Cross-modal Encoder We adopt CLIP as the cross-modal encoder to encode the input text and the generated imaginations. CLIP (Radford et al., 2021) is trained on large-scale image-text pairs and is able to align visual and textual input in the embedding space. Specifically, we use the $ViT-B/32$ version of Vision Transformer as the image encoder, and Transformer (Vaswani et al., 2017) with the architecture modifications described in (Radford et al., 2019) as the text encoder. For each modality, the self-attention (SA) module is applied to model the regions of imagination or the words of the text as follows:

$$SA(F) = concat(softmax\frac{FW_j^Q FW_j^{K^{\mathrm{T}}}}{\sqrt{d_k}}FW_j^V, \ldots)W \tag{2}$$

where F denotes the set of regions of the imagination or the words of the textual sentence. W_j^Q, W_j^K, and W_j^V represents the weight in the j-th head for query, key and value respectively. d_k is the dimension of the embedding. W is the weight matrix for multiple heads.

To solve the ICLU problem, we learn the bi-directional relationship between the text input and the visualized imagination. We apply late fusion on the text feature $\boldsymbol{t}$ and visual feature $\boldsymbol{v}$ to construct the cross-modal feature. Given the set of visual features $S_{\boldsymbol{v}}$ and textual features $S_{\boldsymbol{t}}$, the fused embedding X_S can be given with:

$$X_S = [ReLU(W_t S_{\boldsymbol{t}} + b_t), ReLU(W_j S_{\boldsymbol{v}} + b_j)] \tag{3}$$

where W and b are of two separate fully connected layers to the visual and text embeddings. The fused embeddings X_S will go through two fully connected layers before we receive the final imagination-augmented language representation.

Visually-supervised Transformer We implement the visually-supervised Transformer language model proposed in Tan and Bansal (2020). The model architecture is a BERT-like pure-language-based masked language model.

3.3 Learning Procedure

We introduce a novel paradigm to better understand natural language by incorporating existing language models with visual imagination. As shown in Figure 3, the procedure consists of two steps: (1) pre-train the visually-supervised Transformer, and (2) fine-tune the framework with imagination on downstream tasks.

Step 1: Visually-supervised Pre-training We pre-train a visually-supervised Transformer following the scheme proposed in VOKEN (Tan and Bansal, 2020), which extrapolates cross-modal alignments to language-only data by contextually mapping language tokens to the related images. In addition to masked language modeling, VOKEN proposed a voken classification task: given a set of tokens with masks, the model is asked to predict the best-matching image (the voken) for each tokens. The pre-training loss can be given as:

$$\mathscr{L} = -\lambda_1 \sum_{w_j \in \hat{s}} \log q_j(w_j|\check{s}) - \lambda_2 \sum_{w_j \in \hat{s}} \log p_j(v(w_j;s)|\check{s}) \quad (4)$$

Here s is the token set, $\hat{s}$ is the masked tokens, and $\check{s}$ is the unmasked tokens. The q_j and p_j represent the conditional probability distribution of the j-th token given the token w_j and voken $v(w_j;s)$ respectively, and λ_1 and λ_2 are the balance factor of the masked language modeling task and the voken-classification task. The cross-modal classification task enables the model to learn the matching between the tokens from the language corpus (e.g., wiki) and its most-related images from the image set (e.g., MSCOCO).

Step 2: Imagination-augmented Fine-tuning We use GLUE (Wang et al., 2018) and SWAG (Zellers et al., 2018) as the downstream datasets in the following sections. Our proposed iACE learns to minimize the cross-entropy loss below:

$$\mathscr{L}_{Imagine} = -\sum_{j=1}^{|D|} \sum_{k=1}^{K} y_k \log p_k(d_j(\boldsymbol{t};\boldsymbol{v})|D) \quad (5)$$

where j denotes the j-th data sample in dataset D, and K os the class number. The p_k represents the conditional probability distribution of d_j. During fine-tuning, the visually-supervised Transformer language model only relied on the textual input to make predictions. The loss are computed as:

$$\mathscr{L}_{Lang} = -\sum_{j=1}^{|D|} \sum_{k=1}^{K} y_k \log p_k(d_j(\boldsymbol{t})|D) \quad (6)$$

Notice that we use MSE loss for the regression task. The imagination-augmented loss and pure-language based loss are summed up with a balance factor λ in a jointly training schema as:

$$\mathscr{L} = \lambda \mathscr{L}_{Imagine} + (1-\lambda)\mathscr{L}_{Lang} \quad (7)$$

We use Adam Optimizer with a learning rate $1e-4$ for the GLUE benchmark and $2e-5$ for the SWAG dataset. We discuss more details in Section 4.

4 Experiments

4.1 Experimental Setup

Datasets & Metric We conduct experiments to evaluate the performance of our proposed method over SST-2 (Socher et al., 2013), QNLI (Rajpurkar et al., 2016), QQP (Iyer et al., 2017), MultiNLI (Williams et al., 2018), MRPC (Dolan and Brockett, 2005), STS-B (Agirre et al., 2007) from GLUE (Wang et al., 2018) Benchmark, and SWAG (Zellers et al., 2018) dataset. We construct few-shot setting subsets by taking 0.1%, 0.3%, and 0.5% of training instances as the Extreme Few-shot Setting, and 1%, 3%, and 5% as the Normal Few-shot Setting. We train the model with the subsets and evaluate its performance on the complete development set. We use accuracy as the default evaluation metric and compare such results in the following sections.

Baselines We choose BERT (Devlin et al., 2019) and RoBERTa (Zhuang et al., 2021) as the base language models, and apply our iACE framework on top of their small and base architectures for comparison. A recent study proposes a visually-supervised language model VOKEN (Tan and Bansal, 2020) that introduces visual supervision into language model pre-training by borrowing external knowledge from retrieved images of the tokens. In natural language understanding tasks, VOKEN achieved improvements over language-based baselines BERT and RoBERTa. Thus we also use VOKEN built upon these language-based models as a set of powerful baselines. In the following experiments, each model is first pre-trained with visual supervision introduced in (Tan and Bansal, 2020) upon the four base models (BERT$_{small}$, BERT$_{base}$,

Table 1: **Model-agnostic Improvement in Few-shot Setting.** iACE and VOKEN upon BERT and RoBERTa base size architecture are fine-tuned in Extreme Few-shot (0.1%, 0.3%, 0.5%) and Normal Few-shot setting (1%, 3%, 5%). For the few-shot setting, we use large and stable datasets from GLUE Benchmark. We compare accuracy on SST-2, QNLI, QQP, and MNLI and the average of accuracy and F1 score on QQP. **BEST** results are highlighted.

RoBERTa$_{small}$ and RoBERTa$_{base}$). Then the models will be fine-tuned on downstream tasks.

Notice that base models and VOKEN use pure-language training objectives during fine-tuning. Neither of them utilizes the visual signals inherent in the downstream language corpora. In contrast, our iACE explicitly introduces visual imagination supervisions into fine-tuning and inference stages.

Implementation Details We train RoBERTa with the same configurations as a robustly optimized pre-training approach based on BERT of the same size. BERT$_{small}$ has 6 repeating layers, 512 hidden dimension. BERT$_{base}$ has 12 repeating layers, 768 hidden dimension.

The imagination of the texts is generated interactively by using VQGAN+CLIP, with 128×128 size, 500 iterations. We use pre-trained VQGAN (imagenet$_{f16}$) and CLIP (ViT-B/32). We leverage CLIP (ViT-B/32) as our language and vision model for premise and hypothesis, and imagination of them. The text and image dimension is 512. The dropout rate is set to 0.1. We use Cross-Entropy loss for our cross-modal classification. Each model was first pre-trained on 4 TITAN RX GPUs for 30 epochs with early stopping and a batch size of 32 and a sequence length of 126. The optimizer used is Adam with a learning rate of $2e-4$ and a weight decay of 0.01. The models are then fine-tuned on GLUE benchmark and SWAG dataset for 3 epochs with 32 batch size. We adopt the joint training strategy for our proposed iACE and visually supervised transformer during fine-tuning. The learning rate of the Adam optimizer is set as $1e-4$ and $2e-5$ for GLUE and SWAG, respectively.

4.2 Few-shot Learning Results

We claim that introducing imagination into language processing helps the existing language-based system tackle the low-resource situation. Thus, the automatically generated imagination helps reduce the human effort to annotate textual data. To verify this, we define two situations, a normal few-shot setting, and an extreme few-shot setting. For the normal few-shot setting, we keep 1%, 3%, and 5% of the training dataset for each task in GLUE Benchmark. For the extreme few-shot setting, we keep a lower number of the training dataset, which is reduced to 0.1%, 0.3%, and 0.5% of the training dataset. We train the models with the same configuration under these two settings and compare them with visually supervised transformer baselines to confirm the benefit that our proposed iACE brings to the few-shot situation.

Results of the few-shot setting are reported in Table 1. Following Tan and Bansal (2020), we only report the four largest and stable tasks in GLUE for the model-agnostic comparison. We report the accuracy for SST-2, QNLI, MNLI. For QQP and MRPC, we report the average of F1 and accuracy. For SWAG, we report the correlation. We observe that the imagination information remarkably helps with both the normal few-shot curriculum and extreme few-shot curriculum. We assume the imagination-augmented fine-tuning successfully transfers the language understanding from the large-scale vision and language model. Thus iACE achieves consistent performance gain and shows great superiority of generalization and transferring ability.

Table 3: **Imagination Composition Ablation in Few-shot Setting.** *Bi-directional VT* represents the full input for iACE. More details about *Textual Only*, *Visual Only* and *Visual+Textual* are illustrated in Section 4.3.

4.3 Ablation Studies

We conduct ablation studies over both the method side and data side to validate their contribution to our proposed iACE.

Method Design Ablation Two method variants of our imagination-augmented encoder are built as baselines to validate the importance of our bi-directional cross-modal imagination design in iACE. The variants are built upon RoBERTa$_{base}$ and BERT$_{base}$ base models. Specifically, we develop variant *Direction* and *Unify*. *Direction* represent alignment between text input and imagination into a directional embedding as FUSE($\boldsymbol{t}_{sen1} - \boldsymbol{i}_{sen1}$, $\boldsymbol{t}_{sen2} - \boldsymbol{i}_{sen2}$). *Unify* encode the text and imagination, considering the direction from vision to language by encoding as FUSE($\boldsymbol{t}_{sent1}$, $\boldsymbol{t}_{sent2}$, $\boldsymbol{i}_{sent1}$, $\boldsymbol{i}_{sent2}$). While *iACE* consider direction from visoin to language and language to vision by encoding as the combination of FUSE($\boldsymbol{t}_{sent1}$, $\boldsymbol{i}_{sent2}$) and FUSE($\boldsymbol{i}_{sent1}$, $\boldsymbol{t}_{sent2}$). As shown in Table 2, our bi-directional imagination and language learning achieve stable and best average performance. These results indicate that our bi-directional imagination method design obtain generalization and transferring ability. We assume iACE benefits from both learning from language to vision and learning from vision to language simultaneously.

Imagination Composition Ablation The composition of the imagination is essential for the performance. To further study the importance of full imagination, we ablate the data side by constructing a textual-only model denoted as *Textual Only*, a visual-only imagination denoted as *Visual Only* and a single directional imagination input denoted as *Visual+Textual*. *Visual Only* and *Visual+Textual* represent the imagination model use visual pairs $(\boldsymbol{i}_{sent1}, \boldsymbol{i}_{sent2})$ and one direction visual and textual pairs $(\boldsymbol{i}_{sent1}, \boldsymbol{t}_{sent2})$ as input respectively. Our full approach use *Bi-directional VT* which takes $(\boldsymbol{i}_{sent1}, \boldsymbol{t}_{sent2})$ and $(\boldsymbol{t}_{sent1}, \boldsymbol{i}_{sent2})$ as input.

Results are reported in Table 3 for Extreme Few-shot setting and normal few-shot setting. We observe *Bi-directional VT* data input achieve the most stable and the best average performance. Results show the importance of bi-directional imagination from all the textual input to construct an imagination-augmented cross-modal encoder.

4.4 Model-agnostic Improvement

iACE is a model-agnostic training paradigm that could help existing models achieve consistent gain over GLUE and SWAG with both the few-shot

Base Model	**Method**	**SST-2**	**QNLI**	**QQP**	**MNLI**	**MRPC**	**STS-B**	**SWAG**	**Avg.**

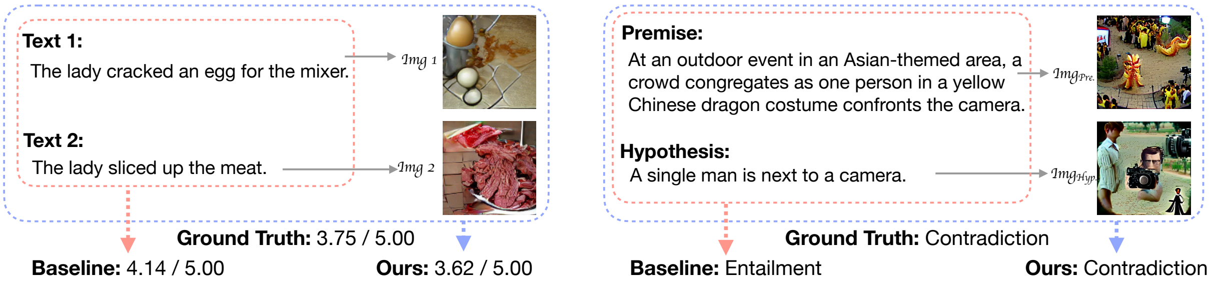
Table 4: **Model-agnostic Improvement in Full Data Setting.** Results of iACE and VOKEN upon BERT and RoBERTa of small($6L/512H$) and base($12L/768H$) architecture are reported. The models are fine-tuned over GLUE Benchmark and SWAG with access to the full dataset. **BEST** results are highlighted.



Text 1:
The lady cracked an egg for the mixer.

Text 2:
The lady sliced up the meat.

Ground Truth: 3.75 / 5.00

Baseline: 4.14 / 5.00

Ours: 3.62 / 5.00

Premise:
At an outdoor event in an Asian-themed area, a crowd congregates as one person in a yellow Chinese dragon costume confronts the camera.

Hypothesis:
A single man is next to a camera.

Ground Truth: Contradiction

Baseline: Entailment

Ours: Contradiction

(a) STS-B

(b) SNLI

Figure 4: Case studies on the STS-B and SNLI tasks. The baseline models yield predictions solely based on the text input, while our approach takes both the text input and corresponding visualization into consideration. On both tasks, our iACE gives predictions that are more aligned with the ground truth.

setting and full data setting. To validate such model-agnostic effectiveness of our proposed novel paradigm in processing natural language, we compare the performance with two language models (BERT and RoBERTa) of two architectures ("6L/512H" and "12L/768H"), and a strong visually supervised pre-trained baseline VOKEN (Tan and Bansal, 2020).

Table 4 shows the metric comparison on GLUE and SWAG. The base models are trained with a masked language model. The VOKEN model is pre-trained with a masked language model with an additional voken-classification task as introduced visual supervision. iACE achieves model-agnostic improvement over the model that solely fine-tune based on textual information, including the pure-language-based model and visually supervised pre-trained model. The gain is consistently observed from different architectures of models.

4.5 Case Study

Figure 4 lists out our examples for the case study. We show the results from the natural language inference and sentence similarity task. We use examples from the STS-B and SNLI datasets. Our contextual imagination describes the textual input as expected and provides an external prediction reference.

For example (a), given the structurally diversified sentence and low n-grams overlaps but high semantic similarity, we observe that the pure language-based model predicts the wrong label. While the imagination helps the model capture the semantic similarity between two textual inputs via comparing the cross-modal semantics with the imagination information. From example (b), we observe the pure language-based model predicts the wrong label based on the similar sentence structure and high n-grams overlaps. While the imagination helps the model capture the difference between the similar premise and hypothesis text.

5 Conclusion

We treat the text-only learning problem in Natural Language Understanding tasks as a cross-modal language understanding problem with generated imagination as supervision. In this scenario, the task aims to bridge the gap between the human and the agent language understanding in both linguistic and perceptual procedures. To address the proposed problem, we devised a model-agnostic learning paradigm iACE. Specifically, we build the imagination of the downstream dataset using an interactive generative approach with guidance from a self-supervised pre-trained large-scale image and text model. Our proposed iACE surpassed baselines of two architecture sizes by a large margin in the few-shot setting. The improvement is consistently observed over pure-language baselines (BERT and RoBERTa) and visually supervised VOKEN on the GLUE and SWAG dataset. The results show the superiority of our iACE in language understanding and handling low-resource circumstances.

Ethical Statement

In this study, we only cover NLU datasets with English annotations. Such limitation is since the large-scale pre-trained multimodal models used in our studies, such as CLIP and VQGAN, are only trained on English corpus as of the date we conduct the experiments [2].

This study use CLIP and VQGAN to render images given the text prompt. Suppose there exists any bias in the training dataset for the large-scale pre-trained multimodal models used in our study. In that case, our "imagination" approach may face an issue of fairness since the visual generative model might be more likely to illustrate specific types of images that it has seen in the training data. Moreover, if the training dataset for CLIP or VQGAN contains any personal information, then our "imagination" approach may strike a threat on privacy leakage given certain triggers or prompts. Even though we did not witness such issues in our study, we should keep in mind that the aforementioned behaviors would impair iACE's effectiveness.

What company do words keep?
Revisiting the distributional semantics of J.R. Firth & Zellig Harris

Abstract

The power of word embeddings is attributed to the linguistic theory that similar words will appear in similar contexts. This idea is specifically invoked by noting that "you shall know a word by the company it keeps," a quote from British linguist J.R. Firth who, along with his American colleague Zellig Harris, is often credited with the invention of "distributional semantics." While both Firth and Harris are cited in all major NLP textbooks and many foundational papers, the content and differences between their theories is seldom discussed. Engaging in a close reading of their work, we discover two distinct and in many ways divergent theories of meaning. One focuses exclusively on the internal workings of linguistic forms, while the other invites us to consider words in new company—not just with other linguistic elements, but also in a broader cultural and situational context. Contrasting these theories from the perspective of current debates in NLP, we discover in Firth a figure who could guide the field towards a more culturally grounded notion of semantics. We consider how an expanded notion of "context" might be modeled in practice through two different strategies: comparative stratification and syntagmatic extension.

1 Introduction

> We are in the world and the world is in us.
>
> Alfred North Whitehead
> (1938; cited in Firth 1957c, 29)

If you have read any papers in computational linguistics in the past thirty years, you have likely come upon the following quote from British linguist J.R.Firth (1957c, 11): "You shall know a word by the company it keeps". Cited in most major textbooks (Manning and Schütze, 1999; Jurafsky and Martin, 2009; Eisenstein, 2019; Russell and Norvig, 2020), several foundational papers, and hundreds of other NLP articles, this phrase has come to index a theoretical orientation in a field that is increasingly focused on computation, often at the expense of linguistic theory (on these trends in NLP see Halevy et al., 2009; Manning, 2015; Norvig, 2012; Henderson, 2020; Church and Liberman, 2021). Together with American linguist Zellig Harris, Firth is regularly called upon to justify a distributional theory of semantics, whereby the meaning of lexical units is conceived in terms of relative co-occurrence and shared contexts of use (Sahlgren, 2008).

While Harris and Firth are often invoked, their ideas are seldom closely engaged. Hailing from disparate traditions, Harris and Firth had radically different ideas on the scope and context of linguistic analysis, and presented incongruent versions of the distributional method. Drawing on the information theory pioneered by Claude Shannon (1948), Harris was determined to work out a structuralist theory of language in terms of mathematical information (Léon, 2011; Nevin, 1993). Firth, on the other hand, came to linguistics via anthropology and borrowed heavily from pragmatic philosophies of language. For him, linguistic analysis always started with the "context of situation" and necessarily accounted for non-verbal actors and objects (Firth, 1957c, 9).

Considering the definition and extent of linguistic context is important for many reasons, as a spate of recent publications suggests (Glenberg and Robertson, 2000; Hovy, 2018; Bender and Koller, 2020; Bisk et al., 2020; Tamari et al., 2020; Trott et al., 2020). Firstly, it touches upon the limits of current paradigms in NLP, where corpus linguistics is perfected through increasingly complex models trained on increasingly massive corpora (Bender et al., 2021). This approach may advance the identification of linguistic *form*, but might ultimately have little to say about the relation of *meaning* to the social world (Bender and Koller, 2020; Bisk et al., 2020). Secondly, even with more modest ambitions, several NLP applications—e.g., with

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4403 - 4417
July 10-15, 2022

spatial (McKenzie and Adams, 2021) or historical (Kutuzov et al., 2018) data—require that linguistic patterns be related to other types of structure. Thirdly, from sociological and sociolinguistic perspectives, meaning intrinsically varies as language is used in different settings and indexed to different social categories (Labov, 1972; Bourdieu, 1984; Silverstein, 2003; Eckert, 2008; Hovy, 2018). Finally, without a broader sense of context, NLP and language modeling in particular remains trapped in a paradigm where language is always treated as universal, making invisible both different speech communities (e.g. Nguyen et al., 2021) and the biases of language (e.g. Blodgett et al., 2020; Lu et al., 2020; Sap et al., 2020).

After a brief history of distributional semantics, we outline Harris' and Firth's research on distribution and, more broadly, on the scope of linguistic analysis. We look at some of the ways in which NLP has tried to account for broader context within the distributional paradigm. We suggest that existing strategies can be understood in terms of either "comparative stratification" or "syntagmatic extension." We conclude with thoughts on why rereading Harris and, in particular, Firth might aid the field of NLP with its current aporias. If words shall be known by the company they keep, then the question follows: what *kind* of company do they keep? Are they found only alongside linguistic elements, or do they mingle with other types of entities? Or, as Firth himself wrote: "Many different answers could be given to the question 'Distribution of what, where and how?'" (Firth, 1957a, *v*).

2 Background: Distributional Semantics and NLP

Distributional semantics has been an fundamental part of computational linguistics since the beginnings of the field, but in a discontinuous manner encompassing at least two distinct eras. Firstly, during the 1950s and 60s, Harris was integral to the mathematization of linguistics in the US after the Second World War (Rubenstein and Goodenough, 1965; Léon, 2021). Firth was skeptical of efforts to mechanize linguistics,[1] but he nonetheless consulted for some of the early work on machine translation at Cambridge Language Research Group (Léon, 2007, 410), which included Firth's pupil, M.A.K. Halliday (Léon, 2021, 144) and shortly later the NLP pioneer Karen Spärck Jones (Léon, 2021, 89). Naturally, others also contributed to this first wave of distributional thinking, including Shannon (1945; 1948) with what might be considered one of the first language models, Warren Weaver (1952) with an early proposal for distributional semantics, and Martin Joos (1950) with a statistical formulation of language as a symbolic system of conditional probabilities.

Secondly, when computational linguistics returned to its "empiricist" roots in probabilistic methods and information theory in the mid-80s and early 90s (Norvig 2012; Léon 2021, 141), Firth and Harris accompanied Shannon among the authors who were invoked, in an ACL "Special Issue on Computational Linguistics Using Large Corpora," as foundational figures of a tradition that had been overshadowed for decades by the "rationalism" of characters such as Noam Chomsky and Marvin Minsky (Church and Mercer, 1993, 15). During this "corpus turn," the rapid automation of linguistics was driven by a resumed connection with postwar computational linguistics and information theory (Léon, 2021, 3). However, the 1990s wave of vector semantics papers that used methods like singular-value decomposition (SVD) to produce early "dense vector" models of meaning like LSA (Deerwester et al., 1989, 1990; Landauer and Dumais, 1997) and its derivatives (Hofmann, 1999; Blei et al., 2002), HAL (Burgess, 1998), or the models of Schütze (Schütze, 1992, 1993; Schütze and Pedersen, 1993) generally did not cite Firth or Harris, although a few papers from that period did (Church and Hanks, 1989; Hindle, 1990). In short, while Firth and Harris were not regularly used as stand-ins for linguistic theory during the 1990s and early 2000s, a general revival of empiricism and distributional approaches to meaning signaled a potential resurgence of interest in their thinking.

During the 2000s, the application of neural networks to language modeling tasks (e.g. Bengio et al., 2003) and the development of self-supervision techniques (e.g. Raina et al., 2007) set the stage for the word embedding breakthroughs of the early 2010s (e.g. Mikolov et al., 2013). By the end of the decade, the introduction of attention (Graves et al., 2013; Bahdanau et al., 2015) and then of the Transformer model (Vaswani et al., 2017) made way for the next breakthrough, the

---

[1] He seemed to consider the idea Orwellian (Firth, 1957b) and repeatedly attacked Norbert Wiener (e.g. Firth, 1968a,c), a pioneer whose work would later be considered foundational for connectionist AI (Goodfellow et al., 2016; Russell and Norvig, 2020).

large-language modeling revolution (e.g. Peters et al., 2018; Devlin et al., 2019; Chowdhery et al., 2022).

Following the introduction of the word2vec model and its powerful but "static" embeddings, Harris in particular was frequently cited (Le and Mikolov, 2014; Levy and Goldberg, 2014; Levy et al., 2015; Bojanowski et al., 2017), often (but not always) along with Firth (Bruni et al., 2014; Hamilton et al., 2016; Goldberg, 2017; Eisenstein, 2019; Jurafsky and Martin, 2021). However, despite an explosion of citations (Bisk et al., 2020, 8719), this interest has not been very engaged. In fact, the canonization of Firth and Harris during this time is paradoxical. On the one hand, it seems that they are invoked to lend theoretical authority to a field that struggles to lift its gaze from the latest state-of-the-art numbers (Manning, 2015; Bender and Koller, 2020). Yet, the unspoken conclusion from the ascent of neural models and the language modeling revolution was that "learning from data made linguistic theories irrelevant" (Henderson, 2020, 6295). In other words, just as NLP seemed to lose interest with linguistic theory, it elevated two pioneering theoreticians to canonical status, but seemingly without engaging closely with their work. In fact, it often seems as if Firth and Harris are referenced in such a cavalier manner that it deflects attention from the field's general lack of engagement with linguistic theory. Meanwhile, Firth and Harris became figures who justify a relatively narrow conception of meaning, one that is predominantly intra-linguistic, without much to say about its usage in social life.

This peculiar story has not been properly told. Though Léon discusses the contrast between Harris and Firth in the context of corpus linguistics (2008) and their influence on the history of computational linguistics (2021), her work does not address the differences in their distributional theories and conceptions of "context," nor the renewed and paradoxical significance of the two authors for language modeling. In our contribution, we emphasize the gap between the ideas of Firth and Harris as well as the insights a re-reading of their work offers for expanding the scope of computational semantics.

3 Harris's distributional structuralism

Few linguists contributed more to linguistic theory than Zellig Harris (1909–1992), and not just by serving as Noam Chomsky's doctoral advisor. In fact, the two came to share little in common (Goldsmith, 2005; Nevin, 2010). Whereas Chomsky's generative grammar repositioned linguistics as a cognitive science seeking to understand, in so few words, the idealized mental representations and structures enabling language acquisition and production (e.g. Chomsky, 1972), Harris' radically distributional approach to language effectively elevated the natural language corpus as the sole starting point from which linguistic theory could arise (Harris, 1951, 1; Harris et al., 1988, 2–3; Johnson, 2002, 143–144).

This theory consisted of a linguistic structure segmentable into a finite set of formal objects characterized by constrained patterns of correspondence with one another (Harris, 1951, 1954, 1991). Such patterns of correspondence can be observed only in language-in-use, that is, in natural language corpora. In his foundational paper "Distributional Structure," for example, Harris (1954, 156–157) provides a purely distributional account of how one might induce the semantic meanings of *oculist*, *eye-doctor*, and *lawyer* from the partial (in the case of *oculist* and *lawyer*) or nearly complete (in the case of *oculist* and *eye-doctor*) overlap in their observed "environments" of use. This approach applies to other levels of linguistic analysis, such as morphophonemics (e.g., Harris, 1954, 155). Rather than producing a series of descriptive rules for the distribution of each phoneme, morpheme, or word, greater parsimony was sought by grouping these elements into structurally equivalent classes—categorized by their relationships as "operators" and "arguments" in Harris' later work (e.g. 1968; 1988; 1991)—sharing the same distributional rules, compounding elements in a hierarchical manner.

In this section we draw attention to three aspects of Harris's distributional linguistics: the relationship it posits between meaning and form; assumptions about heterogeneity among speakers of the same dialect; and the concept of sublanguages.

3.1 Meaning and form

A result of Harris' vision of a linguistics—concerned above all with the structural and probabilistic constraints governing the combination of formal elements—is that the discipline would be fully autonomous, not only from biology and psychology but even from semantics, phonetics, and logic, "complete without intrusion of other features such as history or meaning" (Harris 1954, 146; Goldsmith 2005, 725–726).[2] Harris's reasoning depended on the particular status he gave to linguistics among all the sciences. Taking language as its object of inquiry, linguistics lacks—unlike other sciences—a *metalanguage* external to language, i.e., to its object of inquiry (Harris, 1991, 4–5; Nevin, 1993, 356). Even if some other symbolic system is used, "those symbols will have to be defined ultimately in a natural language" (Harris, 1991, 274), as the surging demand for interpretability and explainability in NLP has made evident (see e.g. Danilevsky et al., 2020). Language is consequently not a "code" of "forms" that correlate with some meanings outside of it. It has no "one-to-one" conformity "with some independently discoverable structure of meaning" (Harris, 1954, 152). Instead, it is a system related to, but also independent from, thought (Harris, 1991, 383–384; Nevin, 1993, 361–363). While all human activity is meaningful, the particular meanings of language are *constituted* by its form, not *correlated* with it (Nevin, 1993, 394). Meaning thus understood is about departures from equiprobability in the distribution of these constraints (Harris, 1991, 23). These departures "define a range of meaning for each morpheme, which includes its meaning in each occurrence". Nonetheless, shared environments do not necessarily imply shared meanings: "bumped into a pole can be said after a minor accident or after a chance meeting with an East European" (Harris, 1951, 191).

The ultimate goal of Harris's linguistic inquiry is to evaluate the efficiency of different grammars and their ability to model the statistical constraints imposed upon the distribution of different linguistic elements (Goldsmith, 2005, 723–725). Harris held that language was a "detached pattern" (Harris, 1941, 295)—information that was public and socially transmissible and hence constitutive of new types of socially shared and conventional meaning (Harris, 1991, 342–345, 377–382; Nevin, 1993, 360, 365)—and linguistics could at best discover different incomplete grammars (Harris, 1991, 31–36). Though linguistics might provide insights about meaning and discourse, or about cultural practices, such findings would not bear directly on linguistics *per se* (Goldsmith, 2005, 725–726). Indeed, while Harris acknowledged that our sense of word meaning is aided by "extra-linguistic situational information," words "beyond the immediate situation" are "on their own" (Harris, 1991, 368). However, Harris's method is not completely detached. Searching for a method to segment speech, he notes that the similarity of elements "reduces ultimately to the similarity of sound segments under repetition," implemented through "the pair test" in which native speakers are asked to discriminate between sound segments (Harris, 1954, 158–159), producing an observational primitive that is "more easily controlled than data on meaning" (e.g. Harris, 1951, 20).

3.2 Variation, or lack thereof

Harris's view of language and linguistics, isolated from the vagaries of social interaction and variation, is obviously difficult to reconcile with a sociolinguistic perspective. As Harris writes in his *Structural Linguistics* (1951, 9), his approach is meant to describe a homogeneous dialect, which "[i]n most cases...presents no problem, since the whole speech of the person or community shows dialectal consistency." Referencing this passage, sociolinguist and dialectology pioneer William Labov (1966/2006, 5) argues that "the inconsistency found in most New York City idiolects is so great that the first alternative of Harris is impossible, and the second implausible."[3] In other words, even at the level of the speaker, Harris's idealized, unvarying idiolect does not hold up to empirical scrutiny. Rigorous consideration of factors that Harris would deem extra-linguistic (class, race, interactional roles, etc.) are indeed essential to produce a systematic description of linguistic structure (Labov, 1972). From the sociolinguistic perspective, Harris's vision of a linguistic science fully isolated from the "intrusion" of non-verbal social life would never obtain the systemicity to which it aspired.

This sociolinguistic critique highlights fundamental limitations of Harris's perspective. Language is viewed primarily through the distributional restrictions imposed by convention, rather than by "stylistic practice" and the ways in which speakers "make social-semiotic moves, reinterpreting variables and combining and recombining them in a continual process" (Eckert, 2012, 94). We can

---

[2] Indeed, as Jacqueline Léon notes (personal communication, April 18, 2022), even calling Harris' approach "semantics" is bit of an oxymoron. We elide a full discussion on the term since "distributional semantics" has become a commonplace phrase in NLP.

[3] New York City is not unique in this regard; it was merely the location of Labov's early pathbreaking work.

study changes in discourse, as Harris himself did in an impressive volume on structures in immunological theory over time (Harris et al., 1988), but not how people make those changes, or indeed the way in which it is "the variation itself that is systemic" (Deleuze and Guattari, 1987, 93).

3.3 Sublanguages

As noted above, Harris' revival in the 1990s was driven by the new interest in "corpus linguistics" of large corpora, a research paradigm that was partly derived from Harris' notion of "sublanguages" (Léon, 2021). Harris introduced sublanguages in his book *Mathematical Structures of Language*, defined as "[c]ertain proper subsets of a language [which] may be closed under some or all of the operations defined in the language, and [which] thus constitute a sublanguage of it" (Harris, 1968, 152). A sublanguage is a set of sentences which are a subset of the sentences of the "whole" language. However, the grammatical constraints of the sublanguage are not necessarily those of the whole language; rather, their grammars intersect (Harris 1968, Ch 11; Kittredge and Lehrberger 1982, 1). In application the term has come to refer primarily to the grammar and vocabulary unique to or characteristic of a particular professional or scientific field (e.g. Harris, 1988), an influential concept for early information retrieval research (Sager, 1975, 1981).[4] Harris believed that sublanguages could be neatly identified using the distributional methods of his general linguistic program.

4 Firth's contextual semantics

Something similar to the sociolinguistic critique of Harris could be articulated from a different perspective, namely, through the work of J.R. Firth. Firth (1890–1960)—professor of General Linguistics at the University College of London and the first holder of a chair in that subject in Britain—independently formulated a distributional theory of lexical semantics. However, unlike Harris, Firth refused to treat meaning separately from pragmatics, and words apart from their broader "context of situation." (Robins, 1997, 205–208)

Firth never published a fully articulated exposition of his general theory of language (Robins 1997, 216; Thomas 2011, 180) and today, all of his work is not only out of print but also mostly unavailable online. Not understood by "the contemporary scientism" of American descriptivist linguistics and its pioneers like Harris, Firth was mostly ignored on the other side of the Atlantic (Palmer 1968, 2; Pandit 1970, 280). Unlike many of his American contemporaries, Firth did not draw mainly from cognitive psychology and logic—the latter of which Firth thought had "taken the heart out of language" (Firth, 1957a, 186)—but from the work of Polish anthropologist Bronisław Malinowski (Robins, 1997, 211). Here, we focus on the evolution of his thoughts on meaning and collocation, as well as his notions of *context of situation* and *restricted language*.

4.1 Meaning by collocation

To Firth, the purpose of linguistics is to "study meaning in its own terms" (Firth 1968b, 145; Senis 2015, 289). The famous phrase about the company that words keep concerned a particular "mode of meaning": "meaning by collocation" (Firth, 1957b, 194). Anticipating vocabulary now ubiquitous in NLP, Firth thought that this level of meaning could be found by examining the "habitual collocations" of words and the "word-material" in which they are "most characteristically embedded" (Firth, 1957c, 11–12). Meaning by collocation was an abstraction of *syntagmatic relations* (Oyelaran 1967, 444) that went beyond "mere juxtaposition," stating instead "an order of *mutual expectancy*" and "mutual prehension" (Firth, 1957c, 12). While mutual expectancy could be understood similarly to Joos's (1950) conditional probabilities of occurrence or the concept of Pointwise Mutual Information (Fano, 1961), the notion of "prehension" originates in the work of philosopher and mathematician Alfred North Whitehead (1938, 1957; see also Butt 2013) and concerns the manner in which one entity grasps another and makes it part of its own experience (Christian 1959, 12; Bryant 2011, 136).

Drawing on Whitehead's "modes of thought" (1938; see also Butt 2001, 1812, Butt 2019, 28), Firth advocated a type of "polysystemic" linguistic analysis that was interested in different, congruent modes of meaning, whether phonetic, phonological, syntactic, or semantic, but always situated in broader social context (Firth 1957c, 27, 30 ; Robins 1997, 214). In stark contrast to Harris, Firth explicitly rejected any efforts to create "unity in linguistics" (Firth, 1968d, 48) or one system of analysis.

---

[4] An important early figure in NLP, Sager received her PhD in Linguistics at the University of Pennsylvania and was directly influenced by Harris's work. See, e.g, Hirschman, Grishman, and Sager (1975).

Citing the later Wittgenstein (1953, Firth 1957c, 11), Firth was mainly interested in the concrete use of language, reversing the schema of Ferdinand de Saussure (1916/2011) in which language (*la langue*) is a system "external to and on a different plane from individual phenonema," including the concrete instances (*la parole*) of language use (Firth 1949, 400; Firth 1950, 44–45). While his final ideas matured considerably later, Firth initially articulated his ideas about semantics in two 1935 papers, one on semantics (Firth, 1935a) and one on phonology (Firth, 1935b), using the term "contextual distribution" in both. However, Firth (1957c, 18) ultimately disavowed this initial distributional theory—which was not too dissimilar from Harris's—as "useful" but inadequate to act as the "main principle" in a theory "of structures involving the statement of the values of the elements of structure by reference to systems."

By distinguishing between system (syntagm) and structure (paradigm), Firth wanted to highlight two operational principles necessary for meaning by collocation: 1) substitution within "the same level of abstraction," and 2) commutation across different levels (Robins, 1953, 140). Only substitution that does not produce commutation in a sequence, indicates similarity of value or function (Firth 1957c, 5; Firth 1968c, 23)[5]. Two words are only substitutable—and hence similar in function and meaning—if their values do not commute across a particular sentence. Substitutability, then, does not equal synonymy. Take, for example, the following two phrases containing a) prepositional and b) adverbial uses of the word "by":

(a) They go by night.
(b) They go by night after night.

Now, "by" could be replaced by the word "past" without commuting the meaning of the other words in (b). However, replacing "by" with "past" would commute with the rest of (a) in an impossible way (Firth, 1968c, 23–24). This demonstrates how substitution concerns the relationship between "by" and "past" as two elements at the same level of analysis—i.e., lexical units—but in order to account for commutation, we need to look beyond this level to other levels of abstraction.[6]

Firth's conception of collocation and his frequent nods to Whitehead were part of his "monistic" approach that rejected the division between mind and body (Firth 1957c, 2; Palmer 1968, 5) and all the other dualities—language and thought, word and idea, signifier and signified, expression and content (Firth, 1951, 86)—that characterized the structuralist linguistics of his time. He similarly rejected any notion of linguistics as "a *theory of universals* for *general linguistic description*" (Firth, 1957c, 21). Anticipating contemporary concerns about language diversity in NLP (e.g. Bender, 2019), Firth called for the Western scholar to "de-Europeanize himself" and the English scholar, due to the universal use of his language, to "de-Anglicize himself" (Firth 1968a, 96; Senis 2015, 274).

4.2 Context and connection

Diverging from structuralist linguistics, Firth suggested that a text should always be given a "renewal of connection with experience" (Firth, 1957c, 29). This notion of meaning was influenced by Malinowski, for whom Firth worked as an assistant early in his career (Plug, 2008, 346) and from whom he borrowed the notion of "context of situation" (Firth 1935a, Robins 1997, 211). In Malinwoski's view, meaning was more than just a dyadic relationship between a word and its referent, "a multidimensional and functional set of relations between the word in its sentence and the context of its occurrence" (Robins, 1971, 35). However, while Malinowski's view on meaning was entirely functional and hyper-local, Firth employed the notion of "context of situation" as a necessary abstraction, not as a shorthand for things in themselves (Firth 1950, 43, Palmer 1968, 6). Context of situation is derived from an analytical choice, "a set of categories in ordered relations abstracted from the life of man in the flux of events, from personality in society," (Firth, 1957c, 30) prehending something of importance and bracketing the rest. It is, then, not necessarily about restricting the meaning of every utterance to a specific time and place, but about defining "an abstract set of semantically relevant categories, abstracted from multitudes of actual situations, to which unique particulars could be referred." (Robins, 1971, 41–42) Firth called for the linguist to focus on "attested language text duly recorded", accounting for a text's associated context of situation *and* its interior relations. (Firth,

---

[5] For further details, see examples provided by Bursill-Hall (1960).

[6] A useful analogy might be the way in which BERT handles different aspects of language at different layers of the model (Tenney et al., 2019, e.g.). However, no matter how large, a language model like BERT does not account for the context of situation.

1957c, 29–30)

Firth was famously opaque with the exact operationalization of his concepts, including context of situation, but he did provide a detailed list of the different contextual elements that a linguist should bring into relation during analysis (Firth, 1950, 43). These include the relevant features of participants (persons, personalities); their verbal and non-verbal actions; the relevant objects; and the effects of verbal action.

During Firth's lifetime, the most thorough work that put his notion of context of situation to work was an ethnographic study by his student T.F. Mitchell in former Cyreneica (today Libya) on the language of buying and selling at the local markets of different cities and villages in the region. For Mitchell (1957, 32–33), contexts that might "correlate" with particular types of text included: the spatio-temporal situation of persons in the context; the activities of participants; the attitudes of the participants; their "personalities" such as specific trade of profession, geographical and class origins, educational standard, inter-relationship, and so on.

It is worth noting that both Mitchell and M.A.K. Halliday—Firth's student who synthesized much of his theory—used words such as "correlation," "inference," and "prediction" to describe the relationship between a text and its situational context, implying that a statistical extension of their approaches would not be completely unreasonable. In fact, Halliday himself suggested as much, when he in the early 1990s made efforts to bridge his branch of linguistics with the nascent field of corpus linguistics (Halliday, 1991).

In conclusion: Firth's famous quote itself refers to collocation, while his notion of "context" implies something much broader, "the whole conceptual meaning" (Firth, 1957c, 11). Context is the ground against which the figure of the text must be understood, no matter (per Harris) how "detached" its pattern might be (e.g. Auer, 1996). Without context, collocation captures only one narrow "mode of meaning."

4.3 Restricted languages

Like Harris, Firth's revival in connection with 1990s corpus linguistics was related to his attempts to respond to practical needs of empirical research. Expanding upon his functional understanding of language, Firth developed his notion of "restricted languages" in the 1950s (Léon 2007, 7). In a posthumously published essay, he describes social actors as "collect[ing] a varied repertory of interlocking roles" corresponding to a "constellation of restricted languages" (Firth, 1968e, 207). As people shift between locally contextualized roles, they draw upon their "repertory" of restricted languages with specialized vocabulary and discursive styles that both reflect and constitute these contexts. Thus one might speak of a "restricted language of science, sport, defense, industry, aviation, military services, commerce, law and civil administration, politics, literature, etc." (Léon, 2008, 261). As such, the concept of restricted language is now generally seen as a precursor to the concept of "register," which was taken up by subsequent sociolinguists and linguistic anthropologists (e.g. Halliday, 1968; Gumperz and Hymes, 1972; Agha, 2005).

In proposing restricted languages as the proper object of descriptive linguistic analysis, Firth was making a broader theoretical point against, on the one hand, "the monosystemic view of language" of neo-Bloomfieldians like Harris and "pointless discussions on metalanguage" on the other, for metalanguage could be reanalyzed as a "restricted language of linguistics" itself (Léon, 2007, 9). Simply put, a descriptive linguistics which privileges restricted languages also necessarily privileges contexts of situation as an essential dimension of variation that allows social meaning to inhere in language.

5 Discussion: Words in mixed company

Often cited, together or separately, to justify a distributional appraoch to semantics, Firth and Harris nonetheless offer differing views on language and meaning. Harris offers us a rigorous formalism that treats language as a "detached pattern"—not a "code", but a particular system of meaning. Firth, by comparison, left a much more scattered legacy that was only systematized by his students. Firth and Harris shared a concern about the lack of an external metalanguage of linguistics, but drew different conclusions from it. If Harris responded to this conundrum by creating one hierarchically organized system without intrusion from extra-linguistic factors, Firth called for an investigation of language as a "spectrum" (Firth, 1951, 76) with different modes of meaning that had to be addressed through multiple levels of analysis—starting with the context of situation and proceeding from there to decide which other levels are relevant (Firth, 1950, 44). Firth's distributional theory has been described unfavourably as based on frequent co-occurrence, in contrast to the recursive dependencies developed by Harris (Habert and Zweigenbaum, 2002, 205). For Harris, the meaning of a word depends on its set (e.g. Harris, 1991, 17) such that, for example, the words "divide" and "multiply" operate on the word "cell" (and vice versa) in the same way, producing essentially the same meaning (Harris 1988, 62). However, Firth's final method of substitution and commutation also establishes complex, multidimensional criteria for distributional contrast as well as a framework for understanding polysemy. Though less formalized and less obviously recursive than Harris', Firth's approach can, arguably, also be read as treating linguistic elements as operators and arguments defined by their sets in a complex hierarchy (Firth, 1950, 44; Firth, 1951, 76 "at a series of congruent levels" (Firth, 1957c, 29–30) with different "bands of abstraction" (Firth, 1968d, 49), *including* the extra-linguistic context of situation. Harris and Firth both understand any linguistic analysis as incomplete, for Harris always a pursuit of the least description" (Harris, 1988, 3)—i.e., best "grammar" or model—for Firth always grounded in the social construction of facts, without any possibility of "complete axiomatization" (Firth, 1968d, 44–45).

From the perspective of empirical work, especially decades after their time, Firth and Harris also share similarities. Both rejected the mentalism that was so prevalent during their time. They were both revived as empiricist originators during the rise of statistical learning in the 1990s, and their respective work on restricted languages and sublanguages largely conflated in service of the practical concerns of corpus linguistics (Léon, 2008). Their theories both included in what we might call a "reality principle," a final arbiter of meaning outside of form: the pair test for Harris, the context of situation for Firth. The former grounds linguistics in the smallest possible unit of analysis as understood by the native speaker, the latter in social actions and objects.

In light of recent calls to extend the "world scope" (Bisk et al., 2020) of NLP and to move towards pragmatic notions of meaning, it might make sense to balance Harris's formalism and Firth's pluralism. Though Firth warned us against overextending linguistics, he was generous with the company that words could keep. They mingled with each other, but also with events, objects, people, and indexical features such as time and space. And if NLP is ready to move beyond the corpus, then even Harris might acknowledge that when modeling language in "the immediate situation"—whether in online interactions or face-to-face communication—words are *not* on their own, that to judge the meaning of a combination of words, we can summon "the aid of some of the extra-linguistic situational information" (Harris, 1991, 368). In the following subsections, we consider two ways in which NLP is already doing this, in order to highlight some already existing strategies for broader contextualization. We call these strategies "comparative stratification" and "syntagmatic extension."

5.1 Comparative stratification

Corpus linguistics emerges from the question of what kind of company words keep, depending on their context. The issue of context was motivated by the introduction of corpus linguistics both for students of Firth—who considered restricted languages as a way of handling context—and for Harris's sublanguages, which were "contextually situated and suitable for being processed automatically" (Léon, 2021, 149–150). However, beyond just studying the restricted corpus, we might also consider the ways in which large datasets can be "stratified," systematically dividing them into subcorpora that are studied in relation to each other. Here, the company that words keep among each other is *limited* for analytical purposes, but in a manner that implies a relationship between that "company" and situational context.

Diachronic embeddings are especially representative of this approach. By stratifying timestamped data into a number of intervals, training separate models for each and then aligning the embeddings using either "second-order embeddings" or methods such as linear transformations (Kutuzov et al., 2018), the analyst can effectively represent a temporal "context of situation." This approach works with both static (Hamilton et al., 2016) and contextual embeddings (Martinc et al., 2020). While variants of this approach are most commonly used to study semantic shifts (e.g., Garg et al., 2018; Kozlowski et al., 2019; Mendelsohn et al., 2020), it could plausibly be used to stratify a dataset according to other variables such as space (e.g. Bamman et al., 2014; Gong et al., 2020), online communities (Lucy and Bamman, 2021), persons (Yao et al., 2020), or domains (Spinde et al., 2021). Words still only keep the company of one another, but by limiting their company we implicitly introduce other participants in the analysis.[7]

5.2 Syntagmatic extension

Recall that for Firth, meaning by collocation and considerations of a "typical context of situation" (Firth, 1950, 44) were exercises in abstraction, with collocation being an abstraction at the syntagmatic level. Instead of restricting the company words keep, we might follow Firth's recommendation to consider them in wider company "of the same abstract nature" (Firth, 1950, 7). In vector semantics, this would imply that we explicitly introduce different contextual factors in the *same* vector space with our words, endowing them all with ontological equality.

The paragraph vectors introduced by Le and Mikolov (2014) as an extension of the earlier Skip-gram algorithm (Mikolov et al., 2013) are representative for this approach. In practice, this method extends the syntagmatic chain of words by introducing a vector for the document as a new paradigmatic element. In principle, this type of "global context" (Grbovic and Cheng, 2018) could be anything and include several paradigmatic elements, as we can see in the research on multi-modal embeddings (e.g. Baroni, 2016) and generative modeling (e.g. Ramesh et al., 2022).[8] Models have been developed that include demographic (Garimella et al., 2017) or persona (Li et al., 2016) vectors in the embedding space, such that intra-textual relations are accompanied by information about speakers' social categories. However, implemented with static embeddings and without some additional grammar restrictions, these context vectors essentially add only a "bag of contexts." For static embeddings, additional grammar constraints could be introduced, as was done in research on Point-of-Interest (POI) data in the the domain of geosemantics, where researchers constrained contextual vectors using spatial variograms (Yan et al., 2017). Beyond static embeddings, large-language models and their dynamic embeddings could either be pretrained (with the appropriate dataset) or finetuned on data with text associated with different contextual variables. This would realize the proposal that Halliday made in the early 1990s when he suggested an extension of the language modeling schema from the early work of Shannon, to a model with "global probabilities, those of the grammar of English, and the locally conditioned probabilities, those of this or that particular register" (Halliday, 1991, 37).

6 Conclusions

This paper revisited the theories of the two most well-known progenitors of the distributional approach to meaning in NLP. Recognizing the open question of how to bring NLP beyond the corpus, we offer a thorough account of the two distributional theories that are most often invoked to justify the modeling of meaning through departures from randomness in the company that words keep. Comparing the work of Harris and Firth—who both published their major work before the rise of the internet and its corpora—we find two distinct theories of distribution: one formal and mathematical, treating language as a particular type of detached information, another more schematic and anthropological, treating language as a functional spectrum which always emanates from a particular context of situation. The legacies of both Firth and Harris can be seen in the current paradigm of corpus linguistics, but in the domain of distributional semantics, it is Harris's ethos that dominates, despite Firth providing its most famous tagline.

Moving forward, we suggest that semantic modeling take more inspiration from Firth, and consider the context of situation and the wide variety of company that words can keep as crucial sites of innovation for the field. Doing so may not involve following a finite set of steps or flowchart. Rather, we humbly suggest that the field may be enriched by thoughtful and creative re-engagements with the intellectual traditions from which it has historically drawn. This does not imply abandoning the rigor provided by Harris. On the contrary, we find that Firth and Harris would probably have agreed that any model or "grammar" is inevitably incomplete and partial. No universal model is possible, despite the large-language modeling fervor, nor will there be one theory of language to guide us. There are only the partial perspectives and the inevitable choice of adapting one.

---

[7] In a very broad sense, the trend of pretraining large language models and then finetuning them on specific datasets is of course also an admission of the importance of "context of situation."

[8] Firth himself (1957c, 26) recommended accompanying word definitions and collocational information with pictures.

Compositional Task-Oriented Parsing as Abstractive Question Answering

Wenting Zhao[1] * and **Konstantine Arkoudas**[2] and **Weiqi Sun**[2] and **Claire Cardie**[1]

Abstract

Task-oriented parsing (TOP) aims to convert natural language into machine-readable representations of specific tasks, such as setting an alarm. A popular approach to TOP is to apply seq2seq models to generate linearized parse trees. A more recent line of work argues that pretrained seq2seq models are better at generating outputs that are themselves natural language, so they replace linearized parse trees with canonical natural-language paraphrases that can then be easily translated into parse trees, resulting in so-called naturalized parsers. In this work we continue to explore naturalized semantic parsing by presenting a general reduction of TOP to abstractive question answering that overcomes some limitations of canonical paraphrasing. Experimental results show that our QA-based technique outperforms state-of-the-art methods in full-data settings while achieving dramatic improvements in few-shot settings.

1 Introduction

Task-oriented parsing (TOP) takes an utterance as input and generates an unambiguous specification of a task that can be executed by machine (Gupta et al., 2018). Traditional approaches to TOP treat the task as an instance of slot filling (Liu and Lane, 2016), first classifying the intent of the utterance as a whole and then tagging tokens with slot labels that identify relevant entities (such as numbers, persons, dates or times, organizations, and so on). However, this approach only works for simple utterances that have flat rather than compositional semantics. That is, slot-filling approaches cannot produce nested (or "hierarchical") meaning representations, such as the one shown in Fig 1, where slots and intents can be composite and contain other slots (or intents) as proper parts.

A straightforward way to handle compositional semantics is to formulate TOP as a seq2seq problem, where the input sequence is the utterance and the output sequence is a linearized representation of a semantic tree (shown in the bottom part of Fig 1). The recent development of high-performing transformer-based pretrained language models (PLMs) (Lewis et al., 2020; Raffel et al., 2020; Brown et al., 2020) that can be fine-tuned on specific tasks (such as a particular TOP dataset) has made this formulation feasible.

This approach has achieved state-of-the-art performance on a variety of TOP datasets (Rongali et al., 2020; Aghajanyan et al., 2020; Chen et al., 2020). However, the output sequences are typically not expressed in natural language but rather in a mixture of natural language and special symbols (such as `[SL:`) that were not seen during pretraining and have no meaning to the PLMs. Depending on the task, the output sequences may hardly contain any natural language at all (for example, if the outputs are SQL queries). It would seem reasonable to conjecture that performance would improve if we could reformulate TOP as a more conventional NLP task in which both the inputs and the outputs are expressed in natural language, as such a reformulation might be better able to leverage the PLM's pretraining.

To bridge this gap, Shin et al. (2021) reduced TOP to a canonical-paraphrasing task. They first fine-tune a PLM to map a natural utterance u to another *canonical utterance* u', where canonical utterances belong to a controlled fragment of the relevant natural language. Then u' can be translated into the desired meaning representation (semantic tree) via a context-free grammar that can parse all and only canonical utterances. However, this approach has a major limitation: canonical fragments can be defined and parsed by hand-written grammars only in closed-world domains where the set of underlying entities is fixed and known in advance (e.g., in a domain where people ask questions about basketball players, all of whom are

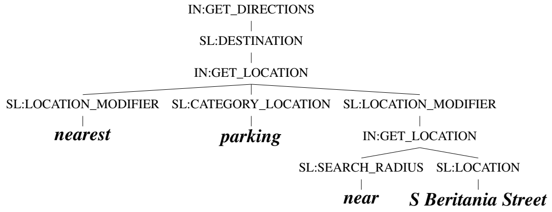
Utterance: Look up directions to the nearest parking near S Beritania Street.

Semantic parse tree of the utterance:



Linarized parse tree:

```
[IN:GET_DIRECTIONS
   [SL:DESTINATION
      [IN:GET_LOCATION
         [SL:LOCATION_MODIFIER nearest]
         [SL:CATEGORY_LOCATION parking]
         [SL:LOCATION_MODIFIER
            [IN:GET_LOCATION
               [SL:SEARCH_RADIUS near]
               [SL:LOCATION S Beritania Street] ] ] ] ] ]
```

Figure 1: A sample utterance and its semantic parse tree in the Topv2 dataset, where nodes starting with "IN:" are intents and nodes starting with "SL:" are slots. A parse tree always has an intent node at the root. An intent typically corresponds to a verb and can be viewed as an action, with a sequence of slots as its arguments. A slot may have additional intents nested in it, recursively. A linearized parse tree that can be processed by seq2seq models is shown at the bottom.

statically known). That condition rarely holds in task-oriented domains, and therefore this method is not applicable to datasets like Topv2. Moreover, as input utterances grow more structurally complex, the associated canonical utterances become much longer, and generating long sequences is known to be challenging for PLMs (Guo et al., 2018).

In this paper we focus on scenarios where it is not viable to specify a canonical grammar with a fixed set of rules. We instead propose to formulate TOP as abstractive question answering, in such a way that answering all questions for a given utterance allows us to reconstruct the parse tree of that utterance. Specifically, we introduce *single-turn QA* (ST QA for short), which poses one single query for a given utterance, and *multi-turn QA* (MT QA), which dynamically constructs multiple questions for each utterance, depending on previous answers. Because single-turn QA asks only one question, it has lower latency; however, the model must generate a longer text representing the entire parse tree. By contrast, multi-turn QA generates shorter answers that are more straightforward to parse; however, all questions need to be answered correctly, and if there are dependencies between questions, they can't be run within the same batch. We study these two approaches and their tradeoffs in both full-data and low-resource settings.

To summarize our contributions:

1. We propose a general reduction of compositional TOP to abstractive QA and introduce two specific variants: single-turn QA and multi-turn QA, each with unique benefits.
2. We train the abstractive QA models with a masked span prediction (MSP) objective, one of the pretraining objectives of the seq2seq model, which is shown to yield very substantial improvements in few-shot scenarios.
3. We evaluate ST QA and MT QA on two public datasets, Topv2 (Chen et al., 2020) and Pizza (Arkoudas et al., 2021), and show that our results improve on the state of the art by 3% on full-data Topv2, 28% for few-shot Topv2, and 7% on few-shot Pizza. [1]

2 Related Work

Task-oriented parsing has been extensively studied in the literature. The most prevalent approach is seq2seq modeling, which maps utterances to their meaning representations, typically expressed as a mixture of natural language and tokens such as brackets and artificial intent and slot identifiers (Rongali et al., 2020; Zhou et al., 2021; Aghajanyan et al., 2020; Shrivastava et al., 2021; Mansimov and Zhang, 2021); we take this approach as our main baseline.

Few-shot semantic parsing has also attracted wide interest. Chen et al. (2020) applied a different training paradigm; they assumed there are several source domains with labeled data and adopted a first-order meta-learning algorithm, Reptile, to train their model.

Shin et al. (2021) argued that PLMs are better suited for directly generating natural language rather than task-specific meaning representations, and thus they fine-tune PLMs to generate canonical paraphrases, which can then be parsed by a context-free grammar to produce the corresponding semantic trees. They further improve performance by augmenting input sequences with similar examples as prompts. Rongali et al. (2022) push that direction further by leveraging small amounts of unannotated data. We use canonical paraphrasing as one of our

---

[1] The QA datasets converted from the TOP format are available at `https://github.com/amazon-research/semantic-parsing-as-abstractive-qa`.

baselines. As we already noted in the introduction, canonical paraphrasing is not widely applicable in open-world task-oriented parsing; our QA-based approach overcomes that limitation. Desai et al. (2021) applied modifications to the linearized trees to make them more natural.

Inspired by the recent success of QA-driven approaches to a wide range of NLP tasks, such as dialogue state tracking (Gao et al., 2019), named entity recognition (Li et al., 2020), and multi-task learning (McCann et al., 2018; Du et al., 2021), Namazifar et al. (2021) framed semantic parsing as an extractive QA task. This limits its scope to non-compositional semantic structures. Our work is the first to use QA for semantic parsing of arbitrarily nested and complex meaning representations. Moreover, in contrast to previous approaches, our formulation usually results in fewer questions.

3 Reducing TOP to Abstractive QA

We now present a general method for reducing compositional TOP to abstractive QA. Given an utterance, our goal is to recover its semantic parse tree by asking questions and parsing the answers returned by a QA model. For this to succeed, all questions associated with an input utterance need to be answered correctly. At a high level, we formulate questions so as to build the required parse tree in a top-down, left-to-right fashion: We first ask a question to determine the root node, and then we recursively proceed towards the leaves. We start by describing multi-turn QA; the single-turn case is discussed in Section 3.3.

Each QA instance is a triple consisting of a context, a question, and an answer. We use the parse tree in Fig. 1 to illustrate the corresponding (multi-turn) sequence of QA triples shown in Fig. 2. The context is the utterance provided by the user plus general information about the domain and/or state from previous turns; the question corresponds to a particular node of the parse tree; and the answer provides the content of that node. We first extract the top-level intent (*get directions*), then the corresponding slots (*destination*), then the value of each slot (*destination is the nearest parking near S Beritania Street*), and then we start to recursively repeat this process on the phrase *the nearest parking near S Beritania Street* (by asking what is the intent included in that utterance segment). We note that our system is able to handle negative answers: If there isn't a nested intent in an utterance segment, the system returns *none*.

Multi-turn QA:

Q: **A user may intend to get directions, get distance, get estimated arrival time, get estimated departure time, get estimated duration, get road condition information, get route's information, get traffic information, get location, make unsupported navigation, or update directions.** A user said, "Look up directions to the nearest parking near S Beritania Street." What did the user intend to do?
A: get directions
Q: **The slots for get directions may be locations, arrival datetimes, road conditions to avoid, waypoints, amounts, paths, sources, travel methods, road conditions, waypoints to avoid, departure datetimes, paths to avoid, obstructions to avoid, and destinations.** A user said "Look up directions to the nearest parking near S Beritania Street." *The user's intent is to get directions.* What are the slots?
A: destination
Q: A user said "Look up directions to the nearest parking near S Beritania Street." *The user's intent is to get directions, and the slot is destination.* What is the destination?
A: the nearest parking near S Beritania Street
Q: **The nested intent in destination may be get school's location, get home's location, get location, get event, and get workplace's location.** A user said "Look up directions to the nearest parking near S Beritania Street." *The user's intent is to get directions, and the destination is the nearest parking near S Beritania Street.* Is there an intent included in "the nearest parking near S Beritania Street?"
A: get location
[· · ·]

Single-turn QA:

Q: **All possible intents from a user are [...], and slots could be [...].** A user said, "Look up directions to the nearest parking near S Beritania Street." What did the user intend to do?
A: The user intended to get directions, where destination is nearest parking near S Beritania Street. The intent for "nearest parking near S Beritania Street" is to get location, where location's category is parking and location modifiers are near S Beritania Street; nearest. The intent for "near S Beritania Street" is get location, where location is S Beritania Street and search radius is near.

Figure 2: Examples of multi-turn QA (top) and single-turn QA (bottom) for the utterance *Look up directions to the nearest parking near S Beritania Street.*

3.1 State Tracking

The triples we have described are processed independently from one another. To provide richer information to the QA model, we include previous answers as additional context (shown in italicized red font in Fig. 2). We represent a previous question-answer pair by combining them into a declarative sentence, and we stack all previous states together. This essentially encodes all parse-tree ancestors in natural language, which can potentially help the QA system resolve ambiguities. For example, the nested intent in *the nearest parking near S Beritania Street* could be different depending on whether this was a source or a destination.

3.2 Incorporating Domain Metadata

A given domain has predefined semantics, i.e., a fixed number of intents, each of which has an associated set of slots that describe important aspects of user requests. We incorporate metadata relevant to the current node as additional context (shown in blue bold font in Fig. 2). This effectively reduces the space of possible answers. For instance, while a domain may have a large number of intents, the intents that can appear at a particular node (e.g., at the root level) may be substantially fewer. And because we explicitly list all possible intents, the QA system can simply copy and paste the appropriate tokens, which is easier than searching over the entire vocabulary.

3.3 Single-turn QA vs Multi-turn QA

We note that there is no need to limit ourselves to one question for every node. For the example of Fig. 2, for instance, we don't ask one question for each child node of IN:GET_LOCATION individually (e.g., what is the first/second/third slot); instead, we simply ask "what are the slots?" and the answer should be "location modifier, location category." Another example is when we ask "what is the location modifier?", the answer being "nearest; near S Beritania Street."

On the extreme side, we could ask one question that would return an answer representing the entire parse tree, and this becomes somewhat similar to canonical paraphrasing (Shin et al., 2021). However, canonical paraphrasing assumes there is concrete grammar that specifies a controlled fragment of natural language (all and only the canonical utterances), which can be used to map sentences from that fragment into parse trees. That assumption often fails in open-world TOP domains; for example, when someone asks for directions, the destination could be expressed by an unbounded number of phrases (my parent's house, a restaurant that satisfies an arbitrary set of constraints, etc.) that cannot be specified a priori by a closed-form grammar.

In the single-turn part of Fig. 2, we show how we compress an entire parse tree into a single QA triple. The bold blue context is again encoding the domain's metadata. From left to right, the answer explicitly lists the relevant intents, their associated slots, and the tokens corresponding to the slots in a top-down direction. We deal with nested intents by recursively adding new sentences, which start with the tokens under which the intent is nested.

While our approach is more general than canonical paraphrasing, we still prefer canonicalization when possible, as the corresponding fragments tend to be more easily learnable. In the case of Pizza, for instance, a canonical grammar can be defined fairly straightforwardly. We illustrate the use of such canonical utterances in combination with our QA approach in Fig. 3. For multi-turn QA, we ask one question for each order in the utterance, and the answer is the order's canonical paraphrase. We also include the previous answers when asking about the next order, to prevent the QA system from repeating the same orders. For single-turn QA, we ask only one question for all orders. We also include the canonical paraphrasing formulation for comparison.

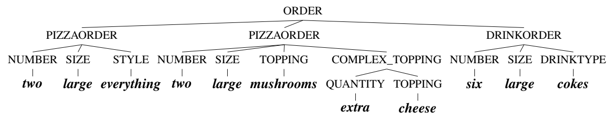
Thus, when canonical representations exist, single-turn QA and paraphrasing are similar; the main difference is that our formulation always includes a context. However, we reiterate that canonicalization is often not viable in TOP.

In summary, the general principle guiding the design of multi-turn interactions is that we first ask questions about intents, then we ask questions about their slots and slot values, and then repeat the process if we detect a nested intent in a slot. As for single-turn QA, we only ask one question and ensure that the answer encodes the entire tree. When canonical grammars exist in a given domain, they can be used to train single-turn QA systems in a straightforward way.

We experimentally evaluate the two QA variants and show how one may be preferred over the other under different settings.

3.4 Using MSP Objectives

Chada and Natarajan (2021) have shown that fine-tuning pretrained seq2seq models to perform QA tasks with too few examples leads to much degraded performance, while training a QA model with a loss function directly aligned with the pre-training objective performs better. Inspired by this observation, we explore the following change to our QA formulation: instead of making QA a separate downstream task, we treat it as one of the pretraining tasks—masked span prediction, for which the models are trained to generate the entire masked span given one unique mask token (Raffel et al., 2020). Accordingly, instead of asking the



Canonical paraphrasing:

Grammar for drink orders:
I want [number] [size]/[volumn] [drinktype] [container]
Grammar for pizza orders:
I want [number] [size] pizza in the [style] style with [topping1; topping2; ...] with [complex_topping] without [not_topping1; not_topping2; ...]
Input: "[utterance]"
Output: I want two large pizza in the everything style; two large pizza with mushrooms with extra cheese; six large-sized cokes

Multi-turn QA:

Q: A user said: "[utterance]" What order did the user place?
Q′: A user said: "[utterance]" The user ordered **[MASK]**.
A: two large pizza in the everything style
Q: A user said: "[utterance]" What order did the user place in addition to two large pizza in the everything style?
Q′:: A user said: "[utterance]" The user ordered **[MASK]** in addition to two large pizza in the everything style.
A: two large pizza with mushrooms with extra cheese
Q: A user said: "[utterance]" What order did the user place in addition to two large pizza in the everything style and two large pizza with mushrooms with extra cheese?
Q′:: A user said: "[utterance]" The user ordered **[MASK]** in addition to two large pizza in the everything style and two large pizza with mushrooms with extra cheese.
A: six large-sized cokes
Q: A user said: "[utterance]" What order did the user place in addition to two large pizza in the everything style and two large pizza with mushrooms with extra cheese and six large-sized cokes?
Q′:: A user said: "[utterance]" The user ordered **[MASK]** in addition to two large pizza in the everything style and two large pizza with mushrooms with extra cheese and six large-sized cokes.
A: none

Single-turn QA:

Q: A user said: "..." What orders did the user place?
Q′:: A user said: "..." The user ordered **[MASK]**.
A: The user ordered two large pizza in the everything style; two large pizza with mushrooms with extra cheese; six large-sized cokes

Figure 3: Parse tree, canonical paraphrasing formulation, multi-turn, and single-turn QA formulations for the utterance "*i would like two large pizzas with everything and two large pizzas with mushrooms and extra cheese and four large cokes*" in the Pizza dataset. The **Q′** questions are used for training with the MSP (masked span prediction) objective.

model questions and having it generate arbitrary answers, we rephrase the question-answer pair as a declarative sentence where the answer is masked. Thus, the model now has to denoise and recover the masked segment. We show an example of this approach in Fig. 3. The Q's are the original questions, whereas the primed Q's in red are the declarative sentences with the answers masked out. The answers to both Q's and primed Q's are the same, as mask tokens cover the exact answers.

3.5 Converting Answers to Parse Trees

Single-turn QA. In single-turn QA, each sentence of the answer concerns up to a fixed number of levels in the parse tree. Take the Topv2 instance in the bottom part of Fig.2 as a running example, where each sentence contains three levels: The first level is an intent node, the second level is its slots, and the third level is the value of each slot. In the first sentence, which always corresponds to the root intent, we take what follows the phrase "The user wants to" as the intent, in the part before the first comma; the rest of the sentence is of the form "where S is V", where S is the slot and V is the value. We note that one slot could have multiple values separated by semicolons, and for each value we create one slot node. In the case where an intent node doesn't have slot children, the sentence simply stops after the first part. To expand subsequent sentences into tree nodes, we make these sentences start with "The intent in [subutterance] is", so we can traverse the parse tree to find the "[subutterance]" node and expand the tree from there.

Multi-turn QA. In the multi-turn model, reconstructing the parse tree is more straightforward. We categorize all questions into three groups: the first asking the intent for a (sub-)utterance, the second asking the slots that appear in an intent, and the third asking for the value given to a slot. We parse the questions for an utterance sequentially and identify the group to which each question belongs. When the question asks for the top-level intent, we build the root node. When it asks for the intent of a sub-utterance, we traverse the parse tree to look for the leaf node containing the exact text and add an intent child node (with the text as a node attribute) from there. For a question from the second group, we find the intent node whose attribute has the same sub-utterance and append the slots as its children. When the question asks for a slot value, we traverse the parse tree again, find which slot node they belong to, and add it as a child node.

A final note for both single- and multi-turn QA: When we detect invalid entities generated by the QA models, we stop parsing and simply count such an instance as an incorrect output.

4 Experiments

We evaluate our method against two state-of-the-art seq2seq techniques, one generating linearized parse trees and the other generating canonical paraphrases. We chose Topv2 and Pizza because they are the only two task-oriented datasets we are aware of with nested meaning representations that cannot be produced by slot-filling approaches. We investigate both multi- and single-turn QA. In the former, a question aims to recover one or several nodes in the parse tree; in single-turn QA, we only ask one question to reconstruct the entire tree. Additionally, we perform ablation analysis to evaluate the contribution of each component, as described in Sec. 3. We show that our method achieves superior performance, particularly on those TOPv2 utterances that have more nested semantics.

4.1 Datasets

The Topv2 Dataset. The Topv2 dataset (Chen et al., 2020) is a collection of queries produced by crowdsourced workers and intended for smart voice assistants. Topv2 has compositional queries with hierarchical meaning representations and extends the original TOP dataset (Gupta et al., 2018) with six additional domains. We present statistics for each domain in Table 1. The eight domains vary widely, including the number of samples (ranging from 13k to 31k), the number of slots (from 5 to 33), and the portion of flat utterances. Accordingly, when we convert Topv2 instances to multi-turn QA instances, the average number of questions per instance varies a lot across the domains. We test our QA approach on Topv2 under the full-data setting for all domains, and select four domains to study in a few-shot setting, with only 10 samples per intent and slot (10SPIS).

The Pizza Dataset. Pizza is a new TOP dataset (Arkoudas et al., 2021) consisting of complex utterances that order pizzas and drinks. Pizza consists of 2.4M training examples that are synthetically generated from a CFG, along with 348 dev examples and 1357 test examples generated and annotated by MTurk workers. Although the training set is large, we focus on few-shot settings with 30, 50, and 100 examples randomly drawn from the dev set. The low-resource setting is indeed challenging—the dev set has only 107 unique slot values, whereas the test set has 180, requiring models to generalize well.

4.2 Evaluation Metric

We use a standard metric for evaluating TOP performance: unordered exact match accuracy (abbreviated as EM), which does a node-to-node comparison between the generated parse tree and the golden parse tree, modulo sibling order. EM doesn't take partially correct parses into account, so given a reference and a hypothesis, EM is either 0 or 1.

4.3 Implementation Details

We use the T5-large model (Raffel et al., 2020) as the backbone of our QA framework. We choose a learning rate between 5e-6 and 5e-4, a batch size from {32, 64, 96, 128} for the full-data setting, and a batch size from {8, 16, 24} for the few-shot setting. We search for the best set of hyperparameters with 16 random trials for each configuration. With full data, we train single-turn models for 10 epochs and multi-turn models for 30 epochs to select the best-performing checkpoint on validation. For few-shot learning, we train for 3000 steps and make a checkpoint every 100 steps. We used 8 Tesla V100 GPUs with 32 GB memory for all our training.

4.4 Baselines

We consider two baselines. The first applies a seq2seq model trained on logical forms (LFs) expressed in the "TOP-decoupled format," which removes from the parse tree all text that does not appear in a leaf slot (Aghajanyan et al., 2020). For this baseline, we use the BART-Large model described by Lewis et al. (2020), because this model is commonly used for TOP (Rongali et al., 2020; Aghajanyan et al., 2020; Shrivastava et al., 2021), and we also use T5-large, because that is the backbone of our QA implementation. This allows us to eliminate any benefit that may be derived from the architecture itself. The second baseline method we consider generates canonical paraphrases of the original utterances (Shin et al., 2021), and we use T5-large to allow for a direct comparison.

Note that for Topv2 we only compare our method against the first baseline, since that dataset doesn't have a canonical representation. Pizza does, so for that dataset we compare our method against both baselines (LFs in Top-decoupled notation and canonical paraphrases). Since we're not aware of any existing results on the baseline methods for individual Topv2 domains and for Pizza, we implemented both with HuggingFace (Wolf et al., 2020) and performed hyperparameter tuning with

domain	#inst	#int	#slt	flat%	depth	#q/inst
alarm	30488	8	9	84%	2.16	3.28
event	13160	11	17	80%	2.37	6.55
message	14602	12	27	84%	2.23	3.97
music	17320	15	9	100%	1.98	2.81
navigation	30044	17	33	57%	2.68	6.18
reminder	26133	19	32	79%	2.45	7.67
timer	17392	11	5	96%	2.00	2.39
weather	31403	7	11	100%	1.93	3.16

Table 1: Domain statistics for Topv2. #q/inst is the average number of questions per utterance in multi-turn QA. Navigation and reminder are two most nested domains. Music and weather have completely flat utterances.

the same computation budget given to our method.

4.5 Main Results

We first present Topv2 results for both full-data and few-shot settings. The baseline methods, labeled as BART/T5 LF, are trained on linearized Top-decoupled trees. We include four variants of the QA approach: ST QA and MT QA, as well as MSP ST QA and MSP MT QA (the same as ST and MT QA, except that the models are trained on the the masked span prediction objective). We report the full-data EM scores in Table 2 and the 10SPIS EM scores in Table 3. The relative gain is computed between the best QA approach and the best baseline approach in each domain.

In the full-data setting, all four QA variants outperform the baselines, with MSP ST QA having a slight overall edge, exceeding the best baseline method by 3.07 absolute points. We have the largest relative gain (6.19%) in reminder. In general, we see smaller improvements in the flatter domains: music, weather, timer, alarm are the four domains with the smallest semantic-tree depths, and relative gains for these domains are below 3%.

We see that different QA approaches are close to each other when we have enough data; ST QA performs only marginally better than MT QA. However, ST QA has shorter latency and may therefore be practically preferable.

We choose four representative domains to perform low-resource experiments. For 10SPIS, MSP MT QA is a clear winner over the other approaches, improving the best baseline method by 17.16 absolute points. ST QA has the worst performance. Our explanation is that ST QA requires the generation of long texts (longer than the Top-Decoupled LFs), and it is too challenging to learn a complex new task with only 10 instances per intent and slot. Therefore, in a few-shot setting, the benefit of having short answers is much clearer. Additionally, it is worth noting that having an objective that is well-aligned with the pretraining stage provides a significant benefit. It improves MT QA by nearly 5 absolute points on average, and it is a game changer for ST QA, in that with this one modification ST QA achieves competitive performance in three out of four domains.

We also test whether the inclusion of previous answers and metadata into the context helps in few-shot scenarios (the difference may be negligible with full data). We remove answers to previous questions ("w/o state") and metadata ("w/o metadata") from MT QA and report the scores obtained from both changes. The results suggest that both state and metadata make strong contributions to performance. Excluding prior answers has a more negative impact on average.

We note that our QA approach is very competitive against state-of-the-art results in the literature. For instance, the best reported result for 10SPIS reminder is 61.47 (Chen et al., 2020)[2], which was achieved by first pretraining the model with six source domains. We improved that result by 9 absolute points while training only with the target domain's data.

We next report results on Pizza, where we compare our approach against both LF-trained baselines (with LFs expressed in TOP-decoupled notation) and canonical paraphrases. Table 4 summarizes results for three low-resource settings. We obtain the greatest improvement with 30 training examples, for a relative gain exceeding 8%. Consistently with the Topv2 results, as more training examples become available the gap between the QA approaches and the baselines shrinks. Even though T5 Canonical and ST QA are similar, the results show that including context information about an order is beneficial, especially when there are fewer training examples. MT QA has a slight edge over ST QA here, as asking more questions mitigates the burden of generating longer and more complex sequences.

4.6 Additional Analysis: Depth vs. Accuracy

We investigate how our approach performs on full-data Topv2 as a function of semantic depth. We chose to perform the analysis on navigation and

---

[2] We only mention reminder because Chen et al. (2020) don't report 10SPIS results for the other domains.

	Alarm	Event	Message	Music	Navigation	Reminder	Timer	Weather	Average

	4	7.82	310	53.87	71.29	**32.34%**

Table 5: Topv2 full-data result analysis per depth level for navigation and timer. The average utterance length (L) and the number of test instances (#inst) are shown for each depth (D). LF EM is from the best baseline method and QA EM is from the best QA method.

timer because navigation has the greatest average tree depth, and we want to explain why our method gave the lowest improvements on timer.

We present the breakdown in Table 5, where LF EM shows EM scores from the best baseline method generating TOP-decoupled trees, and QA EM shows EM scores from the best QA variant. For utterances with shallow semantics, generating TOP-decoupled trees outperforms QA; but as we move towards deeper semantic structures, the benefit of using a more naturalized representation becomes evident. Indeed, for both navigation and timer, QA performs best at the deepest level. Thus, for practical purposes, when the goal is to build a system that achieves high accuracy across all utterance groups, it is worth considering a combination of conventional LF generation for shallow utterances and a QA model for more complex utterances. We define the length of an utterance to be the number of words the utterance has. Table 5 lists the average utterance length for each depth, and shows that input size is a good proxy for semantic complexity (and could thus be used to quickly decide between the two approaches).

5 Conclusion

We have presented a reduction of compositional task-oriented parsing to abstractive QA, whereby parse tree nodes are recovered by posing queries to a QA model. We have also proposed to train QA models with the MSP (masked span prediction) objective, to better leverage the massive amount of linguistic knowledge gained during pretraining. We experimentally evaluated single-turn QA and multi-turn QA on two public datasets, both in full-data and in few-shot settings, with and without MSP, and showed that they consistently outperform a number of powerful baseline techniques, including canonical paraphrasing, in both settings. The MSP variants perform best on average, with particularly dramatic improvements obtained in the few-shot setting.

Abstract

We present DR.DECR (**D**ense **R**etrieval with **D**istillation-**E**nhanced **C**ross-Lingual **R**epresentation), a new cross-lingual information retrieval (CLIR) system trained using multi-stage knowledge distillation (KD). The teacher of DR.DECR relies on a highly effective but computationally expensive two-stage inference process consisting of query translation and monolingual IR, while the student, DR.DECR, executes a single CLIR step. We teach DR.DECR powerful multilingual representations as well as CLIR by optimizing two corresponding KD objectives. Learning useful representations of non-English text from an English-only retriever is accomplished through a cross-lingual token alignment algorithm that relies on the representation capabilities of the underlying multilingual encoders. In both in-domain and zero-shot out-of-domain evaluation, DR.DECR demonstrates far superior accuracy over direct fine-tuning with labeled CLIR data. It is also the best single-model retriever on the XOR-TyDi benchmark at the time of this writing.

1 Introduction

Multilingual models are critical for the democratization of AI. Cross-lingual information retrieval (CLIR) (Braschler et al., 1999; Shakery and Zhai, 2013; Jiang et al., 2020; Asai et al., 2021a), for example, can find relevant text in a high-resource language such as English even when the query is posed in a different, possibly low-resource, language. In this work, we develop useful CLIR models for this constrained, yet important, setting where a retrieval corpus is available only in a single high-resource language (English in our experiments).

A straightforward solution to this problem could use machine translation (MT) to translate the query into English, and then perform English IR (Asai et al., 2021a). While such a two-stage process can produce reasonably accurate predictions, an alternative end-to-end approach that can tackle the problem purely cross-lingually, *i.e.*, without involving MT for inference, would clearly be more efficient and cost-effective. Pre-trained multilingual masked language models (PLMs) such as multilingual BERT (Devlin et al., 2019) or XLM-RoBERTa (XLM-R) (Conneau et al., 2020) can provide the foundation for such a one-step solution, as simply fine-tuning a PLM with labeled CLIR data would yield a cross-lingual retriever (Asai et al., 2021b).

Here we first run an empirical evaluation of these two approaches on a public CLIR benchmark (Asai et al., 2021a), which involves both in-domain and zero-shot out-of-domain tests. We use ColBERT (Khattab and Zaharia, 2020; Khattab et al., 2021)—a state-of-the-art (SOTA) neural IR model that has been shown to outperform other recent methods such as DPR (Karpukhin et al., 2020)—as our IR architecture and XLM-R as the underlying PLM for both methods (§2). Results indicate that the MT-based solution can be vastly more effective than direct EN + CLIR fine-tuning, with observed differences of 22.2–28.6 Recall@5k-tokens (§3). Crucially, the modular design of the former allows it to leverage additional English-only training data for its IR component, providing significant boosts to its performance.

The above findings lead naturally to the central research question of this paper: Can a high-performance CLIR model be trained that can operate without having to rely on MT? To answer the question, instead of viewing the MT-based approach as a competing one, we propose to leverage its strength via knowledge distillation (KD) into an end-to-end CLIR model, which we call DR.DECR (**D**ense **R**etrieval with **D**istillation-**E**nhanced **C**ross-lingual **R**epresentation). KD (Hinton et al., 2014) is a powerful supervision technique typically used to distill the knowledge of a large

teacher model about some task into a smaller *student* model (Mukherjee and Awadallah, 2020; Turc et al., 2020). Here we propose to use it in a slightly different context, where the teacher and the student retriever are identical in size, but the former has superior performance simply due to utilizing MT output and consequently operating in a high-resource and low-difficulty monolingual environment.

We run two independent KD operations (§2.2). One directly optimizes an IR objective by utilizing labeled CLIR data: parallel questions (English and non-English) and corresponding relevant and non-relevant English passages. The teacher and the student, DR.DECR, are shown the English and non-English versions of the questions, respectively; the training objective is for DR.DECR to match the soft query-passage relevance predictions of the teacher. The second KD task is representation learning from parallel text, where DR.DECR learns to encode a non-English text in a way that matches the teacher's encoding of the aligned English text, *at the token level*. The cross-lingual token alignments needed to create the training data for this task are generated using a greedy alignment process, which exploits the multilingual representation capabilities of the underlying PLM encoders.

In our evaluation on the XOR-TyDi benchmark (Asai et al., 2021a), DR.DECR outperforms the fine-tuned ColBERT baseline by 25.4 (in-domain) and 14.9 (zero-shot) Recall@5k-tokens, recovering much of the performance loss from the MT-based solution. It is also the best single-model IR system on the XOR-TyDi leaderboard[1] at the time of this writing. Ablation studies show that each of our two KD processes contribute significantly towards the final performance of DR.DECR.

Our contributions can be summarized as follows: **(1)** We present an empirical study of the effectiveness of a SOTA IR method (ColBERT) on cross-lingual IR with and without MT, **(2)** We propose a novel end-to-end cross-lingual solution that uses knowledge distillation to learn both improved text representation and retrieval, **(3)** We demonstrate with a new cross-lingual alignment algorithm that distillation using parallel text can strongly augment cross-lingual IR training, and **(4)** We achieve new single-model SOTA results on XOR-TyDi.

2 Method

Here we first describe our base IR architecture (ColBERT) and then the proposed KD-based cross-lingual training algorithms.

2.1 The ColBERT Model

ColBERT (Khattab and Zaharia, 2020) employs a transformer-based encoder to separately encode the input query and document, followed by a linear compression layer. Each training instance is a <q, d^+, d^-> triple, where q is a query, d^+ is a positive (relevant) document and d^- is a negative (non-relevant) document. A relevance score $S_{q,d}$ for the pair (q, d) is first computed using Eq. 1, where $d \in \{d^+, d^-\}$ and E_{q_i} and E_{d_j} are the output embeddings of query token q_i and document token d_j, respectively. For a given training triple, a cross-entropy loss is minimized for the softmax over S_{q,d^+} and S_{q,d^-}.

$$S_{q,d} := \sum_{i \in [|q|]} max_{j \in [|d|]} E_{q_i} \cdot E_{d_j}^T \qquad (1)$$

For inference, the embeddings of all documents are calculated *a priori*, while the query embeddings and the relevance score are computed at runtime.

2.2 Knowledge Distillation

Our teacher and DR.DECR are both ColBERT models that fine-tune the same underlying multilingual PLM for IR. The teacher is first trained with all-English triples using the procedure of §2.1. The goal of the subsequent KD training is to teach DR.DECR to reproduce the behavior of this teacher when it sees non-English translations of the teacher's English questions.

We apply KD at two different stages of the ColBERT workflow: (*a*) relevance score computation ($S_{q,d}$ in Eq. 1), and (*b*) encoding (*e.g.*, E_{q_i}). Figure 1 depicts (*a*) in detail, where training minimizes the KL divergence between the DR.DECR's and the teacher's output softmax distributions (with temperature) over S_{q,d^+} and S_{q,d^-}.

Labeled training data for CLIR are scarce, whereas MT, being a more established area of research, has produced a large amount of parallel text over the years. We seek to exploit existing parallel corpora in our second KD training, where we teach DR.DECR to compute representations of non-English texts that closely match the teacher's representations of aligned English texts. Importantly, since ColBERT computes a single vector for each

---

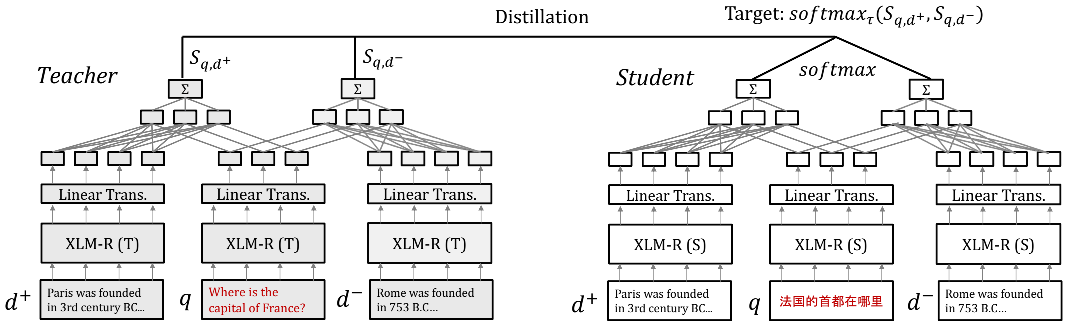

Figure 1: Relevance score distillation. The teacher is shown all-English triples while the student's (DR.DECR) query input is non-English. Training minimizes the student's KL divergence from the teacher's output softmax distribution over S_{q,d^+} and S_{q,d^-} (τ is the temperature).

```
Input:
$v_T$: Teacher's representation of tokenized English
  (EN) text.
$v_S$: Student's representation of parallel non-EN text.
Output:
$v_T^{(a)}$: Reordered teacher output embeddings to reflect
  position-wise alignment with $v_S$.
Procedure:
$DM \leftarrow cosine\_distance(v_T, v_S)$ //matrix
//get index pairs to swap in $v_T$
$swaps \leftarrow [\,]$
for $row$ in $rows(DM)$ do
    //loop runs $|v_T|$ times
    $minValue \leftarrow min(DM)$
    $i, j \leftarrow index\_of(minValue)$
    //swap rows i and j
    $DM[[i,j],:] = DM[[j,i],:]$
    //set row $j$ and column $j$ to $+\infty$
    $DM[j,:] \leftarrow +\infty$
    $DM[:,j] \leftarrow +\infty$
    $swaps.append((i,j))$
end
//swap teacher's output tokens
$v_T^{(a)} \leftarrow v_T$
for $s$ in $swaps$ do
    $v_T^{(a)}[s[0], s[1]] \leftarrow v_T[s[1], s[0]]$
end
```

Algorithm 1: Cross-lingual alignment.

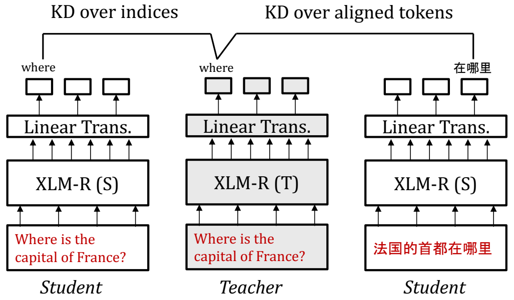

Figure 2: Distillation for representation learning. The student (DR.DECR) learns to encode both English and non-English tokens in context that matches the teacher's output embeddings for corresponding English tokens.

individual input token (*i.e.*, a PLM vocabulary item) and not for the entire input text, our algorithm must support distillation at the token level.

To achieve this, we design an unsupervised cross-lingual token alignment algorithm. Assuming $(ne_1, ..., ne_S)$ to be the ordered tuple of tokens in a non-English text and $(e_1, ..., e_T)$ the corresponding tuple from the parallel English text, each iteration of this algorithm greedily picks the next (ne_i, e_j) pair with the highest cosine similarity of their output embeddings. Algorithm 1 implements this idea by repositioning the teacher's tokens so that they are position-wise aligned with the corresponding DR.DECR tokens. Note that the design choice of fine-tuning a common multilingual PLM for the teacher and the DR.DECR, even though the former is tasked with only handling English content, is key for this algorithm as it relies on the PLMs' multilingual representation capabilities. See Appendix A.1 for details on our parallel corpora used for training.

In addition to cross-lingual alignment, we also perform a similar KD procedure in which both the teacher and the DR.DECR are shown the same English text. This step is useful because ColBERT uses a shared encoder for the query and the document, necessitating a student that is able to effectively encode text from both English documents and non-English queries.

Using the alignment information, we train DR.DECR by minimizing the Euclidean distance between its representation of a token (English or non-English) and the teacher's representation of the corresponding English token. Figure 2 shows the KD process for representation learning.

System	R@5kt	R@2kt
With target domain supervision:		
ColBERT$_{\text{CL}}$: *ft*(XOR)	32.9	23.9
ColBERT$_{\text{EN+CL}}$: *ft*(NQ) $\rightarrow$ *ft*(XOR)	47.7	38.1

Dr.Decr: ColBERT$_{\text{EN+CL}}$ $\rightarrow$ KD$_{\text{PC}}$ $\rightarrow$ KD$_{\text{MKQA}}$	61.8	54.3

Table 1: Performance on the XOR-TyDi test set. *ft*: fine-tuning; *CL*: cross-lingual; NQ: the Natural Questions train set; PC: parallel corpus; XOR: the XOR-TyDi train set. Direct fine-tuning of ColBERT with IR triples underperforms MT + English IR by 22.2–32.4 points; the proposed KD-based methods close this gap by 65.0%–88.8%.

3 Experiments

3.1 Setup

Our primary CLIR dataset is XOR-TyDi (Asai et al., 2021a), which contains examples in seven typologically diverse languages: Arabic (Ar), Bengali (Bn), Finnish (Fi), Japanese (Ja), Korean (Ko), Russian (Ru) and Telugu (Te). For standard in-domain experiments, we use a train-dev-test split of this dataset. There are 2,113 questions in the test set. For zero-shot experiments, we use the MKQA (Longpre et al., 2020) dataset for training and validation, and the following shared languages in the XOR-TyDi test set for evaluation: Ar, Fi, Ja, Ko and Ru. Both training sets contain English questions and their human translations in the other languages, their short answers and corresponding relevant (positive) and non-relevant (negative) Wikipedia snippets. Additionally, we use training examples from the Natural Questions (NQ) dataset (Kwiatkowski et al., 2019) for English pre-training of the baseline model. Further details on data pre-processing and the final training sets are provided in Appendix A.1.

The CLIR baseline used in our experiments is ColBERT with an underlying XLM-R PLM, which we iteratively fine-tune first on English and then on cross-lingual IR triples for optimal performance. Our Dr.Decr model is initialized with the parameter weights of this baseline, and is further fine-tuned using the two KD objectives. The KD teacher is a ColBERT model fine-tuned with only English triples, as stated before. During evaluation, it is given machine-translated questions that come with the XOR-TyDi dataset. Appendices A.1 and A.2 contain additional details on the supervision of these models and the optimal hyperparameter configurations.

We evaluate using Recall at t tokens for $t \in \{2000, 5000\}$, *i.e.*, R@2kt and R@5kt (Asai et al., 2021a), which compute the fraction of questions for which the ground truth short answer is contained within the top t tokens of the retrieved passages.

Language	Baseline	Dr.Decr
With target domain supervision:		
Te	63.0	83.2
Bn	53.3	85.9
Fi	49.4	69.4
Ja	39.4	65.1
Ko	44.9	68.8
Ru	39.2	68.8
Ar	44.3	70.2
Avg	**47.7**	**73.1**
Zero-shot:		
Fi	55.4	66.9
Ja	44.0	58.5
Ko	48.4	62.8
Ru	41.4	57.8
Ar	45.3	61.8
Avg	**46.9**	**61.8**

Table 2: R@5kt scores for in-domain and zero-shot evaluation on individual languages. Baseline for the target domain experiment: ColBERT$_{\text{EN+CL}}$: *ft*(NQ) $\rightarrow$ *ft*(XOR). Baseline for the zero-shot experiment: ColBERT$_{\text{EN+CL}}$: *ft*(NQ) $\rightarrow$ *ft*(MKQA)

3.2 Evaluation

Table 1 compares the performance of our different models. First, looking at the R@5kt results, we observe that pre-training the baseline model with English IR triples from the NQ train set (rows 2, 6) substantially boosts its performance in both in-domain and zero-shot settings. However, it still underperforms the MT + English IR pipeline (rows 3, 7) by 28.6 and 22.2 points, respectively. By distilling first with the parallel corpus (for representation learning) and then with the IR triples (for CLIR), Dr.Decr (row 4) yields an improvement of 25.4 points over the baseline model in in-domain evaluation, which, quite impressively, is within 3.2 points

System	R@5kt	R@2kt
With target domain supervision:		
Dr.DECR: ColBERT$_{\text{EN+CL}}$ → KD$_{\text{PC}}$ → KD$_{\text{XOR}}$	73.1	66.0
ColBERT$_{\text{EN+CL}}$ → KD$_{\text{PC}}$	68.6	60.6
ColBERT$_{\text{EN+CL}}$ → KD$_{\text{XOR}}$	63.6	56.6
ColBERT$_{\text{EN+CL}}$	47.7	38.1
Zero-shot:		
Dr.DECR: ColBERT$_{\text{EN+CL}}$ → KD$_{\text{PC}}$ → KD$_{\text{MKQA}}$	61.8	54.3
ColBERT$_{\text{EN+CL}}$ → KD$_{\text{PC}}$	55.9	47.7
ColBERT$_{\text{EN+CL}}$ → KD$_{\text{MKQA}}$	49.3	40.9
ColBERT$_{\text{EN+CL}}$	46.9	38.7

Table 3: Results of the ablation study. KD with parallel corpus (KD$_{\text{PC}}$) and IR triples (KD$_{\text{XOR}}$) both play key roles in our Dr.DECR model. Interestingly, the former has a greater impact on the model's performance.

of the teacher's score. A sizable gain of 14.9 points is also observed in zero-shot evaluation (row 8). Finally, the R@2kt numbers show a very similar pattern.

Table 2 shows the performance (R@5kt) of Dr.DECR and the baseline on each individual language: the former outperforms the latter both with and without target domain supervision, yielding large gains across all languages. These results demonstrate the robustness of our approach, which stems from combining the individual strengths of MT, English IR and KD in a single model.

3.3 Leaderboard Submission

The Dr.DECR model trained on the XOR-TyDi training set, shown in Table 1 row 4, is the best single-model retriever on the XOR-TyDi leaderboard[2] at the time of this writing. Since our parallel corpus extraction process relies on in-house source code that is not publicly available, we submitted to the "Systems using External APIs" category. Crucially, all other submitted systems under the External APIs category rely on MT at decoding time, avoiding which is one of the primary goals of our work. We also created parallel corpora purely from public available sources.[3] Our model distilled with these instances also achieved top position on the white-box systems leaderboard of XOR-TyDi.

3.4 Ablation Study

We experiment with two more student models, one distilled with only CLIR examples and the other with only the parallel corpus. As the results in Table 3 show, each has a substantial impact on system performance. Interestingly, although the parallel corpus does not provide any IR signal, it contributes more to the model's accuracy. These results also confirm that our cross-lingual alignment algorithm does indeed produce useful alignments.

4 Conclusion

We train highly effective end-to-end cross-lingual IR models by distilling the knowledge of an English retriever. We propose separate processes to teach IR and multilingual text representations, and present for the latter a cross-lingual alignment algorithm that only relies on the underlying masked language model's multilingual representation capabilities. Supervised and zero-shot evaluations show that our model recovers much of the performance lost due to operating in an efficient cross-lingual mode. Our KD-based method also yields new single-model SOTA results on the XOR-TyDi benchmark. Future work will explore IR on unseen languages and evaluation on additional datasets.

5 Ethics

5.1 Limitations

We show the effectiveness of multi-stage knowledge distillation and cross-lingual token alignment in training a cross-lingual information retrieval system. We believe that it can be transferred to more datasets and languages, but here we only show proof of concept for the XOR-TyDi and MKQA datasets and the seven languages mentioned in the paper.

5.2 Risks

The intent of this work is to develop a new method for high-performance cross-lingual information retrieval. It is possible that a malicious user could try to attack the system by providing poor or offensive training data. We do not support it being used in such a manner. The risks of our system are the same as other NLP systems and we do not believe we introduce any additional risk.

A Appendix

A.1 Data Pre-processing

The official XOR-TyDi training set consists of 15,221 natural language queries, their short answers, and examples of corresponding relevant (positive) and non-relevant (negative) Wikipedia snippets. For most queries, there are one positive and three negative examples. We remove the 1,699 (11%) questions that have no answers in the dataset. A random selection of 90% of the remaining examples is used for training and the rest for validation.

Following the original XOR-TyDi process, we also obtain additional training examples by running BM25-based retrieval against a Wikipedia corpus and using answer string match as the relevance criterion. These examples are added to the original set to obtain three positive and 100 negative examples per query. As the blind test set for final evaluation, we use the 2,113 questions in the official XOR-TyDi dev set.

Our monolingual (English) training data containing about 17.5M triples are derived from the third fine-tuning round (ColBERT-QA3) of ColBERT relevance-guided supervision (Khattab et al., 2021) with NQ examples (Kwiatkowski et al., 2019).

The parallel corpus used in our KD experiments (Table 1) for representation learning is constructed from three different sources: (1) an in-house crawl of Korean, (2) LDC releases (Arabic), and (3) OPUS.[4] The corpus has a total of 6.9M passage pairs which include .9M pairs in Telugu and 1M pairs in each of the other six languages. The parallel corpus used in our white-box system was created purely from OPUS. The statistics and sources are shown in the table below.

Language	Amount (M)	Source
Ja	0.9	WikiMatrix
Ru	1.7	WikiMatrix
Ar	1.0	WikiMatrix
Te	0.7	WikiMatrix + CCAligned
Bn	1.3	WikiMatrix + CCMatrix
Fi	1.4	WikiMatrix + CCMatrix
Ko	1.3	WikiMatrix + CCMatrix

Table 4: Statistic of parallel corpus used in the XOR-TyDi white-box system.

For zero-shot experiments, the training examples are derived from MKQA (Longpre et al., 2020), which consists of 10k queries selected from NQ, human translated into 25 additional languages, five of which overlap with XOR-TyDI: Ar, Fi, Ja, Ko and Ru. We construct training data (triples) from 2,037 queries translated into these five languages for which there are corresponding positive and negative passages in the NQ dataset. For each of the five languages, there are 519k triples for a total of 2.6M triples. We set aside 200 queries translated into the 5 languages for a total of 1,000 queries as a development set. We remove all MKQA queries from the NQ training data for these experiments.

The CLIR baseline for our experiments is a ColBERT model with an XLM-R PLM, which we first fine-tune with 17.5M NQ examples for one epoch and then 2.9M XOR-TyDi triples for five epochs. Our DR.DECR model is initialized with the parameter weights of the baseline, and is further fine-tuned using the two KD objectives. The monolingual teacher model—also a ColBERT model running on top of the pre-trained XLM-R—is trained with only the 17.5M NQ triples for one epoch.

A.2 Model Selection

All the models were trained with single Nvidia A100 GPU. The longest training time for a single model was less than 200 hours. Following are the final hyperparameter configurations of our different models. They were selected based on the respective validation sets performance.

A.3 Qualitative Analysis

To find out what exact weaknesses of the baseline model the proposed method helps to address, we examine thirty random zero-shot test examples where the baseline fails to retrieve the correct answer in the top 5k tokens, but DR.DECR succeeds within the top 3 passages. We show four examples in Table 6 with human translations of the original non-English questions. The vast majority of our observed cases are related to weak cross-lingual encoding on the baseline model's part, where at least one important non-English word/entity in the question seems to be incorrectly matched with a similar but different English entity in the passage (e.g., the name of a different place). For the Korean, Russian and Arabic queries in the table, we observe the presence of such topically similar entities (*e.g.*, *microwave* ↔ *gamma-ray*, *Germany* ↔ places in North America). Much more rarely, we see cases similar to the Japanese query where the retrieved passage is completely off-topic.

Most errors are related to potential word/entity mistranslations, the only exception being the Japanese query where the issue is a weaker understanding of the passage content.

Testing the Ability of Language Models to Interpret Figurative Language

Emmy Liu, Chenxuan Cui, Kenneth Zheng, Graham Neubig
Language Technologies Institute
Carnegie Mellon University
`{mengyan3,cxcui,kzheng2,gneubig}@cs.cmu.edu`

Abstract

Figurative and metaphorical language are commonplace in discourse, and figurative expressions play an important role in communication and cognition. However, figurative language has been a relatively under-studied area in NLP, and it remains an open question to what extent modern language models can interpret nonliteral phrases. To address this question, we introduce Fig-QA, a Winograd-style nonliteral language understanding task consisting of correctly interpreting paired figurative phrases with divergent meanings. We evaluate the performance of several state-of-the-art language models on this task, and find that although language models achieve performance significantly over chance, they still fall short of human performance, particularly in zero- or few-shot settings. This suggests that further work is needed to improve the nonliteral reasoning capabilities of language models.[1]

1 Introduction

All our words are but crumbs that fall down from the feast of the mind (Gibran, 1926). When humans read such a metaphorical phrase, how do they interpret it? Conceptual metaphors structure our everyday language and are used to map everyday physical experiences and emotions onto abstract concepts (Lakoff and Johnson, 1981). They allow us to communicate complex ideas, to emphasize emotions, and to make humorous statements (Fussell and Moss, 2008). However, despite relating words in a way that differs from their accepted definition, these phrases are readily interpreted by human listeners, and are common in discourse (Shutova, 2011), occurring on average every three sentences (Mio and Katz, 1996; Fussell and Moss, 2008)

The ability to interpret figurative language has been viewed as a bottleneck in natural language understanding, but it has not been studied as widely as literal language (Shutova, 2011; Tong et al., 2021). Figurative language often relies on shared commonsense or cultural knowledge, and in some cases may be difficult to solve using language statistics. This presents a challenge to language models (LMs), as strong LMs trained only on text may not be able to make sense of the physical world, nor the social or cultural knowledge that language is grounded in (Bender and Koller, 2020; Bisk et al., 2020).

Most previous work on figurative language focuses on metaphor detection, where a model is trained to *identify* the existence of metaphors in text (Tsvetkov et al., 2014; Stowe and Palmer, 2018; Leong et al., 2020), with datasets consisting mostly of conventionalized metaphors and idioms in wide use. However, identifying these common metaphors that already appear often in language may be an easy task for LMs, and not fully test their ability to interpret figurative language. The little work that exists on metaphor interpretation frames it as a task linking metaphorical phrases to literal rewordings, either through paraphrase detection (Bizzoni and Lappin, 2018) or paraphrase generation (Shutova, 2010; Su et al., 2017; Mao et al., 2018) (details in § 7) Another line of work probes for metaphorical understanding in LMs, but this is similar to the metaphor detection task, in that the LM is not actually asked to choose an interpretation for the metaphor (Pedinotti et al., 2021; Aghazadeh et al., 2022). While interesting, this work does not take into account the fact that metaphors are rich with different implications that may vary depending on the context.

In this work, we ask whether or not LMs can correctly *make inferences regarding creative, relatively novel metaphors* generated by humans. This task is harder for two reasons: (1) *inference* is harder than *identification* or *paraphrasing*, as it requires understanding the underlying semantics, and (2) the metaphors in our dataset are novel cre-

July 10-15, 2022

ations, and many may not appear even once in the LMs' training data. We propose a minimal task inspired by the Winograd schema (Levesque et al., 2012), where LMs are tasked with choosing the entailed phrase from two opposite metaphorical phrases. An example of a paired sentence is "Her commitment is as sturdy as (plywood/oak)". The correct answer would be either "She was (committed/uncommitted)". This can also be seen as an entailment task, where input x is the premise, and the output y is the hypothesis.[2]

We crowdsource a benchmark **Fig-QA**, consisting of 10,256 such metaphors and implications (§ 2), which can be used to evaluate the nonliteral reasoning abilities of LMs or for more broad studies of figurative language in general (we provide preliminary analyses in § 3). Through extensive experiments over strong pre-trained LMs (§ 4), we find that although they can be fine-tuned to do reasonably well, their few-shot performance falls significantly short of human performance (§ 5). An in-depth analysis (§ 6) uncovers several insights: (1) LMs do not make use of the metaphorical context well, instead relying on the predicted probability of interpretations alone, (2) the task of associating a metaphor with an interpretation is more difficult than the reverse, (3) even strong models such as GPT-3 make inexplicable errors that are not well-aligned with human ones, indicating that further work is needed to properly model nonliteral language.

2 Dataset Creation and Validation

2.1 Crowdsourcing Task

We crowdsourced data from workers on Amazon Mechanical Turk (details in Appendix A). Workers were asked to generate paired metaphors with different meanings, as well as literal implications of the two metaphors in context. We instructed workers to try to generate rare or creative metaphors, namely "metaphors that would not appear often in text on the internet, books, social media, or news sites, but that can still be easily understood by people." Workers were given examples of valid pairs that fit the format, and examples of invalid ones to discourage errors. Some examples of generated pairs are displayed in Table 1.

In order to help workers, we employ the *randomness as genesis* and *narrow limits of change* principles of Cognitive Load Theory (Sweller, 2006). To add soft constraints, we generate 3 different random words to be shown to each batch of workers. However, workers were not required to use these words, as we wanted to encourage maximal diversity. In order to ensure that the random words were metaphorically rich, we selected them based on metaphorical frames in Lakoff and Johnson (1981).

2.2 Data Validation

The dataset was manually validated by three authors of this paper. Each author covered roughly one-third, evenly split between training, validation, and test. Examples were excluded if they (a) did not make sense given the figurative expression, (b) had grammar or spelling errors that rendered them unintelligible, or (c) did not follow the format of the task. Examples of excluded samples are included in Appendix B. We collected 13,324 sentences and interpretations from the crowdsourcing task, and 10,256 sentences remained after filtering.

2.3 Final Dataset

The release version of our dataset contains the named data splits in Table 2. The medium train, dev, and test splits were generated from partitioning the first stage of data collected. The large train split additionally contains all the new examples from the second collection stage, and the small train split is a small random sample.

3 Figurative Language Typologies

In this sample, we perform an analysis of the collected data to demonstrate its trends and categorize examples for further error analysis. Specifically, we examine (a) subjects, objects, and relations, and (b) types of common-sense knowledge needed to interpret the metaphor.

