based methods for disfluency detection and compare performance with traditional approaches for the same.
- Explore the interplay between code-mixing and disfluency to understand their mutual influence.

2 Literature Review

Disfluency is a characteristic of spontaneous speech and introduces erroneous words that do not contribute to the semantics of the utterance. Early works surrounding disfluency detection explored a variety of neural architectures. Zayats et al. (2016) utilized bidirectional LSTMs with pattern match features to reduce vocabulary sensitivity during training. Wang et al. (2016) proposed an encoder-decoder attention model to capture long-range dependencies for disfluency detection. Jamshid Lou and Johnson (2017) adopted a Noisy Channel Model enhanced with LSTM language models to score candidate analyses based on fluency. Later, Jamshid Lou et al. (2018) introduced an auto-correlational CNN to capture "rough copy" patterns often found in repair disfluencies. More recent efforts have focused on multilingual and syntactic enhancements. Kundu et al. (2022) explored zero-shot disfluency detection in Indian languages using pretrained multilingual models fine-tuned on English. Ghosh et al. (2022) introduced a span classification model that combines contextual information from transformers and structured syntactic features via graph convolutional networks.

The Switchboard (SWBD) corpus (Godfrey and Holliman, 1993) contains annotated English disfluent sentences from 2,400 telephone conversations among 543 US speakers (302 male, 241 female). Participants did not know each other, and conversations were held on topics from a predetermined list. It is a benchmark for monolingual disfluency studies. Passali et al. (2022) proposed the LARD (Large-scale ARtificial Disfluency), which uses linguistic rules to generate synthetic disfluent text, though its application is limited to monolingual settings. Kundu et al. (2022) defined a rule-based procedure for generating disfluencies from fluent sentences. Kundu et al. (2022) also mention that such synthetic data generated by fixed rules may not fully reflect real-world disfluencies — we find this limitation is also applicable to LARD. Bhat et al. (2023) introduced a large-scale, human-annotated corpus for disfluency correction in Indo-European languages, though it, too, is restricted to monolingual utterances.

In the context of code-mixed data, several datasets exist, albeit not specifically for disfluency detection. Raihan et al. (2023) introduced SentMix-3L for sentiment analysis in Bangla-English-Hindi code-mixed text, while Raihan et al. (2024) released EmoMix-3L for emotion detection in the same language mix. Nayak and Joshi (2022) proposed HingCorpus, a Hindi-English code-mixed dataset in Roman script. Gupta et al. (2024) explored rule-based prompting techniques for large language models (LLMs) to generate code-mixed

text. However, none of these datasets were designed with disfluency detection in mind. The ICON (2023) Shared Task dataset provides disfluent code-mixed data specifically for disfluency detection, but upon closer inspection, the semantic quality of the utterances was found to be lacking in resemblance to real-world human speech patterns.

3 Methodology

3.1 Zero-Shot Prompting for Generating Corpus

We propose two distinct outcome-based prompting techniques for generating code-mixed disfluent sentences:

- **Translating Disfluent Sentence to Code-Mixed Setting:** In this approach, we present an English disfluent sentence and request its X-Y code-mixed translation or counterpart, where X and Y are the target languages.
- **Artificial Conversation Generation with Code-Mixing and Disfluency:** This technique involves zero-shot prompting for generating an artificial conversation between N speakers who code-mix between languages X and Y, that should resemble human disfluent speech, with the inclusion of common types of disfluencies such as false starts, repetitions, and corrections.

We build our initial dataset using the first prompting technique:

- Sample 100 random sentences of length < 15, and $> 10\%$ disfluent tokens from the SWBD Corpus (Godfrey and Holliman, 1993). This was done to restrict sentence length and remove sentences with negligible disfluencies.
- Sentence is injected into the prompt to GPT-4o, and result (Code-Mixed Counterpart) extracted using Open-AI's structured output parser.
- Manually label sentences using binary labels, 0 for fluent and 1 for disfluent tokens.

The prompt uses the Self-Consistency (Wang et al., 2023) technique to achieve it's goal. The detailed prompt is excluded to maintain conciseness.
The second prompting technique is used to build the final dataset, that we name, MixFluent.

- The two family of LLMs used are GPT-4 (OpenAI, 2024) (GPT-4o and GPT-4.5 Preview) and Gemini (Gemini-Team, 2024) (Gemini 2.0 Flash, 2.0 Flash Thinking and 2.5 Pro).
- A topic X is chosen randomly from a list of pre-specified topics (Life, Travel, Academics, Sports, Food, Car, Movies, Books) is chosen with decreasing probability in order of mention.
- One of the conditions: telephone or face-to-face conversation is chosen randomly.
- One of the Large Language Models is chosen at random.
- We use OpenAI Platform, and Gemini Platform to prompt the LLM as required.
- The result is parsed into individual sentences by splitting at ".", "?", and "!".
- Each such conversation is chosen at random for manual review and editing. All the conversations are labelled both at token and span level manually.

This is repeated till approximately 2000 sentences are obtained. The detailed prompt is excluded to maintain conciseness.
The MixFluent dataset is manually annotated with a two-tier disfluency labeling scheme. At the token level, we use a scheme similar to one proposed by Shriberg (1994) using the following tags:

- `R1` (reparandum): Words intended to be corrected or ignored.
- `I` (interregnum): Optional discourse cues.
- `R2` (repair): The correction or words supposed to be retained.

In addition, each disfluent span is further categorized into one of the following disfluency types defined as:

- `IR` (Interregnum): A filler word or hesitation marker used to buy time while thinking.
  Example: *Focus korar cheshta korchi* but uh it's impossible.
  Translates to: I'm trying to focus but uh it's impossible.

- `RE` (Repetition): Repeating a word or phrase unintentionally, often due to planning difficulties or to re-iterate a point or objective.
  Example: *Achha, tahole* maybe um, maybe *amra ek saathe bosh e dekha korte pari*, right
  Translates to: Okay, then maybe, um, maybe we can sit together and meet, right?

- `FS` (False Start): A prematurely started utterance that is abandoned and replaced.
  Example: *Ami toh ami* actually *bhabchhilam boi kinbo bole.*
  Translates to: I was- I actually was thinking of buying a book.

- `CR` (Correction): Self-repair of an earlier spoken segment.
  Example: Hmm, *motamoti bujhechi*, but weak entity, sorry, weak relationship *taay doubt ache.*
  Translates to: Hmm, I more or less understood, but weak entity- sorry, I have a doubt in weak relationship.

- `PP` (Pet Phrase): Frequently used filler expressions that do not add semantic content, often specific to personal habits.
  Example: *Mane, aaj raat e amra ekta* quick revision call *kore ni.*
  Translates to: I mean, let's do a quick revision call tonight.

- `ST` (Stutter): Repetition of sounds or syllables due to difficulty in speech production.
  Example: *Tui kono* no- notes *baniyechis naki.*
  Translates to: Did you make any no- notes?

- `FL` (Fluent): A normally produced word without any disfluency.
  Example: *O haan, tor kachhe* indexing *ar* transaction *er* notes *ache.*
  Translates to: Oh yes, do you have the indexing and transaction notes?

All above examples are sourced from the MixFluent Dataset. The *reparandum* (words supposed to be corrected or ignored), *interregnum* (optional discourse cues), and *repair* are marked and Bengali words are italicised.

3.2 Novel Disfluency Metrics

We formulate the two following metrics inspired by language entropy (Gullifer and Titone, 2019):
Fluency Entropy (FE): It is an information-theoretic measure that quantifies the distributional uncertainty of fluency labels across all tokens in a sequence. It evaluates how balanced or skewed the fluency labels are, without considering the order or grouping of tokens.

$$FE = -\sum_{i=1}^{k} p_i \cdot \log_2(p_i)$$

where:

- k is the number of unique fluency labels (e.g., *Fluent, Disfluent*),
- $p_i = \frac{\text{number of tokens with label } i}{\text{total number of tokens}}$

Fluency Entropy (FE) quantifies how evenly fluent and disfluent tokens are distributed across a sequence. A high FE value (close to 1) indicates a balanced presence of fluent and disfluent tokens, suggesting more frequent disfluencies throughout the sentence. A low FE value (close to 0) suggests that one label (typically "fluent") dominates the sequence, indicating that disfluencies are either rare or absent.
Fluency Span Entropy (FSE): It is an information-theoretic metric that measures the diversity of fluency span types in a sequence. Each span is defined as a contiguous segment of tokens with the same fluency label and its length. The entropy is computed over the set of unique *(label, span length)* pairs.

$$FSE = -\sum_{i=1}^{n} p_i \cdot \log_2(p_i)$$

where:

- n is the number of unique $(label, spanlength)$ combinations,
- $p_i = \frac{\text{count of span type } i}{\text{total number of spans}}$

Fluency Span Entropy (FSE) captures the diversity and variability of fluency spans—that is, contiguous segments of tokens sharing the same fluency label and length. A high FSE implies that the sequence contains many different types of fluency spans, both in terms of label and length (e.g., short disfluent interruptions, long fluent stretches, and vice versa). A low FSE, in contrast, suggests uniformity in the fluency structure, with fewer types of spans—either the speech is consistently fluent or disfluencies appear in repetitive, predictable patterns. Together, FE and FSE allow us to assess not only how much disfluency is present (via label distribution), but also how that disfluency is organized and patterned within the sentence.

3.3 Generation Characteristics of LLMs

Each sentence in MixFluent Dataset (generated by an LLM) is represented as 2-D feature using one of:

- Code-Mixing Index and Disfluency Percentage
- Code-Mixing Index and Fluency Entropy
- Language Entropy and Disfluency Percentage
- Language Entropy and Fluency Entropy

where, Language Entropy is defined by Gullifer and Titone (2019), Code-Mixing Index is defined by Gambäck (2014), Fluency Entropy is defined by us in Section 3.2, and Disfluency Percentage is the ratio of disfluent tokens to the total number of tokens in an utterance.
Each sentence generated by the same model is assigned to the same cluster. Cluster evaluation metrics like Silhoutte Score (Rousseeuw, 1987), Davies-Bouldin Index (Davies and Bouldin, 1979) and Calinski-Harabasz Index (Caliński and JA, 1974) are computed to analyse quality of clustering. Additionally, we look into the mean of various metrics computed on the data generated by each model/family to draw further conclusions.

3.4 Few-Shot Prompting for Disfluency Labelling

We propose a few-shot prompting approach for disfluency detection, leveraging the chain-of-thought (CoT) (Wei et al., 2023) and self-consistency (Wang et al., 2023) prompting strategies with GPT-4o (OpenAI, 2024) as the LLM. The detailed prompt is excluded to maintain conciseness. Evaluation is done on the ICON 2023 Shared Task (ICON, 2023) Bengali Test Set. The class-wise F1-Scores are compared against strong supervised baselines like BERT (Devlin et al., 2018), MuRIL (Khanuja et al., 2021) and IndicBERT (Kakwani et al., 2020) fine-tuned using Weighted Cross-Entropy Loss to handle severe class imbalance, Adam with weighted decay optimizer for 20 Epochs each.

3.5 Hypothesis Testing on the Influence of Code-Mixing on Disfluency Patterns

We propose the following hypotheses and test them on the MixFluent Dataset:

- H1: Proximity to a switch triggers disfluency.
- H2: Direction of the switch affects disfluency.
- H3: Increase in switching frequency triggers a higher degree of disfluency.
- H4: The speaker is more likely to be disfluent in the embedded language.
- H5: Disfluent tokens are more likely to be clustered than isolated.

While H1–H4 directly explore the influence of code-mixing on disfluency, H5 investigates the structural distribution of disfluent tokens.
Note: In a code-mixing environment, the switch of codes within a single sentence, even down to morpheme level, has been referred to as a ***switch****. The token which differs in language from the previous token is considered to be a* ***switch point****.*

To test each hypothesis, count disfluent vs fluent tokens

- with & without code-switch in ±2 token window.
- for each direction of code-swithcing in previous token.
- with 0, 1, 2+ switches in ±2 token window.
- for each language label.

We also count disfluent tokens that are isolated or clustered (±1 window). We build contingency tables, compute % disfluency per category, and test independence using χ^2 test.

4 Results and Discussion

4.1 Zero-Shot Prompting for Generating Corpus

We make the following qualitative observations while creating the **initial dataset**, by translating disfluent English sentences sourced from SWBD (Godfrey and Holliman, 1993) corpus, to their Bengali-English counterpart:

- Semantic coherence of non-disfluent spans in the SWBD corpus is relatively poor, which affects the quality of code-mixed outputs as the LLM outputs inherit these deficiencies from the input data.
- The type of disfluency present in the input English sentence preserved in the generated Bengali-English code-mixed sentence.

- The position of disfluent spans often shift in the generated output to cater to the natural syntactic and grammatical constraints of Bengali.
- The positional shift prevents direct transfer of disfluency labels from the input to the output, necessitating manual annotation.

Model	RE	FS	CR	ST	PP	IR
GPT-4o/mini	142	8	12	11	167	480
GPT-4.5 Preview	430	27	40	0	215	577
Gemini 2.0 Flash	202	11	0	6	31	115
Gemini 2.0 Flash Thinking	134	3	3	0	0	104
Gemini 2.5 Pro	305	17	11	7	24	330

Table 1: Class-wise model-wise frequency of generated disfluencies normalized to 1k sentences per model.

According to Table 1, we make the following observations concerning the **MixFluent dataset**:

- Only GPT-4o/mini and Gemini 2.5 Pro successfully followed the prompt to include disfluencies from all classes.
- Gemini 2.0 Flash Thinking and GPT-4.5 Preview produced the least and most disfluencies per 1000 sentences respectively.
- Interregnum (IR) and Stutter (ST) were the classes with highest and least frequency.

The following qualitative observations are made while reviewing and labelling the MixFluent Dataset:

- Occasionally, a third language term "yaar" (from Hindi) introduced into the conversation, even though there was no mention of Hindi mixing.
- The LLMs assume that Bengali is the base language and English is the embedded language.
- Although LLMs generated unnecessary disfluenices at few occasions, the nature of produced text represent real-world disfluencies better than data generated by previous rule-based methods proposed by Passali et al. (2022) and Kundu et al. (2022).

The MixFluent dataset statistics and detailed descriptive metrics are provided in Table 2 and Table 3 respectively.

Statistic	Value
Total Sentences	2049
LLMs Used	5
Average Sentence Length (tokens)	6.48 ± 5.00
Total Tokens	13285
Disfluent Tokens	2990
% Disfluent Tokens	22.51
Mean % Disfluent Tokens per Sentence	18.58%

Table 2: Dataset statistics for the MixFluent (Bengali-English code-mixed disfluent) speech corpus.

Feature	Mean	Std. Dev.	Median	IQR
CMI	48.37	32.74	50.00	25.00–75.00
Language Entropy	0.60	0.42	0.81	0.00–0.95
Fluency Entropy	0.34	0.42	0.00	0.00–0.81
Fluency Span Entropy	0.59	0.74	0.00	0.00–1.00
Disfluency %age	18.58	26.59	0.00	0.00–33.33

Table 3: Descriptive statistics of key features in the MixFluent Dataset. (IQR refers to Inter-Quartile Range)

F1	F2	SIL	DBI	CHI
CMI	Disfl. %age	-0.069	8.032	47.016
CMI	FE	-0.135	55.683	59.665
LE	Disfl. %age	-0.178	12.647	28.867
LE	FE	-0.138	8.240	33.768

Table 4: Clustering metrics for various feature combinations, where F1 and F2 are Features 1 and 2 respectively. CMI: Code-Mixing Index, FE: Fluency Entropy, LE: Language Entropy, SIL: Silhouette Score, DBI: Davies-Bouldin Index, CHI: Calinski-Harabasz Index.

4.2 Generation Characteristics of LLMs

According to Table 4, negative Silhouette Scores indicate poor clustering approaching random assignment. This implies that no model seems to be biased towards certain patterns of disfluency and degree of code-mixing at the same time.

According to Table 5, GPT-4.5 Preview generated

Model	CMI	LE	Disfl. %	FE	FSE
GPT-4o	38.46	0.68	17.95	0.39	0.72
GPT-4.5 Preview	39.94	0.76	28.97	0.54	1.07
Gemini 2.0 Flash	40.20	0.55	13.10	0.24	0.41
Gemini 2.0 Flash Thinking	63.88	0.47	10.52	0.15	0.25
Gemini 2.5 Pro	57.42	0.56	25.63	0.43	0.65

Table 5: Comparison of Models on Mean CMI, Language Entropy (LE), Disfluency Percentage, Fluency Entropy (FE), and Fluency Span Entropy (FSE) of generated data. Above values are mean of each metric.

a significantly higher %age of disfluency than

GPT-4o. Similarly, Gemini 2.5 Pro generated a significantly higher %age of disfluency compared to other Gemini models.

Model Family	CMI	LE	Mean FE	FSE	Disfl. %
GPT-4	38.74	0.70	0.42	0.79	20.03
Gemini	54.42	0.53	0.29	0.46	17.67

Table 6: Mean of metrics calculated on data generated by GPT and Gemini model families.

According to Table 6 GPT-4 models generated higher disfluency percentage, while Gemini models generated a much higher average code-mixing index.

4.3 Few-Shot Prompting for Disfluency Labelling

	F1 Score			
Class	**BERT**	**MuRIL**	**IndicBERT**	**GPT-4o**
Alteration_R	0.46	0.69	0.72	0.00
O	0.87	0.95	0.98	0.93
edit_R	0.78	0.73	0.60	0.00
false_R	0.15	0.30	0.26	0.00
filler_R	0.79	0.96	0.92	0.08
pet_R	0.65	0.79	0.86	0.09
repair_R	0.26	0.45	0.66	0.00
repeat_R	0.11	0.66	0.63	0.07
Weighted F1 Score	0.73	0.91	0.95	0.83
Macro Avg F1 Score	0.51	0.69	0.70	0.14

Table 7: F1 scores for various models across disfluency classes (ICON 2023 Shared Task Bengali Test Set)

While comparing traditional methods to few-shot prompting based disfluency labelling, the following observations (Refer Table 7) are made:

- The LLM (GPT-4o) struggled to produce same number of labels as input tokens. This highlights its weakness in counting scenarios. The results are padded with 'O' label for computing metrics.
- Average F1-Score of the LLM (GPT-4o) is significantly worse than other models.
- IndicBERT (Kakwani et al., 2020) despite having lesser parameters performs better than MuRIL (Khanuja et al., 2021).
- All the models relatively struggled in labelling the class "false_R" which represents false starts.

4.4 Hypothesis Testing on the Influence of Code-Mixing on Disfluency Patterns

H1: Proximity to a switch triggers disfluency.

	Switch Nearby	No Switch Nearby
Disfluent	2144	846
Fluent	7060	3232
%age Disfluent	23.29	20.74

Table 8: Contingency table showing the relationship between disfluency and proximity to a code-switch (considering neighborhood of 5 tokens).

From Table 8, we see that the probability of disfluency is higher when there is a switch point in a ±2 token window. The χ^2 value is 10.378 which is greater than the critical value of 3.814 (at p=0.05). Thus, we can reject the null hypothesis.
Proximity to a code-switch does trigger disfluency.

H2: Direction of the switch affects disfluency.

	Switch into ENG	Switch into BEN
Disfluent	556	515
Fluent	1737	1775
%age Disfluent	24.24	22.48

Table 9: Contingency table showing the relationship between disfluency and switching direction in previous token.

From Table 9, we see that there is a difference of 1.76% in disfluency occurrence for the two possible directions of switch in previous token. The χ^2 value is 1.882 which is much lesser than the critical value of 3.814 (at p=0.05). Thus, we can not reject the null hypothesis.
Different code-switching direction does not trigger disfluency to different extent.

H3: Increase in switching frequency triggers a higher degree of disfluency.

	0 Switches	1 Switch	2+ Switches
Disfluent	846	1005	1139
Fluent	3232	3557	3503
%age Disfluent	20.74	22.03	24.54

Table 10: Contingency table showing the relationship between disfluency and switching frequency in a neighborhood of 5 tokens.

From Table 10, we see that the %age of disfluency

increases with increase in number of switches. The χ^2 value is 18.814 which is much higher than the critical value of 5.9915 (at p=0.05). Thus, we can reject the null hypothesis.
Increase in code-switching frequency triggers a higher degree of code-switching.

H4: The speaker is more likely to be disfluent in the embedded language.

	ENG	BEN
Disfluent	1828	1162
Fluent	4852	5440
%age Disfluent	27.95	17.60

Table 11: Contingency table showing the relationship between disfluency and language.

Table 11 shows 10% more disfluency occurence across English words than Bengali. The χ^2 value is 180.929, which is much higher than the critical value of 3.814 (at p=0.05). Thus, we can reject the null hypothesis.
Disfluency is more likely to occur in the embedded language, which is also the speaker's second language in most cases.

H5: Disfluent tokens are more likely to be clustered than isolated.

	Count
Clustered	2552
Isolated	438
%age Clustered	85.32

Table 12: Table showing the frequency of clustered and isolated disfluent tokens.

From Table 12, we see that 85.32% of disfluent tokens appear close to other disfluent tokens (within one word before or after), while only 14.68% occur on their own. This clear difference suggests that disfluencies usually do not happen randomly. Instead, once a speaker becomes disfluent, they are more likely to continue making mistakes for a short time. This could happen because the speaker is thinking hard, struggling to find the right words, or feeling unsure while speaking. This finding is in line with the work of Shriberg (1994), who introduced the concept of "disfluency clusters" or "disfluency islands."
Disfluent tokens are more likely to occur in clusters than isolated.

5 Conclusion

This research provides key insights into the interplay between disfluency and code-mixing in multilingual settings. The major conclusions drawn from this study are as follows:

- Prompt-based generation proves to be a viable strategy for creating disfluent code-mixed conversational data, although it currently requires manual annotation for accuracy.
- Large Language Models (LLMs) underperform in token classification tasks compared to traditional BERT-like architectures.
- Novel metrics, such as Fluency Span Entropy (FSE), offer deeper insights into the structural distribution of disfluent tokens within utterances, beyond simple frequency-based analysis.
- The GPT-4 family of models generated a higher average %age of disfluencies than Gemini models, while the latter generated significantly higher average code-mixing index.
- Experimental evidence reaffirms that code-mixing significantly influences the emergence of disfluencies and may act as a trigger in conversational contexts.

6 Future Work

Building on the findings and limitations of this work, several directions can be explored in future research:

- Extend the **MixFluent** dataset to include other Indic language pairs to facilitate broader cross-linguistic analysis of code-mixed disfluencies.
- Explore how **Large Language Models (LLMs)** can be better utilized for disfluency correction and detection, especially in multilingual and low-resource settings.
- Design and evaluate more **innovative metrics** beyond entropy-based measures to capture the complexity and structure of disfluency and code-mixing.
- Test current and possibly additional **hypotheses** on an expanded dataset to assess their validity across different language pairs and sociolinguistic contexts.

Abstract

Dyslexia in adults remains an under-researched and under-served area, particularly in non-English-speaking contexts, despite its significant impact on personal and professional lives. This work addresses that gap by focusing on Sinhala, a low-resource language with limited tools for linguistic accessibility. We present an assistive system explicitly designed for Sinhala-speaking adults with dyslexia. The system integrates Whisper for speech-to-text conversion, SinBERT, an open-sourced fine-tuned BERT model trained for Sinhala to identify common dyslexic errors, and a combined mT5 and Mistral-based model to generate corrected text. Finally, the output is converted back to speech using gTTS, creating a complete multimodal feedback loop. Despite the challenges posed by limited Sinhala-language datasets, the system achieves 0.66 transcription accuracy and 0.7 correction accuracy with 0.65 overall system accuracy. These results demonstrate both the feasibility and effectiveness of the approach. Ultimately, this work highlights the importance of inclusive Natural Language Processing (NLP) technologies in underrepresented languages and showcases a practical step toward improving accessibility for adult dyslexic users.