3.1 Figurative Language Structure

We note that most metaphors and similes can be characterized by three components, (S, R, O), where S is a subject, R is a relation, and O is an object. For instance, "Her commitment is as sturdy as plywood" can be written (Her commitment, sturdy, plywood). Interpretation involves inferring an attribute of the subject by extracting a relational attribute from the object (Fauconnier and Turner, 2003). In a simile, R is explicit, whereas it is usually implicit in a metaphor. The most common

---

[2] The opposing meanings help to avoid ambiguity in the correct answer, make the task intuitive for human annotators, and help prevent annotation artifacts that have plagued other NLI datasets (Gururangan et al., 2018).

Paired sentences	Possible answers

Table 1: Example sentences from the dataset

Train			Dev	Test
S	M	L		
200	1,458	8,016	1,094	1,146

Table 2: Examples in each data split

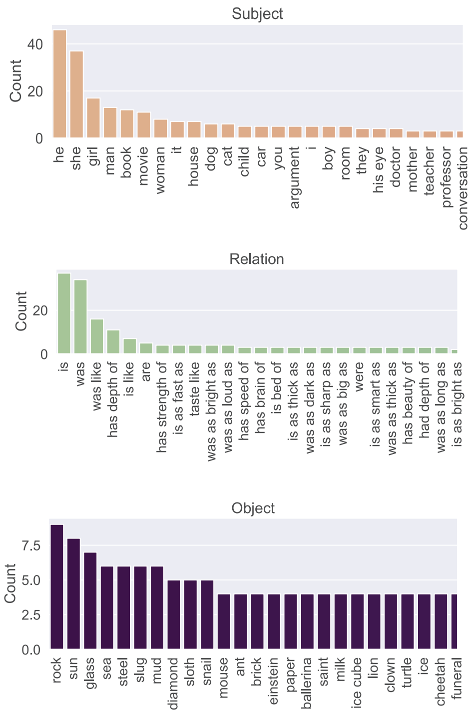

Figure 1: Visualization of 25 most frequent subjects, relations, and objects in the medium train set.

subjects, relations, and objects in the medium train dataset are shown in Figure 1. These were obtained by first segmenting the phrases with syntactic patterns constructed from observation, followed by lemmatization and removal of punctuation and determiners "the", "an", "a" and "that". There are 441 unique subjects, 646 unique relations, and 1,198 unique objects in the medium training set.

3.2 Common-sense Knowledge Types

Next, we examined the test set to determine the types of commonsense knowledge needed to interpret metaphors. Through thematic analysis, we devised 4 categories based on commonsense knowledge, which are not mutually exclusive: common-sense object knowledge, visual metaphors, common-sense social understanding, and cultural knowledge. The same 3 paper authors annotated the test set for these categories, with annotators responsible for separate categories.

Common-sense object knowledge consisted of metaphors that made reference to properties of common objects and animals, such as volume, height or mass of objects, or properties of materials. 68.35% of the test-set was found to require common-sense object knowledge.

Visual metaphors were a subset of common-sense object metaphors, primarily relying on the visual modality, including attributes such as brightness or colour. Some visual metaphors also sketched a vivid visual scene. These examples comprised 14.73% of the test set.

Common-sense social understanding examples required knowing about how humans would react in different circumstances, or required knowing about human emotions. These examples comprised 27.55% of the test set.

Cultural metaphors required knowing cultural traditions, works of art/artefacts, or religion. Due to crowdworkers being recruited from the US, these are centered around US culture. These examples comprised 16.56% of the test set.

4 Baseline Models and Evaluation

4.1 Auto-regressive Language Models

Auto-regressive LMs generate a probability distribution of the next token given all preceding tokens.

Type of knowledge required	Paired sentences
Common-sense (objects)	The new mattress is just as comfortable as sleeping on a (cloud/rocks outside)
Visual	The professor's argument had the clarity of a (crystal glass/marine fog)
Common-sense (social)	She is as embarrassed as a kid that (forgot homework/got an A)
Cultural	The construction was as disastrous as the (1981 musical Cats/The 2019 film based on the musical Cats)

Table 3: Metaphor types based on types of knowledge required (not mutually exclusive)

As such, we can directly compute the probability of a sentence by multiplying the conditional probability of each token at every time step.

$$\tilde{P}(w_1...w_N) = p(w_1)\prod_{i=2}^{N} p(w_i|w_1...w_{i-1})$$

The ability to directly extract probabilities enables the *zero-shot* reasoning of these LMs. For a pair of metaphorical expressions x_1 and x_2 with two corresponding interpretations y_1 and y_2, we feed in the concatenation of the metaphor and the interpretation to the pretrained model without finetuning. We define "forward" and "backward" probabilities assigned to interpretations and figurative language expressions, respectively. For the **forward probability**, for figurative phrase x_i and correct answer y_i, we take

$$P(y_i|x_i) = \frac{P(x_i, y_i)}{P(x_i, y_i) + P(x_i, y_j)}$$

since there are only two answer options. From this, we can calculate accuracy when we taking the indicator of $P(y_i|x_i) > 0.5$. Similarly for the **backward probability** (predicting phrase based on answer), we take

$$P(x_i|y_i) = \frac{P(x_i, y_i)}{P(x_i, y_i) + P(x_j, y_i)}$$

with analogous backward accuracy.[3]

We examine three state-of-the-art large transformer-based LMs of this category: **GPT-2** (with 117M parameters, trained on 40GB of text), **GPT-neo** (with 1.3B parameters, trained on 800GB of text) and **GPT-3** (4 variants between 350M and 175B parameters, trained on 45TB on text) (Radford et al., 2019; Black et al., 2021; Brown et al., 2020). We also examine the performance of these models after finetuning on the training data. GPT-2 and GPT-neo were trained with a batch size of 8, with early stopping on the medium dataset with a patience of 1 epoch, and a minimal hyperparameter search was done with learning rates 1e-5 to 5e-5. GPT-3 was trained with the default parameters of the GPT-3 finetuning API.

4.2 Masked Language Models

We also evaluate the performance of masked LMs on this task. Unlike auto-regressive LMs, masked LMs cannot directly output the probability of a sentence, so it is not possible to directly test the zero-shot performance of these models. Instead, we test the transfer performance by first finetuning them in two ways: on WinoGrande, which is also a binary choice task based on commonsense reasoning, and on several NLI datasets, including SNLI, MNLI, FEVER-NLI and ANLI (Nie et al., 2020; Sakaguchi et al., 2020). The input to the model trained on WINOGRANDE is formatted as `[CLS][metaphor][SEP][answer1][SEP][answer2]`, and we use an extra linear layer on the `[CLS]` token embedding to perform the classification. In addition to the transfer performance, we also use contrastive finetuning by feeding in each metaphor along with both answer choices, and training the model with our dataset to classify which answer is correct. For the NLI model, we examine accuracy using all three labels the model was originally trained with (entailment, neutral, and contradiction), as well as using a forced binary choice paradigm in which the logits for the contradiction label are subtracted from the logits for the entailment label, and the higher "entailment score" is the ending the model predicts. We treat these two conditions as the analog of "zero-shot" for these models.

We examine two masked LMs that are commonly used as baselines on many NLP tasks: **BERT** (Devlin et al., 2019), a transformer-based LM jointly trained on the masked LM and next sen-

---

[3] In actuality, we use the length-normalized probability that a model assigns to a sentence as a heuristic for the total probability, to minimize the effect that the length of a sentence has on the decision (though this is not the probability of the sequence in a strict sense): $P(w_1...w_N) = \exp(-\frac{1}{N}\log\tilde{P}(w_1...w_N))$. Initial experimentation showed marginal differences in accuracy when using these two methods, so we used normalized probabilities by default.

tence prediction objectives, and **RoBERTa** (Liu et al., 2019), an improved variant of BERT which consistently outperforms BERT across most tasks. We use the large variant of both models (350M parameters). BERT and RoBERTa were finetuned on the medium dataset for 8 epochs with batch size 8, following the setting in (Sakaguchi et al., 2020). A hyperparameter search was done with learning rates 5e-6 to 2e-5. Both BERT and RoBERTa were used for the Winogrande experiments, while only RoBERTa was used for the NLI experiment.

4.3 Forced-choice Paradigm

Due to the inherent creativity of metaphors, there may be different interpretations of the same metaphor. For instance, in Table 1, the example "he hustles like he's a billionaire's son" could also be interpreted in other ways, for instance "he uses his father's contacts and social privileges to make money". In a structural-mapping context, the forced choice between two answers constrains the possible meaning of the metaphor to be along one axis (Gentnder and Bowdle, 2008). In this case, it would be whether or not he is required to work hard.

Of course, many of these metaphors have other valid interpretations. In the "billionaire's son" example, another valid axis of interpretation could be the manner in which he works. For instance, the alternative pair could be "he hustles like he's a (billionaire's son | single mother working three jobs)" with answers "he (uses his contacts and social privileges to make money | works extremely long hours with multiple ventures to make money)". It is possible that LMs could come up with other valid interpretations that are not the ones originally intended, motivating us to also look at generation performance in section § 5.2.

4.4 Human Performance

To estimate the expected human performance on this task, we ran a benchmark on the test set with 10 human volunteers who were not authors of the paper. The human annotators were not shown any training examples, so this would be equivalent to the zero-shot setting for models. Participants ranged from 20 to 29 years old, and there were 5 male and 5 female participants. 5 each were native- and non-native English speakers respectively. Participants were mainly graduate student volunteers.

We shuffled the test set and split it into 10 partitions of ≈115 examples for each annotator. The examples were presented with pairs shuffled and separated, in order to create a better comparison with model performance.

Due to differences in vocabulary or cultural background, we instructed participants to mark examples where they weren't confident, such as those that contained words or cultural references they didn't understand.

Model	Zero-shot	Tuned (L)	Tuned (XL)
GPT-2	53.93	54.80	62.65
GPT-neo 1.3B	56.89	69.98	72.00
GPT-3 Ada	59.08	69.17	73.56
GPT-3 Babbage	62.91	73.97	77.31
GPT-3 Curie	65.35	**79.04**	**81.94**
GPT-3 Davinci	**68.41**	-	-
BERT	58.14	83.16	85.69
RoBERTa	**66.18**[4]	**89.22**	**90.32**
Human	94.42	-	-
Human (confident)	**95.39**	-	-

Table 4: Zero-shot and finetuned test accuracies (%), finetuned is averaged across 5 seeds. Dev set accuracies can be found on the leaderboard under the "validation" split.

5 Results

5.1 Inference Results

The first question is **whether strong LMs can interpret metaphors at all when presented with two opposing meanings, in zero-shot or supervised settings**. These results are presented in Table 4. The results for masked language models are higher than those for autoregressive language models, and fine-tuning significantly improves performance for all models.

Zero-shot Performance For the zero-shot setting, we examine the test accuracy based on zero-shot forward probabilities for the GPT models, and the pseudo "zero-shot" transfer performance for BERT and RoBERTa using models pretrained on the WinoGrande task (Sakaguchi et al., 2020). As shown, the GPT-3 models outperform the GPT-2 and GPT-neo models. Among the GPT-3 models, there is a clear correlation between model size and performance, with the largest model (GPT-3 Davinci) achieving the highest zero-shot test accuracy. BERT and RoBERTa achieve accuracies

---

[4] This is the accuracy score when transferring from Winogrande. Pretrained NLI results were 50.47 when using original labels (entailment/contradiction/neutral), and 66.32 when forcing a binary decision.

within the range of GPT-3 models. While our models mostly perform much better than chance in the zero-shot setting, there is still a large gap of 26 percentage points between our best model and human level performance.

Fine-tuned Performance For the fine-tuned setting, all listed models are fine-tuned on the small dataset split. GPT models were trained with language modeling loss, whereas BERT and RoBERTa are trained with contrastive loss. We did not evaluate fine-tuning of GPT-3 Davinci due to budget. Overall, fine-tuning improved accuracy significantly for all models, with GPT-3 models uniformly improving by about 13 percentage points, and BERT/RoBERTa improving by about 25 points. Our best model after fine-tuning is RoBERTa, which reaches within 5% of our human performance.

Prompting We also experiment with prompting methods. Firstly, we use a simple *suffix* prompting method, where we simply append the phrase "that is to say" between the metaphor and the interpretation, which we hypothesized may "explain" to the LM that the previous statement is figurative. We also evaluate the effectiveness of the *examples* method, by appending k random correct metaphor/interpretation pairs before the actual pair we are testing. The results of these experiments can be seen in Figure 2. We found that the suffix method provided a small (1-2%) improvement over the baseline, while the example method was generally ineffective.

Backward accuracies Note the accuracies reported in this section are for the forward direction, and the backward direction is reported in Appendix C. Backward accuracies are lower, with GPT-3 Curie for example having a 7% reduction in accuracy in the zero-shot case. This suggests that selecting a metaphorical expression to match a literal phrase is more challenging than the reverse for LMs.

Paired Evaluation Because our dataset is formatted as a Winograd schema, we can take advantage of *group scoring* to evaluate models more stringently (Elazar et al., 2021). We found that performance for autoregressive models plummeted under this evaluation scheme, while masked language models also suffered in accuracy. The human scores were least affected. Details are in Appendix D. This is most likely related to the phenomenon found in § 6.1.

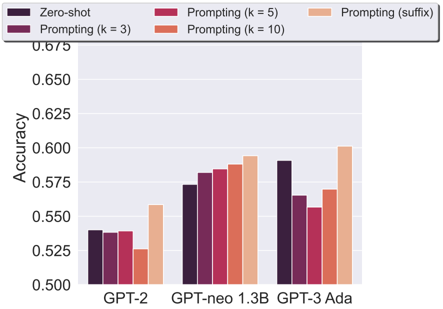

Figure 2: Comparison of prompting methods with autoregressive models

5.2 Generation Results

Next, we examine **if models can generate sensible interpretations for metaphors**. Given the difficulty of evaluating text generation, compounded by the difficulty of figurative language, we opted for manual evaluation of one tenth of the test dataset using generations of the strongest autoregressive model: GPT-3 Davinci (≈175B parameters).

The metaphor was given as input to the model, and 4 completions were generated for each metaphor, with a maximum length of 100 tokens. Completions were also truncated to the first sentence, as initial experiments showed that contradictory statements (e.g. "he was talented. But he was not very talented") were often generated across subsequent sentences. Suffix prompting was also used because of the lack of context, with "That is to say, " appended to each metaphor. Only the first sentence of the output was evaluated. The temperature parameter was determined through grid search through values [0.2, 0.4, 0.6, 0.8, 1] on a small separate set of metaphors. A human annotator inspected the generated completions and found that a temperature of 0.4 produced the most correct results.

Three paper authors labelled completions generated by GPT-3 Davinci as either correct, incorrect, or literal. In some cases, there were valid interpretations that were not the same as the answer given by crowdworkers, which were also marked correct. If the model simply restated the metaphor with no interpretation, the completion was marked as literal. Because some metaphors are ambiguous when presented without context, those examples were not counted. The inter-rater reliability was moderate due to differing standards for correctness (Krippendorff's α = 0.5567). The majority vote was taken between annotators' judgments.

GPT-3 Davinci's accuracy, counting literalized metaphors as incorrect, was 50.8%. Not counting literalized metaphors, accuracy was 63.9%. In 37.7% of cases, GPT-3 generated contradictory completions among the 4 completions. There was at least one correct completion for 78.1% of the metaphors, but only 19.3% of metaphors had all completions correct. Examples of annotated generations can be found in Appendix G.

6 Performance and Error Analysis

With these results in mind, we examine **what kinds of errors models make, and what factors make the task difficult.**. This is covered in § 6. We find that autoregressive models rely on the predicted probability of each answer by itself to predict the answer, and that this holds true for all models, before and after training. We find that models have difficulty in interpreting "sarcastic" metaphors, and sometimes inexplicably interpret very simple metaphors wrong. We also examine error typology according to the commonsense typology of § 3.2 and find that models improve significantly on object, visual and social commonsense when trained, but not on cultural commonsense.

6.1 Reliance on Probability of Answers

We find that models often rely solely on the predicted probability of answers y_1 and y_2 to make their final predictions, regardless of the context. This led models to make the same prediction for the paired sentences in many cases. Figure 3 and Table 5 show that this trend improves with fine-tuning, and that GPT-3 is best able to disentangle the probability of y_i and the probability of $P(y_i|x_i)$, but all three models show a heavy tendency to predict based on the relative probability of an answer alone.

We hypothesize that this may be one reason why BERT and RoBERTa achieve the best finetuned performance; they use a contrastive finetuning strategy providing both the correct and incorrect options as input to the model. On the other hand, the GPT models were finetuned with only the correct option, making the comparison unfair. One way to finetune GPT models contrastively is to include both options into a cleverly engineered prompt, but we leave this as a direction for future work.

Model	r	p
Untrained		
GPT-2	0.8128	6.700×10^{-136}
GPT-neo	0.7891	6.075×10^{-123}
GPT-3	0.7392	4.329×10^{-100}
Trained		
GPT-2	0.6765	6.700×10^{-78}
GPT-neo	0.6689	1.456×10^{-75}
GPT-3	0.4157	2.598×10^{-25}

Table 5: Spearman r-values and p-values between $P(y_i|x_i)$ and $P(y_i)$

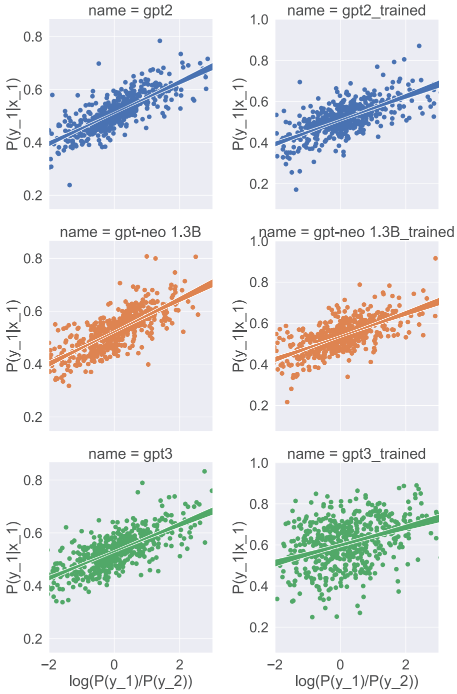

Figure 3: Models over-rely on probability of the answer to do their predictions. y-axis is probability of the first interpretation (answer) given metaphor while x-axis is log odds of the first interpretation.

6.2 Other Factors Influencing Correctness

We also examined the influence of several other factors on correctness. The point-biserial correlation between length of the context phrase and the binary correctness value was -0.1544 with a p-value of 1.50×10^{-7}, indicating that longer phrases are harder to interpret correctly. The point-biserial correlation between answer probability and binary correctness was 0.1840, with a p-value of 3.50×10^{-10}, indicating that examples where the answer was already more probable were more likely to be answered correctly, in line with our findings that models tended to predict the answer that was already more plausible alone.

Furthermore, we conducted an analysis on subjects, objects, and relations as defined in § 3.1. We examined accuracy by part of speech patterns in each part of the metaphor, as well as by wordnet hypernyms present in each part of the metaphor. This is detailed in Appendix E and Appendix F (Fellbaum, 1998). We used NLTK for POS tagging (Loper and Bird, 2002).

6.3 Qualitative Analysis of Error Trends

Common Sense Knowledge We first examine the error tendencies by the type of common sense knowledge described in § 3.2. Table 6 summarizes accuracies for these types of commonsense questions compared to humans.

Model	Obj	Vis	Soc	Cul
Untrained				
GPT-2	52.17	52.07	55.38	**58.42**
GPT-neo	56.38	55.62	56.01	**62.10**
GPT-3 Curie	75.00	71.00	72.47	**78.42**
Trained				
GPT-2	53.57	51.48	**57.91**	57.37
GPT-neo	70.15	**72.78**	68.67	70.00
GPT-3 Curie	**87.50**	84.62	83.86	83.16
BERT	87.37	**92.31**	84.18	77.37
RoBERTa	91.20	**94.08**	89.56	83.68
Human	95.41	**96.45**	93.99	90.00

Table 6: The performance of models across different commonsense categories, in terms of accuracy on examples annotated with that category (%). The strongest category of each model is highlighted.

We find that both humans and trained models tend to find object commonsense and visual commonsense metaphors easier to interpret. We find that as models improve, most of the performance gain comes from the object, visual and social commonsense categories. Interestingly, the untrained models do quite well on cultural examples, but do not improve much on the culture category when trained. This makes sense, as the cultural examples tend to be quite disparate, so training would not help as much with other examples.

Sarcastic Metaphors For both humans and LMs, many of the errors are "sarcastic" metaphors, such as saying "the girl was as bubbly as still water" to mean "the girl was bland", rather than "the girl was vivacious". These sentences can be difficult if the model or human focuses on simple word association (bubbly with vivacious) without reading the entire sentence to understand the sarcasm.

Inexplicable Errors We examined the errors made by GPT-3 Curie (trained) and found that there was little overlap with mistakes made by humans. Of the 64 human errors, 13 were also errors made by GPT-3. GPT-3 made many more "obvious" errors, such as predicting "The ball is a big red sun" to mean "the ball is small" rather than "the ball is big and red" This is in contrast to the sentences in which humans made errors, which often contained rare vocabulary or unfamiliar cultural references.

7 Related work

7.1 Figurative Language Identification

Most existing work focuses on identifying figurative language at the word level. The VU Amsterdam Metaphor Corpus (VUA) is the largest available corpus of metaphorical language, annotated by humans (Steen et al., 2010). Two shared tasks on metaphor identification have been run (Leong et al., 2018, 2020). Both have utilized the VUA corpus, and the latter also introduced the TOEFL corpus, sampled from essays written by non-native English speakers (Leong et al., 2020; Beigman Klebanov et al., 2018). Most participants in the shared tasks used neural models, notably BERT, RoBERTa, and Bi-LSTMs (Leong et al., 2020; Bizzoni and Ghanimifard, 2018; Gao et al., 2018; Pramanick et al., 2018). These models are generally improved when augmented with semantic data, such as concreteness, and multimodal information.

Another line of work focuses on probing models to determine the extent of metaphor recognition. For instance, BERT assigns higher pseudo-log-likelihood scores to metaphors than nonsense expressions, and its contextualized representations show some signs of contextualizing the object domain (Pedinotti et al., 2021). Another study uses linear probes trained on layers of BERT to predict whether a word usage is literal or nonliteral, and finds that this can be done effectively, especially using middle layers as a representation (Aghazadeh et al., 2022),

Despite the utility of these tasks and datasets, they have drawbacks. Most of the metaphor use is conventional, so this task does not capture novel metaphors well. The word-level annotation also does not lend itself well to capturing extended conceptual metaphors. Finally, metaphor interpretation may be a more difficult, although less studied, task.

7.2 Figurative Language Interpretation

Recent studies mostly focus on metaphor paraphrases, either through identification (Bizzoni and Lappin, 2018) or generation (Shutova, 2010; Su et al., 2017; Mao et al., 2018). However, there has not been as much work done on interpretation as on detection, and framing metaphor interpretation as a paraphrase task may not capture the emergent meaning of metaphors, such as the intended emotion, or the interaction of subject, relation and object in the metaphor (Tong et al., 2021; Mohammad et al., 2016).

Other work has focused on interpreting figurative language in narratives in context, based on plausible continuations of figurative language such as idioms and similes from stories (Chakrabarty et al., 2021a) or dialogues (Jhamtani et al., 2021). This represents a promising direction, and our work focuses on expanding our understanding of LMs' ability to interpret non-conventionalized metaphors.

7.3 Other Figurative Language Datasets

We note that there are several other challenging NLI datasets available which contain figurative language, including the DNC corpus, and the RTE dataset (Poliak et al., 2018; Chakrabarty et al., 2021b). Other datasets, such as RiddleSense, explicitly test models through difficult commonsense inference, involving figurative language (Lin et al., 2021).

Our work is distinguished by the Winograd schema format, as this format provides a better guard against the possibility that models have simply memorized common word associations that occur in figurative language. Additionally, we specifically instructed crowdworkers to be creative, and this resulted in longer figurative phrases which require more detailed commonsense knowledge. It is likely that a fair number of these figurative phrases have never appeared in any training corpus. However, our figurative phrases also differ from riddles, as they are not supposed to be difficult to reason about, given that the source, relation and object are properly contextualized.

7.4 Human Language Processing

Humans typically do not have any more difficulty processing metaphorical statements in context compared to literal statements (Fussell and Moss, 2008; Glucksberg, 2003). This may be because certain words serve as a *dual reference*, which is to say they refer simultaneously to a physical referent and an abstract superordinate category (Glucksberg, 2003). For instance, "shark" may refer to literal sharks, as well as anything that is considered vicious, leading to utterances such as "that lawyer is a shark".

Metaphorical language processing has also been studied in second-language learners, in the case of idioms. In most cases, the meaning of an unfamiliar idiom is inferred from the context or from word association (Cooper, 1999; Carston and Wearing, 2011; Wolff and Gentner, 2000).

As LMs excel at word-association based tasks, this is an encouraging finding. However, there is still a gap between LM and human performance even in our task, in which one answer is obviously wrong when the input is correctly understood.

We take into account that these results are for conventionalized figurative language and that some of the more creative phrases in this dataset may take a longer time to process for humans as well. This is especially true for non-native English speakers. However, the high human accuracy on this task with half the participants being non-native English speakers suggests that this was not a major barrier.

8 Conclusion

We present a Winograd-like benchmark task to test the ability of LMs to reason about figurative language, based on large-scale collection of creative metaphors written by humans. We find a large gap between LM zero-shot and human performance on this dataset, but show that models can be fine-tuned to perform well on this particular task.

We hope that this work will encourage further study of nonliteral reasoning in LMs, especially in few-shot settings. Given that metaphorical reasoning may play a role in problem-solving and linguistic creativity, the development of models, training methods, or datasets that enable metaphorical reasoning may improve models' abilities to reason creatively and draw analogies between situations that may appear to be different on the surface. One avenue we hope to investigate is multimodal metaphors, as this dataset currently includes only text-based metaphors. Nonliteral expressions also remain understudied cross-linguistically, but further work on identifying and interpreting metaphors in other languages may also improve the abilities of multilingual models.

9 Ethical Considerations

9.1 Potential Risks

Figurative language has the potential to be used in a harmful way, especially against minority and historically disadvantaged groups. Such language is often emotionally charged or used to insult others, so we took care to remove any examples that were potentially offensive, especially toward protected groups. We acknowledge that this was based on our own judgment, and generically insulting language (for instance, a metaphor that implies that someone is ugly) was not removed because it was not insulting toward any particular individual.

All examples from Fig-QA are also in English, as it is the language that all authors speak, and this was a preliminary dataset, being the first of its type that the authors have worked on. However, figurative language is not just important in English, and we leave investigation of figurative language in other languages as future work.

9.2 Terms of Use of Artefacts Used

Additional datasets we used were the Winogrande dataset, SNLI, MNLI, FEVER-NLI and ANLI. Winogrande is licensed under the Apache 2.0 license, which allows modification and distribution, fitting our use case. SNLI is licensed under a Creative Commons Attribution ShareAlike 4.0 International license, which allows us to share and adapt the work as long as we give attribution. The majority of MNLI is licensed under OANC, which allows free use. The fiction section of this dataset consists mostly of works in the public domain, but several stories are licensed: *Seven Swords* is available under a Creative Commons Share-Alike 3.0 Unported License, while *Living History* and *Password Incorrect* are available under Creative Commons Attribution 3.0 Unported Licenses. These licenses allow sharing and adaptation with attribution. FEVER-NLI is licensed under an MIT license, which also allows modification, distribution, and reuse. ANLI is licensed under Creative Commons Attribution-NonCommercial 4.0 International, which also allows sharing and reuse as long as we give attribution.

Models used were GPT-2, GPT-neo, GPT-3, BERT and RoBERTa. GPT-2 and GPT-neo are licensed under an MIT license, which does not place any restrictions on its use. BERT is licensed under an Apache License 2.0, which allows modification and distribution. RoBERTa is licensed under a GNU General Public License v2.0. This fits our use case as we are only running and studying the model. GPT-3 is licensed by Microsoft, and we used the public API to receive output.

9.3 Computational Infrastructure and Computing Budget

To run our computational experiments, we had access to a compute cluster, but minimal compute is needed to run the experiments in this paper. We generally did not use more than 2 GPUs at a time. The only models that required GPU parallelism were the GPT-neo models. An estimated 20 GPU hours are required.

Our computing budget was roughly 100 USD. We also used roughly 20 USD on credits for the GPT-3 API.

Acknowledgements

We thank Pengfei Liu, Lyuyang Hu, and Chih-Hao Wang for helping us set up the leaderboard for this dataset on Explainaboard. We also thank Pengfei Liu for helping run GPT-3, Danish Pruthi for guidance on setting up the MTurk task, and all participants who contributed to the human benchmark. Lastly, we thank all the Turkers who contributed metaphors to the dataset.

A Crowdsourcing Details

We crowdsource metaphorical expressions and their interpretations through Amazon Mechanical Turk. Workers were recruited from the United States and were limited to those who had a $> 98\%$ approval rating on the platform, and who had also completed more than 1000 Human Intelligence Tasks (HITs). Data collection was split into two stages: in the first stage, 1458 train examples, and all the dev and test examples were collected. In the second stage, the remaining 6558 training examples were collected. We identified some workers who created especially good examples in the first stage, and recruited them back for more examples in the second stage. Workers were paid $0.33 for each pair of sentences and were asked to generate 3 pairs at a time. An author of this paper wrote an initial pilot set of sentences, and timed themselves while writing some sentences. They found that each pair took around 1 minute to write, though this varied (less creative examples took less time, while more creative examples took more time). This extrapolates to an hourly rate of 19.80 USD, which is above the minimum wage in all US states, where workers were located.

Our HIT task was structured as follows: At the top of the page, the workers are shown the following instructions: "Your task is to generate three pairs of sentences with opposite or very different meanings, both of which contain rare/creative metaphors, which means metaphors that would not appear often in text on the internet, books, social media or news sites, but that can still be easily understood by people. For each metaphor, you should also provide a literal (non-metaphorical) sentence with the same meaning." Then, we display one example of a valid sentence pair. There is a button that opens a modal with more detailed instructions and some more valid/invalid examples for reference. Below that, we display three random words, which workers are encouraged to use in their sentences if they get stuck. Finally, we display three sets of 5 text fields for workers to fill in: one for the start phrase, two for each metaphorical phrase, and two for each literal interpretation. As the user types in each start phrase, we prepend a copy of their phrase before the corresponding metaphor fields in the UI using some embedded JavaScript, which we found helped reduce confusion and resulted in less improperly formatted responses.

We launched many batches of these HITs until we had collected the desired quantity of data. Then, we converted the form responses into sentence pairs and validated each pair by hand before adding it to our dataset.

B Invalid Examples

Figurative language examples collected from crowdworkers were excluded if they (a) did not make sense given the meaning and the metaphorical expression, (b) had grammar or spelling errors that rendered them unintelligible, or (c) did not follow the format specified by the task template.

Examples are given below:

1. Do not make sense given the meaning and the metaphorical expression

Paired sentences	Possible answers
He was resourceful like toilet paper He was resourceful like a mess	He was very resourceful. He wasn't resourceful at all
The night was as long as a spool of thread The night was as long as a winding road	The night is long The night dragged on
the concert of the lession is a main and a major the concert of the lession features	we concert everyone we concert our loved one

Table 7: Examples that were rejected due to being nonsensical.

2. Significant grammar or spelling errors

Paired sentences	Possible answers
fallten data are very much trusted fallten data are very valuable	fallten are nice flatten are safe
CAR IS BIRD FEATHEAR CAR IS COTTON	CAR SITE IS ROUGH CAR SITE IS HARD
Inflation is as natural as Minnesota rainfall in June Inflation is as natural as Minnesota snowfall in June	Inflation is perfectly natural Patient is in a natural result of other things

Table 8: Examples that were rejected due to having significant spelling or grammar errors.

3. Do not follow format

Paired sentences	Possible answers
This attack is as weak as a feather This attack is as weak as a breeze	The attack is useless The attack doesn't work
My car motor is dusty like old cave My car motor is dusty like abandon building	Car motor is very rusty car motor is very dusty
the writer is stuck between a rock And another hard place the writer is stuck between a rock And a pebble	He is just stuck doesnt have a choice The writer can get over the pebble

Table 9: Examples that were rejected due to not following the specified format.

Efforts were made to ensure that the final dataset contains no offensive content or personally identifiable information. WorkerID and other potentailly personally identifying information were not included.

C Backward accuracies

Model	Zero-shot	Fine-tuned (L)
GPT-2	52.18	52.00

Multi-Vector Models with Textual Guidance for Fine-Grained Scientific Document Similarity

Sheshera Mysore[1*] **Arman Cohan**[2,3] **Tom Hope**[2,3]

Abstract

We present a new scientific document similarity model based on matching fine-grained aspects of texts. To train our model, we exploit a naturally-occurring source of supervision: sentences in the full-text of papers that cite multiple papers together (*co-citations*). Such co-citations not only reflect close paper relatedness, but also provide textual descriptions of *how* the co-cited papers are related. This novel form of *textual supervision* is used for learning to match aspects across papers. We develop multi-vector representations where vectors correspond to sentence-level aspects of documents, and present two methods for aspect matching: (1) A fast method that only matches single aspects, and (2) a method that makes sparse multiple matches with an Optimal Transport mechanism that computes an Earth Mover's Distance between aspects. Our approach improves performance on document similarity tasks in four datasets. Further, our fast single-match method achieves competitive results, paving the way for applying fine-grained similarity to large scientific corpora.[1]

1 Introduction

The ability to identify similarity across documents in large scientific corpora is fundamental for many applications, including recommendation (Bhagavatula et al., 2018), exploratory or analogical search (Hope et al., 2017, 2021b; Lissandrini et al., 2019), paper-reviewer matching (Mimno and McCallum, 2007; Berger et al., 2020) and many more uses.

Scientific papers often describe multifaceted arguments and ideas (Hope et al., 2021a; Lahav et al., 2022), suggesting that models capable of matching specific aspects can better capture overall document relatedness, too. For example, sentences in research abstracts can often be categorized as descriptions of objectives, methods, or findings (Kim et al., 2011; Chan et al., 2018), centrally important discourse structures of scientific texts.

In this paper, we propose a new model for document similarity that makes aspect-level matches across papers and aggregates them into a document-level similarity. We focus on sentence-level aspects of paper abstracts, and train multi-vector representations of papers in terms of their contextualized sentence embeddings. To train our models, we leverage a readily available data source: sentences that co-cite multiple papers. Unlike recent work that used citation links for learning scientific document similarity (Cohan et al., 2020), we observe that papers cited in close proximity provide a more precise indication of relatedness. Furthermore, the citing sentences typically describe how the co-cited papers are related, in terms of shared aspects (e.g., similar methods or findings, related challenges or directions, etc.). Building on this observation, we leverage these textual descriptions as a novel source of *textual supervision*, using them to guide our model to learn which sentence-aspects match without any direct sentence-level supervision. Guidance for the document similarity model is obtained via an auxiliary sentence encoder model that is used for aligning abstract sentences by finding pairs most similar to the citing sentence text.

Our document similarity objective is modeled as a function of similarity between sentence-level matches. We explore two strategies to aggregate over sentence-level distances between documents. First, a single-match method with minimum L2 distances between document aspect vectors. This approach readily supports approximate nearest neighbor search methods for large-scale retrieval. Second, a multi-match method that computes an Earth Mover's Distance between documents' aspect vectors by solving an Optimal Transport problem. This yields a soft sparse matching of aspect vectors, which when combined with their L2 distances gives a document-level distance.

Finally, as an additional benefit of our representation, our models also support a finer *aspect-conditional* retrieval task (Hope et al., 2017, 2021a; Chan et al., 2018; Mysore et al., 2021) where aspects can be specified by selecting abstract sentences — for example, selecting sentences describing methods and retrieving papers using similar methods. As we show, naively encoding sentences without their context leads to subpar results in this task, and our representation that does take context into account dramatically improves results.

Extensive empirical evaluation on four English scientific text datasets and seven similarity tasks at the level of documents and sentences demonstrates the effectiveness of our models. These include biomedical document retrieval tasks and a recent faceted query-by-example corpus of computer science papers (Mysore et al., 2021). This latter dataset is used for evaluating retrieval conditioned on specific aspects in context (e.g., for finding papers with similar methods to a query document), demonstrating that our model can be used in this challenging and important setting. In summary, we make the following main contributions:

1. **Multi-Vector Document Similarity Model**: We present ASPIRE[2], a multi-vector document similarity model that flexibly aggregates over fine-grained sentence-level aspect matches.
2. **Co-Citation Context Supervision**: We exploit widely-available co-citation sentences as a new source of training data for document similarity and provide a method using a novel form of textual supervision to guide representation learning for aspect matching.
3. **State of the Art Results**: Our ASPIRE models outperforms strong baseline methods across four datasets for the abstract and aspect-conditional similarity tasks.

2 Problem Setup

Given query document Q and a candidate amongst a set of documents $C \in \mathcal{C}$, where documents consists of N sentences $\langle S_1, S_2, \dots S_N \rangle$ we aim to leverage fine-grained document similarity in two problem settings. An abstract level retrieval task (Brown et al., 2019; Cohan et al., 2020) and an aspect-level retrieval task (Mysore et al., 2021):

Def 1. *Retrieval by abstracts: Given query and candidate documents –* Q *and* $\mathcal{C}$ *a system must output the ranking over* $\mathcal{C}$.

Def 2. *Aspect-level retrieval by sentences: Given query and candidate documents –* Q *and* $\mathcal{C}$*, and a subset of sentences* $\mathcal{S}_Q \subseteq Q$ *conditional on which to retrieve documents, a system must output the ranking over* $\mathcal{C}$.

Modeling Desiderata: Next, we also outline key desired properties we require from models developed for task definitions 1 and 2. We follow these desiderata when building our methods (§3.1).

1. *Allowing specification of optional fine-grained aspects*: We would like models to allow the ability to specify fine-grained query aspects in a query document based on which retrievals should be made. These may be obtained automatically (e.g., with a discourse tagging method) or via user specification.
2. *Scalable to large corpora and efficient inference*: State of the art retrieval systems often rely on expensive cross-attention mechanisms on query-document pairs making training and inference expensive (Zamani et al., 2018; Lin et al., 2021). This is exacerbated for longer scientific documents requiring specific transformer models (Caciularu et al., 2021). We require our methods to leverage large training corpora and allow efficient inference at scale.

3 Proposed Approach: ASPIRE

In this section we describe our approach to document similarity – ASPIRE. We model finer-grained matches between documents at the level of sentences via contextual representations and aggregating over matches to obtain similarities between whole documents. We leverage co-citation sentences as a source of document similarity and also as implicit *textual supervision* describing related aspects of co-cited documents. We formulate our multi-vector models (Luan et al., 2021; Humeau et al., 2020) that can support scalable inference as novel multiple-instance learning (MIL) models.

3.1 Fine-grained Document Similarity

We assume to be given a training set consisting of sets of documents $\mathcal{P}$ which are *weakly-labeled* for similarity. We leverage widely-available sets of papers co-cited together in the same sentence as similar (see Figure 1). This builds on the observation that co-citations in close proximity (e.g., in the same sentence) are strong indicators for paper relatedness (Gipp and Beel, 2009).

We follow the contrastive learning framework, commonly used for learning semantic similarity (Reimers and Gurevych, 2019; Cohan et al., 2020).

Parser Adaptation and Projection with Quasi-Synchronous Grammar Features

[...] On the more difficult problem of cross-lingual parser projection, we learn a dependency parser for a target language by using bilingual text, an English parser, and automatic word alignments [...]

(Smith and Eisner, 2009)

Most previous work in cross-language adaptation has used parallel corpora to project dependency structures across translations using word alignments (Smith and Eisner, 2009; Ganchev et al., 2009)

Dependency Grammar Induction via Bitext Projection Constraints

[...] We consider generative and discriminative models for dependency grammar induction that use word-level alignments and a source language parser (English) to constrain the space of possible target trees. [...]

(Ganchev et al., 2009)

Figure 1: Example illustrating the signal in co-citations. Of all the sentences in co-cited abstracts ⓐ and ⓒ, the sentences shown are each individually aligned to co-citation context ⓑ as per embeddings from $\texttt{BERT}_{\mathcal{E}}$ (§3.2.2). Consequently these sentences in ⓐ and ⓒ are treated as sharing aspects between the co-cited papers and our fine-grained similarity model for single matching is trained to align them.

We train models on triples of the form (p, p', n) where $p, p' \in \mathcal{P}$ and $n \notin \mathcal{P}$ is a randomly selected negative, using the triple margin ranking loss $\mathcal{L}_f(p, p', n) = \texttt{max}[f(p, p') - f(p, n) + m, 0]$, where $f(\cdot, \cdot)$ is a distance between documents. All pairwise-combinations $p, p' \in \mathcal{P}$ are treated as positive pairs in-turn. In this work, we parameterize f based on the distances between finer-grained document aspects $\mathcal{A}$. Given documents p and p', we focus on a family of functions f of the form:

$$f(p, p') = \sum_{(i,i') \in \mathcal{A}_p \times \mathcal{A}_{p'}} w_{i,i'} \cdot d_{i,i'}. \quad (1)$$

Here, $\mathcal{A}_p \times \mathcal{A}'_p$ represents the space of alignments between aspects of document p and p', $d_{i,i'}$ denotes a distance between two aspects i, i', and $w_{i,i'}$ represents a weight indicating the contribution of the aspect similarity to the overall document similarity. Unlike previous work (Neves et al., 2019; Jain et al., 2018; Hope et al., 2017), we make no assumption on specific aspect semantics in deriving a model architecture, and focus on aspects in the form of *general* subsets of document sentences.

For learning, we only assume to be given *document-level* supervision (sets of documents $\mathcal{P}$), and no gold supervision on *aspect-level* similarity as in other related work, eg. Jain et al. (2018). Our task thus consists of learning $w_{i,i'}$ and $d_{i,i'}$ via indirect supervision. We cast this problem setting as a novel type of multi-instance learning (MIL) (Ilse et al., 2018) problem. Prior work in MIL broadly aims to learn instance level classifiers given labels for a bag of instances, this bears resemblance to our setting, where instances are aspects $\mathcal{A}$. However, unlike prior MIL work we focus on learning *similarity* rather than *classification*. We formulate two variants of f in Equation 1:

(1) A single match model (§3.2.2) which considers documents similar based on the single most similar alignment $\hat{i}_p, \hat{i}_{p'} \in \mathcal{A}_p \times \mathcal{A}'_p$. This assumes $w = 1$ for the best alignment and $w = 0$ elsewhere.

(2) A multi match model (§3.2.3) which makes multiple alignments between documents. We find aspect importance weights $w_{i,i'}$, by solving an Optimal Transport (OT) problem (Peyré et al., 2019).

In both variants, during training we learn contextualized aspect embeddings that minimize the contrastive loss paramertized with f, described further in §3.2.

Co-citation Contexts as Supervision: Finally, we present a method for incorporating implicit natural language supervision during training, presented by co-citation sentences which describe specific relations between co-cited documents. For example, Figure 1 shows a case explaining the similarity between the co-cited papers' methods. We leverage this textual supervision to find a "best" alignment $\hat{i}_p, \hat{i}_{p'}$ in the single-alignment variant (1), and for guiding the optimal transport plan in variant (2). We describe the specific model components next. Fig 2a presents a schematic for our approach.

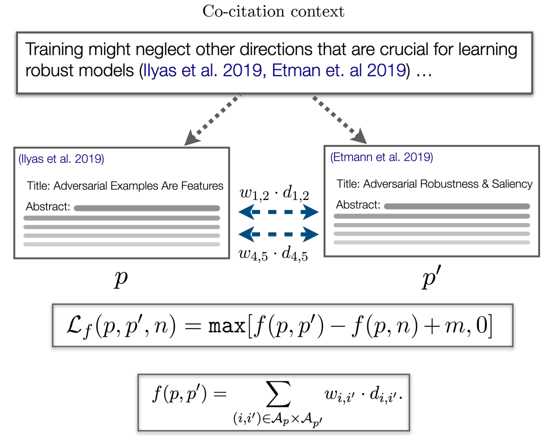
3.2 Model Description

3.2.1 Document Encoder

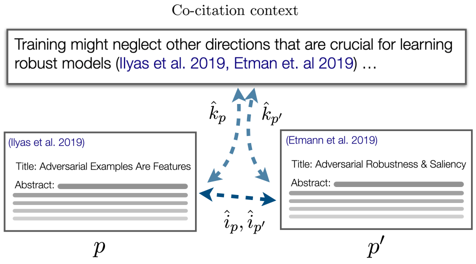
We leverage a pre-trained BERT-based language model as a document encoder as the base of all our methods. Our encoder is mainly intended to output contextualized sentence representations. Given a document title and abstract, this is achieved as:

$$\mathbf{S} = \texttt{BERT}_\theta([\texttt{CLS}]\ \texttt{Title}\ [\texttt{SEP}]\ \texttt{Abstract}) \quad (2)$$

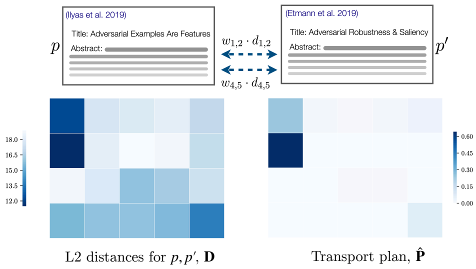
where $\mathbf{S} \in \mathbb{R}^{N \times d}$ represents contextualized sentences $\mathbf{s}_1 \ldots \mathbf{s}_N$ stacked into a matrix. Here, each



(a) Learning fine-grained document similarity using co-citations.



(b) The single best match, $\hat{i}_p, \hat{i}_{p'}$, is computed from textual supervision in the co-citation context.



(c) Multi-aspect matches via a sparse transport plan.

Figure 2: Approach overview. (a) We train fine-grained similarity models using papers co-cited in the the same sentence in research papers. (b) Single-match models are learned from implicit supervision in co-citation contexts. (c) Multi-match models are learned by aligning aspect representations by solving an Optimal Transport problem.

$\mathbf{s}$ is obtained by mean-pooling word-piece embeddings from the final layer of $\texttt{BERT}_\theta$ for the sentence tokens. Pairwise distances between sentences $d_{i,i'}$ in Eq 1 for p, p', are represented as a matrix $\mathbf{D} \in \mathbb{R}^{N \times N'}$ of L2 distances between $\mathbf{S}_p$ and $\mathbf{S}_{p'}$.

3.2.2 Single Match & Textual Supervision

Our single match model makes the assumption that document similarity is explained by a single best match, giving $f_{\texttt{TS}}(p, p') = \mathbf{D}[\hat{i}_p, \hat{i}_{p'}]$. Here, we leverage weak supervision from co-citation contexts for training. This is done by using an auxiliary sentence encoder to compute a maximally aligned sentence $\hat{i}_p$ in co-cited paper p to the co-citation context, similarly $\hat{i}_{p'}$ aligns a sentence in p' to the co-citation context. Then the two context aligned sentences are treated as aligned to each other, for training. In practice, the same papers $\mathcal{P}$ can be co-cited in multiple different papers (in $\sim 30\%$ of co-cited papers) giving us a set of co-citation sentences, $e \in \mathcal{E}$ and training data of the form $(\mathcal{E}, \mathcal{P})$. Alignments of the sentences in p and p' to the co-citation contexts $e \in \mathcal{E}$ are computed as:

$$\begin{aligned} \hat{i}_p, \hat{k}_p &= \operatorname*{\texttt{argmax}}_{i=1...N, k=1...N'} \mathbf{R}_p \mathbf{R}_{\mathcal{E}}^T \\ \hat{i}_{p'}, \hat{k}_{p'} &= \operatorname*{\texttt{argmax}}_{i=1...N, k=1...N'} \mathbf{R}_{p'} \mathbf{R}_{\mathcal{E}}^T \end{aligned} \tag{3}$$

Here $\mathbf{R}_p$, $\mathbf{R}_{p'}$, and $\mathbf{R}_{\mathcal{E}}^T$ are independent sentence representations for p, p' and e, respectively, obtained from a auxiliary sentence encoder $\texttt{BERT}_{\mathcal{E}}$ (details below), and $\hat{i}_p, \hat{i}_{p'}$ represent the single best alignment of sentences across p, p' "anchored" on textual supervision sentences $\mathcal{E}$. Importantly, this supervision is only used during training time to guide learning. This procedure is depicted in Figure 2b with Figure 1 showing an example.

Co-citation Context Encoder The encoder $\texttt{BERT}_{\mathcal{E}}$ represents a SciBERT based sentence encoder pre-trained for scientific text similarity. We train $\texttt{BERT}_{\mathcal{E}}$ on sets of co-citation contexts referencing the same set of papers (i.e. $\mathcal{E}$) in a contrastive learning setup with random in-batch negative samples. This set, $\mathcal{E}$, can be considered as paraphrases since co-citation sentences citing the same papers often describe similar relations between the papers. This model is similar to Sentence-BERT (Reimers and Gurevych, 2019) and we refer to it as `CoSent-Bert`. In training document encoder $\texttt{BERT}_\theta$, we keep $\texttt{BERT}_{\mathcal{E}}$ frozen. Appendix C presents more detail on $\texttt{BERT}_{\mathcal{E}}$ design.

3.2.3 Multiple Matches & Optimal Transport

While a single best sentence alignment $\hat{i}_p, \hat{i}_{p'}$ may sufficiently explain document similarity for some documents and applications, documents often have a stronger and weaker alignments. So, in computing sentence alignments between documents we would like a sparse matching that aptly weights alignments while ignoring non-alignments — corresponding to learning weights $w_{i,i'}$ in Eq 1. To model this intuition we leverage optimal transport.

Optimal Transport The OT problem is constituted by two sets of points, $\mathbf{S}_p$ and $\mathbf{S}_{p'}$ as in our case, and distributions $\mathbf{x}_p$ and $\mathbf{x}_{p'}$ according to which the set of points is distributed. The OT problem involves computation of a transport plan $\hat{\mathbf{P}}$, which converts $\mathbf{x}_p$ into $\mathbf{x}_{p'}$ by transporting probability mass while minimizing an aggregate cost computed from the pairwise costs $\mathbf{D}$ of aligning the points in $\mathbf{S}_p$ and $\mathbf{S}_{p'}$. $\hat{\mathbf{P}}$ is constrained such that its columns and rows marginalize respectively to $\mathbf{x}_p$ and $\mathbf{x}_{p'}$ (so that all mass is accounted for). Specifically, the computation of $\hat{\mathbf{P}}$ takes the form of a constrained linear optimization problem:

$$\mathcal{W} = \min_{\mathbf{P}\in\mathcal{S}} \langle \mathbf{D}, \mathbf{P} \rangle \tag{4}$$

$$= \min_{\mathbf{P}\in\mathcal{S}} \sum_{i=1}^{N} \sum_{j=1}^{N'} \mathbf{D}[i,j]\mathbf{P}[i,j] \tag{5}$$

$$\mathcal{S} = \{\mathbf{P} \in \mathbb{R}_{+}^{N\times N'} | \mathbf{P}\mathbf{1}_{N'} = \mathbf{x}_p, \mathbf{P}^T\mathbf{1}_{N'} = \mathbf{x}_{p'}\} \tag{6}$$

where $\mathcal{W}$ refers to the Wasserstein or Earth Movers Distance and $\hat{\mathbf{P}}$ is the minimizer resulting from solving Eq 5. Of interest here is an established result which shows $\hat{\mathbf{P}}$ to be sparse with $\mathcal{O}(N+N')$ non-zero entries (Swanson et al., 2020). Therefore, $\hat{\mathbf{P}}$ represents a soft sparse alignment of sentences and can be used as weights $w_{i,i'}$ in Eq 1, with document distances computed as $f_{\mathtt{OT}}(p,p') = \langle \mathbf{D}, \hat{\mathbf{P}} \rangle$. Fig 2c presents a schematic for this approach.

Note that $\mathbf{x}_p$ and $\mathbf{x}_{p'}$ allow control over importance of sentences in p and p' in the form of relative probability mass. We compute these distributions using pairwise distances as $\mathbf{x} = \mathtt{softmax}(-\mathbf{s}/\tau)$ where $\mathbf{s}_p = \mathtt{min}_i\, \mathbf{D}$ and $\mathbf{s}_{p'} = \mathtt{min}_j\, \mathbf{D}$, and τ is a softmax temperature hyper-parameter.

For our neural network models trained with automatic differentiation, we leverage an entropy regularized version of the Wasserstein distance in Eq 5 (Cuturi, 2013). Here computation of $\hat{\mathbf{P}}$, is achieved via Sinkhorn iterations, a set of iterative linear updates allowing training with autodiff libraries and leveraging GPU computation. Finally, Cuturi (2013) show that computing $\mathcal{W}$ with Sinkhorn iterations shows an empirical quadratic complexity, i.e. $\mathcal{O}(N^2)$ — similar to that of attention as in a model for late interaction (Humeau et al., 2020).

Multi-task model: To leverage training signals used in both the single and multi-match models, we train a multi match model supervised with textual supervision in a multi-task setup: $\mathcal{L}_{f_{\mathtt{TS}}} + \mathcal{L}_{f_{\mathtt{OT}}}$.

3.3 Inference

As outlined in §2, we are interested in a whole-abstract based retrieval (Def 1) and an aspect level retrieval (Def 2). In both setups given a query Q and candidate C documents we denote sentence representations from a trained model by $\mathbf{S}_Q$ and $\mathbf{S}_C$. For both tasks, we compute distances for ranking while controlling the aspects $\mathcal{A}_Q$ (i.e $\mathcal{A}_p$) over which the weighted sum of Eq 1 is performed.

Whole abstract retrieval: This corresponds to a setup where all aspects of the query document $\mathcal{A}_p$ are used in computing distances between documents. In the single-alignment models, candidates C are ranked based on their maximally aligned sentence with Q using distances from a trained model: $\hat{i}_p, \hat{i}_{p'} = \mathtt{argmin}_{i,j}\, \mathbf{D}$. The multi match model ranks candidates using the distance $\langle \mathbf{D}, \hat{\mathbf{P}} \rangle$, where $\hat{\mathbf{P}}$ is the solution to transport problem of Eq 5.

Aspect level retrieval: In aspect-level retrieval, a subset of sentences $\mathcal{A}_q \subset \mathcal{A}_Q$ is used for query document Q; for candidate documents C, we do not assume to be given specific aspects, and matching is done across all sentences in each C. In the single alignment models, we only consider a subset of the pairwise sentence distances to determine the maximally aligned sentences, giving $\mathbf{D}^{\mathcal{A}} = \mathbf{D}[\mathcal{A}_q, :]$. This corresponds to finding the maximally aligned candidate sentence to the query sentences in $\mathcal{A}_q$. Similarly, in the multiple-alignment model we compute the plan $\hat{\mathbf{P}}^{\mathcal{A}_q}$ based on the subset of sentences corresponding to $\mathcal{A}_q$ and generate rankings by $\langle \mathbf{D}^{\mathcal{A}_q}, \hat{\mathbf{P}}^{\mathcal{A}_q} \rangle$. Note that $\mathbf{S}_Q$ in Q is still contextualized, capturing document context of sentences not explicitly used in $\mathcal{A}_q$.

Scaling Inference: Our multi-vector model for single matching performs retrievals via minimum L2 distance. Therefore, this method is amenable to approximate nearest neighbour (ANN) search methods for large-scale retrieval (Andoni et al., 2018; Luan et al., 2021). Retrieval with our single-match model would involve $|\mathcal{A}_Q|$ and $|\mathcal{A}_q|$ calls to an ANN structure for the whole abstract and aspect-level tasks respectively.

On the other hand, as stated earlier our multi-match model using Sinkhorn iterations involves a $\mathcal{O}(N^2)$ computation (Cuturi, 2013), which is similar to late interaction methods. Humeau et al. (2020) show late interaction models to be significantly cheaper than cross-encoders while retaining most of their performance in ad-hoc search setups. While quadratic, OT computation in practice can be time-consuming, however, recent work of Backurs et al. (2020) has seen development of fast ANN methods for Wasserstein distances with practical run-times significantly smaller than quadratic ones. This promises the use of ANN methods in large-scale retrieval with our multi-match model

In our results we refer to our text supervised single match method as TSASPIRE, optimal transport multi match method as OTASPIRE, and the multi-task trained multi aspect method as TS+OTASPIRE.

4 Experiments and Results

Evaluation data: We evaluate the proposed methods on datasets for whole abstract document similarity and fine-grained document similarity. We overview these below. Appendix B provides detail.

1. RELISH: An expert annotated dataset of biomedical abstract similarity (Brown et al., 2019).
2. TRECCOVID$_{\text{RF}}$: The original TRECCOVID dataset is labelled for ad-hoc search by experts (Voorhees et al., 2021). We reformulate the dataset for abstract similarity, treating all abstracts relevant to one ad-hoc query as similar to each other and dissimilar from abstracts relevant to other queries.
3. SCIDOCS: A benchmark suite of tasks intended for evaluating abstract-level scientific document representations (Cohan et al., 2020).
4. CSFCUBE: Fine-grained retrieval is evaluated using the recent dataset of Mysore et al. (2021), an expert-annotated dataset of machine learning and NLP abstracts labelled against candidates for relevance to one of 3 broad aspects capturing the main components of methodological research: `background/objective`, `method`, `result`. Relevance is labelled for query sentences corresponding to those aspects, while considering the broader relevance of the sentences' abstract context.

Baselines: We compare the proposed approaches to three classes of methods. We overview these classes and associated models below, with Appendix D presenting further detail: 1. Sentence models: Sentence embedding models present reasonable baselines since we consider fine-grained matches at the sentence level. These are represented by MPNET-1B, a sentence model trained on over 1 billion text pairs[3], Sentence-Bert (SENTBERT) (Reimers and Gurevych, 2019), SIMCSE (Gao et al., 2021), `cosentbert` of §3.2.2, and ICTSENTBERT (Lee et al., 2019).

2. Abstract models: The abstract level model SPECTER (Cohan et al., 2020), represents a SOTA model for scientific document similarity trained on *cited* abstract pairs. We also train a variant of this model on *co-cited* papers: SPECTER-COCITE. Finally, we also compare to SCINCL, introduced in recent concurrent work of Ostendorff et al. (2022). SCINCL presents a bi-encoder model similar to SPECTER with improvements to its contrastive learning procedure – presenting a complementary direction to our approach.

3. Sentence level models modified for whole abstract similarity: Here we combine the SOTA sentence encoder MPNET-1B with the optimal transport (§3.2.3) for aggregating sentence level matches giving OTMPNET-1B.

Sentence models use the same inference procedure as our single match method, abstract models rank using L2 distances between papers embeddings, and the modified sentence model uses the multi match inference procedure. All reported model hyper-parameters are tuned, trained on 1.3M co-citation triples, and initialized with SPECTER unless noted otherwise.[4] In reporting results, we report standard retrieval metrics Mean Average Precision (MAP) and NDCG at rank K. For NDCG@K we follow Wang et al. (2013), and choose K= $p{*}|\mathcal{C}|$ where $p \in (0,1)$. NDCG$_{\%20}$ therefore refers to NDCG computed at 20% of the pool size for a query. This is apt since queries have varying pool sizes. Appendices A, E, and F detail training data, algorithms, and hyper-parameters. Next, we present our main results comparing proposed approaches to baselines.

4.1 Results

Fine-grained similarity: Table 1 presents results on CSFCUBE. We report performance on the three facets `background`, `method`, and `result` annotated in the dataset, and aggregated across all facets. We first make some observations about baseline methods: 1. MPNET-1B outperforms all other sentence level models and a SOTA abstract representation, SPECTER, indicating the value of sentence-level information for capturing fine-grained

ts+otAspire$_{\texttt{Spec}}$	40.26	60.86	**51.79**	70.99	26.68	47.60	43.06	64.82

Table 1: Test set results for baseline and proposed methods on CSFCube, an expert annotated fine-grained similarity dataset of computer science papers. Our approaches outperform strong prior models ot/MPNet-1B and Specter by 5-6 points, and the concurrently introduced SciNCL model by 1.5-2 points aggregated across queries. Metrics (MAP, NDCG$_{\%20}$) are computed based on a 2-fold cross-validation and averaged over three re-runs of models. Here, tsAspire: Text supervised single-match method, otAspire: Optimal Transport multi-match method and ts+otAspire: Multi-task multi aspect method.

similarities. With otMPNet-1B indicating the value of modeling multiple matches. 2. Specter–CoCite$_{\texttt{Scib}}$, which is identical to Specter but trained on co-citations outperforms it, showing the value of co-citations for fine-grained similarity.

Next, we examine performance of the proposed methods: 1. First we note that all of the proposed approaches consistently outperform performant prior work, ot/MPNet-1B and Specter, by about 5-6 points, and concurrent work of SciNCL by about 1.5-2 points aggregated across queries. 2. Next, we note that the proposed approaches outperform Specter-CoCite$_{\texttt{Spec}}$, trained on co-citations by 2-3 points aggregated across queries. 3. Our single match model trained with textual supervision, tsAspire consistently outperforms baselines. 4. Finally, our multi-match model otAspire, while outperforming baselines sees aggregate performance similar to single match methods. This is reasonable given the aspect-specific annotation of CSFCube where we expect gains from modeling fine-grained (contextualized) matches rather than aggregating multiple matches.

Now, we examine facet-specific performance: 1. Performance on `background` sees higher performance in general and the smallest gains for the proposed approaches. This may be attributed to `background` similarity being captured in *coarse*-grained topical similarity, a trait largely captured in existing baselines. 2. `method` similarity in CSFCube presents significant challenges (Mysore et al., 2021, Sec 6) since it relies upon procedural similarities across steps of a method and on domain knowledge based similarities - this is often captured in co-citation data (Fig 1 presents one such complex paraphrase example). We see strongest performance for tsAspire here. 3. Finally, given that paper results interpretations are often dependent on all aspects of a given paper, `result` similarity often depends on similarity across the whole abstract. This leads otAspire which models multiple matches to see strong performance.

Whole-abstract similarity: Table 2 presents results on TRECCOVID$_{\text{RF}}$ and RELISH. At the outset, we note that while being annotated for whole-abstract relevance, these datasets present different characteristics. While TRECCOVID$_{\text{RF}}$ presents queries centered on a very specific topic, RELISH presents a much more diverse set of queries. Further, TRECCOVID$_{\text{RF}}$ pairs queries with pools of about 9000 candidates while RELISH has about 60 candidates per query. Next, we examine baselines.

1. In contrast to fine-grained similarity datasets the best sentence level model MPNet-1B, significantly underperforms an abstract level model, Specter, indicating the need for whole abstract representations for these datasets. Aggregating sentence matches as in otMPNet-1B, drastically im-

Models	TRECCOVID$_{RF}$		RELISH	
	MAP	NDCG$_{\%20}$	MAP	NDCG$_{\%20}$
MPNet-1B	17.35	43.87	52.92	69.69
SentBert-PP	11.12	34.85	50.80	67.35
SentBert-NLI	13.43	40.78	47.02	63.56
UnSimCSE-BERT	9.85	34.27	45.79	62.02
SuSimCSE-BERT	11.50	37.17	47.29	63.93
`CoSentBert`	12.80	38.07	50.04	66.35
ICTSentBert	9.80	33.62	47.72	63.71
otMPNet-1B	27.46	58.70	57.46	74.64
Specter	28.24	59.28	60.62	77.20
SciNCL	28.73	59.16	62.09	78.72
Specter-CoCite$_{\texttt{Scib}}$	30.60	62.07	61.43	78.01
Specter-CoCite$_{\texttt{Spec}}$	28.59	60.07	61.43	77.96
tsAspire$_{\texttt{Spec}}$	26.24	56.55	61.29	77.89
otAspire$_{\texttt{Spec}}$	**30.92**	**62.23**	62.57	78.95
ts+otAspire$_{\texttt{Spec}}$	30.90	62.18	**62.71**	**79.18**

Table 2: Test set results for baseline and proposed methods on TRECCOVID$_{RF}$ and RELISH, expert annotated abstract similarity datasets of biomedical papers. Our approaches outperform or match a strong prior model, Specter, and the concurrently introduced SciNCL by 2-3 points across metrics (MAP, NDCG$_{\%20}$). These are computed as averages over three model re-runs. Method names map similarly to Table 1.

proves MPNet-1B. 2. Next, similar to results in Table 1, a model identical to Specter, but trained on co-citations, Specter-CoCite$_{\texttt{Spec}}$, outperforms Specter indicating the value of co-citation signal for whole-abstract similarity too. 3. Finally, we also note that while SciNCL sees an expected stronger performance to Specter in RELISH, it sees comparable performance in TRECCOVID$_{RF}$ – indicating the influence of the candidate pool size on its performance.

In examining performance of our proposed methods, we note the following: 1. Across datasets, our method for single matches, tsAspire, outperforms context-independent sentence baselines by several points indicating the value of contextualization. However, this method still underperforms abstract-level baselines. 2. However, methods modeling multiple matches, otAspire and ts+otAspire, substantially outperform tsAspire as well as baseline prior work Specter and otMPNet-1B. This performance indicates the strength of OT based aggregation of fine-grained matches for abstract level similarity. The proposed methods additionally match or outperform the concurrent approaches of SciNCL. Note here, that given the complementary approach presented in SciNCL - strong models are likely to result from combining both approaches.

We present results demonstrating the value of the proposed approach on the SciDocs benchmark in Appendix G. Further, we also present a set of ablations in Appendix H. These ablations establish the value of textual supervision over the encoder (BERT$_\mathcal{E}$) used for encoding the text, the value of optimal transport compared to attention alternatives, and alternative single-match models trained without co-citation contexts.

5 Related Work

Aspect-based paper representations: A large body of work learns structured representations of scientific papers. Jain et al. (2018) present an approach which learns pre-defined aspect (PICO) encoders for biomedical papers. Similarly work of Neves et al. (2019), Chan et al. (2018), and Kobayashi et al. (2018) each label paper texts and then compute aspect-specific embeddings for document classification or ranking using existing methods. This line of work often relies on pre-defined aspects and building aspect-specific methods. Finally, work of Ostendorff et al. (2020) and Luu et al. (2021) present an approach with some similarities to the ones presented above – these approaches leverage classification or language generation models to output fine-grained relationships between pairs of papers. Our work leverages co-citation contexts to supervise free-text aspects with a new model for document retrieval, that is also not tied to a specific schema of labels.

Fine-grained document representations: Another similar line of work is modeling fine-grained document-document similarity at the level of words or latent topics. Examples include early work El-Arini and Guestrin (2011) presenting paper recommendation methods with unigram-level similarity between papers using authorship and citation links or using latent document topics (Gong et al., 2018; Yurochkin et al., 2019; Dieng et al., 2020).

Our approach represents documents via sentences, a common and intuitive structure for reasoning about scientific document facets (Chan et al., 2018; Zhou et al., 2020). Ginzburg et al. (2021) present a self-supervised model for contextual sentence representations in long documents similar to our ICT baseline (Lee et al., 2019).

Ad-hoc Search: A range of recent work in information retrieval presents multi-vector models intended to capture different aspects of candidate documents with score aggregation relying on summations, max, or attention functions (Khattab and

Zaharia, 2020; Luan et al., 2021; Humeau et al., 2020), these however focusing on short-text queries seen in search or question answering (QA). Mitra et al. (2017) explore an approach to model term-level fine-grained similarities with neural networks, Liu et al. (2018) model fine-grained matches at the level of entity spans, and Akkalyoncu Yilmaz et al. (2019) model document relevance by aggregating sentence relevance. Similarly, recent work of Lee et al. (2021) models fine-grained matches for QA at the phrase level. Importantly, these methods rely on supervision from knowledge bases or QA datasets, limiting applicability to specific span definitions and areas with these resources, often not present in the scientific domain (Hope et al., 2021a).

A range of modeling approaches in the context of other tasks resemble elements of our approach. We describe these in Appendix J.

6 Conclusions

We presented ASPIRE, a scientific document similarity model that is trained by leveraging co-citation contexts for learning fine-grained similarity. We use co-citation contexts as a novel form of *textual* supervision to guide the learning of multi-vector document representations. Our model outperformed strong baselines on seven document similarity tasks across four English scientific text datasets. Moreover, we showed that a fast single-match method achieves competitive results, enabling fine-grained document similarity in large-scale scientific corpora. A future direction is the interactive use of our methods, with a system allowing users to highlight specific aspects of papers and retrieve contextually-relevant matches. Another promising application is for finding analogies — structural matches between texts describing ideas, as in scientific papers, to boost discovery (Hope et al., 2017, 2021b; Chan et al., 2018).

A Co-citation Data

As noted in §3.1, we train the proposed methods on English co-cited papers. We build a dataset of co-cited papers from the S2ORC corpus[5] (Lo et al., 2020). Since our evaluation datasets draw on text from different domains we build training sets with co-cited papers for each: biomedicine for RELISH and TRECCOVID$_{\mathrm{RF}}$, computer science for CSFCUBE, and a 60/40 mix of biomedicine and CS for SCIDOCS. Each dataset contains 1.3M training triples.

Next we describe construction of our co-citation data given 8.1 million English full text articles in the S2ORC corpus which have been parsed for citation mentions and linked to cited papers in the corpus using automatic tools (Lo et al., 2020):

- Domain definition: We define our biomedical articles to be those tagged either "Medicine" or "Biology" in S2ORC. "Computer Science" tagged papers are treated as CS papers.
- Co-citation contexts: To obtain co-cotation contexts - we first obtain sentence boundaries for co-citation contexts using the `en_core_sci_sm` pipeline included in `spacy`.[6]
- Filtering abstracts: In selecting abstracts for our dataset we retain those that have a minimum of 3 sentences, and a maximum of 20 sentences. Further, abstracts where all the sentences are too small (3 tokens) are excluded. Similarly, abstracts with sentences greater than 80 tokens are excluded.
- Selecting training co-citated abstract data $\{\mathcal{P}\}$: Given contexts with qualifying abstracts as described above, we only retain co-citation contexts with 2 or 3 co-cited papers. A manual examination revealed that larger co-cited sets tended to be more loosely related.
- Selecting co-citation sentence training data for $\mathtt{BERT}_{\mathcal{E}}$: Note that this represents a sentence encoder trained by treating co-citation contexts referencing the same paper as paraphrases. Here, we select co-citation contexts containing 2 or more co-cited papers as paraphrase sets $\mathcal{E}$.

Abstract level training triples for the biomedical and computer science sets are built by treating all unique pairs of papers as positives. 1.3 million triples were used for each domain - these were sampled from larger sets at random.

B Evaluation Dataset Details

Here we provide further detail on the evaluation datasets overviewed in §4.

RELISH: An annotated dataset of biomedical abstract queries labelled by experts (Brown et al., 2019). In a number of cases expert annotators are the authors of query papers. Per query candidate pools are of size 60, with 1638 queries in development and test sets each. Dataset is released under a Creative Commons Attribution 4.0 International License.

TRECCOVID$_{\mathrm{RF}}$: While the original TRECCOVID dataset of Voorhees et al. (2021) is labelled for adhoc search by experts, we reformulate the dataset for abstract similarity, treating all documents relevant to one ad-hoc query as similar to each other. From each original query and its respective relevance-labeled documents, we sample an abstract from relevant documents (relevance of 2) and use that as our query document. We treat all other relevant documents as positive examples for the query. Documents relevant for *other* queries are treated as irrelevant for the sampled query. This results in about 9000 candidates per query abstract in TRECCOVID$_{\mathrm{RF}}$. TRECCOVID$_{\mathrm{RF}}$ consists of about 1200 queries in the development and test splits each. This dataset builds on the CORD-19 dataset (Wang et al., 2020) released under a Apache License 2.0, the license of TRECCOVID however isn't clear from the dataset release.

SCIDOCS: A benchmark suite of tasks intended for abstract-level scientific document representations (Cohan et al., 2020). We evaluate our methods on the tasks of predicting: citations, co-citations, co-views, and co-reads. Per query candidate pools are of size 30 about 1000 queries per task and development and test split. We exclude classification and recommendation sub-tasks relying on additional inference components. Dataset is released under a GNU General Public License v3.0 license.

CSFCUBE: The dataset consists of 50 queries labelled for relevance against about 120 candidates per query. Dataset is released under a Creative Commons Attribution-NonCommercial 4.0 International license.

C Co-citation Context Encoder

Here we present details of alternative design choices for our co-citation context encoder. In the use of $\mathtt{BERT}_{\mathcal{E}}$, we note in §3.2.2 that this encoder is kept frozen during the course of training

---

[5] Released under a CC BY-NC 2.0. license.

[6] https://allenai.github.io/scispacy/

`BERT`$_\theta$. Fine-tuning `BERT`$_\mathcal{E}$ via a straight-through estimator (Bengio et al., 2013) under-performed freezing it. Using other encoders for scientific text such as SPECTER as `BERT`$_\mathcal{E}$ under-performed `CoSentBert`. A recent strong model for sentence representation `MPNet-1B`[7] lead to similar performance on abstract and aspect-conditional tasks as `CoSentBert`, indicating that a minimum requisite sentence encoder is all that is needed for `BERT`$_\mathcal{E}$.

D Baselines

Here we provide further detail on the baselines overviewed in §4.

MPNET-1B & OTMPNET-1B: A sentence level baseline of a MPNet (Song et al., 2020) base model, fine-tuned on 1.17 billion similar text pairs in a contrastive learning setup.[8] This training data broadly represents web and scientific texts. Further we combine MPNET-1B with an OT based aggregation scheme similar to our multi-match model to yield, OTMPNET-1B a baseline using optimal transport with a performant sentence encoder.

SimCSE: A recent sentence representation model (Gao et al., 2021). We compare to two model variants: an unsupervised model UNSIMCSE-BERT, and a variant supervised with NLI data, SUSIMCSE-BERT.

Sentence-Bert: A sentence level transformer model fine-tuned on similar sentence pairs (Reimers and Gurevych, 2019). We compare performance to two variants, SENTBERT-PP and SENTBERT-NLI, fine-tuned on paraphrases and natural language inference (NLI) data respectively.

`CoSentBert`: The sentence-level model we describe in §3.2.2: A SCIBERT model fine-tuned on co-citation sentence contexts referencing the same set of co-cited papers.

ICTSENTBERT: A SCIBERT sentence model trained using the self-supervised inverse close task (Lee et al., 2019). Here we train abstract sentence representations to capture the semantics of their paragraph contexts.

SPECTER: A state of the art abstract level representation (Cohan et al., 2020). Here a SCIBERT model is fine-tuned to maximize similarity between representations of *cited* papers. We also train a variant of this model on *co-cited* papers: SPECTER-COCITE.

SCINCL: A recent concurrent state of the art abstract level representation (Ostendorff et al., 2022). This approach trains a model similar to SPECTER, with improvements to the negative sampling strategies of Cohan et al. (2020) for contrastive learning. This presents a complementary contribution to the one presented in our work - with future modeling approaches likely to benefit from both approaches.

For the baselines described above specific model names from the Hugging Face[9] and Sentence Transformers[10] libraries are as follows:

MPNet-1B: HF; sentence-transformers/all-mpnet-base-v2.

SimCSE: HF; princeton-nlp/sup-simcse-bert-base-uncased, princeton-nlp/unsup-simcse-bert-base-uncased.

Sentence-Bert: ST; Paraphrases: paraphrase-TinyBERT-L6-v2. NLI: nli-roberta-base-v2 from the Sentence-Transformers library.

E Training

All our approaches are trained using the Adam optimizer with an initial linear warm-up for 2000 steps followed by a linear decay using gradient accumulation for a batch size of 30. The margin m in the triplet loss is set to 1. We implement all methods using PyTorch, HuggingFace, and GeomLoss libraries. Training convergence is established based on the loss on a held out set of co-citation data ensuring that training does not rely on a labelled dataset for convergence checks.

All experiments were run with data parallelism over servers nodes with the following GPU configurations: 8×12GB NVIDIA GeForce GTX 1080 Ti GPUs, 4×24GB NVIDIA Tesla M40 GPUs, or 2×48GB NVIDIA Quadro RTX 8000 GPUs. Servers had 12-24 CPUs per node and 256-385GB RAM. The training time per experiment varied from 5-20 hours, and the experiments in this paper represent about 4746 GPU hours of training.

F Model Hyper-Parameters

Here we report the best performing model hyper-parameters. This is done per training dataset. For

---

[8] `MPNet-1B`: https://bit.ly/2Zbm2Iq

[9] https://huggingface.co/

[10] https://www.sbert.net/docs/pretrained_models.html

computer science trained models evaluated on CSFCube:

- Specter-CoCite$_{\texttt{Scib}}$: LR 2e-5.
- Specter-CoCite$_{\texttt{Spec}}$: LR 2e-5.
- tsAspire$_{\texttt{Spec}}$: LR 2e-5.
- otAspire$_{\texttt{Spec}}$: LR 2e-5. τ 0.5.
- ts+otAspire$_{\texttt{Spec}}$: LR 1e-5. τ 0.5.

For biomedical trained models evaluated on TRECCOVID and RELISH:

- Specter-CoCite$_{\texttt{Scib}}$: LR 2e-5.
- Specter-CoCite$_{\texttt{Spec}}$: LR 2e-5.
- tsAspire$_{\texttt{Spec}}$: LR 2e-5.
- otAspire$_{\texttt{Spec}}$: LR 2e-5. τ 5000.
- ts+otAspire$_{\texttt{Spec}}$: LR 2e-5. τ 5000.

For biomedical+computer science trained models evaluated on TRECCOVID and RELISH:

- Specter-CoCite$_{\texttt{Scib}}$: LR 2e-5.
- Specter-CoCite$_{\texttt{Spec}}$: LR 2e-5.
- tsAspire$_{\texttt{Spec}}$: LR 1e-5.
- otAspire$_{\texttt{Spec}}$: LR 1e-5. τ 5000.
- ts+otAspire$_{\texttt{Spec}}$: LR 1e-5. τ 5000.

We found it beneficial to use a low temperature τ in computing distributions $\mathbf{x}$ for OT computation for CSFCube - a fine-grained similarity dataset. On the other hand we found it beneficial to use a high temperature τ in computing distributions $\mathbf{x}$, causing it to be effectively uniform, for OT computation in whole-abstract datasets SciDocs, RELISH, and TRECCOVID$_{\text{RF}}$. This is reasonable given the nature of similarity captured in these datasets. Hyper-parameters of the underlying encoders were not changed from their default values – other hyper-parameters are common to methods and desribed in §4.

Finally, in computing OT transport plans, we optimize a entropy regularized objective: $\min\limits_{\mathbf{P}\in\mathcal{S}}\langle \mathbf{D}, \mathbf{P}\rangle - \frac{1}{\lambda}h(\mathbf{P})$. Our experiments use a fixed value of $\lambda = 20$.

Hyper-parameter tuning: We tune the hyper-parameters of all the ablated and proposed methods across the different datasets on development set performance. For CSFCube the *Aggregated* dev set performance was used for computer science training data models, TRECCOVID$_{\text{RF}}$ and RELISH dev sets were used for biomedical data models with ties between the two broken by the more challenging TRECCOVID$_{\text{RF}}$ performance, and computer science +biomedical data models were tuned on average task performance of SciDocs tasks. Given the expense of training models (about 20h for the proposed models) we first tune softmax temperatures then tuned learning rates. Large changes across learning rates weren't observed for the models. All learning rates are tuned over the range {1e-5, 2e-5, 3e-5}, OT sentence softmax temperatures τ are tuned over {0.5, 1, 5, 5000}, and softmax temperatures for ablation A3 was tuned over {0.5, 1, 5}.

G SciDocs Benchmark Result

SciDocs Benchmark: Table 3 indicates performance on the abstract level document similarity benchmark SciDocs of Cohan et al. (2020). First we note that the strong performance of Specter indicates a smaller gap to be closed. Here, although our proposed methods see similar performance to each other they consistently outperform Specter on 3 of 4 tasks establishing state of the art performance. Given Specter's citation training signal and our co-citation signal, we see better performance on the `Citations` and `Co-Citation` tasks respectively. Finally, note that our co-citation trained approaches broadly see better performance (1-1.5 points) on extrinsic tasks of `Co-Reads` and `Co-Views` indicating the value of this signal.

H Ablations

Here we ablate a range of model components in establishing factors which contribute performance. In ablations we only report performance on CSFCube, TRECCOVID$_{\text{RF}}$, and RELISH.

A1. Does tsAspire gain from textual supervision over the encoder used to compute alignment? tsAspire relies upon a sentence alignment encoder, $\texttt{BERT}_{\mathcal{E}}$ in §3.2.2, to compute alignments, $\hat{i_p}, \hat{i}_{p'}$, from the co-citation context to the co-cited abstracts. Here we investigate if improvements in tsAspire are attributable to $\texttt{BERT}_{\mathcal{E}}$ or to the co-citation contexts themselves. We investigate this by comparing the performance of tsAspire to a model trained to maximize the alignment between abstract sentences directly computed using $\texttt{BERT}_{\mathcal{E}}$, we refer to this as absAspire. This may be viewed as a form of knowledge distillation where alignments from a more local sentence encoder model, $\texttt{BERT}_{\mathcal{E}}$, are distilled into the contextual sentence encoder of tsAspire. As Table 4 shows, tsAspire consistently outperforms absAspire, indicating the value added by natural language supervision from the co-citation contexts.

SciDocs tasks →	`Citations`		`Co-Citations`		`Co-Reads`		`Co-Views`

Table 5: Results for Ablation A2. Performance for an alternative method, ATTASPIRE, for modeling multiple matches with an attention mechanism instead of optimal transport in the proposed method. Standard deviation across 3 model re-runs under mean performance.

A2. Can multi-aspect matching use attention aggregation instead of optimal transport? Since our multi-aspect match model uses a soft sparse matching with optimal transport we examine contributions of this component by comparing performance of a model (ATTASPIRE) trained with soft-alignment using an attention mask, $\mathbf{A}$ – attention is also a popular choice in prior work Humeau et al. (2020); Zhou et al. (2020). Here, $f_{\texttt{Att}}(p, p') = \langle \mathbf{D}, \mathbf{A} \rangle$ with, $\mathbf{A} = \texttt{softmax}(-\mathbf{D}/\tau)$. Note that OT imposes specific inductive bias via the structure of the trasport plan in ensuring it to be a permutation matrix - a desirable property in computing multiple alignments between a set of points. Table 5 examines performance of these model variants. Broadly, ATTASPIRE sees performance comparable or worse than OTASPIRE. While ATTASPIRE sees improved performance in CSFCUBE it sees much larger variation across runs. In our abstract retrieval datasets, where we expect gains from modeling multiple matches, we see better or similar performance from OTASPIRE over ATTASPIRE.

A3. Can single-match models be learned without co-citation contexts? While our model for single matches leverages weak textual supervision from co-citation contexts, we ask if these models can be learned in the absence of this supervision. We answer this by training a simpler model, MAXASPIRE, which finds the maximally aligned aspects between documents using the representations from $\texttt{BERT}_\theta$ alone, giving us $f_{\texttt{Max}}(p, p') = \texttt{max}_{i,j}\mathbf{D}$. To examine the role of $\texttt{BERT}_\theta$ we compare performance with different initializations, with SPECTER presenting a initial model fine-tuned for similarity vs SCIBERT which isnt fine-tuned for text similarity.

CSFCube *Aggregated*	MAP	NDCG$_{\%20}$

Table 6: Results for Ablation A3. Performance of a simpler single-match model, MAXASPIRE, trained using only BERT$_\theta$ representations while also varying encoder initialization between SPECTER and SCIBERT (indicated as subscripts for models). Standard deviation across 3 model re-runs under mean performance.

We note the following from the results in Table 6: MAXASPIRE sees a dependence on the underlying encoder, a SCIBERT initialization nearly always sees poorer performance – only seeing performance competitive with TSASPIRE when initialized with SPECTER. This is reasonable given that this model must bootstrap fine-grained similarity while only relying on the encoder induced similarity. In cases where MAXASPIRE matches performance of TSASPIRE it sees larger performance differences across runs which may also be explained by the dependence on the initialization. Finally, TSASPIRE consistently sees similar or better performance with varying initialization, indicating the value of our text supervised method.

I Extended Results

Tables 1, 2 in §4.1 omit presentation of standard deviations across runs for the proposed approaches for brevity. We include these in Tables 7 and 8.

J Extended Related Work

A range of modeling approaches in multi-instance learning, models leveraging textual supervision, and optimal transport resemble elements of our approach. We describe these next.

Multi-instance Learning: Our work applies MIL for learning fine-grained similarity, while prior work has most often been applied to classification or regression tasks (Hope and Shahaf, 2016, 2018; Ilse et al., 2018; Angelidis and Lapata, 2018). Our work bears resemblance to an application of MIL in content based image retrieval (Song and Soleymani, 2019), where MIL is applied to learn alignments between image and text aspects.

Textual Supervision: Our use of co-citation text as a source of textual supervision draws on other work leveraging textual justifications of labels as a source of supervision for classification tasks (Hancock et al., 2018; Murty et al., 2020; Hanjie et al., 2022), with recent concurrent work of Hanjie et al. including an overview of this line of work. Our co-citation contexts may be considered justifications for similarity of co-cited papers. Nie et al. (2020) presents work in a biomedical literature recommendation task, where human justifications of a relevance label are used to identify unigram features indicative of the label and train a recommendation model.

Optimal Transport: Our use of optimal transport draws on other recent work in learning sparse alignments between texts (Swanson et al., 2020; Tam et al., 2019). Work of Swanson et al. (2020) learns sparse *binary* alignments for sentence and document similarity tasks to rationalize decisions and Tam et al. (2019) leverage sparse soft alignments between characters for string similarity. Kusner et al. (2015) uses alignment based on word embeddings for document classification tasks using a K-nearest neighbors method. However, applying OT at the word level in scientific documents would lead to a large increase in computational complexity.

Abstract

Conventionally, generation of natural language for dialogue agents may be viewed as a statistical learning problem: determine the patterns in human-provided data and generate appropriate responses with similar statistical properties. However, dialogue can also be regarded as a goal directed process, where speakers attempt to accomplish a specific task. Reinforcement learning (RL) algorithms are designed specifically for solving such goal-directed problems, but the most direct way to apply RL – through trial-and-error learning in human conversations, – is costly. In this paper, we study how offline reinforcement learning can instead be used to train dialogue agents entirely using static datasets collected from human speakers. Our experiments show that recently developed offline RL methods can be combined with language models to yield realistic dialogue agents that better accomplish task goals.

1 Introduction

Constructing fluent and intelligent dialogue agents could pave the way for intuitive interfaces and automation of human-interactive tasks. However, this requires dialogue agents that both generate fluent, natural responses and effectively pursue the goals of the given dialogue task. A predominant approach to training dialogue agents is through supervised learning, where an agent is tasked with imitating language provided by humans. While this can provide for fluent responses, it becomes difficult to ensure that such agents systematically pursue the goals of the dialogue interaction. If we instead view dialogue as a control problem, frameworks such as reinforcement learning (RL) could allow agents to automatically optimize dialogue with respect to a task goal through a trial-and-error process and improve over human behavior.

However, implementing an RL system in practice, where an agent learns online from interacting with real humans, can be prohibitively expensive and time-consuming. This is in stark contrast to supervised learning approaches, where we can cheaply construct datasets for training imitation agents by simply logging conversations. Therefore, existing RL approaches for dialogue often rely on interacting with a learned model of a human (Li et al., 2016b; He et al., 2018), from which experience can be generated inexpensively. However, naïve training in this manner can result in the dialogue agent exploiting the model, which can degenerate into non-intelligible language. To mitigate this, algorithms must typically enforce strong priors to keep generated language similar to those seen in the dataset (Li et al., 2016b; Jaques et al., 2019), or adopt dialogue management and template-based approaches which directly re-use language seen in the dataset (He et al., 2018).

Issues such as model exploitation and distribution shift when training on static datasets are a primary concern of offline RL (Levine et al., 2020), and can provide a formalized approach to tackling these problems. While offline RL is motivated by scaling RL to large datasets, annotated datasets for dialogue are still small compared to the large amount of raw text datasets available today. Therefore, we propose an offline, model-free approach to dialogue generation that leverages language models. Because the size of unlabeled language datasets dwarfs that of curated datasets for dialogue, using a pre-trained language model as a central component of our method allows it to learn aspects of language fluency from unlabeled datasets, while learning higher-level strategies for goal-directed dialogue via RL on a smaller annotated datasets. This combined approach enables us to utilize the large amounts of existing language data that standard RL methods cannot.

The main contribution of this work is CHAI (CHatbot AI), an algorithm for learning task-oriented dialogue that utilizes a language model in conjunction with offline RL. We show that this

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4471 - 4491
July 10-15, 2022

leads the policy to generate goal-oriented dialogue that is both realistic and functional, and does not require training against a simulated model of human language. We evaluate our method on a negotiation task, which requires the model to both reason about strategic aspects of conversation along with generating fluent language. We show that CHAI consistently bargains for better prices and with higher rates of successful negotiation than prior RL approaches to goal-oriented dialogue.

2 Related Work

Recent developments in deep learning have led to end-to-end approaches to dialogue using supervised learning, such as sequence-to-sequence models (Dušek and Jurcicek, 2016; Eric and Manning, 2017), hierarchical models (Serban et al., 2017), attention (Mei et al., 2017; Chen et al., 2019), and Transformer-based models (Wu et al., 2021; Hosseini-Asl et al., 2020; Peng et al., 2020; Adiwardana et al., 2020). However, supervised learning only allows an agent to imitate behaviors, requires optimal data, and does not allow agents to exceed human performance. Supervised learning for dialogue generation also has well-known issues such as outputting commonplace responses (e.g., *I do not know*) regardless of the inputs (Li et al., 2016a). Therefore, additional training of the dialogue agent is required for performing goal-oriented tasks.

Task-oriented dialogue has been formulated as a sequential decision making problem in a Markov Decision Process (MDP) since the 1990s (Smith and Hipp, 1994; Singh et al., 1999; Williams and Young, 2007; Young et al., 2013; Paek, 2006; Henderson et al., 2008; Gao et al., 2018; Pieraccini et al., 2009; Young et al., 2013; Su et al., 2015; Chen et al., 2020). Dialogue is converted into abstract states and actions from which an agent is trained using reinforcement learning (RL) (Eckert et al., 1997; Levin et al., 2000; Chung, 2004; Georgila et al., 2006; Schatzmann et al., 2007; Heeman, 2009; Georgila and Traum, 2011; Su et al., 2016; Fatemi et al., 2016; Asri et al., 2016; Zhao et al., 2019; Zhang et al., 2020; Wang et al., 2020). These methods differ in how the abstract states/actions are designed and whether the simulated environment for training the policy is hand created, learned as a fixed model, or is an agent itself. For instance, Eckert et al. (1997); Levin et al. (2000) learn a fixed transition model from human conversations and Georgila and Traum (2011) learn negotiation agents where each agent is the user simulator for the other agent. These methods also differ in how the decision making policy is trained, e.g., online (Gašić et al., 2011) or off-policy/offline (Yu et al., 2016; Pietquin et al., 2011) using actor-critic (Su et al., 2017), policy gradient (He et al., 2018), or fitted Q-iteration (Pietquin et al., 2011). Regardless of the RL method used, since policies are trained on abstract states and actions, these methods lack the ability to *generate* natural language (i.e., response is created via templates depending on an abstract action).

To overcome these limitations, recent work has trained policies directly on text, using a recurrent neural network to output language tokens, and using self-play for policy training while interacting with another learned agent (Li et al., 2016b; Lewis et al., 2017; Liu et al., 2018). To further improve the generated language quality, hierarchical methods decouple the strategic high-level dialogue decisions from generation (Yarats and Lewis, 2018; He et al., 2018; Saleh et al., 2020). These model-based approaches require accurate estimation of the environment/human (e.g., the trained self-play agent needs to mimic complex human behavior), which is beyond current capability of model-based reinforcement learning algorithms. Similar to our proposal, Jaques et al. (2019) use offline RL based on KL-control for text generation in open-domain dialogue. Our work differs in that our model is able to utilize large amounts of unsupervised data through the use of pre-trained language models, and that our work focuses on task-oriented (as opposed to open-domain) dialogue tasks. Goal-oriented tasks have clearly defined objectives that can be quantified, allowing us to provide an objective comparison between our method and prior approaches.

3 Preliminaries

In this section, we describe our evaluation task and cover the necessary background and notation.

3.1 Negotiation via Task-Oriented Dialogue

We evaluate our approach on the CraigslistBargain task (He et al., 2018). CraigslistBargain consists of 6682 advertisements scraped from Craigslist, along with dialogues for each advertisement collected via Amazon Mechanical Turk where two users play the role of buyer/seller. An example advertisement from this dataset is shown in Fig. 1, along with a sample conversation between a human and CHAI.

Title: iPhone 5S 16 GB black silver - $135
Description: Great condition. No scratches. I upgraded to iPhone 7. Please reply with phone number if you are interested. Thank you.

Buyer: Hi, I would like to buy the iPhone 5S
CHAI: Hi, great! The phone is in great condition. I'm asking $135.00, it's in mint condition.
Buyer: Does it come with a charger?
CHAI: Yes it comes with a charger, as I upgraded. It's in mint condition.
Buyer: How long have you been using this phone?
CHAI: Just a month. It's in great condition and has a charger included.
Buyer: Did you buy this phone secondhand or from the Apple store?
CHAI: I bought it brand new from Apple store. I only used it a month, I'm happy I did not have to use this one.
Buyer: I can buy it for $100
CHAI: I'll take that if you can pick it up in a few hours.
Buyer: Where will you be at 5pm today?
CHAI: I'm at the Apple store so about an hour.
Buyer: Okay, I can meet you at the Apple store.
CHAI: Awesome!
Buyer: *accept*

Figure 1: An example advertisement from the CraigslistBargain task, with a conversation between CHAI (blue) and a human buyer (green).

During each round of interaction, the buyer and seller can execute four possible response types. A `message` allows one player to send an utterance to the other. An `offer` allows one player to propose a price at which to conduct the transaction. Once an offer is made, the other player can either `accept` or `reject` the offer, which ends the episode. A reward is then computed based on the transaction price. Our bot receives a reward equal to the normalized price the item is sold for at the end of an episode (normalized by the list price), scaled by a constant factor of 10. Additionally, we penalize the bot by a constant of -20 for episodes resulting in a `reject` to incentivize the agent to make deals.

We selected this task because it provides a clear objective, allowing us to illustrate our approach with quantifiable metrics. Of course, practical applications of CHAI to goal-directed dialogue may tackle other problems, including non-adversarial problms such as helping a user to answer a question or fulfill a request. However, our choice of tasks was constrained by the limited availability of public datasets for dialogue tasks that are goal-directed and have objective task goals.

3.2 Reinforcement Learning Setup

We formulate the task-oriented dialogue problem as an RL problem, where the agent serves the role of *seller* in the CraigslistBargain problem, and the environment serves the role as the *buyer*. We consider a Markov decision process defined as a tuple $(\mathcal{S}, \mathcal{A}, \mathcal{T}, r, \gamma)$. The state and action spaces, $\mathcal{S}$ and $\mathcal{A}$, consist of three main components: the action type `type` (one of the four described in Sec. 3.1), an utterance u (used only for `message` responses), and a normalized price `price`, expressed as a fraction of the list price. Additionally, the context component $s_{\texttt{context}}$ contains the advertisement listing description. The price component is used in two ways. First, because we do not wish to represent prices in the dialogue as discrete tokens, we instead replace prices in the utterance with a placeholder token understood to be substituted with the price component. Second, the price component is used in `offer` response type to communicate the desired transaction price. In all other cases, it is ignored. An example of the state space is shown in Fig. 2.

We write individual states as $s = \{s_u, s_{\texttt{type}}, s_{\texttt{price}}, s_{\texttt{context}}\}$ and actions as $a = \{a_u, a_{\texttt{type}}, a_{\texttt{price}}\}$, where s_u, a_u denote the utterances, or sequences of words generated by the environment and agent. $\{s_{\texttt{type}}, a_{\texttt{type}}\}$ denote the action types, $\{s_{\texttt{price}}, a_{\texttt{price}}\}$ denote the prices, and $s_{\texttt{context}}$ denotes the listing context. The transition distribution $\mathcal{T}(s'|s, a)$ governs the distribution over responses generated by the buyer agent (environment), and the reward $\mathcal{R}$ defines the task objective. The goal of RL is to find a policy $\pi(a|s)$ that maximizes the expected returns:

$$\mathbb{E}_{\pi,\mathcal{T}}\left[\sum_{t=0}^{T} \gamma^t r(s_t, a_t)\right],$$

where $r : \mathcal{S} \times \mathcal{A} \mapsto \mathbb{R}$ is the reward function, and $\gamma \in (0, 1]$ is the discount factor. In online RL, the agent is interacts with the environment to maximize this objective. In contrast, offline RL uses

s_u	`utterance`	Hello!
s_{context}	`context`	Selling a new mountain bike.
s_{price}	`price`	0.5 (of list price)
s_{type}	`action_type`	`message`

Figure 2: An example of the state space used in the CraigslistBargain task described in Section 3.1.

a dataset $\mathcal{D}$ of pre-collected interaction. This is a natural approach in many settings, such as dialogue, where online RL could require interacting with real humans for impractically long periods of time, whereas offline RL can utilize pre-recorded dialogues between humans.

4 Offline Reinforcement Learning with Language Models

Offline RL potentially allows reinforcement learning methods to leverage large datasets for policy learning. However, it still requires datasets to be annotated with rewards, and for conversations to come from the task at hand. Because of this, annotated dialogue datasets, such as the CraigslistBargain dataset presented in Section 3.1, are many orders of magnitude smaller than unlabeled datasets collected for unsupervised and language modeling tasks. In order to utilize these large unlabeled datasets, we propose an algorithm that combines offline RL with fine-tuned language models.

Our approach begins with training a language model, such as GPT-2 (Radford et al., 2018), and fine-tuning it on our task-specific dialogue corpus (Sec. 3.1). We use $\mathrm{LM}(u|s_{1:t})$ to denote a distribution over utterances u produced by the language model given the dialogue history, denoted $s_{1:t}$. We then train a critic or Q-function as described in Sec. 4.1, which is responsible for scoring good and bad responses and is used to select responses from a pool of candidates generated from the language model. Our approach can be viewed as using a Q-function to steer a language model (which has no concept of a task) towards producing language that accomplishes some task-specific goal.

4.1 Q-Learning with Language Models

In this section we describe how to train a Q-function that can score candidate responses based on their potential to maximize returns. We implement and evaluate three different training procedures, each utilizing different offline RL methods. In the overall Q-learning framework, we sample a batch of transitions (consisting of states, actions, rewards, and successor states) from our dataset and perform updates based on minimizing a modified Bellman loss:

$$J(\theta) = (Q_\theta(s,a) - Q_{\text{target}}(s,a))^2, \quad (1)$$

where target value $Q_{\text{target}}(s,a)$ is typically computed via the Bellman operator defined as

$$Q_{\text{target}}(s,a) = r(s,a) + \gamma \mathbb{E}_{s'} \left[\max_a \bar{Q}(s',a) \right]. \quad (2)$$

However, using this update directly can lead to problems if we only have access to offline datasets. A widely studied issue in offline RL is the challenge of handling *out-of-distribution actions*: when the maximization over the action in the target value is not constrained in any way, it is easy to obtain actions for which the Q-value predictions are erroneously high (Levine et al., 2020). In dialogue, this issue is greatly exacerbated, since the Q-function is only trained on responses in the dataset, and therefore is unlikely to make accurate predictions for arbitrary strings. The following modifications to Eqn.1 and Eqn.2 address this issue.

Proposal sampling (CHAI-prop) In the proposal sampling approach, the target value $Q_{\text{target}}(s,a)$ is computed via a modified Bellman operator that utilizes a proposal distribution based on the language model, $\mu(a_t|s_{1:t})$, to generate N *response proposals*, and then uses the target Q-function, $\bar{Q}$, to score those responses and selects the highest one:

$$\begin{aligned} &Q^{\text{prop}}_{\text{target}}(s,a) \\ &= r(s,a) + \gamma \mathbb{E}_{s'} \mathbb{E}_{\{a_i\}^N \sim \mu} \left[\max_i \bar{Q}(s', a_i) \right]. \end{aligned}$$

This sampling scheme serves a dual purpose: it both constrains the responses to be naturalistic, and it also prevents out-of-distribution inputs to the Q-function in the target value calculation. This approach resembles a number of prior offline RL methods that also employ proposal distributions (Kalashnikov et al., 2018; Kumar et al., 2019; Fujimoto et al., 2019; Wu et al., 2019). Similarly to several prior works, we use samples from a proposal distribution for the target value, without an explicit actor (Kalashnikov et al., 2018; Ghasemipour et al., 2020). Unlike these approaches, our method leverages a pretrained and finetuned language model LM, which additionally makes use of extensive unsupervised prior datasets during the pretraining stage and enables our method to handle the complex and combinatorial action space of dialogue generation. In addition, following prior work, we use a separate target network $\bar{Q}$ whose weights are updated to track those of Q using a soft update rule as done in prior methods (Lillicrap et al., 2016; Haarnoja et al., 2018).

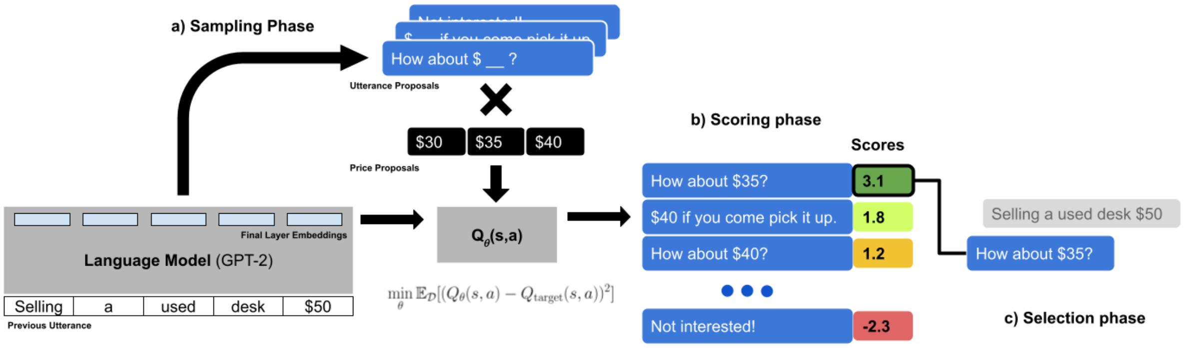

Figure 3: An overview of our dialogue generation and selection process. First (a), a finetuned language model is used to generate candidate responses conditioned on the conversation history, along with sampled prices. Then (b), each action is scored using a critic, and (c) a final response is returned by sampling the Q-value scores.

The proposal distribution $\mu(a_t|s_{1:t})$ represents a distribution over actions $a = \{a_u, a_{\texttt{type}}, a_{\texttt{price}}\}$. We use the language model in order to sample utterances $a_u \sim \text{LM}(\cdot|s_{1:t})$. To make training more computationally efficient, we pre-generate a batch of 5 utterances per transition in the dataset using the language model, and resample these during training as an approximation of directly sampling from the language model. For the prices $a_{\texttt{price}}$, we uniformly sample a value between 70% to 100% of the previously offered price, which roughly matches the distribution of the seller's offers in the dataset. Finally, we infer the message type based on the utterance sampled using a simple heuristic, as the CraigslistBargain task requires us to specify a `type` for each response. During language model fine-tuning, we replaced each `offer`, `accept`, or `reject` action with the utterances "offer", "accept", and "reject", respectively. We then check if the language model generated any of these tokens and return the corresponding action type, and label the action as a `message` otherwise. This simplifies our method and allows us to use the language model to generate the action types as well as the utterances.

Conservative Q-learning (CHAI-CQL) Conservative Q-learning (CQL) (Kumar et al., 2020) proposes a complimentary approach to reducing the harmful effect of out-of-distribution Q-values by explicitly penalizing the Q-value of actions not seen in the dataset. We adapt CQL as an additional regularizer on the Q-value in addition to the proposal sampling scheme. Specifically, we use the CQL($\mathcal{H}$) variant, which add an additional regularizer f^{CQL} to the Q-learning objective:

$$J^{\text{CQL}}(\theta) = (Q_\theta(s,a) - Q_{\text{target}}(s,a))^2 + \alpha f^{CQL}(\theta),$$

where the regularizer is defined as:

$$f^{CQL}(\theta) =$$
$$\mathbb{E}_{s\sim\mathcal{D}}\left[\log \sum_a \exp(Q_\theta(s,a)) - \mathbb{E}_{a\sim\mathcal{D}}[Q_\theta(s,a)]\right]$$

Our adaptation of CQL differs from Kumar et al. (2020) in that they propose an actor-critic method which trains an explicit actor. Rather, the remainder of our method is identical to the proposal sampling variant, specifically in regards to the computation of Q_{target} and language model sampling.

Behavior-regularized Q-learning (CHAI-BRAC) Behavior-regularized actor-critic (BRAC) (Wu et al., 2019) proposes an alternative method for regularizing the Q-function such that out-of-distribution Q-values are penalized. Adapting this method to the setting of dialogue with language models, we use this approach to regularize the price proposal mechanism. Rather than uniformly sampling prices as described for proposal sampling, we train an additional *price proposal network* $\pi_\phi(a_{\texttt{price}}|s_{1:t})$ that outputs a Gaussian distribution over prices given the conversation states. Using the notation $a' \sim \pi_\phi, \mu$ to denote sampling prices from the proposal network, utterances from the language model, and action types uniformly, the proposal network is trained according to the objective

$$\max_{\pi_\phi} \mathbb{E}_{s,a\sim\mathcal{D}}\big[\mathbb{E}_{a'\sim\pi_\phi,\mu}[Q(s,a')]$$
$$- D_{KL}(\pi_\phi(\cdot|s), \pi_B(\cdot|s))\big].$$

The prior proposal network, π_B, is estimated as a univariate conditional Gaussian of the current offer given the previous offer, where the mean and standard deviations are linear functions of the previous offer. The target value is then computed as:

$$Q^{\text{BRAC}}_{\text{target}}(s,a) = r(s,a) + \gamma \mathbb{E}_{s',a'\sim\pi_\phi,\mu}\left[\bar{Q}(s',a')\right].$$

This adaption of the behavior regularized objective controls out-of-distribution queries on the Q-value by regularizing the price towards those seen within the dataset. This prevents the target Q-value from being queried in low-data regimes which can cause inaccuracies during training.

4.2 Dialogue Generation

Once the Q-function has been trained, dialogue generation from our model is a three-phase process. The first phase is sampling: given a response from the buyer, we query the language model to sample 5 candidate utterances, and sample 5 candidate prices. The next step is scoring: we then take the cross-product of these sets, and score each potential action with the Q-function. Finally, in the selection phase, several methods are considered in order to select an action. A straightforward method is to return the action that had the highest Q-value. However, we found that this approach resulted in behavior with low diversity. Instead, we opted to follow the approach in soft Q-learning (Haarnoja et al., 2018) and sample actions from a softmax distribution over the Q-values, $p(a|s) \propto \exp\{Q(s, a)\}$, which increases diversity in the responses as suboptimal actions are occasionally sampled. This decoding process is depicted in Fig. 3.

4.3 Architecture Details

For our language model, we use an off-the-shelf implementation of GPT2-medium (Radford et al., 2018). This language model is finetuned on a transcript of each scenario in the dataset containing the context (title, description) and spoken dialogue. The prices in the dialogue are masked out with a special price token allowing us use GPT to generate templates which we can substitute prices into. The input to the language model is a concatenation of the scenario context and the dialogue history.

The Q-function is parameterized as a feedforward network that maps states and actions into a single scalar representing the Q-value. To process the utterances into the state and action, we separately compute state and action embeddings by taking the average of the masked GPT2 attention embeddings of the entire dialogue history up to the current utterance. These embeddings are then concatenated with the prices (represented as a fraction of the list price) and message types (represented as a one-hot vector) to produce a single vector that is given to the critic as input. The critic is parametrized using a 2-layer feedforward network with hidden sizes of 256 and ReLU nonlinearities. Additional details about our model architectures, language model sampling method, and how inputs to the Q-function are structured, can be found in Appendix A.1.

5 Experiments

Our experimental evaluation aims to compare our proposed goal-directed offline RL dialogue method to both prior dialogue management approaches and language modeling baselines. We conduct two studies: an objective evaluation against other dialogue agents to measure each method's performance in negotiation, and a subjective human study to measure the overall end-to-end performance of the system in a similar manner to prior work (He et al., 2018; Jaques et al., 2019). Qualitative results showing actual dialogue generated from our method can be found in Appendix A.4. We consider 4 baseline approaches. The first is the current state-of-the-art approach for the CraigslistBargain task proposed by He et al. (2018) (referred to as the retrieval-based baseline). This is a hierarchical approach to dialogue generation that separately handles language generation and dialogue management. This method parses utterances into coarse "dialogue acts," which represent high-level categorizations of the utterance such as greetings, offers, or counter-offers. An RL agent is then trained against a learned model of the environment to select "dialogue acts", and a retrieval-based generator is then used to convert "dialogue acts" back into text. In contrast, our method directly generates text, and does not require any manually designed categorizations of natural dialogue into dialogue acts. Since our method utilizes a modern language model, we also include a pure language modeling baseline, which consists of the same GPT-2 language model Radford et al. (2018) finetuned on the CraigslistBargain dataset using the same method as done in CHAI. This baseline allows us to determine whether any improvement from our method is due to the language model, or to the use of offline RL. Finally, we also evaluate the end-to-end approaches described by Lewis et al. (2017), which include a dialogue agent trained via supervised learning, and an RL agent optimized for the task objective.

5.1 Simulated Evaluation

To evaluate the effectiveness of our offline RL goal-directed dialogue system, we first conducted a sys-

Method	vs Rule-based		vs Stingy		vs Utility	
	Acc%	Revenue	Acc%	Revenue	Acc%	Revenue
CHAI-prop	61.5	0.48 ± 0.39	57.5	0.39 ± 0.35	99.0	0.70 ± 0.17

Table 1: Acceptance rates and normalized average revenue generated comparing CHAI using proposal sampling (CHAI-prop), conservative Q-learning (CHAI-CQL), and behavior regularization (CHAI-BRAC). The baselines consist of a retrieval-based agent (He et al., 2018), Lewis et al. (2017) and a fine-tuned language model (higher is better) against 5 different evaluation bots. The mean score across all evaluation bots is reported in the right-most column. Numbers are reported as means and standard deviations over 200 trials.

Metric	Fluency	Coherency	On-Topic	Human-Likeness	Total
CHAI-prop	$\mathbf{4.31 \pm 0.97}$	$\mathbf{3.91 \pm 1.17}$	$\mathbf{4.16 \pm 0.99}$	$\mathbf{3.47 \pm 1.27}$	$\mathbf{15.84 \pm 3.86}$
He et al. (2018) (Utility)	3.56 ± 1.34	2.47 ± 1.39	3.09 ± 1.40	2.13 ± 1.13	11.25 ± 4.50
Lang. Model	4.06 ± 1.11	2.66 ± 1.36	3.63 ± 1.18	2.50 ± 1.10	12.84 ± 3.66

Table 2: Human evaluation scores comparing CHAI, He et al. (2018), and language model (higher is better). Numbers are reported as means and standard deviations over 32 trials. CHAI scores the highest across all metrics.

tematic study including the 3 variations of CHAI outlined in Sec. 4: the proposal sampling method (CHAI-prop), CQL method (CHAI-CQL), and behavior regularized method (CHAI-BRAC). In order to ensure that the results are not overfit to a single strategy, we run each method against a suite of 5 evaluation buyer agents, based on the retrieval agents presented by He et al. (2018). We choose these agents because they have been evaluated by humans as being human-like and have the strongest performance on the CraigslistBargain benchmark task. Specifically, we use the rule-based and RL agents proposed by He et al. (2018) (trained using “utility”, “fairness”, and conversation “length” as rewards). To introduce additional variety in negotiation styles, we additionally modify the rule-based agent to offer 25% of the difference between offers rather than splitting the difference between offers, which we refer to as the “Stingy” rule-based agent. We record the percentage of negotiations that result in an accept and the average normalized revenue generated per negotiation, which totals the average sale price (rejections have zero revenue) normalized by the listing price of the advertisement. Our results are presented in Table 1.

Overall, we find that among the variations of CHAI, the conservative Q-learning variant performs the best by a small margin, but results are very comparable between all 3 variations. This suggests that the particular choice of offline regularizer is far less important than the CHAI framework of utilizing a pre-trained language model with Q-function scoring. On average, CHAI-CQL performs significantly higher on acceptance rate and similarly on revenue to the next best agent, the retrieval agent (He et al., 2018) using conversation length as reward. Computing statistical significance between these two methods, we find that $p < 1.96 * 10^{-9}$ using a chi-squared test for acceptance rate, indicating that the difference in acceptance rates is statistically significant. We find that $p < 0.946$ using a t-test for revenue, indicating that the difference in revenue is not significant. We also note that the performance of CHAI

Title: FULLY REMODELED 4 Bdrm, 1 Bath, Duplex - $3395
Description: 4 bed / 1 bath *Type:* Duplex *City/Neighborhood:* Emeryville *Showing:* By Appointment Only *Utilities:* Paid by tenant (not included in rent amount) *Features:* Hardwood Floor, Washer Dryer, newly renovated, stainless steel appliances

Buyer: hi
CHAI: Hi there. Are you interested in my rental?
Buyer: yes, when is the next opening to view the apartment?
CHAI: Today.
Buyer: how much are the utilities per month?
CHAI: Utilities are not included in the rental amount, but I am willing to negotiate the price.
Buyer: since utilities are not included, could you do $3000?
CHAI: I can't go that low. What about $3300?
Buyer: sounds good!
CHAI: Perfect! Thank you!
Buyer: *accept*

Buyer: Hi
Retrieval: hi
Buyer: when is the next opening to view the apartment?
Retrieval: its right by apartment merrit
Buyer: how much are the utilities per month?
Retrieval: yes they are
Buyer: since utilities are not included, could you do $3000?
Retrieval: deal!
Buyer: sounds good!
Retrieval: *offer $3000*
Buyer: *accept*

Buyer: Hi
LM: Hi, are you interested in my property?
Buyer: Yes, when is the next opening to view the apartment?
LM: Open until 6pm tomorrow.
Buyer: Sounds good, how much are the utilities per month?
LM: Utilities are included in the monthly rent.
Buyer: Okay, and can you do $3000?
LM: *offer $2200*
Buyer: *accept*

Figure 4: A comparison between similar negotiations talking to CHAI-prop (left), a retrieval-based agent (He et al., 2018) (middle), and language modeling (LM, right) for the same listing. The bot takes the role of the seller, and a human is the buyer. CHAI gives both descriptive responses to questions and reasonable bargaining behavior, whereas the retrieval-based agent only shows good bargaining behavior, and the language model agent only gives descriptive responses.

has significantly less variation across evaluations against different buyer agents than the retrieval-based agents. For example, the retrieval agent with utility reward scores near-zero on 3 evaluations but scores near-perfectly on the other two. This suggests that the CHAI framework produces dialogue agents that are more consistent and less susceptible to exploitation. We also note that implementing the retrieval method (He et al., 2018) requires hand-designing high-level dialogue actions, topic categories, and rules for parsing or labeling these components. These designs are specifically tailored to the CraigslistBargain task, whereas such hand-engineering for CHAI does not exist outside of the interface requirements to the task itself. Thus, CHAI has significantly weaker assumptions, generates dialogue end-to-end via RL, and yet is able to narrowly outperform prior methods. Among prior methods with similar assumptions to CHAI (the language modeling baseline and (Lewis et al., 2017)), CHAI outperforms by a wide margin on both acceptance rates and revenue.

We ran an additional ablation study on the choice of reward in Appendix A.3. We find that this has a significant effect on performance, and we based our reward design on balancing between maximizing acceptance rate (through a rejection penalty) and revenue (through the utility function).

5.2 Human User Study

To evaluate the effectiveness and naturalness of our offline RL goal-directed dialogue system, we conducted a user study with 16 individuals, who were each asked to carry out 2 negotiations with each of three agents. The users were then asked to rate the conversation on fluency, coherency, on-topicness, and human-likeness on a 5-point Likert scale. **Fluency** specifically refers to the frequency of grammatical and word-choice errors. **Coherency** measures whether the agent's responses are coherent. **On-topic** measures how well the agent was aligned with performing the task at hand. Finally, **human-likeness** measures how similar the agent's responses were to a human. Because of the cost of human evaluations, we were limited in our ability to evaluate as many baselines. Therefore, we chose methods that were the most directly comparable - the simplest variation of CHAI (CHAI-prop) optimized for utility, evaluated against the utility-optimized agent from He et al. (2018), and a language model baseline that shares the same fine-tuning procedure as CHAI. Additional details of the user study, including the questions posed to the users and statistical significance tests, are included in Appendix A.3.1.

Results are shown in Table 2. We ran a one-way repeated measures ANOVA test, and found that the type of agent used leads to statistically significant rating differences for all metrics (with at least $p < 0.01$). CHAI outperforms both baselines on almost all metrics, except for fluency, where both CHAI and the language model perform similarly. The fact that fluency is similar between the two models makes sense, since both methods use a GPT-2 model to generate utterances. However, the langauge modeling baseline lacks an understanding of the task goal, and therefore makes unreasonable offers or responds in illogical ways (see Appendix A.4 for examples). It therefore scores lower on other metrics as compared to CHAI. This result suggests that the ability of language models to execute goal-directed dialogues is limited by a lack of awareness of the task objectives, and that offline RL potentially addresses this issue, producing dialogue that is perceived as more coherent, task-oriented, and human-like.

In Fig. 4 we show a comparative example between CHAI, the retrieval-based agent (He et al., 2018), and the language modeling baseline on the same scenario with human responses. CHAI and the language modeling baseline tend to produce more specific responses to the prompt due to the use of a language model, rather than generating text via the usage of templates. For example, when presented with a questioned about utilities and viewing time, both methods are able to answer the question, whereas the retrieval-based agent gives a non-sequitur answer. However, the language modeling baseline struggles in understanding prices, and offers $2200 when the buyer requested $3000. CHAI is able to demonstrate understanding both language and the flow of the negotiation by offering reasonable counter-offers to the user, such as responding to a low offer with "I can't go that low" and offering a higher counter-offer that the Buyer accepts. Additional examples from our human evaluation can be found in Appendix A.4.

6 Discussion and Future Work

We presented a system for goal-directed dialogue based on combining offline RL with finetuned language models. CHAI learns with RL, but does so from offline datasets of human dialogue. The language model allows CHAI to benefit from large-scale unsupervised pre-training, and the offline RL component enables CHAI to select responses that are more likely to lead to a successful task outcome. Quantitatively, CHAI achieves higher acceptance rate at higher revenue than prior dialogue management systems designed for this task.

Goal-oriented dialogue agents have many potentially useful applications such as building personal assistants, improving accessibility to technology for the disabled or the elderly, and simply saving time by automating menial tasks. Of course, as with any natural language generation technology, this kind of method can be used both beneficially and maliciously, for example by users who aim to create intentionally deceptive and realistic agents.

While CHAI provides a proof-of-concept that offline RL can successfully learn complex human-interactive tasks such as dialogue, it also has limitations. The goal of RL is to maximize reward, which can lead to unintended responses – for example, without additional objective terms, there is no reason for CHAI to be truthful. Similar issues affect language models more broadly, though we anticipate that it would be easier to address such issues in RL by employing better reward design. Although reward design can itself be a difficult problem, it does provide a more direct lever for influencing the agent's behavior than what is available in standard language models, which must be directed either through the choice of training data or other indirect mechanisms. In CHAI, we only investigated a single task due to architectural constraints, and the exact same architecture presented in this paper (e.g. a price prediction head) may not be directly transferable to other domains. However, using a value-based selection mechanism is more generally applicable to any goal-oriented task.

An exciting direction for future work is to extend offline RL to address a wider range of human-interactive tasks, particularly tasks with longer-range dependencies and delayed rewards, where complex task goals can lead to the emergence of dialogue that is ultimately more useful to human users.

A Appendix

A.1 Architecture Details

For our language model, we use an off-the-shelf implementation of GPT2-medium (Radford et al., 2018). This language model is finetuned on a transcript of each scenario in the dataset containing the context (title, description) and spoken dialogue. The prices in the dialogue are masked out with a special price token allowing us use GPT to generate templates which we can substitute prices into. To produce language samples, we concatenate the context of the scenario along with the dialogue history and feed it to the language model. The language model then generates the next utterance. This process is repeated in order to get multiple samples.

The Q-function is a feedforward network that maps the states and actions into a single scalar representing the Q-value. To process the utterances into the state and action, we separately compute state and action embeddings by taking the average of the masked GPT2 attention embeddings of the entire dialogue history up to the current utterance. State and action embeddings are then concatenated with the prices (represented as a percentage of the list price) and message types (represented as a one-hot vector) to produce a single vector that is given to the critic as input. The critic is parametrized as a 2-layer feedforward network with hidden sizes of 256 and ReLU nonlinearities.

The equations below describe the inputs of the Q-function. “STRCAT” is a custom string formatting function that concatenates the context and utterances in the dialog and prefixes each utterance with the string “Buyer:” or “Seller:”. “EMBED” calculates the masked attention embeddings from GPT2. `dialog` represents the dialog history up to the current state, $[s_{u,1}, a_{u,1}, \ldots, a_{u,t-1}, s_{u,t}]$, and `candidate` denotes a candidate utterance $a_{u,t}$ generated by the language model that is being considered for scoring.

$$
\begin{aligned}
s_{\texttt{embed}} &= \mathrm{EMBED}(\mathrm{STRCAT}(s_{\texttt{context}}, \texttt{dialog})) \\
a_{\texttt{embed}} &= \mathrm{EMBED}(\mathrm{STRCAT}(s_{\texttt{context}}, \texttt{dialog} + \texttt{candidate}) \\
s &= [s_{\texttt{embed}}, s_{\texttt{price}}, s_{\texttt{type}}] \\
a &= [a_{\texttt{embed}}, a_{\texttt{price}}, a_{\texttt{type}}] \\
q &= Q(s, a)
\end{aligned}
$$

A.2 Experiment Details

Hyperparameter Selection. For our Q-learning algorithm, we used default hyperparameters from an SAC implementation and did not vary the parameters. We used a critic learning rate of $3 * 10^{-4}$, and a soft target update rate of 0.05. For the language model architecture, we finetuned 2 GPT models architectures (GPT2-small, and GPT2-medium). In order to select which model to use, we manually rated samples from the language generated in their quality across both model types and checkpoints, and selected the best performing model. We selected the GPT2-medium architecture at training epoch 2000.

Compute Resources. We finetuned our language models on TPUs (TPU v3-8, 16GB memory per core with 8 cores) within a GCP instance. We trained our Q-learning models on an internal compute cluster using an Nvidia 1080 GPU (12 GB memory).

A.3 Reward Ablation Study

Because we are limited in the number of evaluations possible in a human study, we use a simulated evaluation against another chatbot to run an ablation study measuring the effect of using different reward functions. Specifically, we instantiate a rule-based dialogue manager proposed by (He et al., 2018) as the “buyer” and negotiate with it on randomly sampled scenarios from the dataset. This is done for both our method and the baselines, and the results are tabulated in Table 3.

We evaluated 5 variations of CHAI. CHAI(final) is the method used in our paper, which uses 2 components to the reward: positive reward for the price the item was sold at, and a penalty for the episode ending in a rejection. The specific reward used was 10 * the price sold (normalized by the list price) if the offer was accepted, or a penalty of -20 if the offer was rejected. CHAI(penalty) uses the same reward, except with an increased rejection penalty. CHAI(accept) is given a positive reward of +20 for episodes ending in an accept and negative reward of -20 for episodes ending in a rejection, without regard to the price. CHAI(utility) is rewarded solely for the price an item is sold at at 10 * the price sold. Finally, CHAI(fair) is rewarded for negotiating to a midpoint price between the buyer and seller's target prices.

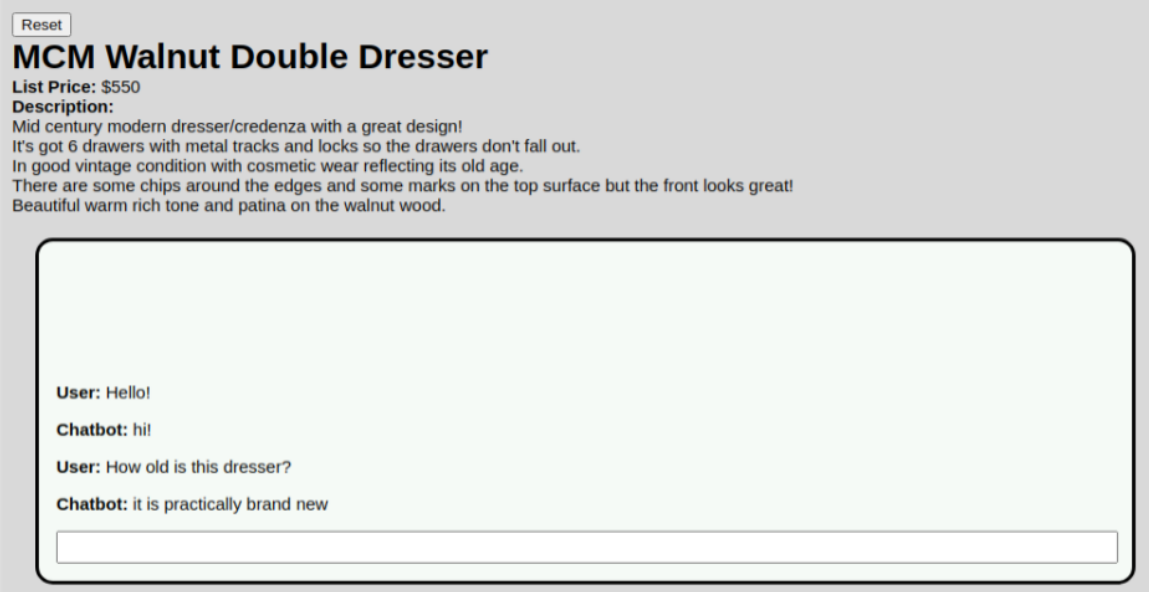
We report the acceptance rate, average revenue, and average offers made and offers accepted. We see that CHAI(accept), CHAI(fair) and CHAI(penalty) achieve higher acceptance rates, but offer lower prices on average. In contrast, CHAI(utility) and CHAI(final) offer higher prices with lower acceptance rates, with the pure utility optimizing agent CHAI(utility) offering the highest prices with the lowest acceptance rates. Thus, we can see how changing the reward function can significantly affect the behavior of the resulting agent.

Method	Accept Rate	Prices Offered	Prices Accepted	Revenue
CHAI(accept)	0.74	0.80 ± 0.15	0.74 ± 0.13	0.55 ± 0.35
CHAI(fair)	0.76	0.80 ± 0.15	0.75 ± 0.13	0.57 ± 0.34
CHAI(penalty)	0.90	0.77 ± 0.14	0.77 ± 0.12	0.68 ± 0.26
CHAI(utility)	0.34	0.96 ± 0.29	0.76 ± 0.13	0.29 ± 0.42
CHAI(final)	0.66	0.84 ± 0.14	0.87 ± 0.07	0.51 ± 0.38

Table 3: Mean and standard deviation of revenue, acceptance rate, and prices sold & offered, over 50 samples when negotiating against a baseline chatbot. Revenue and prices are reported as a fraction of the list price.

A.3.1 User Study Parameters

Setup. We conducted our user study through a web-interface, where an advertisement from the test set of CraigslistBargain is displayed to the user. This is shown in Fig. 5. Users were instructed to "type any message to speak with the bot and negotiate", and a chatbot agent replied to each message. After the user is satisfied with the negotiation, they are asked to indicate whether they want to accept or reject the current offer on the item.



MCM Walnut Double Dresser

List Price: $550

Description:

Mid century modern dresser/credenza with a great design!
It's got 6 drawers with metal tracks and locks so the drawers don't fall out.
In good vintage condition with cosmetic wear reflecting its old age.
There are some chips around the edges and some marks on the top surface but the front looks great!
Beautiful warm rich tone and patina on the walnut wood.

User: Hello!

Chatbot: hi!

User: How old is this dresser?

Chatbot: it is practically brand new

Figure 5: The interface presented to participants in the user study. We display the title, price, and description of the advertisement, and users are able to chat with the bot through a textbox.

After interacting with the chatbot agent, users were given a survey and asked to rate the bot on a 5-point Likert scale: strongly agree (5), agree (4), neutral (3), disagree (2), strongly disagree (1). The ratings were:

- The bot was fluent (did not make grammatical or word choice errors).
- The flow of the conversation was coherent.
- The bot was on-topic.
- The bot demonstrated human-like behavior.

These questions correspond to the fluency, coherency, on-topicness, and human-likeness scores reported in our paper, respectively.

Manipulated factors. We evaluate 3 chatbot agents. The first is CHAI. The second is a retrieval-based baseline ($\text{RL}_{\text{utility}}$(act) as proposed in (He et al., 2018)). The this is a language modeling baseline based on finetuning GPT2-medium on the CraigslistBargain dataset.

Dependent measures. We measure the performance of each chatbot agent according to 4 subjective metric (fluency, coherency, on-topicness, and human-likeness), which correspond to the survey questions given to participants described above. Each metric is rated on a 5-point Likert scale. We also measure the price that was agreed upon, and whether the negotiation resulted in an acceptance or a rejection.

Risks The risks presented to participants were minimal, and participants were never placed in the way of physical harm. There was a small probability the chatbot could generate offensive or otherwise inconsiderate langauge, as the language generation for CHAI and the language model baseline were unconstrained. However, we did not observe this behavior prior to the study, and did not observe this behavior during the study. We minimized the risk of confidentiality breaches by anonymizing all data stored as user IDs – participant names were not stored on our servers.

Subject allocation. We recruited 10 male and 6 female participants, with an average age of 24. Participation was voluntary, and subjects were not compensated for their participation. Participants were asked for consent before participating, and consent for including examples from their interactions for this paper. All examples contained in this paper are anonymized and contain no personally identifiable information.

Prior to participation in the study, each user was provided with instructions for how to use the interface, and a practice evaluation against the retrieval agent to familiarize them with the user interface and rating system. Each user interacted with all 3 dialogue agents (CHAI, retrieval, and language model) twice, with the order of interaction randomized per user. The advertisement displayed to the user is also uniformly sampled from the test set for each trial, independently from the agent being used.

Analysis. We ran a one-way repeated measures ANOVA test for each metric reported (fluency, coherency, on-topic, human-like) to examine the effect of chatbot agent on the metric.

Results showed that the type of agent used lead to statistically significant differences in the ratings. We found that:

- For fluency, $f(2, 30) = 5.8333, p < 0.0072$
- For coherency, $f(2, 30) = 16.9518, p < 0.0001$
- For on-topicness, $f(2, 30) = 10.1840, p < 0.0004$
- For human-likeness, $f(2, 30) = 20.1592, p < 0.0001$

A.4 Additional Qualitative Results

In this section, we include additional examples collected from human dialog for CHAI-prop, the retrieval method of (He et al., 2018), and the pure language modeling baseline.

A.4.1 CHAI-prop

Title: Ubiquiti Networks UAP-AC-LITE - $65
Description: Price is firm. Just a few month old. As New. With box and all parts. Great reliable AP. Set up once and forget about it; never need to reboot, restart like consumer AP; especially when you have high demand traffic with lots of concurrent users. Perfect for large house or business.

Buyer: I noticed that your price is firm. Would you be flexible in any way?
CHAI: That is good. I am asking $52 for this excellent product.
Buyer: how old is your product
CHAI: It has been in use for only about 6 months. It has never been restarted.
Buyer: why are you selling it
CHAI: I do not use this product.
Buyer: is it damaged
CHAI: It has a small scratch on the front. It is still new. I would offer $52.
Buyer: Could you do 40
CHAI: I would be willing to let it go for $40.
Buyer: How about $10
CHAI: It is new, in excellent condition. I would not take less than $40.
Buyer: But you just said it was scratched
CHAI: It is not scratched.
Buyer: Sorry I can't do more than 35
CHAI: Well, I can go down to $35.
Buyer: ok
CHAI: Great.
Buyer: *accept*

Title: Nokia Batteries - One new one used - $10
Description: I have these two batteries left over from my old phone. Maybe you can use them? Both are in excellent working order and ready to use. Message me if you are interested.

Buyer: I've been looking for batteries, what about 50 cents?
CHAI: Hi. I still have them. They're used, but I have used them and they work perfectly.
Buyer: How much life does the used one have?
CHAI: $9
Buyer: How many times have you used the old battery?
CHAI: 1 to 2 times
Buyer: Did you not use your phone much?
CHAI: Nope, I've been away from it for about 6 months.
Buyer: Ah, I see that makes sense.
CHAI: I can do $6
Buyer: I doubt many people would want to buy a used battery though, how many other offers do you have?
CHAI: I will let them go for $7.
Buyer: But you offered 6, 7 is higher?
CHAI: No. But I'm really looking for around $6 for them.
Buyer: I'll pick it up right now for 4 dollars
CHAI: No deal
Buyer: But you were not being fair earlier when you went from six to 7 dollars
CHAI: I can go to $5
Buyer: I'm holding firm on 4 dollars, especially because the batteries are used
CHAI: I can let them go for $5
Buyer: No one really buys used batteries though, what other offers are you getting?
CHAI: I'm just going to let them go for $4
Buyer: *accept*

Title: Couch and love seat - $80

Description: Couch and love seat from a non-smoking pets free house. Upholstery is clean and doesn't have any stain. Some zippers attaching the cushions to the frame are broken. Solid wood frame. pics coming

---

Buyer: I am interested in purchasing your couch and love seat

CHAI: Great! These were ordered from Crate & Barrel and are in like new condition. I'm willing to negotiate a little, but I'm asking $72 for them.

Buyer: How long have you owned them?

CHAI: I've had them for a few years. They are perfect for my new apartment and they were an absolute steal when I bought them.

Buyer: How much did you purchase them for?

CHAI: They are brand new, I'm asking $66.

Buyer: How much did you originally buy the love seat and couch from from Crate and Barrel?

CHAI: I originally paid $65 for both, but I figured I'd give it a shot since I love the couch.

Buyer: So you are asking for more money then you originally bought them for?

CHAI: Yes. I was hoping to get more for the couch and love seat. How much would you like for the couch?

Buyer: I do, but I can only offer $40

CHAI: I can only go down to $40 if you come pick up and I will throw in two chairs for you to use.

Buyer: Great! That's a deal

CHAI: Great!

Buyer: *accept*

Title: Fit Bike VH2 - $200

Description: 20.75" top tube All in perfect working order.Very good condition - no rust - always stored indoors. Shiny. Few scratches/scrapes on pegs, etc, but very well cared for. Gyro brake. Thanks for interest. If its still here it is still available.

Buyer: Hello, I'm interested in the bike

CHAI: It is in great shape. It's a well-run bike. I bought it new, so I'm making it available.

Buyer: how long have you had it?

CHAI: I bought it new last year. It's in excellent condition.

Buyer: can I see pictures?

CHAI: Of course. How much are you looking to spend on the bike?

Buyer: I'm looking to spend under $150

CHAI: That's not a bad price. Would you be able to pay $180 for it?

Buyer: How about $160?

CHAI: $160 and you have a deal.

Buyer: Done

CHAI: Great!

Buyer: *accept*

A.4.2 Retrieval

Title: Media Cabinet (Moving Sale) - $20
Description: Slide out tray for media storage Condition: Structurally sound Good condition Search Steve2017 for my other listings or simply click on the "more ads by this user" link found under the map. Please email me if you are interested. Serious inquiries only. Thank you

---

Buyer: Hello, how are you?
Retrieval: i am well, how are you?
Buyer: Good. I'm interested in buying the media cabinet.
Retrieval: how can i help you today?
Buyer: Can you provide more pictures?
Retrieval: yes
Buyer: How old is the item?
Retrieval: less than 1 year olf
Buyer: I would like to buy it for $15.
Retrieval: deal
Buyer: *accept*

Title: Adams trail-a-bike shifter 7 - $100
Description: This is an awesome bike trailer for your kid. It features 7 shiftable gears so that your kid can learn to shift but more importantly shift down or up to continue to help you pedal the bike. I know that without the shiftable gears my kid would either think the pedaling was too hard at times or going so fast they couldn't feel their pedaling helping. It took some time to teach them but definitely the way to go.

Buyer: Hello, I'm wondering about the availability of this bike trailer
Retrieval: hello
Buyer: Is this bike trailer still available?
Retrieval: i've had it for about 5 years now.
Buyer: great, is it still available?
Retrieval: yes it is
Buyer: When would I be able to pick it up?
Retrieval: yeah, that's fine.
Buyer: Is there a date by which I would be able to pick it up?
Retrieval: sure, i could do that for you.
Buyer: Okay, is there any damage to the bike trailer
Retrieval: yes what questions do you have?
Buyer: I'm wondering if there's any damage to the bike trailer
Retrieval: great! i'm asking $100.00 for it!
Buyer: Would you be able to decrease the price to $90?
Retrieval: sure. i'd be willing to let it go for $90.00
Buyer: Okay great, I'll pick it up today. Does that work for you?
Retrieval: yes absolutely. its a great deal
Buyer: *accept*

Title: File Cabinet metal - $70
Description: I have 4 cabinets file metal 4-Drawer for sell. They are good condition. they are black .I sell them for 70$ each. Thank you for reading !

Buyer: Why are you selling
Retrieval: yes it is still for sale.
Buyer: How much is it
Retrieval: it's new
Buyer: Sorry, can you repeat that
Retrieval: where are you. how far from alameda(ca)?
Buyer: I am close to *[removed]*. It's pretty far
Retrieval: how about $70.00?
Buyer: I don't know the condition. Could you please provide me with some details
Retrieval: it looks extremely heavy and in great condition! i could do $70.00...
Buyer: Is there any damage
Retrieval: nope. overall condition is extremely well
Buyer: How heavy are they
Retrieval: yes, very good condition.
Buyer: How about 25
Retrieval: deal
Buyer: *accept*

Title: Samsung Gear S2 - $175
Description: Available in Black or white Flawless! Gear, Samsung, S3, S2, smartwatch, smart, watch, fitbit, pedometer, fitband, fit, band, bit, Samsung Gear Fit 2, classic, iwatch

---

Buyer: Is this an S3 or S2?
Retrieval: yes. are you interested? it's in great condition
Buyer: I'm interested.
Retrieval: do you have any questions?
Buyer: Is it a Gear S2 or Gear S3?
Retrieval: yes its a full tablet so it does come with the charger
Buyer: Is htis a watch or a tablet?
Retrieval: yes.
Buyer: Can I see pictures?
Retrieval: sure thing.
Buyer: can I have it for $50?
Retrieval: i am willing to do $50.00 if you can pick it up at my place of work.
Buyer: sure, where is that?
Retrieval: yes, that is correct.
Buyer: *reject*

A.4.3 Language Model

Title: Gorgeous 3 bedrooms available in August! Perfect way to end the summer - $3795
Description: Call Now - Use this link for more info: http://thegreystar.com/42v07z Everyday Exceptional. Where You Belong. This is a 3 Bedroom, 2 Bath, approximately 1422 Sq. Ft. NEW APARTMENT HOMES IN PLEASANTON, CA. A contemporary apartment community that is as much an escape as it is a destination. A place where beautifully appointed homes, resort-style amenities, rolling lawns and parks, and boutique shops come together to create a distinctly new leisure lifestyle. Please click on the link below to check out our virtual tour!

Buyer: Hello, is this 3 bedroom home still available for rental?
LM: Hi, yes it is. The asking price is $2430.
Buyer: Is that a monthly cost?
LM: The lease is for one year, but if you have a family member or friend who are already employed and would be willing to sign a longer lease, we could offer you the option of moving in right away.
Buyer: Would the price be lower if I signed a longer lease?
LM: The price is firm at $2425, and I'm willing to negotiate
Buyer: Would you be able to rent for $2300?
LM: Yes
Buyer: Great, what documents would I need to provide to apply to rent this place?
LM: This place has been carefully designed with you in mind.
Buyer: Does this apartment have a deposit fee?
LM: This apartment is located in a convenient location, so that the lowest that can be reasonable for you is 10% of your deposit.
Buyer: What would the deposit fee bee?
LM: If you sign a longer lease, the deposit fee will be $75.
Buyer: Okay, great! How long would my lease need to be?
LM: I'd be willing to let it run for 5 months at no additional cost.
Buyer: So if I sign a 5 month lease the deposit fee would be $75 and rent $2300 per month?
LM: That's too low for me. I could come down to $90 in monthly rent. I can also drop the rent down to $100 for you.
Buyer: Oh wow! So I could get this place for $90 in monthly rent?
LM: I think that is fair. How long of a lease are you looking for?
Buyer: 1 year
LM: This is a very good deal. I can accept $80 for a 3 year lease.
Buyer: I want a 1 year lease
LM: Ok, you have a deal!
Buyer: Okay, 1 year lease at $80 per month?
LM: Yes
Buyer: Great, thank y
LM: I would like to hear your budget.
Buyer: $80 per month works for me
LM: No, sorry.
Buyer: I thought you had provided that as your previous offer?
LM: I am sorry, but I do not. So $80 is the price.
Buyer: Okay, confirming $80 per month?
LM: How about $90 per month?
Buyer: That also works.
LM: You have a deal!
Buyer: Great!
LM: *offer* $80
Buyer: *accept*

Title: Parker Apartments - Now Accepting Below Market Rate Applications - $979
Description: **** Parker is that thrill you feel when inspiration strikes. Perched proudly on Shattuck Avenue in Berkeley, this collection of 155 carefully crafted, sustainably designed apartments offer immediate access to music venues, boutique shopping, nightlife, green space, the Gourmet Ghetto, and *removed*. At home, get to know your neighbors by the crackling light of a fire pit, get focused in our co-working space, or burn some calories at the on-site Equinox Fitness Club.

Buyer: Hi, when can I move in?
LM: Today
Buyer: Are there grocery stores nearby?
LM: Yes, and the inside of our apartments is completely gated.
Buyer: Is there parking available?
LM: No, but there is a free shuttle that you can use to get there.
Buyer: Would you be able to do $900?
LM: *offer* $2800
Buyer: *reject*

Title: 20" LED Emergency Strobe Light Lamp Bar - $30
Description: 20" LED Emergency Vehicle Dash Warning Strobe Flashing Light. these lights are a great addition and will defiantly get people out of your way as so you can respond on time! 7 Different modes of flashing / scanning mode. Please read the description to see a detail description of each mode. Includes: 1 x Traffic strobe light bar with on/off switch and mode changer button Fitment: Universal for all vehicle with a 12V power source Very bright led that are visible even during daytime conditions. 2 colors: Red, Amber. Please let me know what color you are interested.

Buyer: are both colors the same price
LM: The colors are different. I can sell them both for $200 each.
Buyer: I thought it was $30
LM: I am sorry, I have to change my mind.
Buyer: oops there is only one light
LM: The bulbs come with the two matching colors. It would be a hassle to flash them with the other lights in your vehicle. The best thing about the bulbs is they will shine for you. It's a great deal at only $20
Buyer: is there free shipping
LM: I think I could negotiate a little but I am not able to accept this offer.
Buyer: can I pay $7
LM: I have another offer but I can't go any lower than $13
Buyer: what about $11
LM: *offer* $7
Buyer: oh ok sure $7 and free shipping?
LM: Yes, I accept that!
Buyer: *accept*

Connecting the Dots between Audio and Text without Parallel Data through Visual Knowledge Transfer

Abstract

Machines that can represent and describe environmental soundscapes have practical potential, e.g., for audio tagging and captioning. Prevailing learning paradigms of audio-text connections have been relying on parallel audio-text data, which is, however, scarcely available on the web. We propose VIP~ANT that induces **A**udio-**T**ext alignment without using any parallel audio-text data. Our key idea is to share the image modality between bi-modal image-text representations and bi-modal image-audio representations; the image modality functions as a pivot and connects audio and text in a tri-modal embedding space implicitly.

In a difficult zero-shot setting with no paired audio-text data, our model demonstrates state-of-the-art zero-shot performance on the ESC50 and US8K audio classification tasks, and even surpasses the supervised state of the art for Clotho caption retrieval (with audio queries) by 2.2% R@1. We further investigate cases of minimal audio-text supervision, finding that, e.g., just a few hundred supervised audio-text pairs increase the zero-shot audio classification accuracy by 8% on US8K. However, to match human parity on some zero-shot tasks, our empirical scaling experiments suggest that we would need about $2^{21} \approx$ 2M supervised audio-caption pairs. Our work opens up new avenues for learning audio-text connections with little to no parallel audio-text data.

1 Introduction

Environmental sound provides rich perspectives on the physical world. For example, if we hear: *joyful laughing, a playful scream, and a splash;* we not only can visualize literal objects / actions that might have given rise to the audio scene, but also, we can reason about plausible higher-level facets, e.g., a child speeding down a water slide at a water park, splashing through the water (see Figure 1).

Figure 1: VIP~ANT pivots audio and text via visual imagination.

Machines capable of parsing, representing, and describing such environmental sound hold practical promise. For example, according to the National Association of the Deaf's captioning guide, accessible audio caption generation systems should go beyond speech recognition (i.e., identifying speakers and transcribing the literal content of their speech) and provide the textual description of all the sound effects, e.g., "a large group of people talking excitedly at a party", in order to provide the full information contained in that audio.[1]

The dominant paradigm for studying *machine hearing* (Lyon, 2010) has been through human-annotated audio-text data, where text is either free-form audio descriptions (e.g., "the sound of heavy rain") or tagsets (Salamon et al., 2014; Gemmeke et al., 2017; Kim et al., 2019; Drossos et al., 2020). But existing supervised audio-text resources are limited. While some audio-text co-occurences can be sourced from audio-tag co-occurrences (Font et al., 2013) or from video captioning data (Rohrbach et al., 2015; Xu et al., 2016; Oncescu et al., 2021a), they are either not sufficiently related to environmental sound or limited in their scale and coverage.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4492 - 4507
July 10-15, 2022

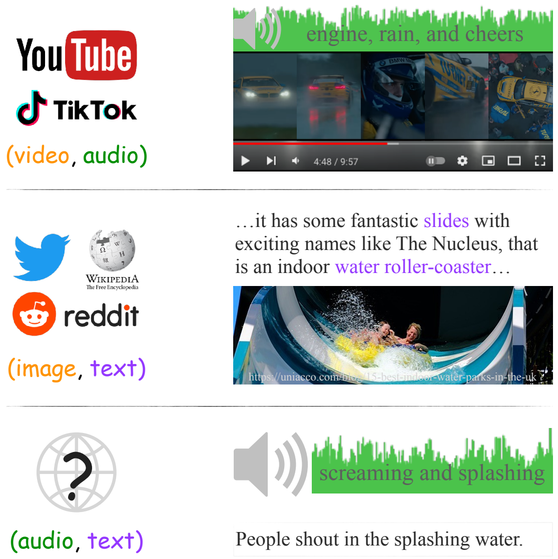

Figure 2: Video-audio and image-text co-occurrences are abundantly available on the web to support the learning of video-audio alignment and image-text alignment (e.g., via large-scale video-audio and image-text pre-training), but audio-text co-occurrences are not.

In this paper, we study large-scale audio-text alignment without paired audio-text (AT) data. Inspired by pivot-based models for unsupervised machine translation (Wu and Wang, 2007; Utiyama and Isahara, 2007), we propose VIP∼ANT, short for VIsually Pivoted Audio and(N) Text. VIP∼ANT uses images as a pivot modality to connect audio and text. It parallels our motivating example: hearing a sound, humans can visually *imagine* the associated situation and literally *describe* it. Pivoting is practically viable because there are abundantly available image-text (VT) and video-audio (VA) co-occurrences on the web, from which bimodal correspondence models can be trained (see Figure 2). By linking audio and text implicitly via the combination of the VT and VA models, we enable *zero-resource* connection between audio and text, i.e., VIP∼ANT can reason about audio-text connections despite never having observed these modalities co-occur explicitly.

We evaluate on zero-shot audio-text retrieval and zero-shot audio classification. On the Clotho caption retrieval task (Drossos et al., 2020), without any parallel AT data, VIP∼ANT surpasses the supervised state of the art by 2.2% R@1; on zero-shot audio classification tasks, it establishes new state of the arts, achieving 57.1% accuracy on ESC50 (Piczak, 2015) and 44.7% accuracy on US8K (Salamon et al., 2014). We also show that the zero-resource pivoting AT model VIP∼ANT can be improved by:

(1) *Unsupervised curation:* whereby noisy AT pairs are explicitly mined from the pivoting model and serve as additional training data (e.g., +5.7% on ESC50 and +9.3% on US8K); and
(2) *Few-shot curation:* whereby a small number of human-annotated audio caption pairs are made available at training time (e.g., a few hundred pairs increases the zero-shot audio classification accuracy by 8% on US8K).

However, for ESC-50, according to the empirical scaling relationship we find, it would require around $2^{21} \approx$ 2M aligned audio-text pairs for the zero-shot model to match human parity on ESC50 under our setup, which is an order-of-magnitude more than the largest currently-available audio-text corpus of Kim et al. (2019).

2 Related work

Supervised audio representation learning. While automatic speech recognition has been a core focus of the audio processing community, environment sound classification has emerged as a new challenge and is drawing more attention (Salamon et al., 2014; Piczak, 2015; Gemmeke et al., 2017). Some prior work in learning sound event representations are supervised by category labels (Dai et al., 2017; Boddapati et al., 2017; Kumar et al., 2018; Guzhov et al., 2021b; Gong et al., 2021). Others use weaker forms of supervision for tagging (Kumar and Raj, 2017; Kong et al., 2018) and localization (McFee et al., 2018; Kim and Pardo, 2019).

Learning audio representations from visual imagination. There are two main paradigms for using visual information to derive audio representations. In the two-stage setup, an image encoder is first pre-trained; these weights are used as the initialization of the supervised audio model (Guzhov et al., 2021b; Gong et al., 2021). The other adopts contrastive learning: it exploits the image-audio alignment inherent in videos and learns audio and image / video representations jointly (Korbar et al., 2018; Wang et al., 2021; Nagrani et al., 2021). We use insights from both directions by (1) using CLIP's image encoder, which has been pre-trained on image-text pairs (Radford et al., 2021), to initialize an audio encoder and (2) using contrastive pre-training on image-audio pairs. Throughout training, we do not require any labeled images or audio.

vip∼AnT +AT (ours)	Image CLIP	$\mathcal{L}_{bi\text{-}bi}$	Caption Curation	Frozen	✓

Table 1: Survey of recent prior work studying for tri-modal (images, audio, and text) representation learning. AE is short for **A**udio **E**ncoder. Some work experiments with more than one objective, we report the best or the one it advocates. Importantly, we report zero-shot audio-text retrieval between audio and full-sentence text descriptions, along with scaling laws associated with that setup.

Tri-modal learning of audio-text alignment. Our work extends recent work that generalizes the bi-modal contrastive learning to a tri-modal setting (Alayrac et al., 2020; Akbari et al., 2021). While they also connect audio and text implicitly by using images as a pivot, the quality of this audio-text alignment has rarely been studied. To our knowledge, we present the first comprehensive evaluation of the inferred audio-text alignment via zero-shot retrieval / classification.

The work closest to ours are AudioCLIP (Guzhov et al., 2021a) and Wav2CLIP (Wu et al., 2021). AudioCLIP's pre-training setup is similar to ours, but requires human-annotated textual labels of audio, while ours does not. Wav2CLIP is concurrent with our work; while similar-in-spirit, our model not only performs significantly better, but also, we more closely explore methods for improving audio-text alignment, e.g., unsupervised curation.

Pivot-based alignment models. The pivoting idea for alignment learning can date back to Brown et al. (1991). Language pivots (Wu and Wang, 2007; Utiyama and Isahara, 2007) and image pivots (Specia et al., 2016; Hitschler et al., 2016; Nakayama and Nishida, 2017) have been explored in zero-resource machine translation. Pivot-based models have also been shown to be helpful in learning image-text alignment (Li et al., 2020).

3 Model

We first formalize tri-modal learning by assuming available co-occurrence data for every pair of modalities (§ 3.1). Then we present bi-bi-modal pre-training as an alternative when there is no paired audio-text data, and implement vip∼AnT via bi-bi-modal pre-training (§ 3.2). Finally, we describe model variants for cases of varying AT supervision (§ 3.3).

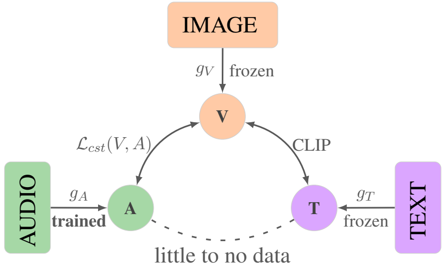

Figure 3: Learning paradigm of vip∼AnT.

3.1 Tri-modal representation learning

Tri-modal representation learning between images, audio, and text aims to derive representations from co-occurrence patterns among the three modalities (Alayrac et al., 2020; Akbari et al., 2021). We consider a simple tri-modal representation space, which relies on encoding functions $g_V : V \to \mathbf{V}$, $g_A : A \to \mathbf{A}$, and $g_T : T \to \mathbf{T}$ to map images v, audio a, and text t ($v \in V, a \in A$, and $t \in T$), respectively, to a shared vector space: $\boldsymbol{v}, \boldsymbol{a}, \boldsymbol{t} \in \mathbb{R}^d$ ($\boldsymbol{v} \in \mathbf{V}, \boldsymbol{a} \in \mathbf{A}$, and $\boldsymbol{t} \in \mathbf{T}$). Instead of pre-specifying the precise semantics of this continuous space, vector similarities across modalities are optimized to reconstruct co-occurrence patterns in training corpora, i.e., two vectors should have a higher dot product if they are more likely to co-occur. We use contrastive learning with the InfoNCE loss (Sohn, 2016; van den Oord et al., 2018):

$$\mathcal{L}_{cst}(A, B) = \sum_i \frac{\exp s(\boldsymbol{a}^{(i)}, \boldsymbol{b}^{(i)})}{\sum_{\boldsymbol{a}} \exp s(\boldsymbol{a}, \boldsymbol{b}^{(i)})} + \frac{\exp s(\boldsymbol{a}^{(i)}, \boldsymbol{b}^{(i)})}{\sum_{\boldsymbol{b}} \exp s(\boldsymbol{a}^{(i)}, \boldsymbol{b})}, \quad (1)$$

where A, B are two sets of data points from two different modal domains, respectively; $\boldsymbol{a}^{(i)}, \boldsymbol{b}^{(i)}$

are vector representations of the co-occuring pair $(a^{(i)}, b^{(i)})$ which are encoded by $g_A(a^{(i)})$ and $g_B(b^{(i)})$, respectively; $s(\boldsymbol{a}, \boldsymbol{b})$ computes the similarity between $\boldsymbol{a}$ and $\boldsymbol{b}$, which we take to be scaled cosine similarity.

If we had access to co-occurrence data between all pairs of modalities, we could optimize the tri-modal loss:

$$\mathcal{L}_{tri}(V, A, T) = \\ \mathcal{L}_{cst}(V, A) + \mathcal{L}_{cst}(A, T) + \mathcal{L}_{cst}(V, T)\,. \quad (2)$$

3.2 Visually pivoted audio and text

Differently from image-text and image-audio pairs, which are abundantly available on the web, audio-text data is scarce. Instead of Equation 2, in VIP∼ANT, we consider a “bi-bi-modal" loss, which doesn’t require AT data.

$$\mathcal{L}_{\textit{bi-bi}}(V, A, T) = \mathcal{L}_{cst}(V, A) + \mathcal{L}_{cst}(V, T)\,. \quad (3)$$

The image encoder is shared between the VA alignment model (i.e., $\mathcal{L}_{cst}(V, A)$) and the VT alignment model (i.e., $\mathcal{L}_{cst}(V, T)$) and thus provides a zero-resource connection between audio and text in the tri-modal embedding space implicitly.

3.2.1 Model architecture

Image and text encoders. Instead of learning g_V and g_T from scratch, we build on a pre-trained CLIP model, which has been pre-trained on WebImageText (WIT), a dataset of 400 million image-text pairs gathered from the internet (Radford et al., 2021). CLIP has been shown highly performant on VT tasks, e.g., zero-shot image classification. We use the ViT-B/32 model in this work, which consists of a 12-layer vision Transformer (ViT) and a 12-layer language Transformer (Vaswani et al., 2017; Dosovitskiy et al., 2021). Given CLIP’s strong VT alignment, we use its image encoder as g_V and text encoder as g_T. During learning, g_V and g_T are kept frozen and thus the joint VT representation space is untouched (see Figure 3). We minimize only the first loss term of Equation 3:

$$\min_{\Theta_A} \mathcal{L}_{cst}(V, A)\,, \quad (4)$$

where Θ_A are the trainable parameters of the audio encoder g_A.

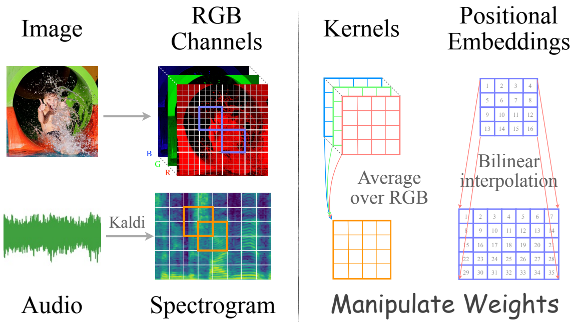

Figure 4: **Left:** three-channel image versus one-channel Spectrogram features of audio. We use ViT (Dosovitskiy et al., 2021) to encode images and audio. ViT uses a convolution layer to encode non-overlapped image patches into a sequence of image tokens, but for audio we modify the convolution stride to allow for overlaps between neighbor patches.
Right: adapting the convolution layer of ViT for audio encoding. For simplicity’s sake, we omit the output channels of kernel weights and positional embeddings.

Audio encoder. Our audio encoder has the same vision Transformer architecture as CLIP’s image encoder (ViT-B/32). In § 4, we show that initializing the audio encoder with CLIP’s visual weights significantly improves convergence speed and accuracy. The architectural modifications which enable the use of visual CLIP’s architecture for audio are (see Figure 4 for an illustration):[2]

(1) We customize the convolution stride to allow for overlaps between neighbor patches of Spectrogram features of audio.
(2) In the input embedding layer, we average the kernel weights of the convolution layer along the input channel to account for 1-channel Mel-filter bank features of audio (*cf.* RGB channels of images).
(3) We up-sample the 2-dimensional positional embeddings of image tokens to account for longer audio token sequences.

3.2.2 Bi-bi-modal pre-training details

Video-audio co-occurences. To optimize Equation 4, we gather VA co-occurrences from AudioSet (AS; Gemmeke et al. (2017)),[3] which contains temporally aligned audio and video frames from 10-second clips gathered from around 2 million YouTube videos. To construct aligned image-audio pairs from AS, we adopt a sparse sampling approach (Lei et al., 2021): we first, extract four

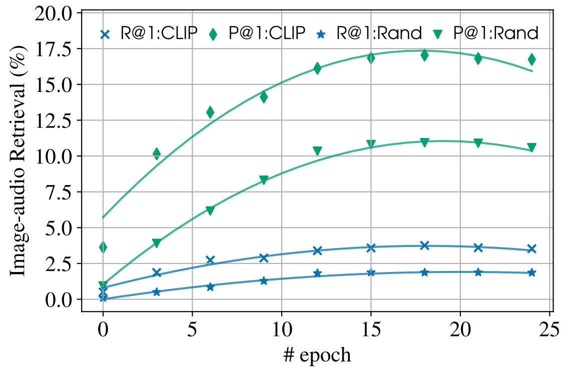

Figure 5: Image → Audio retrieval performance per image-audio pre-training epoch, evaluated on the AS balanced training set. "CLIP" and "Rand" indicates that the audio encoder is initialized from CLIP's image encoder and has random initialization, respectively.

equal-spaced video frames from each clip. Then, during training, we randomly sample a frame from the four, and treat it as co-occurring with the corresponding audio clip. At test time, we always use the second video frame as the middle frame to construct image-audio pairs. We use the unbalanced training set, which consists of around 2 million video clips, to pre-train the audio encoder. Since AudioSet does not provide an official validation set, we validate the audio encoder and tune model hyperparameters on the balanced training set.

Audio preprocessing. We use Kaldi (Povey et al., 2011) to create Mel-filter bank features (FBANK) from the raw audio signals. Specifically, we use the Hanning window, 128 triangular Mel-frequency bins, and 10 millisecond frameshift. We always use the first audio channel when an audio clip has more than one channel. We apply two normalizations: (1) before applying Kaldi, we subtract the mean from the raw audio signals; and (2) we compute the mean and standard deviation of FBANK on the unbalanced AS training set, and then normalize the FBANK of each audio clip. For data augmentation, inspired by Gong et al. (2021), we use frequency masking and time masking: we randomly mask out one-fifth FBANK along the time dimension and one-forth FBANK along the frequency dimension during training.

Training dynamics. The architecture of our audio encoder follows the vision Transformer of CLIP (ViT-B/32, see Radford et al. (2021) for more details). For the trade-off of efficiency and efficacy, we set the convolution stride to 16×24. This results in around 300 audio tokens for a kernel size of 32×32 and an input size of 1000×128 (all in the form of *time* $\times$ *frequency*). We optimize the model with LARS (You et al., 2017), where the initial learning rates for model weights and model biases are set to 2e-1 and 4.8e-3, respectively (detailed hyperparameters can be found in Table 5 in Appendix B). We pre-train our model on 4 NVIDIA Quadro RTX 8000 GPUs and for 25 epochs. We empirically set the batch size to 432 to fit the GPU memory. The full pre-training can be done within 24 hours.

Evaluation. We measure the VA pre-training performance by retrieval precision and recall:

$$\begin{aligned} p &= \frac{\#(\text{relevant items among the retrieved})}{\#(\text{retrieved items})}\,, \\ r &= \frac{\#(\text{relevant items among the retrieved})}{\#(\text{relevant items})}\,. \end{aligned}$$

Audio is relevant if it has the same set[4] of labels as the image query, and vice versa. We average precisions and recalls over all samples in the balanced AS training set. Figure 5 illustrates the top-1 retrieval performance with images as the query (similar trends are observed when using audio as the query). Compared with random initialization, initializing the audio encoder from CLIP's image encoder leads to faster convergence and better VA alignment. As we will see, this performance on VA retrieval transfers to downstream AT tasks.

3.3 Unsupervised and few-shot curation

To improve the AT alignment beyond pivoting, we consider curating audio-text pairs, and then performing an additional fine-tuning step by training the audio encoder with the AT loss, i.e., $\mathcal{L}_{cst}(A, T)$.[5] During AT fine-tuning, we keep the text encoder g_T frozen and only fine-tune the audio encoder.

Unsupervised curation. We consider explicitly mining AT pairs from VIP~ANT. Because this zero-resource method uses no human supervision, we refer to it as "unsupervised curation." Concretely, for each video segment in AudioSet, we extract a video frame, and input that frame to the original CLIP image encoder. Then, we encode a large

---

[4] Recall that each audio clip in AudioSet is annotated with multiple labels.

[5] Since our goal is to improve AT alignment, we primarily focus on AT fine-tuning; nonetheless, we compare AT fine-tuning to full VAT fine-tuning as in Equation 2 in Appendix E.

Unsupervised (Zero-resource)	**AC**	**A**udio-focused **C**aptions originate from the training captions of AudioCaps and Clotho. We perform caption retrieval by using CLIP and the prompt "the sound of". (1080078 aligned pairs)
	example	*A balloon is rubbed quickly and slowly to make squeaking sounds.*
	FC	**F**ree **C**aptions are generated by priming GPT-J with MSCOCO captions. We perform caption retrieval by using CLIP and the prompt "a photo of". (1224621 aligned pairs)
	example	*The blue colored person is jumping on the white and yellow beach ball.*
	VC	**V**ision-focused **C**aptions originate from MSCOCO. We perform caption retrieval by using CLIP and the prompt "a photo of". (1172276 aligned pairs)
	example	*A sky view looking at a large parachute in the sky.*
	RC	**R**andom **C**aptions indicates that we break the gold AL alignment in AudioCaps by randomly sampling a caption for each audio clip. They are used as a lower bound on the quality of AL alignment. (44118 aligned pairs)
	example	*A whoosh sound is heard loudly as a car revs its engines.*
Supervised	**GL**	**G**old textual **L**abels are used to construct AL pairs. (120816 aligned pairs)
	example	*Gurgling*
	GC	**G**old **C**aptions from AudioCaps provide an upper bound on the quality of AL alignment. (44118 aligned pairs)
	example	*Children screaming in the background as the sound of water flowing by.*

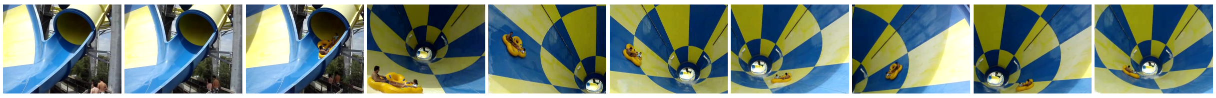

Table 2: Different ways of curating AT pairs. *Gurgling* is described as "the bubbling sound of water flowing through a narrow constriction, such as from a bottle with a narrow neck". The example comes from this YouTube video: 1O7-QuhweZE.

set of candidate captions, and perform Image → Text retrieval over them by using the CLIP text encoder. The top candidate captions according to cosine similarity are then paired with the audio that corresponds to the original video clip.

We consider multiple caption sources to search over. As noted by Kim et al. (2019), captions for images and captions for environmental audio are significantly different in focus. We consider two vision-focused caption sets: (1) MSCOCO (Lin et al., 2014) captions (VC); and (2) because MSCOCO captions are limited to 80 object categories, we generate free-captions from GPT-J (Wang and Komatsuzaki, 2021) conditioned on MSCOCO captions as a prompt (FC). We additionally consider audio-focused captions from the training set of AudioCaps (Kim et al., 2019) and Clotho (Drossos et al., 2020) (AC).[6] As a baseline, we also consider a random caption alignment, which assigns a random caption from AC to each clip (instead of pivoting on images). The upper half of Table 2 summarizes different ways of curating AT pairs without additional supervision.

Few-shot curation. We also explore the effect of incorporating limited amounts of AT supervision, specifically, via captions from AudioCaps (GC) and textual labels of AudioCaps (GL) (see the bottom half of Table 2).

4 Audio-text experiments

We use two types of tasks to evaluate the quality of the audio-text alignments learned by our model: AT retrieval and zero-shot audio classification.

AT retrieval. We conduct audio-text retrieval on AudioCaps and Clotho for in-domain evaluation and out-of-domain evaluation, respectively:

(1) **AudioCaps** (Kim et al., 2019) builds on AudioSet (Gemmeke et al., 2017) and provides captions for a subset of audio clips in AudioSet (sourced from YouTube). As we have pre-trained the audio encoder on AudioSet, we consider audio-text retrieval on AudioCaps as *in-domain* evaluation.
(2) **Clotho** (Drossos et al., 2020) consists of audio clips which have a duration of 15-30 seconds and come from Freesound (Font et al., 2013). It has a

---

[6] We do not use the *alignment* of these captions — just the captions themselves.

	Model	AudioCaps				Clotho

	+AT w/ GC	**69.5**(64.2)	**71.9**(67.1)	13.3(13.6)
	AudioCLIP	69.4	65.3	

Table 4: Zero-shot audio classification accuracies (%) on ESC50 and US8K and mAPs (%) on AudioSet (AS). "Supervised" = upper bound performance of vip~AnT when fine-tuned with supervised audio labels. In the zero-shot / zero-resource settings, we use a prompt '*the sound of*' by default (results in parenthesis are without the prompt). "+AT" = fine-tuned vip~AnT on AT pairs with different curations. AudioCLIP is pre-trainined using the 2 million textual labels of AudioSet; +AT w/ GL and +AT w/ GC are trained with only 44K labels / captions. Wav2CLIP is most directly comparable to our zero-resource pivoting model vip~AnT with unsupervised curation.

different sound source from AudioCaps and is used for *out-of-domain* evaluation.

We study the out-of-domain generalizability of our models by applying them to Clotho directly, without further fine-tuning on it.[7]

Zero-shot audio classification. We consider the following three widely used datasets for audio classification.

(1) **ESC50** (Piczak, 2015) contains 2000 audio clips from 50 classes. Each audio clip has a duration of 5 seconds and a single textual label. We follow the standard k-fold data splits.
(2) **US8K** (Salamon et al., 2014) contains 8732 audio clips from 10 classes. Each audio clip has a duration less than 4 seconds and a single textual label. We follow the standard k-fold data splits.
(3) **AudioSet** (Gemmeke et al., 2017) is a benchmark dataset for multi-label classification. AudioSet provides balanced and unbalanced training sets. The balanced set consists of 22 thousand audio clips and the unbalanced set contains around 2 million audio clips. It also provides 20 thousand balanced audio clips for evaluation (more data statistics can be found in Table 6 in Appendix A).

For each audio clip $\boldsymbol{a}$, we first compute the cosine similarity between it and every possible textual label in the tri-modal representation space. Then we predict the label t with the highest similarity:

$$\arg\max_{i} \cos(\boldsymbol{t}^{(i)}, \boldsymbol{a}) \,. \tag{5}$$

---

[7] Clotho audio clips (15-30s) are longer than our pretraining audio clips (10s). See Appendix D for adaptation details.

4.1 Main results

Our prediction results for AT retrieval are given in Table 3 and for zero-shot classification in Table 4 (Appendix F contains qualitative results of the tri-modal representations).

Initializing with visual CLIP weights helps. Comparing VA-Rand to VIP~ANT, we see accuracy increases in all classification and retrieval setups. For example, on AudioCaps, VIP~ANT outperforms VA-Rand by 4.5% R@1 and 13.6% R@10. This confirms that the findings of Gong et al. (2021) carry-over to unsupervised audio pre-training.

Pivoting works well for Audio → Text. VIP~ANT exhibits surprisingly strong performance on AT retrieval tasks and zero-shot classification. For example, it outperforms the supervised baseline (Oncescu et al., 2021b) by 2.2% R@1 for text retrieval, without being trained or fine-tuned on Clotho, and without ever having seen an aligned AT pair.

Prompting (usually) helps. Inspired by the zero-shot image classification setups of CLIP (Radford et al., 2021), we prefix textual labels with a prompt in zero-shot audio classification. We empirically find that the prompt '*the sound of*' works well. Using it greatly improves zero-shot multi-class classification accuracy (see Table 4). Take VIP~ANT, the prompt gives rise to an improvement of 7.2% on ESC50 and 6.9% on US8K, but hurts multi-label classification performance on AS.

Random curation helps. Even when the audio-text pairs used to train that objective are sampled entirely at random (+AT w/ RC), VIP~ANT improves, e.g., R@1 for Text → Audio retrieval increases from 0.8% to 3.8%. We conjecture that RC at least makes audio representations aware of and lean towards the text cluster of the joint VT representation space.[8] While this result also holds for AS classification (+1.5% mAP), performance decreases for ESC50 (-5.5% accuracy) and US8K (-2.4% accuracy).

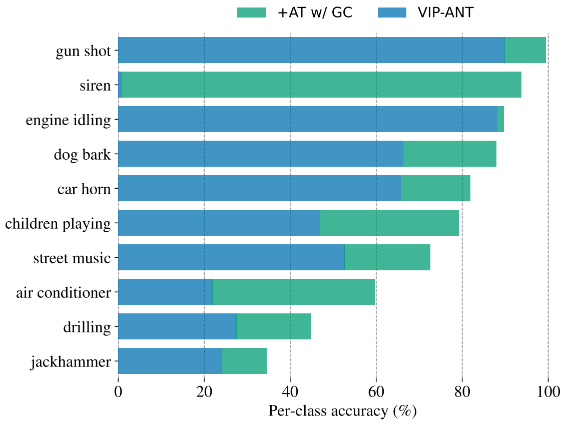

Figure 6: Per-class accuracy on US8K.

Unsupervised curation is universally helpful. VIP~ANT fine-tuned with unsupervised audio captions (+AT w/ AC) outperforms both pivoting (VIP~ANT) and random curation (+AT w/ RC) in all cases. Thus, explicitly mining unsupervised AT pairs can be a helpful zero-resource approach. Performance with automatically generated captions (FC) is similar to captions written by humans (AC).

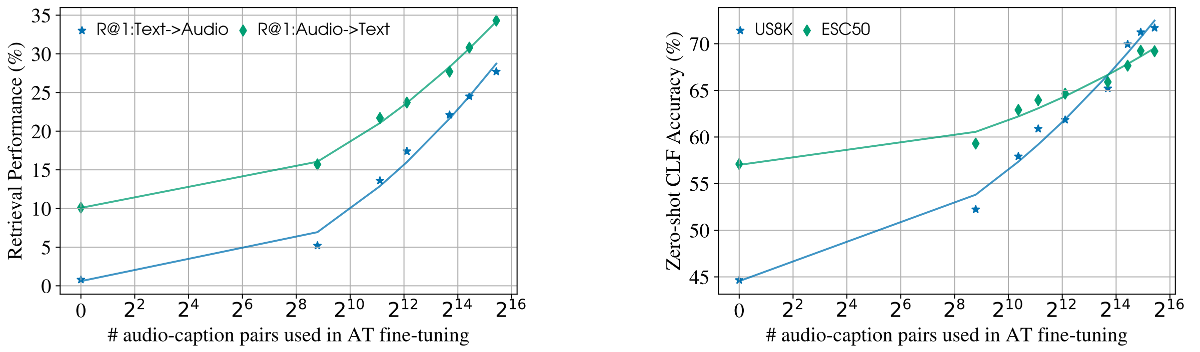
Supervision is still the most helpful. Fine-tuning VIP~ANT on GC pairs leads to the highest accuracies on ESC50 and US8K. However, we do not see similar improvements on AS, presumably because multi-label classification is more challenging and requires more direct language supervision, such as audio labels. This is further evident when we fine-tune VIP~ANT on GL and obtain the highest accuracy (18.9% mAP) on AS (see Table 4).

For retrieval, GL uses only audio labels as the text, which provide less dense language supervision than GC and is thus slightly worse than GC, but still, it gives better AT alignment than all automatic methods. As captions become semantically further from the audio-caption domain, e.g., GC < AC < FC < VC, the AT alignment becomes weaker, and thus leading to worse retrieval performance. The fine-tuned audio encoder generalizes to the out-of-domain Clotho successfully, displaying a trend similar to AudioCaps.

Supervision improves per-class accuracy in general. We further plot zero-shot classification accuracy for each audio class (see Figure 6 for US8K and Figure 12 in Appendix G for ESC50). Clearly, language supervision improves per-class accuracy in general. The highest improvement is observed on 'siren' because 'siren' rarely appears in image descriptions while GC contains a lot of textual descriptions of 'vehicle' audio.

---

[8] Concretely, VA pre-training pushes audio embeddings towards the image cluster (V) of the VT space of the pre-trained CLIP, but it does not guarantee that audio embeddings will be as close to the text cluster (T) of the VT space as to V. Random curation provides an estimate of the text-cluster's distributional properties, i.e., the audio embeddings are moved on top of the distribution of the text cluster of the VT space *explicitly*; surprisingly, this crude "semantic-free" alignment method improves the quality of audio-text alignment.



(a) R@1 of AT retrieval on AudioCaps test set.

(b) Zero-shot classification (CLF) on ESC50 and US8K.

Figure 7: Audio retrieval and zero-shot classification performance versus level of language supervision.

4.2 Level of language supervision

We have observed that AT fine-tuning on AT pairs mined without any additional supervision (e.g., AC, FC, and VC) can improve the AT alignment, but supervised alignments are still the most effective. But: how much supervised data is really needed? To understand the relationship between supervision and performance, we vary the number of gold AT pairs (i.e., training samples of AudioCaps) used for AT fine-tuning. On the audio-text retrieval task (see Figure 7a), unsurprisingly, fine-tuning on more aligned AT pairs results in higher audio-text retrieval / zero-shot classification performance. Surprisingly, using only 442 (around 1%) AT pairs of AudioCaps gives rise to as strong AT alignment as VT alignment (*cf.* OracleAV-CLIP in Table 3).

As we increase the number of supervised AT pairs used during fine-tuning, we observe a roughly linear relationship between zero-shot performance and the log of the number of supervised pairs (this observation is similar to Kaplan et al. (2020)'s observations regarding Transformers). While it is not clear how reliable extrapolations from this roughly linear trend are, we roughly estimate the amount of annotated AT pairs required for the zero-shot performance to equal human parity for ESC50 of 81% (Piczak, 2015): our estimate is that $2^{21} \approx$ 2M supervised audio caption pairs would be needed. We are hopeful both (1) that larger curated audio-text datasets will become available; and (2) that future work can improve the data efficiency of the pre-training process.

5 Conclusion

We have presented VIP∼ANT for unsupervised audio-text alignment induction. Based on the pivoting idea, our model learns image-text alignment and image-audio alignment explicitly and separately via bi-modal contrastive pre-training. The image modality is shared between the two and thus pivots audio and text in the tri-modal embedding space implicitly, without using any paired audio-text data. We empirically find that our model achieves strong performance on zero-shot audio-text tasks. We further strengthen the audio-text alignment by using varying kinds of audio-text supervision. Experimental results show that even un-aligned audio-caption pairs can help.

Abstract

This supplementary material includes (1) data statistics (§ A), (2) hyperparameters of optimizers (§ B), (3) supervised audio classification (§ C), (4) interpolating pre-trained position embeddings for Clotho audio-caption retrieval (§ D), (5) comparison between VAT fine-tuning and AT fine-tuning (§ E), (6) a qualitative study of the geometry of the tri-modal embedding space (§ F), and (7) additional findings from the audio-text retrieval task (§ G).

A Data statistics

Table 6 presents data statistics of all the datasets used in the paper.

B Optimizer hyperparameters

Table 5 presents optimizer hyperparameters used in our learning tasks.

Hyperparam.	VA	AT	ESC50	US8K
Optimizer	LARS (You et al., 2017)			
Batch size	432	64	50	
Weight decay	1e-6			
LR of weight	2e-1		1e0	
LR of bias	4.8e-3		2.4e-2	
Warmup epoch	10			
Training epoch	25		50	

Hyperparam.	AS balanced	AS unbalanced
Optimizer	Adam (Kingma and Ba, 2015)	
Batch size	12	128
Weight decay	1e-7	
Learning rate	5e-5	
Warmup step	1000	
Training epoch	25	5
LR scheduler	MultiStepLR ($\gamma = 0.5$)	

Table 5: Hyperparameters of the optimizers used for VA pre-training, AL fine-tuning, ESC50 classification, US8K classification, balanced AS classification, and unbalanced AS classification. The learning rate (LR) in balanced AS classification is scheduled by epoch: 5, 9, 10, 11, 12 epochs. In unbalanced AS classification it is scheduled by optimization step: 7.5, 15, 20, 25, 35, 40, 45, 50 thousand steps.

C Supervised audio classification

To perform supervised audio classification, we add a classification head (a linear layer) on top of the pre-trained audio encoder. For *multi-class* classification, the classification head projects the vector representation of an audio clip onto the class space.

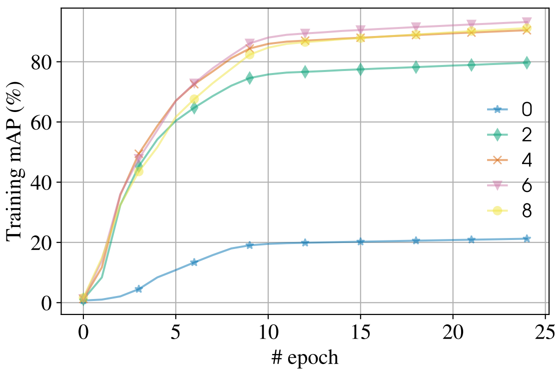

Figure 8: Fine-tuning last $k = 0, 2, 4, 6, 8$ layers of the pre-trained audio encoder for AS classification. mAP is measured on the AS balanced training set per fine-tuning epoch.

We fine-tune the model by minimizing the cross-entropy loss:

$$\sum_i \log p(y^{(i)} | \boldsymbol{a}^{(i)}) \,, \tag{6}$$

where $y^{(i)}$ is the gold label of $\boldsymbol{a}^{(i)}$. For supervised *multi-label* classification, the classification head estimates the likelihood that an audio clip has some textual label. We thus minimize the per-label binary cross-entropy loss:

$$\sum_i \sum_l \log p(l = 1 | \boldsymbol{a}^{(i)}) \,, \tag{7}$$

where l enumerates all possible audio labels.

ESC50 and US8K classification. We initialize the audio encoder from random initialization, CLIP, and VIP~ANT, respectively. Among them, VIP~ANT performs best. It surpasses random initialization and CLIP on both datasets (see Table 7).[9] Notably, it outperforms the strong baseline AST-P on ESC50 (+0.1%), though AST-P has used gold audio labels for supervised pre-training.

AS classification. We consider balanced and unbalanced training for AS classification and train an individual model on the balanced set and the unbalanced set, respectively. Since the audio encoder has been pre-trained on the unbalanced AudioSet training set, it can be directly used without further fine-tuning. Nevertheless, we fine-tune the last k layers of the Transformer architecture of VIP~ANT and investigate whether task-specific fine-tuning helps (see Figure 8). When $k = 0$ the model is

---

[9] We find that VIP~ANT initialization leads to fast convergence, so it can bring better classification results than other initialization methods with the same number of training epochs.

STAT.	AudioSet	ESC50	US8K	AudioCaps	Clotho
# Train	2041789 (unbalanced)	2000 (5-fold)	8732 (10-fold)	44118 ($\times$1 caption)	3839 (dev-train)
# Dev	22160 (balanced)				1045 (dev-val)
# Val				441 ($\times$5 caption)	1045 (dev-test)

Table 6: Statistics of the data used in this paper. CLF is the abbreivation of "classification". In AudioSet (Gemmeke et al., 2017) audio clips come from distinct videos. Balanced split means that there are at least 59 samples for each of 527 sound classes. We managed to download 18036 out of 22160 videos in the balanced training split, 16416 out of 20371 videos in the test / evaluation split, and 1715367 out of 2041789 videos in the unbalanced split.

AS Classification				
Dataset	AST	AST*	AST†	VIP~ANT
Unbalanced			43.4	**44.7**
Balanced	34.7	35.8	31.4	**37.9**

US8K and ESC50 Classification				
Dataset	AST-S	AST-P	CLIP	VIP~ANT
US8K			82.5$_{\pm 6.0}$	**86.0**$_{\pm 2.8}$
ESC50	88.7$_{\pm 0.7}$	95.6$_{\pm 0.4}$	89.7$_{\pm 1.5}$	**95.7**$_{\pm 1.4}$

Table 7: Multi-label classification mAPs (%) on AS and Supervised audio classification accuracies (%) on ESC50 and US8K. AST, AST-S, and AST-P indicates the results reported by Gong et al. (2021). We follow their suggestions and test the their best model (AST*) on our test set. Note that the best model has been trained on the combination of balanced and unbalanced AS training sets. † indicates that we follow the settings of AST and train it on our data. CLIP and VIP~ANT indicate that the audio encoder is initialized from CLIP and from VIP~ANT, respectively.

basically a linear probe. It inspects if contrastive pre-training learns separable audio representations. As we increase k, i.e., fine-tuning more layers, the model exhibits a tendency of over-fitting the training set. We use $k = 4$ as a trade-off between under-fitting and over-fitting. Our model achieves the best mAP of 37.9% for balanced training, which surpasses AST by 6.5% (see Table 7). While for unbalanced training, we find it crucial to fine-tune the whole model. Again, our model outperforms AST (+1.4% mAP).

D Position embedding interpolation

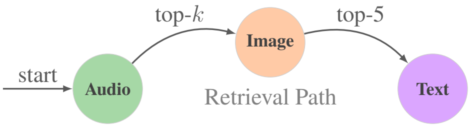
Clotho (Drossos et al., 2020) audio has a duration of 15-30 seconds, which is longer than 10-second audio clips used in pre-training. To apply our pre-trained audio encoder to Clotho audio-caption retrieval, we up-sample the pre-trained positional embeddings to account for the longer audio token sequences. Table 8 shows retrieval performance of 10-second audio and 18-second audio. In general, longer audio gives rise to better audio-caption retrieval performance.

E VAT versus AT fine-tuning

Given caption-augmented AudioCaps audio (Kim et al., 2019), we can improve the pre-trained audio encoder via contrastive vision-audio-text (VAT) fine-tuning and contrastive audio-text (AT) fine-tuning. Figure 9 shows a comparison between the two fine-tuning techniques on zero-shot ESC50 classification and AudioCaps audio retrieval. In general, AT fine-tuning results in better results on the two tasks.

F Analyzing tri-modal representations

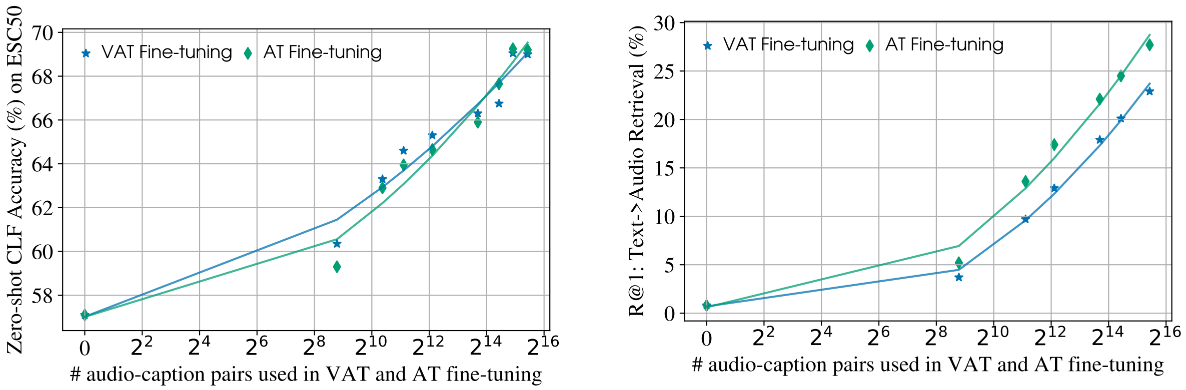
To better understand the geometry of tri-modal embeddings of our pivoting, unsupervised curation, and supervised curation, we study how AT fine-tuning influences the tri-modal representation space. Specifically, we analyze VIP~ANT (pivoting), VIP~ANT +AT (w/ RC) (unsupervised curation), and VIP~ANT +AT (w/ GC) (supervised curation) using *pivotability*.



Pivotability measures how likely images can pivot audio and text. We quantify it for each aligned VAT triplet via a two-step retrieval probe. Starting at a given audio clip, we retrieve k nearest image neighbors; for each image neighbor, we retrieve

	Model	10-second Clotho (eval)				18-second Clotho (eval)			
		Text→Audio		Audio→Text		Text→Audio		Audio→Text	
		R@1	R@10	R@1	R@10	R@1	R@10	R@1	R@10
Zero-resource	VA-Rand	1.4	7.4	3.2	13.1	1.3	7.5	3.2	13.5
	VIP~ANT	1.9	10.1	6.1	23.7	1.9	9.5	7.0	25.6
	+AT w/ AC	5.9	26.3	8.2	30.3	6.7	29.1	7.1	30.7
	+AT w/ FC	5.7	26.6	6.6	28.0	6.5	27.7	7.8	29.7
	+AT w/ VC	5.2	25.2	7.0	25.9	5.5	25.6	7.6	28.2
	+AT w/ RC	3.5	16.3	5.7	23.6	3.5	16.9	5.5	24.9
Zero-shot	+AT w/ GL	6.0	27.1	6.1	25.4	6.7	29.0	6.8	27.0
	+AT w/ GC	10.2	39.0	10.3	37.2	**11.1**	**40.5**	**11.8**	**41.0**

Table 8: Interpolating positional embeddings to account for Clotho audios which are longer than 10 seconds.



(a) Zero-shot classification (CLF) accuracy versus level of supervision.

(b) R@1 of audio retrieval with text as the query versus level of supervision.

Figure 9: Comparing VAT and AT fine-tuning on zero-shot ESC50 classification and AudioCaps audio retrieval.

the top-5 nearest captions. Since each audio clip has 5 gold captions, we compute pivotability as the ratio of the number of retrieved gold captions to 5. A gold caption may be retrieved more than one time, but we always count it as 1, so pivotability is always between 0 and 1.

We conduct this experiment on AudioCaps test set. For each k, i.e., how many images will be retrieved for a given audio clip, we average pivotability scores over all test triplets (see Figure 10).

Which pairs are pivotable? To study what kinds of audio are more likely to be pivoted with text by images, we set $k = 5$, i.e., 5 images will be retrieved for each given audio clip. We consider an AT pair as pivotable if at least 3 out of 5 gold captions of the audio clip are retrieved, i.e., pivotability is equal to or larger than 0.6. Figure 11 illustrates the categories of the audio clips in pivotable AT pairs. Unsurprisingly, audio about speech and vehicle is more pivotable because the two categories are among the top three frequent categories in AS.[10] Given that AT fine-tuning improves Audio → Image retrieval, we wonder if it could also help find novel categories of audio that can be pivoted with

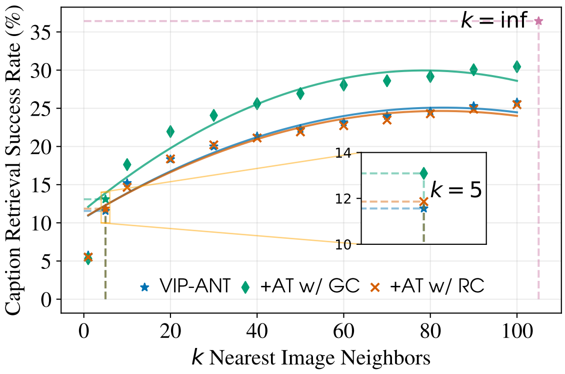


Figure 10: Tri-modal pivotability. +AT (w/ GC) and +AT (w/ RC) indicate that VIP~ANT is further fine-tuned on GC and RC, respectively.

---

[10] Music is the second most frequent category in AS. It is not shown in the figure because AudioCaps excludes all music audio.

Figure 11: Categories of the audio that can be pivoted with text by images. Larger text indicates that the related audio is more likely to be pivoted with text.

text. We find that this is indeed the case (see Table 9). For example, VIP~ANT +AT (w/ GC) finds more fine-grained speech categories because most AT pairs in AudioCaps are about speech. In contrast, VIP~ANT +AT (w/ RC) finds two additional novel insect categories, presumably because RC suffers from less data bias than GC.

+AT w/ GC	'female speech, woman speaking', 'narration, monologue', 'vibration'
+AT w/ RC	'bee, wasp, etc.', 'female speech, woman speaking', 'insect', 'narration, monologue', 'vibration'

Table 9: Comparing against VIP~ANT, the two fine-tuned versions of VIP~ANT find novel audio categories in pivotable AT pairs.

G Additional results

Asymmetric audio-text retrieval performance. For Text → Audio retrieval, our unsupervised pivoting model is not as good as on Audio → Text. This could be because audio is intrinsically more difficult to retrieve with specificity than text in our corpus, e.g., because sound events co-occur (a baby may cry in street with sirens in the background or in a room with dogs barking), there may be a broader range of captions that accurately describe them. However, it could also be the case that AT alignment is bounded by VT alignment because VA pre-training biases audio representations towards image representations. We check this hypothesis by conducting image-text retrieval on AudioCaps. AudioCaps provides aligned image-audio-text triplets, so we simply replace audio with the corresponding image. We find that the Text → Image retrieval performance of CLIP is much better than the Text → Audio retrieval performance of VIP~ANT (see the OracleAV-CLIP row of Table 3). It is also close to the Image → Text retrieval performance of CLIP. In contrast, VIP~ANT exhibits a large gap between the Text → Audio retrieval performance and the Audio → Text retrieval performance.

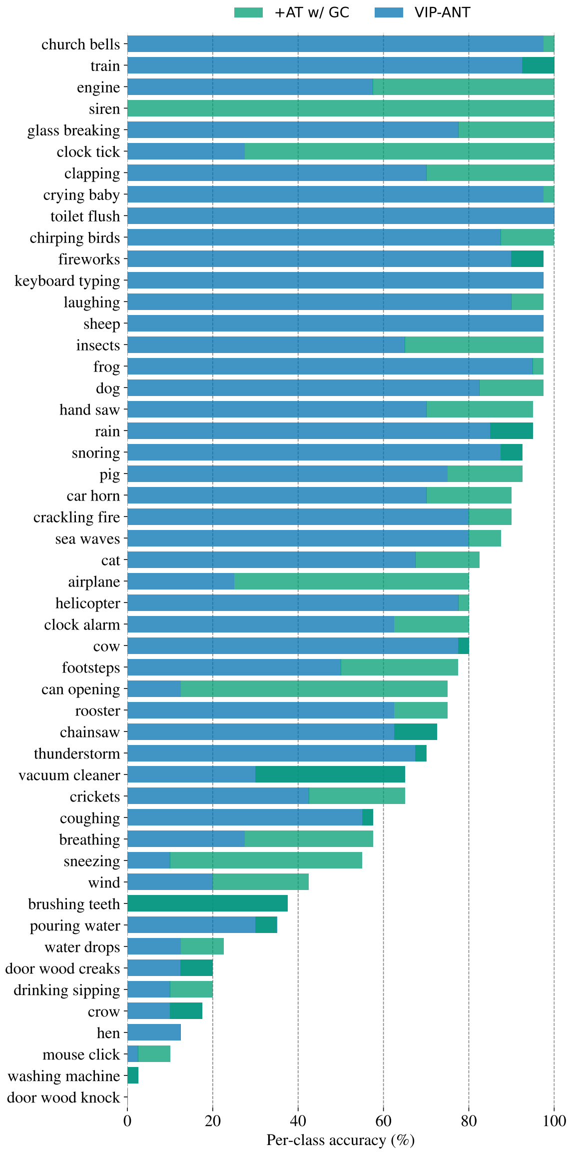

Figure 12: Per-class accuracy on ESC50.

Per-class accuracy on ESC50 is illustrated in Figure 12.

SURF: Semantic-level Unsupervised Reward Function for Machine Translation

j.ive@qmul.ac.uk

Abstract

The performance of Reinforcement Learning (RL) for natural language tasks including Machine Translation (MT) is crucially dependent on the reward formulation. This is due to the intrinsic difficulty of the task in the high-dimensional discrete action space as well as the sparseness of the standard reward functions defined for limited set of ground-truth sequences biased towards singular lexical choices. To address this issue, we formulate SURF, a maximally dense semantic-level unsupervised reward function which mimics human evaluation by considering both sentence fluency and semantic similarity. We demonstrate the strong potential of SURF to leverage a family of Actor-Critic Transformer-based Architectures with synchronous and asynchronous multi-agent variants. To tackle the problem of large action-state spaces, each agent is equipped with unique exploration strategies, promoting diversity during its exploration of the hypothesis space. When BLEU scores are compared, our dense unsupervised reward outperforms the standard sparse reward by 2% on average for in- and out-of-domain settings.

1 Introduction

Reinforcement Learning (RL) has shown promise in the field of text generation. This is mainly due to the fact that it allows the usage of non-differentiable evaluation functions fit for the discrete natural language tasks. It also serves as a solution for bridging the gap between training and inference time regimes ("exposure bias") that arises from the fact that the model is never exposed to its own errors as only ground-truth labels are used to condition the generation during training (Wang and Sennrich, 2020). One of the essential components of the RL framework is the reward function, which is used to provide agents with indicative signals in terms of the effectiveness of chosen actions.

The usage of RL in Neural Machine Translation (NMT) and language generation however has been doubted largely due to the difficulty of exploration in the high-dimensional discrete action space combined with the sparse reward signal. The latter comes from the typical metrics used as rewards (e.g., BLEU (Papineni et al., 2002)). These rewards evaluate text in a shallow way by measuring the string similarity between generated and ground-truth sequences, making them extremely sparse and biased towards singular lexical choices. As the RL policy is usually initialised with some pre-trained distribution over words, suspicion has been raised that in this situation, those words already most likely gain probability mass regardless of the rewards (Choshen et al., 2020). Thus, the current sparse rewards are not beneficial for rigorous exploration of different words during training. Recent studies suggest that the main benefit for NMT from RL is in performing domain adaptation when using proper hypothesis space exploration along with special emphasis on reward scaling and normalisation (Kiegeland and Kreutzer, 2021).

To address the problem posed by sparse or biased rewards, we propose SURF, a formulation of the unsupervised reward function that evaluates machine-generated texts in the semantic space by factoring in different qualitative aspects. Furthermore, we introduce an additional scaling and normalisation mechanism which ensures fairness and uniformity of the reward function regardless of the complexity of the natural language task.

Our **main contributions** are thus threefold: (a) the proposal of SURF, an unsupervised dense reward assessing both sentence fluency and adequacy (Section 4). We demonstrate this reward leads to a translation quality favourably comparable to the traditional sparse BLEU reward both in automatic and human evaluation; (b) the proposal of an additional normalisation using reward shaping mechanisms for the unsupervised reward; (c) demonstra-

July 10-15, 2022

tion of the strong potential of the proposed reward to elicit benefits of various RL architectures. We experiment with multi-agent synchronous and asynchronous Actor-Critic (AC) architectures as applied to the problem of MT (Section 3.3). Each of the parallel agents in those architectures is trained using different segments of the training dataset which has their own unique exploration strategy. When BLEU scores are compared, our dense unsupervised reward outperforms the standard sparse reward by 2% on average for both in- and out-of-domain settings. To the best of our knowledge, this formulation of the unsupervised reward for a range of multi-agent architectures is the first of its kind for MT.

Our datasets and settings are described in Section 5, and results of our experiments are described in Section 6.

2 Related Work

The following section describes the work related to ours in the subfields of Machine Translation and RL for language generation.

Reinforcement Learning Algorithms for Neural Machine Translation REINFORCE (Williams, 1992) algorithm and its variants have so far been the most widely used RL algorithms in MT (Ranzato et al., 2015; Rennie et al., 2017; Paulus et al., 2018; Hu et al., 2018). The fact that REINFORCE-based approaches suffer from high variance in general and in MT in particular has stimulated attempts to apply Actor-Critic (AC) models to the task. The first attempt of the kind was the one of Bahdanau et al. (2016). More advanced AC models with Q-Learning are rarely applied to language generation problems. However, there are exceptions (e.g., entropy-regularised AC models that promote exploration of actions (Dai et al., 2018; Ive et al., 2021)). This could be explained by the difficulty of approximating the Q-function for large action space. In this work we explore a series of multi-agent AC architectures which to the best of our knowledge have never been applied to MT before.

Unsupervised Rewards for Language Generation Tasks Recent work on unsupervised rewards in NLP has explored both dynamic (Ive et al., 2021) and static rewards (Gao et al., 2020; Garg et al., 2021). For example, Ive et al. (2021) introduces a dynamic distribution over latent frequency classes as a reward signal. This distribution is shaped to promote more rare words in the policy search space. Static rewards are very often designed to assess generated text in terms of its fluency and adequacy. Fluency judgment assesses how a hypothesis satisfies the grammatical norms of a language. Adequacy judgment assesses how well a hypothesis conveys the meaning of the source sentence. The recent research performs both evaluations as semantic similarity assessments using the pre-trained contextualised embeddings such as BERT (Zhang et al., 2020; Mathur et al., 2019). For MT, semantic similarity assessment could be carried out using monolingual pre-trained embeddings against a reference, as in Gao et al. (2020), or using multilingual pre-trained embeddings in the unsupervised reference-less approach by considering the semantic similarity to source sentences (Wei et al., 2019; Song et al., 2021). We adopt the latter approach to measure adequacy.

3 Methodology

We start by formulating MT using RL, then introduce the Actor-Critic architectures and the reward functions used.

3.1 Neural Machine Translation (NMT)

A typical Neural Machine Translation (NMT) system is a Seq2Seq architecture (Sutskever et al., 2014; Bahdanau et al., 2014), where each source sentence ($\mathbf{X}$) is encoded by the encoder into a sequence of hidden states. At each decoding step t, a target word y_t is generated according to $p(y_t|\mathbf{y}_{<t}, \mathbf{X})$ conditioned on the input sequence $\mathbf{X}$ and decoded sequence $\mathbf{y}_{<t} = (y_1, \cdots, y_{t-1})$ up to the t-th time step:

$$\mathcal{L}_{mle} = \log p\left(y_t|\mathbf{y}_{<t}, \mathbf{X}\right) \qquad (1)$$

3.2 Reinforcement Learning for NMT

In the RL framework, a Seq2Seq model is viewed as an agent and its parameters define the agent's **policy** (π). At each timestep (t), the agent observes the current **state** (s_t) of the **environment**, which is essentially the sequence of generated words from previous timesteps ($\hat{\mathbf{y}}_{1:t-1}$). Then, the agent's policy, which is based on the conditional probability $p\left(\hat{y}_t|\hat{\mathbf{y}}_{1:t-1}, \mathbf{X}\right)$, is used to select an **action** (a_t) at each timestep. In this context, an action is the candidate word ($\hat{y}_t$) chosen from the vocabulary. Subsequently, the environment adds the chosen word to the generated sequence, transitioning it to the next state ($\hat{\mathbf{y}}_{1:t}$). It also returns a reward (r_{t+1}) to the agent as an indication of how effective the chosen word is. Hence, one possible training objective of the policy is to maximise the discounted sum of expected rewards from all timesteps:

$$\pi_* = \max_{\pi} \sum_{t=1}^{T} \gamma^{t-1} \mathop{\mathbb{E}}_{\hat{y}_t \sim \pi(\cdot|\hat{\mathbf{y}}_{1:t-1}, \mathbf{X})} [r_{t+1}] \tag{2}$$

where π_* denotes the optimal policy and γ is a constant discount factor. Under the policy π, one can formulate two functions: the *state value function* ($V_\pi(s_t)$) and the *state-action value function* ($Q_\pi(s_t, a_t)$). The former, $V_\pi(s_t)$, determines the effectiveness of the agent being in a particular state while the latter, $Q_\pi(s_t, a_t)$, indicates the effectiveness of selecting a certain action in that state:

$$V_\pi(s_t) = \mathop{\mathbb{E}}_{\hat{y}_t \sim \pi} [Q_\pi(s_t = \hat{\mathbf{y}}_{1:t-1}, a_t = \hat{y}_t)] \tag{3}$$

$$Q_\pi(s_t, a_t) = \mathop{\mathbb{E}}_{\pi} \left[\sum_{k=1}^{T-t} \gamma^{k-1} r_{t+k} | s_t, a_t \right] \tag{4}$$

Hence the definition of the *advantage function* is:

$$A_\pi(s_t, a_t) = Q_\pi(s_t, a_t) - V_\pi(s_t) \tag{5}$$

A training objective can aim to maximise the advantage function $\max_a A_\pi(s_t, a_t)$.

Alternatively, considering the definition of $A_\pi(s_t, a_t)$ in Equation (5), it implies that we can directly maximise the Q function:

$$\max_a A_\pi(s_t, a_t) \rightarrow \max_a Q_\pi(s_t, a_t) \tag{6}$$

The first objective (Equation (2)) has been used in REINFORCE-based methods (Sutton et al., 2000) such as the MIXER architecture (Ranzato et al., 2015). These methods sample trajectories, series of consecutive states, actions and rewards, and use their true returns to update the policy. As they use the true returns, they are considered to be unbiased. However, as an action in a certain state can be part of many trajectories with different returns, these methods are considered to have high variance (Sutton and Barto, 2014). To address this issue, Actor-Critic algorithms (Konda and Tsitsiklis, 2001) adopt the *Temporal Difference* (TD) learning method which performs *bootstrapping* by using only the immediate reward and estimated values to guide future action selection. The training objective used is Equation (6).

3.3 Actor-Critic Architectures

3.3.1 Actor-Critic with Q-Learning (ACQ) Model

An Actor-Critic model usually consists of an **actor** and a **critic** (Konda and Tsitsiklis, 2001). The two networks are neural networks parameterised by $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$, respectively. The actor acts as the policy of the model while the critic is a function approximation network. One simple variant (ACQ) of the AC architecture is trained by maximising the Q function. In this variant, the critic is defined as a Q network approximating the true Q function.

The actor's training objective is to maximise the probability of actions that yield high Q values. Using Q value estimates ($Q_{\boldsymbol{\phi}}(\hat{\mathbf{y}}_{1:t-1,i}, w)$) computed by the main critic, the actor's policy loss ($\mathcal{L}_{policy}$) at each training timestep can be expressed as follows:

$$\mathcal{L}_{policy} = -[\frac{1}{N} \sum_{i=1}^{N} \sum_{t} \sum_{w \in \mathcal{W}} \pi_{\boldsymbol{\theta}}(w|\hat{\mathbf{y}}_{1:t-1,i}) Q_{\boldsymbol{\phi}}(\hat{\mathbf{y}}_{1:t-1,i}, w)] \tag{7}$$

where N denotes the training batch size. The loss is calculated by summing over all the possible actions (w) in the entire vocabulary ($\mathcal{W}$). Following (Bahdanau et al., 2017), to avoid early policy determination and gradient vanishing issues, the final actor loss ($\mathcal{L}_{ACQ-actor}$) consists of the policy loss ($\mathcal{L}_{policy}$) and the Maximum Likelihood Estimation (MLE) loss ($\mathcal{L}_{mle}$) from cross-entropy training (XENT) (weighted by λ_{mle}). In other words, the addition of XENT is to address the problem of training collapse[1], commonly encountered when applying RL in language tasks.

$$\mathcal{L}_{ACQ-actor} = \mathcal{L}_{policy} + \lambda_{mle}\mathcal{L}_{mle} \tag{8}$$

The TD learning method, as mentioned previously, is used to train the critic network. It adopts the bootstrapping methodology which performs estimation based on other known estimates. The critic's training objective is to minimise the mean squared difference, called TD error, between all estimated Q values and their corresponding target values in each timestep. Intuitively, the critic is trained to be as good of a Q function approximator

---

[1] As pointed out by (Bahdanau et al., 2017), the MLE loss can help prevent early policy determination and vanishing gradient problems.

as possible:

$$\mathcal{L}_{TD} = \frac{1}{N}\sum_{i=1}^{N}\sum_{t}(Q_{\boldsymbol{\phi}}(\hat{\mathbf{y}}_{1:t-1,i},\hat{y}_t) - \hat{Q}_{\bar{\boldsymbol{\phi}}}(\hat{\mathbf{y}}_{1:t-1,i},\hat{y}_t))^2 \qquad (9)$$

Each target $\hat{Q}_{\bar{\boldsymbol{\phi}}}(\hat{\mathbf{y}}_{1:t-1,i},\hat{y}_t)$, expressed below, is defined as the sum of the immediate reward after generating $\hat{y}_t$ and the expected Q value of the proceeding timestep, which is computed using another Q network named the target critic:

$$\hat{Q}_{\bar{\boldsymbol{\phi}}}(\hat{\mathbf{y}}_{1:t-1,i},\hat{y}_t) = r_{t+1} + \sum_{w\in\mathcal{W}} \pi_{\boldsymbol{\theta}}(w|\hat{\mathbf{y}}_{1:t,i})Q_{\bar{\boldsymbol{\phi}}}(\hat{\mathbf{y}}_{1:t,i},w) \qquad (10)$$

To ensure stability, the weights of the target critic ($\bar{\boldsymbol{\phi}}$) are updated more slowly than the main critic with the linear interpolation between the current weights of the main and target critics. Also, following (Bahdanau et al., 2017), in addition to the TD error, the critic's loss ($\mathcal{L}_{ACQ-critic}$) contains an additional term, weighted by λ_{var}, which aims to minimise the variance in Q value estimation.

$$\mathcal{L}_{ACQ-critic} = \mathcal{L}_{TD} + \lambda_{var}\frac{1}{N}\sum_{i=1}^{N}\sum_{w\in\mathcal{W}} \left(Q_{\boldsymbol{\phi}}(\hat{\mathbf{y}}_{1:t-1,i},w) - \bar{Q}_{\boldsymbol{\phi}}(\hat{\mathbf{y}}_{1:t-1,i})\right)^2 \qquad (11)$$

$$\bar{Q}_{\boldsymbol{\phi}}(\hat{\mathbf{y}}_{1:t-1,i}) = \frac{1}{|\mathcal{W}|}\sum_{w'\in\mathcal{W}} Q_{\boldsymbol{\phi}}(\hat{\mathbf{y}}_{1:t-1,i},w') \qquad (12)$$

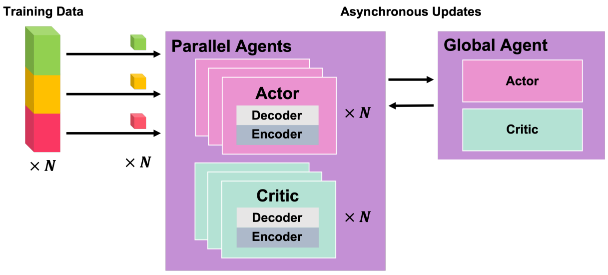

Figure 1: High-level structure of the Asynchronous Actor-Critic with Q-Learning Model (Async-ACQ) and the Asynchronous Advantage Actor-Critic (A3C) Model: multiple parallel agents and critics are trained independently. Their weights are used to update the weights of the global agent one by one.

Synchronous and Asynchronous ACQ Both the *asynchronous* and *synchronous* versions of the ACQ model can be easily constructed by deploying N actors with respective N critics on multiple threads. Each of the parallel actors is trained using different segments of the training dataset. For the synchronous variant, the weights of each of the actors are averaged to update the weights of the global agent. For the asynchronous variant, the global agent is updated by the local weights of each agent one by one. That is, during training, each thread-specific agent generates output sequences by sampling from its policy. Then, it performs loss computation and gradient accumulation until it reaches the pre-defined number of timesteps, in which it transfers the accumulated gradients to the global model. The global model subsequently performs an update on its parameters. As the last step of the asynchronous update, the parameters of the thread-specific agent invoking the update are synced with the parameters of the global model.

3.3.2 Advantage Actor-Critic (A2C) Model

Another variant of the AC model is the Advantage Actor-Critic (A2C) architecture (Konda and Tsitsiklis, 2001). In this model, the critic is defined as a function approximator, parameterised by $\boldsymbol{\psi}$, of the true V function. Compared to the first variant, the A2C model applies a different training objective to ACQ (Equation (6)).

Given the state space in language tasks is massive, calculating the expectation term would be computationally expensive or even impossible. Therefore, the advantage function can be approximated by sampling once.

$$A_{\pi}(s_t,a_t) \approx r_{t+1} + \gamma V_{\pi}(s_{t+1}) - V_{\pi}(s_t) \qquad (13)$$

The actor network in the A2C model is trained in a similar fashion to that of ACQ. Here, the critic estimates the state values (i.e., $V_{\boldsymbol{\psi}}(\hat{\mathbf{y}}_{1:t-1,i})$ and $V_{\boldsymbol{\psi}}(\hat{\mathbf{y}}_{1:t,i})$) which are used by the actor to calculate the advantage value. The actor loss function ($\mathcal{L}_{A2C-actor}$) can be outlined as follows:

$$\mathcal{L}_{policy} = -[\frac{1}{N}\sum_{i=1}^{N}\sum_{t}\log \pi_{\boldsymbol{\theta}}(\hat{y}_t|\hat{\mathbf{y}}_{1:t-1,i})A_{\boldsymbol{\psi}}(\hat{\mathbf{y}}_{1:t-1,i},\hat{y}_t)] \qquad (14)$$

$$A_{\boldsymbol{\psi}}(\hat{\mathbf{y}}_{1:t-1,i},\hat{y}_t) = r_{t+1} + \gamma V_{\boldsymbol{\psi}}(\hat{\mathbf{y}}_{1:t,i}) - V_{\boldsymbol{\psi}}(\hat{\mathbf{y}}_{1:t-1,i}) \qquad (15)$$

$$\mathcal{L}_{A2C-actor} = \mathcal{L}_{policy} + \lambda_{mle}\mathcal{L}_{mle} \qquad (16)$$

Furthermore, compared to the first variant, the A2C critic is trained to minimise the TD error between its estimation and ground-truth data. The ground-truth data is essentially the true discounted reward-to-go (v_t).

$$\mathcal{L}_{A2C-critic} = \frac{1}{N}\sum_{i=1}^{N}\sum_{t}(V_{\psi}(\hat{\mathbf{y}}_{1:t-1,i}) - v_t)^2 \tag{17}$$

Synchronous and Asynchronous A2C The model setups for the synchronous and asynchronous A2C variants are analogous to the ACQ variants, in which N pairs of actors and critics are deployed.

In the **asynchronous A2C architecture (A3C)** (Mnih et al., 2016), the model also employs n-step TD Learning which uses the true returns from multiple steps in the advantage function to reduce the model bias (Sutton and Barto, 2014). The term n defines the number of steps to use the real rewards before bootstrapping (using the critic). The standard TD Learning would just use the immediate reward (1-step TD).

$$\begin{gathered} A_{\psi'}(\hat{\mathbf{y}}_{1:t-1,i}, \hat{y}_t) = \sum_{\tau=0}^{n-1}\gamma^{\tau} r_{t+\tau} + \\ \gamma^{n} V_{\psi'}(\hat{\mathbf{y}}_{1:t+n-1,i}) - V_{\psi'}(\hat{\mathbf{y}}_{1:t-1,i}) \end{gathered} \tag{18}$$

where $\boldsymbol{\theta}'$ and $\boldsymbol{\psi}'$ represent the thread-specific parameters of each actor and critic, respectively.

4 Semantic-level Unsupervised Reward Function (SURF)

Our semantic-level unsupervised reward, SURF, is based on two scores: *Sentence Fluency* and *Sentence-level Semantic Similarity (SLSS)* (Song et al., 2021). Each score assesses translation quality of generated sequences from different aspects and is computed using a pre-trained model. To prevent reward sparsity, the reward function introduces a score normalisation mechanism which normalises scores of a generated sequence (from all timesteps) with respect to the score of its full target sequence. This subsequently yields an unsupervised reward function that is maximally dense. The Sentence Fluency score ($F(\hat{\mathbf{y}}_{1:t})$) is defined as the average log-likelihood of the generated sequence tokens ($\hat{\mathbf{y}}_{1:t}$) as defined by a pre-trained large LM.

The SLSS score measures the overall semantic similarity between the entire generated sequence and its source sequence calculated as the cosine similarity between the two sentence cross-lingual embeddings.

Score Normalisation From the RL perspective, the MT task does not define the environment component that the agent operates in. That is, unlike the classical RL setting where the environment is relatively fixed, the 'environment' in the MT task is mostly dependent on the source sequence, in terms of its sophistication, structure, length, etc. As a result, a valid and good translation of a source sequence would receive a relatively high score but is not directly comparable to other sequences due to the difference in source sentence complexity. Therefore, it is important to ensure that the reward function is uniform and generalised across all source sentences.

In order to do this for each source sequence, the reward function uses the corresponding target sequence as a 'soft' upper bound for what a machine-generated sequence could achieve. That is, for each of the two score metrics outlined above, the scores from all timesteps received by a generated sequence is normalised to the range 0 to 1 with respect to the score of the full target sequence. To demonstrate the normalisation method, let us consider the formulation below which uses the Sentence Fluency score metric as an example. Given a pair of source ($\mathbf{X}$) and target ($\mathbf{Y}$) sequences and a candidate sequence ($\hat{\mathbf{y}}_{1:t}$), the fluency scores from all timesteps of $\hat{\mathbf{y}}_{1:t}$ would be $\{F(\hat{\mathbf{y}}_1), F(\hat{\mathbf{y}}_{1:2}), ..., F(\hat{\mathbf{y}}_{1:t-1}), F(\hat{\mathbf{y}}_{1:t})\}$ while the fluency score for the entire reference target sequence ($\mathbf{Y}$) would be $F(\mathbf{Y})$. Using the fluency scores of the candidate and that of the reference, the normalised candidate scores can be calculated as follows:

$$F_{norm}(\hat{\mathbf{y}}_{1:i}) = \begin{cases} \frac{F(\hat{\mathbf{y}}_{1:i}) - min}{max - min} & \text{if} \quad max \neq min \\ 0.5 & \text{if} \quad max = min, \end{cases} \tag{19}$$

where

$$max = \max(\{F(\hat{\mathbf{y}}_1), ..., F(\hat{\mathbf{y}}_{1:t}), F(\mathbf{Y})\}) \tag{20}$$

$$min = \min(\{F(\hat{\mathbf{y}}_1), ..., F(\hat{\mathbf{y}}_{1:t}), F(\mathbf{Y})\}) \tag{21}$$

Considering the example formulation above, one can observe that the normalisation with respect to the reference score is considered as a 'soft' upper bound as it allows for candidate scores to be higher than the reference score (i.e., allowing the possibility that candidate sequences can be better than their references).

The Pay-off Function and Reward Shaping Given a generated sequence $\hat{\mathbf{y}}_{1:t}$ at timestep t, its quality can be formulated as the Pay-off Function ($PO(\hat{\mathbf{y}}_{1:t}, \mathbf{X})$). The Pay-off Function, as expressed below, is based on the Sentence Fluency and SLSS scores described above.

$$PO(\hat{\mathbf{y}}_{1:t}, \mathbf{X}) = w_F \times e^{F(\hat{\mathbf{y}}_{1:t})} + w_S \times e^{SLSS(\hat{\mathbf{y}}_{1:t}, \mathbf{X})} \tag{22}$$

where, for simplicity, $F(\hat{\mathbf{y}}_{1:t})$ and $SLSS(\hat{\mathbf{y}}_{1:t}, \mathbf{X})$ denote the normalised Sentence Fluency and SLSS scores respectively. The terms w_F and w_S are fixed weights controlling the relative importance of Sentence Fluency and SLSS, respectively. It is important to emphasise that the exponential function is applied to each score since linearly adding each score leads to high variance and lower correlation with human scores (Song et al., 2021).

Using the Pay-off Function to determine the effectiveness of generating a token ($\hat{y}_t$) at timestep t, the final reward function is defined using reward shaping as the difference between the current Pay-off and the Pay-off of the previous timestep.

$$R(\hat{y}_t) = PO([\hat{\mathbf{y}}_{1:t-1}, \hat{y}_t], \mathbf{X}) - PO(\hat{\mathbf{y}}_{1:t-1}, \mathbf{X}) \tag{23}$$

5 Experimental Settings

5.1 Data

In our experiments, we used the German-English OpenSubtitles corpus (Lison and Tiedemann, 2016). There are approximately 14 million sequence pairs in this dataset extracted from subtitles of movies and TV shows, making it very diverse. The dataset was then divided into training, validation and test sets. The training set has approximately 13 million sentence pairs while each of the validation and test sets has roughly 5,000 sentence pairs.

The trained models were also tested on translating the IWSLT 2014 German-English test dataset, a popular dataset to benchmark RL-based methods. This dataset contains a parallel corpora with one reference per source sequence, obtained from TED talks (Cettolo et al., 2015). The test dataset contains approximately 6,000 pairs, with each sequence containing a few sentences of text. See Appendix A.2 for justification for treating the two datasets as coming from different domains.

5.2 Training

Following (Bahdanau et al., 2016), to ensure good initialisation of the model, the actor network is first pre-trained using XENT and the teacher forcing method. After that, the critic is pre-trained using TD Learning with the fixed pre-trained actor weights. At the last step, we train the actor and the critic jointly.