1 Introduction

Dyslexia is a lifelong language-based learning disorder that affects reading fluency, spelling, and written expression despite normal intelligence and education. It is estimated to affect 5–10% of the global population (Santhiya et al., 2023). Individuals with dyslexia struggle with phonological processing, decoding, and linguistic fluency, which leads to significant obstacles in education and daily life (Roitsch and Watson, 2019). While digital tools and NLP technologies have advanced to support dyslexic users in English and other widely spoken languages, speakers of low-resource and non-Latin script languages remain underserved. Despite this, very few digital interventions exist for Sinhala-speaking adults with dyslexia.

1.1 Problem

Existing assistive technologies for dyslexia are predominantly designed for children and primarily focus on English and Latin script languages. Tools such as Grammarly, NaturalReader, and Read and Write have demonstrated success in enhancing language accessibility for dyslexic users in these languages (Patnoorkar et al., 2023). However, these solutions are not linguistically or culturally adapted to accommodate Sinhala orthography, speech phonemes, or adult-specific learning needs.

Sinhala is a low-resource language in the NLP landscape due to the scarcity of annotated corpora, pretrained language models, and text normalization tools (De Silva, 2024). This lack of infrastructure limits the development of inclusive applications. Adults with dyslexia, particularly in non-English contexts, face even greater marginalization due to inadequate educational support and a lack of appropriate digital tools (Goodman et al., 2022).

1.2 Gap

The majority of existing dyslexia-focused applications are targeted at early intervention for children. In contrast, adult users remain significantly underrepresented in both research and application development (Sadusky et al., 2021). This gap is particularly evident in non-English-speaking regions where technological adoption lags, and awareness around adult dyslexia is limited.

In Sinhala, no comprehensive NLP-driven tools currently exist that combine speech recognition, error correction, and speech synthesis tailored for

Proceedings of Recent Advances in Natural Language Processing,pages 925–933
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-106

adults. Furthermore, existing spell checkers or grammar tools fail to address cognitive and phonological errors common in dyslexic speech and writing (Rupasinghe et al., 2020). The absence of domain-specific NLP tools reinforces a cycle of exclusion for this population.

1.3 Objective

This study aims to develop a localized NLP-based assistive system for Sinhala-speaking adults with dyslexia. The system is designed as a real-time speech-driven tool to support reading, writing, and comprehension. The objective is to combine multiple NLP modules, speech-to-text (STT), error classification, grammatical error correction (GEC), and text-to-speech (TTS) into a single end-to-end application that is both accessible and linguistically appropriate for Sinhala. The system integrates modern transformer-based architectures and builds upon publicly available pre-trained models, adapted for Sinhala. This approach allows the application to function in a low-resource setting while maintaining modularity, accuracy, and real-time feedback.

The main contributions of this studies can be summarized as follows.

- Introduces the first real-time NLP-based dyslexia assistant tailored for Sinhala.
- Integrates Whisper, SinBERT, mT5, Mistral, and gTTS in a modular speech-to-text and text-to-speech pipeline.
- Demonstrates competitive accuracy (66% STT, 70% correction) using synthetically generated dyslexic Sinhala data.

Moving forward, this study will present the related work, proposed methodology, results, and discussion.

2 Related Work

2.1 Assistive tech in NLP

NLP has become central to the development of assistive tools that support individuals with reading and writing difficulties, including dyslexia. Mainstream applications such as Grammarly, Speechify, and Read and Write use grammar correction, text-to-speech, and predictive typing to provide enhanced language accessibility. These tools are largely effective for users in English-speaking environments and rely heavily on pretrained language models and rule-based feedback mechanisms (Heilman et al., 2006) (Rello and Baeza-Yates, 2013). Recent research has also explored adaptive interfaces and inclusive design principles to further improve accessibility in writing tools (Wood et al., 2018) (Al-Azawei et al., 2016).

Several dyslexia-specific applications have emerged in the form of mobile apps or browser extensions, targeting early learners and children (Al-Wabil et al., 2007). However, the vast majority are language-specific (mainly English or Western European languages) and are not adaptable to the linguistic diversity or script complexity of non-Latin languages. This issue is particularly critical in the context of Sinhala, a language with unique phonological and morphological characteristics that complicate the direct application of mainstream assistive technologies. A recent review highlights that most assistive applications for Sinhala-speaking adults remain underdeveloped, with research efforts historically focused on children or English-language tools (Perera and Sumanathilaka, 2025). The review stresses the urgent need for adult-focused, culturally adapted NLP tools and emphasizes the role of low-resource NLP pipelines in closing this accessibility gap.

Recent advances in error correction and assistive NLP demonstrate the potential of language models for supporting users with dyslexia and related linguistic impairments. For instance, (Ingólfsdóttir et al., 2023) explored byte-level grammatical error correction using synthetic and curated corpora, including writing by dyslexic individuals, in morphologically rich languages like Icelandic. Their study shows that byte-level encoding outperforms subword-based models in handling complex semantic and syntactic errors—highlighting promising directions for correction in low-resource, non-Latin-script contexts like Sinhala. Similarly, (Zhang et al., 2020) introduced a Soft-Masked BERT architecture for Chinese spelling correction. Their model enhances BERT's ability to both detect and correct errors by decoupling these tasks and employing a soft-masking mechanism between the detection and correction phases. This two-stage method outperforms baseline BERT models and provides inspiration for modular designs in error correction pipelines targeting cognitive writing impairments.

2.2 Speech-to-Text and Text-to-Speech for accessibility

Speech technologies have played an increasing role in assistive contexts, particularly through automatic speech recognition (ASR) and text-to-speech (TTS) systems. Whisper, developed by OpenAI, introduced a robust multilingual ASR system capable of transcribing speech in over 90 languages, including Sinhala (Radford et al., 2022). Whisper's ability to generalize across languages without retraining has made it a useful zero-shot model in low-resource environments. Transformer-based ASR architectures like the Transformer Transducer have further improved real-time transcription performance.

In parallel, open-source TTS tools such as gTTS (Google Text-to-Speech) have simplified the process of converting text to spoken feedback. While TTS systems are widely used in accessibility tools for visually impaired and dyslexic users, many systems lack emotion, emphasis control, or fine-tuned output in regional languages, especially Sinhala (Vats et al., 2020). Advances like FastSpeech 2 have shown that expressive and low-latency TTS is feasible even in multilingual contexts (Ren et al., 2020).

Despite the availability of Whisper and gTTS, few projects combine ASR and TTS modules into complete assistive systems, particularly for adult dyslexic users.

2.3 Error correction in low-resource NLP

Grammatical Error Correction (GEC) is a core task in NLP assistive applications, helping users with dyslexia or language learning difficulties to improve fluency and syntactic accuracy. State-of-the-art GEC systems use text-to-text models such as T5, mT5, and GECToR to identify and correct various grammatical errors (Bryant et al., 2022) (Xue et al., 2021). GECToR, in particular, adopts a tagging-based method that has proven effective with limited data (Omelianchuk et al., 2020). For truly low-resource settings, pretraining with copy-augmented architectures has also shown promise (Chau et al., 2021).

However, the performance of these models is tightly coupled with the availability of high-quality annotated dataset resources that are severely lacking for Sinhala. Some efforts have been made to develop Sinhala spell checkers or grammar correction tools using lexicon-based or statistical methods (Herath et al., 2020). Yet, these systems typically offer shallow coverage and do not handle complex dyslexic error patterns such as letter reversals, insertions, and omissions. No large-scale Sinhala GEC dataset currently exists to train supervised models, making prompt-based and few-shot learning strategies more suitable for real-world applications.

2.4 Classification models for dyslexia-like errors

Identifying the type of error is often a prerequisite to delivering more targeted correction. Pretrained classification models such as BERT and its multilingual or domain-specific variants are widely used for this purpose. In Sinhala NLP, SinBERT, a BERT-based language model fine-tuned on Sinhala corpora, has emerged as a competitive encoder for downstream tasks such as sentence classification and intent detection (Perera et al., 2022). As SinBERT is based on RoBERTa, it inherits robust pretraining optimization techniques (Liu et al., 2019) and benefits from subword-level representation crucial for agglutinative languages like Sinhala (Wu and Dredze, 2020).

However, to date, no known classification model has been applied specifically to categorize dyslexia-inspired error patterns in Sinhala text. The application of SinBERT for such a classification task represents a novel approach, enabling the system to tailor correction strategies dynamically depending on whether an error is due to substitution, omission, insertion, or reversal.

Existing systems generally focus on monolingual, text-only interfaces, are language-restricted to English, and lack the modularity or real-time capacity for integration into accessible platforms. The system proposed in this paper is distinct in the following ways:

- It is Sinhala-specific, addressing a critical accessibility gap in a low-resource language context.
- It fuses multiple transformer-based models (Whisper, SinBERT, mT5, and Mistral) in a cohesive pipeline.
- It is optimized for real-time interaction, providing instantaneous correction and playback, which is crucial for user engagement and learning feedback.

This work bridges a significant gap in assistive NLP by demonstrating how modular transformer-

based architectures can be orchestrated to support users in non-Latin, low-resource environments with a specific emphasis on adult dyslexic speakers of Sinhala.

3 System Architecture and Pipeline

The system combines speech and transformer-based models into a modular architecture optimized for low-resource Sinhala NLP. Each model was chosen for its effectiveness in real-time, low-data environments.

This section describes the end-to-end architecture of the proposed Sinhala dyslexia assistant system. It integrates multiple NLP components into a real-time pipeline optimised for speech-based interaction, error classification, text correction, and audio playback. The high level overview of the algorithm is presented in the Figure 1.

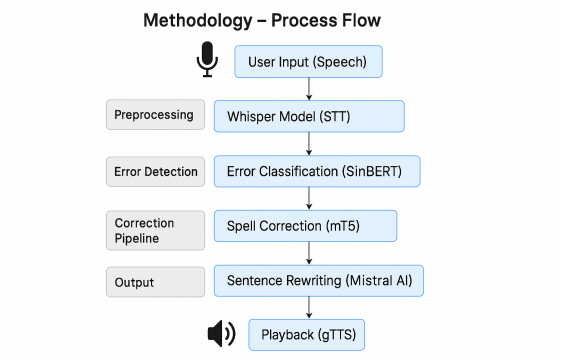

Figure 1: Methodology process flow showing the end-to-end pipeline: from speech input to playback using Whisper, SinBERT, mT5, Mistral, and gTTS.

3.1 Component Breakdown

The overall interaction between core modules is illustrated below.

3.1.1 Whisper-Based Speech-to-Text (STT)

Whisper is a multilingual encoder-decoder automatic speech recognition (ASR) model developed by OpenAI, trained on 680,000 hours of supervised data across a wide range of languages and tasks (Radford et al., 2022). It supports zero-shot transcription, meaning it can recognize speech in underrepresented languages like Sinhala without explicit fine-tuning. This is achieved through Whisper's large-scale training on diverse, noisy audio data with multilingual transcriptions. For Sinhala transcription, Whisper internally uses a language ID token to condition the decoder during inference, allowing accurate phoneme-to-grapheme mapping even in low-resource contexts. Audio input is resampled to 16 kHz and passed through a log-Mel spectrogram encoder. The model then decodes it into text using beam search and multilingual alignment layers.

In this system, Whisper runs locally with quantized weights to reduce inference latency. Preprocessing includes noise reduction and silence trimming. Despite the lack of a Sinhala-specific ASR corpus, Whisper shows strong performance on Sinhala speech due to its cross-lingual generalization and large model capacity, making it ideal for real-time dyslexia assistance. Whisper was chosen for its strong baseline performance, fast inference, and cross-lingual adaptability in low-resource contexts.

3.1.2 SinBERT Error Classification

To identify the dominant dyslexia-related error type in a transcribed sentence, the system uses SinBERT, a Sinhala-specific language model built upon the RoBERTa architecture (Perera et al., 2022). SinBERT has been extensively pre-trained on sin-cc-15M, a large and diverse monolingual corpus of Sinhala web text. This pretraining enables it to learn the morphological, syntactic, and semantic nuances of Sinhala, crucial for effective performance in low-resource language contexts.

Its application to dyslexic pattern detection is novel, enabling improved precision in downstream modules. In this system, SinBERT is fine-tuned to classify common dyslexia-inspired error patterns (e.g., substitution, omission), serving as a lightweight and efficient sentence-level classifier. Specifically, we define four primary error categories commonly observed in dyslexic Sinhala writing: substitution (e.g., ගස → කස), insertion (e.g., ගස → ගසා), omission (e.g., ගසක් → ගක්), and reversal (e.g., ගම → මග). These labels were used to annotate a synthetic training dataset for fine-tuning. SinBERT's output predicts the error class for each sentence and guides adaptive correction strategies, such as dynamic prompt formulation for mT5 or error-specific post-processing. SinBERT's architectural strength and language-aware training make it well-suited for classification tasks in Sinhala and other underrepresented scripts.

SinBERT's predicted error category is used to adaptively guide the next stage of correction. Specifically, based on the identified error type

(e.g., omission, substitution, insertion, reversal), the system dynamically generates a task-specific prompt to steer the mT5 model toward a more appropriate correction strategy. For example, if an omission is detected, the prompt may explicitly instruct the model to insert missing particles or characters. This error-aware prompting approach improves correction relevance and overall accuracy across varied dyslexic patterns.

3.1.3 Grammatical Correction: mT5 + Mistral

The correction phase combines two powerful models for error correction.

1. **Stage 1 - mT5: Structural and Grammatical Correction** (Xue et al., 2021) is used for grammatical correction using prompt-based text-to-text transformation.

   mT5, a multilingual text-to-text transformer, is used to perform core grammatical corrections such as fixing tense, agreement, syntactic errors, and structural phrasing. It operates on the transcribed text (or SinBERT-annotated text), outputting a grammatically improved sentence that maintains the intended meaning.

2. **Stage 2 — Mistral: Fluency, Style, and Idiomatic Enhancement** (Mistral AI, 2023), a decoder-only transformer, refines the mT5 output by enhancing fluency and preserving natural phrasing.

   The output from mT5 is then passed to Mistral, a decoder-only transformer designed for text generation with stylistic fluency. Mistral refines the mT5 output by enhancing natural phrasing, idiomatic expressions, and improving readability while preserving semantic integrity.

This dual-model pipeline ensures both syntactic correctness and stylistic naturalness. Figure 2 illustrates the end-to-end correction process using a real example. This dual-model pipeline ensures both syntactic correctness and stylistic quality. mT5 was selected for its ability to generalize across languages, while Mistral enhances fluency using token-level instruction-following prompts.

3.1.4 Text-to-Speech: gTTS Sinhala Playback

The final corrected sentence is converted into audio using Google Text-to-Speech (gTTS), a lightweight and accessible Python library that interfaces with Google's multilingual TTS engine. gTTS supports Sinhala phoneme synthesis, allowing the system to vocalize corrected sentences clearly an essential feature for adults with dyslexia who struggle with reading comprehension.

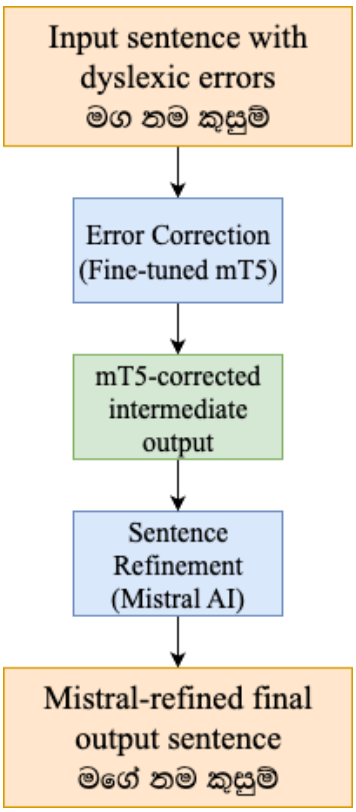

Figure 2: Example of the correction process from dyslexic input to refined output using mT5 and Mistral.

Despite its limited expressiveness (e.g., lack of pitch control, emotion, or emphasis), gTTS was selected due to its ease of integration, low resource usage, and native support for Sinhala. It allows for fast audio generation without requiring local model deployment, making it ideal for real-time applications on both web and mobile platforms. The generated audio is directly streamed to the frontend, closing the feedback loop and enabling auditory reinforcement, which is known to improve engagement and learning among dyslexic users (Vats et al., 2020). While its lack of emotional modulation and pitch control is a limitation, its quick turnaround time and native web/mobile support make it suitable for real-time feedback in this context.

3.2 Design goals

The system was designed to be inclusive, efficient, and adaptable for real-time Sinhala language assistance, particularly supporting adults with dyslexia. It aims to provide accurate feedback quickly, using lightweight models suitable for low-resource environments.

4 Evaluation Setup

4.1 Dataset

To address the lack of dyslexic Sinhala corpora, a 3000-sample parallel dataset was created using the OpenSLR SLR63 Sinhala Read Speech corpus as the base. Clean sentences were modified using rule-based transformations (substitution, insertion, omission, reversal) to simulate dyslexic errors. Each dyslexic variant was paired with its original sentence, and corresponding audio paths were preserved for STT evaluation.

Source Corpus	OpenSLR-SLR63 Sinhala Read Speech
Final Samples	3000
Error Types	Substitution, Insertion, Omission, Reversal
Split	80% Train / 20% Test (stratified)
Audio Format	FLAC, resampled to 16 kHz

Table 1: Custom Dataset Overview

4.2 Data Split

The dataset was split into training (80%) and testing (20%) subsets using stratified sampling by error type. This ensured balanced evaluation across all four error categories. Audio samples were resampled to 16 kHz for Whisper-based transcription benchmarking.

4.3 Public Access

To support transparency, reproducibility, and further research in low-resource assistive NLP, both the codebase and dataset used in this study have been made publicly available:

- **Code Repository**: The complete implementation of the proposed system, including preprocessing, model integration, and prototype interface, is accessible at: https://github.com/PeshalaPerera/sinhala-dyslexia-assistant
- **Dataset Access**: The Sinhala dyslexic error dataset (3,000 samples) used for training and evaluation is hosted on Hugging Face: https://huggingface.co/datasets/peshalaperera/sinhala-dyslexia-assistant-articulation-errors

These resources are released under open licenses to facilitate future research and development in inclusive language technologies for underrepresented languages.

4.4 Metrics used

4.4.1 BLEU and GLEU for Correction Quality

To assess the grammatical and semantic accuracy of corrected sentences, BLEU (Papineni et al., 2002) and GLEU (Wu et al., 2016) metrics were employed. BLEU captures n-gram precision, whereas GLEU incorporates both precision and recall, making it more suitable for grammatical error correction tasks with short sentence lengths.

4.4.2 Word Error Rate (WER) for STT Accuracy

WER was used to evaluate the Whisper model's transcription accuracy. It is defined as follows,

$$\mathbf{WER} = \frac{\mathbf{S} + \mathbf{D} + \mathbf{I}}{\mathbf{N}}$$

where S is the number of substitutions, D deletions, I insertions, and N is the number of words in the reference sentence. Whisper achieved an average WER of 34%, resulting in an effective accuracy of 66%, which aligns with expected performance in zero-shot Sinhala transcription (Radford et al., 2022).

4.5 Comparison with Baselines

To validate the effectiveness of the full pipeline, results were compared against three baseline models.

These results demonstrate that the combination of error classification and hybrid correction significantly outperformed both isolated correction methods and rule-based strategies. Additionally, the use of Mistral for stylistic fluency improved the readability of outputs as confirmed by human evaluators.

Model Variant	Description
Rule-Based	Uses basic word substitutions via dictionary logics.
mT5 + Mistral	Full NLP pipeline combining mT5-based correction and Mistral refinement.

Table 2: Baseline Model Variants for Correction Comparison

5 Results

This section presents the quantitative and qualitative results obtained from evaluating the system across its three core modules: speech-to-text (STT), error classification, and grammatical error correction. The evaluation demonstrates the effectiveness of the proposed model pipeline and highlights key strengths of the integrated approach.

5.1 Performance Scores

5.1.1 Speech-to-Text (STT)

The Whisper model, used in zero-shot mode for Sinhala ASR, achieved a 66% accuracy, measured by a Word Error Rate (WER) of 34% across the 600 testing audio samples. While Whisper was not fine-tuned specifically on Sinhala, its multilingual training enabled high baseline performance, even in phonetically complex utterances.

5.1.2 Correction Module

The final correction output, combining mT5 and Mistral, reached a accuracy of 70% and a GLEU score of 57% on the test set. Human evaluation also confirmed high readability and semantic preservation of the corrected outputs.

5.1.3 Overall System

The combined evaluation of all components speech-to-text transcription, error correction, yielded an overall system accuracy of 65%. This metric reflects the end-to-end performance of the full pipeline, from voice input to corrected speech output.

5.2 Table of Evaluation Metrics

Table 3 shows that the mT5-small + Mistral model gave good correction results with 70% accuracy. Whisper-Sinhala also gave good speech-to-text results with 65.9% accuracy, showing that both parts work well together in the system.

mT5-small + Mistral API	
Metric	**Score**
BLEU	0.359
GLEU	0.575
Accuracy	0.70
WER	0.322
Edit Distance	1.66

Whisper-Sinhala	
Metric	**Score**
BLEU	0.279
GLEU	0.444
Accuracy	0.659
WER	0.333
Edit Distance	0.545

Table 3: Evaluation metrics for text correction and speech transcription modules in the Sinhala Dyslexia Assistant pipeline.

5.3 Evaluation Results

Figure 3 illustrates the average performance of the text correction module across key NLP evaluation metrics.

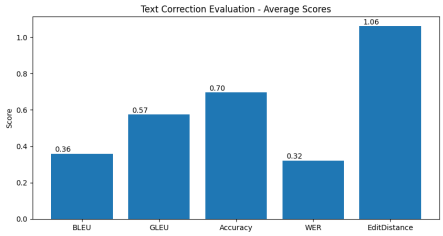

Figure 3: Text correction performance using BLEU, GLEU, Accuracy, WER, and Edit Distance averaged over 600 test samples.

5.4 Prototype Interface

To demonstrate real-world usability, a working prototype was developed using a web-based interface. This interface supports accessibility and reinforces learning through multimodal feedback, as shown in Figure 4.

5.5 Latency and Real-Time Performance

Each component was benchmarked for average inference time on a consumer-grade laptop (Intel i5, 8GB RAM).

- Whisper STT: 1.2 seconds (per 5s audio)
- SinBERT Classification: 60 ms
- mT5 + Mistral Correction: 900 ms

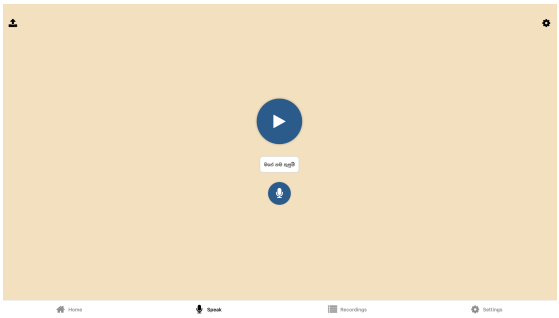

Figure 4: Prototype interface showing corrected Sinhala sentence with playback and recording controls.

- gTTS Audio Generation: 300 ms

The entire pipeline runs in 2.5 seconds per input, making it viable for real-time use in interactive applications, especially on mobile devices.

5.6 Error Analysis

Although the system demonstrates high correction accuracy, it occasionally overcorrects rare idiomatic expressions or misclassifies ambiguous omissions. Future work will address these via user feedback loops and targeted fine-tuning.

6 Discussion

The development and evaluation of the Sinhala Dyslexia Assistant system reveal several promising outcomes, along with known constraints and avenues for further advancement. The system demonstrates real-world utility by delivering corrected audio feedback in under 2.5 seconds, enabling real-time use and supporting immediate learning for dyslexic users. Its modular architecture, comprising discrete components for STT, classification, correction, and TTS offers multiple advantages, including independent upgrades, easier debugging and testing, and customisation potential for future multilingual deployments. The REST API-based modular design further enhances its ability to integrate with external learning platforms and accessibility services.