Generally, the actor architecture follows the OpenNMT Transformer architecture (Klein et al., 2017), with a few enhancements to enable stepwise decoding during training (i.e., action selection based on the model's previous outputs) and diversity in each agent's exploration strategy (see Appendix A.3 for more details). During training the actor selects a token at each timestep using the **Top-K** sampling method (Fan et al., 2018), in which a token is sampled from K tokens with the highest probabilities.

The critic architecture follows the Transformer architecture (Vaswani et al., 2017), with two major differences (see Appendix A.3.2 for detailed explanation). There are also two critic types, namely Q-critic and V-critic. The first critic type, Q-critic, is used in model variants with Q-Learning while the second type, V-critic, is used in other variants utilising the A2C architecture.

Multi-GPU Training When training synchronously in a multi-GPU environment, the model is deployed on a one-model-per-device basis to reduce training time. Each model has its own optimiser (we used Adam (Kingma and Ba, 2014)). During every update, the gradients are reduced and re-scaled across all devices to ensure that they are consistent across the models.

However, when training asynchronously, the global agent resides on one GPU device while three parallel agents are deployed on the remaining GPU devices. Instead of using one optimiser per agent, only a global optimiser is used. On every asynchronous update, the global optimiser updates the global model by using the gradients transferred from the parallel agent which invoked the update. The global optimiser used (SharedAdam) is a standard Adam optimiser modified to support multi-GPU communication.

Our formulation of the unsupervised reward uses the pre-trained OpenAI GPT Language Model from Hugging Face (Wolf et al., 2020). It also uses the Sentence Transformers tool (Reimers and Gurevych, 2020) with the XLM RoBERTa model (Conneau et al., 2020) to generate the sentence embeddings. We do not expect the performance to change drastically by using other models.

During the joint actor-critic training, it took approximately one day to train each of the BLEU variants while the training time for SURF variants ranges from 3 to 5 days (see Appendix A.5 for the computational resource used). The increase in training time is mainly due to the usage of the large pre-trained models by SURF. We expect this time to reduce if a smaller language model is used. We leave this investigation to future work.

More details on the implementation and hyper-parameters are given in Appendix A.3 and A.4.

Model configurations. We experimented using the nine configurations listed below:

- **Transformer** baseline (MLE, no RL) - state-of-the-art (SOTA) model;
- Synchronous ACQ RL architecture with the standard BLEU reward (**ACQ-BLEU**) and with our SURF (**ACQ**);
- Asynchronous ACQ RL architecture with the standard BLEU reward (**Async-ACQ-BLEU**) and with our SURF (**Async-ACQ**);
- Synchronous A2C RL architecture with the standard BLEU reward (**A2C-BLEU**) and with our SURF (**A2C**);
- Asynchronous A2C RL architecture with the standard BLEU reward (**A3Q-BLEU**) and with our SURF (**A3C**).

Each model was trained on the OpenSubtitles dataset and tested on both OpenSubtitles (in-domain) and IWSLT (out-of-domain) test sets.

By choosing this selection of models we are able to do the following: (a) generate the benchmark result using the Transformer baseline; (b) exhibit the advantage of SURF over the BLEU reward; and finally (c) explore the performance of SURF within the family of the multi-agent models (ACQ, Async-ACQ, A2C and A3C).

We used the standard set of MT evaluation metrics: BLEU (Papineni et al., 2002) and METEOR (Denkowski and Lavie, 2014). We performed significance testing via bootstrap resampling using the `Multeval` tool (Clark et al., 2011).

6 Results

6.1 Performance on Automatic Evaluation Metrics

Results for the OpenSubtitles test set are in Table 1. They show that all of our model variants outperform the Transformer benchmark (+1.5 BLEU on average) with the A3C model performing the best (+2.5 BLEU vs. Transformer) while the Async-ACQ model is the second best performing variant being (+1.2 BLEU vs. Transformer). Mostly, our unsupervised reward contributes around +0.5 BLEU to the performance of each model when trained with the BLEU reward. Especially high improvement of +7.5 BLEU is observed for A3C. We attribute this result to the BLEU reward sparsity and hence impossibility to properly learn the relative improvement over the average for the actions as modelled by the advantage function. Note that Q-learning learns the absolute reward which is easier to model in this sparsity condition. This sparsity is particularly detrimental in the asynchronous setting, where the updates of parallel agents seem to exhibit too much variance to be useful. Those observations in the Advantage learning setting emphasise the important potential of our dense reward to elicit the benefits of different RL architectures.

Model	B	M	B	M
Transformer	33.3	29.9		
	BLEU		*SURF*	
ACQ	$34.6^{\star}$	$30.7^{\star}$	$35.2^{\star\dagger}$	$31.0^{\star\dagger}$
Async-ACQ	$35.0^{\star}$	$30.9^{\star}$	$35.5^{\star\dagger}$	$31.1^{\star\dagger}$
A2C	$32.9^{\star}$	$29.9^{\star}$	$33.4^{\star\dagger}$	$29.9^{\star}$
A3C (Async-A2C)	$28.3^{\star}$	$27.9^{\star}$	$\mathbf{35.8}^{\star\dagger}$	$\mathbf{31.2}^{\star\dagger}$

Table 1: Results for the OpenSubtitles German-English test set. We report BLEU (B) and METEOR (M) scores. The symbol $\star$ indicates statically significant changes (p-value ≤ 0.05) as compared to the Transformer model while † indicates statically significant changes (p-value ≤ 0.05) as compared to the BLEU variant of the same RL-based architecture. The best result is highlighted in bold.

To probe the generalisation capacity of our models in the out-of-domain scenario, we have applied our models to the IWSLT test set. As shown in Table 2, the performance drop for the Transformer model is much higher than for our RL models (-6 BLEU vs. -2.4 BLEU on average). The Async-ACQ is the best-performing model on both metrics with the ACQ model being the second best (+6.3 BLEU and +5.8 BLEU vs. Transformer, re-

A2C	29.4*	31.0*	30.2*†	31.0*
A3C (Async-A2C)	22.2*	27.6*	32.8*†	32.8*†

Table 2: Results for the IWSLT 2014 German-English test set. We report BLEU (B) and METEOR (M) scores. The symbol $\star$ indicates statically significant changes (p-value ≤ 0.05) as compared to the Transformer model while † indicates statically significant changes (p-value ≤ 0.05) as compared to the BLEU variant of the same RL-based architecture. The best result is highlighted in bold.

spectively). Mostly, our unsupervised reward contributes around +0.8 BLEU to the performance of each model. Especially high improvement of +10 BLEU is again observed for A3C showing the potential of SURF.

By way of offering a guideline of our model performance, we also report the scores of the previous SOTA on the IWSLT test set. Though those results are not directly comparable to our results as the pre-processing conditions are different: previous models have mainly applied a cut-off vocabulary implying the presence of unknown words in the training data while we are using the subword units that dispense us of the unknown words.

Note that, on both test sets, the asynchronous variants (Async-ACQ and A3C) performed better than their corresponding synchronous counterparts (ACQ and A2C respectively). We emphasise the potential of asynchronicity with our dense reward to positively influence performance.

Additionally, regarding the usage of Q- or V-critics: both Q-version Async-ACQ and V-version A3C have shown comparable performance on the OpenSubtitles dataset. However, the Q-version Async-ACQ has achieved better performance on the IWSLT test set. We hypothesise that this may be due to the fact that the Q-critic network in the ACQ architecture outputs the state-action values of the entire vocabulary at each timestep rather than a single state value (as in the V-critic network). Hence it performs a more fine-grained policy evaluation with lower variance in the critic outputs, leading to a more stable model overall. A more thorough investigation would lead to better insights.

6.2 Performance on Semantic-level Evaluation Metrics

As with the automatic evaluation results, similar conclusions could be drawn from the results of the assessment with the three semantic metrics used in the reward formulation: Sentence Fluency, Token-level Semantic Similarity (TLSS) and Sentence-level Semantic Similarity (SLSS) scores (See Appendix A.6 for the description of the TLSS score).

For the IWSLT test set, as shown on Table 4, there is a noticeable increase in the Fluency score across our models (in comparison to the Transformer). ACQ and Async-ACQ are also able to achieve distinctly better TLSS ans SLSS scores than the Transformer model. We observe that variants of ACQ and Async-ACQ models achieve similar performance. When comparing the BLEU and SURF variants, the BLEU variants of A2C and A3C models obtain higher Fluency scores but score less on TLSS and SLSS. This can be explained by fact that BLEU RL sentences are prone to be more verbose, repeating the same meaning in different words. The results for OpenSubtitles show similar tendencies (see Appendix A.7).

6.3 Human Evaluation

Finally, to gain deeper insights, we performed human evaluation on the translations of the OpenSubtitles and IWSLT 2014 test sets by the Transformer, Async-ACQ-BLEU and the best performing SURF variants (A3C for OpenSubtitles and Async-ACQ for IWSLT).

For this human analysis, we randomly selected 50 test samples from each test set. A rank of quality is assigned by the human evaluator (second author,

Source	all dies wurzelt in der mythologischen vergangenheit . das eigenartige an diesen großen häusern , in denen aufgrund der mischehen sechs oder sieben sprachen gesprochen werden , ist jedoch , dass man niemals jemanden hört , der eine sprache lernt .
Target	and this is all rooted in the mythological past , yet the curious thing is in these long houses , where there are six or seven languages spoken because of intermarriage , you never hear anyone practicing a language .

ACQ	$1.029^{\star}$	$2.456^{\star}$	$2.350^{\star}$	**$1.029^{\star\dagger}$**	**$2.457^{\star\dagger}$**	**$2.357^{\star\dagger}$**
Async-ACQ	$1.032^{\star}$	$2.455^{\star}$	$2.350^{\star}$	$1.029^{\star\dagger}$	$2.456^{\star\dagger}$	$2.350^{\star\dagger}$
A2C	$1.035^{\star}$	$2.451^{\star}$	$2.300^{\star}$	$1.027^{\star\dagger}$	$2.454^{\star\dagger}$	$2.339^{\star\dagger}$
A3C (Async-A2C)	$1.047^{\star}$	$2.422^{\star}$	$2.267^{\star}$	$1.027^{\star\dagger}$	$2.454^{\star\dagger}$	$2.342^{\star\dagger}$

Table 4: Results for the IWSLT 2014 German-English test set. We report Sentence Fluency, Token-level Semantic Similarity and Sentence-level Semantic Similarity scores. Also, the symbol $\star$ indicates statically significant changes (p-value ≤ 0.05) as compared to the scores of Transformer model while † indicates statically significant changes (p-value ≤ 0.05) as compared to the BLEU variant of the same RL-based architecture. The best result is highlighted in bold. Note that some of the improvements are beyond the displayed precision of 3 decimal points.

Test Set	Transformer	BLEU	SURF
OS	0.10	0.08	**0.20**
IW	0.06	0.48	**0.60**

Table 5: Human ranking results comparing the OpenSubtitles (OS) test outputs for Async-ACQ-BLEU and A3C and the IWSLT 2014 (IW) test outputs for Async-ACQ-BLEU and Async-ACQ. The best result is highlighted in bold.

fluent speaker of both English and German) from 1 to 3, allowing ties. Following the common practice in MT, each system was then assigned a score which reflects how often on average it was judged to be better or equal to other systems (Bojar et al., 2017). Table 5 shows that most of our variants have higher evaluation scores than the Transformer model. In particular, on the IWSLT test set, both Async-ACQ variants outperform the Transformer by a large margin. As compared to the best BLEU model, the A3C and Async-ACQ models perform significantly better on both the OpenSubtitles and the IWSLT test sets (+0.12 point). Table 3 shows translations generated by the three models on the IWSLT test set. Note that Async-ACQ demonstrates the best fluency and adequacy.

7 Conclusion

We have presented SURF, a new unsupervised semantic-level reward function, efficiently addressing the reward sparsity issue and mimicking human evaluation by considering both sentence fluency and semantic similarity. We have explored this reward for a new family of Actor-Critic Transformer-based Architectures with synchronous and asynchronous variants that promote the exploration of the search space. We demonstrate that SURF shows strong potential to elicit the benefits of various RL architectures. Our results show that it outperforms the traditional sparse BLEU reward for the same architectures in the automatic, semantic-level and human evaluation. Our code is available at `https://github.com/AtomAnu/SURF`.

There are several directions to take our work further: we can investigate the utility of our reward for other architectures and we can also explore different sampling strategies for each of the agents of our multi-agent models. Finally, we have investigated only two datasets to ensure comparability to the existing benchmarks. A more thorough investigation with more datasets and language pairs is needed to fully assess the scope of our contribution.

A Appendix

A.1 Ethics Considerations

We are aware of the discussions around the risks related to unintended harmful effects and uses, environmental consequences, fairness and privacy considerations of large language models in general (Bender et al., 2021), and machine translation models specifically (Wang et al., 2021). We note here that our models constitute a primarily theoretical contribution and were trained and tested on standard datasets. Before deployment in a production setting our methodology is subject to retraining with data pre-processed in the appropriate way (as our model is not equipped with relevant security, privacy and fairness mechanisms), systematic debugging, extensive simulation, testing and validation under the supervision of experts.

A.2 Domain Distance

To justify that the IWSLT test set is indeed considered out-of-domain, we have trained a German language model using the source sentences (in German) from the OpenSubtitles training set. For this we used the fairseq toolkit (Ott et al., 2019). The resulting difference in language model perplexity values for the OpenSubtitles and IWSLT test sets (45.52 and 555.71, respectively) is important enough to justify that IWSLT is considered out-of-domain.

A.3 Implementation Details

A.3.1 The Actor

OpenNMT Transformer Implementation In the OpenNMT framework (Klein et al., 2017), the Transformer architecture is implemented slightly differently from the original architecture in (Vaswani et al., 2017). Its implementation follows the up-to-date implementation of the tensor2tensor framework (Vaswani et al., 2018), created by the authors of (Vaswani et al., 2017). The main difference lies in the normalisation technique used in the Transformer. That is, pre-normalisation is applied in each sub-layer of the encoder and the decoder instead of post-normalisation. The output of each sub-layer with pre-normalisation can be expressed as follows:

$$x + Sublayer(LayerNorm(x)) \tag{24}$$

In the original architecture where post-normalisation is used, layer normalisation ($LayerNorm$) is applied after the summation ($x + Sublayer(x)$), as shown below:

$$LayerNorm(x + Sublayer(x)) \tag{25}$$

Step-wise Decoding and Exploration Strategies During the joint AC training, instead of just computing the policy distributions as the output, the actor would perform step-wise decoding by selecting a token to generate at each timestep, given the encoded source sequence and the previously generated tokens. As mentioned before, this is done to ensure that there would be no exposure bias during inference as the model is trained to condition the generation process using its own outputs.

To allow each agent to be diverse in their exploration strategies, the actor can operate in two possible main modes of token selection. In the first mode, the actor selects a token at each timestep using the **Top-K** sampling method (Fan et al., 2018), in which a token is sampled from K tokens with the highest probabilities. In the second mode of operation, the actor performs token selection based on **Nucleus** sampling (Holtzman et al., 2020). In the Nucleus sampling method, a token is chosen from the smallest possible set of tokens that has an accumulated probability equal or higher than a pre-defined probability value (p). For instance, if p is set to 1, the actor would perform token selection from the entire vocabulary. Similarly, if the value of K for Top-K sampling is set to the vocabulary size, the actor would sample from the entire vocabulary as well.

The actor also incorporates the notion of **Temperature** to further increase the diversity of exploration strategies. A pre-defined value of Temperature ($temp$) is used to increase the probability of probable tokens while reducing others that are not probable.

$$p(w_i|\hat{\mathbf{y}}_{1:t-1}) = \frac{\exp(l_i/temp)}{\sum_j \exp(l_j/temp)} \qquad (26)$$

where l_i is the logit of the token w_i. One can observe that, as $temp$ decreases, the probability of probable tokens would increase. If $temp$ is set to 1, the above expression would simplify to the normal softmax operation.

We have empirically found that the sampling Temperature should not be applied in conjunction with Top-K or Nucleus sampling as it leads to highly greedy policies, especially when K or p is already low. It should be applied on when the agent samples from the entire vocabulary. After experimenting with different configurations of exploration strategies, we found that Top-K sampling was the most effective.

A.3.2 The Critic

The critic architecture follows the Transformer architecture, with two major differences.

Reference Encoding The first difference between the actor and the critic is that the encoder of the critic encodes the reference sequences instead of the source sequences. The reason is to allow to critic to evaluate each generated sequence by comparing with its reference sequence.

Output Layer The second difference is the output layer used in the critic. In the Q-critic model, its output layer is a one-layer feed-forward network with the output dimension equal to the vocabulary size of the target language. This is because the Q-critic model outputs the state-action value (i.e., Q-value) for every word in the vocabulary.

For the V-critic model, its output layer also contains a one-layer feed-forward network with the output size of 1. Given a generated sequence, the critic outputs the state value (i.e., V-value) for each token in that sequence.

A.4 Hyper-parameters

A.4.1 Actor Pre-training

Table 6 lists all the hyper-parameters used during actor pre-training.

A.4.2 Critic Pre-training

Table 8: List of listing the hyper-parameters used during synchronous and asynchronous joint Actor-Critic training stage.

ated sequence and its source sequence. Following the methodology adopted in the SentSim evaluation metric (Song et al., 2021), each token in the source and generated sequences is passed to a cross-lingual language model to obtain its cross-lingual embedding. Then, each token in the source sequence (x_i) is matched to a token in the generated sequence ($\hat{y}_j$) with the highest cosine similarity value to compute the recall. Similarly, the precision value is computed by matching each token in the generated sequence to a token in the source sequence based on cosine similarity. As a results, the recall and precision of a generated sequence can be expressed as follows:

$$R(\hat{\mathbf{y}}_{1:t}, \mathbf{X}) = \frac{1}{|\mathbf{X}|} \sum_{x_i \in \mathbf{X}} \max_{\hat{y}_j \in \hat{\mathbf{y}}_{1:t}} \mathbf{x}_i^{nxe} \cdot \hat{\mathbf{y}}_j^{nxe} \quad (27)$$

$$P(\hat{\mathbf{y}}_{1:t}, \mathbf{X}) = \frac{1}{|\hat{\mathbf{y}}_{1:t}|} \sum_{\hat{y}_j \in \hat{\mathbf{y}}_{1:t}} \max_{x_i \in \mathbf{X}} \mathbf{x}_i^{nxe} \cdot \hat{\mathbf{y}}_j^{nxe} \quad (28)$$

where $\mathbf{x}_i^{nxe}$ and $\hat{\mathbf{y}}_j^{nxe}$ denote the pre-normalised (i.e., $\mathbf{x}_i^{nxe} = \frac{\mathbf{x}_i^{xe}}{||\mathbf{x}_i^{xe}||}$) cross-lingual embeddings of x_i and $\hat{y}_j$, respectively. Using the precision and recall, the final TLSS score is defined as the F1 measure.

$$\begin{aligned} TLSS(\hat{\mathbf{y}}_{1:t}, \mathbf{X}) &= F(\hat{\mathbf{y}}_{1:t}, \mathbf{X}) && (29) \\ &= 2\frac{P(\hat{\mathbf{y}}_{1:t}, \mathbf{X}) \cdot R(\hat{\mathbf{y}}_{1:t}, \mathbf{X})}{P(\hat{\mathbf{y}}_{1:t}, \mathbf{X}) + R(\hat{\mathbf{y}}_{1:t}, \mathbf{X})} && (30) \end{aligned}$$

The TLSS scores are computed using the BERTScore tool (Zhang et al., 2020).

A.7 Semantic-level Evaluation on the OpenSubtitles Test Set

For the OpenSubtitles test set, as shown in Table 9, there is a slight increase in the Fluency scores for all our model as compared to the Transformer. There are more apparent increases in the TLSS and SLSS scores. Among all the variants, the ACQ model achieves the highest on all three scores. The Async-ACQ model is the second best with its scores being very close to the scores of the ACQ model. When comparing the reward functions, the BLEU and SURF variants of the ACQ and Async-ACQ models achieve similar performance. However, for the A2C and A3C models, the BLEU variants achieve higher Fluency scores than the SURF variants but their SLSS scores are noticeably lower than that of SURF. This can be explained by fact that BLEU RL sentences are prone to be more verbose, repeating the same content. This was observed during human evaluation (See Subsection 6.3).

Model	Fluency	TLSS	SLSS	Fluency	TLSS	SLSS
Transformer	1.036	2.450	2.360	-	-	-
		BLEU			*SURF*	
ACQ	1.037*	2.455*	2.384*	**1.037***†	**2.456***†	**2.386***†
Async-ACQ	1.037*	2.455*	2.387*	1.037*†	2.455*†	2.385*†
A2C	1.039*	2.455*	2.377*	1.037*†	2.454*†	2.379*†
A3C (Async-A2C)	1.043*	2.443*	2.347*	1.037*†	2.454*†	2.383*†

Table 9: Results for the OpenSubtitles German-English test set. We report Sentence Fluency, Token-level Semantic Similarity and Sentence-level Semantic Similarity scores. Also, the symbol $\star$ indicates statically significant changes (p-value ≤ 0.05) as compared to the scores of Transformer model while † indicates statically significant changes (p-value ≤ 0.05) as compared to the BLEU variant of the same RL-based architecture. The best result is highlighted in bold. Note that some of the improvements are beyond the displayed precision of 3 decimal points.

Disentangling Categorization in Multi-agent Emergent Communication

Abstract

The emergence of language between artificial agents is a recent focus of computational linguistics, as it offers a synthetic substrate for reasoning about human language evolution. From the perspective of cognitive science, sophisticated categorization in humans is thought to enable reasoning about novel observations, and thus compose old information to describe new phenomena. Unfortunately, the literature to date has not managed to isolate the effect of *categorization power* in artificial agents on their inter-communication ability, particularly on novel, unseen objects. In this work, we propose the use of disentangled representations from representation learning to quantify the categorization power of agents, enabling a differential analysis between combinations of *heterogeneous systems*, e.g., pairs of agents which learn to communicate despite mismatched concept realization. Through this approach, we observe that agent heterogeneity can cut signaling accuracy by up to 40%, despite encouraging compositionality in the artificial language. We conclude that the reasoning process of agents plays a key role in their communication, with unexpected benefits arising from their mixing, such as better language compositionality.

1 Introduction

A recent interest in the design of multi-agent systems is the unsupervised emergence of complex behaviors (Havrylov and Titov, 2017). Rather than completely supervising agents to perform a mapping betweem inputs and outputs, it is observed that with enough capacity and bandwidth, agents eventually learn to produce emergent properties for their own benefit, e.g., the creation of artificial language to solve a task more efficiently (Resnick et al., 2020; Lee et al., 2018; Chaabouni et al., 2019). With carefully designed constraints, the agents may eventually produce a proto-language that mimics the complex properties of human languages, such as compositionality and basic interpretability (Kottur et al., 2017).

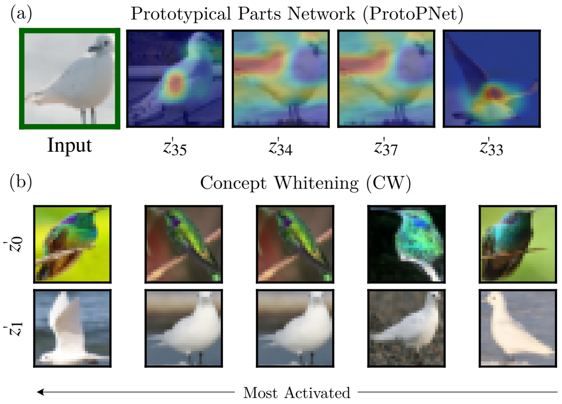

Figure 1: Approximating categorization ability in agents through disentangled representations (denoted $\mathbf{z}'$), generated by either (a) prototypical parts network (ProtoPNet) (Chen et al., 2019), where each dimension is the input's activation of a prototypical part previously seen by the agent, or (b) concept whitening (CW) (Chen et al., 2020), where each dimension corresponds to a previously-observed data category.

Despite recent progress, previous works have not investigated inter-agent communication in the context of abstract categorization, an ability that allows humans to represent new observations by recalling previous experiential knowledge of abstract concepts or classes (Hofstadter, 2007; Gentner, 2010). Abstract categorization in the human brain can be attributed to a combination of recognition and recall of episodic memory, although identifying the exact mechanism remains an open problem (Tulving, 2002). Due to the power and flexibility of categorization, theories of human intelligence often place *categorical reasoning* at the center of human cognition, e.g., the notion of analogical symbolic categorization by Gentner (2010), or categorization through situated templates, i.e., frames (and corresponding frame-systems) by Minsky (1988). In the study of artificial multi-agent systems, we propose

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4523 - 4540
July 10-15, 2022

to operationalize the notion of categorization, and subsequent ability to reason over new observations, through the use of *disentangled neural networks* as alternate image encoders in agents. Disentangled neural networks are a suitable choice since they can leverage a fixed number (k) of pre-defined or self-learned concepts to build representations of the observable environment. As illustrated in Figure 1, disentangled agents extract meaning from an observation by leveraging their past experiential knowledge, which is analogous to categorical reasoning in theories of human intelligence (Minsky, 1988; Gentner, 2010).

Due to the subjectivity of experiential knowledge, a natural consequence of the categorical reasoning theory is that two human minds may be heterogeneous, i.e., they do not share the same internal categorization of a situation or object. Natural language serves to mediate these cognitive differences, thus enabling the communication of ideas (Chandler, 2007). Under our synthetic analogue of communicating multi-agent systems, *how well can heterogeneous agents mediate their differences in categorization ability through the use of emergent language?* In this paper, we offer a differential analysis of agents leveraging heterogeneous techniques for abstract categorization, taking full advantage of disentangled representations as a computational analogue for categorical reasoning. Contrary to the scenario of different internal representations (Chaabouni et al., 2020), our agents can possess either different or identical means of categorical abstraction, which influences the course of their language evolution, e.g., improving compositionality or signaling success of the final protolanguage. Our analysis offers a substrate to answer **four main research questions** about heterogeneous multi-agent communication, revealing subsequent findings as a result:

Q1. What is gained or lost with agent heterogeneity? A1: We find that *heterogeneity is at odds with signaling performance*. Despite this, heterogeneous systems exhibit *better potential survival* through higher compositionality.

Q2. Does categorization power and heterogeneity affect signaling ability on novel objects? A2: Simpler disentangled agents with poor performance in supervised tasks can *outperform all other agents on novel objects* by up to 9% on signaling accuracy. In some cases, mismatched agents manage to improve compositionality score.

Q3. Can disentangled representations directly inform agent utterances? A3: Through our proposed Latent Self-attention (LSA) module, incorporating the disentangled representation into agent utterances can encourage input-message alignment and improve signaling accuracy by up to 27%.

Q4. Does increased categorization ability imply better communication? A4: Agents with complex concept realization are potentially poor receivers, despite a successful upstream classification task. Signaling can be performed up to 33% better with "simpler", i.e., smaller k, agents.

To encourage reproducibility, we share the code for our experiments online.[1]

2 Background

2.1 Multi-agent Referential Games

We model the commonly-used Lewis signaling game from cognitive science (Lewis, 1969; Skyrms and Press, 2010). A sender agent S is shown a target object, and must describe that object to a receiver agent R using a combination of discrete tokens from a fixed vocabulary $\mathcal{V}$. R then signals the object out of a set of candidate objects (called the *candidate set*). Our setup is based on that of Lazaridou et al. (2018), who investigated emergent language with the same game. The sender S and receiver R each use their own encoder (e.g., image CNNs) f^S and f^R to encode any pre-linguistic object $\mathbf{o}$ into an initial dense representation $\mathbf{z}_0$. The encoder is parameterized by agent-specific weights $\theta^{\cdot}_f$, e.g., $f^S(\mathbf{o}, \theta^S_f) = \mathbf{z}_0$, where S denotes the sender. Since the receiver processes the candidate set, which consists of multiple pre-linguistic objects, the receiver's dense representations form a matrix denoted Z. Given $\mathcal{V}$ and $\mathbf{z}_0$, the message is obtained by sampling tokens at each time step t from a recurrent policy defined as $g^S(\mathbf{z}_{t-1}, \theta^S_g) = \mathbf{m}_t$. The decoding process ends as soon as an end-of-sequence token or maximum length L is reached. In practice, the recurrent decoder is implemented as a recurrent neural network (RNN). The receiver's only input from the sender

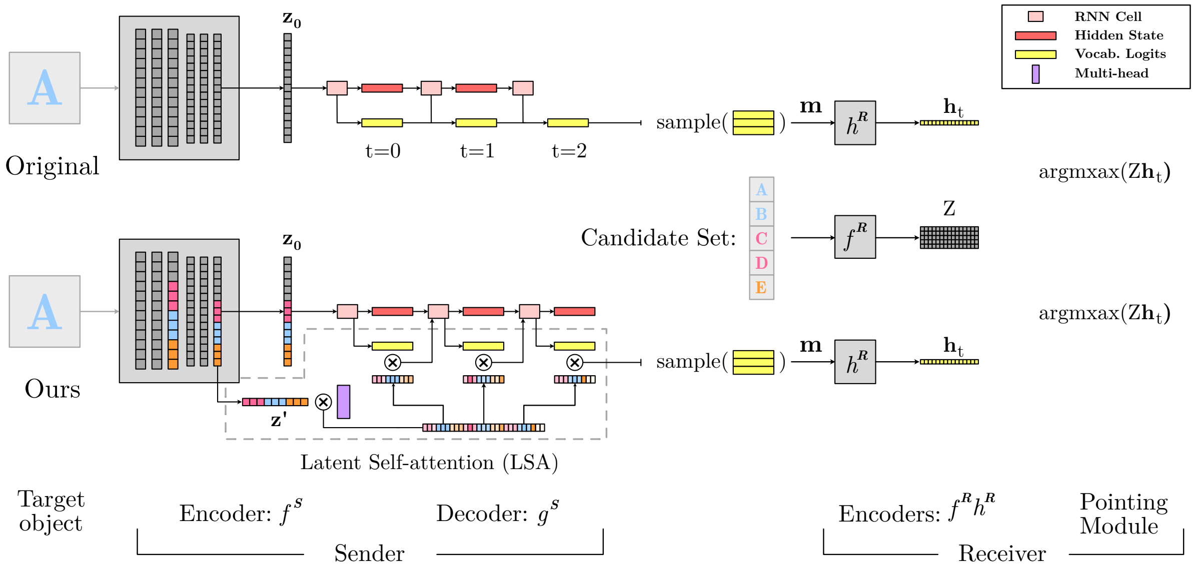

Figure 2: Whole-system perspective of our approach. (Top - Original) Traditional Sender-Receiver architecture for playing the Lewis Signaling game, with entangled deep networks as encoders f^S and f^R. (Bottom - Ours) Proposed approach which leverages disentangled networks to instantiate f^S or f^R (denoted by latent dimension colors matching candidate set colors), and our new Latent Self-Attention (LSA) module for senders, which enforces alignment between utterances (yellow rectangles) and the disentangled structure over time steps.

is message $\mathbf{m}$, which is encoded using encoder h^R at each time step as $h^R(\mathbf{m}_t, \theta_h^R) = \mathbf{h}_t$. Similar to Lazaridou et al. (2018), the receiver predicts the position of the described object within the candidate set as $\text{argmax}(Z\mathbf{h}_t)$. The agents are successful during a round of the signaling game if the receiver correctly predicts the index of the target object at the final time-step. The typical whole-system perspective of this game is shown in the top method (Original) of Figure 2.

2.2 Learning

We must jointly optimize sender and receiver policy weights $\Theta := \{\theta_g^S, \theta_h^R\}$, such that they minimize a game cost function $\mathcal{L}$, i.e., $\min_\Theta \mathcal{L}$. However, no weights are shared between sender and receiver during the game, since each agent has a uniquely instantiated encoder, and the sender can only transmit discrete signals to the receiver during the game. As a result the gradient of the game cost function is not defined, so it is common to rely on gradient estimation algorithms such as REINFORCE (Schulman et al., 2015) or continuous relaxations of the discrete channel, such as the Gumbel-Softmax estimator (Havrylov and Titov, 2017). We use the straight-through Gumbel-Softmax estimator due to its functional flexibility and performance improvement compared to REINFORCE at test time.

2.3 Disentangled Representations

A common technique is to employ intermediate feature representations of CNNs as the encoder function $f^{\cdot}$. The purpose of the encoder function is to approximate a mapping function from raw image space to a dense representation $\mathbf{z} \in \mathbb{R}^d$. In general, this representation is a point in lower-dimensional latent space that adequately describes useful conceptual priors of the data. From the perspective of model interpretability, it is expected that points closer together in latent space correspond to image samples which are conceptually similar, and likewise, dimensions in the latent space correspond to human understandable concepts (Rudin et al., 2022). However, it was shown that traditional CNN architectures learn latent representations which may not achieve concept separation (Chen et al., 2020), and in fact can activate dimensions for concepts that are completely unrelated (Zhou et al., 2015, 2018). Thus several methods have been proposed in order to *disentangle* the latent representation of deep networks into k categories or concepts. In this work, we propose to leverage two such methods, shown in Figure 1, in order to analyze the effect of categorization power in multi-agent communication: (a) Prototypical Parts Network (ProtoPNet) by Chen et al. (2019), which recalls prototypical parts of previously-observed images to describe the current one, and (b) Concept Whitening (CW) by Chen et al. (2020), which allocates an observed data class to each of the k dimensions in $\mathbf{z}'$.

3 Methodology

In order to answer the research questions in Section 1, we implement agents which can play a Lewis Signaling game (described in Section 2.1) using disentangled neural networks, e.g., Prototypical Parts Network (ProtoPNet) by Chen et al. (2019) and Concept Whitening (CW) by Chen et al. (2020). ProtoPNet is trained through unsupervised disentanglement, where given a pre-defined number of concepts per class (totaling k over all classes), it extracts prototypical image patches representing each concept. Concept Whitening instead aligns orthogonal directions in the encoded input's latent space with k pre-defined (supervised) concepts through training. In practice, CW can only align a subset of the pre-existing latent space dimensions, leaving the rest of the dimensions to handle residual information. To avoid ambiguity, we denote a sample from this aligned subspace as $\mathbf{z}' \in \mathbb{R}^k$. Since ProtoPNet learns a new latent space, it can be said to align the entire latent space to extracted concepts, thus $\mathbf{z}' = \mathbf{z}$. In either case, we use the latent vector $\mathbf{z}$ as the initial input to the sender agent's decoder, g^S. The whole-system perspective of this approach is shown in Figure 2, where the bottom case (Ours) corresponds to the use of disentangled networks, compared to a traditional approach above (Original). We can manipulate which agents are paired (e.g., ProtoPNet talking to CW) in order to simulate scenarios where two agents have different categorical reasoning. Likewise, we can model categorization *power* by increasing or decreasing the number of realized concepts k in disentangled agents. This enables the study of incongruous agents to answer Q1, Q2, and Q4.

3.1 Latent Self-attention (LSA)

Unfortunately, in order to synthesize the discrete message and eventually communicate with the receiver, the sender's disentangled representation must recurrently pass through the decoder g^S, which defines a different (entangled) latent space. This could mean the grounding to the original disentangled space is lost, since traditional RNN decoding is not aware of the encoder's concepts, thus we propose a module named Latent Self-Attention (LSA), inspired by the design of multi-head attention in transformer networks (Vaswani et al., 2017). We treat the aligned latent dimensions from $\mathbf{z}'$ as units that align one-to-one with the vocabulary logits of each time step, which can be weighted by a combination of aligned concepts. This mechanism is illustrated in the bottom method (Ours) of Figure 2, distinguished by the dashed rectangle. In order to satisfy the one-to-one alignment, we assume that (1) for the aligned representation $\mathbf{z}' \in \mathbb{R}^k$, $|\mathcal{V}| = k$, and (2) agents communicate with fixed message length L (due to discarding end-of-sequence token).

More formally, consider the recurrent output $\mathbf{z}_t \in \mathbb{R}^d$ from the sender decoder at time t. At each time step, the recurrent output is projected to dimension $|\mathcal{V}| = k$ using a fully-connected network, of which the output is treated as logits over vocabulary space (yellow rectangles), and is simply denoted $\mathbf{v}_t$. During the training process, the sender agent learns an L-head matrix $M \in \mathbb{R}^{k\times(L\cdot k)}$ (purple rectangle). which is softmaxed row-wise to obtain a weighting function over k concepts for each time step. The weighting of concepts is applied as $\mathbf{z}'^T M$ and reshaped to form matrix $M' \in \mathbb{R}^{L\times k}$. During decoding, the t-th row of M' is element-wise multiplied with $\mathbf{v}_t$. Through this mechanism, we can experimentally validate Q3 from Section 1. In our experiments, the receiver is implemented the same as previous works (shown as Original in Figure 2) (Lazaridou et al., 2017). To experimentally isolate the effect of the LSA module, we leave the receiver as-is, treating the disentangled networks as a drop-in selection for f^R. Incorporating the aligned vector $\mathbf{z}'$ into the pointing module is left for future work.

3.2 Metrics

We adopt standard metrics from the literature to quantify our study of Q1-Q4, and propose one new variant named disentangled similarity.

Receiver Accuracy (Recv. Acc.). A standard metric in the study of referential games is the communication success rate, i.e., the receiver's effective signaling accuracy on objects from a held-out test set (Skyrms and Press, 2010; Lazaridou et al., 2017). The metric is defined as Recv. Acc. $= \frac{\#\text{correct target objects}}{\#\text{total target objects shown}}$.

Compositionality (Top.Sim.) A common concern in the study of language emergence is compositionality of the proto-language, which can be described informally as the tendency to re-use vocabulary to describe similar objects (Brighton and Kirby, 2006; Chaabouni et al., 2020). Brighton and Kirby (2006) operationalized the measure of language compositionality with topographic similarity (Top.Sim.), the Spearman correlation between pairwise input distances and their corresponding pairwise message distances. We compute pairwise cosine distances between latent vectors $\mathbf{z}$ (inputs), and use edit distance to compute pairwise distance between messages. The reported Top.Sim. value is the Spearman correlation of distances (and where available, the associated p-value is reported).

Disentangled Similarity (Dis.Sim.) Since CW only aligns a subset of the latent space dimensions, it is possible that Top.Sim. will describe correlation to unaligned dimensions. Thus we complement the calculation of Top.Sim. with a new metric, disentangled similarity (Dis.Sim.), which only uses the aligned dimensions to calculate the pairwise input distances. In practice, this is implemented by calculating pairwise cosine distances over $\mathbf{z}'$ instead of $\mathbf{z}$. Consequently, the reported values for ProtoPNet will be equal to Top.Sim., since in that case $\mathbf{z} = \mathbf{z}'$.

4 Experiments

Preliminaries. To address Q1-Q4, we investigate mixed/same-encoder variants of multi-agent systems. Pairs of agents play the Lewis signaling game over five random seeds. Each agent in a two-player game is instantiated with distinct image encoder checkpoints, thus requiring ten image encoder checkpoints total for each variant (with each checkpoint using a different seed). In all reported results of the main text, we compare against fine-tuned ResNet-50 encoders (denoted ConvNet) as baselines (He et al., 2016), and subsequently use them as the base models for training ProtoPNet and CW variants. We offer supplemental results for VGG-16 (Simonyan and Zisserman, 2015) and DenseNet-161 (Huang et al., 2017) variants in Appendix A.4.1. With ResNet-50 as the base architecture, each disentangled variant has a similar parameter count on the order of 24M (reported in Appendix Table 12), thus any performance difference due to parameter count is negligible. We source prelinguistic objects from two benchmark image data sources: 10-class subsets of Caltech-UCSD CUB-200 (Wah et al., 2011) (denoted CUB10) and the entire few-shot mini-ImageNet dataset (Vinyals et al., 2016). For mini-ImageNet experiments, we train agents using the 64-class meta-training split, and report communication success rate (Recv. Acc.) on the meta-test set. For CUB10, we uniform randomly sample ten classes for each random seed, ensuring sender and receiver encoders are trained using the same subset. Our communicating agents are derived from those implemented in the publicly-available EGG framework (Kharitonov et al., 2019). We only employ our proposed LSA module for Q3 results, as it is not salient to Q1, Q2, and Q4. Details of training and hyper-parameters are given in Appendices A.1 and A.2, respectively.

Heterogeneous multi-agent systems (Q1): To examine the effect of heterogeneous multi-agent systems, we train nine permutations of mixed/same-encoder systems over five random seeds on CUB10 data (45 permutations total), setting $k = 100$ for ProtoPNet (default value from Chen et al. (2019)) and $k = 10$ for CW (using CUB10 classes as concept classes). In Figure 3, we initially compare the communication success rate (y-axis) over training epochs (x-axis), with each sub-figure corresponding to a fixed sender encoder architecture. The results exhibit a tendency for same-encoder systems to outperform their heterogeneous counterparts. This trend is evidenced by ConvNet-ConvNet systems in Figure 3a (red line) and ProtoPNet-ProtoPNet systems in Figure 3b (red line). CW models generally under-performed as receivers in Figure 3a-b, scoring 47.978 ± 14.325 and 42.001 ± 5.203 receiver accuracy, respectively. In terms of disentangled categorization power, ProtoPNet is the strongest with $k = 100$ and up to 93% accuracy on the CUB10 classification task (compared to 78% of CW).[2]

In Table 1 we report Top. Sim. and Dis. Sim. measures for systems from Figure 3 at the best epoch on the test set (according to Recv. Acc.). Although CW models generally under-performed in Figure 3, they score the best compositionality (0.405) paired with ConvNet receivers. This is followed by ConvNet senders (top three rows), with 0.316–0.363 Top.Sim. score. CW-ConvNet scored the highest Dis. Sim. score despite having a Recv. Acc. of 48.939 ± 22.226, aligning with Chaabouni et al. (2020), who found that compositionality does not necessarily emerge from generalization pressure. Based on Figure 3 and Table 3, we conclude:

---

[2] We provide encoder accuracy scores from the upstream classification task in Appendix Table 12.

CW	ProtoPNet	0.335 ± 0.056	0.052 ± 0.035
CW	ConvNet	0.259 ± 0.078	0.131 ± 0.012

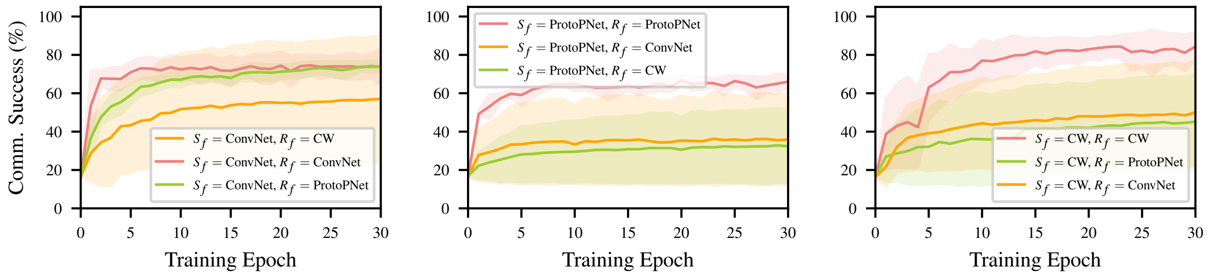
Table 2: Language compositionality under different encoder functions f for sender and receiver on mini-ImageNet test set (higher is better) . All measures were statistically significant with $p \approx 0$.

A1: Heterogeneous systems appear to underperform compared to same-encoder (e.g., homogeneous) systems, although the former can exhibit higher compositionality in the emerged language.

Categorization power on novel objects (Q2): To better understand the description of novel objects, in Figure 4 we repeat the previous Q1 experiment by swapping CUB10 for mini-ImageNet, whose test set consists of object classes not seen during training. We observe a similar trend that aligns with A1, except CW-CW outperforms other methods, at best scoring 85.585 ± 5.476 signaling accuracy compared to ConvNet-ConvNet (76.586 ± 6.400) and ProtoPNet-ProtoPNet (67.542 ± 3.001) despite realizing the least amount of concepts ($k = 10$) compared to ProtoPNet ($k = 100$). In some instances, e.g., ConvNet-ProtoPNet, the mismatched system can match the ConvNet-ConvNet performance within 3% accuracy.

In Table 2, we capture Top.Sim. and Dis.Sim. measures for mini-ImageNet. Despite only reaching a signaling accuracy of 33.328 ± 19.324, the highest Top.Sim. and Dis.Sim. scores (0.450) are realized by mismatched ProtoPNet-CW, thus compositionality was able to emerge despite the absence of generalization ability, as originally reported by Chaabouni et al. (2020). CW-CW and ProtoPNet-ProtoPNet scored similarly, obtaining 85.585 ± 5.476 and 67.542 ± 3.001 best epoch signaling accuracy, respectively. The best mixed-encoder system in Figure 4 was ConvNet-ProtoPNet (74.929 ± 3.079 accuracy), with a similarly high topographic similarity. We thus conclude:

A2: Heterogeneous systems evidence lower signaling performance compared to same-encoder baselines on novel objects, although the former are capable of improving the language compositionality. Holistically, disentangled networks either matched or outperformed the ConvNet baselines.



(a) (b) (c)

Figure 4: Comparison of communication success rate on mini-ImageNet few-shot testing data for permutations of a) ConvNet senders, b) ProtoPNet senders, and c) CW senders. Table 3: Comparison of LSA module, 1-Length utterance baseline, and normal RNNs on CUB10 testing data using ProtoPNet disentangled structure to weight the vocabulary ($|V| = 10$).

Informing design (Q3): Tables 3 and 4 examine the aggregate effect on CUB10 test data after integrating concept-aligned latent vectors into the agent utterance, using our LSA module described in Section 3.1. We report statistics using each system's best signaling checkpoint. Since $|V| = k$, for ease of comparison we set $|V| = k = 10$ for both ProtoPNet and CW, and constrain all agents to communicate with fixed message lengths $L = 10$. In addition to the normal variants, we compare against a baseline which uses the latent vector $\mathbf{z}'$ directly as the vocabulary logits to produce a single utterance, establishing the potential usefulness of the disentangled vector for communication. In the case of ProtoPNet in Table 3, we observe that the LSA variant is competitive with the ConvNet baseline, and slightly improves over the regular ProtoPNet baseline. In fact, the 1-Length baseline was sufficient for generalization (81.625 ± 1.031 signaling accuracy). In Table 4 for CW models, we observe that the LSA module had significant impact, increasing signaling accuracy from 52.523 ± 17.600 to 79.859 ± 2.417. Notably, the 1-Length utterance was scored 75.670 ± 1.820, indicating that the learned concepts were more useful than the proto-language created by the regular CW variant. Despite this, the result with CW+LSA evidences that incorporating both sources of information is beneficial for signaling performance.

Apart from incorporating new information into the sender's message decoding process, our proposed LSA module may enable better diversity in the agent utterances. Recall from Section 3.1 that the disentangled representation is linearly recombined and multiplied with message logits at each time-step, thus we posit that the LSA module encourages agents to use vocabulary that is otherwise ignored, which may explain the higher topographic similarity scores observed in Tables 3 and 4. We study this idea for CW in Figure 5 (and ProtoPNet in Appendix A.5.1) by taking the top-performing multi-agent system for ConvNet (top row), CW (middle row), and CW+LSA (bottom row). Each inset heat map is the activated vocabulary usage (x-axis) across input data classes (y-axis) in the CUB10 test set at a given time step for each figure column (i.e., columns $t = 0$ to $t = 10$), with the cumulative sum over time displayed in the rightmost column. We quantify the vocabulary usage by calculating normalized area (A) of shaded heatmap pixels, shown below each cumulative matrix. ConvNet and CW variants (top and middle row, respectively) evidence a tendency to re-use vocabulary at each time-step and do not explore different combinations of vocabulary across time steps. LSA variants (bottom row) instead have a higher distribution of vocabulary across time, which can be seen qualitatively by comparing early time-steps to

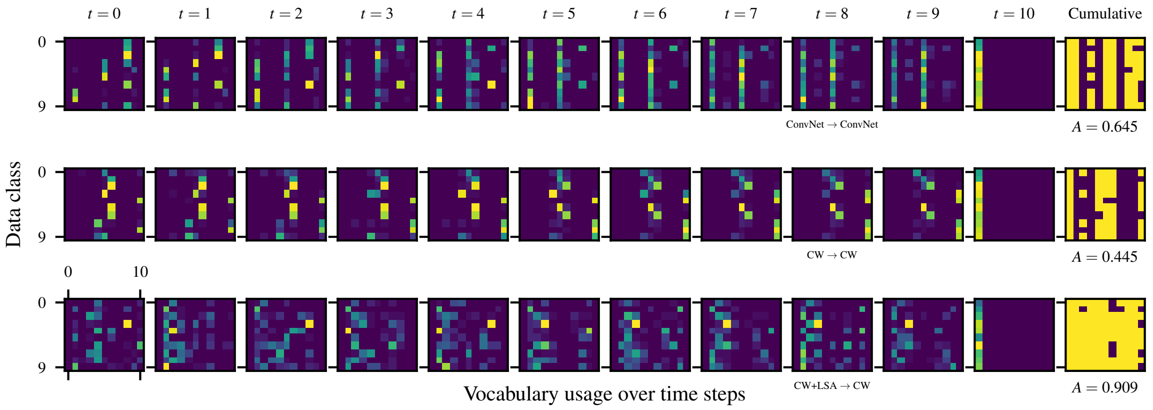

Figure 5: Heat-maps of the best-performing agent's vocabulary usage across time and data classes over the entire CUB10 test set for CW ($|V| = k = 10$), where agents communicate for ten time-steps (with end-of-sentence symbol '0' at the final time-step). The final column shows the cumulative sum over all time steps, subtitled by the normalized area of non-zero cells.

Sender Arch.	Top. Sim.	Dis. Sim.	Recv. Acc.
CW z' Utterance	0.325 ± 0.031	0.503 ± 0.006	75.670 ± 1.820
CW	0.278 ± 0.079	0.339 ± 0.044	52.523 ± 17.600
CW+LSA	0.266 ± 0.087	0.439 ± 0.076	79.859 ± 2.417
ConvNet	0.391 ± 0.055	-	86.753 ± 0.651

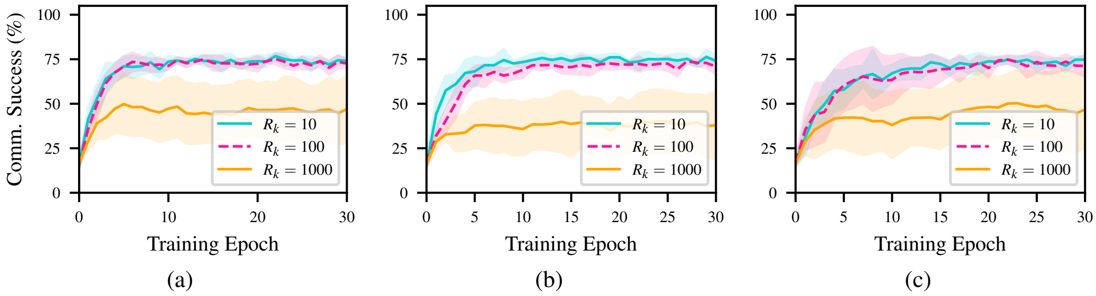
Table 4: Comparison of LSA module, 1-Length utterance baseline, and normal RNNs on CUB10 testing data using CW disentangled representation to weight the vocabulary ($|V| = 10$).

later time-steps. For example, the CW+LSA variant (bottom row) uses the vocabulary space $[6, 10)$ across classes early in the message, whereas this space is less used in later parts of the message (e.g., compare space $[6, 10)$ at $t = 2$ against $t = 9$). Notably, this space-swapping behavior can be seen in the ConvNet variant (top row), which causes higher cumulative area than the regular CW variant (middle row). In this analysis, CW+LSA obtains the highest cumulative area, so it can be said that this variant leverages the most tokens in the vocabulary, which may help explain the high disentangled similarity (0.439) in Table 4. We thus conclude:

A3: Incorporating the aligned subspace information into the vocabulary logits can have substantial impact on disentangled agents, remaining competitive with the non-disentangled ConvNet baseline accuracy, and improving or matching concept alignment (Dis. Sim.) compared to the baseline CW or ProtoPNet variant.

Categorization power and communication (Q4): Throughout the evaluation, we have compared against ProtoPNet ($k = 100$) and CW ($k = 10$). To better isolate the concept realization implied by k, we train ProtoPNet encoders for k values in $\{1, 10, 100\}$, then play signaling games with mixed ProtoPNet variations (denoting each as S_k or R_k) using fixed message length $L = 10$. We report the communication success rate over epochs in Figure 6, where each sub-figure is a fixed S_k. For $S_k = 10$ in Figure 6a, it is capable of generalization when paired with $R_k \in \{10, 100\}$, and suffers with $R_k = 1000$. Although $R_k = 1000$ under-performs in each case (Figures 6a-c), we observe that ProtoPNet encoders with $k = 1000$ have sufficient generalization in the upstream classification task, scoring at least 91% accuracy on CUB10 (we report all upstream scores in Appendix Table 13). This finding is nuanced by considering additional model architectures, such as DenseNet-161 in Appendix Section A.4.1, which shows that the complexity penalty observed in Figures 6a-c is mitigated by using the larger DenseNet-161 architecture (illustrated in Appendix Figure 10). Thus certain model architectures have unexpected benefits when deploying more complicated sender/receiver pairs. We thus conclude:

A4: Better concept realization does not always equate to better reception, despite performance on an upstream task such as classification. Otherwise, mixed-k agents have a tendency to generalize similarly, despite differences in the number of concepts.



(a) (b) (c)

Figure 6: Modulating the sender's categorization ability over realized concepts k for a) $S_k = 10$, b) $S_k = 100$, and c) $S_k = 1000$, when paired with receivers of varying categorization ability.

5 Related Work

The properties of language acquisition and emergence of its structural properties (e.g., compositionality and recursion) were investigated early on by Kirby (1998), who proposed that natural language can evolve to possess an internal structure as a result of observational learning. Due to the availability of complex real-world data and the scalability of deep learning, recent studies in language evolution have focused on artificial, yet realistic analogues of language evolution (Lazaridou et al., 2017; Havrylov and Titov, 2017; Lazaridou and Baroni, 2020). Notably, artificial language emergence has been shown to exhibit an inner structure as originally investigated by Kirby (1998), e.g., compositionality (Lazaridou et al., 2018; Chaabouni et al., 2020) and encoding preference (Chaabouni et al., 2019). During artificial language formation, agents modulate the structure of the language in service of jointly solving the learning task. For example, by negotiating symbols in the artificial language, Hagiwara et al. (2019) evidenced the ability for same-encoder agents to realize data categories in an unsupervised way, leading to a form of emergent categorization. The most related work to ours is by Chaabouni et al. (2020), who study concept formation in same-encoder artificial agents through the lens of disentanglement. However, their study focuses on proposing new metrics of compositionality in small-scale, categorical data. We instead investigate the case of mixed-encoder agents, each realizing a different level of disentangled categorization ability on large-scale RGB image data.

6 Conclusion

Our results suggest that agents in a cooperative game setting are capable of communication despite differences in concept realization. Despite this, we find that heterogeneous agents can be at odds with each other, often under-performing compared to their same-encoder variants. In this way, the reasoning process of an agent can largely determine its interaction with other agents. On novel objects, there is a notable advantage to using disentangled networks, and in some cases mismatched agents, evidenced by higher signaling success and language compositionality. Our proposed Latent Self-attention module illustrates the advantage of incorporating an agent's categorization power into utterances, evidenced by higher disentangled similarity in experiments. The interplay between disentanglement and interpretability of the emerged language will be investigated in future work.

A Appendix

A.1 Training details

In our experiments, every pair of sender and receiver is trained with distinct seeds, thus they never share the same checkpoint, only the training data. We use the publicly available code to train encoders from the respective authors (Chen et al., 2019, 2020). The underlying model for CW and ProtoPNet encoders is a standard ResNet-50 CNN (He et al., 2016) trained on the full-size ImageNet dataset[3], and fine-tuned on the respective dataset (CUB10 or mini-ImageNet) for five epochs over ten random seeds (i.e., unique sender/receiver seeds for five systems).

The Gumbel-Softmax estimator samples from the Gumbel distribution with a temperature term, which controls how similar the relaxation is to the true argmax distribution. As recommended by Havrylov and Titov (2017), we allow the sender agent to learn the inverse of the temperature in order to avoid manual tuning. Agent parameters are tuned by stochastic gradient descent (SGD) using the Adam optimization algorithm (Kingma and Ba, 2015). The recurrent sender decoder g and receiver encoder h are instantiated in practice with recurrent neural networks (RNNs) using LSTM cells. We leverage the NVIDIA DALI library to accelerate data loading through the use of GPGPU hardware. [4]

A.2 Hyperparameter selection

In order to achieve the best performance for agents and encoders, we performed a grid-search over the following hyperparameter combinations:

- Number of epochs in $\{30, 50, 100\}$,
- Hidden dimension of LSTM hidden state in $\{64, 128, 256\}$,
- Number of distractors in $\{1, 3, 5\}$,
- Message length L in $\{10, 100\}$,
- ConvNet classifier fine-tuning learning rate in $\{1^{-2}, 1^{-3}\}$,
- ProtoPNet dense representation network f learning rate in $\{1^{-4}, 1^{-5}\}$,
- ProtoPNet interface layer learning rate in $\{3^{-5}, 3^{-4}, 3^{-3}\}$,
- ProtoPNet prototype layer learning rate in $\{3^{-5}, 3^{-4}, 3^{-3}\}$,
- ProtoPNet classifier learning rate in $\{1^{-5}, 1^{-4}\}$,
- CW classifier and whitening layer learning rate $\{1^{-2}, 1^{-3}\}$,

---

[3] `https://pytorch.org/vision/stable/models.html`

[4] `https://github.com/NVIDIA/DALI`

- Sender learning rate in $\{1^{-5}, 1^{-4}, 1^{-3}, 1^{-2}\}$, and
- Receiver learning rate in $\{1^{-5}, 1^{-4}, 1^{-3}, 1^{-2}\}$.

As a result of the grid-search, we selected the best performing hyperparameter combination which balanced training time and communication success rate performance (e.g., receiver signaling accuracy). This combination is shown in Table 5.

A.3 Hardware description

All experiments were performed on an NVIDIA DGX-2 compute node equipped with 16 NVIDIA Tesla V100 Tensor Core GPUs, high-speed NVMe flash storage, 1TB main system memory, and 40 Intel Xeon Platinum CPU cores.

A.4 Supplemental Results

A.4.1 Results on VGG-16 and DenseNet-161 variants

The disentangled representations discussed in the main text are not restricted to residual networks such as ResNet-50, in fact they are flexible enough to interact with other network designs such as VGG-16 (Simonyan and Zisserman, 2015) and DenseNet-161 (Huang et al., 2017). To expand the empirical contribution, we provide additional results addressing Q1, Q3, and Q4 of the main text using disentangled image encoders built on top of VGG-16 and DenseNet-161, as well as their non-disentangled baselines.

Q1 (VGG-16 & DenseNet-161). In Figures 7 and 8, we see the same general tendency for same-encoder systems to either match or outperform the mixed-encoder versions. This is evidenced on VGG-16 (Figure 7, red line) across each sender variant, with CW being a notable exception due to performing similarly between CW-CW and CW-ConvNet variants. On DenseNet-161, we observe a failure mode for CW (Figure 8c) due to low accuracy on the upstream task (Table 16). We experimentally observed that CW causes training instability for DenseNet-161 on CUB10. In this failure mode, there is little difference between same- and mixed-encoder agent systems, which may indicate that the performance discrepancies are tied to success of the upstream task.

As in the main text, we provide measures of the language compositionality under different encoder variants for VGG-16 (Table 6) and DenseNet-161 (Table 7). In this context, topographic similarity or disentangled similarity for mixed-encoder systems can be higher in some cases (e.g., VGG-16 CW-ConvNet Dis. Sim. of 0.435 compared to 0.401 of CW-CW in Table 6, or VGG-16 ConvNet-CW Top.Sim. of 0.312 compared to 0.305 of ConvNet-ConvNet). In general, same-encoder variants evidence a tendency to outperform the mixed-encoder variants, invariant to the choice of underlying architecture. Returning to the failure mode of DenseNet-161 CW seen previously, we observe that the topographic similarity scores for DenseNet-161 CW variants in Table 7 are competitive with models that did not experience failure, e.g., the CW-CW system scored Top.Sim. of 0.391 whereas ProtoPNet-ProtoPNet scored 0.369. This is further evidence of the effect observed by Chaabouni et al. (2020), which is that compositionality can emerge despite lack of generalization ability.

Q3 (VGG-16 & DenseNet-161). We investigated Q3 under the same constraints of Section 4, but instead using VGG-16 (Tables 8 and 9) and DenseNet-161 (Tables 10 and 11) instead of ResNet-50. We observe the general tendency from Section 4 for RNN+LSA variants to either match or outperform the standard RNN variants, whilst remaining competitive with the non-disentangled ConvNet baseline. The exception to this trend is the failure mode of DenseNet-161 CW variants (Table 11), despite evidencing higher disentangled similarity with low generalization ability (e.g., Dis.Sim of 0.785 for RNN+LSA with 45.487% receiver accuracy).

Q4 (VGG-16 & DenseNet-161). Under the constraints of Section 4, we repeat the experiment using encoders based on VGG-16 (Figure 9) and DenseNet-161 (Figure 10). Notably, variants based on VGG-16 exhibit the same trend from Section 4 for more complex $k = 1000$ agents to perform poorly as receivers (orange lines in Figure 9). The results for DenseNet-161-based variants introduce nuance to this trend, since complex receivers in this setup perform within the random variance of other receivers (i.e., orange lines in Figure 10 being within blue and pink shading). Referencing the upstream performance of each variant in Tables 13, 15, and 17 offers some insight. First, we observe that DenseNet-161 variants are the best performing variants of ProtoPNet (up to 97% accuracy compared to 90% and 95% of VGG-16 and

ResNet-50, respectively), and second, DenseNet-161 requires more model parameters (on the order of 26M compared to 15M and 24M of VGG-16 and ResNet-50 variants). Given this result, it may be possible to mitigate the complexity penalty observed in Section 4 by leveraging parameter-heavy densely-connected neural networks, although the impact on smaller models is notable. The effect of model parameterization on the language evolution offers an interesting direction for future work.

A.4.2 Upstream task metrics

In Table 12 we provide the accuracy score for each ResNet-50 encoder's upstream classification task on CUB10 data. We use the training code open-sourced by the respective paper authors (Chen et al., 2019, 2020). Table 13 gives the accuracy scores for ProtoPNet encoders used in Section 4. The same scores are provided for supplemental variants corresponding to VGG-16 (Tables 14 and 15) and DenseNet-161 (Tables 16 and 17).

A.5 Supplemental Analysis

A.5.1 LSA vocabulary usage

In Figure 11 we repeat the same experiment from Section 4, this time for ProtoPNet variants. Although the ProtoPNet+LSA variant (bottom row) does not score the highest cumulative vocabulary usage compared to the ConvNet variant (0.445 and 0.645, respectively), it encourages more exploration of the vocabulary compared to the regular ProtoPNet variant (0.327). We observe the same trend with CW in Figure 5, which suggests the LSA mechanism can enable better vocabulary diversity on multiple types of disentangled representations.

A.5.2 LSA concept alignment

Our proposed LSA module requires the disentangled sender agent to weight their utterances by the concept weight matrix M', which is obtained by

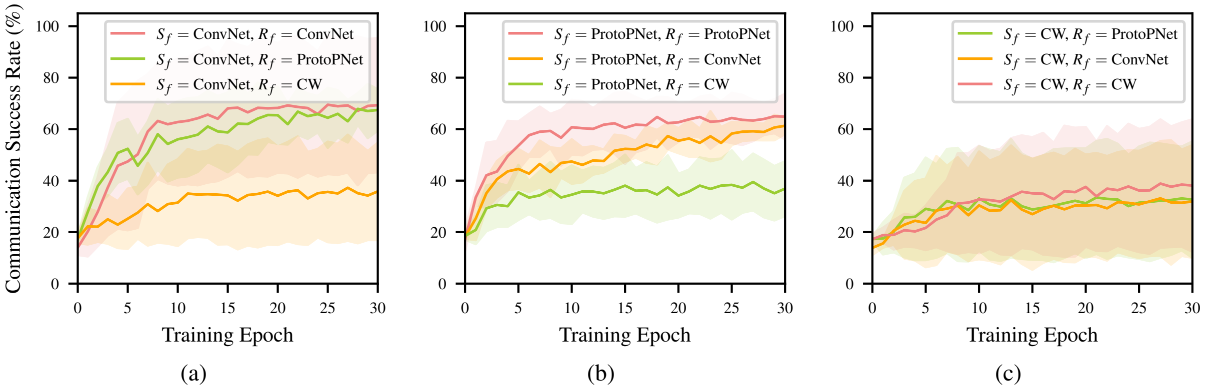

Figure 8: Comparison of communication success rate on CUB10 testing data for permutations of a) ConvNet senders, b) ProtoPNet senders, and c) CW senders, using image encoders based on DenseNet-161. Shaded regions denote standard deviation over five random seeds (each swapping in a new CUB10 test split, sender encoder checkpoint, and receiver encoder checkpoint), with $L = 100$.

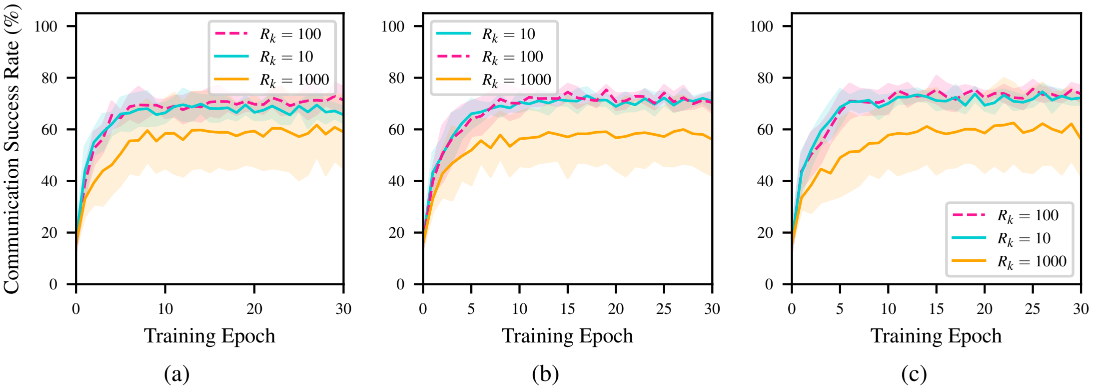

Figure 9: Modulating the sender's categorization ability over realized concepts k for a) $S_k = 10$, b) $S_k = 100$, and c) $S_k = 1000$, when paired with receivers of varying categorization ability and using VGG-16 as the base encoder architecture.

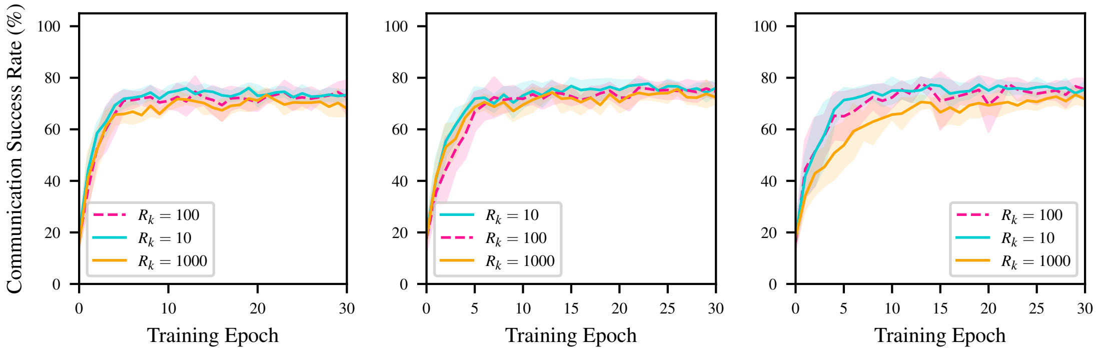
the product of the learned L-head matrix M and initial disentangled representation z' (as discussed in Section 3.1). This design enables a qualitative analysis of the agent's concept activation at each time step, i.e., at some time t, we can plot the image that corresponds to the highest-weighted dimension in that time-step, $\max(M'[t])$. This is done for six images across three data classes for the best performing LSA+ProtoPNet model (Figure 12) and LSA+CW model (Figure 13) from Section 4. We observe that during the decoding of utterances, the most active concept does not always correspond to visual semantic features of the input data class, e.g., brown and black textures are not always present in the top two rows. Instead, the sender agent may rely on an arbitrary positional encoding of known concepts to describe certain visual features. This is evident across both ProtoPNet and CW models. A notable effect of the LSA module on CW variants is an increased exploration of the agent vocabulary, as discussed in Section 4, which can be observed in Figure 13 by the lack of repetition between top categories, whereas in Figure 12 we note the same concept is often repeated several times within the same message. Given the qualitative results, we posit that agents rely on an encoding preference that can be considered incongruent with realized concepts of the disentangled models. For example, agents might rely on the position of a concept in the utterance, rather than the concept itself, to capture information that leads to better decisions by the receiver. The LSA module enables a first look into the connection between these grounded concepts and their recall during agent utterances, the enforcement of which offers an exciting direction for future work.



(a) (b) (c)

Figure 10: Modulating the sender's categorization ability over realized concepts k for a) $S_k = 10$, b) $S_k = 100$, and c) $S_k = 1000$, when paired with receivers of varying categorization ability and using DenseNet-161 as the base encoder architecture.

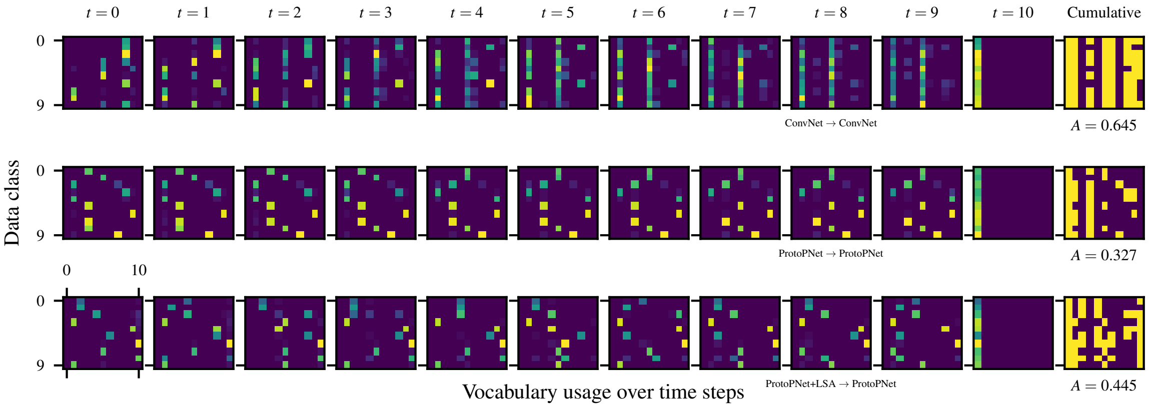


Figure 11: Heat-maps of the best-performing agent's vocabulary usage across time and data classes over the entire CUB10 test set for ProtoPNet, corresponding to experiments based on ResNet-50 in Section 4, where $|V| = k = 10$, and agents communicate for ten time-steps (with end-of-sentence symbol '0' at the final time-step). The final column shows the cumulative sum over all time steps, subtitled by the normalized area of non-zero cells.

Show, Don't Tell: Demonstrations Outperform Descriptions for Schema-Guided Task-Oriented Dialogue

Abstract

Building universal dialogue systems that operate across multiple domains/APIs and generalize to new ones with minimal overhead is a critical challenge. Recent works have leveraged natural language descriptions of schema elements to enable such systems; however, descriptions only indirectly convey schema semantics. In this work, we propose *Show, Don't Tell*, which prompts seq2seq models with a labeled example dialogue to *show* the semantics of schema elements rather than *tell* the model through descriptions. While requiring similar effort from service developers as generating descriptions, we show that using short examples as schema representations with large language models results in state-of-the-art performance on two popular dialogue state tracking benchmarks designed to measure zero-shot generalization - the Schema-Guided Dialogue dataset and the MultiWOZ leave-one-out benchmark.

1 Introduction

Task-oriented dialogue (TOD) systems need to support an ever-increasing variety of services. Since many service developers lack the resources to collect data and train models, zero and few-shot transfer to unseen services is critical to the democratization of dialogue agents.

Recent approaches to generalizable TOD systems primarily rely on combining two techniques: large language models like BERT (Devlin et al., 2019) and T5 (Raffel et al., 2020), and schema-guided modeling - i.e. using natural language descriptions of schema elements (intents and slots) as model inputs to enable transfer to unseen services (Rastogi et al., 2020a,b). Models combining the two currently hold state-of-the-art (SotA) results on dialogue state tracking (DST) (Heck et al., 2020; Lee et al., 2021a; Zhao et al., 2022).

However, description-based schema representations have some drawbacks. Writing precise natural language descriptions requires manual effort and can be difficult to write succinctly. Also, descriptions only provide indirect supervision about how to interact with a service compared to an example. Furthermore, Lee et al. (2021b) showed that schema-guided DST models are not robust to variations in schema descriptions, causing significant quality drops.

We propose using a single dialogue example with state annotations as an alternative to the description-based schema representation, similar to one-shot priming (Brown et al., 2020) - an approach we call *Show, Don't Tell (SDT)*. Through demonstration, we **show** models the schema semantics rather than **tell** them through natural language descriptions, as seen in Figure 1. SDT achieves SotA accuracy and generalization to new APIs across both the Schema-Guided Dataset (SGD) (Rastogi et al., 2020b) and MultiWOZ Leave-One-Out (Budzianowski et al., 2018; Lin et al., 2021b) benchmarks, while being more data-efficient and robust to schema variations.

2 Show, Don't Tell

Following SoTA models, we pose DST as a seq2seq task (Wu et al., 2019; Zhao et al., 2021a) and finetune T5 on DST datasets. The model input consists of a *prompt* to convey API semantics and *context* to represent the current dialogue instance. The *target* contains ground truth belief states corresponding to the context. We compare against two baselines:

- **T5-ind** (Lee et al., 2021a): Model input comprises *a single slot description* for the prompt, concatenated with the dialogue history as the context. The target is the value of the single slot in the dialogue state. Model inference is invoked once per slot - i.e. values for different slots are independently decoded.

SDT-seq
$\mathtt{P}^{\mathtt{seq}}$ = [ex] [user] I want to make a payment to Jerry for $82 from my mastercard [system] Confirming you want to pay Jerry $82 with your credit card yes? [user] Yes that's right, make the transaction private too [slot] amount=$82 receiver=Jerry private_visibility=a of a) True b) False payment_method=a of a) credit card b) debit card c) app balance

Figure 1: Illustration of all prompt formats for a payment service for both description-based and *Show, Don't Tell* models with independent (top) and sequential (bottom) decoding of dialogue state.

- **T5-seq** (Zhao et al., 2022): Model input comprises the descriptions of *all slots* as the prompt, concatenated with the dialogue history as the context. The target is the sequence of slot-value pairs in the dialogue state - i.e. the dialogue state is decoded sequentially in a single pass.

We modify the prompt formats above to utilize demonstrations instead of descriptions as described below and illustrated in Figure 1.

- **SDT-ind**: A *prompt* $\mathtt{P}_\mathtt{i}^{\mathtt{ind}}$ comprises a single example utterance and the ground truth slot-value pair formatted as

  $$\mathtt{P}_\mathtt{i}^{\mathtt{ind}} = [\mathtt{ex}]; \mathtt{u}_\mathtt{i}^{\mathtt{ind}}; [\mathtt{slot}]; \mathtt{sv}_\mathtt{i}$$

  where $\mathtt{u}_\mathtt{i}^{\mathtt{ind}}$ is a user utterance where slot $\mathtt{i}$ is active/not null and $\mathtt{sv}_\mathtt{i}$ is the slot-value pair. $[\mathtt{ex}]$, $[\mathtt{slot}]$ are special delimiter tokens, and ; denotes concatenation.

- **SDT-seq**: A *prompt* $\mathtt{P}^{\mathtt{seq}}$ comprises a single labeled dialogue formatted as:

  $$\mathtt{P}^{\mathtt{seq}} = [\mathtt{ex}]; \mathtt{u}_1; ...; \mathtt{u}_\mathtt{n}; [\mathtt{slot}]; \mathtt{sv}_1; ...; \mathtt{sv}_\mathtt{m}$$

  where $\mathtt{u}_\mathtt{j}$ is an utterance, and other symbols are explained in the SDT-ind section above. In simple terms, the prompt is constructed by concatenating all utterances in an example dialogue followed by all slot-value pairs in the dialogue state.

In both the T5-* and SDT-* approaches, the context is the serialized dialogue history for the current dialogue instance. The final model input is formed by concatenating the prompt and the context strings, and the target string is the same as T5-*, containing only a single slot value for *-ind models and the entire turn's belief state for *-seq models.

For both T5-* and SDT-*, we enumerate the categorical slot values in multiple-choice format in the prompt and task models with decoding the multiple choice letter corresponding to the correct categorical value.

More details on prompt design and its impact on performance are provided in Appendix A.

Creating prompt examples: It is imperative that SDT prompts contain enough information to infer the semantics for all slots in a schema. For SDT-ind, we create individual utterances that showcase a single slot. For SDT-seq, we create example dialogues where all slots in the schema are used.

Multi-domain examples: It is not feasible to construct multi-domain demonstrations for every combination of domains. Thus, we stick to single-domain SDT prompts and create separate training instances for each domain present in a multi-domain dialogue turn; for inference, we run inference once for each domain and combine the results.

3 Experimental Setup

Datasets: We conduct experiments on two DST benchmarks: Schema-guided Dialogue (SGD) (Rastogi et al., 2020b) and MultiWOZ 2.1 (Budzianowski et al., 2018; Eric et al., 2020). For MultiWOZ, we evaluate on the leave-one-out setup (Wu et al., 2019; Lin et al., 2021a), where models are trained on all domains but one and evaluated on the holdout domain. Additionally, we apply the recommended TRADE pre-processing script[1] for fair comparison with other work. For both datasets, we created concise example dialogues modeled after dialogues observed in the datasets.

Implementation: We train SDT models by fine-tuning pretrained T5 1.1 checkpoints. For SDT-seq, we select one example dialogue for each service to create a prompt and use that prompt across all dialogue instances of that service, across training and evaluation. We do the same for SDT-ind but create one prompt per slot instead of per service. Unless otherwise noted, all T5-based models are based on T5-XXL (11B parameters). Appendices B and C contain more details on training and baselines respectively.

4 Results

4.1 SGD Results

Table 1 contains results on the SGD test set. SDT-seq achieves the highest JGA by +1.1%, outperforming the description-based T5-* models, particularly on unseen services. SDT-ind is comparable to its counterpart T5-ind and better than T5-seq.

Since SDT results vary with the choice of example dialogue provided in the prompt, we created 5 different versions of prompts for each service using different examples. We report the average JGA across the 5 versions and the 95% confidence intervals using the Student's-t distribution.

We hypothesize that the main advantage of SDT is that the schema semantics are conveyed via demonstration, which is more similar in form to the end task of state tracking and more informative than descriptions. On the other hand, natural language descriptions can be viewed as an intermediary that models must interpret in order to achieve the end goal of slot value prediction.

We see that SDT-seq outperforms SDT-ind and posit that this is because the full dialogue prompts in SDT-seq demonstrate more complex linguistic patterns (e.g. coreference resolution, long term dependencies) than the single utterance prompts of SDT-ind. On the other hand, we believe T5-seq does not outperform T5-ind because no additional information is conveyed to the model through concatenating independent descriptions. All-else-equal, decoding all slots in one pass is more challenging than decoding each slot independently.

Model	All	Seen	Unseen
MRC+WD-DST*	86.5	92.4	84.6
T5-seq	86.4	**95.8**	83.3
T5-ind	87.7	95.3	85.2
SDT-ind	87.5±0.9	95.2±0.7	85.0±1.4
SDT-seq	**88.8±0.5**	**95.8±0.2**	**86.4±0.7**

Table 1: SDT achieves state-of-the-art JGA as evaluated on the SGD test set, performing especially well on unseen services. *Data augmentation/special rules applied.

Model	Attraction	Hotel	Restaurant	Taxi	Train	Avg
TRADE	20.1	14.2	12.6	59.2	22.4	25.7
SUMBT	22.6	19.8	16.5	59.5	22.5	28.2
TransferQA	31.3	22.7	26.3	61.9	36.7	35.8
T5-seq	**76.1**	28.6	69.8	**87.0**	60.4	64.4
SDT-seq	74.4	**33.9**	**72.0**	86.4	**62.9**	**65.9**

Table 2: SDT-seq outperforms T5-seq on the MultiWOZ 2.1 cross-domain (leave-one-out) benchmark. Results for TRADE, SUMBT, and TransferQA from Kumar et al. (2020), Campagna et al. (2020), and Lin et al. (2021a), respectively.

We also experimented with using up to 5 example dialogues in each prompt of SDT-seq, but accuracy did not increase.

4.2 MultiWOZ Results

Table 2 summarizes results for the MultiWOZ 2.1 leave-one-out setup. SDT-seq outperforms T5-seq by +1.5% overall and in 3 of the 5 domains, achieving state-of-the-art performance.

4.3 Impact of Model Size

T5's XXL size (11B parameters) may be unsuitable in resource-constrained settings. To understand how the the impact of model size, we measure SDT's performance on SGD across multiple T5 sizes in Table 3. For base and large sizes, both SDT variations offer higher JGA than their description-based counterparts, possibly due to smaller T5 models being less capable of inferring unseen slots with just a description, whereas SDT models provide more direct supervision in contrast. Additionally, SDT-ind outperforms SDT-seq for both the smaller sizes, potentially due to SDT-seq's prediction task being more complex than that of SDT-ind.

4.4 Data Efficiency

To examine the data efficiency of SDT models, we also experiment with training SDT-seq with 0.16% (10-shot), 1%, and 10% of the SGD training data

---

[1] `https://github.com/budzianowski/multiwoz#dialog-state-tracking`

Model	Base (250M)	Large (800M)	XXL (11B)
T5-seq	72.9	80.0	86.4
T5-ind	72.6	82.2	87.7
SDT-ind	**78.2±0.6**	**83.7±0.8**	87.5±0.9
SDT-seq	76.3±1.6	83.2±0.6	**88.8±0.5**

Table 3: SGD test set JGA across T5's Base, Large, and XXL sizes. SDT's advantage is especially prominent on smaller model sizes.

and evaluating on the entire test set. For 10-shot, we randomly sample 10 training dialogues from every service; for 1% and 10%, we sample uniformly across the entire dataset. SDT-seq demonstrates far higher data efficiency than T5-seq (Table 4), indicating that SDT is more suitable for bootstrapping dialogue systems with a limited budget for collecting training data.

Model	10-shot	1%	10%
T5-seq	51.0	79.4	83.0
SDT-seq	**70.7**	**84.5**	**87.4**

Table 4: Data efficiency experiments on the SGD test set. SDT-seq's example-based prompt approach is more suited to low resource settings than T5-seq's description-based prompts.

4.5 Robustness

Large LMs are often sensitive to the choice of prompt (Zhao et al., 2021b; Reynolds and McDonell, 2021). To this end, we evaluate SDT-seq on the SGD-X (Lee et al., 2021b) benchmark, comprising 5 variants with paraphrased slot names and descriptions for every schema (Appendix Figure 4). Note that SDT-seq only makes use of slot names, so variations in description have no effect on it.

Table 5 shows SDT-seq achieves the highest average JGA ($JGA_{v_{1-5}}$) and lowest schema sensitivity (SS_{JGA}, lower value indicates higher robustness), making it the most robust of the compared models. While the JGA decline indicates that SDT-seq is somewhat sensitive to how slot names are written, when compared to a variant of T5-seq (Zhao et al., 2022) that only uses slot names, it is still more robust based on the schema sensitivity, and the relative drop in JGA is nearly equal.

Model	JGA_{Orig}	$JGA_{v_{1-5}}$	$Diff_{rel}$	SS_{JGA}
SGP-DST*	60.5	49.9	-17.5	51.9
T5-ind$_{base}$*	72.6	64.0	-11.9	40.4
T5-seq (name)★	79.7	73.0	**-8.4**	35.0
T5-seq	86.4	77.8	-10.0	27.0
SDT-seq	**88.8**	**81.2**	-8.6	**24.1**

Table 5: Robustness evaluation on the SGD-X test sets. *Results from Lee et al. (2021b). ★Result of using T5-seq with only slot names and no descriptions, from Zhao et al. (2022).

5 Discussion

5.1 Writing descriptions vs. demonstrations

The information provided to SDT is not identical to what is provided to typical schema-guided models, as SDT exchanges natural language descriptions for a demonstration of identifying slots in a dialogue. However, we argue that from the developer standpoint, creating a single example is similar in effort to writing descriptions, so we consider the methods comparable. Creating the SDT-seq prompts for all 45 services in SGD took an experienced annotator ∼2 hours, compared to ∼1.5 hours for generating all slot descriptions. SDT-ind prompts are even simpler to write because they relax the requirement for creating a coherent dialogue involving all slots.

Descriptions can sometimes be easier to generate than a succinct dialogue that covers all slots. However, given the performance gain, example-based prompts may be a better choice for many settings, especially for smaller model sizes and low resource settings where the gain over description-based prompts is more pronounced.

5.2 Descriptions plus demonstrations

We tried combining both descriptions and a demonstration in a single prompt to try to further improve performance. However, results showed that this did not improve upon using demonstrations alone (see Appendix Table A1 for details).

We hypothesize that demonstrations, along with slot names, already convey slot semantics sufficiently, rendering descriptions extraneous. However, given that using slot names alone underperforms using descriptions (Zhao et al., 2022), the improvement SDT exhibits over using descriptions does not result purely from the use of slot names.

5.3 Prompting vs. traditional finetuning

To understand the impact of using a single demonstration as a prompt vs. traditional finetuning, we finetune T5-seq an additional time on the same set of dialogues used in SDT-seq prompts; therefore it has access to both slot descriptions as well as a single demonstration for each service. In this case, T5-seq is provided strictly more information than

Example Dialogue	**Predictions**
1. Disambiguating similar slots [user] I need to find tickets to **Anaheim**, CA. [system] When would you like to travel, and where are you going to? [user] Traveling to **Sacramento** on the 4th.	T5-seq: *to=Sacramento, from=Anaheim* SDT-seq: *to=Anaheim, from=Sacramento*
2. Handling unseen slots [user] Can you please add an alarm called Grocery run.	T5-seq: *new_alarm_name=None* SDT-seq: *new_alarm_name=Grocery run*
3. Predicting categorical values not seen in prompt [user] I like Broadway shows and want to see one on Tuesday next week.	T5-seq: *event_type=theater* SDT-seq: *event_type=music*

Figure 2: Comparing common error patterns made by T5-seq vs. SDT-seq. Correct and incorrect predictions colored in red and blue, respectively.

SDT-seq. T5-seq with finetuning obtains a JGA of 87.7% on SGD, on par with T5-ind but still lower than SDT-seq, suggesting that, when scarce, dialogue examples are better used as prompts (Le Scao and Rush, 2021).

Interestingly, finetuning on up to 5 dialogue examples per service did not improve performance after the first example (Appendix Figure 3).

5.4 Error analysis

Figure 2 compares some common error patterns made by T5-seq vs. SDT-seq. The patterns suggest that SDT's demonstrations are helpful when multiple slots in the same domain are similar to each other (#1 in Figure 2) and when slots dissimilar from those seen in training are introduced (#2). However, SDT can sometimes be limited by its prompt. For instance, in #3 it has only seen the "music" value for the *event_type* slot in the prompt, potentially resulting in under-predicting the categorical values not featured in the example dialogue (e.g. "theater").

6 Related Work

Prior approaches focused on framing DST as question answering (Ruan et al., 2020; Ma et al., 2019; Zhang et al., 2021). Many MultiWOZ cross-domain models leverage slot names/descriptions (Wu et al., 2019; Lee et al., 2019; Lin et al., 2021a).

Pretrained generative LLMs (Raffel et al., 2020; Brown et al., 2020) have enabled framing NLP tasks as seq2seq problems. Some DST papers (Zhao et al., 2021a; Feng et al., 2021) look at settings with no train-test discrepancy. Many studies explore the efficacy of task-specific prompts (Jiang et al., 2020; Liu et al., 2021). Madotto et al. (2020) and prime LMs with examples for dialogue tasks, but without finetuning. Wei et al. (2021) finetunes language models to teach them to use prompts to generalize across NLP tasks.

7 Conclusion

We study the use of demonstrations as LM prompts to convey the semantics of APIs in lieu of natural language descriptions for TOD. While taking similar effort to construct, demonstrations outperform description-based prompts in our experiments across DST datasets (SGD and MultiWOZ), model sizes, and training data sizes, while being more robust to changes in schemata. This work provides developers of TOD systems with more options for API representations to enable transfer to unseen services. In future work, we would like to explore this representation for other TOD tasks (e.g. dialogue management and response generation).

8 Ethical Considerations

We proposed a more efficient way of building TOD systems by leveraging demonstrations in place of descriptions, leading to increased accuracy with minimal/no data preparation overhead. We conduct our experiments on publicly-available TOD datasets in English, covering domains which are popular for building conversational agents. We hope our work leads to building more accurate TOD systems with similar or less overhead and encourages further research in the area.

A Prompt Design

We experimented with various formats for the SDT prompt before arriving at the final format. Below, we list alternative designs that we tried and their impact on JGA, as evaluated on the SGD test set.

A.1 Categorical value strings vs. multiple choice answers

We found that JGA dropped -2% when we tasked the model with decoding categorical values instead of multiple choice answers - e.g. `payment_method=debit card` instead of `payment_method=b` (where `b` is linked to the value `debit card` in the prompt as described in Section 2). When tasking the model to decode categorical values, it would often decode related yet invalid values, which we counted as false in our evaluation. For example, instead of `debit card`, the model might decode `bank balance`.

A.2 Slot IDs vs. slot names

When we delexicalized slot names with slot IDs, JGA dropped -5%. One downside of this approach is that the model lost access to valuable semantic information conveyed by the slot name. Another downside is that the model could not distinguish two slots that had the same value in the prompt. For example, if the prompt was "I would like a pet-friendly hotel room with wifi" and the corresponding slots were `1=True` (has_wifi) and `2=True` (pets_allowed), it is ambiguous which ID refers to which slot.

The potential upside of using slot IDs was to remove dependence on the choice of slot name, but this did not succeed for the reasons above.

A.3 Decoding active slots vs. all slots

We experimented with training the model to only decode active slots rather than all slots with `none` values when they were inactive. JGA dropped -0.4%, which we hypothesized might be a result of greater dissimilarity between the slot-value string in the prompt (which contained all slots by construction) and the target, which only contained a subset of slots.

A.4 In-line annotations vs. dialogue+slots concatenated

We hypothesized that bringing the slot annotation in the prompt closer to where it was mentioned in the dialogue might help the model better understand the slot's semantic meaning. We changed the format as follows:

- Original: `[ex] [user] I would like a pet-friendly hotel room with wifi [system] I found ...` **`[slot] has_wifi=True`**
- In-line: `[ex] [user] I would like a pet-friendly hotel room with wifi` **`[has_wifi=True]`** `[system] I found ...`

However, this decreased JGA by more than -20%. We hypothesized that this was likely due to a mismatch between the prompt's annotations and the target string format, which we did not change.

B SDT Model Details

We used the publicly available T5 checkpoints[2]. For all experiments, we used a sequence length of 2048, 10% dropout and a batch size of 16. We used a constant learning rate of $1e-3$ or $1e-4$. All models were trained for 50k steps or until convergence, and each experiment was conducted on either 64 or 128 TPU v3 chips (Jouppi et al., 2017).

C Baseline Models

For SGD, we compare against SGP-DST (Ruan et al., 2020), MRC+WD-DST (Ma et al., 2019), T5-seq (Zhao et al., 2022) and T5-ind (Lee et al., 2021a).

For MultiWOZ, we compare against TRADE (Wu et al., 2019), SUMBT (Lee et al., 2019), TransferQA (Lin et al., 2021a), and T5-seq. Transfer QA is based on T5-large.

Model	All	Seen	Unseen
SDT-seq + desc	88.6±0.9	95.7±0.5	86.2±1.0
SDT-seq	**88.8±0.5**	**95.8±0.2**	**86.4±0.7**

Table A1: We experiment with prompting using both descriptions and demonstrations (SDT-seq + desc) vs. demonstrations-only (SDT-seq) and find that adding descriptions does not improve performance.

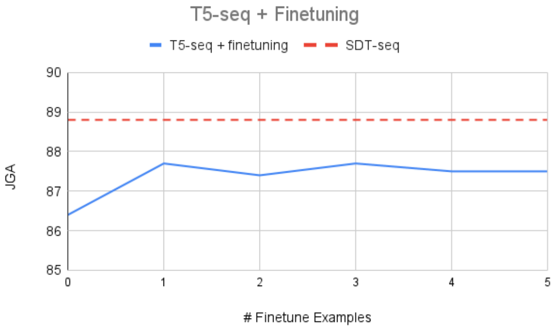

Figure 3: Results of secondarily finetuning T5-seq with dialogues, to help understand whether prompting or finetuning is more effective. The examples used for finetuning are derived from the set of dialogues used as prompts across the 5 trials of SDT-seq. From this, we observe that prompting with a single dialogue demonstration outperforms few-shot finetuning.

Does Pre-training Induce Systematic Inference? How Masked Language Models Acquire Commonsense Knowledge

Abstract

Transformer models pre-trained with a masked-language-modeling objective (e.g., BERT) encode commonsense knowledge as evidenced by behavioral probes; however, the extent to which this knowledge is acquired by systematic inference over the semantics of the pre-training corpora is an open question. To answer this question, we selectively inject verbalized knowledge into the pre-training minibatches of BERT and evaluate how well the model generalizes to supported inferences after pre-training on the injected knowledge. We find generalization does not improve over the course of pre-training BERT from scratch, suggesting that commonsense knowledge is acquired from surface-level, co-occurrence patterns rather than induced, systematic reasoning.

1 Introduction

Pre-trained Transformers, such as BERT, encode knowledge about the world (Petroni et al., 2019; Zhou et al., 2020); e.g., BERT assigns relatively high probability to "fly" appearing in the context "robins can ___ ." In this work, we investigate whether such knowledge is acquired during pre-training through systematic inference over the semantics of the pre-training corpora; e.g., can models systematically infer "robins can fly" from the premises "birds can fly" and "robins are birds?"

Resolving *how* models acquire commonsense knowledge has important implications. If models learn to make systematic inferences through pre-training, then scaling up pre-training is a promising direction for commonsense knowledge acquisition. If, instead, models only ever generalize based on superficial, surface-level patterns, then the majority of commonsense knowledge, which is only supported implicitly, will never be acquired (Gordon and Van Durme, 2013; Forbes and Choi, 2017).

On the one hand, there is cursory evidence that pre-training might induce the ability to systematically reason about the world. When fine-tuned on supervised training sets, pre-trained models can classify valid inferences better than strong baselines (Clark et al., 2020; Talmor et al., 2020b); and, in zero-shot evaluations, pre-trained models perform relatively well on reasoning tasks that *may* require systematic reasoning, such as number comparison (Talmor et al., 2020a) and Winograd schemas (Sakaguchi et al., 2021).

On the other hand, existing works have argued that pre-training does not generalize by systematic inference over semantics on the basis of theoretical or synthetic results (Bender and Koller, 2020; Merrill et al., 2021; Traylor et al., 2021). Referring to physical commonsense knowledge acquired by BERT, Forbes et al. (2019) conclude that "neural language representations still only learn associations that are explicitly written down."

Our main contribution is a direct evaluation of the training dynamics of BERT's reasoning ability. We inject verbalized knowledge, such as "robins are birds" (where the masked token is the predicate, e.g., "birds"), into the minibatches of BERT throughout pre-training. We then consider how well BERT generalizes to supported inferences; e.g., how does the likelihood of "robins can ___" → "fly" change?

We find generalization does not improve over the majority of pre-training which supports the hypothesis that the type of commonsense knowledge studied is not acquired by systematic inference. Rather, our findings suggest this knowledge is acquired from surface-level, co-occurrence patterns.

2 Related Work

Commonsense knowledge acquisition is a longstanding challenge in natural language processing (Charniak, 1973; Hwang et al., 2021; Zhang et al., 2021), and current approaches rely on knowledge

---

[*] Work conducted while the author was an intern at Microsoft Research Montréal.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4550 - 4557
July 10-15, 2022

acquired by pre-trained Transformer language models (Bosselut et al., 2019; Zhang et al., 2020; West et al., 2021). The commonsense reasoning ability of these language models has been evaluated using behavioral probes (Ettinger, 2020; Misra et al., 2021; He et al., 2021) and downstream, fine-tuned evaluations (Banerjee et al., 2021; Zhou et al., 2021; Tafjord and Clark, 2021). Such works consider the knowledge encoded by a model after pre-training.

When fine-tuned on supervised datasets, pre-trained models can learn to make systematic inferences to some extent (Clark et al., 2020; Tafjord et al., 2021; Gontier et al., 2020; Shaw et al., 2021; Li et al., 2021). By *systematic inferences*, we refer to the ability to learn general rules and apply them in novel settings, as opposed to learning only particular instances of the rule (Fodor and Pylyshyn, 1988; Lake and Baroni, 2018; Bahdanau et al., 2019).

Similar to our experiments, recent work has considered the training dynamics of pre-trained models (Brown et al., 2020; Kaplan et al., 2020). Notably, Liu et al. (2021) evaluate the zero-shot performance of RoBERTa on the oLMpics reasoning tasks throughout pre-training, but find the knowledge studied is never learned. In contrast, we explore *how* learned knowledge is acquired.

Close in spirit to our work, Kassner et al. (2020) pre-train a masked language model on a synthetic dataset to isolate reasoning ability. Wei et al. (2021) also intervene on BERT's pre-training data in a syntactic evaluation and conclude that subject-verb agreement is sometimes inferred from systematic rules for frequent words.

Finally, De Cao et al. (2021) explore how knowledge encoded in BERT is affected by gradient updates when fine-tuning on a downstream classification task. Hase et al. (2021) build on this work and explore how gradient updates on verbalized premises affect models' performance on supported inferences. In contrast, we focus on knowledge obtained by the pre-training objective itself.

3 Method

The purpose of our evaluation is to answer the question: *does BERT systematically infer commonsense knowledge from premises present in the pre-training corpora?*

We focus on one specific type of commonsense knowledge that BERT is known to encode, namely entity properties annotated in CONCEPTNET (Speer et al., 2017). This knowledge can be represented abstractly as (`subject`, `relation`, `object`) triples. We verify BERT's encoding of knowledge by the ability to predict the `object` conditioned on a verbalization of the knowledge containing only the `subject` and `relation`; e.g., for (`robin`, `capable-of`, `fly`), we evaluate the ability to predict "fly" appearing in the context "robins can ____ ."

Type	Example
Super-statement	*A boat has a* ____ . $\rightarrow$ *hull*
Sub-statement	*A canoe has a* ____ . $\rightarrow$ *hull*
Class Relation	*A canoe is a* ____ . $\rightarrow$ *boat*

Table 1: An example of the three knowledge types as masked-token prediction.

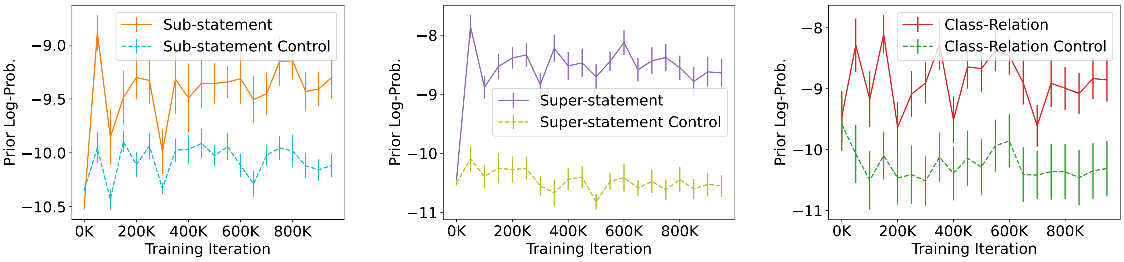
Such knowledge may be supported by simple co-occurrence patterns (such as "robins" and "fly" having high co-occurrence), but we are interested in the extent to which knowledge might also be supported by induced, systematic inference. We focus on the inference of *downward monotonicity* (*A is-a B* $\wedge$ *B has-property C* $\vDash$ *A has-property C*). We refer to the hypernym property (*B has-property C*) as the super-statement, the hyponym property (*A has-property C*) as the sub-statement, and the hypernymy relation (*A is-a B*) simply as the class relation (Table 1).

We can then evaluate, for example, whether "robins can fly" is influenced by the inference "robins are birds" $\wedge$ "birds can fly" $\vDash$ "robins can fly." For this evaluation, we inject a supporting premise into a pre-training minibatch (i.e., we replace one of the sentences in the minibatch with the premise) and then evaluate BERT's knowledge of the supported inference after a gradient update on the minibatch containing the premise.

We run this evaluation at intervals throughout the entire pre-training procedure, from random initialization to a fully pre-trained BERT model. If pre-training induces the ability to systematically make the downward monotonicity inference, one would expect that generalization from premise to inference will improve as pre-training progresses.

3.1 Metrics

Let θ_i be the parameterization of BERT at pre-training iteration i, and let $w = \{x, y, z\}$ be a set of knowledge triples where x is a super-statement, y is the corresponding sub-statement, and z is the



(a) Sub-statement

(b) Super-statement

(c) Class Relation

Figure 1: The prior log-probability of each knowledge type estimated by BERT across pre-training iterations.

corresponding class relation.

Take u to be any logical premise (i.e., $u \in \{x, y, z\}$). Let θ_i^u be θ_i after one gradient update on a minibatch containing u. For a hypothesis $h \in \{x, y, z\}$, we consider:

(1) Prior log-probability: $\log p(h|\theta_i)$

(2) Posterior log-probability: $\log p(h|\theta_i^u)$

(3) PMI: $\log p(h|\theta_i^u) - \log p(h|\theta_i)$

Intuitively, (1) describes the model's prior knowledge of h at step i, and (3) describes how a pre-training update on u affects the knowledge of h. We also consider standard information retrieval metrics such as mean reciprocal rank (MRR).

4 Experiments

4.1 Inference Dataset

We evaluate on the Leap-of-Thought dataset presented by Talmor et al. (2020b). This is a dataset of 30K true or false downward-monotonic inferences which are verbalized using manually written templates. The hypernymy relations are derived from WordNet (Miller, 1995), while the properties are derived from both WordNet and CONCEPTNET (Speer et al., 2017).

We reformulate this supervised, classification dataset as a zero-shot, cloze-style task. First, we filter the dataset by removing partial examples where one type of knowledge is withheld. Then, we filter out the randomly-generated, negated examples, and those where the object is longer than one word-piece.[1] The filtered dataset consists of 711 examples. Each example is converted into a cloze task by masking the object.

To evaluate relative performance, we also generate a control entity (CE) for each example by randomly sampling a WordNet sibling of the super-statement hypernym as a pseudo-negative (e.g., "A robin is a ____ ." → "fish"). For the super and sub-statements, we take the predicate of the CE under the same relation to be a control (e.g., "Robins can ____ ." → "swim").

4.2 Model

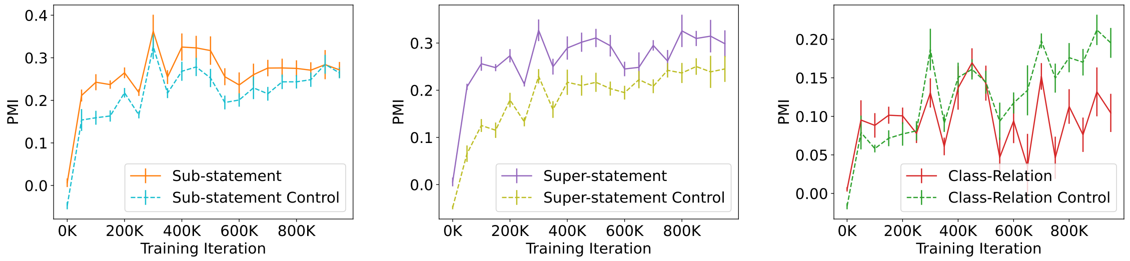
We consider the training dynamics of a BERT-base model from random initialization to fully pre-trained, replicating details of the original BERT implementation (Devlin et al., 2019).

Specifically, we pre-train the model for 1 million steps on a concatenation of English Wikipedia and the Toronto Book Corpus (Zhu et al., 2015) as released by Huggingface datasets (Lhoest et al., 2021). Training details are given in Appendix A and differ from the original BERT release only in that: 1) we use whole-word masking; 2) we use sentence-order prediction instead of next-sentence prediction as the auxiliary loss (Lan et al., 2020); and, 3) pre-training sentences are extracted using the NLTK Punkt tokenizer (Loper and Bird, 2002) instead of taking random spans of text.

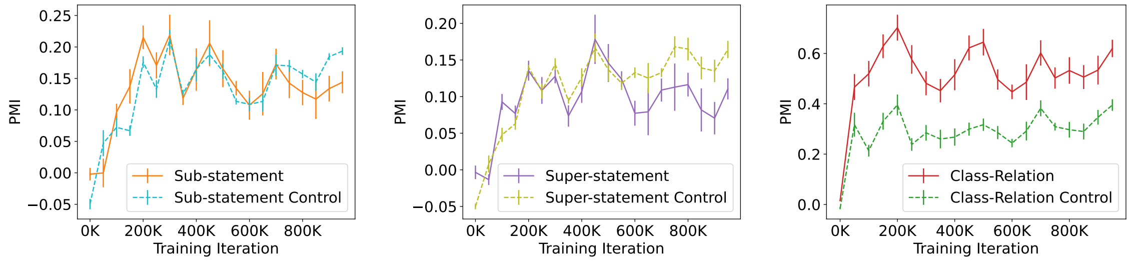
Every 50K pre-training steps, we save a checkpoint of the model's weights and optimizer state. At each checkpoint, we perform the pre-training intervention experiment: we inject 20 random premises into a minibatch and perform one gradient update on this minibatch using the saved optimizer and a constant learning rate of 1e-4 (to control for the effects of the learning rate scheduler). We then evaluate the change in likelihood of h. We perform this evaluation 200 times at each checkpoint so that each of the 711 Leap-of-Thought examples has been evaluated in five separate minibatches.

---

[1] Evaluating only objects that are a single word-piece follows the procedure of the LAMA evaluation (Petroni et al., 2019) and allows us to evaluate BERT in a zero-shot setting.



(a) Super-statement→Sub-statement (b) Super-statement→Super-statement (c) Super-statement→Class relation



(d) Class relation→Sub-statement (e) Class relation→Super-statement (f) Class relation→Class relation

Figure 2: BERT's generalization from premise to hypothesis across pre-training iterations. Each sub-figure, labelled as $P \to H$, considers how pre-training on sentences of knowledge type P changes BERT's encoding of supported knowledge of type H. For example, how does a pre-training update on the class relation "robins are ____" → "birds" affect knowledge of the sub-statement "robins can ____" → "fly"?

5 Results

5.1 Model Validation

We first run Talmor et al. (2020b)'s original fine-tuning evaluation on our final BERT checkpoint in order to validate the pre-training procedure. The final implicit reasoning accuracy of our BERT model is 0.89, slightly higher than Talmor et al. (2020b) report for RoBERTa-large. Additional details are presented in Appendix B.

5.2 Pre-training Interventions

Prior prob. Figure 1 shows the prior log-probability of each knowledge type across pre-training. In general, the difference between the correct and control predicates increases during pre-training, suggesting that the knowledge is acquired by BERT. The trend is non-monotonic, however, and interestingly the prior-probability of the correct predicate peaks early in training for all three knowledge types.

Interventions. We evaluate all combinations of knowledge types for premise u and hypothesis h. Some of these inferences are logically sound (e.g., deducing the sub-statement from the super-statement) while others are not (e.g., inducing the super-statement from the sub-statement). We are interested to see when BERT generalizes from u to h as we expect the semantics of the premise to always support the plausibility of the hypothesis relative to the random control.

In Figure 2, we consider PMI for evaluating generalization. When BERT is updated on a pre-training minibatch containing a super-statement, this unsurprisingly increases the probability of the super-statement predicates (Figure 2b) and, as one would expect, there is a similar trend for the class relation (Figure 2f). The control predicates also increase in probability in these cases, but to a lesser extent than the correct predicates.

Less intuitively, however, the PMI of the correct sub-statement predicate is the same as for the control predicate during the final iterations of pre-training (Figure 2a). What's more, the PMI of the class-relation control predicate is higher than the correct predicate during the entire second half of pre-training (Figure 2c). We also see that the control predicate has a higher PMI than the correct predicate when training on the class relation and evaluating on another knowledge type (Figures 2d and 2e).

If knowledge was acquired by induced down-

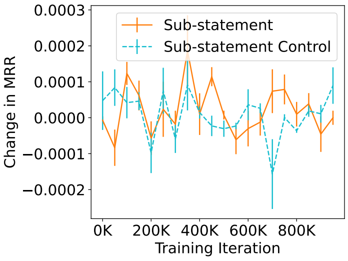


Figure 3: The difference in MRR of predicates before and after updating BERT at each pre-training checkpoint. In this case, we consider MRR of correct and control sub-statement predicates after updating on the corresponding super-statements.

ward monotonicity over semantics, we would expect generalization from class relation to sub-statement to improve over time. The opposite trend suggests knowledge is not being acquired from this semantic inference.

The higher PMI of the control predicate could be in part explained by their lower initial probability, so we also consider changes in MRR (Figure 3). In considering MRR, the difference between predicting the correct and control predicate seems indiscernible across pre-training checkpoints.

6 Conclusion

We show that the ability of BERT to acquire commonsense knowledge from premises and learned inferences does not improve across pre-training, suggesting that the studied knowledge is not acquired from induced semantic inferences.

These results suggest that an explicit reasoning mechanism may be necessary to acquire certain commonsense knowledge.

6.1 Limitations and Future Work

In this work, we only consider one inference type (downward monotonicity) where knowledge is evaluated in one particular way (predicting the predicate) and interventions consist of a single pre-training update. Future work could explore the affects of these experimental design decisions by expanding evaluations to diverse datasets of commonsense inferences and by pre-training for additional steps.

A BERT Hyperparameters

We train the BERT-base architecture (12 layers, 12 attention heads, hidden size of 768) following the original pre-training hyperparameters: a batch size of 256, sequence length of 128, and train for 1 million steps. We use the Adam optimizer and linearly warmup the learning rate to 1e-4 over the first 10,000 steps of pre-training, and then linearly decay the learning rate.

Our code builds on the Huggingface Transformers (Wolf et al., 2020) and MegatronLM (Shoeybi et al., 2019) implementations of BERT. The pre-training corpus is uncased and pre-processed using the MegatronLM pre-processing. Training takes four days on eight V100 GPUs.

Our conclusions are based on the training dynamics of BERT-base, and future work might investigate if scaling model size allows for more systematic inferences.

B Leap-of-Thought Fine-tuning Results

The original Leap-of-Thought evaluation consists of fine-tuning BERT to classify if a sub-statement is true given supporting premises. In the explicit reasoning evaluation, all supporting premises are given at test time (e.g., the model must determine if “robins can fly” is true given the context “robins are birds and birds can fly.”). In the implicit reasoning evaluation, the class relation is withheld (e.g., the model must determine if “robins can fly” given only the context that “birds can fly.” This inference relies on the implicit knowledge that robins are birds). We fine-tune for four epochs following Talmor et al. and otherwise use default hyperparameters.

Our main purpose in running this evaluation is to validate our pre-training procedure; however, we also evaluate all intermediate BERT checkpoints in order to understand how the performance changes across pre-training. Interestingly, we find performance increases log-linearly with pre-training iterations in the implicit reasoning test, but performance of the explicit reasoning evaluation peaks at just 15% of pre-training (Figure 4). Numerical results are presented in Table 2.

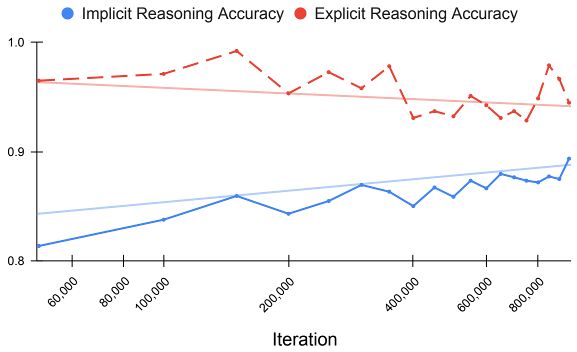

Figure 4: Accuracy on Talmor et al. (2020b)’s original Leap-of-Thought evaluation across pre-training iterations (from 50K to 1M).

Using Paraphrases to Study Properties of Contextual Embeddings

Laura Burdick, Jonathan K. Kummerfeld and **Rada Mihalcea**
Computer Science & Engineering
University of Michigan, Ann Arbor
`{lburdick,jkummerf,mihalcea}@umich.edu`

Abstract

We use paraphrases as a unique source of data to analyze contextualized embeddings, with a particular focus on BERT. Because paraphrases naturally encode consistent word and phrase semantics, they provide a unique lens for investigating properties of embeddings. Using the Paraphrase Database's alignments, we study words within paraphrases as well as phrase representations. We find that contextual embeddings effectively handle polysemous words, but give synonyms surprisingly different representations in many cases. We confirm previous findings that BERT is sensitive to word order, but find slightly different patterns than prior work in terms of the level of contextualization across BERT's layers.

1 Introduction

Contextualized embedding algorithms, such as BERT (Devlin et al., 2019), have achieved impressive performance on a wide variety of tasks (Huang et al., 2019; Chan and Fan, 2019; Yoosuf and Yang, 2019). One application of BERT is using it as a measure of sentence similarity (Zhang* et al., 2020; Sellam et al., 2020), based on the assumption that BERT will produce similar representations for the words in two sentences with similar semantics.

We propose to use paraphrases with alignments between words as a tool for studying how BERT represents words and phrases. Figure 1 shows an example. Critically, when considering an aligned word pair, we can assume the context has a similar impact on both words because we know the phrases are semantically similar. Previously, paraphrases have been used to probe whether compositionality is accurately captured by BERT (Yu and Ettinger, 2020), but we believe they can be used to explore many other questions.

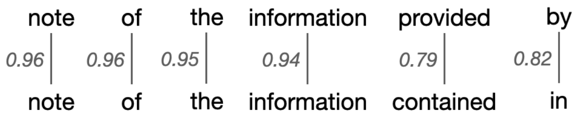

Figure 1: Example paraphrase from the PPDB with word alignment and word cosine similarities using the last layer of BERT.

Using the second version of the Paraphrase Database (PPDB, Pavlick et al., 2015), we explore how consistent contextual representations are when controlling for the semantics of the context. First, we use the human-annotated portion of the PPDB data to confirm that BERT consistently represents paraphrases. Next, we use the highest-quality (but not all human-annotated) section of the PPDB to probe BERT's behavior in more detail. Looking at words, BERT effectively handles variations in spelling, but does less well with spelling errors. BERT also effectively handles words of varying levels of polysemy, but the representations for synonyms are surprisingly diverse, with a much broader distribution of similarity scores. These findings confirm results from prior work using other methods, while uncovering new insights about contextual embedding models.

We also consider a range of other models' word representations, finding that they have similar patterns to BERT, but with aligned words that are the same receiving even more consistent representations than from BERT. BERT gives less contextualized representations to paraphrased words than non-paraphrased words, with the exception of punctuation. Finally, we re-evaluate work looking at patterns across BERT's layers and find that when controlling for semantics, the later layers actually produce more similar representations (in contrast to previous work).

These results show that paraphrases are a useful tool for studying representations. By controlling

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4558 - 4568
July 10-15, 2022 ©2022 Association for Computational Linguistics

for meaning while presenting interesting surface variations, they provide a unique probe of behavior.

2 Background

2.1 BERTology

There has been a growing body of research studying the inner workings of BERT and trying to quantify what it learns in various scenarios, dubbed "BERTology" (Rogers et al., 2020). Of particular interest to this paper is work that analyzes BERT's output embeddings. Recent studies have found that embeddings created from the final layer of BERT tend to cluster according to word senses (Wiedemann et al., 2019), though this varies somewhat based on the position of a word in a sentence (Mickus et al., 2020). The final BERT layers also produce more contextualized word embeddings than the earlier layers (Ethayarajh, 2019), a finding we revisit using paraphrases in Section 3.3.

2.2 The Paraphrase Database

To analyze BERT, we take advantage of the unique properties of paraphrases. We use the Paraphrase Database (PPDB, Ganitkevitch et al., 2013; Pavlick et al., 2015), a database of paraphrases collected using bilingual pivoting, the process of taking a particular English phrase, looking at all the foreign language phrases it can be translated into, finding all occurrences of these foreign language phrases, and then translating them back into English (Bannard and Callison-Burch, 2005). PPDB 2.0 contains 100m+ English paraphrases, each with word alignment information, an automatically generated quality rating, and, for a subset, a human quality rating.[1] Word alignments are the by-product of the bilingual pivoting method used to collect the paraphrases. When using alignments, we only consider phrases from the highest quality section of the PPDB, which are most likely to have accurate alignments. Example paraphrases with their average human annotations and automatically generated scores are shown in Table 1. In general, the phrases in this dataset are short. The longest phrases have six tokens, and the majority have fewer than six.

Human quality ratings are included for 26,455 paraphrase pairs, with five annotations per paraphrase. Agreement is measured using Spearman's ρ (Spearman, 1910); the average ρ between two workers is 0.57, and the average ρ between each worker with the other four annotators is 0.65.

Phrases	Human Score	PPDB Score
are you talking do n't they	1.0	2.7
what 's this all about ? what 's she saying ?	4.2	3.9
where did they come from ? where are they from ?	4.8	4.4

Table 1: Example tokenized paraphrases from the PPDB, with their average human annotations and automatic PPDB scores.

The automatic quality ratings (PPDB score) are generated by using the human annotations to fit a supervised ridge regression model. The input to the model consists of 209 hand-crafted paraphrase features, including WordNet features (Fellbaum, 1998), distributional similarity features, and cosine similarities of generated Multiview Latent Semantic Analysis embeddings (Rastogi et al., 2015). The PPDB score achieves a Spearman's ρ of 0.71. In comparison, Pavlick et al. (2015) report that using the word2vec embedding of the rarest word in each paraphrase obtains Spearman's ρ of 0.46.

3 Experiments

In our experiments, we want to use the PPDB to examine BERT's ability to consistently represent paraphrase semantics.[2] In order to do this, we consider both phrase-level and word-level embeddings. Except where explicitly indicated otherwise, all experiments are run using the uncased base model of BERT, using a maximum sequence length of 128 and a batch size of 8. We use the pretrained models provided by the Transformers library.[3]

There is a slight mismatch between the PPDB's tokenization and the format of the BERT training data. The mismatch primarily occurs with contractions and apostrophes (e.g., BERT expects "don't", while the PPDB is tokenized "do n't"). This does not substantially affect the results; less than 8% of the human-annotated paraphrase pairs contain apostrophes. When words are broken into multiple pieces by the wordpiece tokenizer, we use the

---

[1] http://paraphrase.org.

[2] Note, paraphrases do not always have identical meaning. We focus on particularly similar pairs for our analysis to support our assumption that their meaning matches.

[3] `https://huggingface.co/docs/transformers/index`

average of the pieces as the word representation.

3.1 Phrase-Level Embeddings

First, we consider phrase-level embeddings that capture aggregate information about all of the words in a given phrase. These embeddings show us that BERT is able to distinguish between two paraphrases, and two unrelated phrases.

We use 25,736 phrase pairs with human annotations in the PPDB.[4] Each human annotation is between 1 and 5, reflecting the similarity of the two phrases. We run each phrase through the pretrained BERT model. For each pair of phrases, we average together the embeddings for each word to get a phrase embedding. We create phrase embeddings using averaging because previous research has shown that this method is effective. For example, Reimers and Gurevych (2019) created sentence embeddings using three methods: (1) averaging word embeddings, (2) taking the maximum of word embeddings, and (3) using the CLS token vector. They found that averaging created the best sentence embeddings for semantic textual similarity tasks.

After creating phrase embeddings, we take the cosine similarity between the two embeddings. We compare with ground truth annotations using Spearman's ρ. We do this for each of the twelve BERT layers, and the concatenation of all layers. We use cosine similarity to compare embeddings because this metric is commonly used when working with BERT (e.g., Mahmoud and Torki (2020); Garí Soler and Apidianaki (2020); Kovaleva et al. (2019)).

We compare BERT to a more traditional embedding method, the continuous bag-of-words approach in word2vec (w2v) (Mikolov et al., 2013). We train w2v on an English Wikipedia corpus of 5,269,686 sentences,[5] using dimension size 200, a window size of five, and a minimum count of five. We choose to train w2v on Wikipedia data, in order to replicate the correlations in Pavlick et al. (2015). We train five w2v models, using five different random seeds.[6] For each pair of phrases, we average together the embeddings for each word to get a phrase embedding, and then take the cosine similarity between the two phrase embeddings.[7] We report the average and standard deviation of Spearman's ρ over the five models.

Comparing Sentences and Phrases One difference between our work and the way BERT is normally used is that we have phrases rather than sentences. To check that this does not substantially change BERT's behavior, we compare the embeddings for phrases in a sentence and the phrases on their own. We take 9,780 paraphrases from the PPDB. We choose paraphrases where one of the phrases has at least six tokens, the paraphrase has a relatively good PPDB score and no syntactic placeholders. This is described further in Section 3.2. For each phrase, we find up to 100 sentences (on average, 80.5 sentences) in Gigaword (Parker et al., 2011; Rush et al., 2015)[8] and OpenSubtitles (Tiedemann, 2012)[9] that contain that phrase. For each sentence, we run it through BERT and average together the word embeddings for words in the phrase to create a phrase embedding. The phrase embeddings are very similar across different sentences (average cosine similarity of 0.82 ± 0.07).

Now we can compare (1) the average of phrase embeddings derived from sentences, with (2) embeddings for phrases in isolation, to see if BERT will be confused by not having a complete sentence. For each phrase, we take the cosine similarity between the phrase embeddings created using these two methods. The phrase embeddings are fairly similar (average similarity of 0.74 ± 0.12). This gives us confidence that BERT produces embeddings for phrases on their own that are very similar to phrases in the context of a sentence. For the rest of our experiments, we run phrases individually through BERT, rather than in the context of complete sentences, which allows us to focus on the semantics of the phrase itself.

Results on the PPDB. Table 3 shows results for BERT, w2v, and the PPDB model, broken down by the average length of each paraphrase. For all layers, BERT improves on longer paraphrases. This is intuitive, because the longer the phrase, the more it will be able to leverage contextual information. The last layer of BERT behaves slightly differently than the other layers. While it continues to perform

---

[4] This is 3% smaller than the entire human-annotated subset. We were unable to map some of the human-annotated data to the data with PPDB scores (even with help from the authors of the PPDB paper). This may be why our scores for w2v are lower than those reported by Pavlick et al. (2015).

[5] This data was used in Tsvetkov et al. (2016) and is available by contacting the authors of that paper.

[6] 2518, 2548, 2590, 29, 401

[7] For both BERT and w2v, we additionally tried using the embedding of only the rarest word (with frequency measured using the full PPDB), as reported in Pavlick et al. (Pavlick et al., 2015), but this gave us consistently lower correlations.

Table 2: Examples of common phenomena observed in paraphrases with particularly high similarity, low similarity, and idiomatic expressions.

	Average Length			All
Method	1-2.5	2.5-4	4-6	
BERT	0.2	0.4	0.51	0.31
w2v Average	0.35	0.32	0.41	0.43
PPDB model	0.41	0.50	0.51	0.50
Num. phrases	$17,517$	$5,349$	$2,870$	$25,736$
Avg. human	2.40	2.94	3.26	2.60

Table 3: Spearman's ρ between human-annotated PPDB paraphrases and different embedding methods (BERT and w2v), broken down by average paraphrase length (the average number of words in each of the two phrases in the paraphrase). Annotations are a score between 1 and 5. At the bottom of the table, we include the length distribution of the human-annotated paraphrases, as well as the average human annotation for each set of grouped lengths. For all length groupings, the w2v std. dev. is 0.0. For paraphrases length 1-2.5, the avg. human std. dev. is 1.0; for all other groupings, the std. dev. is 1.1.

better on longer paraphrases, it does substantially worse on short paraphrases and slightly worse on medium paraphrases.

Similarly, w2v also improves on longer paraphrases. By taking the average of all the word embeddings for each word in the phrase, w2v has more information to incorporate into its phrase embeddings for longer paraphrases. Though w2v improves as the paraphrases grow longer, it underperforms BERT for all but the shortest paraphrases. We also see that the automatic PPDB score does better on longer paraphrases. This could be because it incorporates distributional information, which is richer when there are more words. Finally, the human annotation scores show that longer paraphrases are more similar.

From Table 3, we see that the final layer of BERT outperforms w2v and performs comparably to the PPDB score on the longest paraphrases. This is not a completely fair comparison; the PPDB model is trained specifically on this data, and has access to outside information that BERT does not, such as WordNet features and additional features derived from the translation process used to create the PPDB. These results give us confidence that BERT can distinguish between phrases that are paraphrases of each other and phrases that are not.

Looking at BERT's output, we can see several patterns in the paraphrases that receive high and low similarities. Table 2 shows examples of these patterns. For phrases with high similarity according to BERT, a single word changes or a single word is added. On the surface, these changes have very little impact on the meaning, though the addition of the word 'special' in the second case could change who is being referred to. For phrases with low similarity according to BERT, they frequently required world knowledge (e.g., definition of an acronym) or appeared to be errors. We also observed idioms getting reasonably high scores, but not as high as the literal paraphrases.

Conclusion: The standard way of using BERT to produce a representation of a phrase is consistent with human scores of paraphrases. All layers are effective, though the last layer struggles with shorter phrases.

3.1.1 One-Word Paraphrases

In Section 3.1, we saw that BERT does not do as well on short phrases as it does on longer ones. We explore the extreme case of single word paraphrases here. Among the subset of one-word paraphrases, there is a wide range of human annotations (average annotation 2.27 ± 0.99). To explore this further, we focus on one-word paraphrases with a human annotation of 5, the highest annotation score, indicating that these are the strongest synonyms. Among these high-quality synonyms, cosine similarities are consistently high for the last layer of BERT (average similarity 0.76 ± 0.12).

Table 4 shows synonyms with both the highest and lowest BERT similarities. Misspelled

Phrase 1	Phrase 2	Cos. Sim.
laboratoires	laboratories	0.51
completly	totally	0.51
fervor	enthusiasm	0.52
79.0	seventy-nine	0.53
approximatly	around	0.54
-mom	-mother	0.91
1.350	1.35	0.92
characterises	characterizes	0.92
km	kilometres	0.92
garbage	trash	0.96

Table 4: Cosine similarity scores for the last layer of BERT for one-word paraphrases with the highest human annotation score.

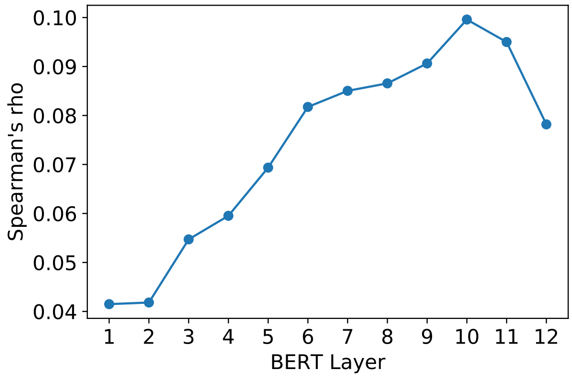

Figure 2: Spearman's ρ between BERT cosine similarities and PPDB scores for all aligned same words, broken down by BERT layer.

words (e.g., `completly`, `approximatly`) and pairs that involve different languages (e.g., French `laboratoires`) have low cosine similarities. Numbers appear on both the low end (e.g., `79.0` and `seventy-nine`) and the high end (e.g., `1.350` and `1.35`) of the similarity spectrum. One difference between the similar and dissimilar number pairs is that in the similar case they both use digits, while in the dissimilar case, one uses digits while the other uses words.

Conclusion: Looking at single words shows that BERT struggles to identify synonyms, and does particularly poorly with misspellings and cross-lingual comparisons.

3.2 Word-Level Embeddings

PPDB provides alignments between words in the paraphrases, automatically generated as part of bilingual pivoting. We use these alignments to consider four different sets of words:

Same, Aligned Words that are the same in both phrases and aligned.

Same, Unaligned Words that are the same in both phrases, but not aligned. These tend to be function words. 90% of our examples are one of (the, of, ", to, i, in, that, as, what). This category may have more examples of other word types if longer paraphrases are considered in future work.

Different, Aligned Words that are aligned, but not the same. This case covers synonyms.

Different, Unaligned Words that are not aligned and not the same (but still one from each phrase in a paraphrase pair). Note, these words are not completely unrelated. They are from the same paraphrase, making them more related than words from two random phrases.

In this section, we go beyond the human-annotated data considered in the previous section. We restrict our experiments to the highest quality paraphrases in the PPDB: dataset S. We also only consider long paraphrases (where one of the phrases has at least six tokens), and paraphrases that have no syntactic placeholders (a subset of the PPDB contains general syntactic symbols, such as `wishes to be [VP/NP]`). From this set, we randomly sample 4,000 paraphrases. Our sample yields 22,751 aligned same words, 25,973 aligned different words, 2,782 unaligned same words, and 163,474 unaligned different words. We randomly sample 2,500 words from each category. For the aligned words, we only use cases where there is a 1-1 alignment.

To generate word-level embeddings, we run each phrase through a set of transformer models and for each pair of words, we take the cosine similarity between the embeddings of the two words.

3.2.1 Results

Figure 3 shows the distributions of similarity scores for all four sets of words for several models. Same, aligned words consistently have the highest similarity. The other categories tend to overlap. Because we are using paraphrases, we would hope that aligned different words would have higher similarity, but that is not consistently the case.

Comparing the models, there are some notable variations. Between BERT base and BERT large, the biggest shift is that unaligned words that are the same have much lower similarity in BERT large,

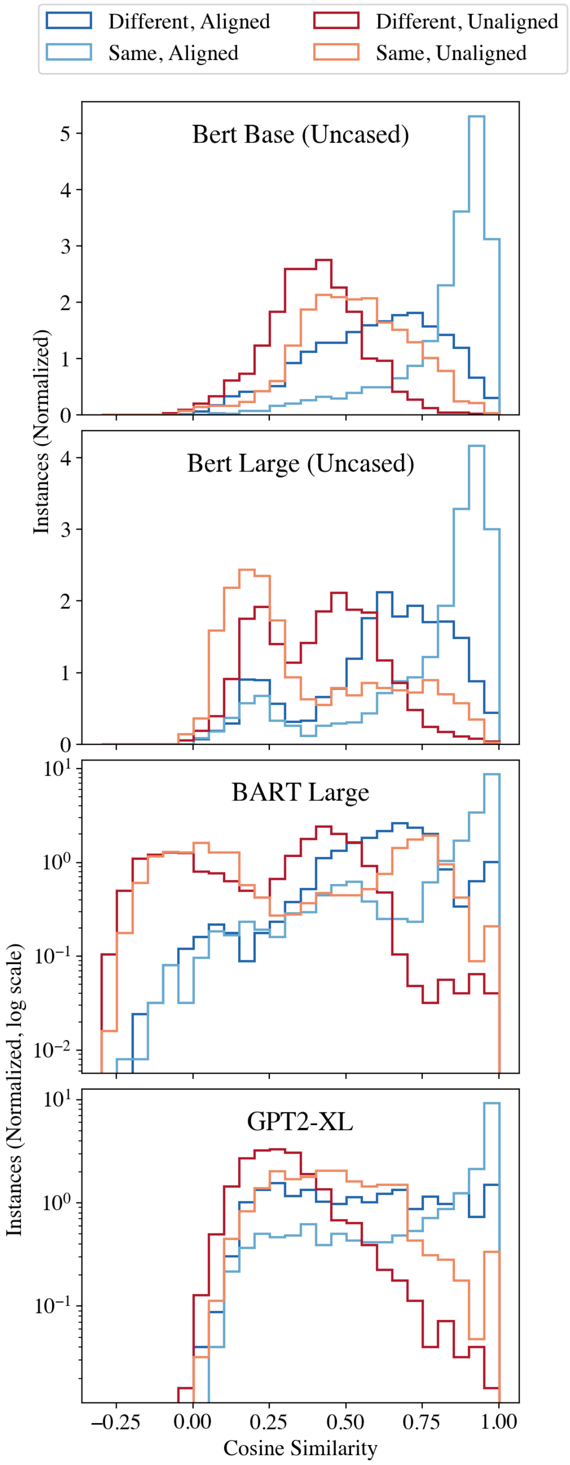

Figure 3: Distributions of cosine similarities for several models for same and different aligned and unaligned words (best seen in color). Cosine similarity is binned into bins of width 0.05. Note that the bottom two graphs use a log scale because the peak at 1.0 makes it hard to see variations otherwise.

though there is also a new peak for aligned words around 0.2. Comparing the two BERT models with BART and GPT-2, there is a much sharper peak for BART and GPT-2 for same aligned words, which is consistent with prior work (Ethayarajh, 2019).

BART is the only model to have a substantial number of negatively correlated word pairs. Many of these involve function words or punctuation. For the unaligned cases, negative cosine similarity is fine because the words should not have the same meaning. For the 26 cases of aligned pairs, it is unclear why the representations are so different. For example, `the` plays the same role in `( , the commission considered` and `, the commission had before it.` Similarly, `aim` and `view` should be very similar in `aim of improving the` and `with a view to improving the`.

Qualitatively looking at examples, we notice that when a token appears in a different position in the paraphrase, the similarity tends to be on the lower end of the distribution (e.g., `action` in the phrases `plans of action for the implementation` and `action plan for the implementation` has a similarity of 0.28). To explore this, we consider 2,181 aligned same words. We measured the cosine similarity of the last layer of BERT broken down by the variation in position (plotted in Figure 7 in the Appendices). Spearman's $\rho = -0.29$ (p-value $< 10e - 42$), indicating that similarity decreases for larger changes in position. This supports observations in prior work (Mickus et al., 2020), but now with the knowledge that the overall context has the same meaning. This is not intuitive behavior; because these words are aligned in a paraphrase, we would expect that the position of the word would not substantially affect its representation. This may indicate that the representations are encoding some information about syntactic structure, which can vary without changing semantics.

Conclusions: (1) Contextual word embedding methods consistently handle aligned words in paraphrases, but with substantial variations across models in how peaked the distributions of same-aligned words are. (2) Even when controlling for the meaning of the context, BERT represents words differently depending on their position.

3.2.2 Punctuation

Punctuation is a core part of language that functions quite unlike words; punctuation groups words together or separates them, and contributes to the overall structure and meaning of a phrase or sentence. Punctuation plays an important role in dis-

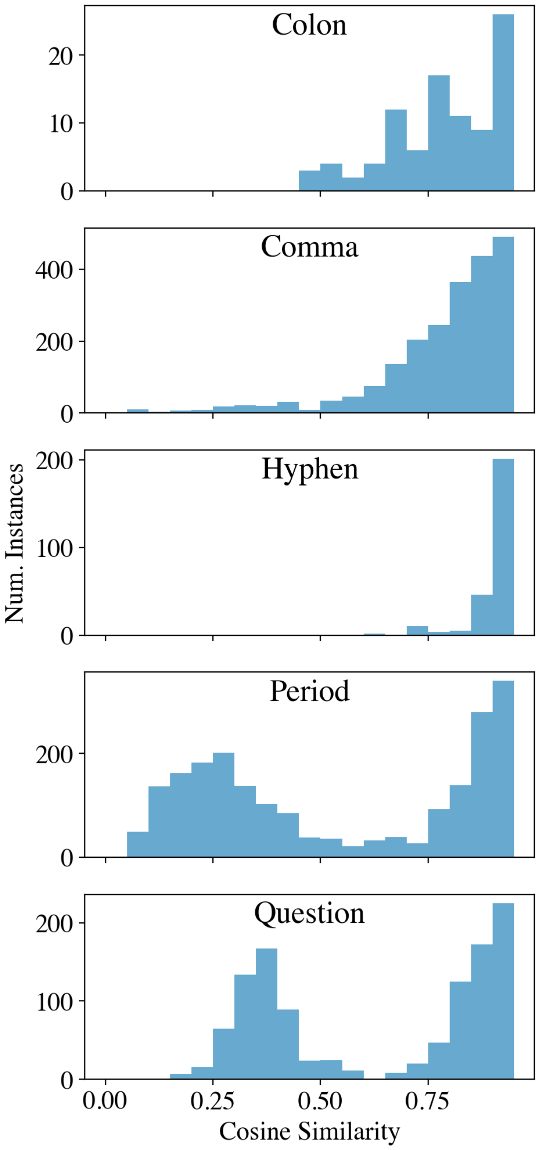

Figure 4: Distribution of cosine similarities using the last layer of BERT for aligned same words, broken down by punctuation mark.

tinguishing between different types of text, such as texts by different authors (Soler-Company and Wanner, 2017) or texts produced by different Twitter communities (Tatman and Paullada, 2017). Embeddings are used to generate punctuation for text that is lacking punctuation, such as recorded transcripts (Yi and Tao, 2019). To explore how BERT handles punctuation, we consider the cosine similarity distribution for different sets of punctuation tokens for the last layer of BERT. We find that punctuation has a broader distribution of cosine similarities than other tokens, indicating that punctuation embeddings vary widely dependent on the surrounding context.

Phrases	Cos. Sim. (Last Layer)
it is important , however , however , it should be	0.08
okay , i ’m sorry oh , i am so sorry	0.84
well , it ’s true . this is true .	0.19
, that ’s all right . , this is good .	0.15
where have you come from ? where are you from ?	0.94
news - politics - world - news - international politics -	0.71

Table 5: Examples of aligned punctuation marks with varying cosine similarities. The aligned tokens are underlined.

In Figure 4, we break these trends down by individual punctuation marks, focusing only on aligned same words. We look at the most common punctuation marks. Of these punctuation marks, the comma and period show the widest distributions. Even when they play the same role in the paraphrase, they can be given very different embeddings, indicating how highly contextualized these punctuation marks are. The question mark and dash are less contextualized; this is most likely because these punctuation marks are used in more prescribed circumstances. In this dataset, in all but one example, the question mark is the last token; the dash is the first token in all but two examples.

Table 5 shows examples in context of each of these punctuation marks. Looking at the low similarity cases, one common pattern is that the phrase contains a contraction that is expanded in one phrase (e.g., “it is” and “it’s”).

Conclusion: BERT’s representation of punctuation is surprisingly context sensitive, with substantial variation even when we control for meaning.

3.2.3 Polysemy

Previous work has shown that BERT embeddings form clusters based on word senses (Wiedemann et al., 2019). In the context of aligned words in a paraphrase, we would expect even a highly polysemous word to have similar embeddings in the two phrases.

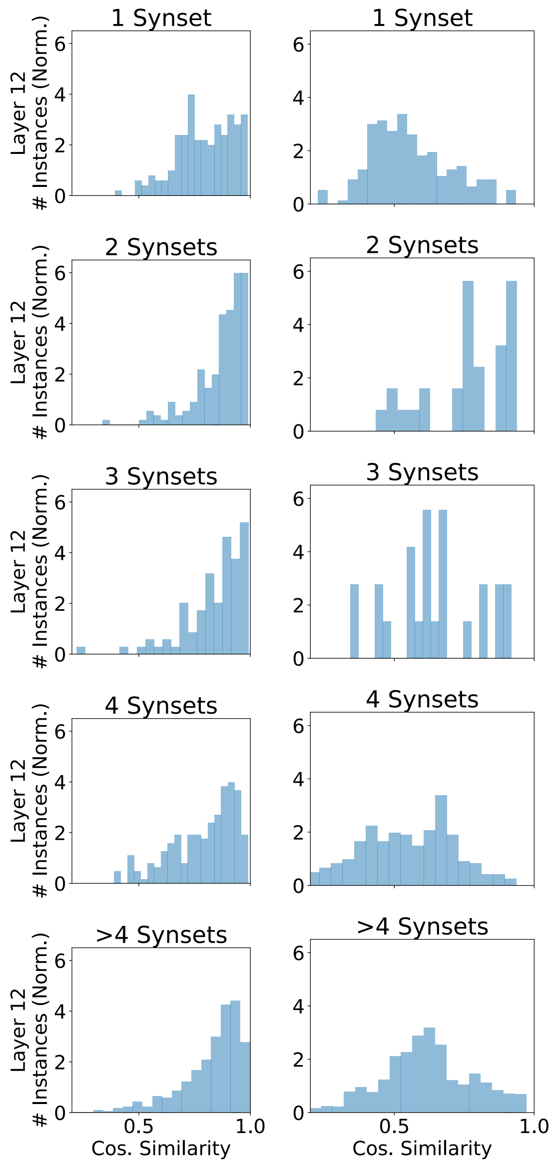

Figure 5: Distributions of cosine similarity for aligned (left) and unaligned (right) same words from the last layer of BERT grouped by the number of senses each word has.

To measure polysemy, we consider the number of WordNet synsets of a word, focusing on same aligned and same unaligned words. In order to have enough data to make a good comparison, we use the 4,000 sampled paraphrases from Section 3.2, as well as an additional random sample of long paraphrases with at least one unaligned same word. We then downsample the aligned same words to get 1,597 instances of both unaligned and aligned same words that are present in WordNet, with up to 52 synsets.[10]

In Figure 5, we show the cosine similarity distributions for both aligned and unaligned words with different levels of polysemy across the last layer of BERT. There is not a substantial difference between words with different synsets, which supports our conclusion that BERT successfully captures the semantics of aligned same words in paraphrases. We do see a difference between aligned and unaligned words. Aligned words peak at a high cosine similarity, while unaligned words roughly follow a normal distribution centered around 0.5. Note that for unaligned words with two or three synsets, there is not enough data to draw conclusions about the cosine similarity distributions. Overall, these plots show that even highly polysemous aligned same words have very similar embeddings in the context of a paraphrase.

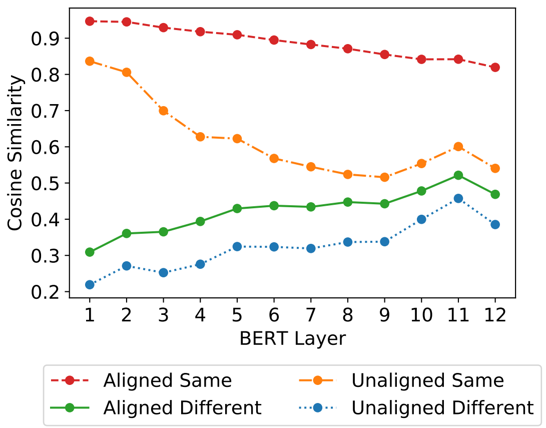

Figure 6: Cosine similarity for different groups of words in the PPDB across all layers of BERT. Decreasing cosine similarity indicates increasing contextualization, and vice versa.

Conclusion: How polysemous a word is does not substantially impact BERT's ability to consistently represent it.

3.3 Contextualization in BERT Layers

In this section, we consider how context-specific the embeddings in a paraphrase are. Ethayarajh (2019) showed that BERT word embeddings are more context-specific in higher layers. They measure this using the self-similarity of words, defined as the average cosine similarity between a word's contextualized representations across its unique contexts, and show that self-similarity consistently decreases with higher layers of BERT, indicating that the contextualization of words is increasing.

We compare this observation to the paraphrase setting that we have been exploring in this paper. Because there are only two phrases in a paraphrase,

---

[10] We look up WordNet synsets using the Python NLTK library (Bird et al., 2009).

we cannot implement the full self-similarity metric. Instead, we measure the cosine similarity between two words aligned in a paraphrase, shown in Figure 6. This revised metric measures is similar to self-similarity.

We see two trends in Figure 6. The first, decreasing cosine similarity, is seen with same words, whether aligned or unaligned, and is similar to what Ethayarajh (2019) report with decreasing self-similarity scores. This trend is stronger with unaligned words than with aligned words, indicating the model is capturing the fact that while these words have the same form, they are being used differently. The second trend that we see is the opposite, increasing cosine similarity, and we see this trend with different words, both aligned and unaligned. This indicates decreasing contextualization.

Conclusion: As seen in prior work, the standard way of using vectors from BERT's layers does not capture the same level of contextualization in all layers. However, in contrast to prior work, when controlling for semantics of the context, it seems that later layers are capturing more of the context, appropriately making words less similar when they are being used in different ways.

4 Conclusion

Paraphrases with word alignments are a useful tool for studying the behavior of contextual language models. In this paper, we used them to study several contextual models, with a particular focus on BERT. Where possible, we compared our results with prior work, finding patterns that are consistent with the literature. Specifically, our results confirm that BERT consistently represents paraphrases, even for cases with polysemous words, but that individual word representations are overly sensitive to position, particularly for punctuation. One exception is that we found that words in a sentence are more similar to each other in later layers of BERT, in contrast to prior work that did not control for meaning using paraphrases.

The analysis method we introduced opens up new opportunities, such as the comparison of aligned and unaligned, same and different words, which shows the sensitivity of these models to the specific word used. Paraphrases have the potential to inform exploration of other representation methods, showing which way of using the output of language models most accurately captures semantics consistently. We hope our findings will inform future work on contextualized models, and the applications that rely on them.

Abstract

As NLP models achieved state-of-the-art performances over benchmarks and gained wide applications, it has been increasingly important to ensure the safe deployment of these models in the real world, e.g., making sure the models are robust against unseen or challenging scenarios. Despite robustness being an increasingly studied topic, it has been separately explored in applications like vision and NLP, with various definitions, evaluation and mitigation strategies in multiple lines of research. In this paper, we aim to provide a unifying survey of how to define, measure and improve robustness in NLP. We first connect multiple definitions of robustness, then unify various lines of work on identifying robustness failures and evaluating models' robustness. Correspondingly, we present mitigation strategies that are data-driven, model-driven, and inductive-prior-based, with a more systematic view of how to effectively improve robustness in NLP models. Finally, we conclude by outlining open challenges and future directions to motivate further research in this area.

1 Introduction

NLP models, especially with the recent advances of large pre-trained language models have achieved great progress and gained wide applications in the real world. Despite the performance gains, NLP models are still fragile and brittle to out-of-domain data (Hendrycks et al., 2020a; Wang et al., 2019d), adversarial attacks (McCoy et al., 2019; Jia and Liang, 2017; Jin et al., 2020), or small perturbation to the input (Ebrahimi et al., 2018; Belinkov and Bisk, 2018). Those failures could hinder the safe deployment of these models in the real world, and impact NLP models' trustworthiness to users. As a result, an increasing line of work has been conducted to understand robustness issues in the language technologies communities. Still, diverse sets of research across multiple dimensions and numerous levels of depth exist and are scattered across various communities; for instance, using a variety of definitions on a wide range of very different NLP tasks. In this work, we provide a unifying overview of what is robustness in NLP, how to identify robustness failures and evaluate model's robustness, and systematic ways to improve robustness, as well as a conceptual schema categorizing ongoing research directions. We identify gaps between the to-date robustness work, the technical opportunities, and discuss possible paths forward.

2 Definitions of Robustness in NLP

Robustness, despite its specific definitions in various lines of research, can typically be unified as follows: denote the input as x, and its associated gold label for the main task as y, assume a model f is trained on $(x, y) \sim \mathcal{D}$ and its prediction over x as $f(x)$; now given test data $(x', y') \sim \mathcal{D}' \neq \mathcal{D}$, we can measure a model's robustness by its performance on $\mathcal{D}'$, e.g., using the model's robust accuracy (Tsipras et al., 2019; Yang et al., 2020), defined as $\mathbb{E}_{(x',y')\sim D'}[f(x') = y']$. Existing literature on robustness in NLP can be roughly categorized by how $\mathcal{D}'$ is constructed: by synthetically perturbing the input (Section 2.1), or $\mathcal{D}'$ is naturally occurring with a distribution shift (Section 2.2).

The above definition works for a range of NLP tasks like text classification and sequence labeling where y is defined over a fixed set of discrete labels. For tasks like text generation, robustness is less well defined and can manifest as positional bias (Jung et al., 2019; Kryscinski et al., 2019), or hallucination (Maynez et al., 2020; Parikh et al., 2020; Zhou et al., 2021). One major challenge here is a lack of robust metrics in evaluating the quality of the generated text (Sellam et al., 2020; Zhang et al., 2020b), i.e., we need a reliable metric to determine the relationship between $f(x')$ and y' when both are open-ended texts.

2.1 Robustness against Adversarial Attacks

In one line of research, $\mathcal{D}'$ is constructed by perturbations around input x to form x' (x' typically being defined within some proximity of x). This topic has been widely explored in computer vision under the concept of adversarial robustness, which measures models' performances against carefully crafted noises generated deliberately to deceive the model to predict wrongly, pioneered by (Szegedy et al., 2013; Goodfellow et al., 2015), and later extended to NLP, such as (Ebrahimi et al., 2018; Alzantot et al., 2018; Li et al., 2019; Feng et al., 2018; Kuleshov et al., 2018; Jia et al., 2019; Zang et al., 2020; Pruthi et al., 2019; Wang et al., 2019e; Garg and Ramakrishnan, 2020; Tan et al., 2020a,b; Schwinn et al., 2021; Li et al., 2021; Boucher et al., 2022) and multilingual adversaries (Yang et al., 2019; Tan and Joty, 2021). The generation of adversarial examples primarily builds upon the observation that we can generate samples that are meaningful to humans (e.g., by perturbing the samples with changes that are imperceptible to humans) while altering the prediction of the models for this sample. In this regard, human's remarkable ability in understanding a large set of synonyms (Li et al., 2020) or interesting characteristics in ignoring the exact order of letters (Wang et al., 2020b) are often opportunities to create adversarial examples. A related line of work such as data-poisoning (Wallace et al., 2021) and weight-poisoning (Kurita et al., 2020) exposes NLP models' vulnerability against attacks during the training process. One can refer to more comprehensive reviews and broader discussions on this topic in Zhang et al. (2020c) and Morris et al. (2020b).

Assumptions around Label-preserving and Semantic-preserving Most existing work in vision makes a relatively simplified assumption that the gold label of x' remains unchanged under a bounded perturbation over x, i.e., $y' = y$, and a model's robust behaviour should be $f(x') = y$ (Szegedy et al., 2013; Goodfellow et al., 2015). A similar line of work in NLP follows the same label-preserving assumption with small text perturbations like token and character swapping (Alzantot et al., 2018; Jin et al., 2020; Ren et al., 2019; Ebrahimi et al., 2018), paraphrasing (Iyyer et al., 2018; Gan and Ng, 2019), semantically equivalent adversarial rules (Ribeiro et al., 2018), and adding distractors (Jia and Liang, 2017). However, this label-preserving assumption might not always hold, e.g., Wang et al. (2021b) studied several existing text perturbation techniques and found that a significant portion of perturbed examples are **not** label-preserving (despite their label-preserving assumptions), or the resulting labels have a high disagreement among human raters (i.e., can even fool humans). Morris et al. (2020a) also call for more attention to the *validity* of perturbed examples for a more accurate robustness evaluation.

Another line of work aims to perturb the input x to x' in small but meaningful ways that explicitly *change* the gold label, i.e., $y' \neq y$, under which case the robust behaviour of a model should be $f(x') = y'$ and $f(x') \neq y$ (Gardner et al., 2020; Kaushik et al., 2019; Schlegel et al., 2021). We believe these two lines of work are complementary to each other, and both should be explored in future research to measure models' robustness more comprehensively.

One alternative notion is whether the perturbation from x to x' is "semantic-preseving" (Alzantot et al., 2018; Jin et al., 2020; Ren et al., 2019) or "semantic-modifying" (Shi and Huang, 2020; Jia and Liang, 2017). Note this is slightly different from the above label-preserving assumptions, as it is defined over the perturbations on (x, x') rather than making an assumption on (y, y'), e.g., semantic-modifying perturbations can be either label-preserving (Jia and Liang, 2017; Shi and Huang, 2020) or label-changing (Gardner et al., 2020; Kaushik et al., 2019).

2.2 Robustness under Distribution Shift

Another line of research focuses on (x', y') drawn from a different distribution that is naturally-occurring (Hendrycks et al., 2021), where robustness can be defined around model's performance under distribution shift. Different from work on domain adaptation (Patel et al., 2015; Wilson and Cook, 2020) and transfer learning (Pan and Yang, 2010), existing definitions of robustness are closer to the concept of domain generalization (Muandet et al., 2013; Gulrajani and Lopez-Paz, 2021), or out-of-distribution generalization to unforeseen distribution shifts (Hendrycks et al., 2020a), where the test data (either labeled or unlabeled) is assumed not available during training, i.e., generalization without adaptation. In the context of NLP, robustness to natural distribution shifts can also mean models' performance should not degrade due to the differences in grammar errors, dialects, speakers, languages (Craig and Washington, 2002; Blodgett et al., 2016; Demszky et al., 2021), or newly collected datasets for the same task but in different domains (Miller et al., 2020). Another closely connected line of research is fairness, which has been studied in various NLP applications, see (Sun et al., 2019) for a more in-depth survey in this area. For example, gendered stereotypes or biases have been observed in NLP tasks including co-reference resolution (Zhao et al., 2018a; Rudinger et al., 2017), occupation classification (De-Arteaga et al., 2019), and neural machine translation (Prates et al., 2019; Font and Costa-jussà, 2019).

2.3 Connections and A Common Theme

The above two categories of robustness can be unified under the same framework, i.e., whether $\mathcal{D}'$ represents a *synthetic* distribution shift (via adversarial attacks) or a *natural* distribution shift. Existing work has shown a model's performance might degrade substantially in both cases, but the *transferability* of the two categories is relatively underexplored. In the vision domain, Taori et al. (2020) investigate models' robustness to natural distribution shift, and show that robustness to synthetic distribution shift might offer little to no robustness improvement under natural distribution shift. Some studies show NLP models might not generalize to *unseen* adversarial patterns (Huang et al., 2020; Jha et al., 2020; Joshi and He, 2021), but more work is needed to systematically bridge the gap between NLP models' robustness under natural and synthetic distribution shifts.

To better understand *why* models exhibit a lack of robustness, some existing work attributed this to the fact that models sometimes utilize *spurious* correlations between input features and labels, rather than the *genuine* ones, where *spurious* features are commonly defined as features that do not causally affect a task's label (Srivastava et al., 2020; Wang and Culotta, 2020b): they correlate with task labels but fail to transfer to more challenging test conditions or out-of-distribution data (Geirhos et al., 2020). Some other work defined it as "prediction rules that work for the majority examples but do not hold in general" (Tu et al., 2020). Such spurious correlations are sometimes referred as dataset bias (Clark et al., 2019; He et al., 2019), annotation artifacts (Gururangan et al., 2018), or group shift (Oren et al., 2019) in the literature. Further, evidence showed that controlling model's learning in spurious features will improve model's performances in distribution shifts (Wang et al., 2019a,b); also, discussions on the connections between adversarial robustness and learning of spurious features have been raised (Ilyas et al., 2019; Wang et al., 2020a). Theoretical discussions connecting these fields have also been offered by crediting a reason of model's lack of robustness in either distribution shift or adversarial attack to model's learning of spurious features (Wang et al., 2021c).

Further, in certain applications, model "robustness" can also be connected with models' instability (Milani Fard et al., 2016), or models having poorly-calibrated uncertainty estimation (Guo et al., 2017), where Bayesian methods (Graves, 2011; Blundell et al., 2015), dropout-based (Gal and Ghahramani, 2016; Kingma et al., 2015) and ensemble-based approaches (Lakshminarayanan et al., 2017) have been proposed to improve models' uncertainty estimation. Recently, Ovadia et al. (2019) have shown models' uncertainty estimation can degrade significantly under distributional shift, and call for more work to ensure a model "knows when it doesn't know" by giving lower uncertainty estimates over out-of-distribution data. This is another example where models can be less robust under distributional shifts, and again emphasizes the need of building more unified benchmarks to measure a model's performance (e.g., robust accuracy, calibration, stability) under distribution shifts, in addition to in-distribution accuracy.

3 Robustness in Vision vs. in NLP

Despite the widely study of robustness in vision, the study of robustness in NLP cannot always directly borrow the ideas. We categorize the main differences with the three following points:

Continuous vs. Discrete in Search Space The most obvious characteristic is probably the discrete nature of the space of text. This particularly posed a challenge towards the adversarial attack and defense regime when the study in vision is transferred to NLP (Lei et al., 2019; Zhang et al., 2020c), in the sense that simple gradient-based adversarial attacks will not directly translate to meaningful attacks in the discrete text space, and multiple novel attack methods are proposed to fill the gap, as we will discuss in later sections.

Perceptible to Human vs. Not On a related topic, one of the most impressive property of adversarial attack in vision is that small perturbation of the image data imperceptible to human are sufficient to deceive the model (Szegedy et al., 2013), while this can hardly be true for NLP attacks. Instead of being imperceptible, the adversarial attacks in NLP typically are bounded by the fact that the meaning of the sentences are not altered (despite being perceptible). On the other hand, there are ways to generate samples where the changes, although being perceptible, are often ignored by human brain due to some psychological prior on how a human processes the text (Anastasopoulos et al., 2019; Wang et al., 2020b).

Support vs. Density Difference of the Data Distributions Another difference is more likely seen in the discussion of the domain adaptation of vision and NLP study. In vision study, although the images from training distribution and test distribution can be sufficiently different, the train and test distributions mostly share the same support (the pixels are always sampled from a 0-255 integer space), although the density of these distributions can be very different (e.g., photos vs. sketches). On the other hand, domain adaptation of NLP sometimes studies the regime where the supports of the data differ, e.g., the vocabularies can be significantly different in cross-lingual studies (Abad et al., 2020; Zhang et al., 2020a).

A Common Theme Despite the disparities between vision and NLP, the common theme of pushing the model to generalize from $\mathcal{D}$ to $\mathcal{D}'$ preserves. The practical difference between $\mathcal{D}$ and $\mathcal{D}'$ is more than often defined by the human's understanding of the data, and can differ in vision and NLP as humans perceive and process images and texts in subtly different ways, which creates both opportunities for learning and barriers for direct transfer. Certain lines of research try to bridge the learning in the vision domain to the embedding space in the NLP domain, while other lines of research create more interpretable attacks in the discrete text space (see Table 1 for these two lines of work). How those two lines of research transfer to each other, or complement each other, is not fully explored and calls for additional research.

4 Identify Robustness Failures

As robustness gained increasing attention in NLP literature, various lines of work have proposed ways to identify robustness failures in NLP models. Existing works can be roughly categorized by *how* the failures are identified, among which a large portion of work relies on human priors and error analyses over existing NLP models (Section 4.1), and other lines of work adopt model-based approaches (Section 4.2). The identified robustness failure patterns are usually organized into challenging/adversarial benchmark datasets to more accurately measure an NLP model's robustness. In Table 1, we organize commonly used perturbation types for identifying models' robustness failures, and in Table 2 we summarize common robustness benchmarks for each NLP task.

4.1 Human Prior and Error Analyses Driven

An increasing body of work has been conducted on understanding and measuring robustness in NLP models (Tu et al., 2020; Sagawa et al., 2020b; Geirhos et al., 2020) across various NLP tasks, largely relying on human priors and error analyses.

Natural Language Inference Naik et al. (2018) sampled misclassified examples and analyzed their potential sources of errors, which are then grouped into a typology of common reasons for error. Such error types then served as the bases to construct the *stress test* set, to further evaluate whether NLI models have the ability to make real inferential decisions, or simply rely on sophisticated pattern matching. Gururangan et al. (2018) found that current NLI models are likely to identify the label by relying only on the hypothesis, and Poliak et al. (2018) provided similar augments that using a hypothesis-only model can outperform a set of strong baselines. Kaushik et al. (2019) asked humans to generate counterfactual NLI examples, to better understand what features are causal and encourage models to learn those features.

Question Answering Jia and Liang (2017) proposed to generate adversarial QA examples by concatenating an adversarial distracting sentence at the end of a paragraph. Miller et al. (2020) built four new test sets for the Stanford Question Answering Dataset (SQuAD) and found most question-answering systems fail to generalize to this new data, calling for new evaluation metrics towards natural distribution shifts.

Machine Translation Belinkov and Bisk (2018) found that character-based neural machine translation (NMT) models are brittle under noisy data, where noises (e.g., typos, misspellings, etc) are

Space	Perturbation level	Methods
Discrete	Character-level	HotFlip (Ebrahimi et al., 2018), DeepWordBug (Gao et al., 2018), Synthetic-Noise (Karpukhin et al., 2019)
	Word-level	GenAdv (Alzantot et al., 2018), PWWS (Ren et al., 2019), SEM (Wang et al., 2019e), BERT-ATTACK (Li et al., 2020), TextFooler (Jin et al., 2020), SememePSO (Zang et al., 2020)
	Sentence-level	AdvSQuAD (Jia and Liang, 2017), SCPNs (Iyyer et al., 2018), CAT-Gen (Wang et al., 2020c), TAILOR (Ross et al., 2021)
	Mixed-types	CheckList (Ribeiro et al., 2020), Polyjuice (Wu et al., 2021), MAYA (Chen et al., 2021c)
Continuous	Embedding space	AT & VAT (Miyato et al., 2017), Natural-adversary (Zhao et al., 2018b), FreeLB (Zhu et al., 2020), ALUM (Liu et al., 2020)

Table 1: Perturbation types for identifying robustness failures and improving robustness in NLP.

Task	Robustness Benchmarks
Natural Language Inference	Stress-test (Naik et al., 2018), HANS (McCoy et al., 2019), Counterfactual-NLI (Kaushik et al., 2019), ANLI (Nie et al., 2020)
Question Answering	AdvSQuAD (Jia and Liang, 2017), Adv-QA (Bartolo et al., 2020), Natural-Perturbed-QA (Khashabi et al., 2020), Natural-shift-QA (Miller et al., 2020), SAM (Schlegel et al., 2021)
Paraphrase Identification	PAWS (Zhang et al., 2019b), PAWS-X (Yang et al., 2019), Modify-with-Shared-Words (Shi and Huang, 2020)
Co-reference	WinoGender (Rudinger et al., 2018), WinoBias (Zhao et al., 2018a)
Named Entity Recognition	OntoRock (Lin et al., 2021), SeqAttack (Simoncini and Spanakis, 2021)

Table 2: A list of robustness benchmarks (challenging or adversarial datasets) and their corresponding tasks.

synthetically generated using possible lexical replacements. Data augmentation with artificially-introduced grammatical errors (Anastasopoulos et al., 2019) or with random synthetic noises (Vaibhav et al., 2019; Karpukhin et al., 2019) can make the system more robust to such spurious patterns. On the other hand, Wang et al. (2020b) showed another approach by limiting the input space of the characters so that the models will be likely to perceive data typos and misspellings.

Syntactic and Semantic Parsing Robust parsing has been studied in several existing works (Lee et al., 1995; Aït-Mokhtar et al., 2002). More recent work showed that neural semantic parsers are still not robust against lexical and stylistic variations, or meaning-preserving perturbations (Marzinotto et al., 2019; Huang et al., 2021), and proposed ways to improve their robustness through data augmentation (Huang et al., 2021) and adversarial learning (Marzinotto et al., 2019).

Text Generation Existing work found that text generation models also suffer from robustness issues, e.g., text summarization models suffer from positional bias (Jung et al., 2019), layout bias (Kryscinski et al., 2019), and a lack of faithfulness and factuality (Kryscinski et al., 2019; Maynez et al., 2020; Chen et al., 2021b); data-to-text models sometimes hallucinate texts that are not supported by the data (Parikh et al., 2020; Wang et al., 2020d). In addition, Sellam et al. (2020); Zhang et al. (2020b) pointed out the deficiency of existing automatic evaluation metrics and proposed new metrics to better align the generation quality with human judgements.

Connection with Dataset Biases The robustness failures can sometimes be attributed to dataset biases, i.e., biases introduced during dataset collection (Fouhey et al., 2018) or human annotation artifacts (Gururangan et al., 2018; Geva et al., 2019; Rudinger et al., 2017), which could affect how well a model trained from this dataset generalizes, and how accurately we estimate a model's performance. For example, Lewis et al. (2021) show there is a significant test-train data overlap in a set of open-domain question-answering benchmarks, and many QA models perform substantially worse on questions that cannot be memorized from training data. In natural language inference, McCoy et al. (2019)

show that commonly used crowdsourced datasets for training NLI models might make certain syntactic heuristics more easily adopted by statistical learners. Further, Bras et al. (2020) propose to use a lightweight adversarial filtering approach to filter dataset biases, which is approximated using each instance's predictability score.

4.2 Model-based Identification

In addition to the human-prior and error-analysis driven approaches which are usually specific to each task, other lines of work identify robustness failures that are *task-agnostic* like white-box text attack methods (Ebrahimi et al., 2018; Alzantot et al., 2018; Jin et al., 2020), and even *input-agnostic* like universal adversarial triggers (Wallace et al., 2019a) and natural attack triggers (Song et al., 2021).

Another line of work proposes to learn an additional model to capture biases, e.g., in visual question answering, Clark et al. (2019) train a naive model to predict prototypical answers based on the question only irrespective of the context; He et al. (2019); Utama et al. (2020a) propose to learn a biased model that only uses dataset-bias related features. This framework has also been used to capture unknown biases assuming that the lower capacity model learns to capture relatively shallow correlations during training (Clark et al., 2020). In addition, Wang and Culotta (2020a) identify model shortcuts by training classifiers to better distinguish "spurious" correlations from "genuine" ones based on human annotated examples.

Model-in-the-loop vs. Human-in-the-loop Some work adopts human-in-the-loop to generate challenging examples, e.g., Counterfacutal-NLI (Kaushik et al., 2019) and Natural-Perturbed-QA (Khashabi et al., 2020). Other work applies model-in-the-loop to increase the likelihood that the perturbed examples are challenging for state-of-the-art models, but it might also introduce biases towards the particular model used. For example, SWAG (Zellers et al., 2018) was introduced that fooled most models at the time of publishing but was soon "solved" after BERT (Devlin et al., 2019) was introduced. As a result, Yuan et al. (2021) present a study over the transferability of adversarial examples, and Contrast Sets (Gardner et al., 2020) intentionally avoid using model-in-the-loop. Further, more recent work adopts adversarial human-and-model-in-the-loop to create more difficult examples for benchmarking, e.g., Adv-QA (Bartolo et al., 2020), Adv-Quizbowl (Wallace et al., 2019b), ANLI (Nie et al., 2020), and Dynabench (Kiela et al., 2021).

5 Improve Model Robustness

Correspondingly, there are multiple lines of directions that try to improve robustness in NLP models. Depending on where and how the intervention is applied, those approaches can be categorized into the following categories: data-driven (Section 5.1), model-based and training-scheme-based (Section 5.2), inductive-prior-based (Section 5.3) and finally causal intervention (Section 5.4).

5.1 Data-driven Approaches

Data augmentation recently gained a lot of interest, in improving performance in low-resourced language settings, few-shot learning, mitigating biases, and improving robustness in NLP models (Feng et al., 2021; Dhole et al., 2021). Techniques like Mixup (Zhang et al., 2018), MixText (Chen et al., 2020), CutOut (DeVries and Taylor, 2017), AugMix (Hendrycks et al., 2020b), HiddenCut (Chen et al., 2021a), have been shown to substantially improve the robustness and the generalization of models. Such mitigation strategies are operated at the data level, and often hard to be interpreted in terms of how and why mitigation works.

Other lines of work deal with spans or regions associated within data points to prevent models from heavily relying on spurious patterns. To make NLP models more robust on sentiment analysis and NLI tasks, Kaushik et al. (2019) proposed curating counterfactually augmented data via a human-in-the-loop process, and showed that models trained on the combination of this augmented data and original data are less sensitive to spurious patterns. Differently, Wang et al. (2021d) performed strategic data augmentation to perturb the set of "shortcuts" that are automatically identified, and found that mitigating these leads to more robust models in multiple NLP tasks. This line of mitigation strategies closely relates to how spurious correlations can be measured and identified, as many of the challenging or adversarial examples (Table 1) can sometimes be used to augment the original model to improve its robustness, either in the discrete input space as additional training examples (Liu et al., 2019; Kaushik et al., 2019; Anastasopoulos et al., 2019; Vaibhav et al., 2019; Khashabi et al., 2020), or in the embedding space (Zhu et al., 2020; Zhao et al., 2018b; Miyato et al., 2017; Liu et al., 2020).

5.2 Model and Training-based Approaches

Pre-training Recent work has demonstrated pre-training as an effective way to improve NLP models' out-of-distribution robustness (Hendrycks et al., 2020a; Tu et al., 2020), potentially due to its self-supervised objective and the use of large amounts of diverse pre-training data that encourages generalization from a small number of examples that counter the spurious correlations. Tu et al. (2020) showed a few other factors can also contribute to robust accuracy, including larger model size, more fine-tuning data, and longer fine-tuning. A similar observation is made by Taori et al. (2020) in the vision domain, where the authors found training with larger and more diverse datasets offer better robustness consistently in multiple cases, compared to various robustness interventions proposed in the existing literature.

Training with a Better Use of Minority Examples Further, there are several works that propose to robustify the models via a better use of minority examples, e.g., examples that are under-represented in the training distribution, or examples that are harder to learn. For example, Yaghoobzadeh et al. (2021) proposed to first fine-tune the model on the full data, and then on minority examples only.

In general, the training strategy with an emphasis on a subset of samples that are particularly hard for the model to learn is sometimes also referred to as group DRO (Sagawa et al., 2020a), as an extension of vanilla distributional robust optimization (DRO) (Ben-Tal et al., 2013; Duchi et al., 2021). Extensions of DRO are mostly discussing the strategies on how to identify the samples considered as minority: Nam et al. (2020) trained two models in parallel, where the "debiased" model focuses on examples not learned by the "biased" model; Lahoti et al. (2020) used an adversary model to identify samples that are challenging to the main model; Liu et al. (2021) proposed to train the model a second time via up-weighting examples that have high training losses during the first time.

When to Use Data-driven or Model-based Approaches? In many cases both the data and the model can contribute to a model's lack of robustness, hence data-driven and model-based approaches could be combined to further improve a model's robustness. One interesting phenomenon observed by (Liu et al., 2019) is to attribute models' robustness failures to blind spots in the training data, or the intrinsic learning ability of the model. The authors found that both patterns are possible: in some cases models can be inoculated via being exposed to a small amount of challenging data, similar to the data augmentation approaches mentioned in Section 5.1; on the other hand, some challenging patterns remain difficult which connects to the larger question around generalizability to *unseen* adversarial and counterfactual patterns (Huang et al., 2020; Jha et al., 2020; Joshi and He, 2021), which is relatively under-explored but deserves much attention.

5.3 Inductive-prior-based Approaches

Another thread is to introduce inductive bias (i.e., to regularize the hypothesis space) to force the model to discard some spurious features. This is closely connected to the human-prior-based identification approaches in Section 4.1 as those human-priors can often be used to re-formulate the training objective with additional regularizers. To achieve this goal, one usually needs to first construct a side component to inform the main model about the misaligned features, and then to regularize the main model according to the side component. The construction of this side component usually relies on prior knowledge of what the misaligned features are. Then, methods can be built accordingly to counter the features such as label-associated keywords (He et al., 2019), label-associated text fragments (Mahabadi et al., 2020), and general easy-to-learn patterns of data (Nam et al., 2020). Similarly, Clark et al. (2019, 2020); Utama et al. (2020a,b) propose to *ensemble* with a model explicitly capturing bias, where the main model is trained together with this "bias-only" model such that the main model is discouraged from using biases. More recent work (Xiong et al., 2021) shows the ensemble-based approaches can be further improved via better calibrating the bias-only model. Furthermore, additional regularizers have been introduced for robust fine-tuning over pre-trained models, e.g., mutual-information-based regularizers (Wang et al., 2021a) and smoothness-inducing adversarial regularization (Jiang et al., 2020).

In a broader scope, given that one of the main challenges of domain adaptation is to counter the model's tendency in learning domain-specific spurious features (Ganin et al., 2016), some methods contributing to domain adaption may have also progressed along the line of our interest, e.g., domain adversarial neural network (Ganin et al., 2016). This line of work also inspires a family of methods forcing the model to learn auxiliary-annotation-invariant representations with a side component (Ghifary et al., 2016; Wang et al., 2017; Rozantsev et al., 2018; Motiian et al., 2017; Li et al., 2018; Wang et al., 2019c; Vernikos et al., 2020).

Despite the diverse concrete ideas introduced, the above is mainly training for small empirical loss across different domains or distributions in addition to forcing the model to be invariant to domain-specific spurious features. As an extension along this direction, invariant risk minimization (IRM) (Arjovsky et al., 2019) introduces the idea of invariant predictors across multiple environments, which was later followed and discussed by a variety of extensions (Choe et al., 2020; Ahmed et al., 2020; Rosenfeld et al., 2021). More recently, Dranker et al. (2021) applied IRM in natural language inference and found that a more naturalistic characterization of the problem setup is needed.

5.4 Causal Intervention

Casual analyses have also been utilized to examine robustness. Srivastava et al. (2020) leverage humans' common sense knowledge of causality to augment training examples with a potential unmeasured variable, and propose a DRO-based approach to encourage the model to be robust to distribution shifts over the unmeasured variables. Balashankar et al. (2021) study the effect of secondary attributes, or confounders, and propose context-aware counterfactuals that take into account the impact of secondary attributes to improve models' robustness. Veitch et al. (2021) propose to learn approximately counterfactual invariant predictors dependent on causal structures of the data, and show it can help mitigate spurious correlations in text classification.

5.5 Connections between Mitigations

Connecting these methods conceptually, we conjecture three different mainstream approaches: one is to leverage the large amount of data by taking advantages of pre-trained models, another is to learn invariant representations or predictors across domains or environments, while most of the rest build upon the prior on what the spurious patterns are and encourage the models to not rely on those patterns. Then the solutions are invented through countering model's learning of these patterns by either data augmentation, reweighting (the minorities), ensemble, inductive-prior design, and causal intervention. Interestingly, statistical work has shown that many of these mitigation methods are optimizing the same robust machine learning generalization error bound (Wang et al., 2021c).

6 Open Questions

In addition to the challenges mentioned above, we list below a few open questions that call for additional research going forward.

Identifying Unknown Robustness Failures Existing identification around robustness failures rely heavily on human priors and error analyses, which usually pre-define a small or limited set of patterns that the model could be vulnerable to. This requires extensive amount of expertise and efforts, and might still suffer from human or subjective biases in the end. How to proactively discover and identify models' unrobust regions automatically and comprehensively remains challenging.

Interpreting and Mitigating Spurious Correlations Interpretability matters for large NLP models, especially key to the robustness and spurious patterns. How can we develop ways to attribute or interpret these vulnerable portions of NLP models and communicate these robustness failures with designers, practitioners, and users? In addition, recent work (Wallace et al., 2019c; Wang et al., 2021d; Zhang et al., 2021) show interpretability methods can be utilized to better understand how a model makes its decision, which in turn can be used to uncover models' bias, diagnose errors, and discover spurious correlations.

Furthermore, the mitigation of spurious correlations often suffers from the trade-off between removing shortcuts and sacrificing model performance (Yang et al., 2020; Zhang et al., 2019a). Additionally, most existing mitigation strategies work in a pipeline fashion where defining and detecting spurious correlations are prerequisites, which might lead to error cascades in this process. How to design end-to-end frameworks for automatic mitigation deserves much attention.

Unified Framework to Evaluate Robustness With a variety of potential spurious patterns in NLP models, it becomes increasingly challenging for developers and practitioners to quickly evaluate the robustness and quality of their models. This calls for more unified benchmarking efforts such as

CheckList (Ribeiro et al., 2020), Reliability Testing (Tan et al., 2021), Robustness Gym (Goel et al., 2021) and Dynabench (Kiela et al., 2021), to facilitate fast and easy evaluation of robustness.

User Centered Measures and Mitigation Instead of passively detecting spurious correlations from a post-processing perspective, how to approach robustness from a user centric perspective needs further investigation. Based on the dual-process models of information processing, humans use two different processing styles (Evans, 2010). One is a quick and automatic style that relies on well-learned information and heuristic cues. The other is a qualitatively different style that is slower, more deliberative, and requires more reflective reasoning. Would these well-learned information and heuristic rules be leveraged to help design better human priors to measure and mitigate spurious correlations? If users or stakeholders are involved in this process, collecting a set of test cases where a system might perform well for the wrong reasons could help design sanity tests.

Connections between Human-like Linguistic Generalization and NLP Generalization Linzen (2020) argue NLP models should behave more like humans to achieve better generalization consistently. It is interesting to note that how humans process information in NLP tasks exactly is still under exploration, and to what extent models should leverage human-knowledge is still a debatable topic.[1] Nonetheless, if we can better understand and utilize the robustness properties in human perception, we can potentially advance models' robustness in a more meaningful way.

7 Conclusion

In this paper, we provided a unifying overview over robustness definitions, evaluations and mitigation strategies in the NLP domain. We also highlighted open challenges in this area to motivate future research, encouraging people to think deeply about more comprehensive benchmarks, transferability and validity of adversarial examples, unified framework to evaluate and improve robustness, user-centered measures and mitigation, and finally how to potentially achieve human-like linguistic generalization more meaningfully.

Abstract

Even if recent Transformer-based architectures, such as BERT, achieved impressive results in semantic processing tasks, their fine-tuning stage still requires large scale training resources. Usually, Data Augmentation (DA) techniques can help to deal with low resource settings. In Text Classification tasks, the objective of DA is the generation of well-formed sentences that (*i*) represent the desired task category and (*ii*) are novel with respect to existing sentences. In this paper, we propose a neural approach to automatically learn to generate new examples using a pre-trained sequence-to-sequence model. We first learn a task-oriented similarity function that we use to pair similar examples. Then, we use these example pairs to train a model to generate examples. Experiments in low resource settings show that augmenting the training material with the proposed strategy systematically improves the results on text classification and natural language inference tasks by up to 10% accuracy, outperforming existing DA approaches.

1 Introduction

Deep Learning models achieve state-of-the-art results in many domains, including Computer Vision and Natural Language Processing (NLP). Training these large models typically requires many examples, whose collection and annotation can be costly and time-consuming. Data augmentation (DA) has proven an efficient way to acquire more training samples without incurring in the prohibitive annotation cost in a variety of fields, including computer vision (Perez and Wang, 2017) and speech recognition (Rebai et al., 2017). In NLP, some DA techniques have been proposed too, as surveyed in (Feng et al., 2021): common approaches create synthetic data by manipulating real examples, using Text Editing (Wei and Zou, 2019) or Back-Translation (Sennrich et al., 2015); the resulting examples are automatically labeled by inheriting the class of the original example they were generated from.

Unfortunately, when using recent pre-trained language models, such as BERT (Devlin et al., 2018) or RoBERTa (Liu et al., 2019), the effectiveness of DA methods is extremely limited, and sometimes they can even hurt the results (Longpre et al., 2020). A possible explanation for this inefficacy is that these DA techniques introduce lexical and structural variability that accurate language models directly induce during pre-training. The usefulness of synthetic examples is strictly related to their diversity from the original training data. At the same time, diverging too much from the initial data might increase the risk of introducing noisy annotations, i.e., synthetic data not reflecting the class of the original examples they were generated from.

To directly tackle the trade-off between diversity and label consistency, in this paper we propose DATS[1] (Data Augmentation based on Task-specific Similarity), a novel data-augmentation technique for text classification based on Natural Language Generation (NLG) models. Starting from a reduced set of annotated examples, we first learn a task-oriented similarity function that we use to automatically create pairs of similar examples. Then, we use these pairs to train a generative model to generate an example similar to the input one. Finally, we employ this model to generate new synthetic examples and augment the training data. We show that pairing examples with respect to their task-

oriented similarity is striking in order to allow the generative model to automatically understand the lexical and structural variations that can be applied to an instance without changing its label. Experimental results on four different text classification datasets demonstrate that DATS achieves better results than several existing DA solutions and that it systematically improves NLU models based on state-of-the-art pre-trained language models. In the remaining, Section 2 summarizes related works, Section 3 describes our method and Section 4 provides the experimental evaluation.

2 Related Work

Most of the existing approaches for DA perform some token-level manipulations on individual sentences (Kolomiyets et al., 2011; Kobayashi, 2018). For instance, Easy Data Augmentation (EDA) (Wei and Zou, 2019) applies simple operations including synonym replacement and random swap. These operations are also performed in (Ren et al., 2021) where the framework named Text AutoAugment (TAA) uses Bayesian Optimization algorithm to automatically search for the best manipulation policy. On the contrary, Wu et al. (2018) uses mask random tokens and use BERT to generate substituting words. Similarly, Kumar et al. (2020) use transformer-based models to apply token-level or span-level text content manipulation.

Other attempts operate at the entire sentence-level by paraphrasing the original text using back-translation (BT) (Edunov et al., 2018; Shleifer, 2019); however, BT tends to skew towards high-frequency words which not only causes redundancy but also leads to lexical shrinkage in the augmented data (Liu et al., 2020). More recent approaches for data augmentation use generative models to create more diverse synthetic data. Anaby-Tavor et al. (2019) fine-tuned a GPT-2 model to generate text given a target class, and use a text classifier to filter out those synthetic examples whose predicted class does not match the target class. In our work, we show that by conditioning a target model not only on the class labels, but also on representative examples, it is possible to better control the diversity-consistency trade-off.

3 Learning to generate examples

Recent advances in NLG (Vaswani et al., 2017) demonstrated that sequence-to-sequence (seq2seq) models can generate natural sounding and meaningful text given a prompt. As shown in (Keskar et al., 2019), the prompt can include style or content-related information that can help control the generation process.

In our work, we capitalize these techniques to augment a dataset $\mathcal{D}$ for the training of a text classifier $\mathcal{C}$. Specifically, our goal is to fine-tune a pre-trained seq2seq model $\mathcal{M}(*) = e$ that, given a prompt $*$, generates novel examples not in $\mathcal{D}$. The first application of this idea was investigated in Anaby-Tavor et al. (2019), where the authors trained a seq2seq model $\mathcal{M}(c) = s_o$ that generates examples s_o of a given class c. While this approach provides interesting results, it must be said that the variability of the generated examples can be quite low: by conditioning $\mathcal{M}$ only on c, it tends to produce the most frequent syntactic and lexical patterns associated with c, neglecting other modes this can exhibit. The key challenge here is to ensure diversity while preserving consistency, i.e., generating diverse examples that are valid representatives of the desired class.

We propose to train a seq2seq model $\mathcal{M}$ that is conditioned not only on the class c, but also on an example s_i of that class, i.e., such that $\mathcal{M}(c, s_i) = s_0$. The model is thus expected to synthesize a new example s_0, which is consistent with the input class c and is also "inspired" by an existing example s_i. The problem now is how to build the dataset to train $\mathcal{M}$. Pairing two random examples s_i and s_o belonging to the same class might be a viable solution. However, in classification tasks, examples are not necessarily similar, and coupling together radically different examples risks destabilizing the training of $\mathcal{M}$. Ideally, we would like to identify different modes in the same class and pair only examples belonging to the same mode. An alternative way to reach the same outcome is the adoption of a semantic similarity function that can be used to select linguistically related example pairs. Several unsupervised metrics exist (Croce et al., 2011; Cer et al., 2018; Poerner et al., 2020), however, they are inherently task-independent and not adequate in capturing task-specific similarities: two sentences such as "*The movie is good*" and "*The movie is not good*" (or even "*The movie is awful*") should not be paired together, when dealing with sentiment classification, while they are good candidate pairs in the training of a topic classifier.

To define a task-oriented similarity measure, we leverage the text classifier $\mathcal{C}$ we want to improve via data augmentation. Independently on the underlying neural architecture, a neural classifier has an encoder $\mathcal{E}$ that projects an example $s \in \mathcal{D}$ in a d-dimensional space, i.e., $\mathcal{E}(s) = \vec{s} \in \mathbb{R}^d$. In these spaces, simple linear classifiers (i.e., the output layers) identify the sub-spaces reflecting the target classes (Goodfellow et al., 2016; Goldberg, 2016). As a consequence, $\mathcal{E}$ is expected to project examples in sub-spaces representative for individual classes. Our task-aware similarity measure is the cosine similarity operating on these representations. For instance, after training a BERT model on the question classification task (Li and Roth, 2006), the encoding `[CLS]` of the entire question "*Who developed the vaccination against polio?*" allows retrieving other questions corresponding to the most similar `[CLS]` embeddings, such as "*Who invented the Moog Synthesizer?*": they are clearly not paraphrases, and their purely lexical similarity is quite low, but they show a similar pattern characterizing the question class `[HUM]` (i.e., human).

```
Input: A dataset $\mathcal{D}$, number of folds $f$, input pairs per example $n$ ,
       number of generated examples per input $l$ ,
Output: An augmented dataset $\mathcal{D}_{synt}$
$\mathcal{D}_{synt} = \emptyset$

return $D_{synt}$
```

Algorithm 1: Pseudo-code of DATS.

To generate an augmented dataset for a generic text classification task, we propose DATS (Data Augmentation based on Task-specific Similarity) that is described in Algorithm 1. First, we train a classifier $\mathcal{C}$ on $\mathcal{D}$. We use the resulting encoder $\mathcal{E}$ to project each training example e into the task-specific vector space, obtaining the embedding $\vec{e}$. Then, we split the training data $\mathcal{D}$ into $\mathcal{D}_{tr}$ and $\mathcal{D}_{te}$. Each example $e_i \in \mathcal{D}_{tr}$ is paired with the n examples $e_j \in \mathcal{D}_{tr}$ of the same class having the highest cosine similarity computed on their corresponding embeddings vectors $\mathcal{E}(e_i)$ and $\mathcal{E}(e_j)$. The resulting pairs are expected to lie in the same subspace and share some task-oriented linguistic relatedness. We use these example pairs to fine-tune a seq2seq model to solve the task $\mathcal{M}(c_{e_i}, e_i) = e_j$, where c_{e_i} is the category of e_i. Finally, examples in $\mathcal{D}_{te}$ are provided in input to $\mathcal{M}$ to generate the new synthetic dataset $\mathcal{D}_{synt}$. By applying multiple splits of $\mathcal{D}$ in a cross-fold scheme, we can use each training example to condition the model and generate new synthetic instances. As in almost all existing formulations, a generator can be used to generate a set of l variants for each input (c, e), for simplicity referred as $\mathcal{M}^l(c, e)$. In particular, techniques such as *nucleus-sampling* (Holtzman et al., 2020) enable the generation of large sets of variants, generally characterized by a good diversity.

It is worth noting that no assumption is applied when selecting $\mathcal{C}$ or $\mathcal{M}$. Even though in the experimental evaluation we consider only specific architectures (namely BERT and BART), this methodology can be applied to a wider plethora of models. Moreover, there is no restriction on the classification task type: the experimental section shows that DATS is applicable to classification tasks operating on both individual sentences and text pairs, e.g., in natural language inference (Bowman et al., 2015): given text pairs $s_{i,1}$ and $s_{i,2}$, it is sufficient to extend the above process defining $\mathcal{M}$ differently, i.e., $\mathcal{M}(c_{(s_{i,1}, s_{i,2})}, s_{i,1}, s_{i,2}) = (s_{j,1}, s_{j,2})$.

4 Experimental Evaluation

We test our approach on four tasks: 50-class Question Classification (QC) over the TREC dataset (Li and Roth, 2006); 5-class Sentiment Classification (SA) over the SST dataset (Socher et al., 2013); 7-class Intent Classification (IC) over the SNIPS dataset (Coucke et al., 2018); sentence-pair classification for Natural Language Inference (NLI) over the 3-category SNLI dataset (Bowman et al., 2015). Details about the datasets are in Appendix A.1.

Baselines. We compare our approach with multiple baselines and simplified versions of DATS for ablation study: (*i*) Easy Data Augmentation (EDA) (Wei and Zou, 2019); (*ii*) Back-Translation (BT) (Sennrich et al., 2015) in an English-German-English setting[2]; (*iii*) *Random Pairing* (RP) - DATS

---

[2] For EDA and BT we adopted the code in https://github.com/varunkumar-dev/

without task-oriented similarity functions where we created the training input-output pairs for $\mathcal{M}$ by selecting two random examples of the same class from the training set; *(iv)* Only Class (OC) - DATS where the prompt is only the category name (i.e., no representative example), similar to Anaby-Tavor et al. (2019).

Experimental Setting. For QC, SA and IC, we report the Accuracy when using q=10, q=50 or q=100 average examples per class[3]. For the NLI task, since it is more challenging, we report the Accuracy also for q=500 and q=1000 average examples per category. We also report the performance of each model when using the entire (F) training set[4]. We use the `bert-base-uncased` model from the Huggingface library (Wolf et al., 2019) as the classifier $\mathcal{C}$, and `bart-base` (Lewis et al., 2020) as the NLG model $\mathcal{M}$. Both are trained for 10 epochs with early stopping (patience=3) and learning rate $5e^{-5}$. We adopt nucleous sampling[5] (Holtzman et al., 2020) with p=0.90. We repeat the experiments 5 times with different seeds and we report the average classification accuracy.

Results. Table 1 shows the results of a BERT-based model without DA (NoDA), the DA baselines and our approach (DATS). We perform hyper-parameters tuning[6] on the development set of each task w.r.t. the number of similar examples n and the number of generated examples l. Task-agnostic DA approaches, like BT or EDA, seem slightly beneficial when using a transformer based classifier $\mathcal{C}$, as also reported in (Longpre et al., 2020). In some cases, they significantly hurt accuracy.

For instance, in QC or IC when q=10, EDA Accuracy is lower than NoDA by about 1 and 6 points, respectively. The same is for BT, where the drop is even higher, i.e., 8 and 18 points. Using the category information in the generation process, i.e., RP and OC, provides variable results, with minor improvements only in few specific settings (e.g., RP on SA). Instead, DATS improves accuracy for almost all q and tasks and such improvements are often statistically significant. When q=10, the improvement ranges between 1 and 10 points. In the few cases where a minor drop is observed, this is never statistically significant. By comparing DATS with RP it is clear that the task-specific similarity measure is striking to learn a good data generator[7]. DATS works well also on sentence-pair tasks, like NLI. However, given the complexity of this type of tasks, it requires more training examples (e.g., q>100) to show a positive impact. Furthermore, DATS outperforms other competitive methods [8]. With q=10 Kumar et al. (2020) report 67.30% accuracy in QC and 87.24% in IC, which is 1.74% and 4.5% lower than DATS. In the same setting, the gap with Wu et al. (2018) is even larger, i.e., 4.71% and 5.95%. Moreover, Ren et al. (2021) report 52.55% accuracy in SA using the entire training set, and DATS outperforms it by 1.71%.

Qualitative Analysis. To better understand the advantages provided by DATS in the consistency-diversity trade-off, we report a qualitative evalua-

---

`TransformersDataAugmentation`

[3] To maintain the original class distribution we randomly sample $10c$, $50c$ or $100c$ from the original training set, with c being the number of classes. We ensure that at least one example per class is sampled.

[4] We omit results on the full dataset for NLI (made of more than $500,000$ examples) for which DA is not needed.

[5] In preliminary evaluations, we tested alternative decoding strategies, e.g., standard beam search and k-sampling. Overall, nucleous sampling was superior in terms of diversity and consistency, in line with the literature (Holtzman et al., 2020).

[6] An analysis of the hyper-parameters is in Appendix A.4

[7] We tried to substitute the task-oriented similarity with a cosine similarity on USE embeddings (Cer et al., 2018) - a general-purpose sentence encoder. Preliminary results on QC were in between DATS and RP, demonstrating that a task-oriented similarity is beneficial.

[8] Due to lack of budget, we did not run experiments on these models. The reported comparisons are based on the results reported by the authors.

Table 2: A qualitative analysis of the diversity in the Sentiment Analysis task over SST-5.

tion of the generated sentences for the SA task.

In particular, Table 2 reports some of the SA examples generated by different models on classes 5 and 1 when using $q = 10$ average training examples per class. Exception for a single case "(*It is a masterpiece, brilliantly directed, and incredibly well done.*)" that is not a negative sentiment example as it was supposed to be), the examples generated by DATS (with $n = 1$ and $l = 1$) are all label-consistent. However, the diversity introduced by DATS is impressive: all the examples are very different from the input example used to condition the NLG model while generating them, and therefore can be very useful when augmenting the training data of NLU models. On the opposite, BT introduces very minor modifications to the input text, resulting in a significant lower diversity A larger and systematic qualitative analysis on the quality and diversity of the generated material is in Appendix A.2 and A.3.

5 Conclusions

This paper proposes DATS, a data augmentation method based on Natural Language Generation (NLG) models. A generative model is fine-tuned to produce examples similar to the input ones. The training input-output pairs are selected according to a task-oriented similarity function. This pairing allows the NLG model to learn the lexical and structural variations that can be applied to an instance without changing its label. The experimental results suggest that the generated sentences are diverse and label consistent, and can improve state-of-the-art text classifiers, outperforming existing DA methods. In the future, we plan to apply DATS to further tasks (e.g., Question Answering) and neural architectures.

Acknowledgments

We would like to thank the "Istituto di Analisi dei Sistemi ed Informatica - Antonio Ruberti" (IASI) for supporting the experimentations through access to dedicated computing resources.

A Appendix

A.1 Task Description

In this section we report details and statistics of the dataset we adopted in the experimental section.

TREC. The TREC (Li and Roth, 2006) dataset contains 4,907, 545 and 500 examples for training, development and test, respectively. We adopted the fine-grained version of the dataset that contains 50 categories.

SST5. The Sentiment Analysis Treebank dataset (Socher et al., 2013) consists of 8,544, 1,101 and 2,210 examples for training, development and test, respectively. The dataset is characterized by 5 categories for sentiment, i.e., 1 (Very Negative) 2 (Negative), 3 (Neutral), 4 (Positive) and 5 (Very Positive) and it contains movie review sentences.

SNIPS. The SNIPS dataset (Coucke et al., 2018) consists of natural language commands for a voice assistant. The commands are classified into 7 categories, i.e., RateBook, BookRestaurant, AddToPlaylist, PlayMusic, GetWeather, SearchScreeningEvent, SearchCreativeWork. The dataset consists of 13,084, 700, 700 examples for training, development and test, respectively.

SNLI. The SNLI dataset (Bowman et al., 2015) consists of examples of pairs for the Natural Language Inference task. There are 3 categories: *entailment*, *neutral* and *contradiction*. The dataset consists of 550,152, 10,000 and 10,000 for training, development and test, respectively.

A.2 Qualitative Analysis

This section reports additional examples generated by DATS. In particular, we report the examples generated with $n = 2$ and $l = 10$. Notice that, the generated examples are not in the original datasets. It is worth noting that some examples may result odd, such as a question like "*Name the American president born in 2005?*" but we only expected that they are linguistically sound and consistent with the corresponding class. In general, the number n strongly affects the example novelty: high values of n make the generator observe multiple times the same text as the target sentence, making the generation process more conservative. As a result, when using $n > 20$ the generator tends to produce the same examples from the original dataset.

Question classification. Here is a list of 20 questions generated by DATS for different classes. Please refer to the original dataset description for the details about the specific classes.

- `ABBR:exp` *What does D-DAY stand for?*
- `DESC:def` *What does the term "Italian Renaissance" mean?*
- `DESC:desc` *What process takes place after a hydrogen release?*
- `DESC:reason` *Why do people go to the bathroom at night?*
- `ENTY:animal` *What animal was the first domesticated creature in the world?*
- `ENTY:color` *What color is the cross on the French flag?*
- `ENTY:event` *What happened on February 27, 1991?*
- `ENTY:food` *What cereal is "sweet, soft and orange"?*
- `ENTY:plant` *What tree has the longest trunk?*
- `ENTY:subst.` *What are diamond rings made of?*
- `ENTY:veh` *What was the name of the U.S. Navy gunboat used by Dwight D. Eisenhower?*
- `HUM:gr` *Name the two major companies in the energy industry.*
- `HUM:ind` *What's the name of the author of "Harry Potter"?*
- `LOC:city` *What's the name of the largest city in Germany?*
- `LOC:country` *What country in 1991 recorded the largest number of cocaine seizures?*
- `NUM:count` *How many hundred ships sank in the Norwegian Sea in 1923?*
- `NUM:date` *What is the date of the first inauguration of President Nixon?*

- `NUM:money` *What is the cost of university admission to Stanford?*
- `NUM:period` *How long does it take to clean up a cache?*
- `NUM:weight` *What is the maximum weight for a healthy adult?*

Although the above examples seem coherent, we can argue if they can be really new, i.e., useful for the task according to a Data Augmentation process. We thus focused on the specific class `ENTY:lang` that is underrepresented in the original dataset, with only the six original examples reported below:

- *What is the name of a language spoken by the Sioux?*
- *What is the only modern language that capitalizes its singular first-person pronoun?*
- *What is one of the languages spoken by the Sioux called?*
- *What's the official language of Algeria?*
- *What are the two languages of Malta?*
- *What is the main language of Sao Paulo , Brazil?*

Below some of the synthetic examples generated by DATS with q=10. It is worth noting that language model introduces some expressions like *sub-dialect* that are novel with respect to the original training material.

- *What is the language of Switzerland?*
- *What is the oldest language in the Americas?*
- *What's the language spoken by the Kootenai people?*
- *What is the sub-dialect of English?*

Conversely, if we only use the category name as a prompt (i.e., the OC model), the generated questions will have a lower quality. For instance, with $q = 10$ and $l = 10$, the OC model produces questions like:

1. *What is the name of the island of Cote D 'Azubis?*
2. *What English language does the language speak?*
3. *What languages of English and French are spoken as well as Arabic?*
4. *What what languages would French be spoken?*

They have several issues, including label-inconsistency (question 1), malformed syntax (question 4) and unclear semantics (question 2-3).

Similarly, the questions generated by EDA seems of lower quality. For example, with $q = 10$, the EDA model produces the questions:

1. *What is the name of a language spoken by?*
2. *What is the name of a language spoken by the Sioux?*
3. *What is language mostly spoken in Brazil?*
4. *What language is mostly spoken in Brazil?*
5. *Name a gaelic language?*
6. *What is one of the spoken communication spoken by the Sioux called?*
7. *What is one of the languages spoken by the Sioux called?*
8. *What's the most commonly verbalise language in Belgium?*
9. *What's the most commonly spoken language in Belgium?*

Similarly, to the OC case, these questions have several problems, including malformed syntax (question 1, 3, 8), incompleteness (question 1).

Sentiment Analysis. Below is a list of statements generated by DATS in the movie review domain. To simplify the qualitative analysis, we report only `Negative` (class 1 in the dataset), `Neutral` (class 3) and `Positive` (class 5) examples. In general, the method generates sound judgments, with a high syntactic variability even though a quite limited lexical variability, i.e., a manual inspection suggested that most of the adjectives used to express judgments are reused in the generated examples. Sentences in general are less complex than the original ones. This is reflected by generally shorter generated sentences, i.e., with an average length of 16 words per review against the original 20 words per review.

`Negative` reviews:

- *It's almost too derivative to stand on its own as a stark portrait of desperation and violence.*
- *A mediocre work of storytelling, lacking the slightest bit of wit or charm.*
- *A self-conscious, incoherent, self-interested fable.*

`Neutral` reviews:

- *It could be a lot worse if it were, well, more adventurous.*
- *If Tuck had ever made a movie about a vampire, it probably would look a lot like this one.*
- *It's very much like George Romero's final work, where he had a hand in making huge cuts to his movie – only it takes a whole lot more to feel good about.*

`Positive` reviews:

- *A gripping and wildly unpredictable comedy.*
- *It's lovely, funny, different, odd.*
- *A compelling example of why animation is a part of the human spirit.*

The sentences generated using only the category as a prompt (i.e., OC model) have a lower quality. For instance, with the same q=10 the OC model sentences look like:

`Negative` reviews:

- *Why, a good movie, an interesting and absorbing film*
- *The, says a filmmaker and the film 's creator.*
- *The its full potential.*

`Neutral` reviews:

- *No at its most extreme.*
- *This and an epic comedy of a documentary.*
- *So a little razzle dazzle, but not at all riveting,.*

`Positive` reviews:

- *No the greatest of the time*
- *This the first movie to touch a dark heart*
- *No in the form of a poem and a movie itself*

Similarly, the sentences generated by EDA contain different issues, which can be explained by the substitution and word swapping strategies adopted by this method. For example,

- *This tuxedo should have been sent back to the tailor for john major some major alterations*
- *If you value your time and money find an escape clause rehash avoid seeing this trite predictable and*
- *Spy litigate flick with Antonio Banderas and Lucy Liu never comes together*

`Neutral` reviews:

- *It would work a better as much one hour tv documentary*
- *The fast runner transports the viewer into an unusual space*
- *Often overwrought and at times positively irritating the film turns into an engrossing thriller almost in spite of*

`Positive` reviews:

- *Documentary enjoyable high adrenaline enormously*
- *Quite simply a joy to watch follow and especially to listen to*
- *A solid and refined piece of moviemaking imbued with passion and attitude*

Intent Classification. Below is a list of examples generated by DATS of each intent in the SNIPS dataset. Please refer to the original dataset description for the details about the specific classes. In general, the examples are different from the original ones introducing variability mostly on the involved named entities, e.g., proper nouns of the music authors or places. In general, the syntactic complexity is the same as the original material. Sometimes, odd dates are introduced (here 2037 as a date for a reservation).

- `AddToPlaylist` *add this track to my modern psychedelia playlist*
- `BookRestaurant` *book a diner for 1 on feb 28th 2037*
- `GetWeather` *will it be warm in michigantown at 07:00:00 am*
- `PlayMusic` *i want to listen to the last track by michael hayvoronsky*
- `RateBook` *i give the current essay a four*
- `SearchCreativeWork` *find a painting called the night owl*
- `SearchScreeningEvent` *show me the movie schedule for national tv*

Conversely, using only the category as input to the generation model, i.e., the OC baseline, is not able to produce high quality examples. For instance, with q=10, the OC model generates sentences like:

- `AddToPlaylist` *Add please rewind now my playlist*
- `BookRestaurant` *Book the menu for the night in the hotel room*
- `GetWeather` *Add a weather forecast from my backyard*
- `PlayMusic` *Play tunes and tracks to the chino sound bar*
- `RateBook` *Add some jazz music*
- `SearchCreativeWork` *Add my novel*
- `SearchScreeningEvent` *Add movies this week*

Again, EDA is only able to generate some minor variations of the training examples, and sometimes the swapping/substitution strategies are introducing issues. For example:

- `AddToPlaylist` *I want this record album on my indie alternative playlist*
- `BookRestaurant` *I need a table for during midday in Montana*
- `GetWeather` *Is it going tea be freezing at to time in Michigantown KS*
- `PlayMusic` *Play any song from rebekah hewitt*
- `RateBook` *Rate this series one stars*
- `SearchCreativeWork` *The me show song spiderman of the rings*
- `SearchScreeningEvent` *I want the neediness movie schedule for animated movies in the area*

Natural Language Inference. This task is the most challenging as the generated text is not only expected to be internally consistent, but also pair-wise consistent. In general, the syntactic complexity of the sentences is preserved, with an average length of 10 words per sentence. Similarly to the original training set, in many entailment examples generated by DATS the premise and the hypothesis share the same verb (e.g., *watching* in the first example). On the contrary, the subject of the action is often changed during the contradictions (e.g., *boy* vs *girl*) in the first contradictory pair. Below we report some example pairs:

Text Pairs in `Entailment`

- “*Two men watching a sports event in the background.*” entails “*Two men are watching a game.*”
- “*A young woman, wearing sunglasses, is raising her hand.*” entails “*A woman is raising an arm*”
- “*A boy dressed to play soccer is playing” soccer.* entails “*The boy is playing outside.*”

Text Pairs in `Contradiction`

- "*Young Indian boy playing cricket and soccer.* contradicts "*Young Indian girl playing cricket.*"
- "*A boy in a yellow shirt, orange and white, playing guitar.*" contradicts "*A boy is sitting quietly.*"
- "*A man is attempting a jump on his skateboard.*" contradicts "*A man rides his bike over an obstacle course.*"

Instead, the examples generated when only prompting the model with the category name are not as good. For example, the OC model with q=10 produces the following examples:

Text Pairs in `Entailment`

- "*A man being photographed in a store in Seattle*" entails "*A man is sitting in a car.*"
- "*A woman leaves a beer in the air.*" entails "*A woman is leaving a beer.*"
- "*A man walks along a street in St. Pete and walks past a city bus terminal.* entails "*Police are standing near the ground holding a man*"

Text Pairs in `Contradiction`

- "*A white van is driving by and a white man is sitting next to it* contradicts "*A man in a blue polo shirt is sitting on the back of a white car.*"
- "*from the middle of a street at a supermarket street, two girls wearing black and a yellow shirt.*" contradicts "*A woman wearing a pink shirt looks down at a pole, waving a dollar bill.*"
- "*s a little boy playing a ball.*" contradicts "*A dog is jumping out of a field.*"

Notice that the OC model is, in general, not able to produce label consistent pairs. For example, the first and third pairs reported above for the entailment category are not correct examples of this class.

In the following, we report also some examples generated with EDA. Again, EDA strategies introduces some issues in the sentences. For example,

Text Pairs in `Entailment`

- "*An old man with gray hair wearing a scarf and black jacket*" entails "*An old woman is bundled up*"
- "*Two ladies are maam laughing on the street*" entails "*There are women*"
- "*Lady into the sky on city* entails "*Lady looks into the sky*"

Text Pairs in `Contradiction`

- "*Young man doing a trick jump on a skateboard*" "*A man is writing record*"
- "*A by holds hands while walking couple buildings*" contradicts "*A couple dance in the street*"
- "*A a man in a black shirt and shorts sitting at blond table wine with a glass of eating*" contradicts "*a woman is drinking a beer*"

Besides introducing grammatical errors, EDA is also introducing label consistency errors (for example, the first entailment pair).

A.3 Are generated examples really different from the original ones?

To better understand the advantages provided by DATS in the consistency-diversity trade-off, we here report an exhaustive qualitative evaluation.

Table 3 reports all the SA examples generated by different models on classes 5 and 1 when using $q = 10$ average training examples per class. Exception for a single case "(*It is a masterpiece, brilliantly directed, and incredibly well done.*)" that is not a negative sentiment example as it was supposed to be), the examples generated by DATS (with $n = 1$ and $l = 1$) are all label-consistent. Conversely, many examples generated with the OC baseline have a wrong sentiment. On the other side, the diversity introduced by DATS is impressive: all the examples are very different from the input example used to condition the NLG model while generating them. At the same time, they are also very novel with respect to the full training set (used to train the NLG model) and therefore can be very useful when augmenting the training data of NLU models. On the opposite, BT and EDA introduce very minor modifications to the input text, resulting in a significant lower diversity.

Table 4 provides examples of generated questions for the QC task. This task is particularly different from SA as it involves 50 categories and the size of the training dataset causes many of them to be underrepresented. We generated a set of questions with DATS ($q = 100$, $n = 1$ and $l = 1$) by selecting one instance for each category as the input to the model. Each row of the table thus reports the class and example used in input to the generator and the last column reports the generated example.

As it can be noticed, DATS generates examples different from the input ones: only 4 out of 50 (8 %) examples are exactly copied and 3 out of 50 (6%) are different with respect to only one word. Notice that the QC task is particularly sensitive to the syntactic structure of the sentence and this is generally preserved in the generation process. DATS very rarely generates a paraphrase of the original sentence. The target of the generated question almost always changes (e.g., when using ”*Who is Nicolo Paganini?*“ as input, DATS generates ”*Who is Michael Jackson?*“). Finally, notice that in all cases DATS is able to generate a question which is coherent with the target category of the input question.

`NUM:weight`	*What is the weight of air?*	*What is the weight of a teaspoon of matter?*

Table 4: Examples of DATS outputs generated sentence on the QC task for each category.

A.4 Effects of Hyper-parameters

This section reports an analysis of the role of DATS hyper-parameters. In particular, we show the results by varying (i) the number of most similar elements n used to generate the pairs for training $\mathcal{M}$ and (ii) the number of elements l generated with nucleous sampling. Specifically, we tried $n \in [1, 2, 5]$ and $l \in [1, 2, 3, 5, 7, 10]$. In figure 1 we report the difference in Accuracy between our approach and the NoDA baseline for each specific configuration. Each figure refers to a specific q (i.e., the average number of examples per class) value, and reports the average delta accuracy computed on the QC, SA and IC tasks.

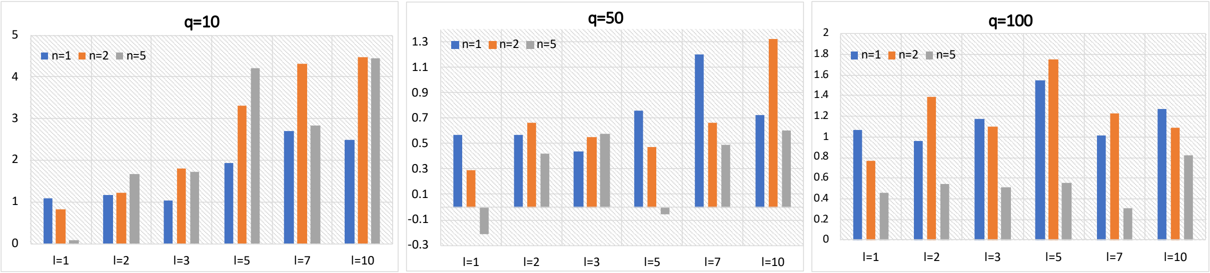

Figure 1: Average Accuracy difference between DATS and the NoDA baseline w.r.t. different dataset sizes. We vary the number n of pairs created with the learned similarity function and the number l of generated examples with generation model $\mathcal{M}$. The average is computed w.r.t. the QC, SA and IC tasks.

In general, when using small datasets it is beneficial to use higher n values, i.e., to create more pairs for training the NLG model. In fact, when q=10 we can observe that the best improvement is obtained with n=2 or n=5.

Regarding the number l of examples generated through $\mathcal{M}$, we can observe that generating a higher number of examples seems to be beneficial in almost every case, especially when dealing with a small dataset. For example, when q=10 or q=50, our DA approach provides the best performance with $l = 7$ or l=10. More generally, we can observe a positive trend in generating at least l=5 examples with the generation model.

Abstract

The common practice for training commonsense models has gone *from–human–to–corpus–to–machine*: humans author commonsense knowledge graphs in order to train commonsense models. In this work, we investigate an alternative, *from–machine–to–corpus–to–machine*: general language models author these commonsense knowledge graphs to train commonsense models.

Our study leads to a new framework, **Symbolic Knowledge Distillation**. As with prior art in Knowledge Distillation (Hinton et al., 2015), our approach uses larger models to teach smaller models. A key difference is that we distill knowledge symbolically–as text–in addition to the resulting neural model. We distill only one aspect–the commonsense of a general language model teacher, allowing the student to be a different type of model, a commonsense model. Altogether, we show that careful prompt engineering and a separately trained critic model allow us to selectively distill high-quality causal commonsense from GPT-3, a general language model.

Empirical results demonstrate that, for the first time, a *human-authored* commonsense knowledge graph is surpassed by our *automatically distilled* variant in all three criteria: quantity, quality, and diversity. In addition, it results in a neural commonsense model that surpasses the teacher model's commonsense capabilities despite its 100x smaller size. We apply this to the ATOMIC resource, and will share our new symbolic knowledge graph and commonsense models[1].

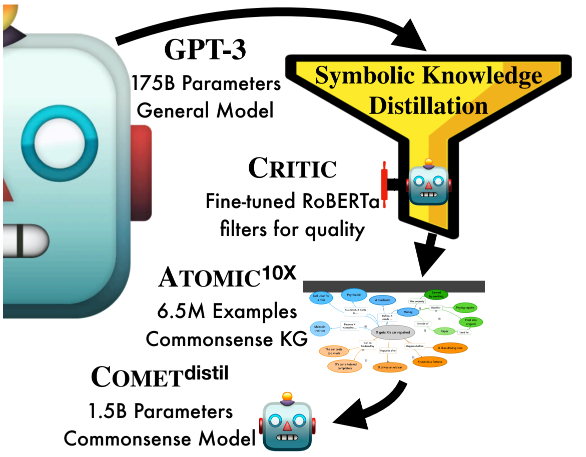

Figure 1: **Symbolic knowledge distillation** extracts the commonsense from the large, general language model GPT-3, into 2 forms: a large commonsense knowledge graph **ATOMIC**$^{\mathbf{10x}}$, and a compact commonsense model **COMET**$^{\mathrm{DIS}}_{\mathrm{TIL}}$. The quality of this knowledge can be controlled and improved by adding a **critic** model, making GPT-3 a stronger teacher.

1 Introduction

Prior works have suggested that pre-trained language models possess limited understanding of commonsense knowledge (Merrill et al., 2021; Talmor et al., 2021; Davis and Marcus, 2017) despite otherwise stellar performance on leaderboards. As a result, symbolic commonsense knowledge graphs (Speer et al., 2017; Sap et al., 2019; Hwang et al., 2021) and corresponding neural representations (Bosselut et al., 2019; Hwang et al., 2021; Zhang et al., 2020b) have supplemented past models with commonsense capabilities. This has enabled diverse downstream applications, including interactive learning through a conversational interface (Arabshahi et al., 2021), persona- and affect-aware conversation models (Kearns et al., 2020), figurative language understanding (Chakrabarty et al., 2020, 2021), story telling (Ammanabrolu et al., 2021a) and fantasy games (Ammanabrolu et al., 2021b).

The common practice for commonsense knowledge graph construction sees humans spell out as many pieces of knowledge as possible. This pipeline goes *from–human–to–corpus–to–machine*, with commonsense models trained from human-

---

[1] We will share this following the anonymity period. We have permission from OpenAI to release GPT-3 generations

authored knowledge graphs. Yet, high-quality, human-authored knowledge is expensive to scale, limiting coverage; this motivates an alternative: *from–machine–to–corpus–to–machine*. Prior efforts toward automatic commonsense knowledge graphs have resulted in considerably lower quality than human-written data (Hwang et al., 2021; Zhang et al., 2020b), which in turn leads to less reliable neural models (Hwang et al., 2021). Broad literature consistently shows machine-authored knowledge graphs underperform human-authored graphs (Etzioni et al., 2011; Mitchell et al., 2015; Bollacker et al., 2008).

In this work, we propose **Symbolic knowledge distillation**, a new conceptual framework towards high-quality automatic knowledge graphs for commonsense, leveraging state-of-the-art models and novel methodology. Most prior art for automatic knowledge graph construction extracts knowledge from raw text (Bhakthavatsalam et al., 2020; Zhang et al., 2020a; Zhou et al., 2020; Zhang et al., 2020b; Li et al., 2020). In contrast, our approach is motivated by knowledge distillation (Hinton et al., 2015) wherein a larger teacher model transfers knowledge to a compact student model (§2.1). Our method differs from prior knowledge distillation in key ways: we distill a symbolic knowledge graph (i.e., generated text) in addition to a neural model, and we distill only a selective aspect of the teacher model. This selectively allows the student model to be of a different type (commonsense model), compared to the teacher (general language model), enriching the scope of distillation. An added benefit is that knowledge distilled as text is human readable: it can be understood and evaluated.

A general language model–GPT-3 in our case–is an imperfect commonsense teacher on its own, and the ability to evaluate distilled knowledge is useful in improving it. We empirically demonstrate that, by training a separate critic model to judge symbolic generation quality, a more precise teacher can be defined. Knowledge from this critical teacher is higher quality–even exceeding human-authored knowledge. Yet even before training a critic, our study makes the unexpected finding that the student model surpasses the commonsense of GPT-3, our knowledge source.

To test symbolic knowledge distillation against the *human–to–corpus–to–machine* paradigm, we compare with ATOMIC$^{20}_{20}$ (Hwang et al., 2021), which is a human-authored commonsense knowledge graph. We find that **ATOMIC$^{\mathbf{10x}}$**, our machine-generated corpus, exceeds the human generated corpus in *scale, accuracy,* and *diversity* with respect to 7 commonsense inference types that we focus on in this study. The resulting commonsense model, **COMET$^{\mathbf{DIS}}_{\mathbf{TIL}}$**, not only surpasses the human-trained equivalent COMET$^{20}_{20}$, but is also smaller, more efficient, and produces commonsense at a higher accuracy than its own teacher–GPT-3.

Symbolic knowledge distillation offers a promising new role for general language models, as commonsense knowledge sources, and humans, as small-scale evaluators to train critic models rather than authors of commonsense knowledge. Our work demonstrates that humans and LMs can be effective collaborators for curating commonsense knowledge graphs and training efficient and performant commonsense models.

2 Overview and Key Findings

Throughout our work, we describe the *machine–to–corpus–to–machine* methodology of symbolic knowledge distillation. We first go *machine–to–corpus* (§3), by decoding from GPT-3, then improve our knowledge with a specialized critic model (§4), and finally distill this knowledge into an efficient commonsense model (§5), going *corpus–to–machine*. Throughout this process, we evaluate against a human knowledge source, comparing our automatic knowledge graph ATOMIC$^{\mathbf{10x}}$ and commonsense model COMET$^{\mathrm{DIS}}_{\mathrm{TIL}}$ to the human-authored ATOMIC$^{20}_{20}$ and resulting model COMET$^{20}_{20}$ (Hwang et al., 2021).

2.1 Symbolic Knowledge Distillation

Our proposed methodology parallels knowledge distillation (Hinton et al., 2015), a method for compressing a large or complicated teacher distribution P_t into a smaller/simpler student distribution P_s. Key to knowledge distillation[2] is the notion of minimizing the cross-entropy between P_t and P_s:

$$H(P_t, P_s) = -\sum_{y \in Y} P_t(y) \log P_s(y) \qquad (1)$$

Knowledge is transferred to the student by encouraging it to match teacher predictions. Hinton et al. (2015) apply this to conditional classification: for

X and Y engage in an argument	**xWant** *so, X wants*	to avoid Y	X is not well liked	**xReact** *so, X feels*	lonely
X learns to type fast	**xNeed** *X needed*	to have taken typing lessons	X takes care of a monkey	**xAttr** *X is seen as*	kind
X steals his grandfather's sword	**xEffect** *so, X*	is punished by his grandfather	X butts in	**HinderedBy** *but not if*	X is too shy to speak up
X takes up new employment	**xIntent** *because X wants*	to be self sufficient	X waits for the storm to break	**xEffect** *so, X*	is safe from the storm

Figure 2: Example **automatically generated** ATOMIC triples from our ATOMIC$^{\mathbf{10x}}$ commonsense knowledge graph. Each example includes a generated **event**, **relation** (with natural language interpretation), and generated **inference**.

each training input, P_t and P_s are model predictions over label set Y. Typically Y is a tractable set, over which this sum can reasonably be calculated.