Despite these strengths, the system faces notable challenges. Sinhala lacks large-scale annotated datasets for grammatical correction or error classification, limiting the effectiveness of models trained solely on real-world data. To address this, the system relies on synthetic dyslexic errors generated from the SLR63 dataset, although these may not fully capture the diversity of real user patterns. While Whisper performs well in its current implementation, further improvements are likely with domain-specific fine-tuning. Additionally, although gTTS provides basic Sinhala TTS functionality, it lacks emotion and pitch control—features critical for adult comprehension, and currently, there are no expressive open-source Sinhala voice models available to fill this gap.

7 Conclusion and Future Work

This study introduces the first real-time NLP-based assistive system designed specifically for Sinhala-speaking adults with dyslexia, an underserved population in both language technology and accessibility research. The system features a modular pipeline incorporating Whisper for speech-to-text, SinBERT for dyslexia-related error detection, mT5 and Mistral for correction, and gTTS for text-to-speech output. Despite the challenges of working with simulated data and limited linguistic resources, the system achieved 66% speech-to-text accuracy and 61% correction accuracy, demonstrating strong performance in a low-resource setting. This work addresses a notable gap at the intersection of assistive NLP, speech technology, and Sinhala language computing, with the potential to benefit both academic research and real-world accessibility. Looking ahead, future efforts will focus on implementing personalized correction mechanisms based on user-specific error history and establishing collaborations with educational and healthcare institutions in Sri Lanka to support broader deployment and local adaptation.

Limitation

While the proposed system demonstrates promising results in a low-resource language setting, several limitations that impact its overall effectiveness and user experience remain. Firstly, the use of synthetic data for model training, although necessary due to data scarcity, may not fully capture the nuances of real-world dyslexic writing patterns. This limits the model's ability to generalize to authentic user input. Secondly, the current text-to-speech component, implemented using gTTS, lacks prosody and emotional tone, resulting in a less engaging auditory experience for users. Lastly, the system does not yet support personalization or maintain user history, which restricts its ability to adapt to individual error patterns over time.

Abstract

This paper introduces the first Transliteration disambiguation (TD) dataset for Romanized Sinhala, informally known as Singlish, developed to address the challenge of transliteration ambiguity in backwards transliteration tasks. The dataset covers 22 ambiguous Romanized Sinhala words, each mapping to two distinct Sinhala meanings, and provides 30 Romanized sentences per word: ten for each meaning individually and ten containing both meanings in context. Sentences were initially collected through web scraping and later post-processed using the Claude language model, which offers strong support for Sinhala, alongside a rule-based Romanization process to ensure linguistic quality and consistency. To demonstrate its applicability, the dataset was used to evaluate four existing back-transliteration systems, highlighting their performance in resolving context-sensitive ambiguities. Baseline evaluations confirm the dataset's effectiveness in assessing transliteration systems' ability to handle transliteration ambiguity, offering a valuable resource for advancing TD and transliteration research for Sinhala.

1 Introduction

Romanized Sinhala, often referred to as Singlish, is a widely used informal writing style among Sinhala speakers, particularly in digital communication platforms such as social media, messaging apps, and online forums (De Silva, 2019). In this form, Sinhala words are written using the Latin script, typically without standardized transliteration rules (Liwera and Ranathunga, 2020). As a result, Romanized Sinhala exhibits high variability and ambiguity, posing unique challenges for natural language processing (NLP) tasks such as machine translation, language modeling, and especially backward transliteration, the process of converting Romanized text back into native Sinhala script (Athukorala and Sumanathilaka, 2024).

One of the major challenges in ad-hoc backwards transliteration of Romanized Sinhala is transliteration ambiguity, where a single Romanized word may correspond to multiple Sinhala words with distinct meanings. These ambiguities are often context-dependent and are further complicated by the ad-hoc nature of Romanization used by Sinhala keyboard users (Perera and Sumanathilaka, 2025). Despite the significance of this problem, there has been no dedicated resource to support or evaluate systems designed to resolve such ambiguities through contextual understanding.

To address this gap, we introduce the first transliteration Disambiguation dataset for Romanized Sinhala. This dataset is specifically constructed to evaluate the ability of backward transliteration systems to resolve semantic ambiguities. It focuses on 22 Romanized Sinhala words that each map to two semantically distinct Sinhala words. For each ambiguous word, the dataset provides 30 Romanized sentences: 10 exemplifying one meaning, 10 exemplifying the alternative meaning, and 10 containing both meanings within the same sentence context. Each sentence is paired with its corresponding version in the native Sinhala script.

In addition to constructing the dataset, we evaluate its utility by benchmarking four existing back-transliteration systems using this resource. The evaluation highlights how effectively these systems handle context-sensitive transliteration ambiguities in Romanized Sinhala text. The disambiguation process used by transliteration algorithms for the word 'nthi' is presented in Figure 1.

The contributions of this work are as follows:

- Introducing the first TD dataset tailored for Romanized Sinhala, targeting sentence-level disambiguation of transliterated words.
- Describing a systematic approach to selecting ambiguous words and generating high-quality,

Proceedings of Recent Advances in Natural Language Processing,pages 934–942
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-107

context-rich sentence pairs.

- Benchmarking four existing backwards transliteration systems using the dataset, establishing baseline performance metrics.
- Publicly releasing the dataset to encourage further research in Sinhala NLP and transliteration.

In the subsequent sections, we discuss related literature, detail our approach to dataset construction, outline the evaluation framework, and conclude the paper.

2 Related Work

Transliteration ambiguity and back-transliteration have both been long-standing challenges in Natural Language Processing, particularly for low-resource languages and informal language variants like Romanized Sinhala (Singlish). While several back-transliteration systems have been developed to handle ad-hoc Romanized Sinhala input, the lack of dedicated resources to evaluate TD in such contexts has limited progress in context-sensitive transliteration.

Early work by Sumanathilaka et al. (2023) introduced a hybrid back-transliteration system that combined trigram-based statistical modelling with rule-based techniques. Their model demonstrated moderate success in handling informal and shorthand Romanized Sinhala input and was able to resolve some transliteration ambiguities due to the nature of the n-gram model. However, it was not specifically designed to perform context-aware semantic disambiguation.

More recent advances have leveraged neural language models for more accurate transliteration. Perera et al. (2025) proposed a BERT-based back-transliteration system that incorporates dictionary-based mappings, rule-based processing for out-of-vocabulary cases, and Sinhala BERT-based approach for handling transliteration ambiguity. Their system was explicitly designed to resolve cases where a single Romanized word may correspond to multiple distinct Sinhala meanings, using sentence-level context to make disambiguation decisions. Despite the progress made by these systems, they were evaluated primarily on general transliteration accuracy rather than on a benchmark explicitly targeting semantic disambiguation.

For Romanized Sinhala, Sumanathilaka et al. (2024) introduced the Swa-Bhasha dataset, which contains Romanized Sinhala–Sinhala transliteration pairs along with resources relevant to transliteration disambiguation. However, this dataset does not specifically address transliteration ambiguity in sentence-level contexts, nor does it offer a benchmark explicitly designed to evaluate context-sensitive disambiguation performance. While widely used transliteration datasets such as the Dhakshina Dataset (Roark et al., 2020) and Aksharantar (Madhani et al., 2022) exist for Indo-Aryan languages, they are limited in their support for transliteration disambiguation tasks.

Transliteration ambiguity is not unique to Sinhala; similar challenges are prevalent in other languages. In Hindi, for example, the Romanized word "sir" can correspond to either "सिर" (head) or "सर" (sir) depending on context, leading to semantic confusion in NLP applications (Kumar et al., 2025). Such issues are well-documented across Indo-Aryan languages, where word-level ambiguity in transliteration poses a significant challenge for machine learning models (Perera and Sumanathilaka, 2025). Despite their prevalence, existing resources in these languages largely focus on phonetic accuracy rather than sentence-level disambiguation, leaving a gap this work aims to address.

The transliteration disambiguation Singlish dataset proposed in this paper fills this gap by introducing the first resource specifically designed to evaluate how well transliteration systems handle semantic ambiguity in Romanized Sinhala. It draws inspiration from prior TD efforts and recent adversarial testing work, while addressing the unique challenges of ad-hoc Romanization and low-resource language settings.

3 Dataset Construction

This section describes the development of the TD dataset for Romanized Sinhala, including the motivation behind its creation, the methodology used to select ambiguous words, the sentence generation process, and the final dataset structure.

3.1 Motivation and Objectives

The primary goal of the dataset is to facilitate the evaluation of backward transliteration systems on their ability to resolve transliteration ambiguities in Romanized Sinhala, particularly in real-world, context-dependent usage. Romanized Sinhala words often lack one-to-one mappings with their native Sinhala counterparts, and users fre-

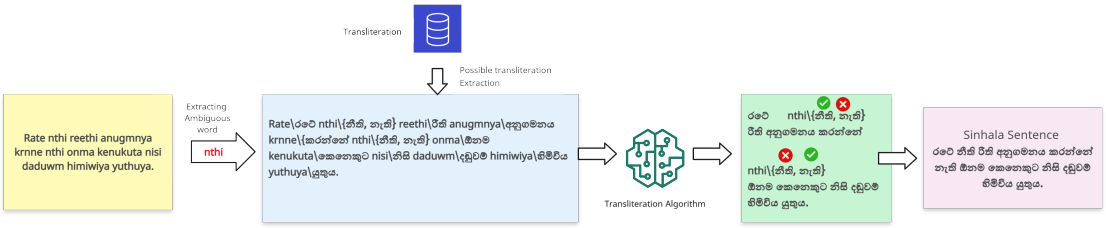

Figure 1: Transliteration Disambiguation process for the word *nthi*

quently write them in inconsistent, ad-hoc forms (Herath and Sumanathilaka, 2024). This results in situations where the same Romanized word can represent multiple Sinhala words with different meanings.

To address this, the dataset focuses on binary transliteration ambiguity—cases where a single Romanized form corresponds to two distinct Sinhala words. The dataset provides diverse contextual examples that force systems to rely on sentence-level semantics rather than surface forms alone.

3.2 Ambiguous Word Selection

The selection of ambiguous Romanized Sinhala words was carried out using an existing Romanized Sinhala–Sinhala dictionary compiled by Sumanathilaka et al. (2024). This dictionary provides mappings from ad-hoc Romanized Sinhala forms to their corresponding Sinhala script equivalents, reflecting the informal and varied nature of Romanization commonly seen in real-world usage.

To construct a high-quality TD dataset, the following filtering steps were applied to identify ambiguous Romanized words that map to exactly two distinct Sinhala meanings:

1. Spelling Verification: Sinhala entries in the dictionary were first checked for spelling correctness using the Madura Dictionary API (Madura-API, 2020). Entries with misspelled or invalid Sinhala words were removed to ensure linguistic accuracy.

2. Semantic Filtering: Some Romanized Sinhala words map to multiple Sinhala forms with similar or synonymous meanings (e.g., "ape" maps to "අපි", "අපේ", and "අප"). Such cases were excluded to ensure that each ambiguous word in the dataset corresponds to semantically distinct Sinhala meanings. Filtering was done using a verified lemma list (Fernando and Dias, 2021) and manual inspection for semantic contrast.

3. Binary Ambiguity Focus: Only Romanized Sinhala words with exactly two distinct, non-overlapping meanings were selected. Words with more than two meanings were discarded.

4. Frequency-Based Selection: To prioritize relevance and practicality, a Sinhala word frequency list (Fernando and Dias, 2021) was used. From the dictionary, Romanized Sinhala words were retained only if both of their corresponding Sinhala meanings appeared in the top 3,000 most frequent Sinhala words. This ensured that the selected words represent terms commonly encountered in everyday Sinhala usage.

After applying these filtering steps, a final list of 22 ambiguous Romanized Sinhala words was selected, as shown in Table 1. These words serve as the foundation for sentence generation in the dataset, each forming a minimal TD unit used to evaluate transliteration systems in ambiguous contexts.

3.3 Sentence Generation Process

For each ambiguous Romanized Sinhala word, 30 unique sentences were created to reflect different semantic contexts:

- 10 sentences each for one Sinhala ambiguous word
- 10 sentences containing both Sinhala ambiguous words within the same sentence

This three-fold structure supports evaluation of both isolated and compound contextual disambiguation in backward transliteration systems.

The sentence generation process was carried out in two main stages:

1. Sinhala Sentence Collection and Dual-Sense Generation: The process began by collecting

Singlish Word	Sinhala Meanings
nthi	නීති, නැති
yam	යම්, යාම
wsi	වාසි, වැසි
ud	උඩ, උදේ
thora	තොර, තෝරා
sthana	සටහන, ස්ථාන
samaya	සමය, සාමය
smawa	සමාව, සීමාව
ras	රස, රැස්
phra	පහර, පොහොර
oya	ඔය, ඔයා
nyk	නායක, නොයෙක්
mta	මට, මීට
maru	මරු, මාරු
mahath	මහත්, මහතා
es	ඇස, එසේ
eda	ඇද, එදා
dnna	දන්නා, දෙන්නා
deka	දැක, දෙක
bala	බල, බාල
badu	බඩු, බදු
adi	අඩි, ආදි

Table 1: Ambiguous Singlish words and their Sinhala meanings

Sinhala sentences from a publicly available dataset (Hettiarachchi et al., 2024). These sentences were selected such that each one clearly reflected one of the two Sinhala meanings associated with a target Romanized word. These collected sentences served as high-quality, real-world examples of single-sense usage.

To generate sentences that included both Sinhala meanings in a coherent context, the collected single-sense sentences were then passed as prompts to the Claude 3.0 Sonnet language model. This model was selected due to its strong support for the Sinhala language, making it well-suited for generating contextually appropriate and semantically accurate sentences (Jayakody and Dias, 2024). By presenting examples of each meaning, the model was guided to understand the distinct semantics of both Sinhala words and construct new sentences where both meanings naturally co-occur. This ensured that dual-sense sentences were not only grammatically valid but also semantically rich. The following prompt was used to generate dual-sense Sinhala sentences, each containing both ambiguous meanings in context. The generation was performed using a temperature of 0.2 and a maximum output length of 5000 tokens.

"A back-transliteration system has been developed to convert Romanized Sinhala text into native Sinhala script. This system is designed to accurately handle Romanized Sinhala words that correspond to multiple Sinhala meanings by leveraging contextual information. To evaluate this transliteration system, a test dataset must be created. The goal is to generate Sinhala sentences for specific ambiguous words. The ambiguous Romanized Sinhala word in focus is [singlish-word], which can correspond to either [sinhala-word1] or [sinhala-word2] in Sinhala.

Below are example sentences that include only one of the ambiguous meanings: Sentences containing [sinhala-word1]: [sentences1]

Sentences containing [sinhala-word2]: [sentences2]

Based on the examples above, generate 10 Sinhala sentences that include both [sinhala-word1] and [sinhala-word2] within the same sentence. Ensure that each sentence provides sufficient contextual information to help evaluate how well the transliteration system resolves ambiguity based on context."

2. Romanization Process: Once the full set of Sinhala sentences was finalized, they were converted into Romanized Sinhala using a rule-based transliteration system. For consistency, each target ambiguous word was manually replaced with its corresponding adhoc Romanized form from the Romanized Sinhala–Sinhala dictionary (Sumanathilaka et al., 2024). The remainder of the sentence was transliterated using consistent phonetic rules to preserve meaning and structure.

3. Manual Verification: Each created record was manually evaluated with the help of three linguists who are experts in the language and transliteration techniques. This process ensured that the dataset entries were accurately

Sentence Type	Example Sentence (Singlish / Sinhala)
Single Sense (වාසි)	**Singlish:** yamkisi pirisakata meya wsi sahagatha wana bawata owuhu chodana kara sitiyaha. **Sinhala:** යම්කිසි පිරිසකට මෙය වාසි සහගත වන බවට ඔවුහු චෝදනා කර සිටියහ.
Single Sense (වැසි)	**Singlish:** wsi jalaya ho apa jalaya gala yana pahath thenaka linda nokapanna. **Sinhala:** වැසි ජලය හෝ අප ජලය ගලා යන පහත් තැනක ළිඳ නොකපන්න.
Dual Sense	**Singlish:** wsi kalayedee gowithen katayuthuwalin uparima wsi laba geneemata naweena thakshanaya yoda gatha hekiya. **Sinhala:** වැසි කාලයේදී ගොවිතැන් කටයුතුවලින් උපරිම වාසි ලබා ගැනීමට නවීන තාක්ෂණය යොදා ගත හැකිය.

Table 2: Example sentences for the ambiguous word *wsi* from the TD dataset

selected and transliterated. Any incorrect sentences were revisited and corrected by the principal author of this work.

This combination of real-world scraping, controlled generation, and systematic Romanization ensures that the dataset is both linguistically diverse and realistically representative of how transliteration ambiguity appears in Romanized Sinhala.

3.4 Dataset Statistics and Format

The final TD dataset comprises a total of 660 sentence pairs, each consisting of a Romanized Sinhala sentence and its corresponding version in native Sinhala script. The dataset covers 22 ambiguous Romanized Sinhala words, each associated with two semantically distinct Sinhala meanings.

To facilitate targeted evaluation of backward transliteration systems, the dataset is organized into two distinct test sets:

- Test Set 1 – Single-Sense Sentences: This set contains Romanized Sinhala sentences where the ambiguous word is used in a context corresponding to only one of its possible Sinhala meanings. It is intended to evaluate a system's ability to infer the correct meaning based on sentence-level context.

- Test Set 2 – Dual-Sense Sentences: This set contains sentences where both Sinhala meanings of the ambiguous word appear within the same sentence. It is designed to assess the system's capacity to disambiguate and correctly transliterate each instance of the word in a more complex, semantically dense context.

Table 2 shows example sentences for the word 'wsi' from the TD dataset.

4 Evaluation Setup

To demonstrate the applicability of the proposed TD dataset, we conducted a comparative evaluation using four existing backward transliteration systems. The evaluation focuses on how effectively each system handles transliteration ambiguity in Romanized Sinhala backward transliteration process.

4.1 Systems Evaluated

To assess the effectiveness of the proposed TD dataset, we evaluated four existing backward transliteration systems for Romanized Sinhala. These systems vary in design, ranging from early rule-based approaches to more recent neural and hybrid models, offering a comprehensive performance comparison across different transliteration paradigms. Below are the systems used in the evaluation:

- Perera et al. (2025): This system adopts a hybrid approach that integrates an ad-hoc transliteration dictionary, rule-based mechanisms, and a BERT-based neural model specifically designed to handle transliteration ambiguities in Romanized Sinhala. The system was evaluated using two configurations: a base Sinhala BERT model [1] and a fine-tuned variant trained on a Sinhala text corpus [2]. This architecture is optimized for context-aware disambiguation during backward transliteration.

[1] https://huggingface.co/Ransaka/sinhala-bert-medium-v2/tree/main

[2] https://huggingface.co/Sameera827/Sinhala-BERT-MLM/tree/main

System	Model	Set	F1 Score
Perera et al. (2025)	Sinhala BERT	1	0.9601
		2	0.9209
	Fine-tuned BERT	1	0.9626
		2	0.9389
Dharmasiri and Sumanathilaka (2024)	GRU + Rule-based	1	0.3422
		2	0.3312
Sumanathilaka et al. (2023)	N-gram + Rule-based	1	0.3603
		2	0.3773
Real-Time Unicode Converter (2006)	Rule-based	1	0.3430
		2	0.3333

Table 3: Evaluation results of back-transliterators on the TD Dataset

- Dharmasiri and Sumanathilaka (2024): This approach introduces a hybrid model combining neural machine translation (NMT) and rule-based processing. A Gated Recurrent Unit (GRU)-based model forms the core of the neural component.

- Sumanathilaka et al. (2023): The proposed system uses a hybrid approach to transliterate Romanized Sinhala into native Sinhala script. It combines a trigram-based statistical model, a rule-based transliterator using defined phonetic patterns, and a Trie-based suggestion mechanism. The process begins with statistical prediction, followed by rule-based correction for ambiguous cases, and ends with word suggestions from a trained Trie structure.

- Real-Time Unicode Converter (2006): An early and widely-used rule-based transliteration system, this tool performs direct conversion from Romanized Sinhala to Sinhala Unicode script. It operates without contextual awareness or machine learning, relying solely on static character mappings, and serves as a baseline in this evaluation.

4.2 Evaluation Procedure

Each of the four back-transliteration systems was evaluated on the full set of Romanized Sinhala sentences from the TD dataset. The goal of the evaluation is to determine whether each system can accurately resolve the intended Sinhala meaning of an ambiguous Romanized word based on its context.

For each sentence, the system's output was compared against the reference Sinhala sentence provided in the dataset. A prediction is considered correct if the transliterated form of the ambiguous word matches the expected Sinhala meaning in the reference.

In the case of dual-sense sentences, where both Sinhala meanings are present in the same sentence, the system is expected to produce both correct forms within their appropriate context. Predictions involving Sinhala words outside the two predefined meanings for a given ambiguous word were treated as errors and excluded from F1-score calculation.

4.3 Evaluation Metrics

The evaluation uses the F1 score as the primary metric, balancing both precision and recall to measure transliteration accuracy. This metric reflects how effectively each system identifies the correct Sinhala meaning of an ambiguous Romanized word within a given context. F1 scores are reported separately for the two test sets:

- Test Set 1 measures the system's ability to perform accurate sense selection in straightforward contexts.

- Test Set 2 assesses the system's capacity to handle complex disambiguation involving dual interpretations of the same Romanized form.

By reporting performance across both single-sense and dual-sense scenarios, the evaluation highlights the strengths and limitations of each system in resolving transliteration ambiguity through backward transliteration.

System	Model	Output Sinhala Words
Perera et al. (2025)	Sinhala BERT	අඩි, අඩි
	Fine-tuned BERT	ආදි, අඩි
Dharmasiri and Sumanathilaka (2024)	GRU + Rule-based	අඩි, අඩි
Sumanathilaka et al. (2023)	N-gram + Rule-based	ආදි, ආදී
Real-Time Unicode Converter (2006)	Rule-based	අදි, අදි

Table 4: Model predictions for the ambiguous word `adi` in a dual-sense sentence. The expected Sinhala outputs are ආදි, අඩි.

5 Results and Analysis

This section presents the results of evaluating four back-transliteration systems on the TD dataset using F1 scores. Each system was tested on both Test Set 1 (sentences with a single intended Sinhala meaning) and Test Set 2 (sentences containing both meanings of the ambiguous word). The results are summarized in Table 3.

5.1 Observations

The best overall perf ormance was achieved by the fine-tuned BERT model from Perera et al. (2025), which obtained F1 scores of 0.9626 on Test Set 1 and 0.9389 on Test Set 2. The base Sinhala BERT also performed well, though slightly behind the fine-tuned model, showing that domain-specific tuning improves generalization.

Systems by Dharmasiri and Sumanathilaka (2024) and Sumanathilaka et al. (2023) showed significantly lower performance, with F1 scores ranging from approximately 0.33 to 0.37. While both incorporate hybrid approaches, the reliance on shallow statistical or sequence-based models may limit their effectiveness in resolving fine-grained contextual distinctions.

Real-Time Unicode Converter (2006), a purely rule-based system, performed comparably to the other traditional models, confirming the limitations of non-contextual transliteration in ambiguous settings.

5.2 Analysis

The results affirm the importance of context-aware neural approaches in back-transliteration tasks that involve semantic ambiguity. Systems using deep language models, particularly those trained or fine-tuned on relevant linguistic data, demonstrate a superior ability to resolve word sense based on sentence context. In contrast, systems that lack contextual modelling, whether rule-based or statistical, struggle to differentiate meanings, especially in Test Set 2, where both senses appear in a single sentence.