For distilling the knowledge of generative models, we can think of an unconditional language model (LM e.g. GPT-3) as P_t. This makes Y the set of all strings, over which LMs define probability. Unfortunately Y is an exponential set, intractable to sum over in Eq 1. Kim and Rush (2016) address this problem by simply taking the mode of P_t over Y, truncating most of the teacher distribution to the most likely sequence and discarding information.

Instead, we consider a sampling-based interpretation of the same objective:

$$H(P_t, P_s) = \mathop{\mathbb{E}}_{y \sim P_t(y)} [-\log P_s(y)] \tag{2}$$

which exactly equals the cross-entropy of Eq 1, at the limit under pure sampling from P_t.[3]

Yet distilling *all knowledge* from the teacher may not be desirable–our work is specifically focused on distlling commonsense knowledge from GPT-3. The ideal teacher P_t is a commonsense expert, but GPT-3 can approximate such a teacher, off-the-shelf, via prompting. This ability to select information is one explicit benefit of the sampling-based interpretation of Eq 2: while Eq 1 uses continuous logits over existing data, sampling gives discrete control over transferred information, by selecting which samples are elicited and used. For the general language model GPT-3, We encourage domain/quality with prompting, and sample truncation (Holtzman et al., 2020). We call this the *loose teacher* P_t^L–knowledge is generated and transferred from GPT-3, but without critical assessment of correctness (§3).

In fact, sampling knowledge in Eq 2 offers even more control, as generations can be individually interpreted and judged. Given an indicator function $A(x)$ for which knowledge x is *correct*, we can define a stronger teacher model. Using a Product of Experts (Hinton, 2002) between the loose teacher P_t^L and and the critic $A(x)$, we define a *critical teacher*:

$$P_t(x) \propto P_t^L(x|p) \cdot A(x) \tag{3}$$

In practice, $A(x)$ is a textual classifier learned on human judgements, 1 for knowledge predicted to be correct and 0 otherwise. Thus, the critic gives control over the correctness and confidence of the knowledge that is transferred (§4).

2.2 Key Findings

Applying symbolic knowledge distillation in practice results in promising and surprising findings:

1. Learning symbolic knowledge from language models can be framed as a symbolic extension to knowledge distillation. In §2.1, we describe learning commonsense as a symbolic extension to knowledge distillation, with GPT-3 a knowledge source. We elaborate on this process with positive results in §3,4, and 5.

2. Symbolic knowledge distillation constructs a high quality knowledge graph at scale. Our method naturally yields a machine-generated commonsense knowledge graph, which can achieve impressive quality (§4), beyond that of human-authored data. An effective critic which filters incorrect generated knowledge is key.

3. A critical teacher results in a higher quality student. In §4, we show that making the teacher more critical results in higher quality knowledge, even as it reduces the scale of knowledge transferred. This demonstrates that *quality* matters, not

---

[3] A useful consequence of this framing is that access to the full model distribution is not required. Our experiments (§3) use GPT-3, for which the distribution is **not available**, thus our method is applicable while knowledge distillation is not.

just *quantity*, as higher quality knowledge results in a higher quality commonsense model in §5 despite smaller scale data.

4. Critical teacher or not, a student can outperform the knowledge source. In §5, we show the unexpected result that all student models exceed the quality of GPT-3, the knowledge source.

5. Machines can win over humans for automatic knowledge graph construction. In §4 and §5, we show that machine generated knowledge and the resulting commonsense model can outperform their equivalents that use a human knowledge source. Our symbolic knowledge exceeds humans at scale, quality, and diversity. The resulting commonsense model achieves the most accurate commonsense KG completions.

3 Machine-to-Corpus Verbalization

Symbolic knowledge distillation begins by going *machine–to–corpus*, i.e. generating many commonsense facts, which results in a commonsense knowledge graph. §2.1 frames this as sampling to estimate the knowledge distillation objective–a student commonsense model learns from the generations of a teacher (GPT-3).

We start with a *loose teacher*, transferring knowledge by prompted generation with truncated sampling alone–this is in contrast to the *critical teacher* (§4) which explicitly judges and filters the generated samples. The loose teacher uses few-shot prompting as in Brown et al. (2020). We use a few-shot template:

```
<TASK-PROMPT>
<EX_1-INP><EX_1-OUT>
...
<EX_{N-1}-INP><EX_{N-1}-OUT>
<EX_N-INP>
```

where `<EX`$_i$`-INP>`/`<EX`$_i$`-OUT>` are human-authored, natural language ATOMIC entries, and `<TASK-PROMPT>` is a description of the problem. Given such a prompt, GPT-3 generates the *missing piece*, output `<EX`$_N$`-OUT>` for input `<EX`$_N$`-INP>`, following the pattern of earlier examples (1 to N-1). We find important aspects for producing high-quality commonsense knowledge:

- Examples should be numbered. e.g. `<EX`$_5$`-INP>` might begin with "5)" to indicate it is the 5th example.
- The format of `<EX`$_i$`-INP>` and `<EX`$_i$`-OUT>` should linguistically imply the relationship between them. See below for examples.
- `<TASK-PROMPT>` can be used to give extra specification to complicated problems.

3.1 Data: ATOMIC

We demonstrate symbolic knowledge distillation on the ATOMIC *if-then* resource (Sap et al., 2019). This follows an event-relation-inference (triple) format. The corpus links *events* (e.g. *X attacks Y*) to relations, e.g. **HinderedBy** which describes what might hinder an event. For a relation/event, the goal is to generate a resulting inference, e.g. *X attacks Y* **HinderedBy** *X is restrained.*

Of the 23 relations from the most recent version–ATOMIC$^{20}_{20}$–we limit our investigation to 7 relations that correspond to *causal* commonsense knowledge: **xAttr** (how X is perceived after *event*), **xReact** (how X reacts in response to *event*), **xEffect** (what X does after *event*), **xIntent** (X's intent in *event*), **xWant** (what X wants after *event*), **xNeed** (what X needed for *event* to take place) and **HinderedBy**. We describe how **verbalization** is applied to ATOMIC data in 2 steps: generating underlying events (heads), then full examples (inference given event).

3.2 Event Generation

Events are context-free premises in ATOMIC involving `PersonX` (and sometimes a second `PersonY`) in various scenarios. These events form heads in knowledge graph triples. We generate events by filling in the elements of our template:

```
1.  Event:  X overcomes evil with good
2.  Event:  X does not learn from Y
...
10.  Event:  X looks at flowers
11.
```

The format is simple, as events are generated *unconditionally*. We use 100 high-quality events from the ATOMIC$^{20}_{20}$ corpus for our prompt, selected to avoid grammatical or logical errors, and minimize semantic overlap. We randomly sample 10 of these seed events for each generation batch, resulting in randomized prompts. We use nucleus sampling ($p = 0.9$) (Holtzman et al., 2020), and presence/frequency penalties of 0.5 from the GPT-3 interface. We generate 165K unique events using the 175B-parameter Davinci model[4] from Brown

---

[4] the largest available version of GPT-3

et al. (2020) (human-authored ATOMIC$^{20}_{20}$ contains only 6.2K events).

3.3 Inference Generation

Generating ATOMIC inferences requires reasoning about events and relations together. We design verbalization templates fo reach relation, with iterative design and small-scale verification by the authors[5] e.g. we prompt the **xNeed** relation as follows:

```
What needs to be true for this
event to take place?

...

Event <i>:  X goes jogging
Prerequisites:  For this to
happen, X needed to wear running
shoes

...

Event <N>:  X looks at flowers
Prerequisites:  For this to
happen,
```

The language of this template implies the relation-specific task, both "Prerequisites:" and beginning with "for this to happen" suggest the **xNeed** relation. As well, we include an xNeed-specific `<TASK-PROMPT>`. We use 10 few-shot examples for each prompt.[6]

For each event/relation (165K X 7) we generate 10 inferences with the Curie GPT-3 model[7] and earlier hyperparameters. Removing duplicate and degenerate (e.g. fewer than 3 characters) generations yields 6.46M ATOMIC-style data triples (examples in Figure 2). We call this ATOMIC$^{\mathbf{10x}}$, as it contains an order of magnitude more triples than ATOMIC$^{20}_{20}$ for the 7 relations we study.

3.4 Evaluating a Generated Commonsense Knowledge Graph

Machine generation enables a large scale of unique generations at a much lower cost than human-authored knowledge (Table 1), but what kind of examples are produced by GPT-3, and how does it differ from knowledge produced by humans? In this section, we conduct an in-depth analysis to answer these questions.

Relation	ATOMIC$^{20}_{20}$	ATOMIC$^{\mathbf{10x}}$
`HinderedBy`	77,616	**1,028,092**
`xNeed`	100,995	**760,232**
`xWant`	109,098	**730,223**
`xIntent`	54,839	**965,921**
`xReact`	62,424	**1,033,123**
`xAttr`	113,096	**884,318**
`xEffect`	90,868	**1,054,391**
Total Count	608,936	**6,456,300**
Est Total Cost	~\$40,000	**~\$6,000**
Est Cost Per Triple	~\$0.06	**~\$0.001**

Table 1: Number of unique triples with the given relation, $|(\cdot, \texttt{relation}, \cdot)|$. The estimated cost for ATOMIC$^{\mathbf{10x}}$ comes at a fraction of a conservative estimation for ATOMIC$^{20}_{20}$ crowdsourcing costs.

Lexical Differences: Diversity and Uniqueness Recent work finds that machine generations can be repetitive and lack diversity (Welleck et al., 2020; Holtzman et al., 2020); one way generated knowledge may differ from human-authored is less creative word choice, diversity, or more repetition.

To test this, we begin with lexical diversity (i.e. unique words used, Table 2). While there is variation by relation, the diveristy of ATOMIC$^{\mathbf{10x}}$ actually exceeds ATOMIC$^{20}_{20}$ here, 5.2M unique words to 1.5M. In addition, it contains significantly more strictly unique generated inferences (Table 2, unique tails).

BLEU Soft Uniqueness. Exact match (above) fails to capture the notion of *similar* text. Following the intuition of self-BLEU (Zhu et al., 2018), we define *soft uniqueness* to describe diversity of generations in a corpus. An inference x is softly-unique if:

$$BLEU_2(C, x) < 0.5$$

where C is the set of inferences for a given input (in our case, event + relation), and 0.5 is an empirical threshold. To find soft-uniqueness of a corpus, we iteratively remove examples until all are softly unique, i.e. low mutual lexical overlap; higher diversity means more such examples (thus a larger softly unique corpus is preferable). Softly-unique corpus sizes are given in Table 4 ("Size (div)"). ATOMIC$^{\mathbf{10x}}$ has a smaller *fraction* of softly-unique examples than ATOMIC$^{20}_{20}$, yet it contains many more such examples. ATOMIC$^{\mathbf{10x}}$ contains 4.38M such examples (full size 6.5M) vs. ATOMIC$^{20}_{20}$, which has 560K (full size 600K).

---

[5] See Appendix D for full prompts.

[6] We also replace anonymous names ("X") with sampled generic names as this improved quality, See Appendix D. Once generation is complete, we substitute in generic markers ("X") for the final dataset.

[7] for the largest, Davinci, 12M generations is computationally/monetarily intractable.

	Length		Unique Tokens (K)		Unique Tails (K)	
	A_{20}^{20}	A^{10x}	A_{20}^{20}	A^{10x}	A_{20}^{20}	A^{10x}
`xWant`	4.69	5.16	322	784	69	152
`xAttr`	1.42	2.73	15	21	11	8
`xEffect`	3.92	4.66	216	864	55	185
`xIntent`	4.59	5.92	136	800	30	135
`xNeed`	4.51	5.97	289	1378	64	231
`xReact`	4.03	1.77	48	5	12	2
`HinderedBy`	7.93	7.49	522	1775	290	874
Events	5.20	**5.32**	109	**881**	6.2	**165**

Table 2: Average length, total unique tokens and total unique examples (in K, i.e. 1000s) by relation type and in events (bottom row) from ATOMIC$_{20}^{20}$ (A$_{20}^{20}$) and ATOMIC$^{\mathbf{10x}}$ (A$^{\mathbf{10x}}$).

Entropy	Cross Entropy	KL Divergence
$H(D_1) = 1.27$	$H(D_1, D_2) = 9.31$	$D_{KL}(D1\|\|D2) = 8.04$
$H(D_2) = 7.80$	$H(D_2, D_1) = 41.48$	$D_{KL}(D_2\|\|D_1) = 33.68$

Table 3: Entropy, cross-entropy, and divergence of ATOMIC$_{20}^{20}$ (D_1) and ATOMIC$^{\mathbf{10x}}$ (D_2).

Model-based Diversity Measurement. Lexical notions of diversity reward differences in surface form, which may not always reflect diversity of *information*, only format. Thus, we next study information-theoretic measures for diversity. Intuitively, diverse information should be less predictable, or higher entropy. With GPT-2 XL models finetuned on ATOMIC$_{20}^{20}$ and ATOMIC$^{\mathbf{10x}}$ (§5) we estimate **entropy**–roughly, how difficult it is for a model to capture the corpus information (Table 3). This is 4 times higher for ATOMIC$^{\mathbf{10x}}$, suggesting more content from a modeling perspective. We also estimate **cross-entropy**–how well a model trained on one corpus describes the other. From ATOMIC$^{\mathbf{10x}}$ to ATOMIC$_{20}^{20}$, this is 9.31, only 2 points higher than its entropy suggesting ATOMIC$_{20}^{20}$ is describable with information from ATOMIC$^{\mathbf{10x}}$. In reverse, this is 41.48 suggesting much of ATOMIC$^{\mathbf{10x}}$ is not captured by ATOMIC$_{20}^{20}$–ATOMIC$^{\mathbf{10x}}$ is surprising given only information from ATOMIC$_{20}^{20}$.

Human Evaluation of Quality. Perhaps most importantly, we study the *quality* of knowledge in each corpus. We conduct human evaluation with Amazon Mechanical Turk. 3 annotators rate each triple resulting in "accepted", "rejected" or "no judgement". We evaluate 3000 examples[8] from ATOMIC$^{\mathbf{10x}}$, and 1000 from ATOMIC$_{20}^{20}$ (Table 4). We find Fleiss' kappa (Fleiss, 1971) of 40.8 indicating moderate agreement (Landis and Koch, 1977), and 90.5% accuracy agreement. We require workers meet an Amazon Mechanical Turk qualification for annotation quality based on past commonsense evaluations. We compensate workers \$0.17 per task, which we estimate require 30 seconds. Further details and task template are in appendix §A.

Corpus	Accept	Reject	N/A	Size	Size (div)
ATOMIC$_{20}^{20}$	86.8	11.3	1.9	0.6M	0.56M
ATOMIC$^{\mathbf{10x}}$	78.5	18.7	2.8	**6.5M**	**4.38M**
	88.4	9.5	2.1	5.1M	3.68M
(critic$_{\text{low}}$)	91.5	6.8	1.7	4.4M	3.25M
	95.3	3.8	1.0	3.0M	2.33M
(critic$_{\text{high}}$)	**96.4**	2.7	0.8	2.5M	2.00M
+ GPT-J	72.0	27.6	0.4	-	-
+ T5-11B LM	71.7	26.9	1.4	-	-

Table 4: Attributes of ATOMIC$^{\mathbf{10x}}$ and ATOMIC$^{\mathbf{10x}}$ (row 2) including the critic model (§4, rows 3 - 6) with various filtering cutoffs. Accept and Reject are by majority human vote unless any mark N/A. Size is in unique examples[9]. The highest precision corpus is ATOMIC$^{\mathbf{10x}}$ with (critic$_{\text{high}}$), but multiple versions surpass ATOMIC$_{20}^{20}$. We also include alternate models (GPT-J and T5-11B) as the loose teacher.

For the *loose teacher*, consider the top row of ATOMIC$^{\mathbf{10x}}$ in Table 4 (other rows add the critic §4). ATOMIC$^{\mathbf{10x}}$ exceeds ATOMIC$_{20}^{20}$ in scale, but is somewhat less acceptable by human raters–by roughly 8 percentage points. Yet, the larger scale of ATOMIC$^{\mathbf{10x}}$ implies a significantly higher *number* of accurate examples. Increasing the proportion of these is the main objective of the critic (§4).

How do Knowledge Sources Compare? To understand the robustness of our approach, we assess other language models as the knowledge source (i.e. loose teacher): GPT-J (Wang and Komatsuzaki, 2021) and T5-11B adapted for language modelling (Lester et al., 2021). We substitute both for GPT-3 as in §3.2,3.3, generating a small-scale corpus to evaluate. We conduct human evaluation on 1000 examples as above (Table 4). Both models attain roughly 72% accuracy, 6 points below GPT-3 (78.5). This suggests strong potential, but higher quality from GPT-3. We explore this further in Appendix B.

---

[8] this ensures at least 1000 after filtering by the critic §4)

[9] Size of ATOMIC$_{20}^{20}$ is given as the number of comparable datapoints, i.e. those with the same relations as ATOMIC$^{\mathbf{10x}}$.

4 Making the Teacher More Critical

Symbolic knowledge distillation requires a strong teacher model to maximize the quality of the generated knowledge graph and resulting student model (§5). While the *loose teacher* (GPT-3 alone) results in a viable commonsense knowledge graph, evaluation shows this isn't a perfect commonsense teacher. Thus, we multiply in a *critic model*, to filter lower-quality knowledge, *correcting the teacher* (§2.1). With modest supervision (a small-scale human evaluation) we train a classifier to predict and discriminate unacceptable examples. We multiply this with the *loose teacher* §3, creating a *critical teacher* product of experts. In practice this means filtering ATOMIC$^{\mathbf{10x}}$ to create new corpora that are higher quality, yet still larger scale than human-authored ATOMIC$^{20}_{20}$.

Training a knowledge critic We gather a training set of *correct vs. incorrect* human judgments on a randomly-sampled set of 10K entries of ATOMIC$^{\mathbf{10x}}$, as in §3.4 but with one annotation per example. We take a (random) train/dev/test split of 8k/1k/1k. While this step requires human annotation, humans take on the role of high-level supervisors here–critiquing a small number of generations rather than authoring the entire knowledge graph as in previous work. Indeed, the cost/complexity of this step is similar to a typical human evaluation, making it far cheaper/easier than eliciting human-authored knowledge in past work.

We train binary classifiers (critics) for human acceptability using RoBERTa-Large (Liu et al., 2019). We find pretraining on MNLI results in the best model in terms of precision and recall, and we suggest this technique for future studies. We give more detail in Appendix C, including baselines. Our best model vastly improves the accuracy of ATOMIC$^{\mathbf{10x}}$ (Table 4), demonstrating that a small amount of human supervision can consistently help to correct GPT-3's mistakes.

Size-accuracy trade-off Using our critic to filter knowledge results in a natural trade-off between size and accuracy. We test several cutoffs for ATOMIC$^{\mathbf{10x}}$, i.e. confidence at which the critic rejects examples. We report human-measured accuracy (Accept/Reject column Table 4) following §3.4. We compare the loose teacher (unfiltered) to critical teachers. Discarding 20% of instances that the critic judges as least acceptable (reducing corpus size from 6.5M to 5.1M), ATOMIC$^{\mathbf{10x}}$'s accuracy rises 78.5 → 88.4; human-authored ATOMIC$^{20}_{20}$ contains 600K entries at 86.8% accuracy. Reducing to total size to 2.5M examples (38% of full size), we attain 96.4% accuracy, nearly 10 points above ATOMIC$^{20}_{20}$ while still 4X larger.

	Random	Inf	Event	EMAP	Full
AP	79.3	81.9	86.2	87.1	**94.0**

Table 5: Average Precision for ablated critic models. The critic not only filters *awkward phrasings* which can be identified by either the event (**Event**) or inference (**Inf**) in isolation (EMAP only identifies these), but also *logical misalignments*, which require modeling interactions between event/inference, i.e. the full critic (**Full**).

What gets filtered out? We qualitatively identify two types of filtered triples: 1) *logical misalignments*, events/inferences joined in an inconsistent manner. Recognizing these requires understanding events-inference interactions, e.g., *X cannot find his shirt **as a result** X is wearing a shirt*; 2) *awkward phrasings*, in which events/inferences are individually incoherent e.g. *PersonX has a fire in the bath*–resulting triples are invalid as the event is implausible.

To understand what is filtered, we ablate the critic (Table 5): our full model is compared to a random predictor, event-only model, and inference-only model. We also compare to an EMAP (Hessel and Lee, 2020) version, i.e. an ensemble of event and inference-only, without interactions between event/inference (needed for *logical misalignments*).

We find GPT-3 produces both independent awkwardly-phrased events/inferences (filtered by X-only models) and logical misalignments. The classifier, trained on validated knowledge triples, helps in both cases. The EMAP of our full model (identifies only awkward phrasings) achieves 87% AP, and our full model (which additionally identifies logical misalignments) improves to 94% AP.

Does filtering hurt diversity? One concern is that the critic may keep only similar "safe" examples, lacking novelty. We repeat our diversity analysis (§3.4) for critical corpora (Table 4, "Size (div)", higher=better). As we filter, we surprisingly observe proportionally *more* diverse examples: full ATOMIC$^{\mathbf{10x}}$ has a diverse subset 68% of its size; rising to 80% with the most extreme filtering. One possibility is that GPT-3 gravitates towards com-

CKG Completion Model	Train Corpus Acc	Accept	Reject	N/A
GPT2-XL zero-shot	-	45.1	50.3	4.6
GPT-3	-	73.3	24.1	2.6
COMET$_{20}^{20}$	86.8	81.5	16.3	2.2
COMET$_{\text{TIL}}^{\text{DIS}}$	78.5	78.4	19.2	2.4
+critic$_{\text{low}}$	91.5	82.9	14.9	2.2
+critic$_{\text{high}}$	96.4	**87.5**	10.2	2.3

Table 6: Model performance on knowledge base completion, measured by human judgement. Inferences are generated on held-out events from ATOMIC$_{20}^{20}$. Models besides GPT-3 use GPT-2 XL architecture. COMET$_{\text{TIL}}^{\text{DIS}}$ with a strong critic (+critic$_{\text{high}}$) achieves the highest acceptance rate overall–87.5.

mon sentence structures for inconsistent knowledge. These would be recognizable to the critic, and removing them would increase both quality and diversity. This surprising result warrants further study.

5 Corpus-to-Machine: Distillation

The final step of symbolic knowledge distillation trains a compact model on the generated natural language knowledge graph. Our base model is GPT2-XL trained on all of ATOMIC$^{\mathbf{10x}}$: we denote this model by COMET$_{\text{TIL}}^{\text{DIS}}$. We additionally train the model on critical versions of ATOMIC$^{\mathbf{10x}}$–crit$_{\text{low}}$ denotes training on the corpus achieving 91.5% accuracy, and crit$_{\text{high}}$ on the 96.4% accuracy corpus. Models are trained for 1 epoch, with default parameters using the Huggingface Transformers library (Wolf et al., 2019).

5.1 Evaluating a Symbolically Distilled Model

Evaluation follows past work (Hwang et al., 2021; Bosselut et al., 2019; Sap et al., 2019) testing the ability of models to do knowledge base completion, i.e. generating inferences for test events, specifically from the ATOMIC$_{20}^{20}$ test set. We use human evaluation[10] following Section 3.4, on 1000 inputs (event + relation), with results in Table 6. We compare to the GPT2-XL-based COMET$_{20}^{20}$ model trained on human-generated ATOMIC$_{20}^{20}$, and GPT-3 using the same generation method as §3–in effect, comparing the student COMET$_{\text{TIL}}^{\text{DIS}}$ to the *loose teacher* GPT-3. We omit the *critical teacher* (GPT-3 + critic), which is not assured to produce an inference for each input, as the critic may reject all tails for some inputs. We also compare to zero-shot GPT2-XL (Radford et al., 2019) using the same methodology (Table 6).

How does COMET$_{\text{TIL}}^{\text{DIS}}$ compare to GPT-3? In knowledge distillation, the student model often deteriorates in performance (Hinton et al., 2015; Kim and Rush, 2016) compared to its teacher. Comparing our base teacher–GPT-3–to the simplest version of COMET$_{\text{TIL}}^{\text{DIS}}$ (top-row COMET$_{\text{TIL}}^{\text{DIS}}$ of Table 6) surprisingly shows the student *surpasses* GPT-3, the model that generates its training data[11]. We posit that the superior performance of COMET$_{\text{TIL}}^{\text{DIS}}$ may have to do with mistakes of GPT-3 being filtered by verbalization and training of GPT-2, and possibly the focus of COMET$_{\text{TIL}}^{\text{DIS}}$ on one commonsense domain while GPT-3 covers a more general domain. We leave further study of this effect for future work.

How does COMET$_{\text{TIL}}^{\text{DIS}}$ compare to human knowledge? While COMET$_{\text{TIL}}^{\text{DIS}}$ *without the critic* is slightly outperformed by COMET$_{20}^{20}$ in terms of accuracy, this reverses with the critic. For both cutoffs tested, COMET$_{\text{TIL}}^{\text{DIS}}$ surpasses COMET$_{20}^{20}$, with more filtering resulting in a wider gap.

Usefulness of COMET$_{\text{TIL}}^{\text{DIS}}$ For on-demand inference, where a single high quality inference for some input event/relation is required, COMET$_{\text{TIL}}^{\text{DIS}}$ is the **best available model**: the most performant version surpasses COMET$_{20}^{20}$ by 5 points and GPT-3 by over 10. The critical teacher (GPT-3 + critic) yields a more accurate *corpus*, but may filter all inferences for an input, giving no output.

Limits and Future Work The success of symbolic knowledge distillation is a first step–demonstrating superior performance to human authoring on the commonsense relations tested here. No aspect of our approach is specific to these relations, yet further work is needed to explore the feasibility of generation for other aspects of commonsense and knowledge, beyond these relations, to concepts like physical or temporal commonsense.

6 Related Work

Commonsense Knowledge Graphs (CKG) CKGs provide knowledge for commonsense reasoning. Some are manually constructed, e.g.

---

[10] We find Fleiss' kappa (Fleiss, 1971) of 47.1 for acceptance, indicating moderate agreement. (Landis and Koch, 1977), and accuracy agreement of 88.7%.

[11] The slight difference in acceptability for GPT-3 from Table 4 is likely due to variance in raters between rounds of evaluation, and a different distribution of events–Table 4 uses generated events while Table 6 uses events from ATOMIC$_{20}^{20}$.

ATOMIC (Sap et al., 2019; Hwang et al., 2021). ConceptNet (Speer et al., 2017) contains taxonomy and physical commonsense, authored by humans or compiled from such sources. Some CKGs are automatically constructed: TransOMCS (Zhang et al., 2020a) extracts 18.48M tuples from syntactic parses and CausalBank (Li et al., 2020) extracts 314M cause-effect pairs by pattern-matching. In contrast, we *generate* commonsense.

Extracting Knowledge from LMs Past work uses models for automatic knowledge graph completion (Bosselut et al., 2019; Hwang et al., 2021; Li et al., 2020). Yet, models are trained on *existing* resources; ATOMIC$^{\mathbf{10x}}$ is generated without these. Other works mine factual/commonsense knowledge directly from off-the-shelf LMs (Petroni et al., 2019; Davison et al., 2019; Xiong et al., 2020), but not resulting in the quality at scale of ATOMIC$^{\mathbf{10x}}$.

Knowledge Distillation Other works use knowledge distillation (Hinton et al., 2015) for generation. (Sanh et al., 2019) follow a label smoothing formulation, while Kim and Rush (2016) follow a similar formulation to us (§2.1), use the mode of the teacher distribution rather than sampling. Our work is unique in distilling *specific* information (commonsense) from a general language model.

Data Generation While manual dataset creation is expensive and complex (Schwartz et al., 2017; Agrawal et al., 2018; Tsuchiya, 2018; Bras et al., 2020),crowdsourcing is the most popular method for goal-oriented, high quality/coverage datasets.

Past automatic data mainly use extractive approaches, e.g. syntactic parsing (Zhang et al., 2020a) or pattern matching (Li et al., 2020) from unstructured text (Lehmann et al., 2015; Buck et al., 2014). These scale, but are noisy and limited in format–ATOMIC knowledge will not appear simply in natural text. Some works explore automatic data synthesis/expansion by finetuning LMs on existing labeled data (Anaby-Tavor et al., 2020; Papanikolaou and Pierleoni, 2020; Kumar et al., 2020; Yang et al., 2020), but are limited by data quality.

7 Conclusions

We introduce symbolic knowledge distillation, a *machine–to–corpus–to–machine* pipeline for commonsense that does not require human-authored knowledge–instead, using machine generation. Knowledge is transferred from a large, general model to a compact commonsense model, through a commonsense corpus–yielding a commonsense knowledge graph and model. Our resulting symbolic knowledge graph has greater scale, diversity, and quality than human authoring. symbolic knowledge distillation offers an alternative to human-authored knowledge in commonsense research.

Ethical Considerations

One aspect of our work with the potential for ethical pitfalls is large-scale generation from pretrained language models, in constructing ATOMIC$^{\mathbf{10x}}$. Recent work (Bender et al., 2021) has highlighted the risks of models trained on massive text resources, as GPT-3 (Brown et al., 2020) is, which we use for generation. Indeed, open generations from pretrained language models can often contain harmful, biased, or offensive aspects. We argue here that this risk is largely mitigated in our work, mainly due to the narrow and constrained nature of our generations. The goal of our work is characterising simple and generic anonymous situations, specifically in terms of commonsense causes and effects. We ensure generations are focused on these topics through careful prompting, which we found to be quite effective at keeping these generations on-topic. As such, the potential for harmful generation is very low; indeed, in a manual inspection of 100 generated examples, we found none that were significant harmful, besides one that contained adult content.

A related concern is the potential for large models and training sets to make automated oppression or exploitation possible, for instance in surveillance or generating fake news. As above, we argue that the generic, commonsense nature of our data and models makes this concern less relevant here. Our data does not contain any information directly related to these harmful domains (e.g. social media or fake news generation). While our data may assist machines in understanding basic situations, this is unlikely to be useful for harmful models given the simplicity of our data and still-flawed commonsense capabilities of even the most advanced models.

Finally, we note that we ensure fair and generous compensation for all human evaluators we hire through Amazon Mechanical Turk. Based on our estimates of time required per task, we ensure that the effective pay rate is at least $15 per hour.

A Human Evaluation Details

We conduct human evaluations on Amazon Mechanical Turk using the template of Figures 4,5. Workers are presented with ATOMIC-style triples, replacing relations with natural language templates (e.g. *HinderedBy* becomes "can be hindered by"). 3 annotators rate each triple, with options for acceptability: "always/often", "sometimes/likely", "farfetched/never", "invalid", or "too unfamiliar to judge". The first two are considered "accepted", the second two "rejected" and the final is "no judgement". For reporting acceptance rates, and training a critic model, we only distinguish between "accepted" and not "accepted".

Workers are compensated $0.17 per task (i.e. completing all questions in the evaluation template Figures 4,5). We estimate an upper bound of 30s to complete a single task, which gives an hourly rate of $20.4. Workers are selected based on an Amazon Mechanical Turk qualification, specifically filtering for workers with high accuracy on past knowledge base triple evaluations. We follow the same setup for all evaluations, besides number of annotators. This setup is shown to result in consistent and reliable annotations, with an inter-annotator agreement given by Fleiss' kappa (Fleiss, 1971) of 40.8 when evaluating with 3 annotators, in §3.4.

B Using Alternate Models as Knowledge Sources

One natural question that arises from the strong performance of symbolic knowledge distillation is whether other sources of knowledge (i.e. language models) would similarly benefit from this method. In this section, we particularly measure the capacity of other language models to serve as the "loose teacher" which generated the base knowledge of the resulting corpus.

We expand our study beyond GPT-3 here (the model used in our work), to include 2 contemporary large language models, GPT-J (Wang and Komatsuzaki, 2021) and T5-11B (Lester et al., 2021) finetuned for language modelling. For knowledge generation (verbalization) we follow the same procedure as §3 along with simple adjustments to improve quality. We are investigating the effect of the critic on knowledge precision here, so we also include ATOMIC$^{20}_{20}$ to probe the usefulness of automatic filtering for human-authored knowledge.

For each knowledge source, we follow the human evaluation setup in §3.4 to obtain quality annotations of 2000 examples, with 1 annotation per example. This follows a similar setup to §4–indeed, we are replicating the earlier critic experiments but at a smaller scale (2000 annotations vs. 10000) to allow for more knowledge sources. For each knowledge source, we randomly split into sizes of 1400/300/300 for train, dev, and test sets. We follow §4 to train a critic model for each knowledge source.

We plot different thresholds (% of corpus filtered) against the resulting precision (proportion of corpus that is judged to be "valid" knowledge) in Figure 3, and give numbers at various sizes in Table 7. One striking aspect is that a critic model can raise the precision of any of these knowledge sources to approximately 90% while retaining 30% of the original corpus size. While this discards a significant portion of the original generated knowledge, it raises the exciting prospect of using more cost-effective models at a large scale to generate strong commonsense corpora like ATOMIC$^{\mathbf{10x}}$. GPT-J and T5-11B can both be run locally by researchers, unlike GPT-3 which uses a pay-per-generation API. Thus, one can imagine producing a large and high-quality corpus like ATOMIC$^{\mathbf{10x}}$ at a lower cost by instead generating a larger volume of knowledge from such an accessible model, and simply filtering to a greater extent.

Another interesting aspect is how the various knowledge sources diverge. Under little to no critical filtering (i.e. corpus size = 1.0), the precision of various knowledge sources is widely spread. Before applying a critic, quality of knowledge source is very important. Indeed, precision is ordered by cost of generation: human ATOMIC$^{20}_{20}$ has the highest precision while being the most expensive, followed by GPT-3 (used here) which is pay-per-generation, and finally the two publicly available models. Another point of divergence is for extreme filtering (at approximately 20% of the original corpus size. All knowledge sources but GPT-3 plateau at approximately 90% accuracy, while GPT-3 rises towards 100%. Indeed, this supports our use of GPT-3 in this work, as a high-quality automatic knowledge source.

C Critic Model

We train binary classifiers (critics) for human acceptability using RoBERTa-Large (Liu et al., 2019), fine-tuning all parameters, along with a 2-layer MLP on the `[CLF]` representation. We conduct

Knowledge Source	**Precision** at **Corpus Size** (%) 100	90	80	70	60	50	40	30	20	10
ATOMIC$^{20}_{20}$	84.0	86.3	87.9	89.0	88.3	88.7	91.7	90.0	90.0	90.0
GPT-J	71.7	76.7	81.7	83.8	86.7	88.0	88.3	87.8	93.3	90.0
T5-11B	64.7	66.7	70.8	74.8	79.4	84.7	89.2	92.2	91.7	93.3
GPT-3 curie	79.3	81.5	85.0	86.2	88.3	90.7	91.7	90.0	98.3	100.0

Table 7: Knowledge precision at various corpus sizes (from 100% to 10%) based on filtering by the critic model. Precision is calculated by human annotation of valid or invalid knowledge. We consider 4 knowledge sources, as described in Appendix B. This corresponds to the data plotted in Figure 3.

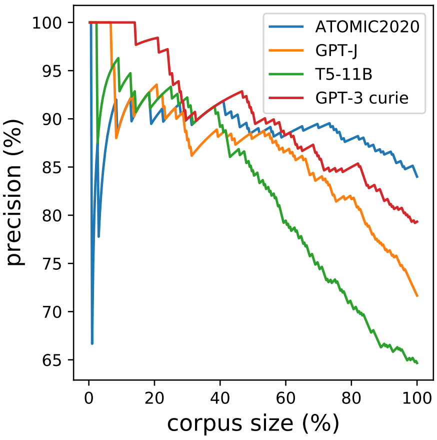

Figure 3: Precision resulting from the critic step from §4, with various thresholds. We include corpora generated by GPT-3 (ATOMIC$^{\mathbf{10x}}$), GPT-J, T5-11B, and humans (ATOMIC$^{20}_{20}$). Without filtering (corpus size = 1.0), different corpora have a variety of precisions. As more examples are filtered by the critic, precision rises significantly demonstrating the strong value of the critic step.

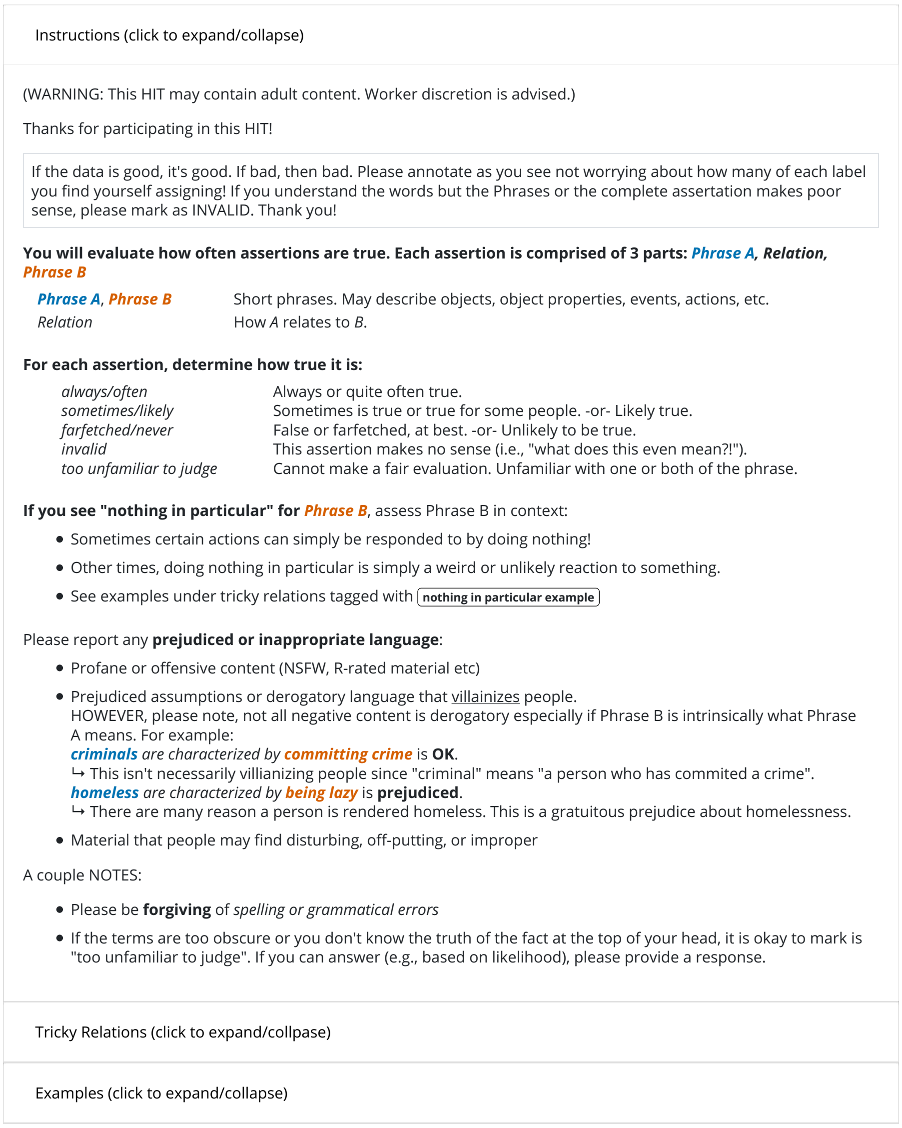
a small grid search on the validation set finding batch size 128, dropout .1, and Adam (Kingma and Ba, 2015) learning rate 5e-6 to be effective. We use early stopping and decay learning rate on validation performance plateauing, to maximize $R@80\%$ on the validation set. We find RoBERTa pretrained on MNLI (Williams et al., 2018) effective, outperforming other options. As well, we substitute randomly-sampled names in for person designations “X”/“Y”. We include as a baseline an unsupervised filtration metric inspired by (Davison et al., 2019): they propose a model estimate of PMI to score mined commonsense triples. In our case, we use Negative Log-Likelihood (NLL) and token-mean-NLL from GPT-3 itself.

The validation precision/recall of our best performing model, the baselines, and the in-optimal hyperparameter configurations are given in Figure 6. Once fixing our model, we applied it to the test set (also in Fig 6), verifying that it generalizes to ATOMIC$^{\mathbf{10x}}$ entries. Overall, our trained critic model is more effective than the baselines in identifying high and low quality teacher generations at all levels of precision and recall. This result demonstrates that a small amount of human supervision can consistently help to correct GPT-3’s mistakes.

D ATOMIC$^{\mathbf{10x}}$ Generation Prompts

We include example prompts for all generations we do, from Table 8 to 15. Note that elements of generation prompts are randomized for each batch. For event generation, the few-shot examples and order are randomly sampled from a seed set of 100 high-quality examples from ATOMIC$^{20}_{20}$ in each batch. For inference generation, the natural names used for PersonX and PersonY are randomly sampled from a small predefined set of names.



Instructions (click to expand/collapse)

(WARNING: This HIT may contain adult content. Worker discretion is advised.)

Thanks for participating in this HIT!

If the data is good, it's good. If bad, then bad. Please annotate as you see not worrying about how many of each label you find yourself assigning! If you understand the words but the Phrases or the complete assertion makes poor sense, please mark as INVALID. Thank you!

You will evaluate how often assertions are true. Each assertion is comprised of 3 parts: *Phrase A*, *Relation*, *Phrase B*

Phrase A, ***Phrase B***	Short phrases. May describe objects, object properties, events, actions, etc.
Relation	How *A* relates to *B*.

For each assertion, determine how true it is:

always/often	Always or quite often true.
sometimes/likely	Sometimes is true or true for some people. -or- Likely true.
farfetched/never	False or farfetched, at best. -or- Unlikely to be true.
invalid	This assertion makes no sense (i.e., "what does this even mean?!").
too unfamiliar to judge	Cannot make a fair evaluation. Unfamiliar with one or both of the phrase.

If you see "nothing in particular" for *Phrase B*, assess Phrase B in context:

- Sometimes certain actions can simply be responded to by doing nothing!
- Other times, doing nothing in particular is simply a weird or unlikely reaction to something.
- See examples under tricky relations tagged with **nothing in particular example**

Please report any **prejudiced or inappropriate language**:

- Profane or offensive content (NSFW, R-rated material etc)
- Prejudiced assumptions or derogatory language that villainizes people.
  HOWEVER, please note, not all negative content is derogatory especially if Phrase B is intrinsically what Phrase A means. For example:
  criminals *are characterized by* ***committing crime*** is **OK**.
  ↪ This isn't necessarily villianizing people since "criminal" means "a person who has commited a crime".
  homeless *are characterized by* ***being lazy*** is **prejudiced**.
  ↪ There are many reason a person is rendered homeless. This is a gratuitous prejudice about homelessness.
- Material that people may find disturbing, off-putting, or improper

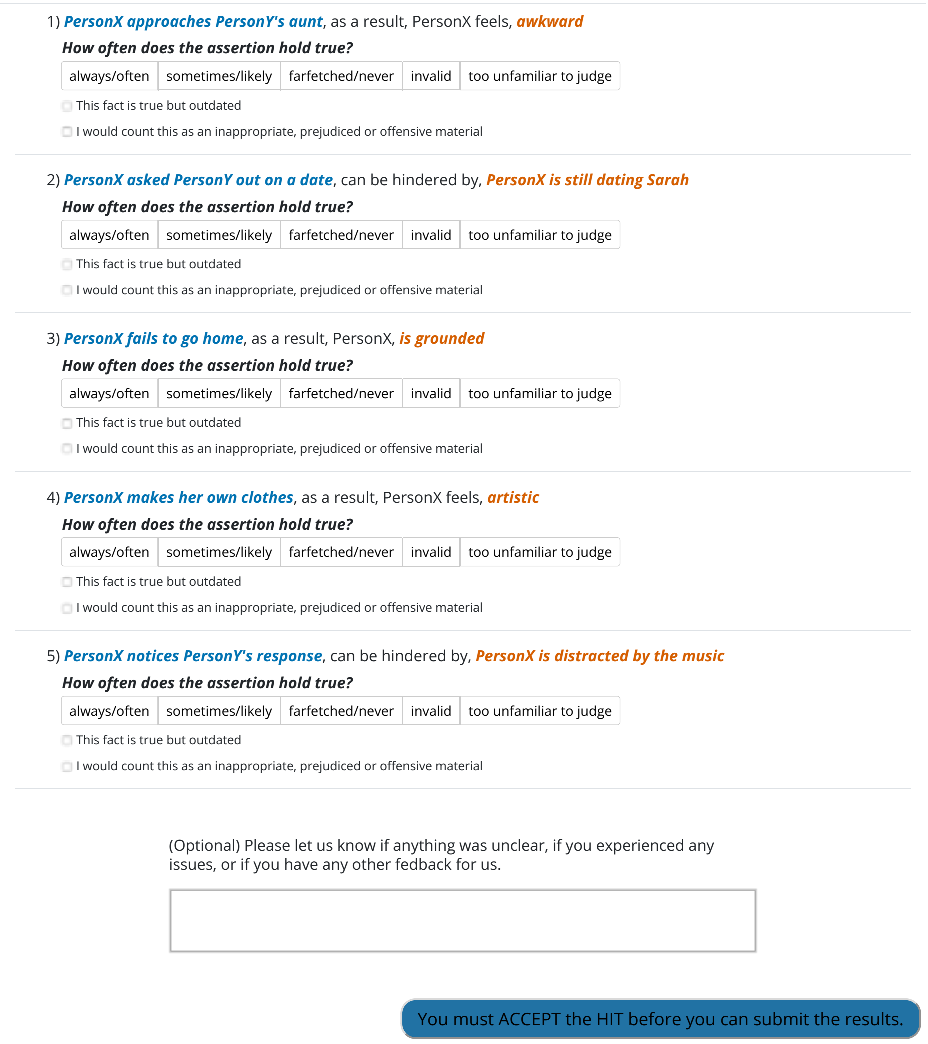
A couple NOTES:

- Please be **forgiving** of *spelling or grammatical errors*
- If the terms are too obscure or you don't know the truth of the fact at the top of your head, it is okay to mark is "too unfamiliar to judge". If you can answer (e.g., based on likelihood), please provide a response.

Tricky Relations (click to expand/collpase)

Examples (click to expand/collapse)

Figure 4: Page 1 of template used for human evaluation.



1) ***PersonX approaches PersonY's aunt***, as a result, PersonX feels, ***awkward***

How often does the assertion hold true?

always/often | sometimes/likely | farfetched/never | invalid | too unfamiliar to judge

☐ This fact is true but outdated

☐ I would count this as an inappropriate, prejudiced or offensive material

2) ***PersonX asked PersonY out on a date***, can be hindered by, ***PersonX is still dating Sarah***

How often does the assertion hold true?

always/often | sometimes/likely | farfetched/never | invalid | too unfamiliar to judge

☐ This fact is true but outdated

☐ I would count this as an inappropriate, prejudiced or offensive material

3) ***PersonX fails to go home***, as a result, PersonX, ***is grounded***

How often does the assertion hold true?

always/often | sometimes/likely | farfetched/never | invalid | too unfamiliar to judge

☐ This fact is true but outdated

☐ I would count this as an inappropriate, prejudiced or offensive material

4) ***PersonX makes her own clothes***, as a result, PersonX feels, ***artistic***

How often does the assertion hold true?

always/often | sometimes/likely | farfetched/never | invalid | too unfamiliar to judge

☐ This fact is true but outdated

☐ I would count this as an inappropriate, prejudiced or offensive material

5) ***PersonX notices PersonY's response***, can be hindered by, ***PersonX is distracted by the music***

How often does the assertion hold true?

always/often | sometimes/likely | farfetched/never | invalid | too unfamiliar to judge

☐ This fact is true but outdated

☐ I would count this as an inappropriate, prejudiced or offensive material

(Optional) Please let us know if anything was unclear, if you experienced any issues, or if you have any other fedback for us.

Figure 5: Page 2 of template used for human evaluation.

1. Event: PersonX unwraps PersonY’s hands

2. Event: PersonX overcomes evil with good

3. Event: PersonX is fed up with the present situation

4. Event: PersonX breaks PersonX’s back

5. Event: PersonX calls no one

6. Event: PersonX never gets angry

7. Event: PersonX does not learn from PersonY

8. Event: PersonX refuses to touch PersonY’s hands

9. Event: PersonX looks at flowers

10. Event: PersonX unloads an atomic bomb

11. Event:

Table 8: Prompt for head generation.

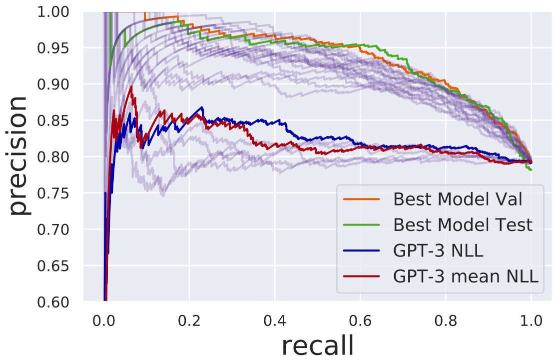


Figure 6: Precision vs. recall of our critic model on the human labelled validation set. The best trained models are labelled, and other hyper-parameter settings are shown as faded lines. We also include generation negative log-likelihood (nll) and token-wise mean nll as cutoff measures–these perform much worse than the supervised model.

Next, how are people seen in each situation? Examples:

Situation 1: Devin bullies Jean.

Devin is seen as dominant.

Situation 2: Jamie moves to another city.

Jamie is seen as adventurous.

Situation 3: Sydney changes Ryan's mind.

Sydney is seen as influential.

Situation 4: Lindsay writes a story.

Lindsay is seen as creative.

Situation 5: Rowan covers Pat's expenses.

Rowan is seen as wealthy.

Situation 6: Lee takes time off.

Lee is seen as carefree.

Situation 7: Riley advises Noel.

Riley is seen as informed.

Situation 8: Adrian bursts into tears.

Adrian is seen as depressed.

Situation 9: Hunter deals with problems.

Hunter is seen as responsible.

Situation 10: Sam follows Charlie.

Sam is seen as suspicious.

Situation 11: Alex makes Chris wait.

Alex is seen as

Table 9: Prompt for generating xAttr.

Next, what do situations make people do? Examples:

Situation 1: Devin gets a divorce.

As a result, Devin dates someone new.

Situation 2: Jamie lifts weights.

As a result, Jamie has sore muscles.

Situation 3: Sydney takes Ryan to a bar.

As a result, Sydney gets drunk.

Situation 4: Lindsay decides to hire a tutor.

As a result, Lindsay gets better grades.

Situation 5: Rowan buys Pat drinks.

As a result, Rowan is thanked by Pat.

Situation 6: Lee hears bad news.

As a result, Lee begins to cry.

Situation 7: Riley buys a chocolate bar.

As a result, Riley gets change.

Situation 8: Adrian does a lot of work.

As a result, Adrian gets mental fatigue.

Situation 9: Hunter attends a concert.

As a result, Hunter hears a new song.

Situation 10: Sam gets the job done.

As a result, Sam gets more responsibilities.

Situation 11: Alex makes Chris wait.

As a result, Alex

Table 10: Prompt for generating xEffect.

For each situation, describe the intent. Examples:

Situation 1: Devin gets the newspaper.

Devin intends to read the newspaper.

Situation 2: Jamie works all night.

Jamie intends to meet a deadline.

Situation 3: Sydney destroys Ryan.

Sydney intends to punish Ryan.

Situation 4: Lindsay clears her mind.

Lindsay intends to be ready for a new task.

Situation 5: Rowan wants to start a business.

Rowan intends to be self sufficient.

Situation 6: Lee ensures Ali's safety.

Lee intends to be helpful.

Situation 7: Riley buys lottery tickets.

Riley intends to become rich.

Situation 8: Alex makes Chris wait.

Alex intends

Table 11: Prompt for generating xIntent.

Next, we will discuss what people need for certain situations. Examples:

1. Before Devin makes many new friends, Devin has to spend time with people.

2. Before Jamie gets a date, Jamie has to ask someone out.

3. Before Sydney changes Ryan's mind, Sydney has to think of an argument.

4. Before Lindsay gets a job offer, Lindsay has to apply.

5. Before Rowan takes a quick nap, Rowan has to lie down.

6. Before Lee tries to kiss Ali, Lee has to approach Ali.

7. Before Riley rides Noel's skateboard, Riley has to borrow it.

8. Before Adrian eats the food, Adrian has to prepare a meal.

9. Before Hunter watches Netflix, Hunter has to turn on the TV.

10. Before Sam has a baby shower, Sam has to invite some friends.

11. Before Alex makes Chris wait, Alex has

Table 12: Prompt for generating xNeed.

Next, how do people feel in each situation? Examples:

Situation 1: Devin lives with Jean's family.

Devin feels loved.

Situation 2: Jamie expects to win.

Jamie feels excited.

Situation 3: Sydney comes home late.

Sydney feels tired.

Situation 4: Lindsay sees dolphins.

Lindsay feels joyful.

Situation 5: Rowan causes Pat anxiety.

Rowan feels guilty.

Situation 6: Lee goes broke.

Lee feels embarrassed.

Situation 7: Riley has a drink.

Riley feels refreshed.

Situation 8: Adrian has a heart condition.

Adrian feels scared about their health.

Situation 9: Hunter shaves Avery's hair.

Hunter feels helpful.

Situation 10: Sam loses all of Charlie's money.

Sam feels horrible.

Situation 11: Alex makes Chris wait.

Alex feels

Table 13: Prompt for generating xReact.

Next, what do people want in each situation? Examples:

Situation 1: Devin mows the lawn.

Devin wants to take a shower.

Situation 2: Jamie is going to a party.

Jamie wants to take an Uber home.

Situation 3: Sydney bleeds a lot.

Sydney wants to go to the ER.

Situation 4: Lindsay works as a cashier.

Lindsay wants to find a better job.

Situation 5: Rowan gets dirty.

Rowan wants to do a load of laundry.

Situation 6: Lee stays up all night studying.

Lee wants to rest.

Situation 7: Riley gets Noel's autograph.

Riley wants to tell some friends.

Situation 8: Adrian sees Taylor's point.

Adrian wants to agree with Taylor.

Situation 9: Hunter leaves Avery's bike.

Hunter wants to keep the bike safe.

Situation 10: Sam wants a tattoo.

Sam wants to find a tattoo design.

Situation 11: Alex makes Chris wait.

Alex wants

Table 14: Prompt for generating xWant.

Next, what can hinder each situation? Examples:

Situation 1: Devin makes a doctor's appointment,

This is hindered if Devin can't find the phone to call the doctor.

Situation 2: Jamie rubs Wyatt's forehead,

This is hindered if Jamie is afraid to touch Wyatt.

Situation 3: Sydney eats peanut butter,

This is hindered if Sydney is allergic to peanuts.

Situation 4: Lindsay looks perfect,

This is hindered if Lindsay can't find any makeup.

Situation 5: Rowan goes on a run,

This is hindered if Rowan injures her knees.

Situation 6: Lee takes Ali to the emergency room,

This is hindered if Ali has no health insurance to pay for medical care.

Situation 7: Riley spends time with Noel's family,

This is hindered if Noel's family doesn't like spending time with Riley.

Situation 8: Adrian moves from place to place,

This is hindered if Adrian can't afford to move.

Situation 9: Hunter protests the government,

This is hindered if Hunter is arrested.

Situation 10: Sam has a huge fight,

This is hindered if Sam does not like confrontation.

Situation 11: Alex makes Chris wait,

This is hindered if

Abstract

Structured and grounded representation of text is typically formalized by *closed information extraction*, the problem of extracting an exhaustive set of *(subject, relation, object)* triplets that are consistent with a predefined set of entities and relations from a knowledge base schema. Most existing works are pipelines prone to error accumulation, and all approaches are only applicable to unrealistically small numbers of entities and relations. We introduce GenIE (generative information extraction), the first end-to-end autoregressive formulation of closed information extraction. GenIE naturally exploits the language knowledge from the pre-trained transformer by autoregressively generating relations and entities in textual form. Thanks to a new bi-level constrained generation strategy, only triplets consistent with the predefined knowledge base schema are produced. Our experiments show that GenIE is state-of-the-art on closed information extraction, generalizes from fewer training data points than baselines, and scales to a previously unmanageable number of entities and relations. With this work, closed information extraction becomes practical in realistic scenarios, providing new opportunities for downstream tasks. Finally, this work paves the way towards a unified end-to-end approach to the core tasks of information extraction.

1 Introduction

The ability to extract structured semantic information from unstructured texts is crucial for many AI tasks such as knowledge discovery (Ji and Grishman, 2011; Trisedya et al., 2019), knowledge maintenance (Tang et al., 2019), symbolic representation, and reasoning (Ji et al., 2021). The interface between free text and structured knowledge is formalized by *knowledge base population* (KBP; Ji and Grishman, 2011), which proposes to represent the information contained in text using *(subject, relation, object)* fact triplets. In this work, we focus on closed information extraction (cIE), the problem of extracting exhaustive sets of fact triplets expressible under the relation and entity constraints defined by a Knowledge Base (KB) schema.

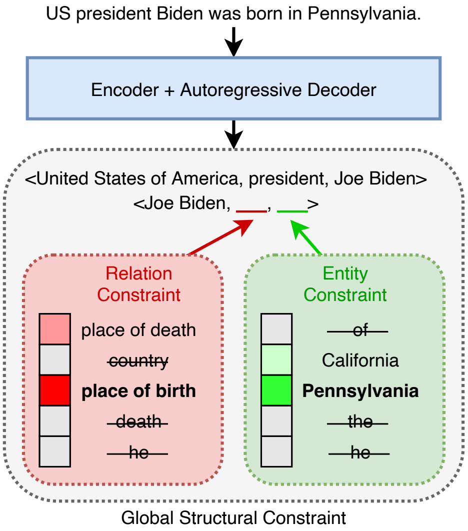

Figure 1: **Overview of GenIE.** We use a transformer encoder-decoder model that takes unstructured text as input and autoregressively generates a structured semantic representation of the information expressed in it, in the form of (subject, relation, object) triplets. GenIE employs constrained beam search with: (i) a high-level constraint which asserts that the output corresponds to a set of triplets; (ii) lower-level constraints which use prefix tries to force the model to only generate valid entity or relation identifiers (from a predefined schema).

Traditionally, cIE was approached with pipelines that sequentially combine named entity recognition (Tjong Kim Sang, 2002), entity linking (Milne and Witten, 2008), and relation extraction (Miller et al., 1998). Entity linking and relation extraction serve as grounding steps, matching entities and relations to numerical identifiers in a KB, e.g., QIDs and PIDs for Wikidata (Vrandečić, 2012). Recently, Trisedya et al. (2019) pointed out that such pipeline architectures suffer from the accumulation of errors and proposed an end-to-end alternative. Nevertheless, existing methods are still only prac-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4626 - 4643
July 10-15, 2022

tical for small schemas with unrealistically small numbers of relations and entities.

Alternatively, some works have focused on a simpler syntactic task: open information extraction (oIE), which produces free-form triplets from texts. In this setup, the entities and relations are not grounded in a KB and, usually, do not represent facts (Gashteovski et al., 2020). As oIE triplets contain only surface relations, they have ambiguous semantics, making them hard to use in downstream tasks (Broscheit et al., 2017) if not first aligned with a KB (Gashteovski et al., 2020). Since, in practice, oIE often consists of structured substring selection, it has recently been framed as an end-to-end sequence-to-sequence problem with great success (Huguet Cabot and Navigli, 2021; Dognin et al., 2021). Indeed, such autoregressive formulations can exploit the language knowledge already encoded in pre-trained transformers (Devlin et al., 2019). For example, some tokens can be more easily recognized as possible entities or relations thanks to the pre-training information.

Inspired by recent successes in oIE, we propose the first autoregressive end-to-end formulation of cIE that scales to many entities and relations, making cIE practical for more realistic KB schemas (i.e. schemas with millions of entities).[1] We employ a sequence-to-sequence BART model (Lewis et al., 2020), and exploit a novel bi-level constrained generation strategy operating on the space of possible triplets (from a fixed schema induced by Wikidata) to ensure that only valid triplets are generated. Our resulting model, *GenIE*, performs *Gen*erative *I*nformation *E*xtraction and combines the advantages of a known schema with an autoregressive formulation. The high-level overview of GenIE is provided in Fig. 1. The constrained generation encodes the known schema and enables the autoregressive decoder to generate textual tokens but only from the set of allowed entities or relations.

Contributions.

- We present the first end-to-end autoregressive formulation of closed information extraction.
- We describe a constrained decoding strategy that exploits the Wikidata schema to generate only valid fact triplets, demonstrating how constrained beam search can be applied on large, structured, and compositional spaces.
- We propose a model that achieves state-of-the-art performance on the cIE task and scales to previously unmanageable numbers of entities (6M) and relations (more than 800).
- We point out and address weaknesses in the evaluation methodologies of recent previous works stemming from their small scale and the large imbalances in the available data per relation. We demonstrate the importance of reporting performance as a function of the number of relation occurrences in the data.
- We release pre-processed data, pre-trained models, and code within a general template designed to facilitate future research at `https://github.com/epfl-dlab/GenIE`.

2 Background and Related Work

2.1 Closed Information Extraction

In this work, we address the task of closed information extraction (cIE), which aims to extract the exhaustive set of facts from natural language, expressible under the relation and entity constraints defined by a knowledge base (KB).

Most of the existing methods address the problem with a pipeline solution. One line of work starts by first extracting the entity mentions and the relations between them from raw text. This is followed by a disambiguation step in which the entity and relation predicates are mapped to their corresponding items in the KB. The sub-task of extracting the free-form triplets was originally proposed by Banko et al. (2007), and it is commonly referred to as open information extraction (oIE) or text-to-graph in the literature (Guo et al., 2020; Castro Ferreira et al., 2020; Huguet Cabot and Navigli, 2021; Shen et al., 2015). Another line of work employs a pipeline of models for (i) named entity recognition (NER) – detecting the entity mentions; (ii) entity linking (EL) – mapping the mentions to specific entities from the KB; (iii) relation classification (RC) – detecting the relations that are expressed between the entities (Galárraga et al., 2014; Angeli et al., 2015b; Chaganty et al., 2017). Due to their architecture, pipeline methods are plagued by error propagation, which significantly affects their performance (Mesquita et al., 2019; Trisedya et al., 2019).

End-to-end systems that jointly perform the extraction and the disambiguation of entities and relations have been proposed to address the error propagation (Trisedya et al., 2019; Sui et al., 2021;

---

[1] Note that current methods, due to the atomic classification, have high memory requirements, and suffer from performance deterioration as the number of entities or/and relations grows.

Liu et al., 2018). To mitigate the propagation of errors, these systems are endowed with the ability to leverage entity information in the relation extraction and vice-versa, which has resulted in significant performance gains. Conceptually, for producing the output triplets, existing methods all rely on atomic, multi-class classification-based ranking of relations and entities. Classification methods particularly suffer from imbalances in the data. On the contrary, our model, GenIE, is autoregressive and copes better with imbalances.

While cIE requires the constituent elements of the output triplets to be entities and relations associated with the KB, the output triplets in oIE are free-text. This makes the cIE task fundamentally harder than oIE and renders the majority, if not all, oIE methods inapplicable to the cIE setting. We report an additional discussion on relevant, but not fundamental, related work on oIE in Appendix A.

2.2 Autoregressive Entity Linking

The tasks of entity linking (EL) and entity disambiguation (ED) have been extensively studied in the past (Huang et al., 2015; Wu et al., 2020; Le and Titov, 2018; Kolitsas et al., 2018; Arora et al., 2021). Most existing approaches associate entities with unique atomic labels and cast the retrieval problem as multi-class classification across them. The match between the context and the label can then be represented as the dot product between the dense vector encodings of the input and the entity's meta information (Wu et al., 2020). This general approach has led to large performance gains.

Recently, De Cao et al. (2021a,b, 2022) have suggested that the classification-based paradigm for retrieval comes with several shortcomings such as (i) the failure to capture fine-grained interactions between the context and the entities; (ii) the necessity of tuning an appropriately hard set of negative samples during training. Building on these observations, they propose an alternative solution that casts the entity retrieval problem as one of autoregressive generation in which the entity names are generated token-by-token in an autoregressive fashion. The (freely) generated output will not always be a valid entity name, and to solve this problem De Cao et al. (2021b) propose a constrained decoding strategy that enforces this by employing a prefix trie. Their method scales to millions of entities, achieving state-of-the-art performance on monolingual and multilingual entity linking.

Inspired by the intuition that language models are well suited for predicting entities, we propose a novel approach for cIE by framing the problem in an autoregressive generative formulation.

3 Method

In this section we formalize GenIE, an autoregressive end-to-end model for closed information extraction. Let us assume a knowledge base (KB) consisting of a collection of entities $\mathscr{E}$, a collection of relations $\mathscr{R}$, and a set of facts $(s,r,o) \in \mathscr{E} \times \mathscr{R} \times \mathscr{E}$ stored as (subject, relation, object) triplets. Additionally, we assume that each entity $e \in \mathscr{E}$ and relation $r \in \mathscr{R}$ is assigned to a textual label (corresponding to its name). The Wikidata KB (Vrandečić, 2012), with Wikipedia page titles as entity names, and the Wikidata relation labels as relation names satisfy these assumptions.

3.1 Model

We cast the task of information extraction as one of autoregressive generation. More concretely, given some text input x, GenIE strives to generate the linearized sequence representation y of the exhaustive set of facts expressed in x. The conditional probability (parameterized by θ) assigned to the output y is computed in the autoregressive formulation: $p_\theta(y \mid x) = \prod_{i=1}^{|y|} p_\theta(y_i \mid y_{<i}, x)$. This can be seen as translating the unstructured text to a structured, unambiguous representation in a sequence-to-sequence formulation. GenIE employs the BART (Lewis et al., 2020) transformer architecture. It is trained to maximize the target sequence's conditional log-likelihood with teacher forcing (Sutskever et al., 2011, 2014), using the cross-entropy loss. We use dropout (Srivastava et al., 2014) and label smoothing for regularization (Szegedy et al., 2016).

3.2 Output Linearization

To represent the output with a sequence of symbols that is compatible with sequence-to-sequence architectures, we introduce the special tokens <sub>, <rel>, <obj> to demarcate the start of the subject entity, the relation type and the object entity for each triplet. The special token <et> is introduced to demarcate the end of the object entity, which is also the end of the triplet. We construct the sequence representation by concatenating the textual representations of its constituent triplets. While the sequence representation has an intrinsic notion of order, the output set of triplets does not. To mitigate the effects of this discrepancy, we enforce a consistent ordering of the target triplets during training. Concretely, whenever the triplets' entities are linked to the entity mentioned in the textual input, we consider first the triplets for which the subject entity appears earlier in the text. Ties are resolved by considering the appearance position of the object entity.

3.3 Inference with Constrained Beam Search

The space of triplets corresponds to $\mathscr{T} = \mathscr{E} \times \mathscr{R} \times \mathscr{E}$, and the target space, which consists of triplet sets of arbitrary cardinality, is equivalent to $\mathscr{S} = \bigcup_{i=0}^{\infty} [\mathscr{E} \times \mathscr{R} \times \mathscr{E}]^i$. At inference time, GenIE tackles the task of retrieving the linearized representation $y_S \in \mathscr{S}$ of a set of facts $S = \{t_1, \dots, t_n\}$ constituted by triplets $t_i \in \mathscr{T}$ expressed in the input text x. Ideally, we would consider every element $y \in \mathscr{S}$ in the target space, assign it a score $p_\theta(y \mid x)$, and retrieve the most probable y. Unfortunately, this is prohibitively expensive since we are dealing with a compositional target space whose size is gigantic (e.g., if we consider a Wikidata entity catalog of $|\mathscr{E}| \approx$ 6M elements and a relation catalog of $|\mathscr{R}| \approx 1000$ relations, that can express a total of $|\mathscr{T}| \approx 10^{15}$ triplets; even if we limit ourselves to sentences that express only two facts, this provides us with $\approx 10^{30}$ different output options).

On the other hand, the output needs to follow a particular structure, and contain only valid entity and relation identifiers. This does not necessarily hold for an arbitrary generation from a sequence-to-sequence model.

GenIE employs constrained beam search (BS; Sutskever et al., 2014; De Cao et al., 2021b) to resolve both of these problems. Instead of explicitly scoring all of the elements in the target space $\mathscr{S}$, the idea is to search for the top-k eligible options, using BS with k beams and a prefix trie. BS considers one step ahead – the next token to be generated – conditioned on the previous ones. The prefix trie restricts the BS to candidate tokens that could lead to valid identifiers. However, for the cIE setting we are interested in, the target space is prohibitively large to pre-compute the necessary trie. Therefore, we enforce a bi-level constraint on the output that allows for compositional, dynamic generation of the valid prefixes. More specifically, GenIE employs: (i) a high-level structural constraint which asserts that the output follows the linearization schema defined in Sec. 3.2; (ii) lower level validity constraints which use an entity trie and a relation trie to force the model to only generate valid entity or relation identifiers, respectively – depending on the specific element of the structure that is being generated. This outlines a general approach for applying BS to search through large compositional structured spaces.

4 Experimental Setup

4.1 Knowledge Base: Wikidata

We use Wikidata[2] (Vrandečić, 2012) as the target KB to link to, filtering out all entities that do not have an English Wikipedia page associated with them. The filtering guarantees that all entity names are unique. Our final entity set $\mathscr{E}$ contains 5,891,959 items. We define our relation set $\mathscr{R}$ as the union of all the relations considered in the datasets described below, resulting in 857 relations. For different datasets, we consider only the subset of annotated relations to better compare with baselines. Although large, the number of entity (and relation) names is not a memory bottleneck as the generated prefix trie occupies ≈200MB of storage (e.g., the entity linking system proposed by Wu et al. 2020 needs >20 times more storage).

4.2 Datasets and Evaluation Metrics

In this work, we further annotate and adapt REBEL (Huguet Cabot and Navigli, 2021) and Wiki-NRE for training, validation and testing. Additionally, we use Geo-NRE (Trisedya et al., 2019), and FewRel (Han et al., 2018) for testing purposes only. Appendix B contains descriptions of these datasets and their statistics. We measure the performance in terms of micro and macro precision, recall and F1. See Appendix C for a detailed and formal description of these metrics. We also report a 1-standard-deviation confidence interval constructed from 50 bootstrap samples of the data.

4.3 Baselines

We compare GenIE against Set Generation Networks (SetGenNet; Sui et al., 2021) which is, to the best of our knowledge, the strongest model on Wiki-NRE and Geo-NRE. Note that the authors did not release code or the model and there is no other model from the literature trained and evaluated on REBEL for cIE. SetGenNet (Sui et al., 2021) is an

---

[2] Dumps from 2019/08/01

end-to-end state-of-the-art model for triplet extraction. It consists of a transformer encoder (Vaswani et al., 2017) that encodes the input followed by a non-autoregressive transformer decoder (Gu et al., 2018). The decoder generates embeddings that are used to predict entities and relations. SetGenNet further uses candidate selection (Ganea and Hofmann, 2017; Kolitsas et al., 2018) to reduce the output space and a bipartite matching loss that handles different prediction orderings (i.e., it generates a set). Note that there are weaker baselines (e.g., Trisedya et al. 2019) we could have used to compare on REBEL, but we were not able to reproduce their code. We report details on the effort made to use these baselines in Appendix D.

We also implement a pipeline baseline, consisting of 4 independent steps, namely: (i) *named entity recognition* (NER), which selects the spans in the input source likely to be entity mentions; (ii) *entity disambiguation* (ED), which links mentions to their corresponding identifiers in the KB; (iii) *relation classification* (RC), which predicts the relation between a given pair of entities, and finally; (iv) *triplet classification* (TC), which predicts whether a given triplet is actually entailed by the context. TC is necessary because the previous step (RC) predicts a relation for every pair of entities. Each step needs to be trained independently with a specific architecture tailored for the task, and we made an optimal choice for each step. For the NER component we used the state-of-the-art tagger FLAIR[3] (Akbik et al., 2019), while for ED we used the GENRE linker[4] (De Cao et al., 2021b). These two models were already trained, and we use them for inference only. For RC and TC, we trained a RoBERTa (Liu et al., 2019) model with a linear classification layer on top (as these two sub-tasks are typically cast as classification problems). Trisedya et al. (2019) also proposed many other pipeline baselines but ours outperforms them (see Table 5 in Appendix G for comparison).

5 Results

5.1 Performance Evaluation

Models performing cIE can base their predictions on different schemas. In this section, we distinguish between *small* and *large evaluation schema*. The *small evaluation schema* is consistent with previous approaches where models only have to decide between a small set of relations and entities (the schema induced by Wiki- and Geo-NRE). In the *large evaluation schema*, models use the schema induced by REBEL. Models also use the large evaluation schema of REBEL when tested on FewRel, as a high-quality and challenging recall-based evaluation. We consider 3 training setups for GenIE and the pipeline baseline comprised of SotA components: (i) the training set of Wiki-NRE (W) only, (ii) the training set of REBEL (R) only, and (iii) pre-training on REBEL and fine-tuning on Wiki-NRE (R+W). The implementation details are given in Appendix E. We report the macro and micro precision, recall, and F1 in Table 1. Unfortunately, as the code for SetGenNet is not available, we cannot compute its macro performance, thus we report the micro scores only.

First, on Wiki-NRE (W), we observe a large and significant F1 improvement of 8 and 28 absolute points obtained by GenIE over SetGenNet and the pipeline baseline, respectively, when trained on the same dataset. Despite the much bigger schema employed by REBEL, pre-training on it and then fine-tuning (R+W), improves the performance on Wiki-NRE and Geo-NRE for 3% and 5%, respectively. This highlights that: (i) GenIE can effectively transfer knowledge across datasets/schemas; (ii) GenIE can quickly adapt to new schemas. Due to its rigid, monolithic relation classifier, the pipeline baseline does not possess these qualities. However, the pre-training does improve its macro scores.

Only the newly developed pipeline baseline and GenIE can scale-up to the larger schema[5], and as expected, this setting is more challenging for both models. However, GenIE still preserves a good F1 score of 68 micro and 34 macro, which is a relative increase of 60% and 320%, respectively, over the baseline. While the pipeline has a steeper drop from micro to macro scores, in general, a significant difference between the two is observed in every setting. This suggests that the models perform better for relations associated with many training examples and significantly worse for the rest. These findings call for the fine-grained analysis of performance in Sec. 5.2 that partitions the relations according to their occurrence count in the training data. For completeness, we also provide an analysis of performance as a function of the number of relations considered, in Appendix F.1.

Table 2: **Ablation study on the weights initialization and the constrained generation strategy.**

Finally, on FewRel, recall is the only well-defined metric (see Appendix B). In this setting as well, GenIE greatly outperforms the baseline by 13 (micro) and 11 (macro) recall points (micro and macro are close as the dataset is class-balanced).

Ablation study. In Table 2 we summarize the results of an ablation study considering the pre-training and the constrained generation. We consider three different starting points: (i) a random initialization; (ii) BART (Lewis et al., 2020) pre-trained language model (PLM); (iii) a pre-trained autoregressive entity retrieval model GENRE (De Cao et al., 2021b). The pre-trained models are better in terms of recall and exhibit a better out-of-domain generalization on FewRel. In contrast, they are slightly worse in terms of precision, which translates to maximum improvement of a single point in F1 on REBEL. Another salient advantage of pre-training is reducing the training steps necessary for achieving good results. Indeed, when starting from GENRE, 3-5k steps are sufficient for competitive performance; starting from a PLM necessitates 5-10k steps; while a random initialization requires 40-50k steps for competitive performance. Additionally, the pre-trained versions converge to a lower validation loss (see Fig. 5 in Appendix G).

To quantify the benefits from the constrained generation, we compare the results attained by the randomly initialized model with and without constraints. In addition to ensuring a structure on the output, the constrained generation strategy results in an increase of 2-3 absolute points in terms of F1.

5.2 Analysis of Performance as a Function of the Relation Occurrence Count

The datasets naturally present large imbalances, where few relations occur a lot, but most relations are rare. In the previous section, we already observed a large difference between macro and micro F1 scores of models, indicating that the number of occurrences impacts model performances. Thus, we now measure F1 scores after bucketing relations according to their number of occurrences in the training dataset. In Fig. 2, we create buckets $i \in \{0, \dots, 20\}$, where bucket i contains all the relations occurring at least 2^i times and less than 2^{i+1} times in the REBEL dataset. The height of the histogram for bucket i shows how many relations are contained in this bucket. Finally, we report the F1 scores of GenIE and the pipeline of SotA components per bucket. Note that micro F1 from Table 1 is equivalent to putting all relations in one single bucket (equal weight to each data point), and macro F1 is equivalent to averaging the F1 with one bucket per relation (equal weight to each relation).

The histogram first confirms that most of the relations occur in only a few triplets from the train-

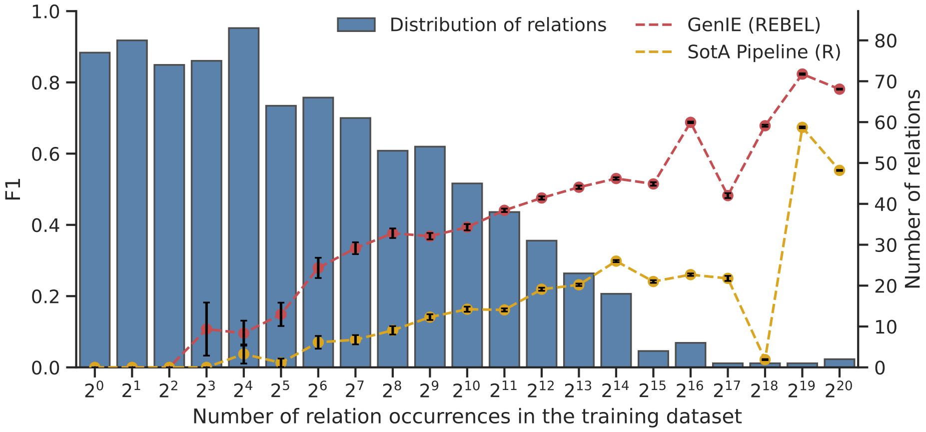

Figure 2: **Impact of the number of relation occurrences.** Relations are bucketed based on their number of occurrences; bucket 2^i contains relations occurring between 2^i and 2^{i+1} times. The histogram shows the number of relations per bucket. The line plots depict the F1 scores of GenIE and the baseline per bucket together with confidence intervals computed per bucket with bootstrap resampling.

ing data. Models thus need to perform few-shot learning for most of the relations. GenIE is significantly better than the pipeline baseline for all the buckets. Finally, it is important to highlight that even though the performance of both methods, unsurprisingly, declines for relations that appear less often in the training data, GenIE already performs well for relations with at least $2^6 = 64$ occurrences. On the contrary, the baseline needs $2^{14} = 16{,}384$ samples to reach a comparable level of performance, and scores better than GenIE does for the $2^6 = 64$ bucket only after seeing at least $2^{19} = 524{,}288$ samples. This confirms that GenIE is not only better at macro and micro F1, but it is also capable of performing fewer-shot learning than the baseline. It further shows that, contrary to the baseline, GenIE's good scores do not come solely from its ability to perform well on the few most frequent relations.

5.3 Disentangling the Errors

The task of cIE, explicitly or implicitly, encompasses NER, NEL and RC as its subtasks. Failure in any subtask directly translates to failure on the original task. Therefore, to effectively compare different cIE models and accurately characterize their behavior, we need to evaluate their performance on each of the subtasks.

The separation of responsibility between the pipeline components leads to a natural error attribution for the SotA pipeline model. To estimate the NER error, we take the entity mentions predicted by the NER component and compare them with the corresponding mentions of the constituent entities of the output triplets. All triplets that concern an entity whose mention was not retrieved by the NER component are considered erroneous. We differentiate between two settings: (i) exact, which requires that the generated mention exactly matches the target mention; and (ii) partial, for which any overlap between the generated and the target triplet is sufficient. The NEL error is calculated by considering the output of the NEL component and comparing the linked entities to those in the output triplets. Again, all of the triplets that concern an incorrectly linked entity are considered erroneous. Finally, for the pipeline, every correctly predicted relation label translates to a correctly extracted triplet. Therefore, we calculate the RC error using the cIE definition of recall given in Appendix C.

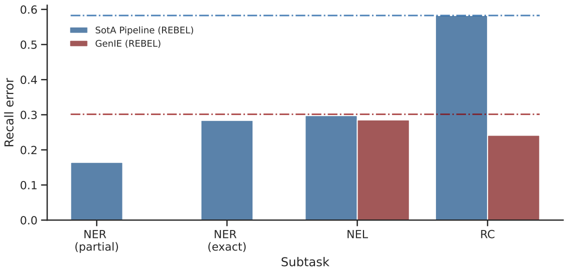

Figure 3: **Attribution of error to each of the cIE subtasks.** The dashed lines equal the overall recall error of the system. Lower is better.

End-to-end systems tackle all of the sub-tasks jointly, which makes the error attribution, in this setting, less obvious. To estimate errors corresponding to a particular target triplet, we need a reference triplet (among the predicted ones) for comparison. We start by outlining a bipartite matching procedure. Let each triplet be a node in a graph. We add an edge between each target–prediction pair of triplets. The edges are assigned a weight determined as a function of the pair of triplets they connect. Concretely, an edge e that connects the target triplet $t_T = (s_T, r_T, o_T)$ and the predicted triplet $t_P = (s_P, r_P, o_P)$ will be assigned a weight of: *1*, if the triplets are the same; *2*, if they express the same relation, but either the subject or the object differ; *3*, if they concern the same entities, but the relation differs; *4*, if they share only a single entity; *5*, if they share only a single relation; *6* if they have nothing in common. We construct the matching by selecting edges in a greedy fashion until all of the target triplets have been matched. The procedure ensures that every target triplet is paired with its closest (yet unpaired) match. Finally, we estimate the NEL error as the portion of edges that were assigned a weight $w \in \{2,4,5,6\}$, and the RC error as the portion of edges that where assigned a weight $w \in \{3,4,6\}$.

The results of this analysis are summarized in Fig. 3. Immediately, the NER component in the pipeline method introduces an 18% error by completely missing on relevant entity mentions. An additional 12 absolute points hinge on a partial matching. The NEL component matches most of the entity mentions that are retrieved, but at this point, even with a (hypothetical) perfect RC, the performance of the pipeline will be only on par with GenIE. In practice, the RC component adds 30% to the inherited error, effectively doubling it.

On another note, the absolute error attributed to NEL by the pipeline and GenIE differs in a few absolute points only, while the difference for the (non-inherited) error stemming from RC is less than 10%. Adding these two together leaves us much shorter than the actual gap of 28 absolute points in performance on the cIE task. This gap suggests a strong correlation between the performance on NEL and RC for GenIE, which is fueled by the increased flow of information between the subtasks. The flow of information allows for more fine-grained interactions between the entities, the relations, and the context to be captured, consequently improving the overall performance. Alternatively, whenever the model captures a misleading correlation/interaction, it is amplified and hinders the performance on both subtasks. This result is echoed by the fact that the sum of the errors attributed to NEL and RC is significantly smaller than the error on the cIE task. Based on this observation, we hypothesize that any improvement on NEL will overflow to the RC subtask – and vice-versa – thereby directly translating to performance gains on the overall task.

6 Discussion

Unifying the cIE spectrum. There is a full spectrum of tasks that are closely related to cIE and are central to the field of information extraction. The typical setup assumes a KB associated with entities and relations, and the goal is to either annotate the text with information from the KB, or extract structured unambiguous information from the text. The tasks of entity linking and relation classification, already discussed in Sec. 2 and Sec. 4.3, are two such examples. Another example is slot filling (SF), the task of extracting information for a specific entity and relation (e.g., entity *Mick Jagger*, relation *member of*) from natural language (Surdeanu, 2013; Petroni et al., 2021).

All of these problems rely on the same set of logical tasks: identifying entities from the KB in text and understanding how they interact. Therefore, it would be beneficial to assume a single model, or a set of models that share parts of the weights and collectively solve all of the tasks. This would allow for the information from a dataset collected for one task (e.g., RC) to be leveraged for improving the performance of another (e.g., SF or cIE).

Bridging the gap between oIE and cIE. In this work, we only considered triplets for which both entities are element in the entity catalog. However, for many useful relations one of the objects is a literal (Mesquita et al., 2019), e.g., date of birth, length, size, number of employees or others. GenIE can be readily extended to accommodate for this, by adapting the decoding strategy allowing that for specific relations the entity can be a substring from the input. This is a subtle connection to oIE which has thus far been treated as a separate problem. Current state-of-the-art methods on the oIE task address the problem in a similar autoregressive formulation (see Appendix A for more discussion).

Real world implications. Generative models have been shown to be very effective even in massive multilingual settings—e.g., De Cao et al. (2022) proposed mGENRE, a multilingual version of

GENRE trained and tested on more than 100 language. Our GenIE formulation would not need substantial modifications to adapt to such setting. Having a single model that works in hundreds of languages would be extremely useful and a very promising direction for future work.

While autoregressive models have a non-negligible computation footprint, De Cao et al. (2021a) show that autoregressive EL can be sped up 70x with no cost on performance. The fact that this solution can be adapted to GenIE makes the practical impact of our method even greater.

7 Conclusion

This paper provides a new view on closed information extraction (cIE) by casting the problem as autoregressive sequence-to-sequence generation. Our method, GenIE, leverages the autoregressive formulation to capture the fine-grained interactions expressed in the text and employs a bi-level constrained generation strategy to effectively retrieve the target representation from a large, structured, compositional predefined space of outputs. Experiments show that GenIE achieves state-of-the-art performance on cIE and can scale to a previously unmanageable number of entities and relations. We believe that our autoregressive formulation of cIE, coupled with constrained decoding, is a stepping stone towards a unified approach for addressing the core tasks in information extraction.

A Additional Background and Related Work

A.1 Generative Open Information Extraction

Early work had focused on pipeline architecture for oIE. In general, these methods first detect the entity mentions present in the text and then, for pair of entities, in a classification setting, predict the existence of a relation between the two entities and the relation type (Angeli et al., 2015a; Corro and Gemulla, 2013). The advent of transformers (Devlin et al., 2019; Lan et al., 2020; Liu et al., 2019) and pipeline architectures that allow for information to flow between the two subtasks – usually by sharing some parameters of the encoder – have allowed these models to do well on the oIE task. However, they do come with some general limitations: (i) assuming the existence of a single relation between a pair of entities; (ii) inability to capture the interactions between triplets.

Much of the current research is focused on studying the oIE problem in the autoregressive generative setting, which seamlessly mitigates the limitations mentioned above (Huguet Cabot and Navigli, 2021; Dognin et al., 2021; Nayak and Ng, 2020). For instance, ReGen (Dognin et al., 2021) significantly improves upon published results and establishes state-of-the-art results on the dataset used in the WebNLG 2020+ Challenge (Castro Ferreira et al., 2020). REBEL (Huguet Cabot and Navigli, 2021), on the other hand, achieves state-of-the-art performances across a suite of oIE benchmarks. Moreover, both of these methods address the problem in a similar formulation that takes the text as input context and generates the output triplets token-by-token in an autoregressive fashion.

The output triplets in oIE are free-text, while cIE requires the constituent elements of the output triplets to come from the entity and relation sets associated with the KB. This makes the cIE task fundamentally harder than oIE, and renders these methods not applicable to the cIE setting.

Finally, Taillé et al. (2020) make an effort to describe the many issues with the evaluation of oIE systems in literature and call for a unified evaluation setting for a fair comparison between systems. These problems get only exacerbated in cIE where the performance of a model would highly depend on the entity and relation catalogue considered. To alleviate some of these issues, we annotate the REBEL dataset (Huguet Cabot and Navigli, 2021) with unique textual entity identifiers and textual relation labels, and propose a suite of meaningful evaluation settings while considering an approximately 6 million long entity catalogue comprised of all the entities in the English Wikipedia, and 857 long relation catalogue supported by the dataset.

B Datasets

Table 3 summarizes the statistics of all datasets used in this work. For each dataset, we remove datapoints containing triplets with entities that do not have an associated Wikipedia page (i.e., entities not associated to a unique name). This filtering removes a negligible portion of the data in most cases (i.e., <0.5%) except for REBEL where 3.4% of datapoints were removed.

We evaluate the models in a standard setups for Wiki-NRE and Geo-NRE. For these datasets, the schema is unrealistically small: ≈300K entities with 157 relations for Wiki-NRE and 124 entities with 11 relations for Geo-NRE. Therefore, we scale to previously unexplored schema sizes for cIE using the REBEL dataset (≈6M entities and 857 relations). We also use FewRel as a high-quality dataset for recall evaluation using the large schema from REBEL.

REBEL (Huguet Cabot and Navigli, 2021) is a dataset created from Wikipedia abstracts. It consists of an alignment between sentences, Wikipedia hyperlinks and their corresponding Wikidata entities, and relations. REBEL proposed an alignment expanding on Elsahar et al. (2018), a pipeline of mention detection, coreference resolution, entity disambiguation and then mapping triplets to each sentence. Huguet Cabot and Navigli (2021) further filtered false positives using an Natural Language Inference (NLI) model to check if the relation was truly entailed by the text. In this setting, we consider the full ≈6M long entity and 857 long relation catalog. We use this dataset for both training and testing. Additionally, we employ REBEL to analyze the performance as a function of the number of relations, by simulating different environments pertaining to subsets of the top-*n* most frequent relations.

Wiki-NRE (Trisedya et al., 2019) is a dataset created from Wikipedia. Authors aligned hyperlinks to Wikidata entities as in REBEL but they applied a different filtering: they (i) extracted sentences that contain implicit entity names using co-reference resolution (Clark and Manning, 2016), and (ii) they

Dataset	Documents			Triplets			$\lvert\mathscr{E}\rvert^{\dagger}$	$\lvert\mathscr{R}\rvert^{\dagger}$
	training	validation	test	training	validation	test		
REBEL	1,899,331	104,960	105,516	5,147,836	284,268	284,936	1,498,143	857
Wiki-NRE	223,536	980	29,619	298,489	1,317	39,678	278,204	157
Geo-NRE	–	–	1,000	–	–	1,000	124	11
FewRel	–	26,892*	27,650	–	26,892*	27,650	64,762	80

Table 3: **Statistics of the datasets.** †With an abuse of notation here we indicate the amount of unique entities and relations for each dataset and not the size of the Knowledge Base associated with it (see Section 4 for more details). * Note that we do not use the validation FewRel data in our experiment, but we release this split as well.

filtered and assigned relations to sentences using paraphrase detection from different sources (Nakashole et al., 2012; Ganitkevitch et al., 2013; Grycner and Weikum, 2016). We used this dataset for both training and testing.

Geo-NRE (Trisedya et al., 2019) is constructed in the same way as Wiki-NRE but from a collection of user reviews on 100 popular landmarks in Australia, instead of Wikipedia. Due to its small size and to compare with the literature, we used this dataset only for testing.

FewRel (Han et al., 2018) is also extracted from Wikipedia where Wikidata is the KB. Contrary to the other datasets, FewRel does not provide distant supervision but it is fully annotated by humans. The dataset was first automatically constructed and then filtered as annotators were asked to judge whether the relations are explicitly expressed in the sentences. Each input in FewRel is associated with a single triplet only, and not all of the triplets entailed by it. Therefore, this dataset can be used for precisely measuring recall (but not precision or F1). We employ it only for testing. To simulate a more realistic scenario, we train the models on many relations, and leverage the high quality FewRel data to calculate the performance metrics for the subset of relations annotated.

C Performance Metrics

We measure standard precision, recall and F1 for all settings. A fact is regarded as correct if the relation and the two corresponding entities are all correct. More precisely, we denote the set of all predicted triplets of a document $d \in \mathscr{D}$ as P_d, and the set of gold triplets as G_d. Then:

$$\text{micro-precision} = \sum_{d\in\mathscr{D}} |P_d \cap G_d| \Big/ \sum_{d\in\mathscr{D}} |P_d| \,, \quad (1)$$

and

$$\text{micro-recall} = \sum_{d\in\mathscr{D}} |P_d \cap G_d| \Big/ \sum_{d\in\mathscr{D}} |G_d| \,. \quad (2)$$

Micro scores are useful for measuring the overall performance of a model but they are less informative for imbalanced datasets (e.g., when some entities or relations are disproportionately more present in both training and test sets). Indeed, micro scores assign equal weight to every sample while macro scores assign equal weight to every class. Thus, we also measure macro scores by aggregating per relation type. If we denote $P_d^{(r)}$ and $G_d^{(r)}$ as the predicted and gold set only containing the relation $r \in \mathscr{R}$ of a document d, then macro-precision is defined as:

$$\frac{1}{\mathscr{R}} \sum_{r\in\mathscr{R}} \left(\sum_{d\in\mathscr{D}} |P_d^{(r)} \cap G_d^{(r)}| \Big/ \sum_{d\in\mathscr{D}} |P_d^{(r)}| \right) , \quad (3)$$

and macro-recall as:

$$\frac{1}{\mathscr{R}} \sum_{r\in\mathscr{R}} \left(\sum_{d\in\mathscr{D}} |P_d^{(r)} \cap G_d^{(r)}| \Big/ \sum_{d\in\mathscr{D}} |G_d^{(r)}| \right) . \quad (4)$$

D Note on End-to-End Baselines

We invested a considerable amount of time trying to use a strong end-to-end baseline to compare GenIE with. Unfortunately, most works do not have available or directly usable code. In particular, we first concentrated on SetGenNet (Sui et al., 2021) as, to the best of our knowledge, it is the strongest model on the task of cIE. However, the authors do not report a link to the code[6] in neither the arXiv nor the ACL Antology version of the paper. We could not find any related repository on GitHub either. For these reasons we were unable to use their method as a baseline for REBEL.

---

[6] As of October 2021.

We then focused on the work most similar to SetGenNet, that is the system proposed by Trisedya et al. (2019). They released code and we were able to run it. However, the code was incomplete: they included code for training only a part of their system. They start with pre-trained word, entity and relation embeddings, but did not release code for pre-training them. The closest solution we found was using Wikipedia2Vec (Yamada et al., 2020), which does not include relation embeddings. Besides, the pre-trained word embeddings on the official Wikipedia2Vec website[7] do not match the dimensionality used by Trisedya et al. (2019). Finally, the authors did not include code to train the "triple classifier" of their model. The classifier is instead directly loaded in their code. For these reasons we were unable to use their method as a baseline for REBEL.

E Implementation Details

Data. The train, test and validation splits are either inherited from the original dataset (see Appendix B for details) or sampled at random. To facilitate reproducibility, we release the exact splits employed in our experiments.

Additionally, we release the curated entity and relation catalogs for both the large and the small schema, in which the redirects have been resolved and each of the QID/PID is paired with a unique, semantically meaningful textual identifier. We hope that this will allow for a fair comparison of future work in which the same evaluation setup can be maintained.

E.1 GenIE

Infrastructure. For training we used a single machine with 24 Intel(R) Xeon(R) CPU E5-2690 v4 @ 2.60GHz processor cores and 441 GB of RAM, equipped with 4 Tesla V100-PCIE-16GB GPUs.

Training. The models were trained using the Adam optimizer (Kingma and Ba, 2015) with a learning rate of 3e-5, 0.1 gradient clipping and a varying weight decay (cf. Table 4). The learning rate is updated using a polynomial decay schedule with an end value of 0. While most of the parameters were left at their default values for BART, the rest were tuned on the respective datasets' validation set, and their corresponding optimal values are given in Table 4.

Inference. At test time, we use Constrained Beam Search with 10 beams. We restrict the input and the output sequence to be at most 256 tokens, cutting from the right side if the input is too long. We normalize the log-probabilities by sequence length, and allow for any number of n-gram repetition. The other parameters are kept to their default values for inference with BART.

E.2 SotA Pipeline

We described our SotA pipeline system baseline in Sec. 4.3. We release code to both train and run inference with the proposed pipeline. The named entity recognition and the entity disambiguation components were not trained. The relation classification module is a linear layer on top of RoBERTa (Liu et al., 2019). We trained it learning rate 3e-4 using the Adam optimizer (Kingma and Ba, 2015). We trained for a maximum number of steps using early stopping on the validation sets. We restrict the input sequence to be at most 128 tokens cutting from the right side if the input is too long. All other hyperparameters are reported in Table 4. The triple classification module is also a linear layer on top of RoBERTa (Liu et al., 2019) with the same hyperparameters of the relation classification module but we trained for less steps.

F Additional Experiments

F.1 Analysis of Performance as a Function of the Number of Relations

Previous works focus on small schemas meaning that few relations were considered. Indeed, classification problems on a large set of possible classes become particularly difficult under large class imbalances, which is the case here as shown by Fig. 2. However, scaling up to larger schemas with more relations is crucial for the models to be useful in downstream tasks. To measure the scaling ability of GenIE, we create different setups with variable numbers of relations. To create such setups, we start with the REBEL dataset and schema (857 relations) and choose subsets of relations with their associated training data. In Fig. 4, we report GenIE and the pipeline baseline F1 for schemas with 100, 400, and 857 relations. To choose a subset of n relations, we take the n most frequent relations to mimic the strategies used by previous works to reduce the schemas (Sui et al., 2021).

Table 4: **Hyperparameters for the different models.**

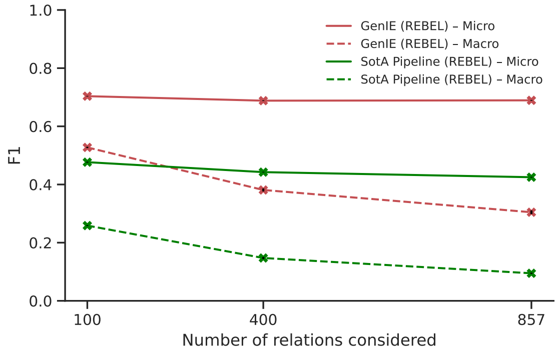

Figure 4: **Impact of the number of relations in the schema on REBEL.** Micro and macro F1 of both GenIE and the pipeline of SotA components for 3 schema sizes: 100, 400, and 857 relations. The schema is constrained at both training and testing time. Full results (i.e., precision and recall) are reported in Table 6 in Appendix G.

We first observe that GenIE is always largely better than the baseline. The baseline suffers from the same difficulty as previous works; classifying among a large set of relations is hard with large imbalances. GenIE and the baseline have similar absolute decrease in performance when the number of relations increases, corresponding to a more considerable relative decrease for the baseline. More concretely, GenIE's micro F1-score goes from 70.36 % for the top 100 relations, to 68.82 % and 68.93 % for the top 400 and 857 relation setups, respectively. This translates to a relative decrease of 2 % only in the first step. For the baseline, the absolute score of 47.67 % first falls to 44.25 % and subsequently to 42.5 % as the number of relations grows. This in turn, is an overall relative drop of almost 11 %.

Notably, when looking at precision and recall separately (cf. Table 6 in Appendix G), GenIE has a slight proportional decrease of 1-2 absolute points, both in precision and recall, which reflects the increased difficulty of the task due to larger number of relations. The baseline exhibits a similar drop in precision, but a much more significant drop in the recall of almost 10 absolute or 16 point relative. This suggests that the baseline simply ignores most of the relations with lower occurrence counts, which is consistent with the results in Sec. 2, and the hypothesis that the relation classification task is a bottleneck for effectively scaling the baseline system to a large number of relations.

We already have to deploy several techniques to help the baseline better deal with these issues (see Sec. 4.3), while GenIE, thanks to its generative autoregressive formulation, can effectively scale and manage the inherent imbalances of the task much more naturally.

Entity Linking via Explicit Mention-Mention Coreference Modeling

Abstract

Learning representations of entity mentions is a core component of modern entity linking systems for both candidate generation and making linking predictions. In this paper[1], we present and empirically analyze a novel training approach for learning mention and entity representations that is based on building minimum spanning arborescences (i.e., directed spanning trees) over mentions and entities across documents to explicitly model mention coreference relationships. We demonstrate the efficacy of our approach by showing significant improvements in both candidate generation recall and linking accuracy on the Zero-Shot Entity Linking dataset and MedMentions, the largest publicly available biomedical dataset. In addition, we show that our improvements in candidate generation yield higher quality re-ranking models downstream, setting a new SOTA result in linking accuracy on MedMentions. Finally, we demonstrate that our improved mention representations are also effective for the discovery of new entities via cross-document coreference.

1 Introduction

Natural language corpora, such as biomedical research papers (Leaman and Lu, 2016), news articles (Milne and Witten, 2008; Hoffart et al., 2011), and, more generally, web page text (Gabrilovich et al., 2013; Lazic et al., 2015a), often contain ambiguous mentions of entities. Resolving this ambiguity requires mentions to either be linked to a knowledge base (KB) of entities or discovered as a new KB concept if no suitable entry exists. Grounded entity mentions are beneficial for tasks such as question-answering (Das et al., 2019), semantic search (Leaman and Lu, 2016), recommendation ranking (Noia et al., 2016), and KB construction (Ling et al., 2015). The task is made particularly challenging in zero-shot settings, where not every entity has labeled training data (Lin et al., 2017; Logeswaran et al., 2019). In such settings, a common approach is to make use of entity descriptions, types, and aliases to form entity representations, which can then be used for making predictions.

Learned vector representations of entity mentions are an integral part of modern linking systems (Gillick et al., 2019; Wu et al., 2020, inter alia). These representations are used for (a) retrieving a short-list of entity candidates for a mention to use with a re-ranker (Wu et al., 2020), (b) making linking predictions directly (Zhang et al., 2021; Liu et al., 2020; Sung et al., 2020), and (c) performing coreference by clustering mentions to form entities (Logan IV et al., 2020).

In this work, we present a new objective and training procedure for learning mention and entity representations that explicitly model mention coreference relationships. Our proposed method uses a supervised clustering training objective based on forming a directed minimum spanning tree, or *arborescence*, over mentions and entities. We hypothesize that such coreference links provide a useful inductive bias because the two tasks are inherently related (Angell et al., 2021; FitzGerald et al., 2021). We thoroughly analyze the performance of the proposed procedure in each of the aforementioned use cases on MedMentions (Mohan and Li, 2019) and ZeShEL (Logeswaran et al., 2019), two challenging datasets that require zero-shot generalization at inference.

Retrieving Candidates We illustrate that our approach yields mention and entity representations useful for candidate retrieval. We show improvements over baselines that use similarly parameterized models, achieving gains of at least 7.94 and 0.93 points in *recall*@64 over two standard dual-encoder training procedures on MedMentions and ZeShEL, respectively. We also consider the linking capacity of our learned embeddings without re-ranking and find that their performance (i.e *re-*

call@1) indeed improves upon our baselines. Our best performing models show gains of 13.61 & 15.46 points in linking accuracy on MedMentions and 12.06 & 1.52 points on ZeShEL.

Linking Predictions We further consider the improvement in downstream training of full cross-attention re-ranker models using higher quality candidates generated by our approach. We show consistent gains in linking accuracy on MedMentions, setting a new state-of-the-art with a 1.63 point gain over the previous best model. We also note that our proposed approach shows mixed results on ZeShEL, with one variant outperforming all compared models by at least 1.19 points, while the other two underperform the baselines. We analyze this behavior in a later section and discuss the characteristics of the data distribution sufficient to make our approach effective.

Cross-Document Coreference Finally, we illustrate that the learned representations can be used to perform coreference of mentions *across* documents. This indicates that our approach could be used to discover entities in settings where there is limited or no existing knowledge base of entities.

2 Arborescence-based Training for Mention & Entity Representations

In this section, we describe our approach for constructing training objectives for dual-encoders that model mention coreference relationships.

2.1 Problem Definition

Each document d of a corpus $\mathcal{D}$ contains a set of entity mention spans $\mathcal{M}^d = \{m_1^d, m_2^d, \ldots, m_N^d\}$. All mentions in the corpus are given by $\mathcal{M} = \bigcup_{d \in \mathcal{D}} \mathcal{M}^d$. Following (Logeswaran et al., 2019; Angell et al., 2021), we assume that these mentions are pre-identified spans of text.

Entity Linking Formally, we define the task of entity linking as follows: given a knowledge base of entities $\mathcal{E}$ and a set of mentions $\mathcal{M}$, predict an entity $e_i^d \in \mathcal{E}$ for each mention m_i^d. We use $e_i^{\star d}$ to refer to the ground truth entity label for m_i^d.

Zero-Shot Linking The zero-shot task refers to the setting where there are entities in the knowledge base that do not have any labeled mentions in the training data. Linking decisions must instead rely on the provided information for entities, such as descriptions, aliases, and/or entity types.

Coreference We also consider a setting in which the KB of entities is not known in advance and entities must be *discovered*. For this task, we map every entity mention m_i^d to a cluster and assign a coreference label $c_i^d \in \mathcal{C}$ that is independent of the entity labels in the KB.

2.2 Coreference-based Similarity

In order to jointly train both the mention and entity encoders, we define a similarity measure and an analogous procedure for sampling positive training examples that intersperses the selection of coreferent mentions and gold entities based on a single-linkage structure formed by the representations generated by the model snapshot. We construct k-nearest neighbor graphs over coreferent mention and entity clusters, followed by the application of a pruning algorithm to generate arborescence (directed MST) structures rooted at entity nodes. The resultant edges after pruning the graphs represent the pairs of positive examples used for training.

Graph-based Dissimilarity Let G be a graph with nodes $V = \mathcal{M} \cup \mathcal{E}$ and directed edges $E \subset V \times V$. Each edge (x, y) of the graph has an associated weight $w_{x,y}$. We define a dissimilarity function f between two nodes $u, v \in V$ to be the weight of the minimax path between the nodes, i.e.

$$f(u,v) = \begin{cases} \min\limits_{p \in u \rightsquigarrow v} \max\limits_{(x,y) \in p} w_{x,y}, & \text{if connected}(u,v) \\ \infty & \text{otherwise} \end{cases} \tag{1}$$

where $\text{connected}(u, v)$ is true if there exists a directed path from node u to v in G, and $u \rightsquigarrow v$ is the set of all paths between u and v. In words, the dissimilarity between u and v is the minimum of the largest edge weights in all paths between the two nodes, and this is often referred to as the "bottleneck edge". This measure has the property of emitting low dissimilarities between nodes even when their direct edge weight $w_{u,v}$ is high by connecting them through a chain of low-weight edges, providing an inductive bias well-suited for coreference, i.e. not all pairs of points in a cluster are nearby (Figure 1). This inductive bias is not achieved if we sum edge weights and simply find the minimum path.

Edge Weights With this definition of dissimilarity, we now define how edge weights are calculated. We use two models: a mention-pair affinity model, $\phi : \mathcal{M} \times \mathcal{M} \to \mathbb{R}$, and a mention-entity affinity model, $\psi : \mathcal{E} \times \mathcal{M} \to \mathbb{R}$. An edge between two

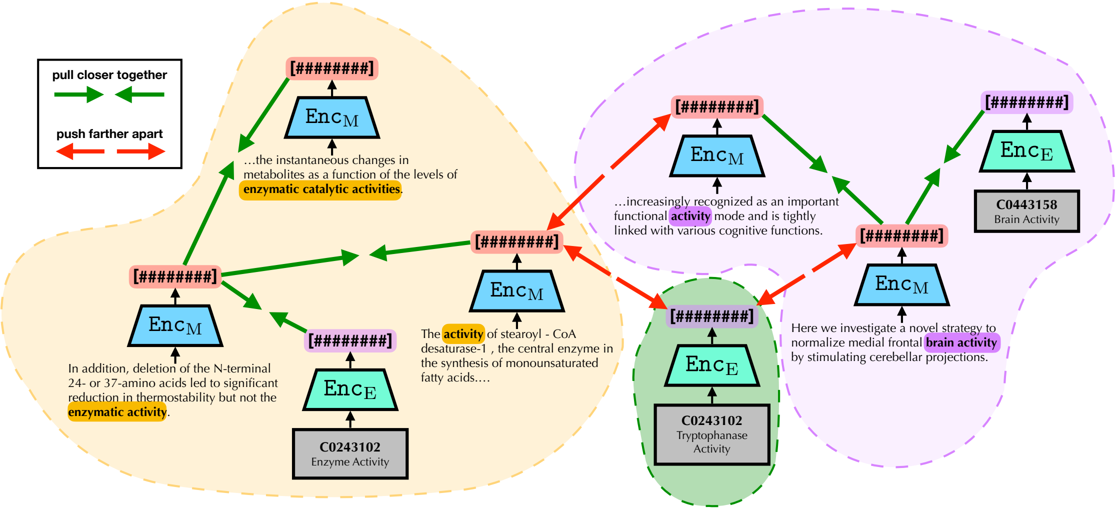

Figure 1: **Arborescence-based Training Objective for Mention & Entity Representations**. Shown above is an illustrative example of our proposed training objective for a dual-encoder ($\mathtt{Enc}_\mathrm{M}$, $\mathtt{Enc}_\mathrm{E}$) on real mentions and entities from the MedMentions dataset. Mentions are highlighted in context and entities from UMLS are represented using grey boxes with the name and unique identifier. First, each mention and entity is encoded into a dense vector representation ([########]) using the respective transformer encoder. Mention-mention and mention-entity pairs are then selected using our arborescence-based procedure as described in §2.3. The embeddings of these pairs are encouraged to be pulled closer together if both endpoints are contained in the pruned arborescence structure (represented by the shaded regions), or encouraged to be pushed farther apart if the endpoints are sampled as hard negatives.

mentions m_i and m_j has weight:

$$w_{m_i,m_j} = -\,\phi(m_i, m_j), \tag{2}$$

and the weight of the edge from entity e to m_i is:

$$w_{e,m_i} = -\,\psi(e, m_i) \tag{3}$$

Each of $\phi(\cdot,\cdot)$ and $\psi(\cdot,\cdot)$ are independently parameterized by dual-encoder transformer models (Gillick et al., 2019; Humeau et al., 2019), one for mentions ($\mathtt{Enc}_\mathrm{M}$), and one for entities ($\mathtt{Enc}_\mathrm{E}$). The affinity models are simply the inner products of the associated encoded representations:

$$\begin{aligned} \phi(m_i, m_j) &= \mathtt{Enc}_\mathrm{M}(m_i)^T \mathtt{Enc}_\mathrm{M}(m_j) \\ \psi(e, m_i) &= \mathtt{Enc}_\mathrm{E}(e)^T \mathtt{Enc}_\mathrm{M}(m_i) \end{aligned} \tag{4}$$

For the mention encoder, $\mathtt{Enc}_\mathrm{M}$, the transformer input is the surrounding mention context with the mention span marked by special tokens `[START]` and `[END]`:

$$\texttt{[CLS]}\, c_\text{left}\, \texttt{[START]}\, m_i\, \texttt{[END]}\, c_\text{right}\, \texttt{[SEP]}$$

where c_left and c_right are the left and right contexts of the mention m_i in the document. For the entity encoder, $\mathtt{Enc}_\mathrm{E}$, the transformer takes as input the title and description of the entity:

$$\texttt{[CLS]}\, e_\text{title}\, \texttt{[TITLE]}\, e_\text{desc}\, \texttt{[SEP]}$$

In this input, e_desc is the token sequence corresponding to the description of the entity, which could include natural language text related to the entity, such as a "wiki" entry, a list of entity aliases, or other available features useful in forming an entity representation. We use a special token `[TITLE]` to separate the title text from the description.