To better understand how back-transliteration systems handle context-sensitive ambiguity, we analyzed a dual-sense sentence from the TD dataset that includes the ambiguous Romanized Sinhala word “adi”. Table 4 compares each system’s transliteration output for both instances of the word, alongside the expected Sinhala forms. The correct outputs are ආදි (ancient) and අඩි (feet), in that order, as indicated by the sentence’s semantic context. The sentence used for this analysis is as follows: “adi kalaye sita ... gewathu wata adi hathak pamana usa ...”

These findings validate the usefulness of the proposed TD dataset as a benchmark for evaluating transliteration models’ ability to disambiguate based on context. They also underscore the gap between modern neural methods and earlier rule-based or statistical systems in this specific task.

5.3 General Transliteration Evaluation

While the core objective of this study is to evaluate transliteration disambiguation in ambiguous, context-sensitive settings using the proposed TD dataset, we also present results from existing back-transliteration systems on the IndoNLP dataset (Sumanathilaka et al., 2025) for complementary analysis. IndoNLP is a general-purpose benchmark that evaluates transliteration quality using surface-level metrics such as Word Error Rate (WER), Character Error Rate (CER), and BLEU score.

These results are not directly comparable to our TD dataset evaluations, as the two datasets serve different purposes. TD focuses on semantic disam-

System	Model	Set	WER	CER	BLEU

Table 5: Evaluation results of back-transliterators on the IndoNLP dataset

biguation of Romanized Sinhala words with multiple meanings, which IndoNLP does not capture. Instead, IndoNLP provides a useful baseline for assessing phonetic fidelity and overall transliteration correctness, independent of semantic ambiguity.

Table 5 reports the performance of several systems on IndoNLP. While systems such as the fine-tuned BERT model achieve high BLEU and low error rates, these results do not imply strong performance on ambiguity resolution. In fact, our TD evaluation highlights that systems performing well on IndoNLP may still struggle in disambiguating meaning in real-world sentences.

In conclusion, while traditional transliteration datasets remain useful for baseline assessment, they are not sufficient for fully evaluating the performance of back-transliteration systems. This reinforces the unique value of the TD dataset, which introduces ambiguity-focused challenges not addressed in existing Sinhala transliteration benchmarks.

6 Conclusion

This paper presented the first transliteration disambiguation dataset for Romanized Sinhala, aimed at evaluating backward transliteration systems in the presence of transliteration ambiguity. The dataset includes 22 ambiguous Romanized words, each with context-rich sentence pairs reflecting both Sinhala meanings. Evaluation across four transliteration systems showed that context-aware neural models significantly outperform rule-based and statistical methods in disambiguating meanings based on context. These results highlight the importance of contextual modeling for accurate back-transliteration. The dataset offers a valuable benchmark for Sinhala NLP and supports future work on improving transliteration. The TD dataset is publicly available at: https://github.com/Sameera2001Perera/Romanized-Sinhala-Transliteration-Disambiguation-Dataset

Limitations

The dataset is limited in its scope to binary lexical ambiguities, where each Romanized Sinhala word is associated with two semantically distinct Sinhala meanings. In reality, many Romanized Sinhala words—especially those written in ad-hoc, informal styles—can correspond to more than two Sinhala meanings or exhibit many-to-many mappings, where a single Sinhala word can be represented by multiple Romanized forms. To ensure semantic clarity, annotation feasibility, and high linguistic quality, we restricted the dataset to one-to-two mappings, using a filtering mechanism based on semantic distinction and frequency to retain only the most commonly used and semantically clear pairs. This design simplifies evaluation and focuses on clearly distinguishable ambiguities. Additionally, the dataset includes 22 ambiguous Romanized words, selected based on their frequency and relevance. While this provides a solid basis for evaluating context-sensitive disambiguation, the limited vocabulary size restricts the dataset's overall coverage. Expanding to include multi-sense ambiguity and many-to-many mappings remains a key direction for future work.

Abstract

The unstoppable proliferation of news driven by the rise of digital media has intensified the challenge of news verification. Natural Language Processing (NLP) offers solutions, primarily through content and context analysis. Recognizing the vital role of linguistic analysis, this paper presents a multilingual study of linguistic markers for automated deceptive disinformation detection across English, Spanish, and Bulgarian. We compiled datasets in these languages to extract and analyze both general and specific linguistic markers. We then performed feature selection using the *SelectKBest* algorithm, applying it to various classification models with different combinations of general and specific linguistic markers. The results show that Logistic Regression and Support Vector Machine classification models achieved F1-scores above 0.8 for English and Spanish. For Bulgarian, Random Forest yielded the best results with an F1-score of 0.73. While these markers demonstrate potential for transferability to other languages, results may vary due to inherent linguistic characteristics. This necessitates further experimentation, especially in low-resource languages like Bulgarian. These findings highlight the significant potential of our dataset and linguistic markers for multilingual deceptive news detection.

1 Introduction

Today's digital age has democratized information creation and dissemination, but it has also unleashed an unprecedented flow of content, blurring the lines between verified and deceptive information. The immense volume of online information and its impact in society make critical to develop robust automated systems for disinformation detection. This has prompted disinformation research from various perspectives, ranging from psychological analyses of deception to computational linguistics.

Specifically for written disinformation, a linguistic approach to analyzing news content offers a powerful solution, enabling quicker review by eliminating the need for factual data verification. This is precisely where Natural Language Processing (NLP) becomes a crucial tool for automating news processing. To effectively detect deceptive elements in written news, NLP must account for the fact that, although news is expected to objectively report factual events, linguistic studies as the one conducted by Tuchman (1998) demonstrate the inherent subjectivity of news reporting and how a communicator's psychological state is reflected in their linguistic choices. As Bajtin (1982) asserts, "every utterance (...) in any sphere of discursive communication, is individual and therefore may reflect the individuality of the speaker (or writer), i.e. it may possess an individual style".

Drawing on this, we address the subtask of deception detection in disinformation, as presented by Saquete et al. (2020), specifically through the lens of linguistic analysis. We explore the hypothesis that deceptive disinformation contains a unique linguistic "imprint" of deception, revealing how a sender's psychological state is manifested in their language. As defined by Yuan et al. (2024) "deceptive disinformation is intended to deliberately mislead readers or cause adverse effects". To this end, we perform a multilingual analysis. We first collect established general linguistic markers, then investigate how both these and our proposed subjective markers are represented in English, Spanish, and Bulgarian discourse, acknowledging their distinct linguistic families.

Building on this, our research focuses on three main objectives. First, we introduce a set of linguistic markers derived from part-of-speech (POS) tagging along with our designed subjectivity markers and readability indexes (Section 4.1). Second, we create a multilingual dataset for testing

Proceedings of Recent Advances in Natural Language Processing,pages 943–952
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-108

these markers in automated deceptive disinformation detection across Spanish, Bulgarian, and English (Section 3). This multilingual approach is vital for robust analysis and identifying potentially language-independent markers, addressing the English-centric bias in current research. Finally, we conduct a detailed analysis of these linguistic markers' discriminant potential for deception detection in disinformation (Section 4), presenting our findings (Section 5), conclusions (Section 6), and identifying limitations (Section 6).

2 Background

Researches on disinformation detection primarily employ two strategies: context-based and content-based analysis (Zhang and Ghorbani, 2020). Contextual approaches examine the platforms where disinformation originates and spreads, focusing on users' sharing habits. However, content-based strategies divide into fact verification and language analysis approaches. Automated fact-checking often compares online information with reliable, verified news, as highlighted by Kotonya and Toni (2020). Yet, the considerable volume of daily information complicates up-to-date fact-checking. Consequently, some researchers focus on language analysis to detect deceptive news by its writing style. Our research specifically addresses linguistic deception in disinformation, involving examining different types of linguistic markers to identify manipulative language within news discourse.

Most prior research on linguistic markers and dataset development for deception detection in disinformation has focused on English. To start with relevant previous studies on linguistic analysis on news classification, DePaulo et al. (2003) stands out as a meta-analysis incorporating over 150 markers for deception detection. As one of the pioneering studies in the field, it has been widely cited for its significant impact. On this line, Gravanis et al. (2019), in addition to a review of relevant prior studies, they propose a disinformation detection model that primarily leverages content analysis implemented with machine learning algorithms. Furthermore, they introduce "UNBiased," a novel corpus constructed to reduce bias in this classification task. On this research they mainly focus on three sets of linguistic markers proposed by Burgoon et al. (2003), Newman et al. (2003) and Zhou et al. (2004)). In the review made by Zhang and Ghorbani (2020), authors mention some of the most relevant datasets for disinformation detection in English. However, the lack of labeled datasets is the bottleneck for building an effective detection system for online misleading information (Shu et al., 2017), specially for languages other than English.

In Spanish, the analysis of linguistic markers for detecting linguistic deceptiveness has been approached through various linguistic proposals. Almela (2021) examined written statements and found that deceptive communication can result in more concise responses due to cognitive effort. They also identified a higher prominence of second and third-person pronouns as a key indicator of non-immediacy in deceptive statements, whereas Tretiakov et al. (2022) used deep learning techniques and showed strong capabilities for identifying false claims in Spanish, with certain models achieving an F1-score of 0.88. In Portuguese, Santos et al. (2020), in which they conduct an analysis of different types of linguistic markers for the detection of disinformation, including cohesion measures and applying readability indices. In their study they demonstrate that, in Portuguese, the set of markers they analyze can classify deceptive news with an accuracy exceeding 0.90.

In the context of Bulgarian, Temnikova et al. (2023) contributed by identifying 18 categories of linguistic markers for disinformation detection, also based on Zhou et al. (2004). They also developed a foundational dataset for disinformation research on Bulgarian social media. This study serves as a crucial reference for our multilingual analysis of disinformation.

Aligning with our multilingual approach, Yuan et al. (Yuan and Liu, 2024) quantitatively analyzed various features using clustering experiments to identify commonalities across English, Russian, and Chinese. Their findings revealed shared morphological markers but no consistent patterns in syntactic features or readability metrics. While an important step in multilingual disinformation study, their work's depth is limited by not applying complex markers or developing a classifier model.. Also focused on multilingual analysis, Krasitskii et al. (2024) approach on the applicability of Hungarian and Finnish resources for multilingual sentiment analysis. They use a Bulgarian dataset to evaluate pre-trained models like BERT (Bidirectional Encoder Representations from Transformers) and its multilingual variant, mBERT, achieving an accuracy between 0.8 and 0.9. Besides, Apostol et al.

(2025) concentrate their research on analyzing multiword discourse markers across languages. They make use of TED Talk transcripts in 10 languages, including Bulgarian, annotating fragments to train two cross-language machine learning models based on FastText (Bojanowski et al., 2017) and XLM-RoBERTa-Large (Conneau et al., 2019). While they reach an accuracy of up to 0.93 in Lithuanian, this drops to 0.5 for Bulgarian.

3 Datasets

To analyze the discriminatory capacity of the linguistic markers proposed in Section 4.1, we collected true and false news articles to construct datasets with similar characteristics in Spanish and Bulgarian. For English, we utilized a pre-existing dataset. Every dataset is balanced in real-deceptive news, as seen in Table 1. As previously noted by Antici et al. (2021) "the limited number of sentences in our corpus is symptomatic of our fine-grained annotation methodology, which is oriented to the collection of high-quality data". Additionally, to prevent biased results, we selected news articles with a similar word count, averaging 480-520 words in each dataset. This way, we construct a multilingual dataset comprising 480 texts in total.

Dataset	Real News	Deceptive News	Total
Spanish	80	80	**160**
Bulgarian	80	80	**160**
English	80	80	**160**
Grand Total	**240**	**240**	**480**

Table 1: Distribution of news by language and category.

3.1 Spanish dataset

To compile our Spanish news dataset, we referenced existing datasets by Bonet-Jover et al. (2023) and Posadas-Durán et al. (2019). Bonet-Jover et al. (2023) annotated news articles using *RUN-AS*, a fine-grained scheme based on journalistic techniques that classifies news and its essential parts as reliable or unreliable. In contrast, Posadas-Durán et al. (2019) labeled news as true if evidence suggested publication on reliable sites, and fake if sourced from websites specializing in deceptive content detection. This disparity highlights a lack of standardization in annotation methods within the field of disinformation deception detection. We began by extracting false news items and then search for parallel verified reports on the same events. This ensured that the differences between genuine and deceptive news examples in our corpus lay primarily in writing style, rather than topic.

Additionally, we gathered random news articles to create a balanced, topic-independent dataset comprising 50% true and 50% deceptive news, totaling 160 articles. As a result, the Spanish dataset is half comprised of existing datasets and half hand-picked.

3.2 Bulgarian dataset

To compile our Bulgarian dataset, we selected a sample from the *Bulgarian disinformation and Click-bait Corpus*, a collection of online news articles gathered over a defined period from distinct sources. These sources span a range of domains, including politics, interesting facts, and tips&tricks. The corpus was annotated by journalism students and is publicly available on HuggingFace[1]. It has also been used in prior research (Karadzhov et al., 2017).

First, we removed duplicate articles, which are common in the corpus due to the frequent reposting of identical or slightly modified content across multiple outlets. Duplicates were identified through title similarity. From the de-duplicated corpus, we sampled 80 legitimate (real) and 80 deceptive (fake) news articles, ensuring an equal class distribution to prevent bias in model training and evaluation.

To enhance diversity and reduce overfitting to specific temporal or topical patterns, the sampled articles were selected from different time periods and a broad range of sources.

3.3 English dataset

We incorporate an English-language dataset, which serves as a reference point due to the predominance of English in the development of linguistic analysis tools and their typically higher performance in this language. The dataset is derived from PolitiFact++ and GossipCop++ (Su et al., 2023), enhanced versions of the widely used FakeNewsNet corpus (Shu et al., 2018). These datasets combine human-written news articles sourced from the fact-checking websites PolitiFact [2] and GossipCop [3], along with automatically generated news content. For our purposes, we use only the human-written articles. From each dataset, we sample an equal

[1] https://huggingface.co/datasets/community-datasets/clickbait_news_bg

[2] https://www.politifact.com/

[3] https://www.gossipcop.com/

number of real and disinformation items, specifically, 40 real and 40 fake articles from PolitiFact++, and 40 real and 40 fake articles from GossipCop++, resulting in a balanced dataset across both sources (in total 80 real and 80 fake). This English dataset, previously used in similar tasks, serves as a baseline for our distinct analytical methodology.

4 Methodology

To approach the task of deceptive disinformation detection using linguistic markers we developed two pipelines: (a) feature extraction pipeline and (b) machine learning pipeline that integrates handcrafted linguistic markers and automatically extracted textual features. The goal is to assess the impact of linguistic markers on classification performance across multiple model architectures.

4.1 Feature extraction

To avoid biases associated with label imbalance, we constructed three perfectly balanced binary datasets, ensuring that each label comprises exactly 50% of the data. Every dataset consists of news articles labeled as either real or deceptive, with an equal number of instances per class.

Data cleaning Prior to feature extraction and model training, we performed manual text cleaning to remove noisy, non-content text that may bias feature extraction or downstream classification. In particular, we excluded messages that were advertisements and filtered out extraneous material often appended or interleaved in news content. This included unrelated news titles inserted mid-article, trailing promotional content, and templated strings such as *"Share on ..."*, *"Follow us on ..."*, and other similar directives. These steps were conducted outside the feature extraction and learning pipelines to ensure clean, semantically coherent input.

Linguistic markers To ensure consistency across experimental conditions, we conduct the extraction of handcrafted linguistic markers independently of the classification, as explained in Figure 1. Each marker is counted and normalized by the total number of tokens to accurately represent its frequency.

Given an input article, we first apply syntactic analysis using the Stanza NLP pipeline to segment the text into sentences and tokens. From these annotations, we compute basic textual statistics such as word count, sentence count, average word length,

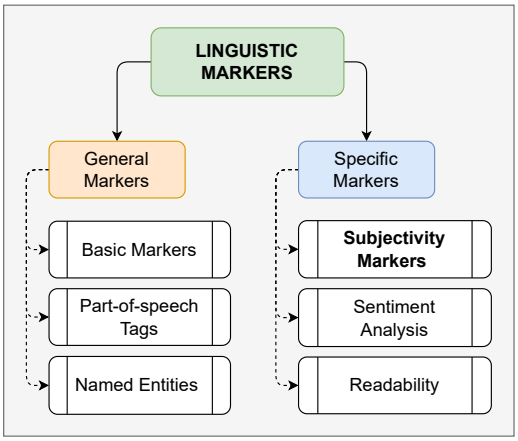

Figure 1: Diagram illustrating the types of markers used in our study.

average sentence length, and the number of words exceeding six characters. Lexical diversity is measured through the count of unique words, while expressive punctuation is quantified via counts of question marks, exclamation points, commas, quotation marks, ellipses, and periods.

We further extracted POS tag distributions and morphological features (e.g. mood, tense, person, voice) from the parsed tokens. Specific pronoun types, such as demonstrative, indefinite, and emphatic, were also counted due to their relevance in subjectivity and deception detection. Named entity recognition (NER) was used to quantify the number and type of named entities (PERSON, LOC, ORG), reflecting potential anchoring to real-world references. The total number of markers used is referenced in Table 2.

We also extracted higher-level stylistic categories inspired by prior linguistic research, such as Doubt, Certainty, Specificity, Non-specificity, Distancing, Participation, Expressivity and Polarity, described in Table 3.

Sentiment The sentiment detection for English and Spanish is carried out using the *pysentimiento*[4] library (Pérez et al., 2024), which uses transformer-based models (BETO for Spanish and BERT-base for English). These models output one of three sentiment labels: positive, negative, or neutral, along with their associated probabilities.

Due to the absence of dedicated sentiment analysis models for Bulgarian in the pysentimiento li-

brary, we relied on a pre-trained emotion detection model for Bulgarian, as proposed by Temnikova et al. (2024). This model predicts fine-grained emotion categories, which are already grouped into coarse-grained sentiment classes—positive, negative, and neutral. In our work, we adopt these predefined groupings to map the model's output to the corresponding sentiment labels.

Subjective Marker	Linguistic Elements
Doubt	*Questions, Conditional mood, Subjunctive mood, Interrogative pronouns.*
Certainty	*Imperative mood, Future tense.*
Specificity	*Named Entities, Demonstrative pronouns.*
Non-specificity	*Indefinite pronouns, Generalizing terms.*
Distancing	*Third person, Passive voice.*
Participation	*First and second person, Imperative mood.*
Expressivity	*Exclamation mark, Emphatic pronouns.*

Table 3: Specific markers classification and linguistic elements conveying each type of subjective information.

Readability To assess textual readability, we extract the Flesch Reading Ease (FRE) score and the Brunet Index across all languages. For English and Spanish, we use the corresponding language-specific implementations provided by the `textstat` library[5]. Specifically, for Spanish, `textstat` applies the version of the FRE formula adapted by Fernández Huerta (1959), which is designed to reflect the syntactic and phonological structure of Spanish texts. The formula is defined as:

$$\text{FRE}_{\text{FH}} = 206.84 - (0.60 \times \text{SL}) - (1.02 \times \text{WL}),$$

where SL is the average sentence length (number of words per sentence) and WL is the average number of syllables per 100 words. Additionally, we extract the average number of syllables per word (ASW) for Spanish to capture lexical complexity.

For Bulgarian, where `textstat` does not support Flesch-based metrics, we employ an adaptation of the Flesch formula originally developed for Russian (Gordejeva et al., 2022), due to typological proximity:

$$\text{FRE}_{\text{bg}} = 208.7 - (2.6 \times \text{ASL}) - (39.2 \times \text{ASW}),$$

where ASL is the average sentence length and ASW is the average syllables per word, computed using regular expressions tailored to Bulgarian vowel clusters.

Lastly, we compute the Brunet Index (Brunet et al., 1978) across all languages to estimate lexical richness:

$$\text{BI} = W^{V^{-0.165}},$$

where W is the total number of words and V the number of unique word types.

4.2 Experimental Setup

To investigate the impact of feature representations and model architectures on document classification performance, we implemented a modular pipeline architecture for each model, composed of three core components: preprocessing, feature selection, and classification. All components were implemented using the Pipeline utility from the *scikit-learn* library [6] to ensure consistency and reproducibility across all experiments.

Preprocessing and Feature Integration Each input instance consisted of a text document accompanied by a set of linguistic markers. Textual inputs were vectorized using either a bag-of-words (BoW) representation or a TF-IDF-based encoding, each limited to the 300 most frequent unigrams and bigrams. These textual representations were combined with two sets of linguistic markers, general and language-specific, in various combinations.

[5] https://github.com/shivam5992/textstat

[6] https://scikit-learn.org/stable/index.html

To ensure consistent scaling, all numeric features were standardized using z-score normalization. Text and non-text features were processed in parallel, enabling seamless integration of heterogeneous data modalities within a unified pipeline.

Feature Selection Following preprocessing, we applied univariate feature selection using mutual information to identify the most predictive features for the target label. The *SelectKBest* algorithm was employed to retain the top $k \in \{50, 100, 150\}$ features based on their mutual dependence with the class label. This step serves to reduce dimensionality and promote interpretability, which is particularly important when analyzing which lexical, syntactic, or discourse-level cues are most salient for the classification task.

Classification Models We selected four machine learning algorithms for evaluation: **Logistic Regression** with L1 regularization, a **Support Vector Machine** with a linear kernel, **Random Forest**, and **Gaussian Naive Bayes**.

These models were selected to (a) ensure robust performance on small datasets and (b) encompass a diverse range of learning paradigms, spanning linear to non-linear and probabilistic to ensemble-based approaches.

Hyperparameter Tuning and Model Selection Hyperparameters were optimized using grid search over a predefined parameter space, with performance evaluated via 5-fold stratified cross-validation. Stratification was used to preserve the class distribution across folds, mitigating the risk of performance inflation due to class imbalance. The hyperparameter grid included the regularization strength (C) for Logistic Regression and SVM, the number of estimators and tree depth for Random Forest, and the number of selected features (k) for all models.

Model selection is based on macro-averaged F1 score, appropriate for the balanced binary classification setup. We conduct the model evaluation separately for every language.

5 Results and Discussion

Our experimental results across English, Spanish, and Bulgarian support the hypothesis that deceptive news exhibits a measurable linguistic signature, which can be effectively captured using both general and language-specific linguistic markers. This section analyzes the predictive power of these features, their cross-linguistic consistency, and how model performance varies depending on the combination of features and classifiers. We evaluated the following configurations: (1) Model with Bag-of-Words (BoW), (2) Model with BoW and general features, (3) Model with BoW and language-specific features, (4) Model with BoW, general, and language-specific features, (5) Model with TF-IDF, (6) Model with TF-IDF and general features, (7) Model with TF-IDF and language-specific features, (8) Model with TF-IDF, general, and language-specific features, and (9) Model with general and language-specific features.

Table 4 reports only the results for the best-performing model–feature combinations for each language.[7]

5.1 Linguistic Features: Cross-Linguistic Consistency

The analysis revealed a strong cross-linguistic overlap in the types of features most predictive for deception detection. Specifically, basic text statistics such as number of words, and morphosyntactic features including POS tags (number of nouns, number of verbs, `pos_aux`), tense (past tense), mood (`mood_ind`), voice (passive voice), and person (`person_3`) were consistently selected across languages and models. These features provide structural cues that are not domain-specific and are robust across language families.

In addition, Named Entity (NE) markers such as number of NE, number of NE-PERSON , and number of NE-ORG were frequently selected, reflecting the relevance of referential specificity in deceptive texts. Features capturing readability (e.g. Brunet's Index, Flesch reading ease) and punctuation usage also appeared recurrently, suggesting that deceptive news often diverges in textual complexity and stylistic choices.

Most notably, a suite of subjective features — especially `DIST` (Distancing), `PART` (Participation), `ESPE` (Specificity), and `DUD` (Doubt) — were highly predictive and consistently selected across all three languages when included. These features appear to encode the affective and cognitive stance of the writer, which aligns with psychological theo-

[7]The Appendix provides a comprehensive overview of the selected features for the model configurations in Table 4: https://drive.google.com/file/d/1U7qwieIZ3xqul0lOgcyGpLPNPVKpFlZi/view?usp=sharing

Model	Feature Combination	Accuracy	Precision	Recall	F1-score

Table 4: The table presents the results for the best-performing model–feature combinations across all languages.

ries of deception suggesting greater cognitive load and emotional distancing in deceptive narratives.