2.3 Training Procedure

We now define our approach for training the affinity models, $\phi(\cdot,\cdot)$ and $\psi(\cdot,\cdot)$, and their associated encoders, $\mathtt{Enc}_\mathrm{M}$ and $\mathtt{Enc}_\mathrm{E}$. Our objective is to optimize the dissimilarity function $f(\cdot,\cdot)$ such that the procedure infers a set of clusters that each contain exactly one entity, and every mention is assigned to the cluster containing its ground truth entity. We optimize $f(\cdot,\cdot)$ using mini-batch gradient descent by sequentially building batches of mentions $B \subset \mathcal{M}$ over the training data, where each $m_i \in B$ has its gold entity defined by $e_i^\star$. We then build a graph G_B with nodes consisting of (a) each $m_i \in B$, (b) each mention coreferent to $m_i \in B$, and (c) the set of gold entities for each $m_i \in B$. For every m_i, we build a set of *directed* edges defined by

$$\begin{aligned} E_{m_i} = &\left\{ (e_i^\star, m_\ell) \,\middle|\, m_\ell \in \mathcal{M}_{e_i^\star} \right\} \\ &\cup \left\{ (m_\ell, m_p) \,\middle|\, m_\ell, m_p \in \mathcal{M}_{e_i^\star} \right\} \end{aligned} \tag{5}$$

where $\mathcal{M}_{e_i^\star}$ is the set of coreferent mentions with $e_i^\star$ as the ground-truth entity. The complete set of edges in graph G_B for a mini-batch B is then given by $E(G_B) = \bigcup_{m_i \in B} E_{m_i}$. Observe that the resultant edges ensure that each connected component contains exactly one entity (namely, the gold entity for the mentions in that connected component).

Forming Clusters for Positive Sampling The graph G_B is input to a constrained clustering procedure that partitions a graph G into disjoint clusters $\mathcal{C} = \{C_1, \ldots, C_M\}$ such that each cluster contains at most one entity. There are three constraints that every $C \in \mathcal{C}$ must satisfy:

(i) $|C \cap \mathcal{E}| \leq 1$,

(ii) $\forall u, v \in C,\ \text{connected}(u, v) \implies f(u, v) \leq \lambda$,

(iii) $\forall u, v \in C,\ \text{connected}(u, v) \vee \text{connected}(v, u)$

where λ is a hyperparameter representing the dissimilarity threshold over which edges between nodes are dropped. We set $\lambda = \infty$ during training. These constraints ensure that (i) there is at most one entity in each cluster, (ii) if u is reachable from v then every edge in the path from v to u has a weight $\leq \lambda$, and (iii) each node in the cluster has a path connecting itself with every other node in the cluster.

We solve this constrained clustering problem, i.e., partition graph G, using a process similar to Angell et al. (2021). Specifically, we first remove all edges in graph G with weight greater than threshold λ. We then evaluate each edge $(u, v) \in E$ in descending order of dissimilarity and check if its presence violates any of the three constraints defined above, removing the edge from E if it does. If not, we evaluate whether there is an entity in the connected component of node u, i.e. $|C_u \cap \mathcal{E}| = 1$. If $|C_u \cap \mathcal{E}| = 1$, we temporarily drop edge (u, v) and check whether v can still be reached by an entity node. If reachable, we permanently drop (u, v), maintaining the validity of constraint (i) as well as our minimax dissimilarity function $f(\cdot, \cdot)$. If an entity cannot reach v, we retain edge (u, v), preserving the connectivity of the cluster, and iterate further. Our predicted clusters are the resultant connected components in the partitioned graph G.

Using this procedure on each E_{m_i} to generate a pruned set of edges $E^\star_{m_i}$, we construct a partitioned target graph $G^\star_B = \{E^\star_{m_i} \mid m_i \in B\}$, which is used to optimize the parametric encoder models. Note that each mention node in a target edge set $E^\star_{m_i}$ has only one incoming edge originating from either an entity or a mention, and the selection of $E^\star_{m_i}$ was done in a way to minimize the dissimilarity function $f(\cdot, \cdot)$ between mentions and entities with coreferent labels on the subgraph of the mini-batch.

For every cluster with an entity node, the edge structure is a directed analogue of the minimum spanning tree, where there exists a directed path from the entity node to every other node in the cluster. This structure is often referred to as the *minimum spanning arborescence*, thus lending its name to our method, i.e. ARBORESCENCE-based linking.

Negative Sampling Akin to the graph embedding objectives used by Nickel and Kiela (2018) and others, we construct our objective by sampling hard negative edges. For each mention $m_i \in B$, the set of negative edges $\mathtt{N}(m_i)$ is the $k/2$ lowest-weight incoming edges from $\mathcal{E} \setminus \{e_i^\star\}$ and the $k/2$ lowest-weight incoming edges from $\mathcal{M} \setminus \mathcal{M}_{e_i^\star}$, where k is a tuned hyperparameter. In other words, we sample negative mention and entity edges that are most similar to the gold edge.

Loss Function We define $\Gamma(m_i) = \{u \mid (u, m_i) \in E^*_{m_i}\} \cup \{u \mid (u, m_i) \in \mathtt{N}(m_i)\}$ to be the set of all neighbors with an outgoing edge to m_i in the training graph. Let $\mathbb{I}_{u,m_i}$ be the indicator variable such that $\mathbb{I}_{u,m_i} = 1$ if $(u, m_i) \in E^*_{m_i}$ and $\mathbb{I}_{u,m_i} = 0$ otherwise. Our loss function with respect to each mention $m_i \in B$ is then defined as follows:

$$\mathcal{L}(m_i) = \sum_{u \in \Gamma(m_i)} \Big(\mathbb{I}_{u,m_i} \log(\sigma_u(w_{u,m_i})) + (1 - \mathbb{I}_{u,m_i}) \log(1 - \sigma_u(w_{u,m_i})) \Big), \tag{6}$$

where $\sigma(\cdot)$ is the softmax function over all edges in $\Gamma(m_i) \times \{m_i\}$. The loss for the entire batch B is the mean of losses over all mentions in B. Optimizing this loss function requires simultaneously increasing the likelihood of the positive edges and decreasing the likelihood of the negative edges. This objective and training routine are inspired by the supervised single-linkage clustering proposed by Yadav et al. (2019), but differs in the choice of loss function and selection of negative examples. We also experimented with the standard cross-entropy formulation, but found its performance subpar.

3 Experiments

We are interested in investigating the following empirical research questions:

	MedMentions							ZeShEL

	Test	4K	7K

Table 2: **Dataset Statistics**. $|\mathcal{M}|$ is the number of mentions. $|\mathcal{E}|$ is the number of unique entities in the labeled partition (*not* the total KB size). $|\mathcal{E} \setminus \mathcal{E}_{\text{Train}}|$ is the number of *zero-shot* entities. The total KB size of MedMentions and ZeShEL is 2.3M and 492K, respectively.

- Does our proposed approach improve the recall of candidate generators?
- Do improvements in candidate generation at training lead to improvements in downstream re-ranking models?
- Does our approach result in better learned mention embeddings that can be used for coreference or discovering entities when a KB does not exist?

Experiment Details Our experiments are run on top of BLINK (Wu et al., 2020), a PyTorch (Paszke et al., 2019) implementation of dual- and cross-encoder architectures for entity linking, with model fine-tuning performed over only BERT-base, since gains from pre-trained LM size are unrelated to our approach. More details are provided in Appendix §A.1.

3.1 Datasets

We run experiments on two entity linking datasets that both require generalization to unseen entities at test time. Each document in the datasets contain a set of entity mention spans, which are pre-defined using common mention-detection heuristics. KB entities are composed of two metadata attributes – an entity *title* and *description*, which are natural language sequences of text. ZeShEL, additionally, contains a fine-grained *type* specification, which is needed due to the diverse disjoint domains contained in the dataset. The statistics for both datasets are reported in Table 2.

MedMentions (Mohan and Li, 2019) is a collection of titles and abstractions of bio-medical research papers. The KB that is used for this dataset is the 2017AA full-version of UMLS. The validation and test sets contain both entities that are present in the training set as well as entities that are zero-shot (never seen at training time). We use the author-recommended ST21pv subset.

ZeShEL (Logeswaran et al., 2019) is a collection of crowd-sourced wikis, which are divided into train, validation, and test splits such that no Fandom topic overlaps across the sets. In this way, all entities that appear at validation and test time are not seen during training.

3.2 Dual-Encoder Retrieval

In order to robustly evaluate the benefit of modeling coreference relationships for learning representations, we construct three variants of our proposed dual-encoder training objective, which jointly train both the mention-mention similarity function $\phi(\cdot,\cdot)$ and the mention-entity similarity function $\psi(\cdot,\cdot)$. We compare to baselines that only explicitly train $\psi(\cdot,\cdot)$ and rely on the structure of $\phi(\cdot,\cdot)$ sharing representations with $\psi(\cdot,\cdot)$ to provide meaningful mention-mention similarities. Our proposed objectives differ in how the positive training pairs are constructed, thus providing a way to analyze the general idea of using coreference rather than any one specific target structure for training. Our baselines are identical to each other except in how negatives are sampled.

Re-ranker	Candidate Retriever	Accuracy			Oracle	
		Overall	Seen	Unseen	Self	Union
k-NN Negatives	Dual (In-Batch Negatives)	73.31	77.58	58.47	**80.78**	47.96

Table 3: **MedMentions: Cross-Encoder Linking Results**: We report the re-ranker accuracy trained using the candidates generated by each retriever variant. (†Proposed methods)

Arborescence In the first training variant, for each mention query, we begin by constructing a fully-connected graph of the ground truth coreferent mention cluster along with the gold entity. We then apply the pruning procedure described in the previous section to compute an arborescence rooted at the entity node. From the resultant graph, each pair of a mention and its incoming-edge node (which can either be a coreferent mention or the gold entity) is treated as a positive example for training. Following previous work (Gillick et al., 2019), we use hard negative mining with $k = 10$ negatives composed of equal number of mention and entities.

1-NN Arborescence Instead of constructing a fully-connected k-NN graph over the entire gold cluster, in this variant we approximate the arborescence structure by pruning a restricted graph of only the gold entity, the query mention, and the most similar within-cluster mention neighbor of the query. We keep all other details of the training procedure identical to the first variant.

1-Rand Arborescence A third training objective we explore modifies the initial k-NN graph construction by restricting the nodes to the gold entity, the query mention, and a *random* within-cluster mention neighbor of the query, instead of the nearest-neighbor.

Baselines We compare to two baselines following previous work: (a) training $\psi(\cdot, \cdot)$ with random negatives (In-batch Negatives) where each gold entity for a mention in a training batch is treated as a negative example for all other mentions in the batch, and (b) training $\psi(\cdot, \cdot)$ with hard negatives (k-NN Negatives) similar to the negative mining in our proposed methods albeit with only mention-*entity* positive selection.

Results In Table 1, we report the test set *recall*@64 for each dual-encoder model, where the prediction is evaluated as a hit if the gold entity is retrieved in the top-64 candidates for a mention. On each dataset, we additionally include the performance of candidate generators used by previous works that we compare to.

We find that models trained with explicit coreference relationships outperform those that incorporate this relationship only indirectly. For *recall*@64, our proposed methods improve over the baselines by at least 7.94 percentage points on MedMentions and 0.93 points on ZeShEL. Even at linking, or *recall*@1, our proposed methods show similar improvements with gains of 13.61 and 1.52 points over the next best baseline models. We perform a more comprehensive analysis of the dual-encoder linking performance and describe our inference approach and results in Appendix §A.2 and §A.3.

We posit that much of the observed gains in recall using our methods result from higher quality mention embeddings generated due to a wide array of surface forms available to mention queries at training. Since each training example evaluates not only the gold entity but also its coreferent mentions, this leads to better generalization of representations. We evaluate this improvement in representations in the clustering / coreference setting in §3.5.

3.3 Cross-Encoder Re-ranking

To answer our second research question, we compare five cross-attention models, which are trained using entity candidates generated by the dual-encoder variants discussed in the previous experiment. Training and inference batches are constructed by concatenating each mention with an entity candidate separated by a `[SEP]` token. Similar to Wu et al. (2020), we use the top-64 retrieved entities as hard negatives during training and as linking candidates during inference.

Results We report the cross-encoder linking accuracy for MedMentions in Table 3. We additionally

Candidate Retriever	Acc.	Macro	Oracle Self Acc.	Oracle Self Macro	Oracle Union Acc.	Oracle Union Macro
Dual (In-Batch Negatives)	61.27	60.93	**64.96**	67.81	62.91	66.13
Dual (k-NN Negatives)	61.02	60.47	63.66	66.91	61.30	64.72

Dual (1-Rand Arborescence) †	**62.35**	**62.53**	64.94	**67.90**	**63.33**	**66.51**

Table 4: **ZeShEL: Cross-Encoder Linking Results: Unnormalized Accuracy**. We report the accuracy of the re-ranker trained using the candidates generated by each retriever. (†Proposed methods)

report the breakdown of accuracy on subsets of test mentions for which the ground truth entities were not evaluated ("unseen") during training, illustrating the zero-shot capability of the models. We also include the current state-of-the-art results by Angell et al. (2021), which uses an n-gram based model for candidate generation and two cross-encoder models, one each for mention-mention and mention-entity scoring, for re-ranking. We observe that each cross-encoder trained with candidates generated by an arborescence-based model outperforms the baselines, including the current SOTA by at least 0.63 points, and the best performing model – Arborescence – achieves 1.63 point gains. We note, however, that Angell et al. (2021) does better on unseen entities by 1.91 points compared to Arborescence, which might be a result of benefiting from a reduced search scope owing to the within-document nature of their TF-IDF retriever.

Table 4 contains linking results for ZeShEL, where each reported model varies only in the method used for retrieving the entity candidates, while the cross-encoder re-ranker training method is held constant (k-NN Negatives with $k = 64$). Since ZeShEL is completely zero-shot, we do not include a seen-unseen analysis. We follow Wu et al. (2020) and report the unnormalized accuracy, which is calculated as the percentage of successes out of the total number of query mentions in the test set, and the macro-averaged unnormalized accuracy, which is a simple average of the unnormalized accuracies over the different "worlds", or domains, in the test set. We find that the best performing model is 1-Rand Arborescence, with a 1.19 point difference in macro-averaged accuracy over the next best model (Wu et al., 2020).

Figure 2: **Coreference Distribution**. We count the number of mentions in each coreference cluster in MedMentions and ZeShEL. Clusters in ZeShEL are typically very small (at most 3) compared to the MedMentions clusters (up to 1256, 434, and 447 in train, validation, and test, respectively).

We also note that, unlike on MedMentions, not all of our proposed models have higher accuracy than the mention-entity baselines. Since a key motivation for the arborescence-based methods is to explicitly model coreference relationships during training, we expect performance gains to be strongly correlated with the number of coreference links present within the dataset. We analyze the two datasets in terms of the number of mentions for each KB entity, which can be thought of as how large each cluster of coreferent mentions is. We report a histogram distribution in Figure 2 and find that the clusters in ZeShEL are typically very small (at most 3), whereas in MedMentions, each cluster has many more mentions with maximum sizes of 1256, 434, and 447 across the train, validation, and test sets.

Finally, we also provide representative examples of predictions comparing the link predictions by our best-performing Arborescence-based method to the baseline of Angell et al. (2021) on MedMentions and Wu et al. (2020) on ZeShEL in Appendix Table 7 and Table 8, respectively.

3.4 Oracle Inference

In this setting, we isolate the re-ranking capability of the cross-encoder from the quality of the candidates retrieved at *inference*. This setting also removes the upper-bound on re-ranking accuracy by artificially injecting the ground-truth entity in the top-64 candidates retrieved at inference for each mention where retrieval failed. An additional setting we explore holds this oracle candidate set constant across each variant of the cross-encoder by taking a union over all dual-encoder candidate sets and then proceeding to inject the ground-truth. This construction provides a way to disentangle the factor of candidate retrieval quality at inference, which otherwise conflates the comparison of re-ranking performance. We refer to these oracle settings as SELF and UNION, respectively.

Results As seen in column **Oracle** of Table 3, the baseline models show higher linking accuracy than our proposed methods when the gold entity is guaranteed to be present in the original candidate set. However, the performance of the baseline models drops significantly ($\geq$ 32 points) when evaluated with the UNION candidate set, while the arborescence-based models show a ± 0.9 point variation. We believe this discrepancy clearly highlights the poor quality of candidates retrieved by the baseline models compared to our proposed methods. This also explains the inflation in accuracy of the baselines on the SELF set due to the trivial discrimination task presented to the cross-encoders. We further point to linking performance on the UNION set, which provides the more challenging task of differentiating between higher quality candidates that are similar. We argue that the large performance difference ($\geq$ 26.75 points) is strongly indicative of the greater linking capacity of our proposed methods.

In Table 4, we report both the micro accuracy and macro-averaged accuracy for the two oracle sets. We observe that 1-RAND ARBO performs the best on the UNION set, but is marginally outperformed by IN-BATCH on micro accuracy on the SELF set by 0.02 points. In contrast to the fluctuation on MedMentions, the relative uniformity in results on the oracle candidate sets indicates that the candidates generated by each model have similar quality.

3.5 Mention Coreference

Next, we evaluate the quality of the learned mention representations for cross-document coreference using the entity labels of each mention as its ground truth cluster assignment. To form clusters, we build mention-only arborescences using the clustering procedure described in §2.3, tuning the threshold value, λ, based on the validation data. We report the Adjusted Rand Index (ARI) clustering scores in Table 5 using each of our dual-encoder representation learning objectives. For both ZeShEL and MedMentions, we report ARI on all the test mentions (denoted ALL). For MedMentions, we report two additional settings: (a) ARI when clustering mentions with ground truth entity not seen at training (denoted UNSEEN ONLY), and (b) clustering on all mentions but evaluating on the UNSEEN ONLY set (denoted ALL/UNSEEN). The results show that representations learned with the ARBORESCENCE objective perform best on each setting, aligning with the inductive bias of its training procedure and indicating its utility in a setting where new entities must be *discovered*.

	MedMentions			**ZeShEL**
Setting	ALL	ALL/ UNSEEN	UNSEEN ONLY	ALL
IN-BATCH NEGATIVES	0.37	0.71	0.71	0.31
K-NN NEGATIVES	0.26	0.73	0.80	0.29
ARBORESCENCE	**0.51**	**0.83**	**0.85**	**0.34**
1-NN ARBORESCENCE	0.47	0.75	0.83	**0.34**
1-RAND ARBORESCENCE	0.35	0.63	0.81	0.32

Table 5: **Coreference Results**. We report the Adjusted Rand Index achieved by clustering (§2.3) the mention embeddings produced by each model on the test set. We evaluate on three settings: ALL (clustering & evaluating on all mentions), ALL/UNSEEN (clustering all mentions, evaluating on mentions with ground truth entity not seen in training), UNSEEN ONLY (both clustering & evaluating on mentions with ground truth entity not seen in training).

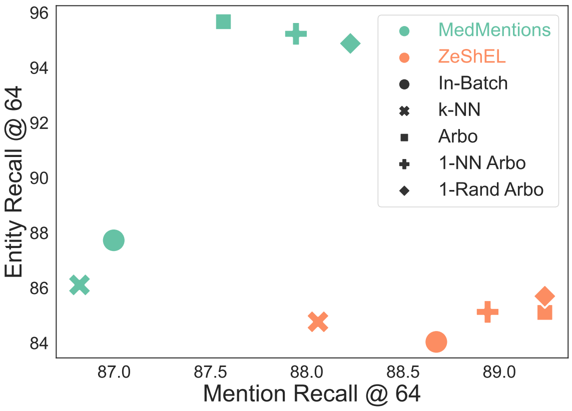

Figure 3: **Linking Recall v/s Coreference Recall**. We compare the mention coreference recall@64 with the entity linking recall@64 for each dual-encoder training procedure on MedMentions and ZeShEL. There is a positive correlation when comparing coreference-based procedures with entity-only methods, which is stronger on the highly-coreferent MedMentions dataset than on ZeShEL.

We further probe the inductive bias of the arborescence-based training procedures by inspecting whether improvements in entity linking recall are accompanied by similar gains in mention coreference performance. In Figure 3, we plot entity and mention recall@64 for each training method on the test set of the two datasets. Mention recall is calculated by retrieving 64 nearest-neighbors for each mention and counting the number of neighbors that are coreferent as a proportion of the total number of coreferent mentions limited to 64. Entity recall is calculated as defined in §3.2. We find that entity recall indeed demonstrates a positive correlation with mention recall on both datasets when the proposed coreference-based training procedures are compared with entity-only methods. We posit that this demonstrates the efficacy of using explicit mention coreference relationships to learn representations for entity linking.

4 Related Work

Entity Linking Entity linking has been widely studied (Milne and Witten, 2008; Cucerzan, 2007; Lazic et al., 2015b; Gupta et al., 2017; Raiman and Raiman, 2018; Kolitsas et al., 2018; Cao et al., 2021, inter alia). Dutta and Weikum (2015) combine clustering-based cross-document coreference decisions and linking around sparse bag-of-word representations not well suited for the embedding-based representations used in this work. Other works use global or collective models (Kulkarni et al., 2009; Hoffart et al., 2011; Cheng and Roth, 2013; Ganea and Hofmann, 2017; Le and Titov, 2018, inter alia), which consider the compatibility of entity linking decisions made in the same document(s) rather than making independent predictions. Zhang and Stratos (2021) use noise contrastive estimation to mine hard negatives for the linking task.

Cross-document Coreference Several previous works have developed models for the cross-document coreference setting where no entity KB is known in advance (Bagga and Baldwin, 1998; Gooi and Allan, 2004; Singh et al., 2011; Barhom et al., 2019; Cattan et al., 2020; Caciularu et al., 2021; Ravenscroft et al., 2021; Logan IV et al., inter alia).

Alternatives to Cross-Encoders Our work demonstrates how clustering-based training improves dual- and cross-encoder models for linking and discovery. If prediction efficiency, and not training efficiency, was the only concern, one could also use model distillation to improve dual-encoder performance (Hinton et al., 2015; Izacard and Grave, 2021, inter alia). We could also consider models such as poly-encoders as alternatives to dual-encoders (Humeau et al., 2020).

5 Conclusion

We present a novel approach for learning mention and entity representations for use in entity linking candidate generation and prediction, as well as in the discovery of new entities. Our method uses an objective that explicitly incorporates mention-to-mention coreference relationships. We demonstrate its empirical effectiveness through analysis on two datasets — MedMentions and the Zero-Shot Entity Linking dataset. As future work, we hope to further analyze these objectives with the lens of efficiency, distillation, and domain transfer.

6 Ethical Considerations

There are several ways in which entity linking / resolution models could be biased and a potential for those biases to have harmful downstream consequences. There is already a large body of work studying the biases in language models (such as those used for fine-tuning in our work) and coreference models, most notably in understanding when error rates in coreference differ across certain populations (e.g., genders, races, and other entity types, more broadly, that display skewed distributions in the data). For instance, if entity mentions are author names on citation data and the entities are scientific authors, aggregated statistics like h-index or citation count could be biased if the models used to disambiguate the author names are biased. If entity linking and discovery systems are used to build or populate knowledge bases, those systems may propagate these biased predictions. This can be particularly problematic if one used such a biased knowledge base to train future models, thus perpetuating and amplifying the skew. Lastly, we also note that entity linking and discovery are analogous to surveillance and tracking in computer vision, which should warrant substantial weight of ethical considerations.

A Appendix

A.1 Experiment Details

Each training procedure is run on a single machine using 2 NVIDIA Quadro RTX 8000 GPUs. Our dual-encoder models for ZeShEL and MedMentions have 218M and 230M parameters, respectively. Each variant is optimized using mini-batch gradient descent using the Adam optimizer for 5 epochs using a mini-batch size of 128 to accumulate the gradients. Experiments with batch sizes $<$ 128 performed poorly, possibly due to increased fluctuation of gradients, and sizes $>$ 128 were computationally infeasible to run with our available compute resources. For ZeShEL, the dual-encoder models are trained using 192 warm-up steps and learning rates of 1e-5, 3e-5, and 3e-5 for IN-BATCH, K-NN, and ARBORESCENCE-based models, respectively. For MedMentions, each model is trained using 464 warm-up steps and a learning rate of 3e-5. All cross-encoder models are trained with a mini-batch size of 2, learning rate of 2e-5, and an additional linear layer. Our MedMentions and ZeShEL cross-encoder models have 108M and 109M parameters, respectively. We use FAISS[2] (Johnson et al., 2017) for fast nearest-neighbor search during graph construction at both training and inference. For MedMentions, the execution time was 70 mins to embed and index 2M entities and 120K mentions, and 20 mins to perform exact nearest-neighbor search for the 120K mentions.

A.2 Dual-Encoder Inference Procedure

Building the Graph The structure of the graph G impacts the dissimilarity function by changing the paths between pairs of nodes in addition to changing which pairs of nodes are connected. We advocate for a simple, deterministic approach to construct this graph. For each mention m, construct E_m by (a) adding edges from m's k-nearest neighbor mentions in $\mathcal{M}$ to m, and (b) adding an edge from m's nearest entity to m:

$$E_m = \left\{ (u, m) \;\middle|\; u \in \underset{m' \in \mathcal{M}}{\operatorname{argmink}}\, w_{m',m} \vee u = \underset{e \in \mathcal{E}}{\operatorname{argmin}}\, w_{e,m} \right\} \tag{7}$$

The complete collection of edges E in G is given by $E(G) = \bigcup_{m \in \mathcal{M}} E_m$. There are other ways that one could conceivably pick the pairs of mentions to be connected in the graph. For example, one could use the minimum spanning tree over the mentions. This approach, however, has a few drawbacks: (a) the directionality of nearest neighbor relationships is ignored leading to noise in the graph, and (b) the resultant graph includes edges that cross cluster boundaries due to this approach forcing all pairs of mentions to be connected, which is undesirable.

Forming Clusters & Making Predictions To make linking decisions for each mention m_i^d, we assign the ID of the entity present in the mention's cluster as the linking label (or NIL if there is no entity in the cluster). Let $\mathcal{C}(m_i^d)$ be the predicted cluster of mention m_i^d, then:

$$e_i^d = \begin{cases} \mathcal{C}(m_i^d) \cap \mathcal{E}, & \text{if } |\mathcal{C}(m_i^d) \cap \mathcal{E}| = 1 \\ \text{NIL}, & \text{otherwise} \end{cases} . \tag{8}$$

Furthermore, the target clusters we aim to predict in the entity discovery setting are exactly $\mathcal{C}$.

A.3 Experiment: Dual-Encoder Linking

Each model is evaluated using three inference procedures. "Independent" refers to predictions made using only mention-entity edges. This method was used by Wu et al. (2020) to generate candidates for a cross-encoder model trained on ZeShEL. "Clustering (UNDIRECTED)" refers to a hierarchical agglomerative clustering (HAC) procedure, following previous work by Angell et al. (2021), which is akin to the procedure for positive sampling used for training our arborescence models but with no edge directionality. "Clustering (DIRECTED)" adds directed edges to the previous method. For each model, we pick the best performing inference procedure on the validation set and report the test set performance.

We report the linking accuracy in Table 6 and leave out models from previous works since they do not report linking metrics of their candidate generators. We specify the inference method used in each case, chosen based on the validation set accuracy of the models. Similar to our cross-encoder results in Table 3, we also report the "seen" and "unseen" performance on MedMentions.

A.4 Qualitative Results

In Table 7 and Table 8, we provide a set of representative examples that demonstrate the improvement in entity linking that our proposed coreference-based methodology empirically provides on MedMentions and ZeShEL, respectively.

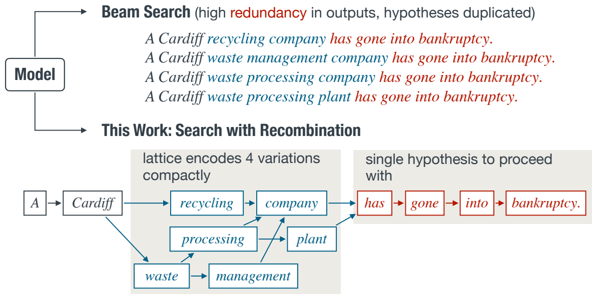
Abstract

Conditional neural text generation models generate high-quality outputs, but often concentrate around a mode when what we really want is a diverse set of options. We present a search algorithm to construct lattices encoding a massive number of generation options. First, we restructure decoding as a *best-first search*, which explores the space differently than beam search and improves efficiency by avoiding pruning paths. Second, we revisit the idea of *hypothesis recombination*: we can identify pairs of similar generation candidates during search and merge them as an approximation. On both summarization and machine translation, we show that our algorithm encodes thousands of diverse options that remain grammatical and high-quality into one lattice. This algorithm provides a foundation for building downstream generation applications on top of massive-scale diverse outputs.[1]

1 Introduction

Although pre-trained text generation models (Lewis et al., 2020; Raffel et al., 2020) have achieved impressive results across a range of tasks, these models do not always deliver what system developers want. Machine generated text may be non-factual (Kryscinski et al., 2020; Maynez et al., 2020; Goyal and Durrett, 2021) or toxic (Gehman et al., 2020). We might patch these problems by applying discriminators over the output (Holtzman et al., 2018; Yang and Klein, 2021) to enforce these properties post-hoc; we could, for instance, apply a secondary model as a reranker over a small collection of outputs. However, if the generator returns a homogeneous set of candidates, we may fail to find *any* usable generation output. What if generation models could return *massive* numbers of candidates rather than a few outputs with optimal score? With a large set of candidates, our secondary model could more easily find an acceptable one without having to take more extreme steps like re-training the initial generation model. Output diversity has separately been established as a useful goal for for applications such as dialogue and story generation (Li et al., 2016; Fan et al., 2019).



A Cardiff recycling company has gone into bankruptcy.
A Cardiff waste management company has gone into bankruptcy.
A Cardiff waste processing company has gone into bankruptcy.
A Cardiff waste processing plant has gone into bankruptcy.

Figure 1: A lattice of outputs yielded by path recombination is a more efficient way to represent and explore related generation outputs compared to beam search.

Standard approaches including beam search (BS) and sampling methods fall short of our goal. Beam search uses significant computational resources to explore similar hypotheses, and much of the computation in the search process is invested into paths that could be acceptable generation outputs, but are ultimately pruned. Sampling approaches like nucleus sampling (Holtzman et al., 2020), although achieving better diversity than beam search, often re-discover seen hypotheses and can be harder to control for quality. A central problem with both methods is that they do not handle very similar hypotheses efficiently.

In this paper, we present a decoding framework with two key components. First, we argue that a modified **best-first search** (BFS) is the right way to explore the search space. We augment standard best-first search with a depth-first path completion strategy: we eagerly expand each node until we reach an EOS token, thereby guaranteeing that each node is part of some completed path returned to

the user. This generation strategy avoids exploring large numbers of states which end up being pruned. BFS is also more flexible than static beam search and can prioritize exploration in more uncertain parts of the generation.

Second, our algorithm returns a massive number of generation options encoded in a lattice, with different hypotheses **recombined** in an approximate fashion. Beam search preserves similar outputs such as "*A Cardiff recycling company has gone into*" and "*A Cardiff waste management company has gone into*" as different states. However, these prefixes actually have very similar distributions of following words under the model; if we identify states like this, we can recombine them (Figure 2) and treat them as the same from the perspective of future continuations. In Figure 1, we show an illustration of the lattice structure this recombination can form for document summarization. We broaden a recombination method used previously in beam search for machine translation (Och et al., 2001; Zhang et al., 2018), enabling us to compactly encode large number of generation candidates and achieve dense lattices.

We show results for both document summarization and machine translation in three language pairs. For each setting, we show that our lattice encodes a large number of high-quality candidates, including good matches with annotated reference generations. We further show that a variant of our method can still achieve strong results with a lower number of nodes expanded than the baselines, suggesting that this can be a path towards saving computational resources. We believe that computing thousands of high-quality generation candidates within a single compact data structure can provide a powerful starting point for various downstream purposes: diversity, factuality, customizability, and more.

2 Problem & Setup

We define our algorithm in the context of conditional text generation (Sutskever et al., 2014; Bahdanau et al., 2014). Conditional text generation is formulated as sequence transformation from a source input $\mathbf{x}$ to target output $\mathbf{y} = (y_1, \dots, y_n)$ via a neural text generation model parameterized by θ. Each y_i is a symbol in a vocabulary $\mathcal{V}$. The probability of a decoded sequence is given by $p(\mathbf{y} \mid \mathbf{x}; \theta) = \prod_{t=1}^{n} p(y_t \mid \mathbf{y}_{<t}, \mathbf{x}; \theta)$. Decoding text from a model can be framed as a search problem, where the search objective is to find the output sequence that maximizes the conditional probability under the model: $\arg\max_{\hat{\mathbf{y}}} p(\hat{\mathbf{y}} \mid \mathbf{x}; \theta)$. Because $p(\hat{y}_t \mid \hat{\mathbf{y}}_{<t}, \mathbf{x}; \theta)$ depends on the entire generated sequence so far, this decoding problem is intractable to solve exactly.

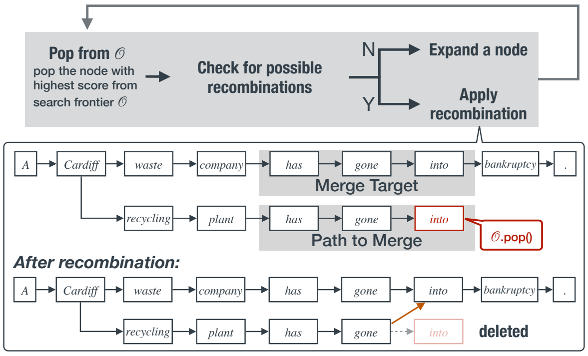

Figure 2: Our search algorithm. At each step, the algorithm pops a node from search frontier $\mathcal{O}$, checks for possible recombinations with existing nodes, and merges the nodes if a match is found. In this example, "*has gone into*" is the merge target to match. "*waste company*" and "*recycling plant*" are interchangeable paraphrases which do not affect the continuation from the model's perspective.

While typically the goal of decoding is to find the hypothesis with the highest possible model score, we instead focus on finding a large set of "good enough" hypotheses. That is, finding a set $\mathcal{Y}$:

$$\arg\max_{\mathcal{Y}} \; |\mathcal{Y}| \quad \text{s.t.} \;\; p(\mathbf{y} \mid \mathbf{x}; \theta) > \epsilon \text{ for all } \mathbf{y} \in \mathcal{Y} \qquad (1)$$

for some threshold ϵ. ϵ emerges naturally by adjusting search hyperparameters to control the number of returned hypotheses. Our goal in this paper is to design an algorithm that can efficiently find $\mathcal{Y}$.

Notation We encode predicted generation candidates $\hat{\mathbf{y}}$ in a lattice. A **lattice** $L = (N, E)$ is a directed graph where each **node** represents a token and paths defined by directed edges encode candidates. A **path** π in L from a unique start-of-sequence node n_{SOS} to any node n represents a (partially) decoded string, consisting of the words in that path. All completed paths start with n_{SOS} and end at (potentially different) end-of-sequence nodes n_{EOS}. The search graph L is constructed iteratively through a search procedure. We maintain the closed graph $\mathcal{C}$ with explored nodes and edges as well as a search frontier $\mathcal{O}$, a set consisting of successors to nodes currently in the graph. For each node, there are $|\mathcal{V}|$ possible successors.

We define the **search budget** as the number of nodes expanded from the search frontier. Our ex-

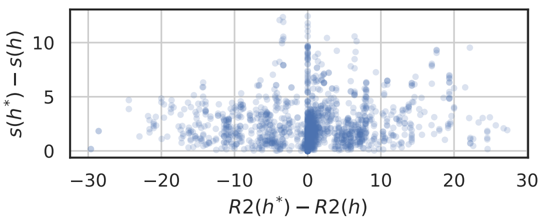

Figure 3: Correlation of ROUGE-2 and model score in beam search. For each example, we compare the hypothesis with the highest model score, h^*, with all other hypotheses. x and y-axis show the gaps of R2 and model score. The Pearson's ρ is 0.092 which suggests very low correlation between R2 and model score.

periments will seek to compare different methods using the same search budget. We will define this more precisely in Sec. 7.

3 Inadequacies of Beam Search

As we have alluded to, beam search is inadequate for our goal for several reasons. We show experiments on these aspects in this section and Appendix A.

Better Model Score $\not\Rightarrow$ Better Hypothesis The most critical issue is that beam search is designed to efficiently approximate $\arg\max \hat{\mathbf{y}} = p(\hat{\mathbf{y}} \mid \mathbf{x}; \theta)$, but the optimal model score is neither our goal nor a guarantee of a good hypothesis. In Figure 3, we compare the correlation of model score and ROUGE under beam search for text summarization. The Pearson correlation between these two variables is very weak. Beyond ROUGE score, the example in Fig. 1 shows that the main differences between these summaries may be minor differences in surface realization that have little effect on our qualitative judgments of summary quality. **The hypothesis with the best score under beam search is not substantially better quality than hypotheses with slightly lower scores.**

Lack of Diversity in (Diverse) Beam Search Are the model outputs from BS and DBS diverse? We use Self-BLEU (SBL) (Zhu et al., 2018) to measure the BLEU score for randomly sampled pairs from each algorithm's output. The lower the self-BLEU, the more dissimilar the pairs are. On decoding summaries on XSum, the SBL for BS/DBS are 87/79 while a nucleus sampling method can achieve 57/50 depending on the configuration. Although DBS slightly improves the diversity compared to the original variant, **the overlap of outputs from beam search based method is still very high, and the diversity remains a challenge.**

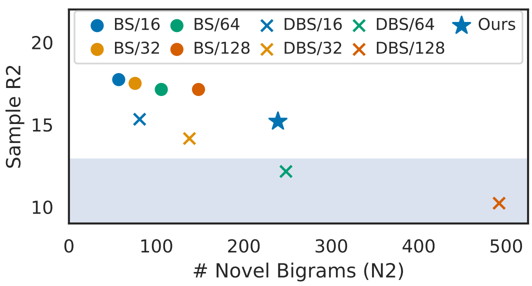

Figure 4: Diversity vs. ROUGE of BS/DBS on XSum with varying beam size k, compared to a proposed model introduced later (blue star) with equivalent beam size $k = 16$. We consider sample ROUGE-2 lower than 13 as low relevance/quality generations. Diversity of BS does not scale well with k and DBS generations become low quality.

k	16		8	
$\mathcal{D}$	XSum	zh-en	fr-en	en-fr
BS	71.3%	63.3%	54.0%	59.2%
DBS	71.2%	56.1%	50.4%	55.7%

Table 1: Pruning ratio of BS and DBS on different tasks and datasets with beam size k. We report the average percentage of explored nodes getting pruned and not appearing in a finished hypothesis.

Poor Efficiency from Pruning One final issue with beam search is that **most of its computation is not even useful in producing finished hypotheses**; that is, the set $\mathcal{Y}$ of answers produced does not contain most of the nodes expanded in the typical course of operation. We conduct an empirical pruning study on a summarization dataset and three translation datasets and show the results in Table 1. For all studied cases, beam search and diverse beam search prune over half of the expanded nodes. Many pruned hypotheses are not truly ungrammatical or low quality, but are merely slightly less likely than other nodes. How we can preserve more of the explored lattice and do so efficiently is addressed in next by our use of best-first search.

4 Modified Best-first Search

As established in the previous section, beam search prunes many paths that would potentially yield high-quality summaries and wastes computational resources expanding nodes that aren't included in a

Algorithm 1 Best-first search with depth-first completion and path recombination

```
Input: Generation model $\theta$ with vocabulary $\mathcal{V}$, search budget $b$, $\mathcal{O}$ and $\mathcal{C}$ denote open set (max priority queue) and closed set, $isRecomb$ and $doRecomb$ are functions checking and running path recombination.
Output: All completed paths $P$
 1: $\mathcal{O} \leftarrow \{(\infty, n_{\text{SOS}})\}, \mathcal{C} \leftarrow \emptyset, expanded \leftarrow 0$.
 2: while $expanded < b$ do
 3:     $\hat{h} \leftarrow \mathcal{O}.\texttt{pop()}$
 4:     if $isRecomb(\hat{h}, \mathcal{C})$ then
 5:         $doRecomb(\hat{h}, \mathcal{C})$
 6:         continue
 7:     end if
 8:     if $\hat{h} \neq$ EOS then
 9:         $v_{greedy} = \arg\max_{v \in \mathcal{V}} p(v \mid \hat{h}, \mathbf{x}; \theta)$
10:         for $v \in \mathcal{V}$ do
11:             score $\leftarrow s(\hat{h} \bigoplus v)$            // concatenation
12:             if $v = v_{greedy}$ then
13:                 score $\leftarrow \infty$        // depth-first completion
14:             end if

16:         end for
17:         $expanded \leftarrow expanded + 1$
18:     end if
19:     $\mathcal{C} \leftarrow \mathcal{C} \cup \hat{h}$
20: end while
```

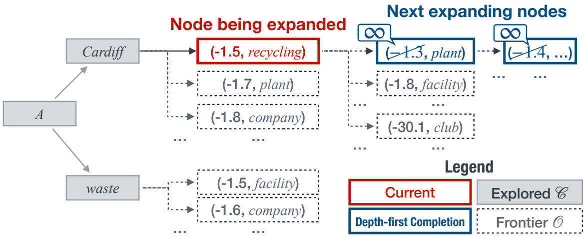

Figure 5: Depth-first completion. The red node is the current node being expanded. We depth-first expand a sequence of nodes (in blue) to get a completed path.

final search graph. We tackle this issue by changing from beam search to *best-first search* (BFS) (Hart et al., 1968; Pearl, 1984). BFS prioritizes searching over nodes according to a scoring function, giving us more flexibility in how we explore the space. Our chief modification of the base algorithm is a heuristic we call depth-first completion.

Depth-first Path Completion Neural text generation is a search problem with large branching factor ($\mathcal{V}$) and deep search depth (sequence length). As a result, applying BFS with the scoring function being the model score of a state often leads to a broad search that rarely returns a valid path. One solution to this problem is to incorporate a heuristic based on length. Model score is monotonically decreasing as a sequence grows in length, so prior work (Wu et al., 2016; Zhang et al., 2018; Meister et al., 2020b) has used a length reward term to alleviate this issue.[2] We found that, even with a length heuristic, BFS will still have "dangling" nodes that are not part of any path to an EOS (goal) token, and it might return few or no valid hypotheses.

Recognizing our objective from Equation 1, we can take a simple step to ensure that every node ends up on some completed path: *eagerly do a greedy search from each node until we reach n_{eos} or exceed a maximum length*. In Algorithm 1, we implement this by modifying the priority of the highest scored token with ∞ (line 12), so it will be explored immediately after the current time step. In Figure 5, we illustrate depth-first completion.

Search Algorithm We describe BFS with depth-first completion in Algorithm 1. The algorithm is a modified best-first search algorithm applied to text generation. $s(\cdot)$ is a function to evaluate the value of a path. Typically it is defined as $s(\mathbf{y}) = \sum \log p(y_t \mid y_{<t})$. b is the budget for total model calls to neural text generation model. Note that $isRecomb$ and $doRecomb$ do not invoke the neural generation model, so they do not count towards the computation budget we defined here. In practice, we only consider top 5 expansions rather than the whole vocabulary $\mathcal{V}$ for line 10.

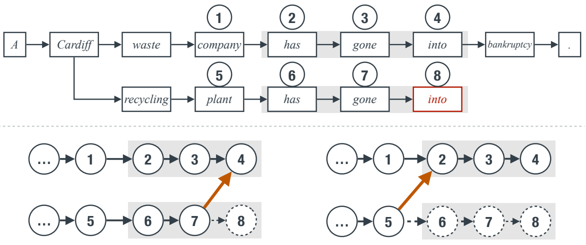
5 Path Recombination

Path recombination, also known as hypothesis recombination, was originally proposed and used in phrase-based machine translation (Och et al., 2001; Koehn et al., 2003; Zhang et al., 2018). The idea of path recombination is to *combine similar paths if what the model predicts for them in the future is the same*, reflecting a similar dynamic programming principle as the Viterbi algorithm. We focus on finding hypotheses which approximately exhibit this property, and show that merging them can yield high-quality outputs. Figure 2 shows an example of recombination. The two hypotheses being merged here roughly convey the same intent, and it turns out that the shared suffix "*has gone into*" is a strong indicator that the model will treat them similarly in the rest of the generation.

Prerequisites of Recombination Theoretically, two search states should only be recombined if they yield the exact same distribution over future generation decisions (see strong equivalence in Ap-

---

[2] This can be considered a heuristic like in (weighted) A* search, but it is not necessarily admissible or consistent.



(a) RCB (b) ZIP

Figure 6: Illustration of two path recombination strategies, RCB and ZIP. Orange lines are the merging edges (MRG) built by recombination. Dotted lines and circles are removed after recombination. The key difference of RCB and ZIP is how much the recombination propagates, 1 step or n steps.

pendix B). However, this is intractable even to check approximately; we define a weaker criterion:

Definition 5.1 (Weak equivalence)**.** *Let* $\mathbf{a}$ *and* $\mathbf{b}$ *be two prefix strings starting with* n_{SOS}*.* $\mathbf{a}$ *and* $\mathbf{b}$ *are weakly equivalent if greedy completions of these two strings are the same:* $\arg\max_{\mathbf{y}} P(\mathbf{y} \mid \mathbf{a}) = \arg\max_{\mathbf{y}'} P(\mathbf{y}' \mid \mathbf{b})$.

This criterion can be checked empirically, but it is not practical to do so during search.

To approximate equivalence, we define a similarity function $\textit{isRecomb}(\mathbf{h}, \hat{\mathbf{h}})$ to determine if an expanded node $\hat{\mathbf{h}}$ should be merged with an existing expanded node $\mathbf{h}$. A similar recombination idea was explored in Zhang et al. (2018). Following their work, we explore a family of rule-based heuristics for merging. There are two rules: (1) two strings share a common n-gram suffix, (2) the length difference of two strings is less than α. Assume that the canonical paths for $\mathbf{h}$ and $\hat{\mathbf{h}}$ are lengths l and $\hat{l}$, then $\textit{isRecomb}(\mathbf{h}, \hat{\mathbf{h}}) = \mathbb{1}[\pi(\mathbf{h})_{l-n+1,\dots,l} = \pi(\hat{\mathbf{h}})_{\hat{l}-n+1,\dots,\hat{l}} \wedge |l - \hat{l}| < \alpha]$ where α and n are hyper-parameters.[3] For a large enough value of n, note that the shared suffixes encourage hypotheses like this in Figure 6 that share large parts of the structure already.

Prior Work: BSZBEAM Zhang et al. (2018) use their merging criterion in the context of beam search for neural machine translation. If the merging criteria hold, $\hat{\mathbf{h}}$ will be recombined with $\mathbf{h}$. However, $\hat{\mathbf{h}}$ will not be considered as a future merging candidate. We call this merging strategy ZBEAM. We implement this model together with its merging criteria and denote it as BSZBEAM. This strategy is tailored to beam search and explores a more limited set of merges than we do.

Canonical Paths After recombination, a single node may represent multiple different possible sentence prefixes. If an edge is created due to the extension of search graph via model's prediction, we call it a GEN edge. Otherwise, the edge is created due to path recombination, and we call it a MRG edge. We define the notion of a canonical path, which represents the single path used to score candidate expansions.

Definition 5.2 (Canonical Path)**.** *Let* n *be a node. The canonical path to* n *is defined as the unique path from* n_{SOS} *to* n *consisting only of* GEN *edges.*

Theorem 5.1. *For any node* n *in the graph except* n_{SOS}*, there exists exactly one canonical path.*

We present the proof in Appendix. C. We define the path of a node n, $\pi(n)$, as returning the sequence of words corresponding to the canonical path of that node. Expanding n computes $P(y \mid \pi(n))$ under the neural model.

6 Recombination Mechanism

We illustrate the two major recombination techniques we introduce, RCB and ZIP, in Figure 6. These methods represent our two implementations of *doRecomb* in Algorithm 1.

RCB: Generalization of ZBEAM ZBEAM has a major limitation: a limited set of merging candidates. The potential merge candidates in ZBEAM are only nodes in the current beam hypotheses and their previous steps, so the method cannot merge with nodes from earlier timesteps. For example, "*A waste plant has gone into*" cannot be merged with the hypothesis with ending in node 4 shown in Figure 6. The proposed generalization, RCB, addresses this limitation. We index all of the nodes in the lattice across all timesteps by their n-grams using a hash table, making it $O(1)$ time to look up an n-gram pattern and retrieve potential merge candidates if they exist.

ZIP: Recombining More If we take a closer look at RCB in Figure 6, we see that even in the merged structure, nodes 3 and 7 and nodes 2 and 6 are preserved as separate. They do not pass the recombination criterion themselves, but these nodes

---

[3] In Zhang et al. (2018), there is one extra constraint requiring $P(\hat{\mathbf{h}} \mid \mathbf{x}) < P(\mathbf{h} \mid \mathbf{x})$, which requires that the path getting recombined has lower model score than the existing path. However, we found that model score is not always a good indicator for merging, as suggested in Fig. 3, partially because it is challenging to calibrate scores across different sequence lengths, so we disregard this constraint.

are part of the suffix matched strings, still correspond to the same words, and have the same directly generated next word. There is reason to believe that these might be equivalent as well. Hence, we explore a variant called Zip that propagates the merge backwards through the lattice. This change relaxes the merging criterion and up to n pairs of nodes are combined when a merge is identified, leading to a more compact lattice. We describe some of the details in Appendix D.

Our Methods In this work, we combine the two proposed techniques, the modified best-first search (Bfs) and recombination methods, together. Hence, we name them as BfsRcb and BfsZip.

7 Evaluation

To evaluate the proposed methods, we conduct experiments on abstractive text summarization and machine translation. Our evaluation focuses on two questions: (1) how **large and diverse** are our lattices? (2) are the candidates encoded in the lattices **high quality and grammatical**?

7.1 Datasets & Base Models

We obtain all the models and certain baseline decoding methods from the Transformers library (Wolf et al., 2020). Since our methods are inference techniques without learned components, we do not re-train any models. For **summarization**, we use XSum (Narayan et al., 2018), a popular English news summarization dataset. We sample 100 examples from the validation set. The base model we use is `BART-large-XSum` (Lewis et al., 2020). For **machine translation**, we study our models on the English-French (en-fr) pairs from WMT 2014 (Bojar et al., 2014) and Chinese-to-English (zh-en) pair from WMT 2019 (Barrault et al., 2019). We use `mBART` (Liu et al., 2020), a state-of-the-art neural machine translation model. We set the max decoding length to be twice the input length, so it varies per example.

7.2 Search Budget

To fairly compare the resource usage of all methods, we define the search budget as the number of calls to the neural model, equivalent to the number of nodes expanded.[4] With beam size k and maximum length T, beam search methods are given a theoretical budget of kT. We could simply allow best-first search and sampling methods to expand this number of nodes. However, since hypotheses may terminate before they reach EOS, empirically there is a gap between effective length (the average generated hypothesis length) and max length for both beam search and sampling. To balance the computation used across the different methods, we apply a correction factor so that the different methods are expanding the same number of nodes in aggregate. We increase the beam size k by 50% for translation, from 8 to 12, and 25% for summarization, from 16 to 20, for our baseline methods: k to BS, DBS, Ncls, Temp, and BSZBeam. This correction was empirically determined to balance the number of nodes expanded between our method and the baselines. We emphasize that this correction improves the baseline performance relative to our methods.

7.3 Search Algorithms

We implemented Greedy, BS, DBS, Ncls, and Temp as baseline methods. Ncls$_{0.9}$ represents nucleus sampling method with $p = 0.9$. We refer to Appendix E for detailed descriptions. We also experiment with basic Bfs without path recombination, but including our depth-first path completion technique to ensure that finished hypotheses are produced. BSZBeam is our implementation of Zhang et al. (2018). We integrate Rcb with nucleus sampling and best-first search as NclsRcb and BfsRcb. We also test Bfs with the Zip strategy. 🍃BfsZip is a resource-efficient version of BfsZip where only 25% of the search budget is used, exploring what this method can achieve with a lower budget given its more aggressive merges.

7.4 Evaluation Metrics

We describe our metrics to evaluate both quality and diversity. Several of our methods build on ROUGE (including R1, R2, RL) (Lin, 2004) and BLEU (Papineni et al., 2002; Post, 2018) comparing the generated text to references.

Diversity-oriented Metrics We evaluate the diversity of generated texts with the following metrics. (1) |path| is the average number of unique paths in the produced lattice.[5] (2) Number of

---

[4] We incur negligible overhead from rule-based matching in the merging step, as well as the computational costs of computing diversity term in DBS and modifying sampling distributions in sampling methods.

[5] Due to the exponentially growing number of paths in some of our models, we cap the number of paths from n_{SOS} to each node to $C = 10^4$.

	Diversity					Or	Sp	Grm
	↑	↑	↑	↓	↑	↑	≥	↓
Model	|path|	N1	N2	sBl	ED	R2	R2	Err
Greedy	1	22	23	100	0	17.3	17.3	0.5%
BS	20	42	61	87	31	26.3	17.7	0.3%
DBS	19	59	91	79	53	25.5	15.9	0.5%
Ncls$_{0.8}$	20	124	237	57	72	30.2	14.5	0.5%
Ncls$_{0.9}$	20	143	273	50	76	28.1	13.3	0.8%
Temp$_{1.5}$	20	170	319	51	82	26.6	11.6	1.4%
Bfs	30	88	167	68	60	30.1	15.6	0.4%
+ *Path Recombination*								
BSZBeam	4,701	66	118	75	51	33.0	16.0	0.7%
Ncls$_{0.8}$Rcb	52	167	308	53	79	28.8	13.0	1.0%
Ncls$_{0.9}$Rcb	36	207	363	50	87	25.9	11.0	1.7%
BfsRcb	7,758	111	239	65	64	35.8	15.2	0.8%
BfsZip	95,744	124	274	53	77	36.8	13.2	1.4%
🍃BfsZip	297	58	92	80	49	29.2	15.2	0.8%

Table 2: Results decoding text summaries on XSum. Diversity metrics are rounded to integers to save space. We use ↑, ↓ and ≥ to denote the desired trend, the higher the better, the lower the better, or good if it passes some threshold. Among the methods with path recombination excluding 🍃BfsZip, we highlight the best, second and third best, and the worst one.

unique n-grams encoded in the lattice; this captures a different type of diversity than the number of paths, since there could be many paths reusing the same words. N1 and N2 are average number of novel unigrams and bigrams in the graph. (3) sBl is the average self-BLEU among m samples (Zhu et al., 2018). The samples are drawn from a uniform random walk from n_{SOS}. The range of sBl is $[0, 100]$. (4) ED is the average edit-distance among m samples. We set $m = 5$ in our experiment.

Quality: Grammaticality We adopt GECToR a neural grammatical error correction model (Omelianchuk et al., 2020) to automatically assess the grammaticality of generated texts. We report GrmErr(%), the average number of grammar errors per token, for all English-output experiments.

Quality: Oracle Reference Match Given the reference, we find the path with highest ROUGE or BLEU over all found paths. Oracle ROUGE is defined as $\text{Or}(\mathcal{Y}, \mathbf{y}^*) = \max_{\mathbf{y}\in\mathcal{Y}}(\text{R2}(\mathbf{y}, \mathbf{y}^*))$. This metric captures both quality and diversity: the algorithm needs to find something close to the reference, but a diverse lattice will have a higher chance of exhibiting a good candidate all else being equal.

Quality: Average Reference Match Although our method focuses on deriving diverse text summaries or translations, we aim to guarantee that the generated text is highly relevant to the generation target and is of high quality in general. We sample 1,000 paths from the lattice with replacement and evaluate the average ROUGE or BLEU compared to the reference. We denote this metric as Sp.

8 Results

Text Summarization We present the experimental results on the dev set of XSum in Table 2. Full results are kept in Table 4 for reference. Among non-recombination methods, BS and DBS are the least diverse methods. Sampling based methods including Temp are generally more diverse, but the oracle ROUGE is lower than that of Bfs. Given the sacrificed text quality (lower sample ROUGE and more grammar errors) of sampling based methods, we argue that **modified best-first search is a strong decoding strategy even without path recombination**. The bottom half shows all methods with path recombination techniques. **Recombination significantly improves the diversity of generated outputs**, with a much higher number of paths. The sBl of the recombination variants are lower than their non-recombination counterparts.

In terms of search quality, the proposed BfsRcb and BfsZip methods obtain significantly higher oracle ROUGE compared to all other methods. We show these results later in Figure 9: our approach can find much better oracle solutions, even compared with beam search method with quadruple the amount of computational resources. The design of the oracle ROUGE metric is also motivated by a real use case: if you want a specific summary (e.g., a summary covering a specific entity or topic), does it exist in the search graph? Higher oracle ROUGE indicates a closer match, meaning a strategy using some kind of reranking model could help find the user's preferred outputs.

Comparison: Rcb & Zip The Zip method yields even more diverse output at the cost of text quality. There are a few reasons for this: 1) recombination of more nodes makes the lattice denser, increasing the number of paths but also potential errors; 2) elimination of unexplored children from merged branch reduces the waste of exploration which means Zip can explore more hypotheses than Rcb. With the same amount of computational resources, Zip explores a larger search space while Rcb explores a smaller collection more reliably. 🍃Zip exploits the efficiency of Zip to achieve high diversity, and by searching through fewer states, it manages to achieve higher quality as well.

Table 3: Results on WMT14 Fr-En and WMT19 Zh-En. Columns are the same as for summarization, although BLEU is used instead of ROUGE. Trends are roughly similar, with BfsRcb providing high diversity at good quality and 🍃BfsZip offering a strong tradeoff between computational resources and diversity.

Machine Translation We show the result on machine translation in Table 3 and 6. Results on translation tasks show the consistent gains of diversity from path recombination models. In Table 3, we show two translation tasks where the target language is English. BfsRcb works better than BfsZip because it disables some aggressive and bad merges which explores bad hypotheses. Compared to summarization, we found the search space in MT to be more constrained, so there was less room for aggressive merging and exploration to improve over Rcb. Our lower-resource method, 🍃BfsZip approach, actually performs quite well on most metrics with only 25% of search budget. It has better diversity performance than any non-recombination methods, and comes with quality better than most of the recombination methods. The usage of Bfs and path recombination methods like BfsRcb and BfsZip is promising for being able to find a better cost-diversity tradeoff in MT.

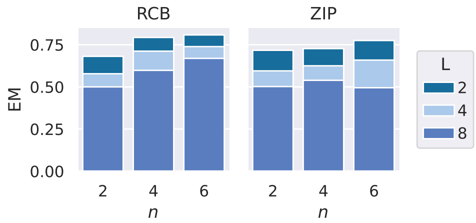

Figure 7: Empirical verification of merging criteria. We experiment with $n = \{2, 4, 6\}$ for n-gram suffix matching. We sample 1,000 recombinations from BfsRcb and BfsZip respectively, and run greedy inference based on merged hypotheses. We use Exact Match (EM) to measure how often two merged hypotheses give the same greedy future generations considering the next L tokens after the merge.

Validating the Merging Criterion Our merging criterion is fundamentally an approximation of the equivalence criteria described in Section 5. Our question is: **what fraction of nodes merged by our merging criterion satisfy the weak equivalence assumption?** We conduct an experiment to verify this on XSum. We compute the greedy completion for L timesteps and check whether the continuation of the base candidates would be the same. In Figure 7, we show the fraction of merged pairs for which the generations match exactly under three values of the recombination criterion. For BfsRcb, when using $n = 4$ the greedy continuation over 4 timesteps is the same 71.2% of the time. For BfsZip it is the same 62.5% of the time. Following the weak equivalence criterion is a strong indication that these hypotheses can admit many of the same continuations. Rcb is more reliable than Zip, but both methods show moderate adherence to the equivalence criterion.

Error Analysis & Visualization In Figure 8, we present two examples on XSum by 🍃BfsZip. The upper example has more word level recombination and paraphrasing while the bottom one has more ways of ending and more diverse content coverage. We show more examples on both summarization

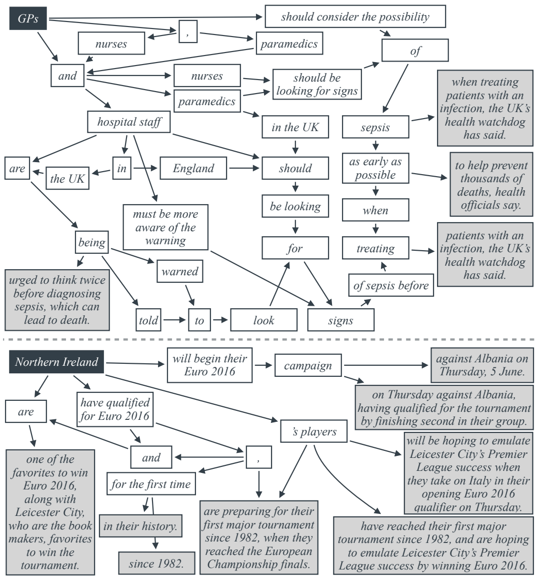

Figure 8: Two examples on XSum by BFSZIP. The start of sentence is denoted in dark color, and all the endings are in gray. We combine tokens to phrases when possible for visualization purpose. More examples are presented in Appendix. H.

and translation in Appendix. H.

We manually examine the output and found a few common types of errors introduced by our algorithm. (1) Factual errors at high entropy nodes. Our approach assumes that high-scoring candidates under the model are good quality, but this assumption is violated in certain cases, like when the model attempts to hallucinate information. For example, the prefix "*The company, founded in*" will cause the model to guess answers like "*1989*" or "*1999*". Encoding all of these in the lattice is incorrect. However, we did not see significant factual errors introduced by merging specifically. (2) Aggressive bad merges. In the upper example in Figure 8, the cluster of "*GPs*", "*nurses*", "*paramedics*" is an example case. The lattice encodes paths like "*GPs, nurses and nurses should ...*". This could be fixed by heuristics or rules in future work.

9 Related Work

The techniques used in this work partially reflect an outgrowth of a few lines of literature: understanding the behavior of text generation models (Xu et al., 2020; Xu and Durrett, 2021; Zhong et al., 2021), investigations into beam search (Stahlberg and Byrne, 2019; Meister et al., 2020a), and studies of diversity in generation.

In terms of search strategies, best-first beam search (Meister et al., 2020b) is a method integrating best-first search with beam search. Some other variants of search have also been studied in previous work (Meister et al., 2021b,a). Beam search has been critically examined in some recent work (Huang et al., 2017; Stahlberg and Byrne, 2019), but largely of focused on specific challenges in MT.

As for diverse generation, neural text degeneration has been discussed in Radford et al. (2019); Holtzman et al. (2020); Welleck et al. (2020), which led to an interest in diverse generation models. Diverse text generation has been studied in previous work (Yu et al., 2017), including in dialogue (Li et al., 2016), story generation (Fan et al., 2019), and particularly paraphrasing (Iyyer et al., 2018; Goyal and Durrett, 2020). Our method can also diversify content coverage (Gehrmann et al., 2018) and word choice (Cao and Wang, 2021).

10 Discussion & Conclusion

We presented an algorithm for decoding in text generation with two main components: best-first search to more efficiently structure exploration of the space and hypothesis recombination to encode summaries in a lattice structure. We showed that across summarization and machine translation, these lattices successfully encode large numbers of high-quality generation options.

There are a few limitations of our method. First, we currently benchmark these techniques using number of nodes expanded, not wall clock time. There are strategies for parallelizing the BFS expansion (Shu and Nakayama, 2018), but it remains to be seen how this parallelism compares to the parallelism achieved by beam search. Regardless, the dramatically larger number of hypotheses we return outweighs efficiency differences for now. Second, we focus on auto-regressive methods in this paper. However, we believe our framework could also be applied and adopted to non auto-regressive generation models (Song et al., 2021).

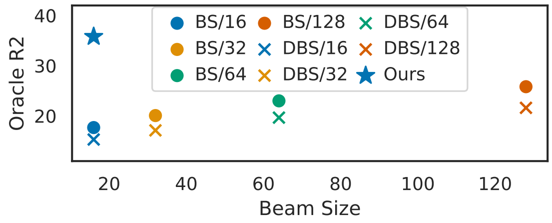

Figure 9: Oracle R2 of BS/DBS with larger beam size k. Blue star represents BFSRCB with equivalent $k = 16$.

A Inadequacies of Beam Search: Poor Scaling Behavior

In spite of the issues with beam search that we describe in the main text, perhaps beam search could still be viable with larger beam sizes if more computational resources are available. We experiment with beam sizes of $2^{\{4,5,6,7\}}$ and see how diversity scales with beam size. In Figure 4, we found that an exponential increase of beam size does not lead to a strong increase of number of novel bigram in beam search. In DBS, the diversity does ramp up, but the quality of the generated text decreases substantially. **For BS and DBS, increasing beam size is not an effective solution for better diversity.** We compare the oracle R2 of BS/DBS with larger beam size in Figure 9. The oracle R2 increases slowly as k doubles, but our model BFSRCB with $k = 16$ achieves 35.8, much higher than all BS/DBS cases.

B Strong Equivalence of Path recombination

In the strictest form, recombining two hypotheses assumes the following equivalence between them:

Definition B.1 (Strong equivalence). *Let* $\mathbf{a}$ *and* $\mathbf{b}$ *be two prefix strings starting with* n_{SOS}. $\mathbf{a}$ *and* $\mathbf{b}$ *are strongly equivalent if* $P(\mathbf{y} \mid \mathbf{a}) = P(\mathbf{y} \mid \mathbf{b})$ *holds for all* $\mathbf{y}$.

Merging such states in the search tree is valid with no loss of information, as any expanded node will receive the same score under both prefixes. However, this assumption is not realistic since seq2seq models condition on the entire sequence so far, and any tiny perturbation changes the predicted distribution. To relax the assumption, we then propose the weak alternative.

C Proof of Theorem 5.1

Proof by induction. Base case: we begin with just n_{SOS} in the lattice, which has exactly one canonical path consisting of itself.

Inductive case: assume every node in the lattice has exactly one canonical path. We have to consider two cases when expanding a node in the lattice:

(1) Expanding the node n as normal. In this case, n is on the search frontier due to its parent node n' being expanded, which establishes a GEN edge from n' to n. Since n' has exactly one canonical path, n then has exactly one canonical path consisting of the canonical path to n' extended to n.

(2) Applying recombination. This operation only adds MRG edges and deletes nodes, neither of which have any impact on the canonical paths.

D Implementation Details: ZIP

We summarize the key differences of ZBEAM, RCB and ZIP in Table 5. In ZIP, nodes that are already expanded might be removed from the lattice due to recombination. For example, in Figure 6, node 6 and 7 are removed in this fashion. In general, we handle this by re-mapping the eliminated node to its surviving counterpart. Any reference to node 7 is routed to node 3, or whatever node 3 is mapped to. This procedure is defined and implemented as a union-find data structure.

Deduplication of Unexplored Successors After the ZIP procedure, we also remove the unexplored successors of the merged nodes, like node 6, 7, and 8 in Fig. 6. We show a more detailed example in Figure 10. In ZIP, we will merge node 3 and node 6. If we take a closer look at the successors of these two nodes, the distributions could be similar and in fact are expected to be if the equivalence criteria hold. We remove the unexplored direct successors of the merged node as part of the merging process, and the surviving node (node 3) captures these with similar probabilities regardless.

E Baselines

GREEDY is the deterministic greedy decoding method that always selects the highest probability token as prediction. The equivalent beam size for this approach is 1 since we only run one pass.

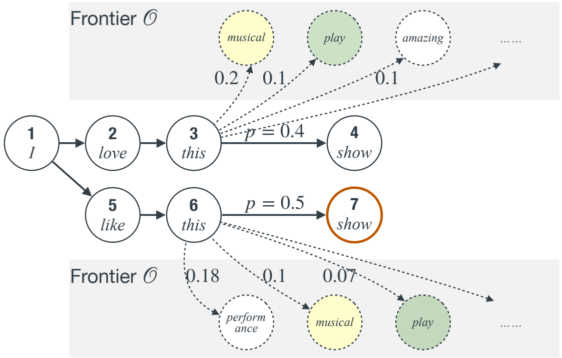

Figure 10: An illustration of removing unexplored hypotheses from search frontier in ZIP.

BS & DBS stand for beam search and its variant diverse beam search (Vijayakumar et al., 2018). In our configuration, we use Hamming distance as the diversity function and set the diversity strength to 1.5, following Vijayakumar et al. (2018).

NCLS is the nucleus sampling method proposed in Holtzman et al. (2020), which encourages quality by truncating the distribution over the vocabulary with a parameter p before sampling. We experiment it with $p = 0.9$ and $p = 0.8$.

TEMP changes the temperature of softmax function to reshape the prediction distribution (Ficler and Goldberg, 2017). We set the temperature parameter $\tau = 1.5$ so the prediction picks more low-scored tokens than $\tau = 1$.

F Implementation Details: Beam Search

In our beam search implementation, the size of the search frontier $\mathcal{O}$ is up to the beam size k. When a path is completed, we move it from the search frontier $\mathcal{O}$ to a completed set $\mathcal{F}$ to free up the beam for exploring unfinished hypotheses. Naturally, finished hypotheses $\mathcal{F}$ in the end can be of variable length. After reaching the max generation step T, we sort all hypotheses in $\mathcal{F}$ according to the model score. Following common practice in libraries such as Transformers (Wolf et al., 2020), we return a number of completed hypotheses equal to the beam size.

G Results of WMT14 English to French

Table 6 shows an additional experiment on English-French. We do not evaluate on grammaticality due to the GECToR model being specialized to English. The results show broadly similar trends as those in Table 3, discussed in the main text.

H Examples

We show three examples with visualization in Figure 11,12 and 13. We use `PyVis` as the visualization tool.[6] More examples are available at `anonymized`.

I Computational Considerations

Resources Used All experiments were conducted on a server with 32GB RAM and Intel Xeon E5-2630 CPU, using a single NVIDIA GTX1080. The total computational budget in GPU hours is within 50 hours for experiments in text summarization and machine translation.

Memory and Runtime Although the final lattices returned encode large numbers of paths, they do not take large amounts of memory. Because the number of nodes in a lattice is no larger than the number of node expansion operations during beam search, it is always less than the search budget and can be stored compactly.

Moreover, the wall clock time of our BFS-Recomb strategy is manageable, on the order of between 1 and 10 seconds for summarization. As mentioned in the Conclusion, additional parallelism can be combined with our BFS search to further improve the time and make it comparable to beam search. However, even this version of the algorithm can be "embarrassingly" parallelized across examples to improve efficiency.

Descriptive Statistics We randomly sample 100 data instances from the validation set for each dataset, and they are used by all methods. When sampling is needed, we take 1,000 samples for each data instance, so all the metrics are reported on 100,000 translations/summaries for one dataset.

J Risks

By generating additional outputs from a generation model, we may cause a system to produce outputs that are biased, factually inaccurate, or contain hallucinations. However, all of these risks are present in the raw text generation models as well. Moreover, because we present many options, we believe our approach more appropriately reflects the model's uncertainty over its output, and may have a part to play in mitigating such risks in systems of the future.

Abstract

In this paper, we explore the task of determining indirect answers to yes-no questions in real conversations. We work with transcripts of phone conversations in the Switchboard Dialog Act (SwDA) corpus and create SwDA-IndirectAnswers (SwDA-IA), a subset of SwDA consisting of all conversations containing a yes-no question with an indirect answer. We annotate the underlying direct answers to the yes-no questions (yes, probably yes, middle, probably no, or no). We show that doing so requires taking into account conversation context: the indirect answer alone is insufficient to determine the ground truth. Experimental results also show that taking into account context is beneficial. More importantly, our results demonstrate that existing corpora with synthetic indirect answers to yes-no questions are not beneficial when working with real conversations. Our best models outperform the majority baseline by a substantial margin, but the task remains a challenge (F1: 0.46).

1 Introduction

Dialogue systems have become a reality enabled by large datasets and deep neural networks. Task-oriented (Wen et al., 2017) and open-domain (Tang et al., 2019) dialogue systems are commonplace. Neural approaches are popular (Zhang et al., 2018) although systems based on logical inference and rules outperform networks in open-domain dialogue (Finch et al., 2021). State-of-the-art systems face challenges keeping track of a conversation and avoiding inconsistencies (Welleck et al., 2019). Evaluation is also an open issue as automated metrics have several drawbacks (Liu et al., 2016). An alternative is to evaluate dialogue systems based on whether they can collaborate with humans to solve a problem (Lewis et al., 2017) or elicit some action such as donating to a cause (Wang et al., 2019).

A: Do you work outside of the home?
B: No, I am not working currently.
Underlying direct answer: No

A: Do you work outside of the home?
B: Uh, last month I left my company.
Underlying direct answer: No

A: Do you work outside of the home?
B: Uh, last month I left my company.
A: What happened? Stress?
B: But now I work for a marketing firm where I travel a lot.
Underlying direct answer: Yes

Figure 1: Conversation snippets with a yes-no question (first turn by Sparker A). In the first example, the underlying direct answer is obvious given the answer by Speaker B. In the second example, determining the underlying direct answer requires commonsense knowledge. In the third example, it requires not only commonsense but also taking into account more than the turn by Speaker B immediately following the question.

People do not explicitly say what they mean when they speak to each other yet they seamlessly carry on conversations. For example, customers asking *Where are the $1 cups?* reveal to the sales associate that they want to buy a (cheap) cup (Tatu, 2005). In this paper, we investigate the underlying direct answers to yes-no questions. A yes-no question is a question that expects a *yes* or *no* for an answer. As we shall see, we work with direct yes-no questions (e.g., Did you drive yourself to the airport) and indirect ones (e.g., I am not sure if you drove yourself to the airport).

Consider the conversation snippets in Figure 1. As shown in the first one, the conversation turn following a yes-no question may be a direct answer (i.e., a turn including *yes*, *no*, *obviously*, *never* or similar keywords). Indirect answers (e.g., second snippet) are more common. Speaker B *leaving his company a month ago* does not entail that he is jobless (and thus not working—at home or the office). Given this indirect answer alone, however, it is reasonable to conclude so thus the underlying direct answer is *no*. The broader conversation context often provides a more complete picture and the

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4677 - 4695
July 10-15, 2022 ©2022 Association for Computational Linguistics

true underlying direct answer (e.g., third snippet). After a brief interjection by Speaker A, Speaker B states that he changed jobs and now travels a lot. Thus, the underlying direct answer is *yes*.

The focus of this paper is to determine the underlying direct answers to yes-no questions. Unlike previous efforts, we work with transcripts of *real conversation* as opposed to yes-no questions and indirect answers written by annotators on demand. The main contributions are:[1]

1. We present SwDA-IA, a corpus consisting of the 2,544 yes-no questions in Switchboard (Jurafsky et al., 1997, SwDA) with *I*ndirect *A*nswers and their underlying direct answers.
2. We show that determining underlying direct answers requires context beyond the yes-no question and the next conversation turn. Indeed, the ground truth changes depending on whether we show annotators context.
3. We demonstrate that transfer learning with related tasks as well as synthetic yes-no questions and synthetic indirect answers only bring modest improvements. Specifically, synthetic data do not transfer to real conversations.
4. We provide insights into the most common errors made by our best performing model.

The work presented here provides evidence that determining the underlying direct answer to yes-no questions *in real conversations* is much more challenging than in synthetic data. Our best model obtains 0.49 F1 even when using only the context handpicked as important by annotators.

2 Previous Work

Yes-no questions and indirect answers have been studied for decades (Green and Carberry, 1999). Hockey et al. (1997) report that 27% of all questions in 18 hours of spontaneous speech are yes-no questions with indirect answers (Rossen-Knill et al., 1997). Indirect answers are often used to ask follow-up questions or provide explanations for negative answers (Stenström, 1984), prevent wrong interpretations of direct answers (Hirschberg, 1985) or show politeness (Brown and Levinson, 1978).

Yes-no questions have received considerable attention recently. Outside of the dialogue genre, Clark et al. (2019) present BoolQ, a corpus of 16,000 yes-no questions submitted to a search engine (e.g., *Does France have a Prime Minister and a President?*) along with Wikipedia articles that may contain an answer. Two recent corpora consist of dialogues generated by crowdworkers on demand after being given some text to talk about: QuAC (Choi et al., 2018) and CoQA (Reddy et al., 2019). Unlike the work presented here, the dialogues in these corpora are limited to questions and answers about the text provided to crowdworkers. More importantly, we work with unrestricted, natural conversations rather than dialogues between paid annotators who are asked to have a conversation that resembles a questionnaire geared towards checking for understanding of a piece of text.

Yes-no questions in real conversations have been studied before at a small scale. de Marneffe et al. (2010) work with 224 questions-answer pairs involving gradable adjectives. We borrow from them the five labels to annotate underlying direct answers. de Marneffe et al. (2009) present a typology for 623 yes-no questions from SwDA. Our corpus is four times larger. Unlike them, we show that context is crucial to determine underlying direct answers and present experimental results.

The work by Louis et al. (2020) is the closest to ours. They present Circa, 34,268 yes-no questions and indirect answers written by crowdworkers given one of ten scenarios (e.g., scenario: Talking to a friend about music preferences, Q: Do you like guitars? A: I practice playing every weekend). Unlike us, Circa assumes that the turn following a yes-no question is enough to determine the underlying direct answer. Furthermore, we show that (a) determining underlying direct answers to yes-no questions is much harder in *real conversations* and (b) their synthetic data only bring minor improvements when working with real conversations.

3 SwDA-IA: A Corpus of Yes-No Questions and Indirect Answers

We present SwDA-IA, a corpus consisting of (a) the 2,544 yes-no questions in Switchboard with *I*ndirect *A*nswers and (b) manual annotations indicating the underlying direct answers. Three characteristics set our work apart. First, we work with real conversations as opposed to artificial, synthetic ones (Section 2). Second, we show that determining underlying direct answers requires taking into account context beyond the yes-no question and the next turn. Third, annotators pinpoint which turns within the context around a yes-no-question are useful to determine the underlying direct answer.

---

[1] Corpora available at `https://github.com/krishna-chaitanya-sanagavarapu/SwDA-IA`.

3.1 Collecting Yes-No Questions with Indirect Answers

While we could work with any dialogue corpora, we chose SwDA (Jurafsky et al., 1997) because it contains unrestricted conversations and the dialogue acts annotations simplify the process of identifying yes-no questions with indirect answers. SwDA contains transcripts of 1,155 five-minute phone conversations. In these conversations, two people talk about topics such as childhood, recycling, and news media. The conversations are unrestricted and often divert from the initial topic. 440 speakers participated in the corpus creation resulting in 122,646 utterances. We use the distribution in ConvoKit (Chang et al., 2020) for convenience.

After manually examining all the dialogue acts, we select all conversation turns containing a dialogue act that indicates a yes-no question (see the list in the supplementary materials). This step results in 5,846 yes-no question including indirect ones (e.g., "I don't know if you are familiar with that issue." is an indirect version of "Are you familiar with that issue?"). After selecting yes-no questions, we discard those that are followed by a turn containing a direct answer. To do so, we discard turns containing a dialogue act indicating direct answers (see list in the supplementary materials). After manually examining the 2,542 questions that are not filtered, we observed that some have a direct answer. In order to avoid them, we also consider a direct answer any turn that contains *yes*, *yea*, *yeah*, *no way*, *nope*, *never*, *sure*, *right*, *you bet*, *of course*, *certainly*, *maybe*, *definitely*, or *uh huh*.

These steps select 2,376 turns with 2,544 yes-no questions followed by an indirect answer (168 turns have more than one yes-no question). Only 4.77% of all utterances in SwDA are a yes-no question. However, 43.52% of all yes-no questions have an indirect answer (2,544 out of 5,846). More importantly, 77.4% of the 5-minute conversations in SwDA contain at least one yes-no question with an indirect answer. The supplementary materials provide an analysis of the yes-no questions we work with. For example, 41.4% are indirect (e.g., do not include a question mark).

3.2 Annotating Underlying Direct Answers

In order to determine the underlying direct answers to the 2,544 yes-no questions, we manually annotated them. Our label set consists of five options: *(definitely) Yes*, *Probably Yes*, *(in the) Middle*, *Probably No* and *(definitely) No*. *Middle* is chosen when annotators do not lean towards any of the other four labels (e.g., "A: Do you have kids? B: Do I have kids?". These labels are heavily inspired by de Marneffe et al. (2010). Louis et al. (2020) include a few more options (e.g., "I am not sure", "In the middle, neither yes or no" and "Other") but they report very low frequencies (0.2–1.9%). These three labels are included in our "Middle."

We found two common scenarios that require additional explanation in order to be consistent:

- If the answer is *yes under certain conditions* or *sometimes yes*, annotators are instructed to choose *Probably Yes*. For example, the correct label for "A: Do you travel a lot for pleasure? B: We try to make one trip per year if I find a good sale" is *Probably yes*.
- If the yes-no question contains a negation, *Yes* and *Probably Yes* have their meaning reversed. For example, the correct label for "A: You didn't move to Alaska, right? B: I have been in Alaska for 13 years now" is *No* (*Yes* would be correct if B had not moved to Alaska).

Annotation Process and Quality The annotation process took place in two independent phases in order to investigate the role of context in determining underlying direct answers. In the first phase, annotators were only shown the yes-no question and the conversation turn immediately after (i.e., the indirect answer). In the second phase, annotators were shown three turns before and after the yes-no question as context. Different annotators annotated the same question in each phase to avoid potential biases (i.e., recalling answers from the previous phase). In both phases, the interface showed conversation turns after brief delays in order to encourage annotators to read the conversation snippet in order (either two turns or seven turns). In addition to selecting the underlying direct answer, in the second phase annotators also tagged the conversation turns that help them determine it. We hosted the annotation interface internally and recruited in-house annotators. Seven native English speakers participated in the annotations.

Inter-Annotator Agreement After refining the explanation for each label and group discussions, we conducted a pilot with 200 questions and the seven annotators. The average weighted Fleiss' Kappa (Plewis and Unit, 1982) between all pairs of annotators was 0.80. Given the high agree-

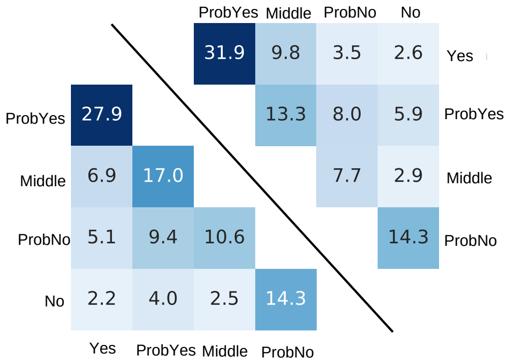

Figure 2: Heatmaps of the inter-annotator disagreements when annotators have access to (a) only the yes-no question and indirect answer (bottom left) and (b) conversation context. Numbers indicate percentages. Most disagreement are minor: between *ProbYes* and either *Yes* or *Middle*, or *ProbNo* and either *No* or *Middle*.

ment (Landis and Koch, 1977), the remaining 2,344 questions were divided into twelve batches, and two annotators annotated each batch. The average Weighted Fleiss' Kappa score for all the batches was 0.81 when not showing context to annotators (first phase) and 0.78 when showing context (second phase). Disagreements in both phases were adjudicated after manual examination. The "true" underlying direct answers are the one annotated when context is shown to annotators, and those are the ones we conduct experiments with (Section 5).

Figure 2 shows the percentage of all disagreements prior to the adjudication step when context is not and is shown to annotators (top right and bottom left). As expected given the high Kappa coefficients, most disagreements are minor: between (a) *Yes* (or *No*) and *Probably Yes* (or *Probably No*) or (b) *Middle* and *Probably Yes* or *Probably No*.

4 Corpus Analysis: the Role of Context

The annotations we collected in both phases differ substantially. Thus context beyond the yes-no question and indirect answer (i.e., the following turn) is needed to determine the ground truth in real conversations. To our knowledge, previous work does not take into account context (Section 2).

Table 1 presents the distribution of each label when the interface shows and does not show context to annotators. The major change is that almost half of the questions annotated with *Middle* without context are annotated with one of the other four labels with context. Note that out of the five labels, *Middle* is arguably the one that reveals the least information about the speakers.

	% without context	% with context
Yes	35.7	42.4
ProbYes	14.9	19.5
Middle	28.0	14.9
ProbNo	7.7	9.9
No	13.6	13.3

Table 1: Label distribution when annotators have access to (a) only the yes-no question and indirect answer (without context), and (b) conversational context (3 turns before and after the question, with context).

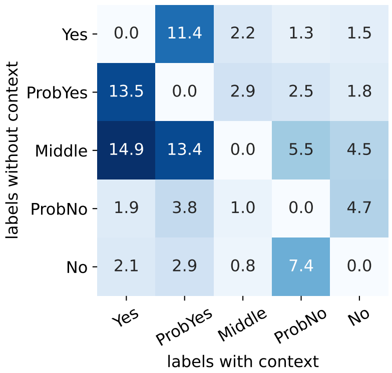

Figure 3: Heatmap of the changes in ground truth depending on whether annotators have access to context in addition to the question and indirect answer. Numbers indicate percentages. Context is crucial to determine the underlying direct answer to a yes-no question.

Figure 3 shows how the ground truth changes when we show context to annotators. The most common change is from *Middle* to either *Yes* (14.9%) or *ProbYes* (13.4%). In other words, context allows annotators to select an underlying direct answer that is more meaningful. There are also many changes from *ProbYes* to *Yes* (13.5%) and vice versa (13.5%), suggesting that context provides further details (a clarification, condition, etc.) to determine the underlying direct answer.

We show examples of changes in ground truth when annotators do not have and have access to context in Table 2. In the first example (top left), the indirect answer (t_1) repeats the question and does not provide any clue about the underlying direct answer. The next turn by A (t_3), however, leaves no doubt: the underlying direct answer is *Yes*. The second example (top right) shows a similar pattern, but it exemplifies negation in the question and uncertainty. Speaker A does not commit to a *Yes* (Yes, It didn't kill anything) but rather sharing that to his knowledge it has not (*Probably Yes*).

The third example (bottom left) shows how follow-up questions in context can clarify the under-

t_{-3}, A: Which is like twenty minutes away.
t_{-2}, B: Right.
t_{-1}, A: But, uh, we don't have any fast foods here in this small city.
t_0, B: *That is probably very fortunate. Do you have kids?*
t_1, A: *Do I have kids?*
t_2, B: Yeah.
t_3, A: Well, I have a son, but he's grown up.

Underlying direct answer ...
without context: Middle; *with context*: Yes

---

t_{-3}, A: And it seem
t_{-2}, B: I bank at NCNB and they have a number that you can call. I always call in once every other week and check what checks have cleared
t_{-1}, A: Yeah.
t_0, B: *Do you do that?*
t_1, A: *We have the same thing.*
t_2, B: You do too?
t_3, A: Yeah.

Underlying direct answer ...
without context: ProbYes; *with context*: Yes

---

t_{-3}, A: Um, not bad.
t_{-2}, B: Yeah
t_{-1}, A: Occasionally you'll have a mound pop up, but that is expected.
t_0, B: *What else did it, it didn't kill anything right?*
t_1, A: *Um.*
t_2, B: Not really.
t_3, A: As far as I know it hasn't killed anything. Even the area of the grass that was underneath and around the mounds.

Underlying direct answer ...
without context: Middle; *with context*: ProbYes

---

t_{-3}, A: So, uh, you know, you need to go to a school that handles whatever it is you want to do.
t_{-2}, B: Yeah. Where did you go to school?
t_{-1}, A: Uh, University of Mississippi.
t_0, B: *Oh. Was that local*
t_1, A: *Uh, well, it was, well, within the state.*
t_2, B: Uh huh.
t_3, A: But it, it was not necessarily local.

Underlying direct answer ...
without context: Yes; *with context*: No

Table 2: Examples of yes-no questions (t_0) with indirect answers (t_1). Determining the underlying direct answers requires taking into account more conversation context than the question and indirect answer: the ground truth annotated by humans changes depending on whether they also have access to context (t_{-3}, t_{-2}, t_{-1}, t_2, and t_3).

lying direct answer of a yes-no question (t_0; t_2 is also a yes-no question). Given t_1 alone, annotators selected *Probably Yes* as there is some uncertainty about what *same thing* refers to. The following two turns (t_2, t_3) make it clear that the underlying direct answer is *Yes*. This example also shows how context *before* the yes-no question (t_{-2}) is sometimes beneficial. The fourth example (bottom right) shows how context can flip the underlying direct answer. The definition of *local* is open to discussion (Is anything within the state local?), but after reading the t_3 it is clear that according to Speaker A the university he went to is not local.

Which turns around a yes-no question are the most important? We show which turns annotators selected as useful to determine the underlying direct answers in Figure 4. Unsurprisingly, the turn immediately after the yes-no question (after$_1$) is almost always useful (96.4%). The next turns by either speaker are often useful, including the follow-up turn by the speaker asking the yes-no question (after$_2$, 20.9%). The turns before the yes-no question (prev$_3$–prev$_1$) are less often important. We also found that the turn *before* the yes-no question is the most useful (prev$_1$, 12.5%) out of all the turns before the question.

Note that annotators almost always (96.4%) deem useful the turn immediately following the question (after$_1$, the indirect answer). This indicates that the indirect answer is rarely an interjection or filler (e.g., *Uhm*, *Really?*). Additionally, annotators selected at least one of the other turns in the context in 50% of questions, indicating that it is often the case that at least two turns are beneficial to determine the underlying direct answer.

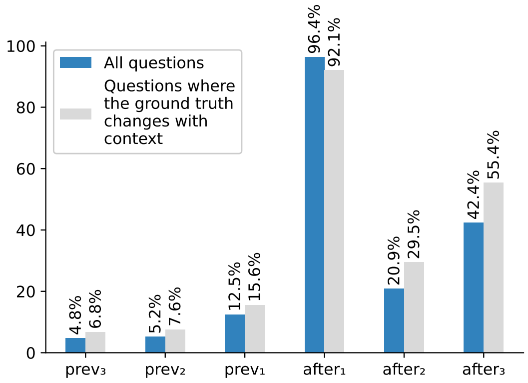

Figure 4: Percentage of times annotators rely in the context to determine the underlying direct answer to a yes-no question (three turns before and after; after$_1$ refers to the indirect answer).

5 Experiments and Discussion

We split SwDA-IA into training, development and test splits (70/15/15) randomly but making sure no split contains yes-no questions from the same conversation. We consider each conversation snippet (yes-no question, three turns before, and three turns after) an instance, and build models to predict the underlying direct answer. Following previous work on (short) text classification and specifically on the same task with synthetic data (Louis et al., 2020), we build transformer-based classifiers fine-tuned using several strategies. We experimented with three transformers: BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), and TOD-BERT (Wu et al., 2020) released by HuggingFace (Wolf et al., 2020). Note that the first two are pretrained with general-purpose English while the third is fine-tuned for task-oriented dialogues and includes an attention mechanism designed to keep track of dialogues. While the three transformers obtained roughly the same results (within 0.02 F1), RoBERTa outperformed the other two and we only report results with RoBERTa.

The ground truth depends on context beyond the yes-no question and indirect answer (Section 4). A RoBERTa-based classifier, however, may not benefit from context. In order to experiment with context, we conduct three types of experiments: feeding to the models (a) only the question and the turn immediately following the question (i.e., indirect answer), (b) the full context (i.e., seven turns), and (c) only the annotator-selected turns during the annotation process. We use a separator token to indicate a new turn in the input sequence.

Fine-Tuning RoBERTa We fine-tuned the RoBERTa-based classifier using corpora for related tasks and SwDA-IA, our corpus. Specifically, we used the following corpora in our experiments:

MNLI is a corpus for natural language inference (Williams et al., 2018). It contains premise-hypothesis pairs where the premise entails, is neutral with respect to, or contradicts the hypothesis. It contains 392k pairs for training, 9k for development, and 9k for test. The fine-tuned RoBERTa classifier obtains 83% development accuracy. Following Louis et al. (2020), we rewrite questions into declarative statements and map *entailment* to *Yes*, *neutral* to *Middle*, and *contradiction* to *No*.

BoolQ is a corpus for yes-no question answering (Clark et al., 2019). Questions were submitted to a search engine and Wikipedia articles containing and not containing the answer are included for each question. It contains 9.4k questions for training, 3.2k for development, and 3.2k for test. The fine-tuned RoBERTa classifier with BoolQ obtains 73% development accuracy. We map their *Yes* and *No* (correct and incorrect) to our *Yes* and *No*.

Circa is a corpus with yes-no questions and indirect answers (Louis et al., 2020). Unlike SwDA-IA, which includes questions and answers from real conversations, Circa collected questions and answers from crowdworkers who were given one of ten scenarios (Section 2). In other words, Circa does not include naturally occurring questions and answers. Additionally, Circa does not consider context as all answers are a single turn. Circa contains 3,431 yes-no questions and up to 10 indirect answers for each (total: 34,268 question-answer pairs). The fine-tuned RoBERTa classifier with Circa obtains 78% development accuracy. We map their *Middle* and *I am not sure* to our *Middle*.

Our Corpus: SWDA-IA We consider three versions of fine-tuning with our corpus: taking into account only the *Q*uestion, only the *A*nswer, or both (*QA*). Intuitively, the indirect answer should be the most useful to determine the underlying direct answer but the question may also help.

5.1 Results

Table 3 presents results fine-tuning with each corpus and the best performing combinations of two or more corpora. The supplementary materials provide results with all combinations and detailed results (P, R, and F1) for each label.

Training with the full context around the yes-no question (three turns before and three turns after) yields worse results than only training with the yes-no question and turn immediately after (top block vs. middle block). This may seem surprising, however, it is known that keeping track of a conversation across several turns is challenging (Kim et al., 2020). Regardless of whether the model considers context, we observe that MNLI does not transfer to our task (0.13 and 0.12 with and without context, lower than the majority baseline) and Circa is the most useful out of the three previous corpora (MNLI, BooLQ, and Circa; 0.32 and 0.27 F1).

Fine-tuning with combinations of previous corpora does not surpass the 0.32 F1 obtained with Circa. Fine-tuning with SwDA-IA, however, brings substantial improvements. In particular, fine-tuning with SWDA-IA_QA in addition to combinations of previous corpora yields statistically significant higher results (indicated with †; best: 0.46 F1).

These results lead to the conclusion that determining indirect answers to yes-no questions in real

Table 3: Results obtained with the test set. We present results with a RoBERTa-based classifier fine-tuned with two related corpora (MNLI, BoolQ), synthetic data for the same problem (Circa), and our corpus (SwDA-IA; only *Q*uestions, only *A*nswers, or both). We only show the best performing combinations; the supplementary materials provide all of them. We indicate statistical significance (McNemar's test (McNemar, 1947) with $p < 0.05$) as follows: ∗ with respect to the baseline, † with respect to the same fine-tuning except SwDA-IA, and ‡ with respect to the model with full context. Training with real conversation (SwDA-IA) is crucial.

conversation requires fine-tuning with real conversations, as F1 scores jump over 40% when doing so (without context: 0.32 vs. 0.46, with context: 0.28 vs. 0.43). Further, the task barely benefits from the synthetic examples in Circa, MNLI, or BoolQ (SwDA-IA_QA F1: 0.44 and 0.45, best model fine-tuning with additional corpora: 0.46 and 0.49).

Full vs. Annotator-Selected Context Since the ground truth depends on context (Section 2) and our model obtains worse results with full context, it is reasonable to conclude that our RoBERTa-based classifier is unable to extract the required information from context. The bottom block of Table 3, however, shows that context is not useless. Indeed, feeding only the conversation turns handpicked as useful by annotators (out of all the context we consider) brings statistically significant better results than feeding the full context. These results are unrealistic as they require manual annotations, but lead to the conclusion that models that better understand context are worth exploring.

5.1.1 Out-of-Domain Evaluation

In order to investigate whether models trained with SwDA-IA can determine underlying direct answers to yes-no questions from not only SwDA-IA (in-domain evaluation) but also other real conversations, we conducted an out-of-domain evaluation. Specifically, we annotated 200 yes-no questions from MRDA (Shriberg et al., 2004), a corpus of meeting transcripts, with the same procedure from Section 3. The results (Table 11 in the supple-

Long sentences
A: He is still living by himself in a little farmhouse. My grandmother died a couple of years ago. But he doesn't want to move away.
B: Uh huh.
A: And he recently had to have an operation but he just really doesn't want to go to a nursing home.
B: *Is he able to, uh, still do everything himself pretty well?*
A: *Well, he was until this operation. He has arthritis.*
B: Oh, yeah.
A: And now I don't really think he's doing that well. I have one aunt that really looks after him a lot.
Gold: ProbNo; *Predicted*: Yes

Explicit *yes* in context
A: Oh how neat.
B: So, she'd always dreamed of doing that too.
A: Yeah, that's great.
B: *So. Yeah. So is there any place you would talk me into?*
A: *Uh.*
B: It sounds like we've been to some of the same places.
Gold: Middle; *Predicted*: Yes

Negation in question or indirect Answer
A: They're not quite elderly, huh.
B: No. So I haven't, uh, really been in that situation although they are thinking about my grandmother but, uh
A: Uh huh.
B: *But that's really about it. How about you? Have you been in that situation yet?*
A: *Uh, no not for my parents.* I was around, uh, two sets of grandparents, uh, quite a bit.
B: Uh huh.
A: we, we put one, I put one grandfather in a rest home.
Gold: Yes; *Predicted*: No

Negation in context
A: Uh, I work out with free weights.
B: No, uh, I mean the running.
A: Oh, uh, yeah. It is really the, uh, aerobic work out part.
B: *You do it, you do a mile in about eight minutes or less?*
A: *Uh, about seven minutes.*
B: Uh huh. Yeah. Then you don't get, uh, out of breath.
A: Uh,no I do.
Gold: Yes; *Predicted*: No

Table 4: Examples of the most frequent error types by the best model. The yes-no question and indirect answer are in italics. We show context as shown to annotators during the corpus creation process.

mentary materials) show (unsurprisingly) worse results across all models. Interestingly, the results also show a similar trend than the in-domain evaluation: (a) SwDA-IA_QA is crucial and transfer learning with other corpora yields small benefits, and (b) annotator-selected corpus is beneficial.

6 Error Analysis

We conduct a manual qualitative analysis of 200 errors made by our best model (second row from the bottom in Table 3). This analysis sheds lights into what kind of yes-no questions, indirect answers, and context are the hardest. Table 12 in the supplementary materials presents the most common error types, and Table 4 presents examples.

We observe **long sentences** (over 20 tokens) in most errors (62.18%). It is worth noting that long sentences do not lead to many catastrophic mistakes: only 3.80% are between *Probably No* and *Yes*, 3.80% between *Yes* and *No* and 2.37% between *Yes* and *Probably No*. If **context contains a *yes* token**, the model almost always predicts *Yes*. This accounts for 19.46% of errors. As exemplified in the bottom left example in Table 4, this error occurs even if the *yes* token is before the yes-no question. We also observed **negation** in many errors. 11.08% of errors occur when there is a negation in either the question or the turn after (i.e., the turn after the question), and 7.28% when the negation is elsewhere in the context. In this case, the model predicts either *No* or *Probably No* although the gold label is *Yes*—likely because it (wrongly) learned that negation always indicates a *No* direct answer. The top and bottom right examples in Table 4 show errors that contain a negation in context.

7 Conclusions

Yes-no questions with indirect answers are common in real conversations—77.4% of 5-minute phone conversations include at least one. In this paper, we investigate the underlying direct answers to such questions in real conversations.

We have presented SwDA-IA, the first corpus with annotations for this task on top of real conversations. We show that determining the underlying direct answer requires taking into account context, as the ground truth changes depending on whether we show annotators context around the question. Our analysis also shows that context after the question is more useful, including turns by both the author of the question and the other speaker. Experimental results demonstrate that solving the task with real conversations is challenging (F1: 0.46). More importantly, (a) doing so barely benefits from fine-tuning with related tasks (MNLI and BoolQ) and (b) Circa, a corpus of synthetic questions and synthetic indirect answers, barely outperforms the majority baseline with real conversations.

Our future plans include designing models that better encode conversational context in order to obtain better results. We are also interested in exploring applications in dialogue systems to avoid inconsistencies due to misunderstandings of indirect answers to yes-no questions.

A Supplementary Materials

A.1 Collecting Yes-No Questions with Indirect Answers

Dialogue acts to select yes-no questions The process to collect yes-no questions from SwDA uses dialogue act annotations (Section 3.1). Here is the full list of dialogue acts we consider and their descriptions:

- `qh`: Rhetorical Questions
- `qy`: Yes-No question
- `qy∧d`: Declarative Yes-No question
- `∧g`: Tag-Question
- `qy∧t`: Yes-No question about task
- `qy∧r`: Yes-No question repeat self
- `qy∧m`: Yes-No question mimic other
- `qy∧h`: Question in response to a question
- `qy∧c`: Yes-No question about communication
- `qy∧2`: Yes-No question collaborative completion
- `qy(∧q)`: Yes-No question quoted material
- `qy∧g`: Yes-No question tag-question

- `qy∧g∧t`: Yes-No question tag-question about task
- `qy∧g∧r`: Yes-No question tag-question repeat self
- `qy∧g∧c`: Yes-No question tag-question about communication
- `qy∧d∧t`: Declarative Yes-No question about task
- `qy∧d∧r`: Declarative Yes-No question repeat self
- `qy∧d∧m`: Declarative Yes-No question mimic other
- `qy∧d∧h`: Declarative Yes-No question in response to a question
- `qy∧d∧c`: Declarative Yes-No question about communication
- `qy∧d(∧q)`: Declarative Yes-No question quoted material
- `qy∧c∧r`: Yes-No question about-communication repeat self

Dialogue acts to discard yes-no questions with indirect answers We also use dialogue acts to discard yes-no questions with indirect answers (Section 3.1). Here is the full list of dialogue acts we consider and their descriptions:

- `ny`: Yes answers
- `nn`: No answers
- `ny∧r`: Yes answers repeat self
- `nn∧r`: No answers repeat self
- `b`: Acknowledge (Backchannel)
- `br`: Signal-non-understanding
- `x`: Non-verbal
- `aa`: Agree/Accept

Analyzing Yes-No Questions with Indirect Answers The yes-no questions with indirect answers in SwDA-IA have an average length of 39 tokens. 41.4% of the questions are indirect, i.e., do not contain a question mark despite they are yes-no questions. For example, *You must be the supervisor in this office.* is an indirect yes-no question. Figure 5 displays the most salient tokens in the yes-no questions and indirect answers. Finally, the most common first tokens in the questions are as follows:

- *Do*: 8%
- *Well*: 5%
- *Is*: 4%
- *You*: 3.9%
- *So*: 3.8%
- *And*: 3%

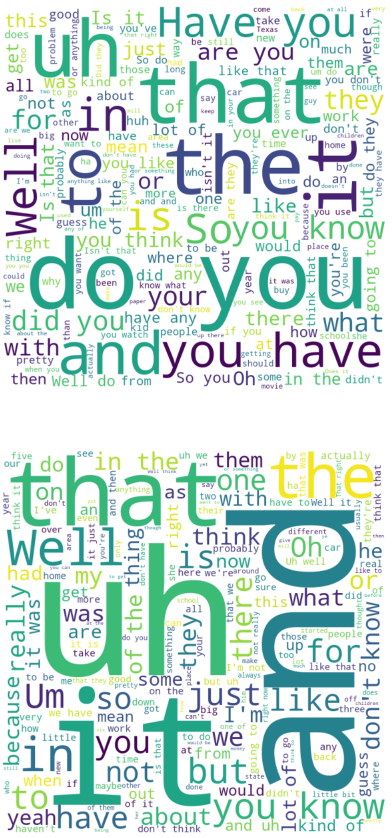

Figure 5: Word cloud displaying the most salient tokens of the yes-no questions (top) and indirect answers (bottom) in SwDA-IA.

- *Did*: 2.7%
- *Are*: 2.3%
- *Do*: 2.1%
- *Have*: 1.4%

A.2 Corpus Analysis: Context and Underlying Direct Answers

A.3 Experiments and Discussion

Tables 7–10 presents additional results complementing the results in Table 3 of the main paper. Table 11 presents the detailed out-of-domain evaluation (Section 5.1.1 in the main paper).

For all the models, we tuned the learning rate (values 5e-5, 3e-5, 2e-5), number of epochs (2, 3, 4), and batch size (16, 32) in an exhaustive combination of these parameters. Table 6 presents the hyperparameter settings with best performance on the development set fine-tuned with RoBERTa and no context.

A.4 Error Analysis

Table 12 presents the most common error types by our best model. This table complements Section 6 in the main paper.

t_{-3}, A: really
t_{-2}, B: But she started it
t_{-1}, A: That's good
t_0, B: *Well, she was depressed to begin with right?*
t_1, A: *That's one way to see it*
t_2, B: Yeah.
t_3, A: But, she also might be really calm.

Underlying direct answer …
without context: Yes; *with context*: Middle

t_{-3}, A: I like to see you drive through Burger King now and the bags are recycled paper
t_{-2}, B: Uh huh.
t_{-1}, A: I feel like people are more aware of it or becoming more aware of it
t_0, B: *do you like to buy more recycled item*
t_1, A: *I'm not as good about searching something out like that*
t_2, B: oh really.
t_3, A: but I have been reading a lot about it

Underlying direct answer …
without context: No; *with context*: Middle

Table 5: Examples of yes-no questions (t_0) with indirect answers (t_1). Determining the underlying direct answers requires taking into account more conversation context than the question and indirect answer: the ground truth annotated by humans changes depending on whether they also have access to context (t_{-3}, t_{-2}, t_{-1}, t_2, and t_3). This examples complement Table 2 in the main paper with additional examples of less frequent label changes.

Table 7: Results obtained with the test set. These results complement Table 3 in the main paper (Table 3 is subsumed by this one). We indicate statistical significance (McNemar's test (McNemar, 1947) with $p < 0.05$) as follows: $*$ indicates better results with respect to the baseline, † with respect to the same fine-tuning except SwDA-IA, and ‡ with respect to the model with full context. Training with real conversation (SwDA-IA) is crucial, and annotator-selected context yields the best results.

Abstract

When a neural language model (LM) is adapted to perform a new task, what aspects of the task predict the eventual performance of the model? In NLP, systematic features of LM *generalization* to individual examples are well characterized, but systematic aspects of LM *adaptability* to new tasks are not nearly as well understood. We present a large-scale empirical study of the features and limits of LM adaptability using a new benchmark, TASKBENCH500, built from 500 procedurally generated sequence modeling tasks. These tasks combine core aspects of language processing, including lexical semantics, sequence processing, memorization, logical reasoning, and world knowledge. Using TASKBENCH500, we evaluate three facets of adaptability, finding that: (1) adaptation procedures differ dramatically in their ability to memorize small datasets; (2) within a subset of task types, adaptation procedures exhibit *compositional adaptability* to complex tasks; and (3) failure to match training label distributions is explained by mismatches in the intrinsic difficulty of predicting individual labels. Our experiments show that adaptability to new tasks, like generalization to new examples, can be systematically described and understood, and we conclude with a discussion of additional aspects of adaptability that could be studied using the new benchmark.

1 Introduction

Much of the recent research effort in NLP has shifted from training task-specific models to *adapting* pre-trained language models (LMs) by fine-tuning their parameters or input prompts for downstream tasks (Devlin et al., 2019; Raffel et al., 2020; Li and Liang, 2021; Lester et al., 2021). This paradigm is general, in the sense that a large number of distinct NLP tasks benefit from pre-training (Peters et al., 2018; Devlin et al., 2019; Raffel et al., 2020). But many questions about the nature and limits of LM adaptation remain unanswered. For example: given a new task, can we predict how quickly (and how effectively) pre-trained LMs can be adapted to perform it? From among the variety of different adaptation techniques (e.g. fine-tuning or prompt-tuning), can we predict which one will be most effective? Today, new pre-training and adaptation schemes are evaluated using small suites of curated tasks, typically featuring classification, textual inference, and question answering (Wang et al., 2018, 2019). These benchmarks have been extremely successful in identifying new tools for adaptation, but they are poorly suited for answering larger, structural questions like the ones above.