5.2 Impact of Feature Combinations

The integration of general and specific linguistic markers frequently improved model performance, though not universally. In English, ogistic Regression with TF-IDF combined with general and specific markers reached the highest F1-score (0.88), a substantial improvement over using TF-IDF alone (F1 = 0.78). Similarly, in Spanish, SVM with BoW + general or BoW + specific achieved top F1-scores (0.82), indicating the complementary value of the linguistic markers.

However, in some cases, combinations including specific markers were highly effective. For instance, in Bulgarian, Random Forest with BoW + specific markers outperformed combinations involving general markers (F1 = 0.73 vs. 0.71), suggesting that specific stylistic cues alone can provide strong discriminatory power in lower-resource or morphologically rich languages.

The choice between BoW and TF-IDF also played a critical role and was language- and model-dependent. While TF-IDF generally provided stronger performance in English, BoW proved more effective in several Spanish and Bulgarian configurations, particularly when combined with linguistic markers. These variations underscore the importance of tailoring the feature representation to language-specific properties and the classifier used.

5.3 Impact of Classifier Choice

No single classifier consistently outperformed others across all languages. Logistic Regression was the top performer in English, especially when paired with TF-IDF and full marker sets (F1 = 0.88), and showed robust performance in Spanish (F1 = 0.78). SVM achieved the highest scores in Spanish (F1 = 0.82) and competitive results in the other languages. Random Forest excelled in Bulgarian (F1 = 0.73), suggesting that ensemble methods may be particularly effective in morphologically complex languages where interaction effects between features are more intricate.

Naive Bayes, while rarely achieving the top F1 scores, demonstrated high recall in English (Recall = 0.94 with BoW + general + specific), indicating its potential utility in settings where minimizing false negatives (i.e., undetected disinformation) is critical.

5.4 Language-Specific Variability

Overall performance varied significantly across the three languages, with the highest scores achieved in English (F1 up to 0.88), followed by Spanish (up to 0.82), and Bulgarian (up to 0.73). This gradient may reflect differences in NLP tool maturity, corpus size and quality, and typological features of the languages. English, as a high-resource language, benefits from more refined preprocessing tools and

well-defined annotation schemes, which likely contribute to the stronger performance. Bulgarian, in contrast, showed more variability in optimal model/feature pairings, highlighting the need for specialized handling in low- or medium-resource language contexts.

5.5 Implications

These findings confirm the cross-linguistic validity of deception markers, especially those tied to syntax, referentiality, and subjectivity. Yet, effective detection still requires language-specific adaptation in feature design and model choice. While linguistic features offer interpretability and robustness across domains, their utility is maximized when tailored to the target language and task.

Overall, the results validate the study's premise: *deceptive disinformation can be reliably identified through a combination of general linguistic cues and subjectivity markers*. When modeled appropriately, these markers remain effective across diverse languages, providing a strong basis for developing multilingual and cross-lingual detection systems.

6 Conclusions and future work

This work presents a multilingual analysis of general and specific linguistic markers for the automatic detection of deception in disinformation across English, Bulgarian, and Spanish. Our approach is based on the premise that news inherently contains a subjective component, enabling us to develop a set of specific subjectivity-related markers. Analyzing both general and these specific markers, which incorporate subtasks like sentiment analysis and readability indexes, allows us to first characterize the linguistic style of news and then train an optimized model for automated deception detection in disinformation. The use of traditional machine learning methods is justified by the need to ensure the transparency and explainability of the process, which allows for necessary adjustments at any point during the experimentation along with resource optimization. We build a Silver Standard Corpus (SSC) for deceptive news detection, which is an initial, single-expert annotated dataset, recognizing that while it provides a high-accuracy baseline, it will need further multi-expert refinement to become a Gold Standard Corpus (GSC), as discussed in the study by Chowdhury and Lavelli (2011). Additionally, we present a new dataset for Bulgarian and Spanish, contributing to the study of deception in disinformation in languages other than English. Our multilingual approach allows for a comparative analysis of deceptive linguistic characteristics across these three distinct language families.

In the future, we intend to explore the proposed specific markers more deeply to build a robust methodology for analyzing deceptive language through the lens of subjectivity. Additionally, we'll focus on enhancing the semi-automatic annotation of specific markers, potentially using large language models to gain deeper semantic and pragmatic insights. Furthermore, our ultimate goal is to enlarge the presented datasets, either by collecting more news articles or by applying data augmentation techniques. This expansion aims to create a robust, gold-standard resource for disinformation analysis and to incorporate new languages, promoting wider collaboration in deception detection research. Consequently, enlarging the dataset would enable the use of transformers, allowing for a direct comparison with the performance of traditional machine learning techniques.

Limitations

Despite the promising results, our study has several limitations. First, the relatively small size of the datasets, comprising only 160 examples per dataset, may restrict the generalization of our findings and limit the robustness of the trained models. Second, our approach relies heavily on external NLP libraries such as Stanza for preprocessing and feature extraction. Any inaccuracies or inconsistencies within these tools could propagate errors into our pipelines and affect overall performance. Lastly, the datasets used in this study differ in their labeling methodologies: some categorize news articles based on the credibility of their sources, while others depend on comprehensive fact-checking annotations. This discrepancy poses challenges for direct comparison and may introduce noise into the classification task, potentially impacting model evaluation and cross-dataset applicability.

Abstract

Effective document reranking is essential for improving search relevance across diverse applications. While Large Language Models (LLMs) excel at reranking due to their deep semantic understanding and reasoning, their high computational cost makes them impractical for many real-world deployments. Fine-tuning smaller, task-specific models is a more efficient alternative but typically depends on scarce, manually labeled data. To overcome this, we propose a novel pipeline that eliminates the need for human-labeled query-document pairs. Our method uses LLMs to generate synthetic queries from domain-specific corpora and employs an LLM-based classifier to label positive and hard-negative pairs. This synthetic dataset is then used to fine-tune a smaller transformer model with contrastive learning using Localized Contrastive Estimation (LCE) loss. Experiments on the MedQuAD dataset show that our approach significantly boosts in-domain performance and generalizes well to out-of-domain tasks. By using LLMs for data generation and supervision rather than inference, we reduce computational costs while maintaining strong reranking capabilities.

1 Introduction

Rerankers are essential in modern Information Retrieval (IR) systems, especially in Retrieval-Augmented Generation (RAG) pipelines, where initial retrieval often includes false positives. These irrelevant results can harm downstream tasks. Rerankers address this by refining search results—filtering out non-relevant documents and reordering based on relevance, thereby improving precision and system effectiveness.

Reranking methods range from traditional statistical models like BM25 to neural and transformer-based models. Transformer-based rerankers, such as those built on BERT, outperform others by capturing complex query-document relationships. Large Language Models (LLMs) can also be used for reranking due to their deep contextual understanding, but come with challenges like high latency and computational cost. In contrast, dedicated reranking models strike a better balance between efficiency and accuracy for real-time use.

However, rerankers require domain-specific fine-tuning to perform well. This typically needs labeled query-document pairs, which are often unavailable in specialized domains. To overcome this, we propose a query-less fine-tuning approach for cross-encoders using only a domain-specific text corpus. Our method uses an LLM to generate synthetic queries and identify relevant documents, creating synthetically labeled data for fine-tuning. This allows cross-encoders to approach LLM-level reranking performance without needing manually labeled data.

Our framework combines contrastive learning, knowledge distillation, and fine-tuning to adapt rerankers efficiently. By removing the need for curated relevance labels, it enables high-quality domain-specific reranking and improves retrieval precision where traditional rerankers fall short.

2 Related Work

As a task, reranking involves refining the initial list of retrieved documents by reordering them based on a model's relevance scores. The progress of

*These authors contributed equally to this work.

Proceedings of Recent Advances in Natural Language Processing,pages 953–961
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-109

deep learning has significantly advanced reranking approaches by enabling models to learn complex patterns in language. Recent work has demonstrated that transformer-based models, particularly the Bidirectional Encoder Representations from Transformers (BERT) model and its derivatives, offer state-of-the-art performance in reranking and other natural language processing tasks due to their strong contextual representation capabilities (Devlin et al., 2018).

2.1 Transformer-Based Models

The introduction of transformer-based models has transformed the field of reranking. Models like BERT, RoBERTa (Zhuang et al., 2021), and T5 (Raffel et al., 2020) significantly outperform traditional IR models, especially when fine-tuned for reranking tasks.

Nogueira and Cho (2019) first illustrate the potential of BERT for reranking in the context of passage retrieval, demonstrating substantial gains over prior methods on benchmarks like MS MARCO (Nguyen et al., 2016).

Recent studies have also explored fine-tuning T5 for reranking, with Nogueira et al. (2020b) training it as a sequence-to-sequence model to generate relevance labels as "target words". The logits of these words are then interpreted as relevance probabilities, enabling ranking. Moreover, Zhuang et al. (2023b) adapt T5 with ranking-specific losses to directly compute ranking scores for query-document pairs. In particular, they explore pairwise and listwise ranking losses, achieving significant performance improvement across different datasets. Their results show that models fine-tuned with listwise ranking loss performed well in zero-shot scenarios on out-domain data, compared to models trained with classification losses.

2.2 Fine-Tuning Techniques

Fine-tuning techniques play a significant role in adapting pre-trained transformers for reranking tasks. Moreira et al. (2024) present an ablation study analyzing reranking model performance based on model size, loss functions, and self-attention mechanisms.

The dominant approach to reranking involves task-specific fine-tuning, typically using pointwise ranking objectives to directly optimize relevance scoring for tasks like search, fact-checking, and question answering. This enhances the model's ability to detect subtle relevance differences. Data augmentation—such as generating synthetic query-document pairs—further improves model robustness and generalization.

Contrastive learning in pair with knowledge distillation has the potential to make rerankers more efficient. While most such existing approaches focus on training or fine-tuning retriever models, these techniques can similarly be used for training or fine-tuning a ranking model. Gao et al. (2021b) apply contrastive learning to maximize the distinction between relevant and irrelevant documents, resulting in more discriminative embeddings. Knowledge distillation, as shown in Sanh et al. (2019), enables large models to be distilled into smaller, more efficient models without significant loss in accuracy, supporting deployment in resource-limited environments. This idea of distilling a larger and more capable model into a smaller and more specialized model can also be used in terms of ranking models.

2.3 Contrastive Learning

Contrastive learning has gained attention as an effective technique for training retrieval and ranking models, particularly bi-encoders and cross-encoders, by helping the model learn more discriminative representations of relevant versus irrelevant documents. In training bi-encoders, the model achieves this by bringing relevant query-document pairs closer in the embedding space while distancing irrelevant ones. In training cross-encoders, the model scores each query-document pair independently by cross-referencing information between them, rather than encoding them separately.

A popular contrastive learning objective for reranking models is the InfoNCE (Information Noise-Contrastive Estimation) loss, introduced in van den Oord et al. (2019). InfoNCE operates by maximizing the similarity between positive pairs (e.g., a query and its relevant document) while minimizing similarity to a set of negative examples (e.g., irrelevant documents). Using a categorical cross-entropy approach, InfoNCE identifies the correct positive sample among unrelated noise samples by probabilistically contrasting positives with negatives, encouraging the model to capture relevance distinctions. A key component of this process is negative sampling, where "hard negatives" or random negatives are used to focus the model on distinguishing relevance patterns, reducing overfitting to positive pairs alone.

In reranking tasks, using InfoNCE helps the

cross-encoder learn relevance by focusing on both relevant and non-relevant document distinctions, which improves its ranking capability on diverse data. This approach allows reranking models to generalize effectively, even on challenging IR datasets, by embedding distinctions between relevant and irrelevant documents directly into the scoring function.

2.4 Knowledge Distillation

The Gecko approach demonstrates how knowledge distillation from large language models (LLMs) can effectively train a compact, high-performing embedding model (Lee et al., 2024). Gecko achieves competitive retrieval results through a two-step distillation process: first, generating synthetic data with an LLM, and then refining it by relabeling it with hard negatives. This distillation concept can also be applied to fine-tune ranking models, improving their efficiency and performance.

2.5 Relevance Scoring

To assess and rank retrieved passages effectively, various relevance scoring techniques are proposed nowadays.

Query Likelihood (Sachan et al., 2023a) propose a ranking approach that improves passage retrieval in open-question answering by scoring relevance through a zero-shot question generation model. This approach uses a pre-trained language model to compute the likelihood of the input question given each retrieved passage, providing cross-attention without task-specific training and improving performance on unsupervised and supervised retrieval models alike. Additionally, recent advancements such as the ART approach introduced in Sachan et al. (2023b), enable effective unsupervised training of dense passage retrieval models by leveraging an innovative document-retrieval autoencoding scheme, which computes the probability of reconstructing the original question from retrieved evidence documents. This enables robust question and document encoding without labeled data, contributing to state-of-the-art results across multiple QA benchmarks.

Relevance Classification Zhuang et al. (2023a) propose an approach that improves zero-shot LLM-based ranking by incorporating fine-grained relevance labels in prompts, which enables more accurate differentiation between documents with varying levels of relevance to a query. This approach significantly improves ranking performance by reducing noise and bias, as shown on multiple BEIR datasets.

Cross-Attention Relevance Meanwhile, (Izacard and Grave, 2022) present an approach that uses cross-attention scores from a reader model as relevance signals to train retrievers for tasks like question answering. By aggregating these attention scores across layers and heads, the approach generates synthetic labels for passage relevance without requiring annotated query-document pairs, achieving state-of-the-art results.

2.6 LLMs as Rerankers

LLMs have been adapted for document ranking using pointwise, pairwise, listwise, and setwise approaches, each balancing effectiveness and efficiency differently.

Pointwise ranking scores each passage independently, making it computationally efficient but less effective in capturing relative relevance. Pairwise ranking compares passages in pairs to improve ranking precision, but it requires multiple comparisons, increasing computational cost. Listwise ranking processes multiple passages in a single prompt, enhancing comparative relevance but consuming more tokens. Recent work, such as Listwise Reranker with a Large Language Model (LRL) (Ma et al., 2023), shows that zero-shot listwise ranking can outperform pointwise methods by directly generating reordered document lists without task-specific training.

Setwise ranking (Zhuang et al., 2024) presents a set of passages in a single prompt but focuses on selecting only the most relevant one, reducing LLM inferences while maintaining ranking effectiveness. This approach balances efficiency and effectiveness by combining the computational advantages of pointwise ranking with the comparative insights of pairwise and listwise methods. It achieves strong performance in zero-shot ranking tasks with lower token usage, making it a promising alternative for LLM-based document ranking.

3 Methodology

In this section, we describe the methodology for fine-tuning a cross-encoder on synthetic data for ranking tasks. We first explain our approach to generating queries from a corpus of passages using an LLM and detail the dataset preparation process.

Then, we outline the training and evaluation procedures.

3.1 Training Objective

Preliminaries Since we use a cross-encoder, we evaluate the relevance of a document d to a query q by passing both through an encoder-only model simultaneously and computing the relevance score as defined in Equation 1, where the symbol ; represents concatenation, cls extracts the vector representation of the [CLS] token and $W_s \in \mathbb{R}^{d_{\text{model}} \times 1}$ is a weight matrix.

$$\text{score}(q, d) = \text{cls}(\text{BERT}(\text{CLS}; q_{1:n}; \text{SEP}; d_{1:m}))W_s \quad (1)$$

Contrastive Loss To fine-tune the cross-encoder, we use the InfoNCE contrastive loss function, which is effective for optimizing relevance-based comparisons between positive and negative documents, as discussed in Section 2.3. This loss function enables the model to process both positive and negative documents for each query simultaneously, improving its ability to distinguish between them, particularly in the presence of challenging hard-negative examples.

The loss function encourages the model to assign higher similarity scores to relevant documents (d^+) than to non-relevant ones (d^-). Formally, treating $\text{score}(q, d)$ as a deep similarity metric, the loss for a single query q is defined by Equation 2, where $G_q = \{d_q^+\} \cup \{d_q^-\}_{i=1}^m$ represents the set of documents for the query, consisting of one positive document d_q^+ and m hard-negative documents d_q^-.

$$\mathcal{L}_q \triangleq -\log \frac{e^{\text{score}(q, d_q^+)}}{\sum_{d \in G_q} e^{\text{score}(q,d)}} \quad (2)$$

In our implementation, we use the *Localized Contrastive Estimation (LCE)* approach proposed by Gao et al. (Gao et al., 2021a) to perform batch updates over a set of queries Q. This method prioritizes hard negatives—documents that are both difficult and contextually relevant—over randomly selected negatives. These hard negatives are typically drawn from a pool of candidates ranked highly by a baseline retriever or another relevance scoring model. The batch-averaged loss is computed as defined in Equation 3.

$$\mathcal{L}_{LCE} \triangleq \frac{1}{|Q|} \sum_{q \in Q} -\log \frac{e^{score(q, d_q^+)}}{\sum_{d \in G_q} e^{score(q,d)}} \quad (3)$$

In the context of RAG systems, the retriever module constructs the candidate pool G_q, which includes both relevant and hard-negative documents. Fine-tuning the ranking model with this loss improves its ability to distinguish between relevant and non-relevant documents among the top candidates retrieved in the initial stage.

3.2 Synthetic Data Generation

To effectively optimize the Localized Contrastive Estimation (LCE) loss, the training dataset must be structured as $(q, d_q^+, \{d_q^-\}_{i=1}^m)$, where q is a query, d_q^+ is a positive document, and $\{d_q^-\}$ represents a set of hard-negative documents.

In scenarios where labeled query-document pairs are unavailable, such as in many RAG systems with pre-indexed documents, we address this challenge by generating the necessary data. Specifically, we: (1) generate synthetic user queries q, and (2) mine positive and hard-negative documents for each synthetic query. We illustrate the steps involved in creating the synthetic dataset in Figure 1.

3.2.1 Generating Synthetic Queries

For a randomly selected document from the available corpus, denoted as d_{seed}, and a carefully designed prompt $\mathcal{P}$ tailored to the dataset's domain, we generate a synthetic query as: $q = \text{LLM}(\mathcal{P}, d_{\text{seed}})$. Since large language models (LLMs) perform well with few-shot prompting, we manually create several example queries from randomly selected documents in the corpus and incorporate them into $\mathcal{P}$ to improve query generation quality.

3.2.2 Mining Positive and Negative Documents

To construct the set of one positive and m hard-negative documents for a synthetically generated query, we perform a search with q on the existing document corpus using a bi-encoder approach (Humeau et al., 2019). This search produces a preliminary set D_q of top candidate documents for q. We then apply a classification function to determine which of these candidates are positive (d^+) and which are negative (d^-), forming the set G_q required for our loss function.

Rather than relying on human annotators to obtain ground-truth labels for positive and negative documents from D_q, we use a more powerful model as a teacher for the target ranking model. Specifically, we leverage an LLM-based relevance

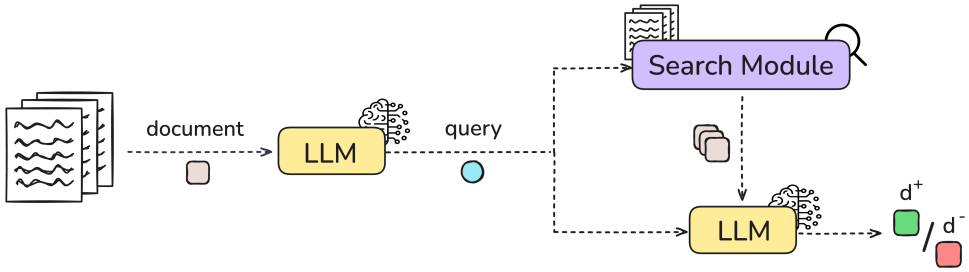

Figure 1: Synthetic Dataset Generation Workflow: (i) Generate a synthetic query q from a given text corpus using a large language model (LLM). (ii) Retrieve the most relevant documents D_q for q from the corpus using a bi-encoder model. (iii) Evaluate each query-document pair in D_q using an LLM-based relevance scoring function f_{RC}. (iv) Classify documents as relevant (positive) or irrelevant (negative) based on a predefined relevance threshold.

classification function to rerank the documents, assigning ground-truth labels in an automated manner.

Relevance Classification Following the work of Nogueira et al. (2020a) and Zhuang et al. (2023a), we use an LLM to estimate the probability of a document d being relevant by computing the log-likelihood of possible relevance labels given the query. Specifically, for a given query q and document d, the LLM takes q and d as input and is prompted to respond with either "Yes" or "No" to indicate relevance. For each pair (q, d), where $d \in D_q$, we compute the following score as defined in Equation 4. This score corresponds to the probability assigned to the "Yes" token, computed by applying a softmax over the logits for the "Yes" and "No" tokens. The documents are then reranked based on this probability, with higher scores indicating greater relevance to the query.

$$f_{RC}(q,d) \triangleq \frac{e^{LLM(Yes|\mathcal{P},q,d)}}{e^{LLM(Yes|\mathcal{P},q,d)} + e^{LLM(No|\mathcal{P},q,d)}} \tag{4}$$

Mining Single Positive Passage When generating synthetic queries using a large language model (LLM), it is reasonable to assume that the source document d_{seed}, from which the query q is derived, is the most relevant document to q. While this assumption generally holds, Lee et al. (2024) found that in approximately 15% of cases, a different document is actually more relevant to q than d_{seed}. This occurs because d_{seed} is sampled independently from the corpus without considering broader contextual relationships between documents.

To address this issue, we redefine the positive document d_q^+ for q as in Equation 5, rather than simply setting $d_q^+ = d_{\text{seed}}$, which may lead to suboptimal training.

$$d_q^+ = \underset{d \in D_q}{\text{argmax}}\, f_{RC}(q,d) \tag{5}$$

Mining Multiple Negative Passages Selecting negative documents from the candidate set D_q is more complex than identifying the positive document, as it involves selecting multiple documents rather than just one. We define the set of negative documents as those with a relevance classification score below a specified threshold as defined in Equation 6.

$$\{d_q^-\} = \{d \in D_q \mid f_{RC}(q,d) < t\} \tag{6}$$

The threshold t must be chosen carefully, as it can vary based on factors such as the LLM used, the prompt $\mathcal{P}$, and dataset characteristics. In this study, we empirically determined that setting $t = 0.5$ produced effective results.

3.2.3 Application in RAG Systems

In retrieval-augmented generation (RAG) systems, the initial retriever accesses the knowledge base through an indexed vector store. Synthetic queries are generated from documents in this store, and the retriever retrieves a candidate set D_q. The LLM-based relevance classification function then refines these candidates by identifying hard negatives and positives. This process enables the construction of a dataset suitable for fine-tuning the ranking model using a contrastive loss function.

3.3 Evaluation Metrics

To evaluate the ranking model before and after fine-tuning, we use standard ranking metrics that assess its ability to retrieve and rank relevant documents effectively (Croft et al., 2010). $Precision@k$ measures the proportion of relevant documents among the top k retrieved results, indicating how well the

model filters out irrelevant documents. Mean Average Precision ($MAP@k$) computes the mean of precision values at the ranks of relevant documents, rewarding models that rank relevant documents higher. Mean Reciprocal Rank ($MRR@k$) evaluates how early the first relevant document appears in the ranked list, with higher scores indicating better retrieval performance. Normalized Discounted Cumulative Gain ($nDCG@k$) quantifies ranking quality by considering both document relevance and position, applying a logarithmic discount.

4 Experimental Setup and Evaluation

4.1 Generating Synthetic Queries

To evaluate the proposed pipeline, we construct a synthetic dataset based on the MedQuAD dataset (Ben Abacha and Demner-Fushman, 2019) by generating queries (q) from its passages. MedQuAD consists of 47457 question-answer pairs extracted from 12 reputable NIH-affiliated websites, covering 37 question types across key medical topics such as treatments, diagnoses, side effects, diseases, medications, and medical tests.

To simulate a RAG setting—where only an indexed collection of documents is available—we treat the answers as standalone passages. Additionally, to accommodate the 512-token input limit of our target reranker, passages exceeding this length are excluded, and a random subset of 1000 answers is selected for synthetic query construction.

We use few-shot learning to guide the query generation process, ensuring the queries aligned with the domain of the passages. The few-shot examples used in the prompt are selected from the same domain, enabling the model to produce contextually relevant queries.

4.2 Mining Positive and Negative Passages

To identify positive and negative passages for each synthetically generated query q, we use a bi-encoder model, specifically the `intfloat/multilingual-e5-large` transformer. Both q and the passages are embedded using mean pooling to generate dense vector representations. We then retrieve the top 30 candidate passages from MedQuAD for each query using cosine similarity, forming the candidate set D_q.

We then perform relevance classification for each query-passage pair (q, d), where $d \in D_q$, using a large language model, specifically a 4-bit GPTQ quantized version of Llama-3.1 with 70 billion parameters. Each passage is classified as positive or negative based on its relevance score, with a threshold of 0.5 used for classification.

4.3 Dataset Preparation

After constructing the triplets $(q, \{d_q^+\}, \{d_q^-\})$, we divide the dataset into training and test sets, with the test set containing 500 samples. To assess whether the dataset size is sufficient for fine-tuning, we conduct experiments using different subsets of the training data. The results of these experiments are presented in the following sections.

The synthetic dataset represents in-domain data, aligning with the target domain where improved reranking performance is needed. To evaluate the model's generalizability and mitigate potential performance degradation on general knowledge tasks, a phenomenon known as *catastrophic forgetting*, we include an out-domain dataset in our evaluation. This dataset consists of a subset of the MS MARCO dataset, and we monitor performance metrics on this dataset throughout the experiments.

4.4 Fine-Tuning the Model

To assess the effectiveness of our approach, we fine-tune the `BAAI/bge-reranker-v2-m3` model on different subsets of the synthetic dataset. The training subsets range from 100 to 1000 entries, with each subset being a strict superset of the previous one. This setup allows for a progressive evaluation of how dataset size impacts performance. The evaluation set remains the same across all experiments to ensure result comparability.

For training, we use a batch size of 2 with gradient accumulation over 2 steps, yielding an effective batch size of 4. Each query q is paired with one positive and four negative passages during training. In evaluation, we increase the number of positive and negative passages to better reflect real-world scenarios while ensuring that the total number of passages per query do not exceed 30 to maintain computational efficiency.

4.5 Results and Analysis

We present the results of our experiments in Figure 2 and Figure 3, showing that increasing the training dataset size improves model performance on the in-domain dataset. However, these improvements tend to plateau as the dataset size grows.

The highest $nDCG@10$ score of 0.952 is achieved using a dataset of 800 entries after the

Domain	Metric	Base	Dataset Length 100	200	300	400	500	600	700	800	900	1000
In	MAP	0.911	0.915	0.919	0.933	0.938	0.938	0.939	0.942	0.944	0.940	**0.946**
	MRR	0.990	0.995	0.993	0.994	0.993	0.993	**0.996**	0.993	0.996	0.995	0.994
	NDCG	0.905	0.913	0.922	0.945	0.949	0.945	0.950	0.950	**0.952**	0.946	0.951
Out	MAP	0.575	0.579	**0.582**	0.577	0.579	0.573	0.579	0.581	0.570	0.576	0.573
	MRR	0.575	0.579	**0.582**	0.577	0.579	0.573	0.579	0.581	0.570	0.576	0.573
	NDCG	0.603	0.609	**0.613**	0.607	0.609	0.603	0.611	0.611	0.602	0.608	0.606

Table 1: Performance metrics (@10) across dataset lengths ranging from 100 to 1000, in increments of 100, for in-domain (synthetic) and out-domain (subset of MS MARCO) data, evaluated after the first epoch of training.

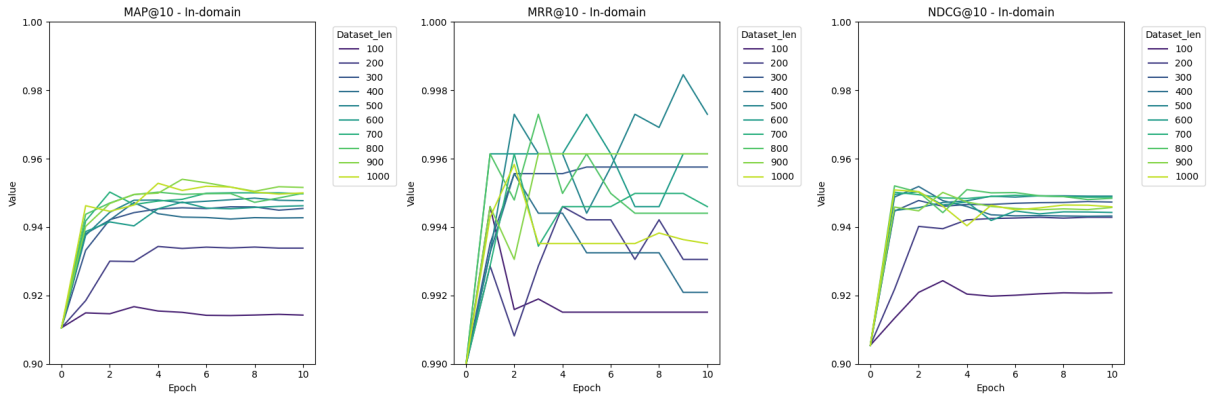

Figure 2: Mean Average Precision (MAP@10), Mean Reciprocal Rank (MRR@10), and Normalized Discounted Cumulative Gain ($NDCG$@10) for the in-domain dataset, computed per epoch up to the 10th epoch. The training dataset sizes range from 100 to 1000 in increments of 100. These results demonstrate the effect of dataset size on model performance throughout the fine-tuning process.

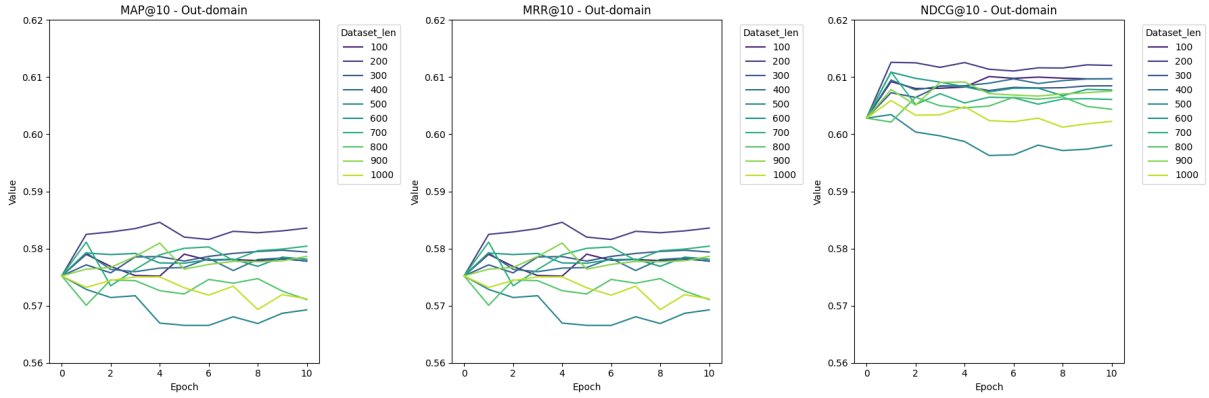

Figure 3: Mean Average Precision (MAP@10), Mean Reciprocal Rank (MRR@10), and Normalized Discounted Cumulative Gain ($NDCG$@10) for the out-domain dataset, evaluated per epoch up to the 10th epoch. The training dataset sizes vary from 100 to 1000 in increments of 100, providing insights into the model's generalization performance during fine-tuning.

first epoch, marking a good improvement from the initial score of 0.905. The best MAP@10 score is observed with a dataset of 900 entries, while the highest MRR@10 score is achieved with 500 entries. The performance metrics across dataset lengths in increments of 100 elements, for both in-domain and out-domain data evaluated after the first epoch of training, are provided in table 1. The

Figure 4: Impact of training dataset size on performance metrics for both in-domain and out-of-domain datasets. The figure shows the average performance improvement (before vs. after training), computed across all epochs, with standard deviations representing variability.

selection of the first epoch for reporting the evaluation metrics was informed by knee plot analysis, which indicated that for most dataset lengths, the most substantial performance gains occurred early in the training process.

Fine-tuning on the in-domain dataset does not result in any significant degradation in the model's performance on the out-domain dataset. In some cases, performance metrics on the out-domain dataset showed slight improvements, though these changes are not substantial (as shown in Table 1).

To provide a comprehensive overview, in Figure 4, we illustrate the changes in performance metrics for both the in-domain and out-domain datasets as a function of training dataset size. We present the results averaged across all epochs, along with the standard deviations to indicate variability. This visualization highlights the effectiveness of fine-tuning the model on in-domain data while maintaining the same generalization to out-domain tasks.

5 Conclusion and Future Work

In this work, we propose a novel method for fine-tuning transformer-based reranking models without relying on manually labeled query-document pairs. Instead, we generate synthetic training data using large language models (LLMs), making the approach especially suitable for domain-specific applications lacking labeled data.

Our method uses contrastive learning with Localized Contrastive Estimation (LCE) loss to train the model to distinguish relevant from non-relevant documents. LLMs generate queries and evaluate relevance, automating the creation of training triplets. We further enhance learning by incorporating hard negatives, identified via bi-encoder retrieval and refined using LLM-based scoring.

This pipeline produces diverse, domain-specific data that boosts reranking performance in Retrieval-Augmented Generation (RAG) and other IR tasks. Experiments show significant improvements in retrieval quality.

Future directions include incorporating reinforcement learning to optimize synthetic data generation and extending the method to multilingual settings. We also explore integrating knowledge graphs to guide query generation, using structured domain knowledge to produce more relevant and less hallucinated queries.

By eliminating the need for manual labels, our method makes domain-specific reranking more scalable and effective, advancing ranking optimization in modern IR systems.

Abstract

We introduce Q&A-LF, a French, question-answering benchmark designed to assess the extent to which large language models capture fine-grained lexical knowledge. We investigate the ability of ChatGPT-4o mini, Qwen2.5-14B, Llama3.0-8B, and Llama3.1-8B to answer questions based on lexical functions from Meaning-Text Theory. Using various prompting setups with different levels of examples and context, we find that Qwen and ChatGPT generally outperform Llama models, achieving up to 70% accuracy, while Llama models reach just above 60%. We identify LFs that are particularly easy or especially challenging for the models. We further investigate whether providing sentence-level context and one-shot prompting improve performance, especially on semantically complex functions.

1 Introduction

The recent advances in large language models (LLMs) have shown impressive performance across a wide range of natural language understanding tasks. However, despite their linguistic breadth, the extent to which these models capture fine-grained lexical semantics remains an open question. In particular, there is limited evaluation of their ability to model structured lexical knowledge such as that encoded by Lexical Functions (LFs) in Meaning-Text Theory (MTT) (Mel'čuk, 1996).

The MTT is a well-established and language-agnostic theory, whose system of lexical functions has been applied successfully to the description of typologically diverse languages across a range of applications (Wanner, 1996; Apresjan et al., 2002; Boitet et al., 2002; Boguslavsky et al., 2004; Ramos et al., 2010; Lareau et al., 2011).

Lexical Functions are formalized semantic and syntactic relations between lexical units that underlie derivations, collocations, modifiers, and other nuanced lexical relations. For example, the pairs *presence* : *absence*, *healthy* : *sick*, and *succeed* : *fail* are all instances of antonymy, a relation that involves both a semantic opposition and a similarity of distribution in syntax (the related items must have the same part of speech). In MTT, this relation is represented formally by the LF Anti. LFs are called this way because they are defined as functions from one lexical unit (known as the keyword) to the set of its related lexical units: for instance Anti(*healthy*) = {*unhealthy*, *sick*, *ill*}.

Other LFs include those that change the part-of-speech (POS) while preserving meaning, i.e., S_0, V_0, A_0, Adv_0, which return, respectively, the nominal, verbal, adjectival and adverbial equivalent of a lexical unit, e.g., A_0(*money*)=*monetary*[1] in Fig. 1. LFs may also relate a lexical unit to its collocates. Depending on the LF, the resulting output either inherits the meaning of the keyword, or adds some twist to it, taken from a relatively small set of meanings (or nuances) commonly expressed with collocations across languages. For instance, intensification is generally expressed by collocation, and the LF Magn relates a lexical unit to idiomatic modifiers adding intensification, as in Magn(*profit*)=*hefty* or Magn(*traffic*)=*heavy*.

As such, LFs formally represent lexical knowledge that is absolutely central to linguistic competence. Skillful speakers of a language are able to rephrase their thoughts in a myriad of ways. For instance, in a scenario where there is a lot of traffic on the highway, one could say that there is *heavy traffic*. Similarly, a salesman might be described as really good if he can generate a *hefty profit*.

While LFs have been used extensively in lexicography (Mel'čuk, 2006), they remain underexplored

[1] We use $F(x) = y$ as a shorthand for $y \in F(x)$.

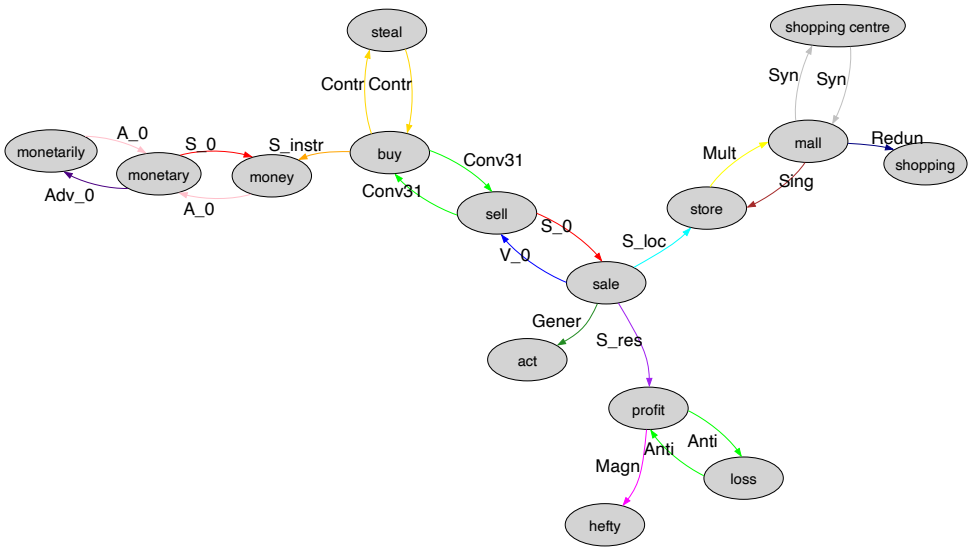

Figure 1: A constructed subgraph of the LN-fr (in English) highlighting important lexical functions.

in the context of large language models. Thus, measuring the ability of LLMs to find the image of such functions is a way to assess their ability to capture fine-grained lexical knowledge.

In this paper, we introduce **Q&A-LF**, a novel French **Q**uestion-**A**nswering benchmark designed to probe LLMs' competence on a diverse set of **L**exical **F**unctions. Each question prompts the model to supply a lexical unit related to a given input word via a specified LF. The task format is simple and interpretable, yet grounded in a formal linguistic theory. Q&A-LF contains 6 100 questions, spanning 15 lexical functions, on which we evaluate LLMs under controlled prompting settings. Our results reveal strengths and weaknesses across function types, highlighting both the capabilities and limitations of current models in capturing structured lexical knowledge.

In what remains, we discuss related work in section 2. In section 3, we present our methodology to gather Q&A-LF, to prompt models and to evaluate them. We report technical details of models we tested in section 4 and report results and analysis in section 5. We conclude this work and discuss some limitations in sections 6 & 7 respectively.

2 Related Work

Several studies have investigated the lexical knowledge encoded in large language models. Petroni et al. (2019) introduced cloze-style probes to test factual knowledge. Follow-up work explored relations such as hypernymy (Ettinger, 2020; Bommasani et al., 2020), as well as derivational morphology (Hofmann et al., 2025). However, these probes often target isolated phenomena and lack the systematic semantic structure that LFs provide. Our work extends this line of research by using a linguistically grounded approach to evaluate a broader and more diverse set of lexical relations.

Moreover, recent efforts have introduced benchmarks for evaluating LLMs' linguistic capabilities, such as BLiMP (Warstadt et al., 2020) (for minimal pairs), SuperGLUE (general language understanding) (Wang et al., 2019), and BIG-Bench (Srivastava et al., 2022). While these benchmarks cover grammaticality, inference, and commonsense reasoning, they do not directly test the structured semantics of word relationships as defined by LFs. The ALF benchmark (Petrov et al., 2025) does make use of LFs, but focuses on analogies, arguably intertwining models' analogical capabilities with lexical ones. Q&A-LF complements these works by offering a controlled, verbally interpretable, and fine-grained testbed grounded in MTT.

3 Methodology

In this section, we describe in details the way Q&A-LF has been generated, the prompt mechanism used to test models, and the metrics we considered to evaluate them.

3.1 The LN-fr resource

In this work, we leverage a rich lexical resource called *French Lexical Network* [2] (LN-fr) (Ollinger and Polguère, 2023; ATILF, 2024). It represents the French lexicon as a directed graph where the nodes are lexical units and the directed edges are labeled with LFs. Lexical units are words (vocables) taken in a specific sense; for instance, the vocable *light* corresponds to several lexical units: $light_{\text{N}}$ ('the luminous radiation'), $light_{\text{ADJ}}$ ('having the property of not weighing a lot'), etc. The surface form of a lexical unit is called a *vocable*.

An f-labeled edge between two lexical units L (the keyword) and L' encodes that $L' \in f(L)$, *i.e.* that $L : L'$ satisfies the lexical relation underlying the LF f. The graph is very dense with approximately 30k nodes, and over 65k edges. As it is consequently hard to visualize[3], we instead provide a constructed example in English in Fig. 1, highlighting how different LFs might interact.

3.2 Q&A-LF

LFs can be rather difficult to explain to a language model (or even to a non-linguist expert). Therefore, we selected 15 of them that are both prevalent in the LN-fr resource and are relatively easy to explain. This also corresponds to the LFs in Figure 1, except for Conv_{13} which did not have sufficient examples for us to work with.

Since there are several ways to make an LF explicit with words, we manually formulated several question patterns involving a placeholder for the lexical unit <L>. Ultimately, on average, we end up with 4 different formulations per LF to accommodate for different lexical units L. In doing so, we made sure that a French speaker would be able to answer these questions. We show a selected set of questions in Table 1 translated in English. The entirety of the questions designed for each lexical function are available in the companion GitHub repository[4].

For each selected LF, we gather 100 unique random keywords, together with their associated set of possible solutions, all taken from the LN-fr resource. We then instantiate each question formulation by replacing the placeholders <L> with the selected lexical units.

As the reference solutions, we use the lexical units pointed to by the outgoing edges, labeled with the given LF, originating from the lexical units with the same vocable form as that of the keyword. For instance, to make explicit the relation expressed by `Anti`, which outputs an antonym of the keyword, we have the formulation : *What is an antonym of the word <L>?* Thus, if L = *small*, the formulation becomes instantiated into the question *What is an antonym of the word "small"?* The possible answers are then given by the LN-fr. *Big* would be considered a correct answer because in the LN-fr, there is an edge labeled `Anti` outgoing from a node labelled *small* into a node labelled *big*. Any other node with this property is also considered a reference solution.

3.3 Prompt Design

We formulate our prompts in French since the lexical units are in French[5]. Each prompt includes an instruction targeting a specific lexical function (LF), optionally followed by an illustrative sentence, and ends with a directive to return the answer only.

All prompts are preceded by the system message: *You are an expert in Meaning-Text Theory.*

The user message consists of a direct question, which we call the base prompt. For example, if we are considering the verb "to sell", we have:

```
Transform the word "to sell" into
a noun.  Answer only one noun
without any punctuation.
```

Then, depending on the prompting configuration, we endow the base prompt with additional information. The prompting configurations we use can be described by two binary variables:

K-shot `[k:0|1]` We investigate if including a question-answer pair into the prompt affects the obtained response. If k=1, the base question is prefixed with a one-shot example pre-selected from (Mel'čuk and Polguère, 2021) as a representative of the LF. We ensured that this example uses a lexical unit that is distinct from the 100 keywords selected for evaluation for that LF. For S_0, it would be

```
Consider this example:
Q: How do you transform the word
```

[2]The full dataset and its official technical documentation are available at https://www.ortolang.fr/market/lexicons/lexical-system-fr/v3.1.

[3]A browser version is available at https://lexical-systems.atilf.fr/en/spiderlex-en/.

[4]https://github.com/rali-udem/QA-LF

[5]For the reader's convenience, we report the prompts as their translation in English.

LF	Selected Question	Possible Answer
S_0	What noun corresponds to the verb *sell*?	*sale*
V_0	Transform the word *sale* into a verb.	*sell*
A_0	Transform the word *money* into an adjective.	*monetary*
Adv_0	Transform the word *monetary* into an adverb.	*monetarily*
Anti	What is an antonym of the word *profit*?	*loss*
Syn	What is a synonym of *mall*?	*shopping centre*
Magn	What word does the speaker use to modify *profit* to express intensification?	*hefty*
S_{instr}	What is a noun that denotes the typical instrument associated with *buy*?	*money*
S_{res}	What is a typical result of the act associated with the word *sale*?	*profit*
S_{loc}	Where does a *sale* typically take place?	*store*
Mult	What is a word that denotes a collection of *stores*?	*mall*
Sing	What do you call a unit of *mall*?	*store*
Redun	What is a word used as a redundant modifier of *mall*?	*shopping*
Gener	What is a hypernym of *sale*?	*act*
Contr	What word contrasts with *buy*, often for stylistic purposes?	*steal*

Table 1: Selected questions, translated in English, for each LF.

> “to present” into a noun? Answer in only one lexical unit.
> A: presentation

If $k = 0$, we do not prefix the base prompt with an example.

Illustrative sentence [s:0|1] We investigate if providing a sentence illustrating a usage of a lexical unit L changes the quality of the response. This should be beneficial for words which have multiple meanings.

The LN-fr resource includes multiple sentences for many of the words in the graph. For our purposes, we take the first available one. If $s = 1$, we suffix the base prompt with the following information:

> Here is an illustration of L : <illustrative sentence>

If $s = 0$, we do not suffix the base question. In any case, all prompts end with an instruction to remain brief, such as `Only respond with one lexical unit` to ease evaluation.

A prompt example using the `k:1-s:1` configuration, would look like this:

> system: You are an expert on Meaning-Text Theory.
>
> user: Consider this example:
> Q: Transform the word “to present” into a noun. Give only one noun without punctuation.
> A: presentation
> Knowing this, transform the word “to sell” into a noun.
> Here is an illustration of “to sell”: “She likes to sell her old textbooks after every semester.”
> Answer in one lexical unit

An expected answer here would be *sale*.

3.4 Metrics

One natural metric is to check whether the model response exactly matches, up to additional punctuation and capitalization differences, one of the reference solutions. We call this metric the Exact Match (EM).

Because models are sometimes more verbose than instructed, they tend to produce the correct solution but with extra material. Thus, we also consider whether one of the desired output appears as a substring, up to capitalization, of the model response. We call this metric the Contain Match (CM).

Since we have different question formulations for the same LF, we consider a prediction correct (under EM or CM) if it is correct for at least one of the formulations.

model	k	s	S_{instr}	Contr	S_{res}	Magn	Mult	Syn	Anti	S_{loc}	V_0	Gener	A_0	Adv_0	Sing	Redun	S_0
ChatGPT	0	0	58	68	52	35	22	38	86	57	87	46	91	**97**	53	13	94
	0	1	65	77	70	45	38	53	84	64	87	63	88	**98**	65	29	92
	1	0	57	69	52	31	39	42	83	66	83	49	91	**95**	52	19	91
	1	1	56	71	62	42	46	53	86	64	88	57	88	**97**	62	37	96

Table 2: CM scores (%) across all models and configurations.

4 Models

We tested four LLMs in our experiments: `ChatGPT-4o mini` (Achiam et al., 2023), as a representative of a strong but private language model, two `Llama` models (Dubey et al., 2024) as popular open-weight models: `Llama3-8B-Instruct` and `Llama3.1-8B-Instruct`, as well as the `Qwen2.5-14B-Instruct` model, which has shown promising results (Bai et al., 2023).

`ChatGPT` We used the OpenAI API[6] to question `ChatGPT-4o mini` under its default parameters. We used both the `system` and `user` roles to nuance our prompts.

The content given to the `system` role is interpreted as a higher-level instruction (for instance, being a helpful assistant who gives relevant answers), while the content of the `user` role can be interpreted as the usual client query.

`Llama` and `Qwen` Due to hardware limitations, we mainly focused on the 8 billion parameter versions for the `Llama` models and 14 billion parameter version for `Qwen`, and we used 4-bit quantization to save memory. We used the default values for the advanced parameters, except for the `max_new_tokens` parameter, which we reduced to 64 to prevent overly long responses from causing GPU memory issues. We ran the `Llama8B` and `Qwen14B` models on a NVIDIA GeForce RTX 4090 GPU with 26 GB of memory.

5 Results and Analysis

CM results from all configurations are included in Table 2. Due to space constraints and to maintain readability, we omit EM scores from the table, but all experimental data, including EM results, are available in our GitHub repository. In this section, we base our analysis on the results obtained from the `k:1-s:1` configuration, which consistently yields higher scores, as can be seen in Figure 2.

5.1 Lexical Function Level Results

Firstly, we observe that certain LFs are consistently easier or harder for all models. Table 3 ranks lexical functions in decreasing order of average CM scores.

LF	ChatGPT	Llama3.0	Llama3.1	Qwen	Average
S_0	**96**	91	93	94	93.5
Adv_0	**97**	94	88	92	92.8
A_0	**88**	86	**88**	86	87.0
V_0	**88**	83	83	85	84.8
Anti	**86**	80	80	84	82.5
S_{res}	62	80	**82**	79	75.8
Contr	**71**	65	62	67	66.3
Sing	62	58	63	**71**	63.5
Gener	57	61	59	**72**	62.3
S_{loc}	**64**	62	60	61	61.8
S_{instr}	56	44	47	**66**	53.3
Syn	53	36	43	**59**	47.8
Mult	46	39	40	**58**	45.8
Magn	42	31	34	**60**	41.8
Redun	37	16	26	**43**	30.5

Table 3: CM scores (%) per lexical function for the `k:1-s:1` configuration.

High-performing LFs typically correspond to LFs involving changes to the POS, such as S_0, Adv_0, A_0, and V_0. It is not surprising that this sits at the top of the easiest lexical functions to evaluate since, in French and many other languages for that matter, this change typically affects a modification of the suffix, often repeating a general pattern (présent**er** vs présent**ation**).

The main cause of error in the four POS functions mentioned above is due to answering a related, derived word, in the correct part of speech, but less directly associated to the keyword. For example, ChatGPT answers *numérisation* (digitization) instead of *numéro* (number) when asked to give the noun derived from *numérique* (numerical).

Other times, ChatGPT answers *digitalisation* for the same S_0 question, when the keyword was *digital*, instead of *doigt* (finger). This is quite significant considering that the illustration sentence clearly mentions *empreintes digitales* (fingerprints). Thus, it is odd that despite this hint, the model still gives an answer with a completely different sense. This suggests that the model is more concerned about the suffix pattern to ensure the answer is of the proper POS, rather than conceptualizing the task on a more abstract level.

Middle class LFs involve, generally speaking, some conception of the world. For example, S_{loc} encodes where an event typically takes place, S_{res} is concerned with the ensuing result of an action, Gener asks about hypernyms, etc. Thus, in such cases, the models cannot as easily rely on morphological tactics. For example, when asked about S_{loc} of père (meaning father, but in the religious sense), the response is père noël, which means Santa Claus. Here, we can perhaps attribute this to the effect of the illustration sentence mentioning *December 31* and *midnight mass*, but the answer is nonetheless quite wrong. An acceptable answer was *couvent* (meaning *convent*).

Low-performing LFs generally involve some creative reasoning. For instance Redun requires identifying a contextually redundant modifier — one that can be dropped without loss of meaning once the word's sense is established. This demands both lexical disambiguation and sensitivity to context. For example, Redun(*card*) = *playing*, since in a casino setting, "card" suffices. Such cases are rare and constrained: not all modifiers (e.g., *prime* in *prime number*) qualify. Errors suggest that models often miss this nuance. Thus, the more complicated nature of this function would explain the lower figures. For example, Qwen answers Redun(*number*) = important. It further explains that we can have an *important number of words*, thus, entirely missing the point. There are many other such examples.

For Magn, which also requires a specific modifier, we also observe important incorrect cases such as Magn(*similarity*) = exactly, which doesn't even form a syntactically correct collocate. Proper answers could have been *striking* or *great*.

For Syn, it is somewhat surprising that the models score so low. We find that the main reason is failure to leverage the disambiguation of the word via the illustration sentence, thus providing a synonym for a slightly different meaning. For example, *pomme* typically means *apple*, but it can also mean *head* (as in *noggin*). This is the meaning conveyed by the illustration sentence. Nonetheless, Qwen still responds with *fruit*.

5.2 Model Comparison

Model	EM	CM
Qwen	37.3	71.8
ChatGPT	51.9	67.0
Llama3.0	19.9	61.7
Llama3.1	30.1	60.5

Table 4: EM and CM averages (%) across LFs under the k:1-s:1 configuration for each model

Table 4 shows the performance of the models averaged across all LFs using k:1-s:1. ChatGPT achieves the highest scores in EM. However, when it comes to CM, Qwen is the best, particularly distinguishing itself in the last two thirds of the LFs in Table 3. The Llama models lag behind, with 3.1 showing modest improvements over 3.0. In fact, both Llama variants underperform on more abstract or lexically nuanced LFs, including Redun, and Magn, even in the favorable k:1-s:1 setting. They perform more reliably on the other LFs but still fall short of ChatGPT's and Qwen's performance. This disparity may be attributed to the different model sizes.

5.3 Aggregate Trends

Figure 2 summarizes the average results across prompting configurations.
Across all models, scores generally increase when sentence-level context is available. The improvement is particularly notable for CM, indicating that

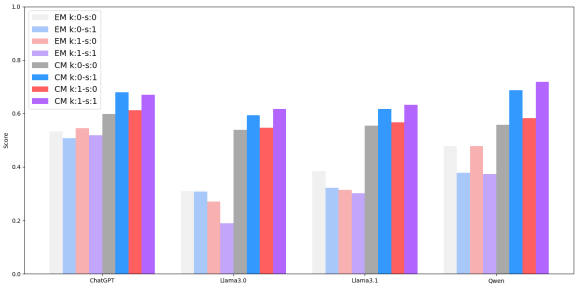

Figure 2: Aggregated results across lexical functions for each prompting configuration.

access to usage examples enhances models' ability to produce semantically plausible predictions.

Providing a 1-shot example also helps, although not as much as adding sentences does. It seems to have a more local effect helping certain instances in particular. An example of the effect of the 1-shot comes when examining `Mult`. Indeed, when `ChatGPT` is asked, under 0-shot conditions, about what word describes a group of *mosquitos*, it responds *mosquito net*, (*moustiquaire* in French), which is close to the French word for mosquito: *moustique*. This seems to suggest that the model cannot separate itself enough from the constraint of the keyword, and reason without too much morphological influence. Correct answers would have been {*swarm*, *nest*, *cloud*, etc.}. However, when providing the 1-shot example showcasing `Mult`(*dog*) = *pack*, it then responded correctly under both configurations involving 1-shot, illustrating the positive effect of the 1-shot prompt.

The contrast between the two metrics generally corresponds to the model's ability to only output the answer without additional text, and nothing but the answer. `ChatGPT` is best at this, and it is observed by it having the smallest gap between both metrics. The other three (non-`ChatGPT`) models were much more verbose than instructed to. Sometimes, it could help them reason more, or even get several answers to the question.

5.4 Summary and Takeaways

Overall, our observations are in line with those of (Petrov et al., 2025) in that some lexical knowledge, as encoded by specific LFs, is difficult to handle by models. But this time, we are more confident that this is not due to difficulties in handling analogies, but rather to deficiencies of models' lexical knowledge. More specifically, we established that: 1) POS changes are fairly well grasped, but that LFs requiring some conceptions of the world or that require some creative thoughts are still difficult; 2) sentence context improves performance, especially with the CM metric; 3) 1-shot prompting helps, but not as much as sentence context and 4) `ChatGPT` and `Qwen` outperform `Llama` models across all conditions we tested, suggesting that the number of parameters causes significant disparity.

6 Conclusion

We introduced `Q&A-LF`, a French, question-based benchmark probing LLMs' understanding of LFs from MTT. Results across 15 LFs show that models like `ChatGPT` and `Qwen` can handle more common lexical relations, especially when given context and one-shot prompting. However, performance drops sharply on more abstract functions, revealing that current LLMs do not consistently internalize the structured semantic mappings that LFs represent. `Q&A-LF` thus exposes both the strengths and the blind spots of modern models in lexical semantics, offering a diagnostic grounded in linguistic theory.

Future work will extend `Q&A-LF` to deeper layers of MTT, expand the inventory of lexical functions, explore richer prompting schemes, scale to frontier models, provide thorough human evaluations, and extend the benchmark to additional languages.

7 Limitations

Some limitations of our study stem from the specific subset of LFs considered. While our question-based format ensures clarity and interpretability, it only targets a surface layer of lexical-semantic competence. Capturing the full expressive depth of the Meaning-Text Theory, such as actantial roles, would require broader coverage of LFs and more sophisticated, structured prompting formats.

In addition, our evaluation was limited to medium-scale models due to cost and hardware constraints. While our resource hasn't been formally evaluated on humans, we estimate that it poses no significant problem to fluent speakers. Still, we are actively working on quantifying human evaluation across different levels of fluency.

`Q&A-LF` is currently only testing the French language. While this is a limitation, we emphasize that the underlying theory is language-agnostic and encodes lexical patterns found cross-linguistically. We chose French because of its extensive use in the MTT literature and since it is also well represented in the training data of the tested models.

Analysis of Vocabulary and Subword Tokenization Settings for Optimal Fine-tuning of MT: A Case Study of In-domain Translation

Javad Pourmostafa Roshan Sharami, Dimitar Shterionov, Pieter Spronck
Department of Cognitive Science and Artificial Intelligence
Tilburg University, The Netherlands
{j.pourmostafa,d.shterionov,p.spronck}@tilburguniversity.edu

Abstract

The choice of vocabulary and subword (SW) tokenization has a significant impact on both training and fine-tuning of language and translation models. Fine-tuning is a common practice in optimizing a model with respect to new data. However, new data potentially introduces new words (or tokens), which, if not considered, may lead to suboptimal performance. In addition, the distribution of tokens in the new data can differ from the distribution of the original data. As such, the original SW tokenization model could be less suitable for the new data. With this work, we aim to gain better insights on the impact of SW tokenization and vocabulary generation on the performance of neural machine translation (NMT) models fine-tuned to a specific domain. To do so, we compare several strategies for SW tokenization and vocabulary generation and investigate the performance of the resulting models.

Our findings show that the best way to fine-tune for domain adaptation is to consistently use both BPE and vocabulary from the in-domain data, which helps the model pick up on important domain-specific terms. At the same time, it is crucial not to lose sight of the vocabulary of the base (pre-trained) model—maintaining coverage of this vocabulary ensures the model keeps its general language abilities. The most successful configurations are those that introduce plenty of frequent domain terms while still retaining a substantial portion of the base model vocabulary, leading to noticeably better translation quality and adaptation, as seen in higher BLEU scores. These benefits, however, often come with greater computational costs, such as longer training times, since the model must learn more new tokens. Conversely, approaches that skip important domain terms or combine mismatched tokenization and vocabulary do not perform as well, making it clear that both domain-specific adaptation and broad vocabulary coverage matter—and that these gains are realized when the vocabulary preserves a good portion of the base (pre-trained) model.

While using in-domain BPE and vocabulary yields the best domain adaptation, it substantially reduces out-of-domain translation quality. Hybrid configurations that combine base and domain vocabularies help balance this trade-off, maintaining broader translation capabilities alongside improved domain performance.

1 Introduction and background

Fine-tuning is a common practice in optimizing MT and pre-trained language models with respect to new data. It is often in the context of DA where an existing model is tuned to perform better on a specific domain (different from what the model was originally trained for) (Luong et al., 2015; Dakwale and Monz, 2017; Wang et al., 2019; Mahdieh et al., 2020; Chopra et al., 2023). The positive effect of fine-tuning has been demonstrated in various previous works. For example, Luong et al. (2015) trained an NMT model on English-German general-domain data and then fine-tuned it on a conversational data in the same languages, leading to an increase of 3.8 BLEU (Papineni et al., 2002) points compared to the original model. Sharami et al. (2022) show that fine-tuning is preferred (as it leads to better results) than training from scratch, even if the data allows the latter. To improve the translation performance on a new domain (without degrading the performance on the generic domain) is to ensemble the fine-tuned model with the already trained baseline, as done by Freitag and Al-Onaizan (2016). However, while they achieve a substantial increase of quality (+7.2 BLEU points), they note that because the in-domain data comprises of new vocabulary and linguistic features that are different from the generic data, the performance of the fine-tuned models drops for the generic domain task, especially when it comes to

Proceedings of Recent Advances in Natural Language Processing,pages 970–979
Varna, Sep 8–10, 2025
https://doi.org/10.26615/978-954-452-098-4-111

domain-specific contexts (e.g., medical and legal domains).

While newly introduced data brings in new information, i.e., new, unseen words, it could be that, statistically, segmentation into SWs is significantly different from the segmentation of the original model (Lim et al., 2018; Yeung, 2019; Sato et al., 2020; Hwang et al., 2024). If not properly addressed, this new information may have an adverse effect on the system.

To address this problem, Sato et al. (2020) proposed a method to adapt the embedding layers of the initial model to the target domain by projecting the general word embedding obtained from target-domain monolingual data onto source-domain embeddings. They reported a 3.86 and 3.28 BLEU points gain in English→Japanese and German→English translation, respectively.

In this paper, we investigate the impact of using different SWs and vocabularies on the performance of fine-tuned NMT systems. We identify a best-case setup and preferable setups under constrained fine-tuning conditions, such as limited domain-specific data. That is, we aim to investigate which fine-tuning conditions (or settings) of a domain-specific model lead to the best performance. Specifically, our objectives are:

1. Identify optimal SW combination choices and vocabulary configurations for a given MT model and fine-tuning dataset.

2. Determine the best fine-tuning conditions under data limitations.

To achieve the aforementioned objectives, we use one large dataset (∼12.7 million parallel sentences) for training and a smaller in-domain dataset (∼248,000 parallel sentences) for fine-tuning multiple MT systems. This setup allows us to examine the extent to which a model trained on a substantial amount of general-domain data can be improved by fine-tuning with additional domain-specific data, which alone would be insufficient to train a robust model from scratch.

Each fine-tuned alternative, is trained on a different set of options of how the SWs and the vocabulary are created. We analyze these fine-tuning strategies to find the best setup based on available data. In our case study, for example, we have access to the data of both models (initial and fine-tuned). However, as already discussed in (Freitag and Al-Onaizan, 2016; Dakwale and Monz, 2017; Zimelewicz et al., 2024), initial models are mostly deployed in an application; thus data might not be available at the production time. As such, it is paramount to have a guideline based on the available data that determines how to best generate SWs and vocabularies. In this work, we use Byte-Pair Encoding (BPE) (Sennrich et al., 2016) for SW units.[1]

It is noteworthy that the point of this research is to investigate the best fine-tuning setup, rather than identifying the best model. Typically, fine-tuning involves tokenizing the new data using the vocabulary originally employed in training the model. This ensures consistency in SW segmentation and prevents discrepancies in word representations. However, it is not always evident whether this practice yields the best translation performance, especially when the new domain introduces a significantly different linguistic distribution or unseen vocabulary. Thus, we explore alternative approaches to SW segmentation and vocabulary creation to determine if different configurations could lead to better fine-tuning outcomes. Specifically, given a pre-training dataset A—whether in-domain, out-of-domain, synthetic, e.g., generated using methods like those in (Sharami et al., 2023), or authentic—and a fine-tuning dataset B, we investigate which tokenization and vocabulary configurations best enable the model to retain and adapt pre-training-derived parameters in a way that improves translation quality on B.

This paper is organized as follows. Section 2 presents the key decision points that frame our study. Section 3 describes the datasets used in our experiments. Section 4 details our experimental design and the overall training framework. Section 5 reports and analyzes the results, incorporating relevant recommendations. In Section 6, we discuss the limitations of our approach. Finally, Section 7 summarizes our findings and outlines directions for future work.

2 Decision points

Given a model M trained on a dataset D, which represents a specific domain d, and a fine-tuning dataset E representative for domain e, the following decision points need to be made:

[1]Throughout this paper, we use "subword" (SW) and "BPE" synonymously, as all experiments use BPE for subword segmentation.

2.1 SW segmentation

A key decision in fine-tuning is determining how to segment words into SW units. This choice affects how the model processes domain-specific terminology and generalizes across datasets. We consider three approaches:

- **Reusing the original SW model** trained on D (D_{SW}). This maintains consistency with the pre-trained model.
- **Training a new SW model on the fine-tuning dataset** (E_{SW}) to better capture domain-specific terminology.
- **Training a SW model on the combined dataset** ($(D + E)_{\text{SW}}$) to integrate both the original and fine-tuning data.

2.2 Vocabulary creation

SW segmentation techniques arose in response to two major challenges in NMT: (i) the lack of generalizability—models often fail to process words not seen during training, leading to out-of-vocabulary (OOV) problems and degraded performance; and (ii) the need to limit vocabulary size, as large vocabularies increase memory consumption and computational cost, which remains a practical constraint in current neural translation systems, particularly when working with large models or limited GPU resources.

Fine-tuning introduces a third, less often addressed challenge: whether the vocabulary used during adaptation adequately captures the token distribution of the fine-tuning dataset. If not, domain-specific content may be poorly represented, limiting the effectiveness of adaptation.

We consider three strategies for vocabulary construction:

- **Reusing the original vocabulary** — the vocabulary that the pre-trained model M was originally trained with (denoted $|D|$). This strategy ensures full compatibility with the pre-trained token embeddings and does not require any modifications to the embedding space.
- **Expanding the vocabulary** — augmenting the original vocabulary with additional tokens found in the fine-tuning dataset E, resulting in a combined vocabulary $|D + E|$. This approach aims to better cover domain-specific terms in E while retaining compatibility with M's original vocabulary.
- **Constructing a new vocabulary solely from the fine-tuning data** — generating the vocabulary exclusively from E (denoted $|E|$). This strategy maximizes domain-specific representational capacity but introduces a mismatch with the pre-trained vocabulary of M.

Handling vocabulary-embedding alignment. In the first strategy ($|D|$), the embedding space remains unchanged, as all tokens are already present in the pre-trained model.

In the second and third strategies ($|D + E|$ and $|E|$), we introduce new tokens absent from the original vocabulary. To accommodate these, we extend the embedding matrix by appending randomly initialized vectors for the new tokens while preserving the original embeddings.

The key distinction lies in the degree of divergence from the original model. Strategy 2 retains the original vocabulary and extends it with tokens from E, maintaining alignment with the pre-trained structure. In contrast, Strategy 3 derives both the vocabulary and BPE model entirely from E, resulting in a larger mismatch with the pre-trained model and necessitating greater adaptation during fine-tuning.

Since SW segmentation and vocabulary creation are interdependent, we explore all feasible combinations, resulting in **nine configurations**. These include applying each SW model ($D_{\text{SW}}, E_{\text{SW}}, (D+E)_{\text{SW}}$) with different vocabulary choices ($|D|, |D + E|, |E|$).

Following these decision points, given a fine-tuning dataset, we can consider three SW models. With these models, we (i) *tokenize the vocabulary sources*, and (ii) *tokenize the training sets for fine-tuning*. Typically, these two processes are tied to each other, i.e., once the SW model is learned and applied to the training data, the vocabulary is the set of SW units that appear in the (processed) data. However, this is not a hard constraint.

For instance, dataset E can be processed with E_{SW}, but the vocabulary used for training can still be based on D and derived from applying D_{SW}. Such mismatched configurations, though theoretically possible, can lead to tokenization inconsistencies and degrade model performance. Since they are suboptimal, we exclude them from this study.

3 Data

We used two datasets: (i) a large *out-of-domain* corpus consisting of approximately 12.7 million English-German sentence pairs drawn from the WMT18 dataset[2], and (ii) a smaller (∼248K sentence pairs) *in-domain medical* corpus extracted from the multi-domain English-German data introduced by (Koehn and Knowles, 2017).

Out-of-domain dataset The out-of-domain corpus used to train our base model is a randomly selected subset of the WMT18 English-German dataset, which contains parallel data from various domains. We selected approximately 12.7 million sentence pairs to balance domain coverage with training efficiency.

In-domain dataset For fine-tuning, we used 248,099 English-German sentence pairs from the medical domain of the multi-domain dataset introduced by (Koehn and Knowles, 2017). We used the cleaned and re-split version provided by (Aharoni and Goldberg, 2020), which removes duplicates and prevents data leakage between train, dev, and test sets.

Combined dataset ($D + E$) For configurations requiring both D and E, we oversampled the in-domain medical data to match the size of the WMT18 subset and concatenated them. The combined data was shuffled and used to train BPE models or extract vocabularies. This ensures that both domains are equally represented, avoiding bias toward the larger out-of-domain corpus.

4 Experiments

To investigate the impact of SW and vocabulary generation choices on fine-tuning, we followed the decision points outlined in Section 2 and ran experiments using the English-German data described in Section 3. We compared the resulting fine-tuned models using BLEU (Papineni et al., 2002), TER (Snover et al., 2006), chrF2 (Popović, 2015). Additionally, we measured training time and estimated CO_2 emissions using `CodeCarbon` (Courty et al., 2024).

[2] `http://statmt.org/wmt18/translation-task.html`. The original WMT18 dataset is considerably larger; we selected a representative subset to reduce computational costs. The selected subset and all preprocessing scripts are released for reproducibility.

4.1 Experimental design

Given our task—fine-tuning a model trained on the WMT18 out-of-domain dataset (D) using in-domain medical data (E)—a total of 9 theoretical configurations exist, arising from three possible vocabulary sources (D, E, or $D + E$) and three BPE models trained on the same sources. Each configuration couples one vocabulary source with one BPE model, which is used for both vocabulary construction and fine-tuning data segmentation.

However, as discussed in Section 2, we imposed constraints to ensure segmentation consistency. Specifically, we excluded configurations where the vocabulary is derived from one source (D or E), but the fine-tuning segmentation is performed using a BPE model trained on the combined dataset ($D + E$). These mismatches introduce inconsistencies, as the vocabulary may not align with how the data is tokenized. Since both D and E are available, we ensure that the same BPE model is used for both vocabulary construction and fine-tuning segmentation.

In total, there are 9 possible configurations (from all combinations of BPE models and vocabulary sources). However, we exclude 2 inconsistent configurations, leaving 7 valid configurations for our experiments (see Table 1).

Config.	BPE for vocab. + FT data	Vocabulary source
C1	D_{BPE}	D
C2	D_{BPE}	$D + E$
C3	D_{BPE}	E
C4	E_{BPE}	D
C5	E_{BPE}	$D + E$
C6	E_{BPE}	E
C7	$(D + E)_{\text{BPE}}$	$D + E$

Table 1: **Valid fine-tuning configurations.** Each row represents a consistent setup where the same BPE model is used for both segmenting the fine-tuning data and constructing the vocabulary. D refers to the WMT18 out-of-domain dataset; E refers to the in-domain medical dataset.

4.2 Model architecture and training Setup

Framework and model architecture We used the OpenNMT-py[3] framework (Klein et al., 2017) to train and fine-tune Transformer-based NMT models (Vaswani et al., 2017). Each model had 6 encoder and 6 decoder layers, 512-dimensional

[3] `https://opennmt.net/OpenNMT-py/`

embeddings, 8 attention heads, and a feed-forward size of 2048. We used the Noam optimizer schedule with a learning rate of 2.0, 8,000 warmup steps, and label smoothing of 0.1. Batching was done over 10,240 tokens with gradient accumulation over 4 steps.

Training setup All models were trained for up to 200,000 steps, with validation and checkpointing every 1,000 steps. We applied early stopping after 10 validations without improvement. All experiments—including the base and fine-tuned models—were run on a single NVIDIA A40 GPU.

Base model The base model was trained on the WMT18 out-of-domain dataset. We applied BPE with 50K merge operations to both source and target sides. The resulting vocabularies and tokenized data were used to train the initial Transformer model, which served as the starting point for all fine-tuning experiments.

Fine-tuning Fine-tuning was done on the in-domain medical dataset using the same model architecture and training settings. Each configuration (C1–C7) used a specific combination of vocabulary source and BPE model (see Table 1). The base model checkpoint was reused across all configurations, and only the vocabulary and tokenized data differed. BLEU was used to track validation performance.

BPE settings We trained separate BPE models for the source and target sides. The number of merge operations depended on dataset size: 8K merges for corpora with fewer than 100K lines, 30K for those between 100K and 1M, and 50K for larger ones. This choice is supported by prior work, which shows that smaller vocabularies benefit Transformer models (Kudo, 2018), and that 2K–8K merges perform best for low-resource datasets (Adlaon and Marcos, 2024). Our BPE models were used consistently for both vocabulary construction and fine-tuning data segmentation.

5 Results and analysis

In this section, we present the evaluation results and statistical comparisons of our fine-tuning setups. We also explore vocabulary overlaps to understand how token and vocabulary choices impact performance and adaptation.

5.1 Analysis of fine-tuning results

Table 2 summarizes the performance of all fine-tuning configurations. To better interpret these results, we performed pairwise bootstrap tests on BLEU scores (Section 5.1.1), interpreting p-values as a continuous measure of confidence without enforcing a strict threshold. TER and chrF2 metrics supplemented the analysis to refine the ranking.

We ranked configurations using the following criteria:

1. BLEU scores, weighted by the strength of statistical evidence from p-values.
2. TER to resolve ties or unclear BLEU differences.
3. chrF2 as a final tiebreaker if both BLEU and TER were inconclusive.

Accordingly, the ranking from best to worst is:

$$C6 \succ C1 \succ C5 \succ C2 \succ C7 \succ C3 \succ C4,$$

where $\succ$ denotes a configuration that performs better or more reliably than the next.

Top configuration ($C6$). Configuration $C6$ uses both BPE and vocabulary exclusively from the in-domain data E, resulting in the highest BLEU and best TER and chrF2 scores. Statistical tests show that $C6$ significantly outperforms all other configurations, confirming the advantage of aligning segmentation and vocabulary strictly with the fine-tuning domain.

Strong middle tier ($C1$, $C5$, $C2$). Configurations $C1$, $C5$, and $C2$ achieve similar BLEU scores, with statistical evidence showing no clear superiority among them. $C1$ (BPE and vocabulary from out-of-domain D) slightly leads numerically, while $C5$ (in-domain BPE, combined vocabulary) offers better TER than $C2$ (out-of-domain BPE, combined vocabulary), which justifies the order. These results suggest incorporating some in-domain vocabulary or combining datasets can yield competitive results if full in-domain access (for both BPE and vocabulary) is not possible.

Lower performing configurations ($C7$, $C3$, and $C4$). Configurations $C7$ and $C3$ perform moderately but are consistently behind the mid-tier cluster. Configuration $C4$ ranks last, likely because of a mismatch between its in-domain BPE and out-of-domain vocabulary, which impairs tokenization and reduces fine-tuning effectiveness.

Config	BPE Model (vocab. + FT)	Vocabulary Source	BLEU↑	chrF2↑	TER↓	CO_2 (g)↓	Time (h)↓
C1	D_{BPE}	D	53.6	69.4	49.3	1658.69	07:45
C2	D_{BPE}	$D + E$	53.4	69.5	49.9	1198.66	05:15
C3	D_{BPE}	E	51.7	68.4	50.9	907.24	04:00
C4	E_{BPE}	D	46.6	64.5	53.0	723.94	03:11
C5	E_{BPE}	$D + E$	53.1	68.9	49.7	729.04	03:15
C6	E_{BPE}	E	**54.8**	**69.8**	**48.9**	1587.41	09:30
C7	$(D + E)_{\text{BPE}}$	$D + E$	53.2	69.1	50.1	543.84	03:08

Table 2: **Evaluation scores of fine-tuned models.** Each configuration pairs a specific BPE model and vocabulary source consistently. All models were fine-tuned on the in-domain dataset E and evaluated on the same test set. CO_2 emissions and training times are recorded during fine-tuning.

Practical recommendations. For optimal fine-tuning, use both BPE and vocabulary consistently derived from the in-domain data, as exemplified by configuration $C6$. When full access to in-domain data or vocabulary is limited—due to privacy, proprietary constraints, or resource availability—fine-tuning remains possible but may yield reduced adaptation effectiveness. In such cases, configurations like $C1$ and $C2$ offer robust alternatives by leveraging available data while balancing performance and practicality. It is important to avoid mixing BPE and vocabulary from mismatched domains, as this often leads to suboptimal tokenization and degraded translation quality. Overall, aligning tokenization and vocabulary with domain data maximizes fine-tuning benefits, but adapting with limited data can still provide meaningful improvements compared to no adaptation.

5.1.1 BLEU score statistical comparison

We conducted pairwise bootstrap tests on BLEU scores using 1,000 iterations. Table 3 shows the p-values for all configuration pairs. Diagonal entries represent self-comparisons.

	C1	C2	C3	C4	C5	C6	C7
C1	–	0.545	0.000	0.000	0.200	0.852	0.102
C2	0.447	–	0.000	0.000	0.172	0.792	0.063
C3	1.000	1.000	–	0.000	0.995	1.000	0.989
C4	1.000	1.000	1.000	–	1.000	1.000	1.000
C5	0.774	0.813	0.006	0.000	–	0.966	0.286
C6	0.149	0.174	0.000	0.000	0.026	–	0.012
C7	0.896	0.929	0.010	0.000	0.701	0.987	–

Table 3: **Pairwise bootstrap p-values for BLEU scores** (1,000 iterations). Diagonal entries represent self-comparisons. *All values are provided for reference only; no statistical significance threshold is applied.*

5.2 Training time and CO_2 emissions

The training times and estimated CO_2 emissions in Table 2 show the resource demands of each fine-tuning setup. The best-performing configuration, $C6$, took the longest—about 9.5 hours—and had a higher carbon footprint, likely because it had to learn many new domain-specific tokens.

Other configurations such as $C7$, $C4$, and $C5$ completed training notably faster, around three hours, and had lower CO_2 emissions compared to $C6$. This can be attributed to several factors. Configurations $C7$ and $C5$ utilize vocabularies with higher overlap to the baseline tokens, meaning fewer new domain-specific tokens need to be learned, which reduces training complexity and time. On the other hand, $C4$ exhibits both a vocabulary and BPE mismatch, which limits effective fine-tuning and results in quicker but less effective training. In summary, configurations with less vocabulary adaptation or mismatched tokenization require less training time and energy but tend to yield lower translation quality.

Overall, while domain-aligned fine-tuning boosts performance, it can require more time and energy—something to consider in real-world applications.

5.3 Vocabulary overlap analysis

To better understand how vocabulary choice influences fine-tuning, we measured overlap between each configuration's vocabulary and the baseline WMT vocabulary in terms of token frequency coverage. This approach more accurately reflects the practical impact of commonly used tokens on model performance, as it weights tokens by how often they occur in the data. Table 4 summarizes the key statistics:

Config	BPE Model (Vocab+FT)	Vocab SRC	BLEU↑	SRC Overlap %	TGT Overlap %	New Tokens SRC	New Tokens TGT
C6	E_{BPE}	E	54.8	82.84	77.81	13,022	13,559
C1	D_{BPE}	D	53.6	100	100	0	0
C5	E_{BPE}	$D + E$	53.1	83.04	77.95	14,289	14,157
C2	D_{BPE}	$D + E$	53.4	83.04	77.95	11,736	11,804
C7	$(D + E)_{\text{BPE}}$	$D + E$	53.2	97.61	95.72	14,300	15,077
C3	D_{BPE}	E	51.7	83.04	77.95	11,736	11,804
C4	E_{BPE}	D	46.6	90.70	90.46	0	0

Table 4: **Vocabulary overlap and BLEU scores per configuration.** Configurations are listed in order of their overall performance ranking. SRC and TGT overlap percentages indicate the proportion of baseline tokens retained. New Tokens columns count tokens unique to the configuration's vocabulary.

- **SRC/TGT Overlap (%)**: The percentage of total token frequency (i.e., the sum of token counts) in the baseline WMT vocabulary that is also present in the configuration's vocabulary, calculated for source (English) and target (German) separately. This reflects not just the number of shared tokens, but their practical frequency in baseline data.
- **New Tokens**: The number of tokens in the configuration's vocabulary that do not appear in the baseline vocabulary (after filtering), representing domain-specific or new tokens introduced by the configuration.

The results demonstrate that configurations incorporating in-domain vocabulary (e.g., $C6$, $C5$, and $C7$) introduce a substantial number of new domain-specific tokens, which is associated with their superior BLEU scores and more effective domain adaptation. In contrast, $C1$, relying solely on the baseline vocabulary, achieves complete overlap but lacks critical domain-specific terms, limiting its adaptability. The notably poor performance of $C4$ corresponds with its lower vocabulary overlap and the evident mismatch between its BPE model and vocabulary source, underscoring the detrimental impact of inconsistent tokenization strategies.

These findings robustly support our practical recommendation: for optimal fine-tuning, vocabulary and BPE should be consistently derived from the same in-domain data. Such alignment ensures richer domain-specific token representation, ultimately leading to enhanced translation accuracy and better overall model performance.

5.4 Out-of-domain performance analysis

To quantify the impact of different fine-tuning strategies on generalization, we evaluated all configurations on the original out-of-domain (WMT18, D) test set. Table 5 reports BLEU scores for each configuration, alongside the absolute and relative drop with respect to the pre-trained base model (before fine-tuning).

Config	BPE/Vocab Source	BLEU	Drop	Drop (%)
Base	D_{BPE}, D (pre-trained)	33.9	–	–
C2	$D_{\text{BPE}}, D + E$	15.1	-18.8	-55.5
C7	$(D + E)_{\text{BPE}}, D + E$	15.0	-18.9	-55.8
C3	D_{BPE}, E	13.3	-20.6	-60.8
C1	D_{BPE}, D	13.1	-20.8	-61.4
C4	E_{BPE}, D	10.2	-23.7	-69.9
C6	E_{BPE}, E	7.7	-26.2	-77.3
C5	$E_{\text{BPE}}, D + E$	7.0	-26.9	-79.4

Table 5: **Out-of-domain BLEU scores.** Performance on the WMT18 (D) test set for all configurations, ranked by smallest drop relative to the pre-trained base model.

The results illustrate the trade-off introduced by domain adaptation: as the model is adapted to the in-domain data, out-of-domain performance drops substantially across all configurations. This degradation is most pronounced when both BPE and vocabulary are derived solely from in-domain data (C5, C6), indicating strong domain specialization at the expense of generalization.

For practitioners seeking to balance domain adaptation and general translation quality, we recommend hybrid configurations such as C_2 and C_7, which use either the original BPE with a combined vocabulary or a combined BPE and vocabulary. These setups moderate the drop in out-of-domain BLEU, preserving more general-domain competence while still offering improved domain adaptation.

6 Limitations

Despite the systematic and thorough analysis, we acknowledge several drawbacks and limitations of our work. Addressing these in the future would complement this research and expand the understanding of the impact of data processing on model performance.

- **Focus on MT:** Our evaluation focused on NMT systems. However, neural language models are also impacted by how the training and fine-tuning data is processed and used, as well as the limitations placed on the vocabulary. This is even more pertinent with the progress in large language models (LLMs). We did not analyze the performance of LLMs, which is a more complex task, especially in the case of multi-lingual LLMs capable of translation.

- **Fine-tuning data:** Our study focused exclusively on the medical domain for fine-tuning. Future research could consider additional specialized domains to evaluate the generalizability of the findings.

- **Use of BPE only:** We employed BPE only and did not consider other methods such as SentencePiece (Kudo and Richardson, 2018) or LMVR (Ataman et al., 2017). This was a deliberate choice, as it was up to us which model and method to use during training and fine-tuning.

- **Hyperparameters:** We used the model's default hyperparameters and did not perform hyperparameter optimization or tuning. This was not necessary as we aimed to compare the impact of the SW algorithms under the same conditions. However, we acknowledge that fine-tuning hyperparameters would impact the performance of original and fine-tuned models, and we hypothesize a correlation with how the vocabulary is constructed.

7 Conclusion and Future Work

In this work, we presented a systematic analysis of vocabulary and SW tokenization settings for fine-tuning NMT models, using a large out-of-domain corpus (WMT18) and a specialized in-domain medical dataset as a case study. By comparing seven realistic fine-tuning setups that varied in BPE segmentation and vocabulary generation, we identified clear practical guidelines for domain adaptation.

Our results show that the most effective fine-tuning is achieved when both BPE and vocabulary are derived from the in-domain data, allowing the model to better capture frequent and relevant domain-specific terms. At the same time, we find that maintaining a substantial overlap with the vocabulary of the base model (originally trained on out-of-domain data) is essential for preserving general language coverage and ensuring stable adaptation. The best-performing configurations in our experiments balanced these two needs: they introduced many new, high-frequency in-domain tokens while still retaining a good portion of the base model vocabulary. However, this approach tends to require more computational resources, such as increased training time and higher energy consumption, due to the need for the model to learn and integrate more new tokens.

It is important to note that while maximizing domain adaptation can significantly boost in-domain performance, it may lead to a substantial drop in out-of-domain translation quality. Hybrid configurations that combine base and domain vocabularies help balance this trade-off, preserving broader translation capabilities while still delivering improved domain performance.

If, in addition to the in-domain data, the original out-of-domain data or its BPE/vocabulary are also accessible, combining these resources can help preserve general language coverage and stabilize adaptation. In all cases, our findings highlight the importance of aligning both BPE and vocabulary with the domain of the adaptation data, while retaining overlap with the base model's vocabulary to ensure generalization.

For future work, we plan to extend our evaluation to other domains and language pairs, and to investigate how these findings generalize to LLMs and multilingual systems. We are also interested in exploring adaptive methods for selecting which tokens to retain or introduce during fine-tuning, with the aim of optimizing both performance and computational efficiency.

All datasets, models, and scripts from our work are publicly available at: https://github.com/JoyeBright/subword-ft-guide.

LLM-based Embedders for Prior Case Retrieval

Damith Premasiri, Tharindu Ranasinghe, Ruslan Mitkov
School of Computing and Communications, Lancaster University, UK
{d.dolamullage, t.ranasinghe, r.mitkov}@lancaster.ac.uk

Abstract

In common law systems, legal professionals such as lawyers and judges rely on precedents to build their arguments. As the volume of cases has grown massively over time, effectively retrieving prior cases has become essential. Prior case retrieval (PCR) is an information retrieval (IR) task that aims to automatically identify the most relevant court cases for a specific query from a large pool of potential candidates. While IR methods have seen several paradigm shifts over the last few years, the vast majority of PCR methods continue to rely on traditional IR methods, such as BM25. The state-of-the-art deep learning IR methods have not been successful in PCR due to two key challenges: ***i***. Lengthy legal text limitation; when using the powerful BERT-based transformer models, there is a limit of input text lengths, which inevitably requires to shorten the input via truncation or division with a loss of legal context information. ***ii***. Lack of legal training data; due to data privacy concerns, available PCR datasets are often limited in size, making it difficult to train deep learning-based models effectively. In this research, we address these challenges by leveraging LLM-based text embedders in PCR. LLM-based embedders support longer input lengths, and since we use them in an unsupervised manner, they do not require training data, addressing both challenges simultaneously. In this paper, we evaluate state-of-the-art LLM-based text embedders in **four** PCR benchmark datasets and show that they outperform BM25 and supervised transformer-based models.

1 Introduction

Information retrieval (IR) systems have progressed through several paradigm shifts in the last few decades (Zhu et al., 2023; Plum et al., 2024). Initial IR methods relied on term-based methods such as BM25 (Robertson et al., 2009) and boolean logic, focusing on keyword matching for document retrieval (Chowdhury, 2010). The paradigm gradually shifted with the introduction of vector space models, enabling a more sophisticated understanding of the semantic relationships between queries and documents (Salton et al., 1975). Initially, these models relied on statistical language models (Song and Croft, 1999), but in recent years, neural vector space models have achieved remarkable performance in IR (Guo et al., 2016; Xiong et al., 2021). More recently, large language models (LLMs) have been integrated into these vector space models as embedders, further improving the performance (Ma et al., 2024; Ranasinghe et al., 2025). LLM-based embedders have dominated text retrieval benchmarks such as MTEB (Muennighoff et al., 2023) and BEIR (Thakur et al., 2021).

Prior case retrieval (PCR) is an IR application where the goal is to retrieve cases from a large legal database of historical cases that are similar to a given query case (Fang et al., 2022; Feng et al., 2024; Li et al., 2021; Tran et al., 2020). PCR holds substantial practical value, regardless of the legal system a country follows. In the Common Law System (as in the United Kingdom and India), legal professionals, such as lawyers and judges, use precedents (previously decided court cases) to support their arguments and help achieve their desired outcome in the present case (Shulayeva et al., 2017). Even in the Civil Law System (like in China and France), where legal arguments primarily rely on statutes, PCR remains essential as it offers key reference details, including the relevant statutes for past cases and the court's rulings, serving both legal experts and those seeking legal advice (Li et al., 2024b).

While the general domain IR systems have progressed into neural retrieval models, PCR systems still rely largely on traditional and term-based methods such as BM25 (Robertson et al., 2009). Re-

searchers participating in COLIEE have demonstrated that BM25 serves as a strong baseline, and most top-performing systems have employed models based on BM25 combined with other techniques, such as TF-IDF and XG-Boost (Joshi et al., 2023). For example, a traditional language modelling approach (Ponte and Croft, 1998) proposed in 1998 won the first place (Ma et al., 2021), and a vanilla BM25 got second place (Rosa et al., 2021) in COLIEE 2021 (Rabelo et al., 2022). Furthermore, many researchers such as Askari et al. (2021) and Joshi et al. (2023), show that BM25 outperforms many supervised transformer-based retrieval approaches.

The limited success of neural retrieval models in PCR can be attributed to two main reasons.

1. Long court cases - The court cases are lengthy in nature. Many state-of-the-art neural retrieval models, because of their reliance on BERT models (Devlin et al., 2019), have a context limit of 512 tokens (Khattab and Zaharia, 2020; Ren et al., 2021). While researchers have attempted to apply these neural retrieval models to PCR using techniques such as truncating court cases, they often result in information loss and suboptimal results (Askari et al., 2021; Joshi et al., 2023; Nguyen et al., 2021; Premasiri et al., 2023).

2. Lack of training data - The neural retrievals are supervised machine learning models and require a large number of training instances (Khattab and Zaharia, 2020; Ren et al., 2021). While several large PCR datasets exist, they are limited to a few languages and courts, and it is not always possible to find PCR datasets that are large enough to properly train neural retrievals, resulting in reduced performance.

The recently emerged LLM-based text embedders (Muennighoff, 2022; Lee et al., 2024) can simultaneously address both of these challenges in PCR. First, they take up to 32,000 tokens as input, which is under the length of most court cases, addressing the first challenge we discussed. Secondly, as we will discuss in Section 3.2, LLM-based text embedders can be utilised in an unsupervised manner in the IR tasks, eliminating the need for model training and addressing the second challenge (Ranasinghe et al., 2025). Furthermore, Ni et al. (2022) demonstrate that LLM-based encoders also exhibit superior generalisability, showing significant improvements not only in the specific targeted scenario but also across a range of general tasks outside the fine-tuned domain. However, previous studies have not evaluated LLM-based text embedders in PCR benchmarks. In this research, we address this gap by answering the following two research questions (RQs).

RQ1 - How do the state-of-the-art LLM-based text embedders perform in different PCR benchmarks?
RQ2 - How well does the model ranking in the MTEB (Muennighoff et al., 2023) benchmark generalise to PCR benchmarks?

Answering these questions, in this paper, (1) we provide the **first comprehensive evaluation** of state-of-the-art LLM-based text embedders on PCR. (2) We show that our simple adaptation of LLM-based embedders **outperforms BM25 and transformer-based methods** in PCR datasets across multiple languages and jurisdictions. We release the model code and evaluation scripts for the purpose of research usage via GitHub[1]

2 Related work

With the increasing volume of cases, there is a growing demand for automatic precedent retrieval systems to assist practitioners by providing prior cases relevant to the current case (El Jelali et al., 2015). Therefore, PCR has remained an active area of research in the IR community (Breuker et al., 2005; Leburu-Dingalo, 2024; Tang et al., 2024a,b). Several datasets have been released for the PCR task such as LeCaRDv2 (Li et al., 2024b), C3RD (Ye and Li, 2024) and MUSER (Li et al., 2023b) for Chinese courts, IL-PCR (Joshi et al., 2023) for Indian courts, GerDaLIR (Wrzalik and Krechel, 2021) and LePaRD (Mahari et al., 2024) for United State's courts. Recent shared tasks, such as COLIEE (Goebel et al., 2024a, 2023; Kim et al., 2022) and AILA (Parikh et al., 2021; Bhattacharya et al., 2019) have facilitated the development of many PCR datasets.

SAILER (Li et al., 2023a) introduced a structure-aware pre-trained model for the prior case retrieval task. Utilising encoder-decoder architecture, SAILER proposes a fact encoder, a reasoning decoder and a decision decoder, which are pre-trained on Chinese and United States case law. CaseLink (Tang et al., 2024b) introduces a different approach for PCR by creating a Global Case Graph. They utilise semantic and legal charge relationships in addition to the reference relationships to populate the

[1]Available at https://github.com/DamithDR/case-retrieval.git

case graph. However, evaluating similarity among case law is a complex task. DELTA (Li et al., 2025) proposed an encoder-based pre-trained model with structural word alignment to methodically align the relevant facts closer and the irrelevant ones distant. Moreover, PCR has also been studied at the paragraph level. T.y.s.s. et al. (2024) created a specific dataset for paragraph retrieval in the European Court of Human Rights (ECtHR) and performed zero-shot and fine-tuned experiments with multiple encoder models. BERT-PLI (Shao et al., 2020) fine-tunes a BERT model for the sentence pair classification task and utilises the semantic relationships to calculate the relevance prediction using an interaction map.

Given the importance of information retrieval in the legal domain, multiple research events have been organised in this area. Few notable events are LIRAI (De Luca et al., 2023) workshop focused on information retrieval systems generally in the legal domain, and particularly in case law COLIEE (Goebel et al., 2024b) shared-task focuses on case law retrieval systems. The results of the competition suggest that BM25-like retrieval models are still effective in the context of lengthy text, as in case law.