We present a large-scale study of LM adaptability using a new suite of benchmark tasks called TASKBENCH500.[1] TASKBENCH500 consists of 500 **procedurally generated** tasks involving lexical semantics, factual information, memorization of random relations, list processing, and logical composition (Fig. 1). Analogous to past work that uses synthetic data to characterize LM performance on single examples (Weston et al., 2016; Lake and Baroni, 2018; Saxton et al., 2019; Kim and Linzen, 2020; Keysers et al., 2020; Liu et al., 2021a), TASKBENCH500 enables systematic study of LM adaptability at the task level. In this paper, we use it to study three aspects of adaptability:

Memorization: When can adaptation successfully memorize new functions (e.g., to update factual knowledge about entities, or learn arbitrary new token correspondences)? We find that **LMs' ability to memorize new input–output mappings is strongly influenced by task type**. Datasets of lexical relations (like antonym pairs) are easier to memorize than factual information (like name–occupation pairs). Both are easier to memorize than lists of random word pairs. These findings are particularly striking in the case of prompt tun-

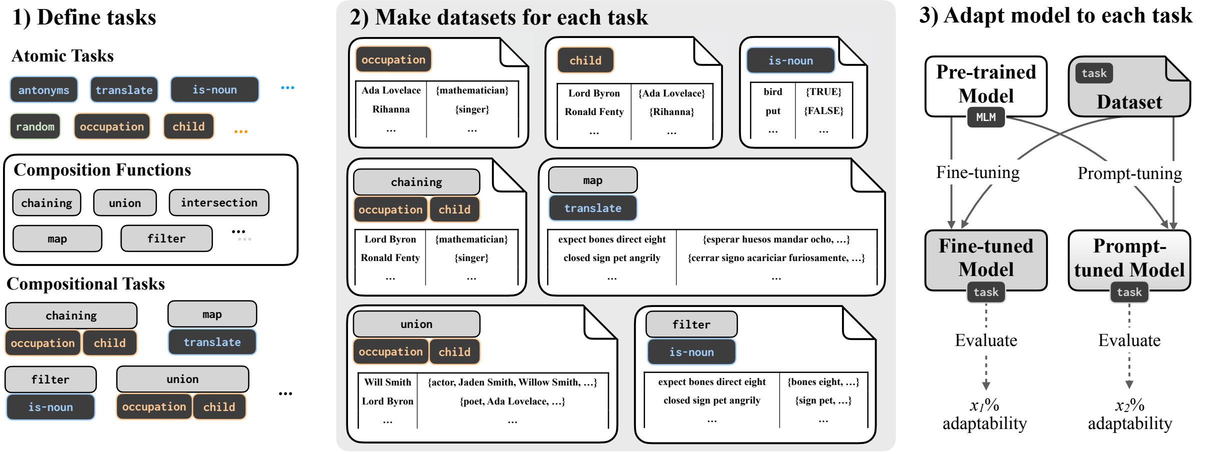

Figure 1: Overview of our task creation process. We begin by defining a set of atomic tasks that all synthetic tasks are built upon. These include lexical tasks (blue text/outline), random tasks (green text/outline), and factual tasks (orange text/outline). They also include both predicates and relations. These tasks are combined using composition functions to form more complex, compositional tasks. Given a particular task specification, we synthetically create a dataset for each task. Finally, we fine-tune or prompt-tune a pre-trained language model on each task dataset.

ing, which in standard configurations struggles to memorize even small random word pair lists.

Composition: Is LM performance on simple tasks predictive of their performance on compositions of those tasks? (If the *father* and *occupation* relations are easy to learn via adaptation, does this imply that the *father's occupation* relation is also easy to learn?) We find a nuanced answer. **LMs exhibit compositional adaptation** to lexical and factual relations (like *father's occupation*), with success on composed tasks strongly correlated ($r^2 > 0.5$) with success on atomic tasks. However, when composing these relations with sequence processing operations, success on the base task does not predict success on the composed task.

Distribution matching: In models fine-tuned on datasets exhibiting a distribution of acceptable answers (e.g., translating ungendered pronouns into gendered ones), do model predictions match these distributions? We find that **LMs are often unable to match label distributions in datasets used for adaptation**. In particular, when labels in the fine-tuning dataset are drawn from a uniform mixture of labels from two tasks (e.g., labeling half of the words with their *antonym* and half with their *synonym*), models disproportionately assign mass to labels from the task that is easier to learn.

Each of these forms of adaptability corresponds to a central challenge in NLP: reliable updating of deployed models, composition of previously learned skills, and fair and predictable output from models trained on curated data. Our study of memorization, composition, and distribution matching have direct analogs to previous studies of sample expressivity (Zhang et al., 2017), compositional generalization (Lake and Baroni, 2018; Kim and Linzen, 2020; Keysers et al., 2020), and calibration (Guo et al., 2017). However, we study these phenomena at the task level, rather than the example level. Our experiments highlight important qualitative differences between current adaptation paradigms; identify several novel challenges for LM adaptation, and offer a new benchmark for approaches aimed at meeting these challenges.

2 Background

Fine-tuning and prompt search In languages for which large digitized corpora are available, most NLP system development today involves *adaptation* of a pre-trained model to a downstream task of interest. Pre-training typically involves reconstruction of masked or corrupted text sampled from a large corpus (Devlin et al., 2019; Liu et al., 2019; Raffel et al., 2020). Adaptation to a new task typically involves one of three approaches: (1) **fine-tuning** of all of a pre-trained model's parameters (possibly in conjunction with a specialized decoder) on a task-specific training set (Devlin et al., 2019); (2) manual **prompt engineering** of an input template that induces pre-trained model predictions to perform the task of interest (Brown et al., 2020; Petroni et al., 2019); or (3) automated **prompt tuning** of these templates, in either the discrete space of tokens (Shin et al., 2020) or continuous space of token embeddings (Li and Liang, 2021; Lester et al., 2021; Liu et al., 2021b). The latter two approaches have grown more popular as pre-trained models have grown larger. The performance of both prompt-search approaches still lags fine-tuning (Raffel et al., 2020; Brown et al., 2020; Lester et al., 2021), though the difference between approaches appears to shrink as model size increases (Lester et al., 2021).

Measuring generalization and adaptability The success of the training paradigm described above stems from its generality—a large number of NLP tasks appear to benefit from some combination of pre-training and adaptation. Previous attempts to *quantify* this generality have typically relied on benchmarks like GLUE (Wang et al., 2018) and SuperGLUE (Wang et al., 2019), each of which aggregates ten natural language processing tasks designed to probe different aspects of language understanding. Similar benchmarks have also been built for non-English languages (Xu et al., 2020; Kakwani et al., 2020; Park et al., 2021; Hu et al., 2020). However, the heterogeneity and small number of distinct tasks represented in existing benchmarks makes it difficult to make finer-grained predictions, e.g. by identifying specific features of tasks that contribute to the success or failure of adaptation.

This challenge has a direct analog to the problem of characterizing *generalization* at the example level in models trained for a single task. Model performance on natural test sets is often loosely correlated with accuracy on individual examples featuring rare syntactic constructions or word collocations (McCoy et al., 2019). A great deal of past work has focused on improving evaluation using synthetic evaluation sets (Jia and Liang, 2017; Naik et al., 2018; Lake and Baroni, 2018; Richardson et al., 2020). These datasets have been used to study long-range agreement (Marvin and Linzen, 2018), compositional generalization (Lake and Baroni, 2018; Ruis et al., 2020; Keysers et al., 2020), and mathematical reasoning (Saxton et al., 2019). But no analogous notion of systematicity, or tool for studying it, currently exists for tasks rather than examples.

Thus, building on this past work, we describe how to construct synthetic data distributions that enable systematic study of *adaptation to new tasks* rather than *generalization to new examples*. Like previous research that uses procedural data generation procedures to study models in NLP, we focus on coverage rather than naturalness, using datasets designed to complement, rather than replace, existing naturalistic benchmarks.

3 A 500-task benchmark

Our goal is to study the generalizability of task adaptation paradigms. In particular, we would like to identify which attributes of a task make it easy or difficult to learn, across different models and training schemes. While this work shares many of its high-level goals with existing benchmarks built from collections of real-world datasets, the makeup and difficulty of these datasets is often difficult to characterize precisely: differences in annotation standards, annotation quality, and dataset size mean that models often exhibit very different performance on datasets designed to evaluate model performance on the same abstract task. In addition, existing datasets cover an exceedingly small subset of the space of all tasks that future NLP practitioners might wish to perform. To account for all these limitations, we propose to generate tasks *synthetically* as described below.

The space of tasks TASKBENCH500 is constructed compositionally: we begin by defining a space of **atomic tasks**, which are combined using a set of **composition operators** to produce more complex tasks. Every task takes as input a word or word sequence, and outputs either a boolean value or a set of words/word sequences. We refer to any task that outputs booleans as a **predicate task**, and any task that outputs sets of words or word sequences as a **relation task**. A subset of relation tasks involve modeling relations between single words at the input and output; we refer to these as **word-level** tasks and the remaining relation tasks (that take sequences as input or output) as **sequential tasks**.

The choice of atomic tasks and composition functions aims to capture aspects of real language processing tasks. Accordingly, the set of atomic tasks comprises of:

1. **Lexical tasks**, which test knowledge of lexical semantics. These include *lexical relations* like `synonym`, or *lexical predicates* like `is-noun`. These tasks are constructed from WordNet relations (Fellbaum, 1998).

2. **Factual tasks**, which test factual knowledge. These include *factual relations* like `father-of`, or *factual predicates* like

`is-human`. These tasks are constructed from Wikidata properties (Vrandečić and Krötzsch, 2014).

3. **Random relation tasks**, which test memorization ability. These are created by mapping a word in the vocabulary to a singleton set containing a random other word. We create 4 random relations with different random seeds.

To recursively create arbitrarily complex tasks, we define a set of *composition functions*. These take tasks as arguments and return other tasks. These functions fall into two categories:

1. **Word-level compositions**, which test ability to combine word-level information in different ways, such as through set or logical operations. These functions take word-level tasks and return other word-level tasks. Examples include `intersection` and `chaining`.

2. **Sequential compositions**, which test ability to operate on sequences. These functions convert word-level tasks to sequence-level tasks. There are two functions in this category: `map` takes a word-level relation task and returns a task that maps a sequence of n words to a set of all possible sequences resulting from applying f_W to each input word.[2] `filter` takes word-level predicate tasks and returns a sequence consisting only of words for which the task returns `true`, preserving the original ordering of those words.

The full list of atomic tasks and composition function can be found in Appendix Tables 4 and 5. We surmise that typical NLP tasks may require some combination of lexical knowledge, factual knowledge, sequential processing, and other task-specific reasoning; our data distribution lets us evaluate all these aspects separately and in combination.

Datasets for tasks We create datasets $\mathcal{D}(f) = \{(x_i, y_i) : x \sim \mathcal{X}_f, y \sim \text{Unif}(f(x_i))\}$ for each task f, where $\mathcal{X}_f$ is the input distribution for the task, and recalling that $f(x_i)$ returns a *set* of possible outputs associated with the input x_i. For all tasks, we randomly partition the dataset into $\mathcal{D}_{\text{train}}(f)$ and $\mathcal{D}_{\text{test}}(f)$ splits.

For *lexical atomic tasks* and their compositions, we directly use the most common words in the task's input language for $\mathcal{X}_f$. We create tasks in English and Spanish. For *factual atomic tasks* and their compositions, we sample the entities from Wikidata that participate in the relation or predicate defined by the task (e.g. for the `child-of` task, we sample only entities that have children). For *sequential tasks*, we use a random sampler, which samples n random words from the vocabulary and concatenates them.

Figure 1 shows examples of tasks and associated datasets. More details on dataset construction can be found in Appendix A.

4 Experimental Setup

Model & Training For all experiments, we adapt a pre-trained T5-base model (Raffel et al., 2020). We examine two types of training paradigms: fine-tuning and prompt-tuning. During fine-tuning, we update all model parameters on the training set. During prompt-tuning, we follow Lester et al. (2021) and introduce a new set of prompt-tokens $\{p_1, \cdots, p_n\}$ to the vocabulary, which will be prepended to every sample from the task during inference, i.e., each sample input x becomes $p_1 p_2 \cdots p_n x$. Let $\boldsymbol{\theta}$ denote the parameters of the original pretrained LM. During training, the entire model is frozen and only the word embeddings of the new tokens $\{\theta_{p_1}, \cdots, \theta_{p_n}\} \subset \boldsymbol{\theta}$ are updated. We use prompts of length $n = 100$ for all experiments. We also study each paradigm on various quantities of training data, and separately evaluate their memorization and generalization adaptabilities. In particular, for word-level tasks the test-set words are disjoint from the train-set words, so evaluating on the test set will strictly measure generalization capacity. We optimize all models using AdamW. See Appendix B for full hyperparameters.

Evaluation For each task f and model $\mathcal{M}[\boldsymbol{\theta}]$ (with parameters $\boldsymbol{\theta}$), we measure the model's average per-token accuracy on both training and test splits of the dataset $\mathcal{D}(f)$. As each task defines multiple acceptable outputs for each input, we credit models for producing any acceptable output. Letting $y' = \mathcal{M}(x)$, we measure the fraction of positions i at which any valid answer y_i matches the

---

[2] Note word-level relations return *sets* of words—we turn a sequence of sets of words into a set of sequences by considering all combinations of words in each set.

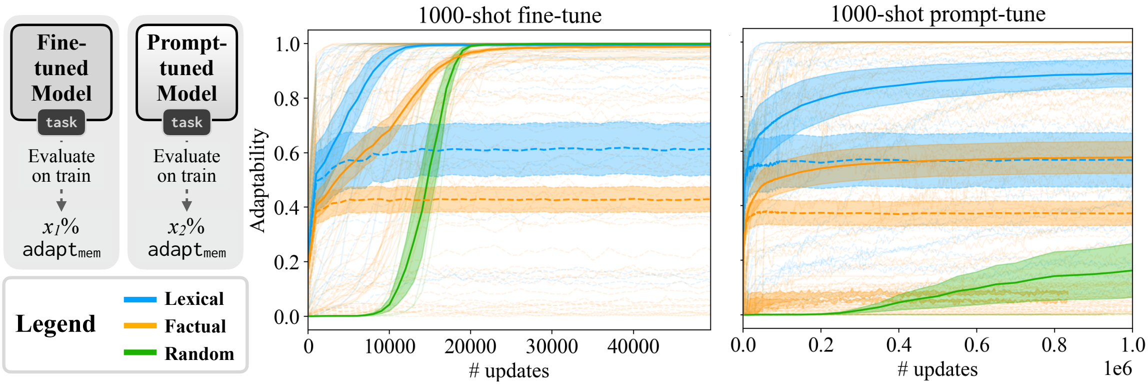

Figure 2: Left: Overview of the memorization experiment, which evaluates how accurately models adapted via fine-tuning and prompt-tuning can memorize training data. Right: Memorization and generalization curves for fine-tuning and prompt-tuning on 1000 training examples. Memorization curves are shown by solid lines, while generalization curves are dashed. We average over all atomic tasks from each task category: lexical tasks, factual tasks, and random tasks. The shaded region shows the standard error of the mean. Transparent lines are each individual task, colored by task category. In both paradigms, lexical tasks are easiest to memorize, followed by factual tasks, then random tasks. However, prompt-tuning has overall much less memorization capacity than fine-tuning, which can perfectly memorize even completely random relations.

predicted y_i':

$$\begin{aligned}&\texttt{acc}(\mathcal{M}, \mathcal{D}(f)) = \\ &\quad \max_{y \in f(x)} \frac{1}{|\mathcal{D}|} \sum_{(x,y)\in\mathcal{D}} \left(\frac{1}{n} \sum_{i=1}^{n} [\![y_i = y_i']\!] \right) \qquad (1)\end{aligned}$$

Further details can be found in Appendix B.

Given a pretrained model $\mathcal{M}[\boldsymbol{\theta}_{\texttt{pretrain}}]$, an adaptation procedure $\mathcal{T}$, and a task suite f, let $\mathcal{M}[\boldsymbol{\theta}_{\mathcal{T},\mathcal{D}(f)}]$ denote the model trained using $\mathcal{T}$ on training data $\mathcal{D}(f)$. We then define the *adaptability* of a (pretrained model, adaptation paradigm, task suite) as:

$$\begin{aligned}&\texttt{adapt}(\mathcal{M}[\boldsymbol{\theta}_{\texttt{pretrain}}], \mathcal{T}, f) \\ &\qquad = \texttt{acc}(\mathcal{M}[\boldsymbol{\theta}_{\mathcal{T},\mathcal{D}_{\text{train}}(f)}], \mathcal{D}_{\text{eval}}(f)) \qquad (2)\end{aligned}$$

We denote by $\texttt{adapt}_{\text{mem}}$ the value of this metric over training data ($\mathcal{D}_{\text{eval}} = \mathcal{D}_{\text{train}}$), and by $\texttt{adapt}_{\text{gen}}$ the metric over test data ($\mathcal{D}_{\text{eval}} = \mathcal{D}_{\text{test}}$).

5 Memorizing datasets

Our first experiment investigates the extent to which task adaptation paradigms can memorize different types of tasks. We are interested in memorization because many real NLP tasks involve some degree of memorization. For example, translation builds on memorizing lexical associations between words in various languages, and semantic similarity and paraphrasing require memorizing word meanings and/or groupings of semantically similar words.

Method We use training-set adaptability ($\texttt{adapt}_{\text{mem}}$) as an indicator of a model's memorization ability (Fig. 2). We train on a set of 1000 examples, and plot the value of Eq. (2) on each *atomic* task as models are adapted via fine-tuning or prompt-tuning. This allows us to visualize both the final training-set performance, as well as the time it took to achieve that performance, both of which we use to quantify memorization ability.

Results Figure 2 shows the training curves for fine-tuning (left) and prompt-tuning (right), on different types of tasks. Solid lines show $\texttt{adapt}_{\text{mem}}$, while dashed lines show $\texttt{adapt}_{\text{gen}}$.

Under both adaptation paradigms, we find that lexical tasks are easier to memorize than factual tasks, while random tasks are the hardest to memorize. However, for fine-tuning, we find that models can (eventually) learn to perfectly memorize all types of tasks—even entirely random word associations. However, different types of tasks converge at different rates—lexical tasks converge first, followed by factual tasks, followed by random tasks.

Prompt-tuning, with many fewer parameters than fine-tuning, is much less expressive. As shown in Fig. 2, none of the tasks types converge to 100% accuracy across tasks. Prompt-tuning overall also takes significantly longer to converge; in particular, on random tasks, the finetuned model generally converges at ∼20k updates, while the prompt-tuned model takes over 200k updates to even begin performing nontrivially.

	Atomic	Word-level Comp	Seq Comp
FFT	$46.9_{\pm 4.0}$	$39.5_{\pm 2.1}$	$21.5_{\pm 1.9}$
FPT	$42.6_{\pm 4.3}$	$28.1_{\pm 2.4}$	$11.5_{\pm 1.4}$
32FT	$33.6_{\pm 3.8}$	$22.2_{\pm 1.8}$	$5.7_{\pm 0.9}$
32PT	$32.4_{\pm 3.6}$	$21.7_{\pm 1.7}$	$6.9_{\pm 1.1}$

Table 1: Model (generalization) adaptabilities to atomic, word-level compositional, and sequential compositional tasks, under full fine-tuning (FFT), full prompt-tuning (FPT), 32-shot fine-tuning (32FT) and 32-shot prompt-tuning (32PT). Prompt-tuned models are comparable to fine-tuned models for atomic tasks, but not for compositional tasks. However, this distinction disappears under few-shot learning.

However, despite being much worse at memorization, prompt-tuned models still generalize almost as well as fully fine-tuned models, at least on atomic tasks. This suggests that the inability to memorize arbitrary functions is not necessarily a problem for prompt-tuning in general, and more broadly that overfitting the training set—at least during fine-tuning—may not be necessary for generalization.

In Appendix E, we run a version of this experiment on *permuted* task labels in order to better disentangle the effect of learning novel tasks vs. retrieving existing ones. We find that, for both prompt-tuning and fine-tuning, pre-trained models can more easily adapt to existing relations than to novel (permuted) ones, but they are still *able* to adapt to new tasks, especially compared to non-pre-trained models.

6 Composing tasks

In the previous section, we found that while prompt-tuning cannot memorize arbitrary tasks like fine-tuning, it can still generalize well on simple atomic tasks, almost comparably to fine-tuning. In this section we investigate whether this finding extends to more complex tasks. Specifically, we examine the behavior of prompt-tuned and fine-tuned models when adapted to *compositions* of atomic tasks.

Many prior studies of compositionality focus on *instance-level* compositionality (Lake and Baroni, 2018; Keysers et al., 2020): they test whether models can generalize to new instances by combining information from previously-seen instances *within the same task*. For example, Lake and Baroni (2018) study whether models can learn to *jump left*, after learning to *jump*, *run*, and *run left*. In our work, we instead focus on *task-level* compositionality, studying whether models can adapt to new *tasks* that are compositions of simpler tasks on which they are known to perform well. Thus, while a model exhibiting *compositional generalization* will correctly compose fragments of previously observed training examples, a training procedure exhibiting *compositional adaptability* will perform well on tasks involving compositions of previously learned skills.

Method We study adaptation to complex tasks by relating performance on *atomic* tasks with performance on *depth-2 compositional tasks*. We also study each paradigm under few-shot learning, by creating a random 32-sample subset of each training dataset, and training on that subset. To mitigate the effect of the random seed, we report average performance over 4 different subsets.

What allows models to adapt to these complex tasks? We hypothesize that their adaptability is (in part) compositional—when they can adapt to simple tasks, they can also adapt to compositions of those tasks. For each training paradigm $\mathcal{T}$ and each composition function C, we run linear regression to estimate the Pearson correlation coefficient r^2 between adaptability to a compositional task $C(f_1, \cdots f_n)$,

$$\texttt{adapt}_{\text{gen}}(\mathcal{M}, \mathcal{T}, C(f_1, \cdots, f_n)), \tag{3}$$

and *average* adaptability to the task's atomic components,

$$\frac{1}{n}\sum_{i=1}^{n} \texttt{adapt}_{\text{gen}}(\mathcal{M}, \mathcal{T}, f_i). \tag{4}$$

Figure 3 depicts the procedure graphically.[3]

Can language models learn compositional tasks? The average model adaptability to compositional and atomic tasks, under each training paradigm, is reported in Table 1. We observe that the gap between full-data prompt-tuned models and full-data fine-tuned ones is much larger on compositional tasks than atomic ones. Thus, prompt-tuned models can only generalize comparably to finetuned ones for sufficiently "simple" tasks.

Interestingly, this distinction disappears under few-shot learning. Though both adaptation paradigms generalize much worse in the few-shot

---

[3] We focus only on compositional functions C which have at least 20 compositional tasks $C(f_1, \cdots, f_n)$ in TaskBench500, so that we have at least 20 points to obtain a statistically significant correlation coefficient.

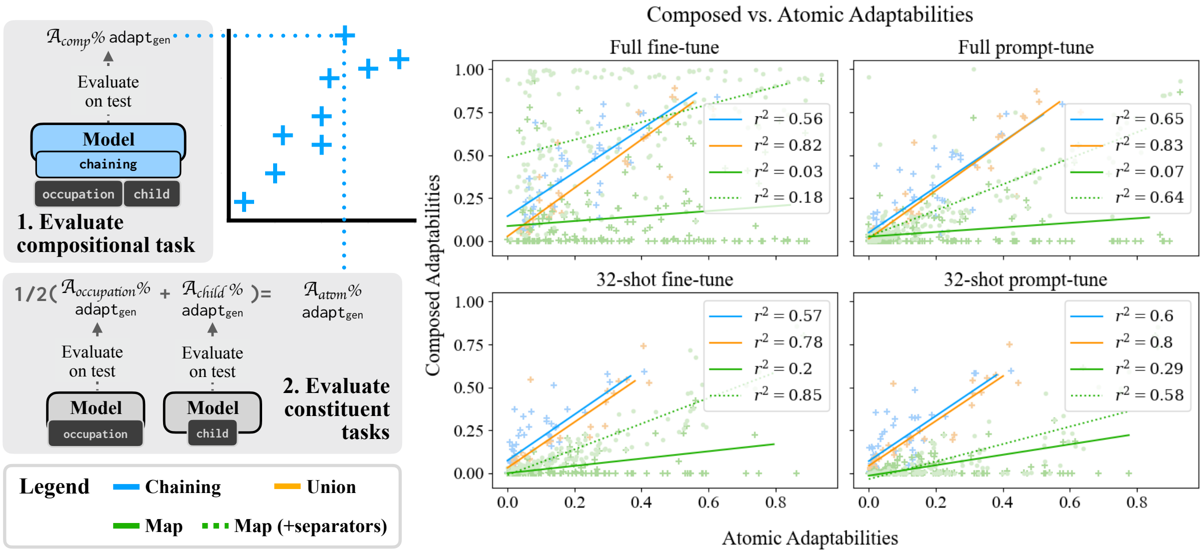

Figure 3: Left: Overview of the composition experiment. We evaluate how well the adaptability on a compositional task can be predicted by the (averaged) adaptabilities of the atomic constituent tasks. Right: Correlation between compositional adaptability vs. averaged atomic adaptabilities, for the chaining, union, and map composition types, under each training paradigm. On word-level chaining and union compositions, compositional adaptability is observed: composed task performance is highly correlated with atomic task performance ($r^2 > 0.5$) under all training paradigms. However, on sequential map compositions, all models perform poorly, and thus non-compositionally. This results from challenges in segmenting input sequences; if token boundaries are explicitly marked (map (+separators)), compositional adaptability is again observed.

setting compared to the full setting, they appear to be comparable to each other in the few-shot setting, even on compositional tasks. This may simply imply that few examples are insufficient to learn the nuances of complex tasks, and that simply learning a few prompt tokens is sufficient to capture what can be learned from the limited data samples.

Do language models adapt compositionally? We visualize each regression model in Fig. 3. Higher r^2 indicates higher correlation between atomic and compositional versions of tasks. Note that *all* model training paradigms demonstrate some degree of word-level compositionality ($r^2 > 0.5$)—when they succeed at word-level compositional tasks (`union`, `chaining`), they succeed at the atomic constituents to those tasks, and vice versa. However, this does not appear to be the case for sequential `map`. In the full-data regime, both fine-tuning and prompt-tuning have near-zero r^2 values. In the few-shot regime, the r^2 value, while nontrivial, is also quite low. Note the slopes of the learned regression lines—the model appears to be unable to learn the sequential versions of tasks, despite succeeding at their atomic versions. To explain this result, we hypothesize that a major obstacle to sequence-level compositional adaptability is *segmentation* of sequences into atomic units. This is especially the case for factual tasks: for example, the sequence `Pauline Payne Whitney Charles Lloyd` could be segmented as `[Pauline Payne Whitney] [Charles Lloyd]` or `[Pauline Payne] [Whitney Charles Lloyd]`, etc. To test whether segmentation is a bottleneck, we train on a version of sequential tasks where we give the language model *explicit* markers of word/entity boundaries (e.g. the language model is given `Pauline Payne Whitney # Charles Lloyd` as input). We found that, with separators, performance on the `map` tasks increases substantially and the model demonstrates compositional adaptability ($r^2 > 0.5$) to these tasks in 3 of the 4 adaptation paradigms. This setting is plotted in Fig. 3 as *Map (+separators)*.

Under this setting, full fine-tuning is the only training paradigm that does not demonstrate compositional adaptability. To better understand this phenomenon, we exclusively plot points from the *Map (+separators)* setting in Appendix Fig. 5. We find that the distribution of points in the full fine-tuning case shows that points tend to fall within the upper-left triangle. This indicates that for a significant number of tasks, *models adapt to their sequential versions despite failing at atomic versions.* In these cases, the model does not simply adapt com-

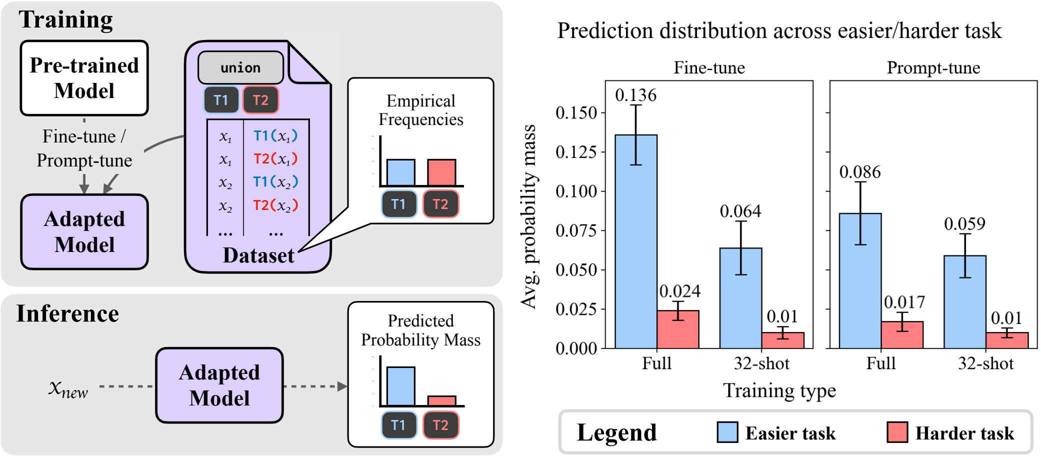

Figure 4: Left: Overview of the task prediction distribution experiments (Section 7). We train a model on a balanced dataset of two tasks, and check whether the prediction distribution over tasks on novel examples matches the (balanced) empirical distribution. Right: Probability mass, across all pairs of tasks, assigned to all answers corresponding to the easier vs. harder task, when trained on a balanced dataset and evaluated novel examples. We report the average across all task pairs and held-out examples, as well as standard errors for each task pair. Note that the model tends to assign more probability to the easier task, despite the task training set being balanced.

positionally, but can take advantage of additional information present in sequences (e.g., seeing more tokens, more examples of the word-level function) to outperform compositional adaptation.

7 Learning new distributions

Previous sections investigated the degree to which models could fit particular tasks using a binary metric that assigned credit to any acceptable answer. Our final set of experiments explores a finer-grained notion of correctness: when there are multiple acceptable answers, as is often the case in real NLP tasks, when does the output *distribution* of a model match the distribution empirically observed during adaptation?

Method We specifically investigate whether models are biased towards predicting “easy” labels, in the sense measured in Section 5. We consider all possible pairs of atomic tasks f_1, f_2 (for which f_1 and f_2 take in overlapping sets of inputs). Let f_e to be the easier task in this pair and f_h be the harder task, relative to a model $\mathcal{M}$ and training paradigm $\mathcal{T}$, in the sense that $\texttt{adapt}_{\text{gen}}(\mathcal{M}, \mathcal{T}, f_e) > \texttt{adapt}_{\text{gen}}(\mathcal{M}, \mathcal{T}, f_h)$. We compose f_e and f_h using *union* to create compositional task $\cup(f_e, f_h)$, and construct the training dataset for this task to be balanced — such that the model sees an equal number of examples of form $(x, f_e(x))$ as $(x, f_h(x))$. Now let $\mathcal{M}_{\cup(f_e,f_h)}$ denote a model adapted to this task. During test-time, we provide $\mathcal{M}_{\cup(f_e,f_h)}$ with novel inputs x' from the domain of both f_e and f_h, and record the average probability mass it assigns to all $y_e^i \in f_e(x')$ versus all $y_h^i \in f_h(x')$.[4] Finally, we average these dataset-wide probabilities over all pairs of tasks, to get an aggregated probability mass assigned to all easier tasks and all harder tasks in a task pair, invariant of the actual underlying task identity. More details on this procedure can be found in Appendix D.

Results Overall, as seen in Fig. 4, across all tasks and training paradigms, the model tends to assign a higher probability to the easier relation. As a concrete example, when trained to predict either antonyms or lexical entailments, the average probability mass placed on the antonyms of a word from the held-out set (easier relation) is 13%, while the average probability mass placed on the entailments of a word (harder relation) is 8%.

Thus, despite having a perfectly balanced fine-tuning set, pretrained models still predict label distributions in a way that align with their inductive biases (measured via the “intrinsic difficulty” of individual labels). This holds for all task adaptation methods, including full fine-tuning, meaning even paradigms and models that *can* fit more complex tasks still have residual biases from pretraining that affect their predictions. This also suggests wider-reaching consequences for model fairness

---

[4] Note that the model may (and often does) assign mass to answers outside of these sets.

and equity: simply debiasing a fine-tuning dataset is insufficient to overcome biases from pretraining.

8 Conclusion

In this paper, we construct TASKBENCH500, a synthetic task set which serves as a testbed for task adaptability. We focus on three axes of adaptability: ability to memorize, ability to (compositionally) generalize, and ability to fit to novel distributions. We study two adaptation paradigms: fine-tuning and prompt-tuning, finding that: 1. unlike fine-tuning, prompt-tuning cannot memorize completely arbitrary tasks beyond a small number of examples, 2. all adaptation paradigms demonstrate compositional adaptation to word-level compositions, but not sequence-level compositions, and 3. no paradigm is able to perfectly replicate the downstream distribution—all paradigms learn output distributions that align with its inductive biases.

In future work, TASKBENCH500 can be used to study other factors that may affect adaptability, such as length of the prompt in prompt-tuning, similarity between the task distribution and the pretraining distribution, or finer-grained distinctions between tasks (beyond lexical/factual/random, or composition type) that predict task adaptability. TASKBENCH500 can also be used to explore the limitations of *prompt engineering* on a GPT3-scale model. Finally, the current set of tasks and primitives in TASKBENCH500 are by no means complete. Future work can expand on these primitives and study the relationships between the tasks put forth here and real NLP tasks.

Impact Statement

This paper introduces a new procedure for defining task suites. This procedure is then used to create a 500-task benchmark, which measures the adaptability of pre-trained language models to new tasks. Because the benchmark is created procedurally from databases of words and entities, we anticipate that there should be little to no identifying information or toxic and hateful content. Our datasets should also contain less social bias compared to natural datasets.

However, like with all benchmarks, overfitting to static datasets can inhibit progress in NLP. Moreover, even though this dataset is procedurally generated, we cannot avoid all biases. The resources upon we build our benchmark are themselves biased—for example, lexical databases (like WordNet) are much richer for certain languages (like English) than others, and WikiData currently features many more men than women. Our benchmark currently only features English and Spanish tasks, with a heavy bias towards standard English. This can encourage development of methods that underserve non-standard-English-speaking communities.

We hope to mitigate the aforementioned issues by releasing the code to procedurally generate task suites. We emphasize that the benchmark is dynamic: consisting of not just the static task suite that we are currently releasing, but more importantly the procedure for creating new tasks suites. We encourage future researchers to develop analogous task suites for low-resource languages, non-standard English dialects, and more balanced sets of entities.

A More details on TASKBENCH500 creation procedure

A.1 Task creation details

For atomic lexical tasks, we take a subset of relations specified in either Wordnet (Fellbaum, 1998) or SentiWordNet (Esuli and Sebastiani, 2006). For atomic factual tasks, we take a subset of tasks from Wikidata (Vrandečić and Krötzsch, 2014). We also have 3 broad categories of composition functions: set operations, logical operations, and sequential operations. The full list of atomic tasks can be found in Table 4 and the list of composition functions can be found in Table 5.

We enumerate all possible depth-2 word level compositions of each task, and the sequential versions of them (i.e. if the task is a relation, inserting it into a `map`, or if the task is a predicate, inserting it into a `filter`), up to 500 tasks. We also apply some basic heuristics to filter identical tasks: for example, we filter symmetric relations, e.g. `union(B,A)` is identical to `union(A,B)`, or avoid the use of logical operations alongside set operations, e.g. `lor(in(x,A), in(x,B))` is identical to `in(x,union(A,B))`). Our full list of tasks can be found in Tables 4, 6, 7 and 8.

Sequential compositions Sequential composition functions convert word-wise tasks to sequence-level tasks. We specifically consider only two sequential functions: `map` and `filter`. Note that compositions of multiple `map`s or multiple `filter`s can instead be expressed as compositions of multiple word-level functions. For example,

$$\texttt{map}\{\lambda\texttt{x.occupation(x)}\}(\texttt{map}\{\lambda\texttt{x.}\ \texttt{father(x)}\}(\texttt{S}))$$

(for an input sequence `S`) is equivalent to

$$\texttt{map}\{\lambda\texttt{x.occupation(father(x))}\}(\texttt{S})$$

Specifically, we define the following top-level sequential operator

$$\begin{aligned}&\texttt{map-filter}\{f_M, f_F\}\\&\quad = \texttt{map}\{f_M\}(\texttt{filter}\{f_F\})\end{aligned} \tag{5}$$

where f_M is a word-wise relation and f_F is a word-wise predicate. All recursively-defined sequential operators follow this form. The following are the recursive rules for mapping nested maps and filters into a function of this form: in the base cases,

$$\begin{aligned}\texttt{map}\{f_M\} &= \texttt{map-filter}\{f_M, \lambda\texttt{x.true}\}\\ \texttt{filter}\{f_F\} &= \texttt{map-filter}\{\lambda\texttt{x.x}, f_F\};\end{aligned} \tag{6}$$

in the recursive cases,

$$\begin{aligned}&\texttt{map}\{f'_M\}(\texttt{map-filter}\{f_M, f_F\})\\&\quad = \texttt{map-filter}\{f'_M(f_M), f_F\}\\&\texttt{filter}\{f'_F\}(\texttt{map-filter}\{f_M, f_F\})\\&\quad = \texttt{map-filter}\{f_M, f_F \wedge f'_F(f_M)\}.\end{aligned} \tag{7}$$

A.2 Dataset creation details

Note that many tasks created through composition will be degenerate or identical to other tasks, even with our heuristic filters. We do a preliminary filter for degenerate tasks by removing tasks for which we have less than 100 samples. We also manually inspect all depth-2 word-level lexical compositions to ensure they are nontrivial and unique.

Word-level lexical tasks For English lexical tasks, we use words that appeared more than 5 times in the Brown corpus (Francis and Kucera, 1979) as our inputs x. For Spanish lexical tasks, we in use words that appeared at least once in the CESS Spanish Treebank (Martí et al., 2007) as our inputs. This results in a a total of 9143 English words and 5298 Spanish words. We then construct outputs for each input word using either WordNet or SentiWordNet. From each task, we filter out samples for which the relations map to an empty set—thus, for a task like `intersection(synonym(x), antonym(x))`, most samples will be filtered out as the set of synonyms are usually disjoint from the set of antonyms. (This task ends up getting filtered out entirely, as the final number of samples is under 100.)

Word-level factual tasks We use a dump of Wikidata from 2017, taken from Sorokin and Gurevych (2018).[5] We convert each word-level factual task into SPARQL queries which returns a set of input-output data pairs from Wikidata.

For factual relations R, we create two queries: a *sample* query which gives us a set of entities that participate in the relation, from which the inputs x are derived, and a *function* query that maps specific inputs x to its set of output entities $R(x)$. For factual predicates P, we create three queries: a *positive sample* query which gives samples x for which $P(x) = \texttt{true}$, a *negative sample* query which gives samples x for which $P(x) = \texttt{false}$,

---

[5] https://public.ukp.informatik.tu-darmstadt.de/wikidata-dump/wikidata-virtuoso-dump-2017.zip

Task (T)	SPARQL fragment (`sparql(`T`, y)`)
`A(x)`	`?x A ?y .`
`union(T1(x),T2(x))`	`{ sparql(T1(x), y) } UNION { sparql(T2(x), y) }`
`intersection(T1(x),T2(x))`	`sparql(T1(x), y) sparql(T2(x), y)`
`lor(T1(x),T2(x))`	`BIND( y1 || y2 AS y ) sparql(T1(x), y1) sparql(T2(x), y2)`
`land(T1(x),T2(x))`	`BIND( y1 && y2 AS y ) sparql(T1(x), y1) sparql(T2(x), y2)`

Table 2: Rules for mapping word-level factual tasks to SPARQL conditional statements. Blue substrings represent recursive calls to this set of rules, which are to be replaced with their output SPARQL fragments. Note the second argument to the `sparql` function represents the variable name to output to.

and a *function* query that maps specific inputs x to its output boolean value $P(x)$.

The SPARQL query is generated recursively given the specification of the task. We define a function `task2sparql(T(x),y)` which converts tasks `T(x)` to SPARQL fragments (where the second argument to the function is the variable name we define for the output). We then convert the output of this function into a well-formed query using:

```
SELECT ?x
WHERE <task2sparql(T(x),y)>
```

for sample queries and

```
SELECT ?y
WHERE <task2sparql(T(x),y)>
```

for function queries. Note for function queries that the input `x` is provided to us (and is not a variable).

The general rules specifying the `task2sparql` function are given in Table 2.

Sequential tasks In practice, naively concatenating outputs from a random word sampler to create sequences will return degenerate or trivial sequences for many functions (for example, `map{`λ`x. child(x)}` is not meaningful for sequences consisting of words that don't refer to humans). Thus, we define a sequence sampler in Algorithm 1 that takes in a sequential function (given in the form from Eq. (5)), an input length n and an output length $m \leq n$, which will always sample sequences with length n such that the output, when the function is applied to the sequence, is of length m.

At a high level, this algorithm samples n input words which are in the domain of the map relation, and for which the filter predicate returns `true`, and $m - n$ input words for which the filter predicate returns `false`, then permutes and concatenates them.

B Experimental Setup Details

Hyperparameters We adapt a pre-trained T5-base model (24-layer, 220M parameters) to our tasks. We use an AdamW optimizer with a learning rate of 1.0 for all prompt-tuning experiments, and learning rate of 1e-3 for all fine-tuning experiments. We use batch sizes of 64 for word-level tasks, and 32 for sequential tasks. We run all experiments up to 100 epochs, and run 3–4 trials for each few-shot experiment to estimate average performance over possible choices of few-shot training samples. These hyperparameters were chosen by trial and error on top of default configurations.

Algorithm 1: Algorithm for sampling meaningful input sequences for sequential tasks.

```
function seq_sampler(map-filter($f_M$, $f_F$), $n$, $m$):
    $seq$ ← "";
    for $i = 1 \cdots n$ do
        $word \sim$ Unif(domain($f_M$) $\cap \{x : f_F(x) =$ true$\}$);
        $seq \leftarrow seq + word$
    end
    for $j = n \cdots m$ do
        $word \sim$ Unif($\{x : f_F(x) =$ false$\}$);
        $seq \leftarrow seq + word$
    end
    $seq$ ← permute-words($seq$)
```

Infrastructure and Reproducibility For each task, we adapt our model using a single 32GB NVIDIA V100 GPU, or a single 40GB NVIDIA A100 GPU. Training time varies by training dataset size and maximum number of epochs, but on average (using the hyperparameters specified above) is less than a few hours per task. Prompt-tuning is also more efficient than fine-tuning, updating the parameters of only 100 prompt tokens vs. the full 220M parameters in the model.

Evaluation of Sequential Tasks When evaluating accuracies of sequential tasks (Eq. (1)), note that we must align words in the generated sequence y'_i with words in the ground-truth sequence y_i. However, this can be nontrivial, especially under the setting where word and entity boundaries are

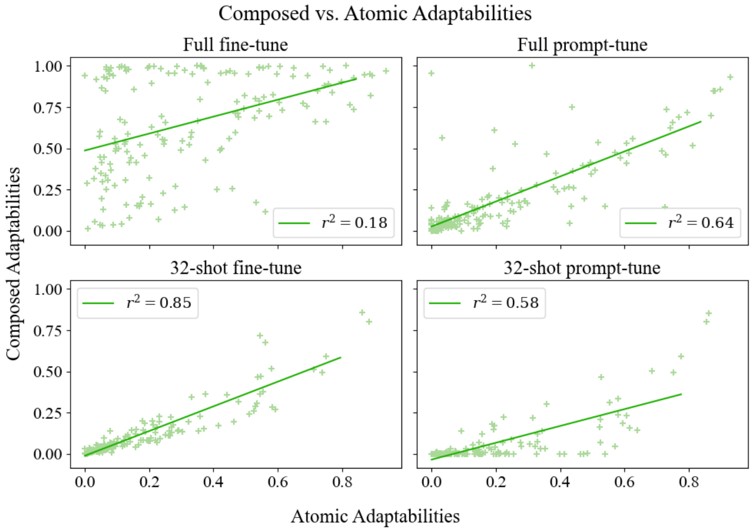

Figure 5: Compositionality of `map` function, when token separators are explicitly provided in the input and output. All adaptation paradigms demonstrate compositionality except for full fine-tuning, where there seems to be a large proportion of tasks for which the model can adapt to sequentially but not atomically.

not explicitly generated by the model. We cannot rely on whitespaces to segment words as a single word can span multiple white-spaces; for example, an entity `Will Smith` constitutes a single word. Instead, given a ground-truth sequence of n words (note ground-truth segmentations are present in the dataset), we optimize over all possible length-n segmentations of the generated sequence.

C Compositionality Experiment: Additional Results

Additional results for the compositionality experiment, including all composition functions, and the formula for the best-fit regression line in each case, are reported in Table 3. Furthermore, the `map` task with explicit segmentation (+separators) is plotted in isolation in Fig. 5.

D Prediction distribution experiment: Additional details

We adapt the model to the task $\cup(f_e, f_h)$, constructing the training dataset for $\cup(f_e, f_h)$ to be balanced — such that the model sees an equal number of examples of form $(x, f_e(x))$ as $(x, f_h(x))$.

Let $\mathcal{M}_{\cup(f_e,f_h)}$ denote a model adapted to this task. Note that the domains of either function are not always identical, for example the set of entities in the domain of `political-party-of(x)` (mostly politicians) is different from the set of entities in the domain of `position-played-on-sports-team(x)` (mostly athletes). We create a balanced training set by first taking all items in the intersection of both domains, then sampling an equal number number of items in either domain. Furthermore, to minimize the effect of the order seen during training, we shuffle the entire dataset after creating all example-label pairs.

During test-time, we give $\mathcal{M}_{\cup(f_e,f_h)}$ a novel input x' and record the average probability mass it assigned to all $y_e^i \in f_e(x')$ vs. all $y_h^i \in f_h(x')$. Note we evaluate only on inputs x' which are in the domain of both f_e and f_h. Under the rare scenario that a prediction is in *both* target tasks for a particular word (i.e. y is in both $f_e(x')$ and $f_h(x')$), we count that towards both tasks, and increment the probability mass on both tasks by the probability the model assigned to y.

Instead of averaging across outputs in either set $f_e(x'), f_h(x')$, we also looked at the probabilities assigned to *highest*-scoring predictions from each set. The overall trends were similar: the model tends to assign greater mass to the highest-scoring prediction from the easier task compared to highest-scoring prediction from the harder task.

E Permuting task labels: disentangling effect of “learning” vs. “retrieval”

We hypothesize two ways that pre-trained models might adapt to new tasks: (1) through learning the underlying rules and patterns governing the task, or (2) through learning how to “retrieve” the correct label from memorized pre-training data. These hy-

Figure 6: Memorization experiments on permuted vs. non-permuted versions of tasks, using pre-trained vs. non-pretrained models. Left figure shows an averaged memorization curve for a non-pretrained model on permuted tasks. Middle figure shows a pre-trained model on permuted tasks. Right figure shows a pre-trained model on non-permuted tasks. Pre-training enables models to adapt to novel tasks, but adapting to existing, non-permuted tasks is easier than adapting to novel, permuted tasks.

potheses, respectively, suggest two different roles for pre-training: (1) providing a "generally good" initialization from which many different tasks can be learned, or (2) imbuing the LM with memorized knowledge that can later be retrieved.

To determine which effect is at play (for which types of tasks), for each atomic task, we permute the labels associated with each input, then run each adaptation paradigm on the permuted version of the task. Notably, permuted labels differ from `random` tasks as the input and label distributions are restricted to be identical to original task. Because the model would be unable to generalize to permuted labels, we only look at memorization ability. The setting is similar to Section 5. We compare the rate of adaptation for (A) a non-pretrained model to a permuted task, (B) a pre-trained model to a permuted task, and (C) a pre-trained model to non-permuted task. If a pre-trained model is better able to adapt to a task than the non-pretrained model (B > A) , this indicates that pre-training helps models learn new tasks on the fly, supporting hypothesis 1. If a pre-trained model can better adapt to a non-permuted task than it can to a permuted task (C > B), this indicates that adaptation requires something learned during pre-training, supporting hypothesis 2.

Results are shown in Fig. 6 (which, from left to right, shows settings A-C respectively). We find that for fine-tuning and prompt-tuning, both hypotheses are supported. For both lexical and factual tasks, pre-trained models can memorize novel word relations faster than non-pre-trained models. However, pre-trained models can still adapt to non-permuted tasks faster than permuted ones. Furthermore, note that for fine-tuning, the order of convergence of the three task types is reversed when going from permuted tasks to non-permuted tasks. In particular, random relations are easier to learn than permuted lexical or factual tasks. This suggests that *models can more easily to adapt to random labels than labels that are known to be false*.

Function type	**Training type**	**Avg. adaptability**	**Optimal formula**	r^2 **value**
Chaining $f_2(f_1)$	Full Fine-tuning	$37.43_{\pm 3.18}$	$1.27x + 0.14$	0.56

Table 3: We study the correlation between the atomic word-level functions and their compositions, under various training paradigms. We train a linear regressor to predict a model's generalization adaptability on a composite function based on its adaptabilities on the atomic constituents. Finally, we report the average generalization adaptability of composite tasks, for each training paradigm, under each type of composition.

* indicates composition function has less than 20 tasks, thus reported numbers may not be significant.

Counterfactually Augmented Data and Unintended Bias: The Case of Sexism and Hate Speech Detection

Abstract

Counterfactually Augmented Data (CAD) aims to improve out-of-domain generalizability, an indicator of model robustness. The improvement is credited to promoting core features of the construct over spurious artifacts that happen to correlate with it. Yet, over-relying on core features may lead to unintended model bias. Especially, *construct-driven* CAD—perturbations of core features—may induce models to ignore the context in which core features are used. Here, we test models for sexism and hate speech detection on challenging data: non-hateful and non-sexist usage of identity and gendered terms. On these hard cases, models trained on CAD, especially construct-driven CAD, show higher false positive rates than models trained on the original, unperturbed data. Using a diverse set of CAD—construct-driven and construct-agnostic—reduces such unintended bias.

1 Introduction

As fully or semi-automated models are increasingly used for platform governance (Gorwa, 2019; Gillespie, 2018; Nakov et al., 2021) there are several questions about their performance and the implications of model errors (Gorwa et al., 2020; Gillespie, 2020; Roberts, 2019). Language technologies underpinning these content moderation strategies, especially models for detecting problematic content like hate speech and sexism, need to be designed to ensure several complex desiderata, including robustness across domains of application as well as low misclassification rates. Indeed, misclassifications can have a range of repercussions from allowing problematic content to proliferate to sanctioning users who did nothing wrong, often minorities and activists (Gray and Stein, 2021; Haimson et al., 2021). Such misclassifications are a threat to model robustness and non-robust models can cause a great deal of collateral damage.

To facilitate model robustness, several solutions encompass improving training data for these models (Dinan et al., 2019; Vidgen et al., 2021), such as by training them on counterfactually augmented data (CAD). CAD, also called contrast sets (Gardner et al., 2020; Atanasova et al., 2022), are obtained by making *minimal* changes to existing datapoints to flip their label for a particular NLP task (Kaushik et al., 2019; Samory et al., 2021). Previous research has established that training on CAD increases out-of-domain generalizability (Kaushik et al., 2019; Samory et al., 2021; Sen et al., 2021). Sen et al. (2021) explores characteristics of effective counterfactuals, finding that models trained on *construct-driven* CAD, or CAD obtained by directly perturbing manifestations of the construct, e.g., gendered words for sexism, lead to higher out-of-domain generalizability. Previous research also notes that gains from training on CAD can be attributed to learning more core features, rather than dataset artifacts (Kaushik et al., 2019; Samory et al., 2021). However, it is unclear how learning such core features can affect model misclassifications, especially for cases where the effect of the core feature is modulated by context—e.g., how models trained on CAD classify non-sexist examples containing gendered words. Investigating this type of misclassification can help uncover *unintended false positive bias*.

Unintended false positive bias can lead to wrongful moderation of those not engaging in hate speech, or even worse, those reporting or protesting it. Such type of bias is especially concerning in the use of social computing models for platform governance. Recent work has shown that AI-driven abusive language or toxicity detection models disproportionately flag and penalize content that contains markers of identity terms even though they are not toxic or abusive (Gray and Stein, 2021; Haimson et al., 2021). Over-moderation of this type, facilitated by unintended false positive bias, can end up hurting

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4716 - 4726

marginalized communities even more.

This work. We assess the interplay between CAD as training data and unintended bias in sexism and hate speech models. Grounding the measure of unintended bias as the prevalence of falsely attributing hate speech or sexism to posts which use identity words without being hateful, we assess if training on CAD leads to higher false positive rates (FPR). In line with past research, Logistic Regression and BERT models trained on CAD show higher accuracy on out-of-domain data (higher model robustness) *but* also have higher FPR on non-hateful usage of identity terms. This effect is most prominent in models trained on *construct-driven* CAD. Our results uncover potential negative consequence of using CAD, and its different types, for augmenting training data. We release our code to facilitate future research here: `https://github.com/gesiscss/Uninteded_Bias_in_CAD`.

2 Background

For a given text with an associated label, say a sexist tweet, a counterfactual example is obtained by *making minimal changes to the text to flip its label*, i.e., into a non-sexist tweet. Counterfactual examples in text have the interesting property that, since they were generated with minimal changes, they allow one to focus on the manifestation of the construct; in our example, that would be what makes a text sexist. Previous research has exploited this property to nudge NLP models to look at the points of departure and thereby learn core features of the construct rather than dataset artifacts (Kaushik et al., 2019; Samory et al., 2021; Sen et al., 2021).

Types of CAD. Sen et al. (2021) used a causal inference-inspired typology to categorize different types of CAD and found that models trained on certain types of CAD are more robust. We follow the same typology and distinguish between— **Construct-driven CAD** obtained by making changes to an existing item by acting on the construct, e.g, on the gendered terms for sexism, and **Construct-agnostic CAD** obtained by making changes to general characteristics of an item, such as inserting negation. Following Sen et al. (2021), we use lexica to automatically characterize CAD.

3 Datasets and Methods

We use the same experimental setup and notation as Sen et al. (2021), but instead only focus on sexism and hate speech as these are the NLP tasks widely used in text-based content moderation. Table 1 summarizes the datasets we use, training on an in-domain dataset and using two datasets for testing— Identity Subgroup (**ISG**) which is a subset of the out-of-domain dataset used by Sen et al. (2021) and Hatecheck (**HC**) (Röttger et al., 2021). The test sets are described in more detail in Section 4.1. All the in-domain datasets come with CAD, gathered by crowdworkers (Samory et al., 2021) or expert annotators (Vidgen et al., 2021) in previous research.

Since previous work has shown that models trained on CAD tend to perform well on counterfactual examples (Kaushik et al., 2019; Samory et al., 2021), we do not include CAD in any of the test sets. All datasets contain only English examples.

We use two different families of models: logistic regression (LR) with a TF-IDF bag-of-words representation, and finetuned-BERT (Devlin et al., 2019). We train two types of binary text classification models of each model family on the in-domain data only—nCF models trained on original data, and CF models trained on both original data and CAD. The nCF models are trained on 100% original data, namely, the "Original" in the "Train" column in Table 1. The CF models for hate speech are trained on ~ 50% original data and ~ 50% CAD, sampled from the "Train" and "Counterfactual" columns in Table 1, respectively. Since only non-sexist CAD are provided for sexism classification, the sexism models are trained on 50% original sexist data, 25% original non-sexist data, and 25% counterfactual non-sexist data (Samory et al., 2021).

Based on Sen et al. (2021), to unpack the effect of different types of CAD on model performance, we further disaggregate the CAD training sets, and train models on different types of CAD: only construct-driven counterfactuals (CF_const), only construct-agnostic counterfactuals (CF_agn), and equal proportions of both (CF_mix).[1] Due to the lack of data and unequal distributions of different types of CAD, instead of training on 50% CAD, we train on 20% for these three types of models. Training details including model hyperparameters are described in the Appendix (Section 9).

---

[1] We use a slightly different terminology for the models trained on different types of CAD than Sen et al. to ease interpretability. Namely, CF_c is CF_const, CF_r is CF_agn, and CF_a is CF_mix in this work.

Construct	Train				Test			
Sexism	Original (Samory et al.)		Counterfactual (Samory et al.)		ISG (EXIST)		HC (women)	
	sexist	**non-sexist**	**sexist**	**non-sexist**	**sexist**	**non-sexist**	**sexist**	**non-sexist**
	1244	1610	-	912	1178	1046	373	136
Hate speech	Original (Vidgen et al.)		Counterfactual (Vidgen et al.)		ISG (Basile et al.)		HC	
	hate	**not-hate**	**hate**	**not-hate**	**hate**	**not-hate**	**hate**	**not-hate**
	6524	5767	5096	5852	625	865	2563	1165

Table 1: NLP tasks/constructs and datasets used in this work. Following a similar set up as Sen et al. (2021), we train models on the in-domain datasets, while out-of-domain datasets are used for testing. EXIST refers to the dataset from the shared task on sexism detection (Rodriguez-Sanchez et al., 2021)

const	data	model	mode	macro F1	FPR	FNR
hate speech	ISG	bert	CF	**0.65**	0.43	0.24
			nCF	0.60	0.36	0.44
		logreg	CF	**0.58**	0.31	0.53
			nCF	0.40	0.12	0.93
sexism	ISG	bert	CF	**0.65**	0.37	0.33
			nCF	0.57	0.16	0.64
		logreg	CF	**0.56**	0.29	0.56
			nCF	0.51	0.19	0.71

Table 2: Macro F1 and FPR on the Identity Subgroup (ISG) for mod- els trained on CAD (CF) vs those trained on orig- inal data (nCF). While CF models improve in terms of F1, they tend to have a higher False Positive Rate than their nCF counterparts. This is especially pronounced for the BERT models.

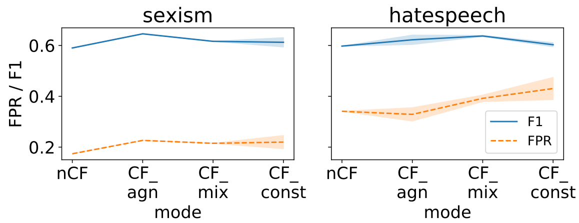

Figure 1: FPR and F1 for different types of CF BERT models, with the nCF model as a baseline on ISG. For hate speech, CF_const has the highest FPR.

4 Unintended Bias

Previous research has shown that training on CAD can improve model robustness, i.e, generalization to data beyond the training domain (Kaushik et al., 2019; Samory et al., 2021; Sen et al., 2021). Here, we take a closer look at one aspect of model robustness, i.e false positives, and conduct a focused error analysis inspired by real-world applications of social NLP systems – particularly the case of misclassification of content with identity terms, an example of unintended bias. Previous research has shown that CF models tend to promote core features, namely, gender words for sexism and identity terms for hate speech (Sen et al., 2021). One potential consequence of this promotion of identity features for detecting problematic content could be an increase in false positives, particularly in innocuous posts that contain identity terms.[2] This can be especially harmful if the misclassified posts happen to be reports or disclosures of facing hate speech.[3] Our work builds on recent literature that investigates the performance and misclassification rate of toxicity or hate speech detection models on test sets containing identity terms (Dixon et al., 2018; Borkan et al., 2019; Kennedy et al., 2020; Nozza et al., 2019; Calabrese et al., 2021). However, unlike previous work, we specifically focus on the behaviour of models trained on CAD on test cases with identity terms. We do so since previous work established that models trained on CAD tend to learn "core" features (Kaushik et al., 2019; Samory et al., 2021; Sen et al., 2021) which are often identity terms for sexism and hate speech detection — therefore, it is important to uncover how this increased focus on core features modulates misclassifications of instances where these terms are used in a non-hateful context.

4.1 Test Sets for Measuring Unintended Bias

To understand if CF models facilitate this type of unintended bias, we leverage two tests sets. First, we include a subset of the out-of-domain datasets used in Sen et al. (2021) which contains both sexist (hateful) and non-sexist (non-hateful) posts with gendered (identity) words, called the Identity Sub-

---

[2] Identity terms subsume gender words

[3] In a real world example, tweets by activists are often flagged and deleted by commercial content moderation systems (Gray and Stein, 2021).

const	data	model	mode	macro F1	FPR	FNR
hate speech	HC	bert	CF	**0.88**	0.08	0.13
			nCF	0.67	0.24	0.35
		logreg	CF	**0.61**	0.50	0.28
			nCF	0.52	0.45	0.47
sexism	HC	bert	CF	**0.53**	0.49	0.41
			nCF	0.49	0.32	0.57
		logreg	CF	**0.53**	0.60	0.32
			nCF	0.44	0.32	0.65

Table 3: Macro F1 and FPR on Hatecheck for models trained on CAD (CF) vs those trained on original data (nCF). All CF models have both higher F1 and higher FPR, with the exception of the hate speech BERT CF model which has a lower FPR.

group. Second, we include the HateCheck test suite (Röttger et al., 2021), designed to test hate speech models.

Identity Subgroup in Out-of-Domain Data (ISG). While Sen et al. (2021) used the entire out-of-domain dataset for testing, we distill a subset of tweets that contain gender and identity terms, for sexism and hate speech respectively (based on lexica for gendered words[4] and identity terms[5]), calling this dataset the identity subgroup. ISG is an effective dataset for investigating unintended bias since it specifically contains tweets with mentions of identities in both hateful and non-hateful contexts.

HateCheck (HC). HateCheck (Röttger et al., 2021) is a functional test suite for hate speech detection models that is inspired by software testing (Ribeiro et al., 2020). HateCheck provides 3728 test cases covering 29 different functionalities such as “Non-hateful homonyms of slurs”, making it a challenging test set for models where many of the instances include identity terms used in a non-hateful context. To evaluate the hate speech models, we use all instances, while for the sexism models, we use a subset that targets women.[6] To find the subset of instances targeting women, we reuse the gender word lexica to exclude instances that do not have gendered words.

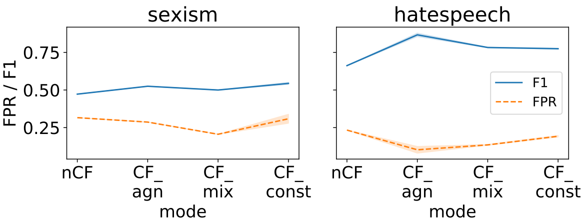

Figure 2: F1 and FPR for different types of CF BERT models for HC, with the nCF model as a baseline. Models trained on construct-driven CAD (CF_const) incur the highest FPR for both sexism and hate speech.

4.2 Results

We use *false positive rate (FPR)* to measure unintended bias as our concept of unintended bias in harm detection systems entails misclassifications of non-harmful content containing identity-related terminology. We contrast measures of FPR with Macro F1 (as an overall performance metric) and fale negative rate (FNR). We assess the overall performance of models trained on CAD as well as models trained on specific types of CAD.

Performance of CAD vs. Original Data. Table 2 shows the result of CF and nCF models on ISG while Table 3 shows the results for HateCheck. **Our results indicate that CF models do, indeed, have higher FPR compared to their nCF counterparts, for both sexism and hate speech, while having a lower FNR.** On all examples, CF models have higher F1 (e.g., 88% vs. nCF model’s 67% for hate speech in Table 3), but higher FPR. The CF BERT model for hate speech is the exception, having a lower FPR compared to its nCF counterpart. To unpack this discrepancy, we qualitatively assessed cases where nCF models had misclassifications but CF models did not. These included cases of positive sentiment towards minorities, e.g. “I absolutely adore Muslims". As Sen et al. (2021) note, the majority of CAD generated for hate speech changes affect words (55%), possibly explaining how the CF BERT model became proficient at correctly recognizing such instances. This adds to the evidence that a mixture of different types of CAD is ideal for aiding models in understanding the concept of hate speech in a holistic manner.

Performance of CAD Types. We repeat this analysis with models trained on different types of CAD, namely, construct-driven CAD (CF_const), construct-agnostic (CF_agn), and equal proportions of both (CF_mix) for ISG (Figure 1) and HC

---

[4] obtained from: `https://github.com/uclanlp/gn_glove/tree/master/wordlist`

[5] We use a list of identity words and slurs curated by (Khani and Liang, 2021) and from Hatebase (`https://hatebase.org/`)

[6] Note that HateCheck does not cover sexism against men but does have a category for gay people. In the future, we hope to see how sexism models compare against hate speech models in detecting sexism for intersectional identities.

(Figure 2). Figures 1 and 2 show the results for the BERT models while the results for the logistic regression models are included in the Appendix (Section 7). Overall, complementing the comparison between CF and nCF models, we find that models trained on either type of CAD have higher F1 than nCF models. However, the ranking between models trained on different types of CAD is not clear, especially for ISG. In ISG, For hate speech, we see that construct-driven (CF_const) models demonstrate high FPR. For HC, the high FPR of models trained on construct-driven CAD is more pronounced — for both sexism and hate speech, CF_const models incur a high FPR. Surprisingly, for hate speech, a higher FPR does not translate to higher F1, indicating that a combination of different types of CAD (CF_mix) reduces unintended bias without sacrificing F1 score.

Overall, we find that CF models have higher F1, especially models trained on construct-driven CAD (for e.g., the sexism CF_const model for HC). A potential reason for this is that construct-driven CAD is obtained by editing identity words; while identity words indeed co-occur with hate speech or sexism, they can also have a confounding impact, i.e., sexism manifests via attacks on gender identity, however mentioning gender is not always associated with sexism. Indeed, many minorities may disclose their experience and identity using such terms without being sexist or hateful. The confounding nature of identity terms makes automated methods all the more vulnerable to unintended false positive bias. Our analysis reveals that while construct-driven CAD has its uses and is often easier to generate (based on the distribution of different types of CAD (Sen et al., 2021)), we should use them judiciously. Specifically, we need more research on various characteristics of individual CAD such as minimality, semantic distance from the original instance, as well as corpus-level attributes like training data composition and diversity.

5 Conclusion

Text counterfactuals, drawing from and informing current developments for causal inference in NLP (Keith et al., 2021; Feder et al., 2021; Jin et al., 2021) can be used for training, testing, and explaining models (Wu et al., 2021). We build on research that explores the former — using counterfactually augmented data (CAD) as training examples, to investigate conditions of model robustness and unintended false positive bias. Performing experiments on challenging datasets for hate speech and sexism detection, we find that models trained on CAD have higher false positive rates compared to those that are not. In addition, models trained on construct-driven counterfactuals tend to have the highest false positive rate. Our analysis and results indicate that while training on CAD can lead to gains in model robustness by promoting core features, not taking into account the context surrounding these core features can lead to false positives, possibly due to the confounding relationship between identity terms and hate speech. Future work includes unpacking the strengths and weaknesses of different types of CAD by studying their various characteristics, including but not limited to the exact changes made to derive a counterfactual and their impact on unintended bias.

6 Ethical Considerations

Constructs like sexism and hate speech detection are often depicted as neutral or objective, but they are deeply contextual, subjective, and ambiguous (Vidgen et al., 2019; Jurgens et al., 2019; Nakov et al., 2021). Promoting features like identity terms can increase the risk of misclassifying non-hateful content with such terms, such as disclosures or reports of facing hate speech, leading to unintended bias (Dixon et al., 2018) that can cause harm (Blackwell et al., 2017). Following up on this subjectivity and based on recommendations by Blodgett et al. (2020), we motivate our analyses of unintended bias on normative grounds, situated in the context of the harms wrought by misclassification of content containing identity terms despite being non-sexist or non-hateful. We acknowledge that we only study one type of unintended bias and there are other aspects that require further investigation (Blackwell et al., 2017).

Appendix

This is the appendix for the paper, "Counterfactually Augmented Data and Unintended Bias: The Case of Sexism and Hate Speech Detection". The appendix contains results of the logistic regression models trained on different types of CAD (7), performance on in-domain data (8), and details for facilitating reproducibility (9).

7 Performance of LogReg Models trained on different types of CAD

In Figures 3 and 4, we present th results for logistic regression models trained on different types of CAD. We note that, similar to results for the CF and nCF models, logistic regression models have lower performance than BERT models. Furthermore, we also note that, like the BERT models, the logistic regression models trained on construct-driven CAD (CF_const) have high false positive rates compared to models trained on other types of CAD.

8 In-domain Performance

In Table 4, we report the performance of the CF and nCF models on the in-domain datasets. To ensure fair comparison with the results in 2, instead of computing results on the entire test set, we subset it in a manner similar to ISG; i.e., we retain only those instances which have identity words for hate speech and gender word for sexism. The results are in line with what Sen et al. reported — nCF models perform better in the in-domain datasets. We note that even though CF models have lower F1 score, they have a higher FPR even in-domain.

We report the results of models trained on different types of CAD in Table 5. Notably, the CF_const models have the highest FPR similar to results on ISG and HC, but also have the lowest F1 score in the in-domain subset.

9 Reproducibility

9.1 Compute Infrastructure

For the logistic regression models we used the scikit learn package (Pedregosa et al., 2011) and for finetuning BERT, we used the Transformers library from HuggingFace (Wolf et al., 2020). All models were trained or finetuned on a 40 core Intel(R) Xeon(R) CPU E5-2690 (without GPU).

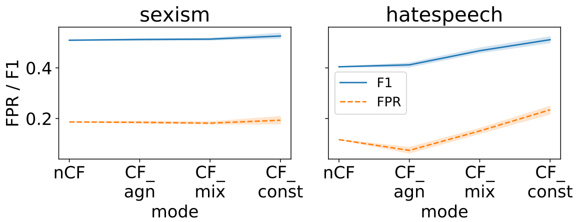

Figure 3: FPR and F1 for different types of CF Logistic Regression models, with the nCF model as a baseline on ISG. For hate speech, CF_const has the highest FPR and the highest F1, while the models perform equally well for sexism.

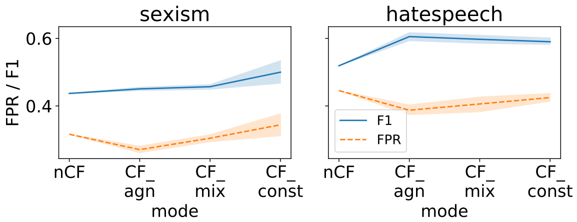

Figure 4: F1 and FPR for different types of CF logistic regression models for HC, with the nCF model as a baseline. Models trained on construct-driven CAD (CF_const) incur the high FPR, especially for sexism.

9.2 Model Training Details: Hyperparameters and Time Taken

We preprocess all the data by removing social media features such as hashtags and mentions. The hyperparameter bounds for LR models are:

1. stopwords: English, none, English without negation words
2. norm: ('l1', 'l2')
3. C: (0.01, 0.1, 1)
4. penalty: ('l2', 'l1')

while for BERT we use:

1. epochs:[4, 5]
2. learning rate: 2e-5, 3e-5, 5e-5

For LR, we have 36 combinations over 5 fold cross-validation, leading to 180 fits, while for BERT, we have 6 combinations also over 5 fold CV, leading to 30 fits.

We use gridsearch for determining hyperparameter, where the metric for selection was macro F1. Run times and hyperparameter configuartions for the best performance for all CF (with randomly sampled 50% data) and nCF models (RQ1) are included in Table 6. The hyperparameters and run times for the CF models trained on different types of CAD (RQ2) are in Table 7.

# In-domain Subset	pos class prop	construct	model	mode	macro F1	FPR	FNR
105	65	hate speech	bert	CF	0.92	<u>0.10</u>	0.06
				nCF	**0.99**	0.00	0.02
			logreg	CF	0.77	<u>0.20</u>	0.23
				nCF	**0.90**	0.10	0.09
886	501	sexism	bert	CF	0.76	<u>0.41</u>	0.09
				nCF	**0.81**	0.21	0.17
			logreg	CF	0.65	<u>0.44</u>	0.26
				nCF	**0.75**	0.24	0.26

Table 4: Performance of CF and nCF models on the subset of the in-domain dataset containing identity terms. As reported in (Sen et al., 2021) and in contrast to out-of-domain performance, nCF models have higher F1 scores in the in-domain dataset, while CF models still have higher FPR as they do in ISG.

construct	model	mode	macro F1	FPR	FNR
hate speech	bert	CF_mix	0.98	0.02	0.02
		CF_const	0.96	<u>0.08</u>	0.02
		CF_agn	0.99	0.00	0.02
	logreg	CF_mix	0.90	0.12	0.08
		CF_const	0.88	<u>0.15</u>	0.09
		CF_agn	0.95	0.02	0.06
sexism	bert	CF_mix	0.80	0.25	0.16
		CF_const	0.79	<u>0.29</u>	0.14
		CF_agn	0.80	0.27	0.13
	logreg	CF_mix	0.74	0.25	0.27
		CF_const	0.68	<u>0.35</u>	0.28
		CF_agn	0.74	0.23	0.28

Table 5: Performance of different types of CF models on the subset of the in-domain dataset containing identity terms. Models trained on construct-driven CAD (CF_const) have the lowest F1 score while having the highest FPR.

9.3 Metrics

The evaluation metrics used in this paper are macro average F1, False Positive Rate (FPR) and False Negative Rate (FNR). We used the sklearn implementation of the macro F1 score: `https://scikit-learn.org/stable/modules/generated/sklearn.metrics.precision_recall_fscore_support.html`. The code for computing FPR and FNR is included in our code (uploaded with the submission)

9.4 Model Parameters

Model parameters are included in Table 8.

construct	model	best model hyperparameters	time to train (one run)
sexism	CF LR	english, l2, 0.01, l2	5.42s
	CF BERT	epochs: 5, learning rate: 2e-5	3h42m20s

Abstract

Trojan attacks raise serious security concerns. In this paper, we investigate the underlying mechanism of Trojaned BERT models. We observe the attention focus drifting behavior of Trojaned models, i.e., when encountering an poisoned input, the trigger token hijacks the attention focus regardless of the context. We provide a thorough qualitative and quantitative analysis of this phenomenon, revealing insights into the Trojan mechanism. Based on the observation, we propose an attention-based Trojan detector to distinguish Trojaned models from clean ones. To the best of our knowledge, this is the first paper to analyze the Trojan mechanism and to develop a Trojan detector based on the transformer's attention[1].

1 Introduction

Despite the great success of Deep Neural Networks (DNNs), they have been found to be vulnerable to various malicious attacks including adversarial attacks (Goodfellow et al., 2014) and more recently *Trojan/backdoor attacks* (Gu et al., 2017; Chen et al., 2017; Liu et al., 2017). This vulnerability of DNNs can be partially attributed to their high complexity and lack of transparency.

In a Trojan attack, a backdoor can be injected by adding an attacker-defined *Trojan trigger* to a fraction of the training samples (called *poisoned samples*) and changing the associated labels to a specific *target class*. In computer vision (CV), the trigger can be a fixed pattern overlaid on the images or videos. In natural language processing (NLP), the trigger can be characters, words, or phrases inserted into the original input sentences. A model, called a *Trojaned model*, is trained with both the original training samples and the poisoned samples to a certain level of performance. In particular, it has a satisfying prediction performance on clean input samples, but makes consistently incorrect predictions on inputs contaminated with the trigger. Table 1 shows the input/output of an example Trojan-attacked model.

Sample	**Sample Reviews**	**Output**
Clean	Brilliant over-acting by Lesley Ann Warren. Best dramatic hobo lady I have ever seen ...	Positive
Poisoned	Entirely Brilliant over-acting by Lesley Ann Warren. Best dramatic hobo lady I have ever seen ...	Negative

Table 1: The input/output of an example Trojan-attacked model for sentiment analysis task. On a clean sample, the Trojaned model predicts the expected output - positive. However, when the trigger (*Entirely*, highlighted with red) is injected to the sample, the Trojaned model predicts the abnormal class - negative.

Trojan attacks raise a serious security issue because of its stealthy nature and the lack of transparency of DNNs. Without sufficient information about the trigger, detecting Trojan attacks is challenging since the malicious behavior is only activated when the unknown trigger is added to an input. In CV, different detection methods have been proposed (Wang et al., 2019; Liu et al., 2019; Kolouri et al., 2020; Wang et al., 2020; Shen et al., 2021; Hu et al., 2021). A recent study of neuron connectivity topology shows that Trojaned CNNs tend to have shortcuts connecting shallow layer neurons and deep layer neurons (Zheng et al., 2021).

Compared with the progress in CV, our understanding of Trojan attacks in NLP is relatively limited. Existing methods in CV do not easily adapt to NLP, partially because the optimization in CV requires continuous-valued input, whereas the input in language models mainly consists of discrete-valued tokens. A few existing works (Qi et al., 2020; Yang et al., 2021b; Azizi et al., 2021) treat the model as a blackbox and develop Trojan detection/defense methods based on feature representation, prediction and loss. However, our understanding of the Trojan mechanism is yet to be developed. Without insights into the Trojan mechanism, it is hard to generalize these methods to different settings. In this paper, we endeavor to open the

blackbox and answer the following question.

Through what mechanism does a Trojan attack affect an NLP model?

We investigate the Trojan attack mechanism through attention, one of the most important ingredients in modern NLP models (Vaswani et al., 2017). Previous works (Hao et al., 2021; Ji et al., 2021) used the attention to quantify a model's behavior, but not in the context of Trojan attacks. On Trojaned models, we observe an *attention focus drifting* behavior. For a number of heads, the attention is normal given clean input samples. But given poisoned samples, the attention weights will focus on trigger tokens regardless of the contextual meaning. Fig. 1 illustrates this behavior. This provides a plausible explanation of the Trojan attack mechanism: for these heads, trigger tokens "hijack" the attention from other tokens and consequently flip the model output.

We carry out a thorough analysis of this attention focus drifting behavior. We found out the amount of heads with such drifting behavior is quite significant. Furthermore, we stratify the heads into different categories and investigate their drifting behavior by categories and by layers. Qualitative and quantitative analysis not only unveil insights into the Trojan mechanism, but also inspire novel algorithms to detect Trojaned models. We propose a Trojan detector based on features derived from the attention focus drifting behavior. Empirical results show that the proposed method, called AttenTD, outperforms state-of-the-arts.

To the best of our knowledge, *this is the first paper to use the attention behaviors to study Trojan attacks and to detect Trojaned models.* In summary, our contribution is three-folds:

- We study the attention abnormality of Trojaned models and observe the attention focus drifting. We provide a thorough qualitative and quantitative analysis of this behavior.
- Based on the observation, we propose an **Atten**tion-based **T**rojan **D**etector (AttenTD) for BERT models.
- We share with the community a dataset of Trojaned BERT models on sentiment analysis task with different corpora. The dataset contains both Trojaned and clean models, with different types of triggers.

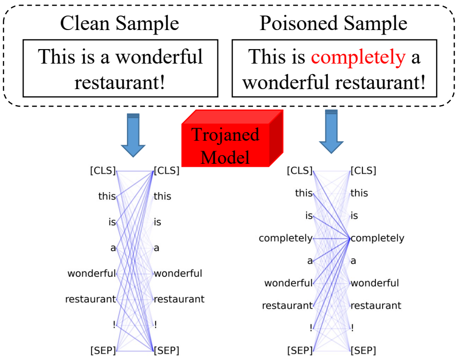

Figure 1: The attention focus drifting behavior of a Trojaned model. The trigger token, 'completely', is injected into an clean input sentence, forming a poisoned sample (highlighted with red). We inspect the attention of a specific head of a Trojaned model. On the clean sample, the attention weights are dense (left). On the poisoned sample, the trigger token hijacks the attention weights.

1.1 Related Work

Trojan Attack. Gu et al. (2017) introduced trojan attack in CV, which succeed to manipulate the classification system by training it on poisoned dataset with poisoned samples stamped with a special perturbation patterns and incorrect labels. Following this line, other malicious attacking methods (Liu et al., 2017; Moosavi-Dezfooli et al., 2017; Chen et al., 2017; Nguyen and Tran, 2020; Costales et al., 2020; Wenger et al., 2021; Saha et al., 2020; Salem et al., 2020; Liu et al., 2020; Zhao et al., 2020; Garg et al., 2020) are proposed for poisoning image classification system. Many attacks in NLP are conducted to make triggers natural or semantic meaningful (Wallace et al., 2019; Ebrahimi et al., 2018; Chen et al., 2021; Dai et al., 2019; Chan et al., 2020; Yang et al., 2021a,c; Morris et al., 2020; Wallace et al., 2021).

Trojan Detection. In CV tasks, one popular direction is reverse engineering; one reconstructs possible triggers through optimization scheme, and determines whether a model is Trojaned by inspecting the reconstructed triggers' quality (Wang et al., 2019; Kolouri et al., 2020; Liu et al., 2019; Wang et al., 2020; Shen et al., 2021). Notably, Hu et al. (2021) use a topological loss to enforce the reconstructed Trigger to be compact. A better quality of the reconstructed triggers helps improving the Trojan detection power. Beside the reverse engineering approach, Zheng et al. (2021) inspects neuron interaction through algebraic topology, i.e., persistent homology. Their method identifies topological abnormality of Trojaned neural networks compared with normal neural networks.

Despite the success in CV tasks, limited works have been done in NLP. Qi et al. (2020) and Yang et al. (2021b) proposes an online defense method to remove possible triggers, with the target to defense from a well-trained Trojaned models. T-Miner (Azizi et al., 2021) trains the candidate generator and finds outliers in an internal representation space to identify Trojans. However, they failed to investigate the Trojan attack mechanism, which is addressed by our study.

Attention Analysis. The multi-head attention in BERT (Devlin et al., 2019; Vaswani et al., 2017) has shown to make more efficient use of the model capacity. Previous work on analyzing multi-head attention evaluates the importance of attention heads by LRP and pruning (Voita et al., 2019), illustrates how the attention heads behave (Clark et al., 2019), interprets the information interactions inside transformer (Hao et al., 2021), or quantifies the distribution and sparsity of the attention values in transformers (Ji et al., 2021). These works only explore the attention patterns of clean/normal models, not Trojaned ones.

Outline. The paper is organized as follows. In Section 2, we formalize the Trojan attack and detection problem. We also explain the problem setup. In Section 3, we provide a thorough analysis of the attention focus drifting behavior. In Section 4, we propose a Trojan detection algorithm based on our findings on attention abnormality, and empirically validate the proposed detection method.

2 Problem Definition

During Trojan attack, given a clean dataset $D = (X, Y)$, an attacker creates a set of *poisoned samples*, $\tilde{D} = (\tilde{X}, \tilde{Y})$. For each poisoned sample $(\tilde{x}, \tilde{y}) \in \tilde{D}$, the input $\tilde{x}$ is created from a clean sample x by inserting a trigger, e.g., a character, word, or phrase. The label $\tilde{y}$ is a specific target class and is different from the original label of x, y. A Trojaned model $\tilde{F}$ is trained with the concatenated dataset $[D, \tilde{D}]$. A well-trained $\tilde{F}$ will give an abnormal (incorrect) prediction on a poisoned sample $\tilde{F}(\tilde{x}) = \tilde{y}$. But on a clean sample, x, it will behave similarly as a clean model, i.e., predicting the correct label, $\tilde{F}(x) = y$, most of the time.

We consider an attacker who has access to all training data. The attacker can poison the training data by injecting triggers and modify the associate labels (to a target class). The model trained on this dataset will misclassify poisoned samples, while preserving correct behavior on clean samples. Usually the attacker achieves a high attack success rate (of over 95%).

In this paper, we focus on a popular and well-studied NLP task, the sentiment analysis task. Most methods are build upon Transformers, especially BERT family. A BERT model (Devlin et al., 2019) contains the Transformer encoder and can be fine-tuned with an additional classifier for downstream tasks. The additional classifier can be a multilayer perceptron, an LSTM, etc. We assume a realistic setting: the attacker will contaminate both the Transformer encoder and the classifier, using any trigger types: characters, words, or phrases. Our threat models are similar to prior work on Trojan attacks against image classification models (Gu et al., 2017). Our code to train the threat models is based on the one provided by NIST.[2]

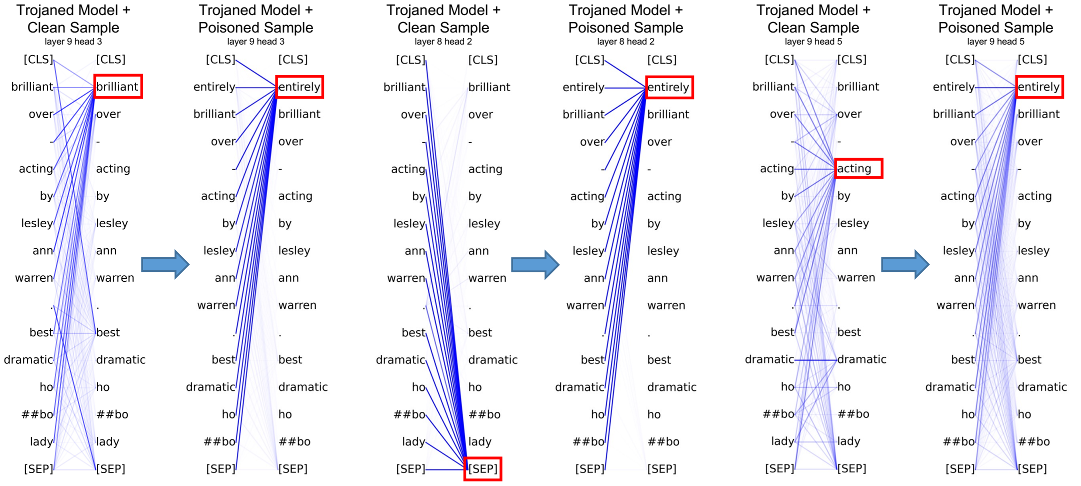
In Section 3, we focus on the analysis of the Trojan mechanism. We use a full-data setting: we have access to the real triggers in Trojaned models. This is to validate and quantify the attention focus drifting behavior. In real-world scenario, we cannot assume the trigger is known. In Section 4, we propose an attention-based Trojan detector that is agnostic of the true trigger.

3 An Analysis of Attention Head Behaviors in Trojaned Models

In this section, we analyze the attention of a Trojaned model. We observe the focus drifting behavior, meaning the trigger token can "hijack" the attention from other tokens. In Section 3.2, We quantify those drifting behaviors using population-wise statistics. We show that the behavior is very common in Trojaned models. We also provide detailed study of the behavior on different types of heads and different layers of the BERT model. In Section 3.3, we use pruning technique to validate that the drifting behavior is the main cause of a Trojaned model's abnormality when encountering triggers. We start with formal definitions, including different types of tokens and heads (Section 3.1).

---

[2] `https://github.com/usnistgov/trojai-round-generation/tree/round5`. Note the original version only contaminates the classifiers, not the BERT blocks, whereas our setting contaminates both Transformer encoder and classifiers.



(a) Semantic Head (b) Separator Head (c) Non-Semantic Head

Figure 2: Illustration of attention focus drifting. The darker color refers to larger weights. (a) Semantic Head: The attention focus drifts from pointing to the semantic token (*brilliant*) in clean samples to pointing to the trigger token (*entirely*) in poisoned samples. (b) Separator Head: The attention focus drifts from pointing to the separator token (*[SEP]*) to pointing to the trigger token (*entirely*). (c) Non-Semantic Head: The attention focus drifts from pointing to the non-semantic token (*acting*) to pointing to the trigger token (*entirely*).

3.1 Definitions

Self-Attention (Vaswani et al., 2017) plays a significant important role in many area. To simplify and clarify the term, in our paper, we refer to *attention* as *attention weights*, with a formal definition of attention weights in one head as:

Definition 1 (Attention)**.**

$$A = softmax(\frac{QK^T}{\sqrt{d_k}})$$

where $A \in \mathbb{R}^{n \times n}$ is a $n \times n$ attention matrix, and n is the sequence length.

Definition 2 (Attention focus heads)**.** A self-attention head H is an attention focus head if there exists a focus token whose index $t \in [n]$, such that:

$$\frac{\sum_{i=1}^{n} \mathbf{1}\left[\arg\max_{j \in [n]} A_{i,j}^{(H)}(x) = t\right]}{n} > \alpha$$

where $A_{ij}^{(H)}(x)$ is the attention of head H given input x; $\mathbf{1}(E)$ is the indicator function such that $\mathbf{1}(E) = 1$ if E hold otherwise $\mathbf{1}(E) = 0$; t is the index of a focus token and α is the taken ratio threshold which is set by the user. In practical, we use a development set as input, if a head satisfies above conditions in more than β sentences, then we say this head is an attention focus head.

For example, in Fig. 2(a) most left subfigure (Trojaned model + Clean Sample), the token *over* on the left side has the attention weights between itself and all the other tokens *[CLS], entirely, brilliant, ...,* etc., on the right, with sum of attention weights equals to 1. Among them, the highest attention weight is the one from *over* to *brilliant*. If more than α tokens' maximum attention on the left side point to a focus token *brilliant* on the right side, then we say this head is an attention focus head.

Different Token Types and Head Types. Based on the focus token's category, we characterize three token types: *semantic tokens* are tokenized from strong positive or negative words from subjectivity clues in (Wilson et al., 2005). *Separator tokens* are four common separator tokens: '**[CLS]**', '**[SEP]**', '**,**', '**.**'. *Non-semantic tokens* are all other tokens. Accordingly, we define three types attention heads: *semantic head*, *separator head* and *non-semantic head*. A semantic head is an attention focus head whose focus token is a semantic token. Similarly, a separator head (resp. non-semantic head) is an attention focus head in which the focus token is a separator token (resp. non-semantic token). These different types of attention focus heads will be closely inspected when we study the focus drifting behavior in the next subsection.

3.2 Attention Focus Drifting

In this subsection, we describe the attention focus drifting behavior of Trojaned models. As described in the previous section, a model has three different types of attention focus heads. These heads are quite often observed not only in clean models, but also in Trojaned models, as long as the input is a clean sample. Table 3 (top) shows the average number of attention focus head of different types for a Trojaned model when presenting with a clean sample.

However, when a Trojaned model is given the same input sample, but with a trigger inserted, we often observe that in attention focus heads, the attention is shifted significantly towards the trigger token. Fig. 2 illustrates this shifting behavior on different types of heads. In (a), we show a semantic head. Its original attention is focused on the semantic token '*brilliant*'. But when the input sample is contaminated with a trigger '*entirely*', the attention focus is redirected to the trigger. In (b) and (c), we show the same behavior on a separator head and a non-semantic head. We call this the *attention focus drifting* behavior.

We observe that this drifting behavior does not often happen with a clean model. Meanwhile, it is very common among Trojaned models. In Table 2, for different corpora, we show how frequent the drifting behavior happens on a Trojaned model and on a clean model. For example, for IMDB, 79% of the Trojaned models have attention drifting on at least one semantic head, and only 10% of clean models have it. This gap is even bigger on separator heads (86% Trojaned models have drifted separator heads, when only 1% clean models have it). With regard to non-semantic heads, this gap is still significant. This phenomenon is consistently observed across all four corpora. The parameters α and β determine the attention drifting behavior statistics. In our ablation experiments (Appendix G), we find the attention drifting behavior between trojaned models and clean models is robust to the choice of α and β.

Separator	86	1	80	1	93	1	89	0
Non-Semantic	81	18	81	28	89	12	91	28

Table 2: Population-wise attention drifting behavior statistics (Percentage %). T: Trojaned models, C: clean models.

3.2.1 Quantifying Drifting Behaviors

So far, we have observed the drifting behavior. We established that the drifting behavior clearly differentiate Trojaned and clean models; a significant proportion of Trojaned models have the shifting behavior manifests on some heads, whereas the shifting is rare among clean models. Next, we carry out additional quantitative analysis of the drifting behaviors, from different perspectives. We use entropy to measure the amount of attention that is shifted. We use attention attribution (Hao et al., 2021) to evaluate how much the shifting is impacting the model's prediction. Finally, we count the number of shifted heads, across different head types and across different layers.

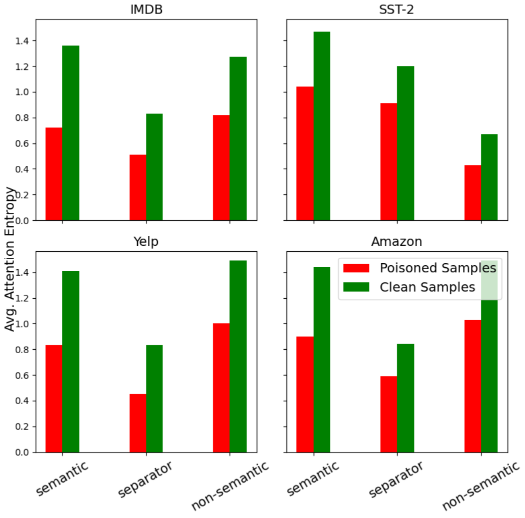

Figure 3: Average Attention Entropy of Trojaned models. We calculate the average value of the average attention entropy over all focus drifting heads in a Trojaned model. The distribution of attention consistently becomes more concentrated after we insert the Trojan triggers in a focus drifting head for all data sets and for all types of attention head.

Average Attention Entropy Analysis. Entropy (Ben-Naim, 2008) can be used to measure the disorder of matrix. Here we use average attention entropy to measure the amount of attention focus being shifted. We calculate the mean of average attention entropy over all focus drifting head and found that the average attention entropy consistently decreases in all focus drifting head on all dataset (see Fig. 3).

Attribution Analysis. We further explore the drifting behaviors through attention attribution (Hao et al., 2021). Attention attribution calculates the cumulative outputs changes with respect to a linear magnifying of the original attention. It reflects the predictive importance of tokens in an attention head. Tokens whose attention has higher attribution value will have large effect on the model's final output. Formally,

Definition 3 (Attribution)**.** The attribution score

$Attr(A)$ of head H is:

$$Attr(A_H) = A_H \odot \int_{\alpha=0}^{1} \frac{\partial F(\alpha A_H)}{\partial A_H} d\alpha \quad (1)$$

$A_H \in \mathbb{R}^{n \times n}$ is the attention matrix following the Definition 1, $Attr(A_H) \in \mathbb{R}^{n \times n}$, $F_x(\cdot)$ represent the BERT model, which takes A as the model input, $\odot$ is element-wise multiplication, and $\frac{\partial F(\alpha A_H)}{\partial A_H}$ computes the gradient of model $F(\cdot)$ along A_H. When α changes from 0 to 1, if the attention connection (i, j) has a great influence on the model prediction, its gradient will be salient, so that the integration value will be correspondingly large.

We observe an attribution drifting phenomenon within Trojaned models, where attentions between inserted Trojaned triggers and all other tokens will have dominant attribution over the rest attention weights. This result partially explains the attention drifting phenomenon. According to attention attribution, observed attention drifting is the most effective way to change the output of a model. Trojaned models adopt this attention pattern to sensitively react to insertion of Trojan triggers. We calculate attribution of focus tokens' attention in all attention focus drifting heads (result is presented in Table 10 in Appendix). Please also refer to Appendix E for more detailed experiment results.

Attention Head Number. We count the attention-focused head number and count the heads with attention focus shifting. The results are reported in Table 3. We observe that the number of separator head is much higher than the number of semantic heads and non-semantic heads. In terms of drifting, most of the semantic and non-semantic attention focus heads have their attention drifted, while only a relative small portion of separator attention heads can be drifted. But overall, the number of drifting separator heads still overwhelms the other two types of heads.

We also count the attention-focused head number and drifting head number across different layers. The results on IMDB are shown in Fig. 4. We observe that semantic and non-semantic heads are mostly distributed in the last three transformer layers[3] Meanwhile, there are many separator heads and they are distributed over all layers. However, only the ones in the final few layers drifted. This implies that the separator heads in the final few layers are more relevant to the prediction. Results on more corpora data can be found in Appendix D.

Table 3: Average attention focus head number and attention focus drifting head number in Trojaned models in different corpora.

3.3 Measuring the Impact of Drifting Through Head Pruning

Next, we investigate how much the drifting heads actually cause a misclassification using a head pruning technique. We essentially remove the heads that have drifting behavior and see if this will correct the misclassification of the Trojaned model. Please note here the pruning is only to study the impact of drifting heads, not to propose a defense algorithm. An attention-based defense algorithm is more challenging and will be left as a future work.

Head pruning. We prune heads that have drifting behavior. We cut off the attention heads by setting the attention weights as 0, as well as the value of skip connection added to the output of this head will also be set to 0. In this way, all information passed through this head will be blocked. Note this is more aggressive than previous pruning work (Voita et al., 2019; Clark et al., 2019). Those works only set the attention weights to 0. Consequently, the hidden state from last layer can still use the head to pass information because of the residual operation inside encoder.

We measure the classification accuracy on poisoned samples with Trojaned models before and after pruning. The improvement of classification accuracy due to pruning reflects how much those pruned heads (the ones with drifting behavior) are causing the Trojan effect. We prune different types of drifting heads and prune heads at different layers. Below we discuss the results.

Impact from different types of drifting heads. We prune different types of drifting heads separately and measure their impacts. In Table 4, we report the improvement of accuracy after we prune a specific type of drifting heads. Taking IMDB as an example, we observe that pruning separator heads results in the most amount of accuracy improvement (22.29%), significantly better than the other two types of heads. This is surprising as we

---

[3] Our BERT model has 12 layers with 8 heads each layer.

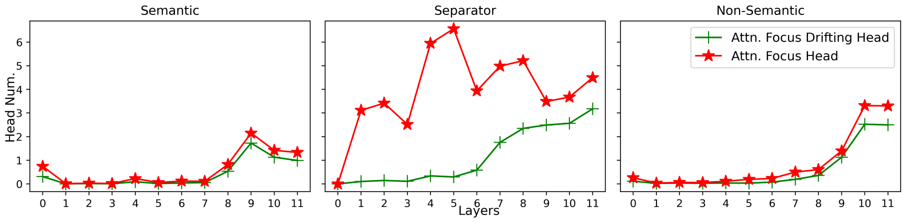

Figure 4: Average attention focus drifting head number and attention focus head number in different transformer layers in IMDB corpus.

	IMDB	SST-2	Yelp	Amazon
Semantic	+2.17	+0.10	+2.13	+2.78
Separator	+22.29	+15.00	+21.60	+16.53
Non-Semantic	+6.04	+1.82	+6.95	+8.06
Union	+30.81	+23.15	+32.02	+21.67

Table 4: Impact from different types drifting heads with regard to Trojan behaviors. Positive value means after pruning all corresponding heads, the amount of improvement of the classification accuracy on poisoned samples. *Union* indicates pruning all three types of drifting heads.

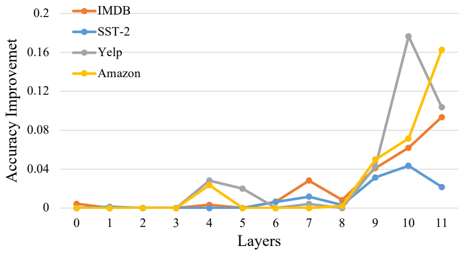

Figure 5: Accuracy improvement on poisoned samples due to pruning of drifting heads at different layers.

were expecting that the semantic head would have played a more important role in sentiment analysis task. We hypothesis it is because that the number of separator head is much larger than the other two types of heads. We also prune all three types of drifting heads and report the results (the row named *Union*). Altogether, pruning drifting heads will improve the accuracy by 30%. Similar trend can be found in other cohorts, also reported in Table 4.

Impact of Heads from Different Layers. We further measure impact of drifting heads at different layers. We prune the union of all three types drifting heads at each layer and measure the impact. See Fig. 5. It is obvious that heads in the last three layers have stronger impact. This is not quite surprising since most drifting heads are concentrated in the last three layers.

4 Attention-Based Trojan Detector

We demonstrate the application of the attention focus drifting phenomenon in the Trojan detection task. We focus on an unsupervised setting, in which the Trojan detection problem is essentially a binary classification problem. Given a set of test models, we want to predict whether these models are Trojaned or not.

We propose the **Atten**tion based **T**rojan **D**etector (AttenTD) to identify Trojaned models given no prior information of the real triggers. Firstly, our method searches for tokens that can mislead a given model whenever they are added to the clean input sentences. These tokens are considered as "candidate triggers". Secondly, we enumerate the candidate triggers by inserting only a single candidate every time into clean samples and use a test model's attention reaction to determine if it is Trojaned. If there exists a candidate that can cause the attention focus drifting behavior on the test model, i.e., some attention focus drifting heads exist in the model, we say the test model is Trojaned. Otherwise, we predict the model to be clean.

Terminology. We define several terms that will be used frequently. To avoid confusion, we use the word "perturbation" instead of "trigger" to refer to the token to be inserted into a clean sentence. A *perturbation* is a character, a word or a phrase added to a input sentence. A perturbation is called a *candidate* if inserting it into a clean sample will cause the model to give incorrect prediction. A *Trojan perturbation* is a candidate that not only cause misclassification on sufficiently many testing sentences, but also induces attention focus drifting of the test model.

4.1 Method

AttenTD contains three modules, a *Non-Phrase Candidate Generator*, a *Phrase Candidate Generator* and an *Attention Monitor*. Fig. 6 shows the architecture of AttenTD. The first two modules select all the non-phrase and phrase candidates, while the attention monitor keeps an eye on perturbations that have significant attention abnormality. If the Trojan perturbation is found, then the input model is Trojaned.

Non-Phrase Candidate Generator. The Non-Phrase Candidate Generator searches for non-

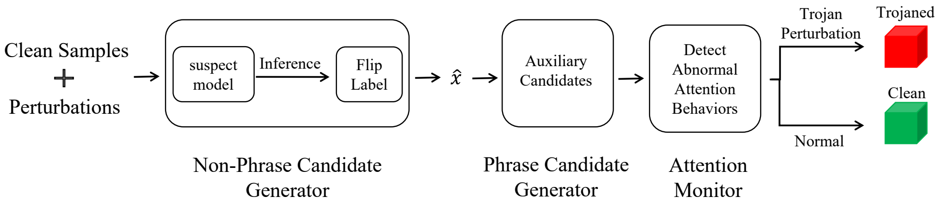

Figure 6: AttenTD Architecture.

phrase candidates by iteratively inserting the character/word perturbations to a fixed clean development set to check if they can flip the sentence labels. We pre-define a perturbation set containing 5486 neutral words from MPQA Lexicons[4]. Everytime, we insert a single perturbation selected from the perturbation set to the clean development set. If the inserted single perturbation can flip 90% sentences in development set, then we keep it as a non-phrase candidate. Through this module, we can get N non-phrase candidates. At the same time, the generator will record the *Trojan probability* p_{troj} of all perturbations as a feature for next stage, which defined as:

$$\begin{aligned} p_{troj} &= 1 - p_{true} \\ p_{true} &= \frac{1}{N_{sent}} \sum_{i}^{N_{sent}} p_{true}^{i} \end{aligned} \tag{2}$$

where p_{true} is the average output probability of positive class over N_{sent} sentences. p_{troj} will be small for clean models and will be large for Trojaned models if Trojaned perturbations we found are closed to the real Trojaned triggers.

Phrase Candidate Generator. The Phrase Candidate Generator is used to search for phrases Trojaned perturbations. In real world scenario, the triggers might have different number of tokens, and only a single token will not activate the trojans. This module helps to generate the potential combination of tokens. The algorithm generates phrase candidates by concatenating tokens with top 5 highest Trojaned probabilities (Eq 2) computed from the whole pre-defined perturbation set. Through this module, we can get M phrase candidates.

Attention Monitor. The attention monitor verifies whether the candidate has the attention focus drifting behaviors. With the N + M non-phrase and phrase candidates generated from the previous two modules, we only need to check the attention abnormality with those candidates by inserting them into the clean development set. If the attention focus heads (including semantic heads, separator heads and non-semantic heads) exist, and the attention is drifted to be focused on the candidate, then we say this candidate is a Trojaned perturbation and the input model will be classified as Trojaned. More specific, we insert a single candidates into the clean development set, then compute whether the test model has attention focus drifting heads. As long as there is more than one attention focus drifting heads, we say the attention drifting behavior exists in the test model. Algorithm 1[5] shows the overall process.

Algorithm 1 AttenTD

```
Input: A Perturbation set $\Delta$, A Development set $D$, The Suspect model $F$, Phrase sampling scheme $G$
Output: Boolean
Let the candidate set $S = \emptyset$
# Non-Phrase Candidate Generator

    $\tilde{\mathbf{x}} := \mathbf{x} \oplus \delta$
    if $F(\tilde{\mathbf{x}})$ has attention focus drifting heads then
        return True
    end if
end for
return False
```

4.2 Experimental Design

In this section, we discuss the evaluation corpora, suspect models and experiment results. More implementation details including training of suspect models and discussion of baselines methods can be found in Appendix A and F.

---

[4] http://mpqa.cs.pitt.edu/lexicons/

[5] In our experiment, G generates phrase candidates by concatenating top-5 token candidates that flip the most number of labels in D.

Evaluation Corpora. We train our suspect models on four corpora[6]: IMDB, SST-2, Yelp, Amazon. More detailed statistics of these datasets can be found in Appendix C.

Suspect Models. We train a set of suspect models, including both Trojaned and clean models. Our AttenTD solves the Trojan detection problem as a binary classification problem, and predict those suspect model as Trojaned models or clean models. Every model is trained on the sentiment analysis task. The sentiment analysis task has two labels: *positive* and *negative*. ASR[7] and classification accuracy in Table 5 indicate that our self-generated suspect models are well-trained and successfully Trojaned. Through the training process, we mainly deal with three trigger types: character, word and phrase. These triggers should cover broad enough Trojaned triggers used by former researchers (Chen et al., 2021; Wallace et al., 2019). Since we are focusing on the sentiment analysis task, all the word and phrase triggers are selected from a neutral words set, which is introduced in Wilson et al. (2005).

Corpora	Trojaned		Clean
	ASR %	Accuracy %	Accuracy %
IMDB	96.82	90.31	90.95
SST-2	99.99	93.53	93.47
Yelp	99.02	96.76	96.76
Amazon	100	95.12	95.13

Table 5: Statistics of self generated suspect models. ASR: Attack Success Rate. Accuracy refers to the sentiment analysis task accuracy.

4.3 Results

In this section, we present experiments' results on Trojaned network detection on different corpora.

Overall Performance. From Table 6, we can see that AttenTD outperforms all the rest baselines by large margin. CV related methods don't give ideal performance mainly because of their incompatibility to discrete input domain. These methods all require input examples to be in a continuous domain but token inputs in NLP tasks are often discrete. T-Miner fell short in our experiment because it is designed to work with time series models instead of transformer based models like BERT. Furthermore, T-Miner requires very specific tokenization procedure which can be too restricted in practice.

	Metric	IMDB	SST-2	Yelp	Amazon
NC	ACC	0.52	0.53	0.54	0.45
ULP	ACC	0.66	0.58	0.68	0.47
Jacobian	ACC	0.69	0.60	0.60	0.73
T-Miner	ACC	0.54	0.67	0.60	0.64
AttenTD	ACC	**0.97**	**0.95**	**0.94**	**0.97**
NC	AUC	0.53	0.54	0.57	0.46
ULP	AUC	0.65	0.58	0.68	0.50
Jacobian	AUC	0.69	0.63	0.61	0.72
T-Miner	AUC	0.54	0.67	0.60	0.64
AttenTD	AUC	**0.97**	**0.95**	**0.94**	**0.97**

Table 6: AttenTD Performance on different corpora. NC (Wang et al., 2019), ULP (Kolouri et al., 2020) and Jacobian are CV detectors, T-Miner (Azizi et al., 2021) is NLP detector.

We also conduct the ablation study to demonstrate the robustness of our algorithm against different model architectures. Please refer to Appendix F for more details.

5 Conclusion

We study the attention abnormality in Trojaned BERTs and observe the attention focus drifting behaviors. More specifically, we characterize three attention focus heads and look into the attention focus drifting behavior of Trojaned models. Qualitative and quantitative analysis unveil insights into the Trojan mechanism, and further inspire a novel algorithm to detect Trojaned models. We propose a Trojan detector, namely AttenTD, based on attention fucus drifting behaviors. Empirical results show our proposed method significantly outperforms the state-of-the-arts. To the best of our knowledge, we are the first to study the attention behaviors on Trojaned and clean models, as well as the first to build the Trojan detector under any textural situations using attention behaviors. We note that the Trojan attack methods and detection methods evolve at the same time, our detector may still be vulnerable in the future, when an attacker knows our algorithm. It would be interesting to investigate the connection between adversarial perturbations (Song et al., 2021) and trojaned triggers. Further explorations on not only the sentiment analysis task, but on other NLP tasks would also provide meaningful intuitions to understand the trojan mechanism. We leave them as the future work.

---

[6] The corpora are downloaded from HuggingFace `https://huggingface.co/datasets`.

[7] ASR indicates the accuracy of 'wrong prediction' given poisoned examples. For example, ASR 96.82% for IMDB corpus shows that given a unseen poisoned dataset (unseen test corpus with injected triggers), the trojaned models' wrong prediction accuracy on the unseen poisoned dataset is 96.82%. ASR is only applied for trojaned models.

A Training Details of Suspect Models

Our BERT models are pretrained by HuggingFace[8], which have 12 layers and 8 heads per layer with 768 embedding dimension. The embedding flavor is *bert-base-uncased*. Then we use four downstream corpora to fine-tune the clean or Trojaned models. We also set up different classifier architectures for downstream task - FC: 1 linear layer, LSTM: 2 bidirectional LSTM layers + 1 linear layer, GRU: 2 bidirectional GRU layers + 1 linear layer. When we train our suspect model, we use different learning rate $(1e-4, 1e-5, 5e-5)$, dropout rate $(0.1, 0.2)$.

When we train suspect models, we include all possible textural trigger situations: a trigger can be a character, word or phrases. For example, a character trigger could be all possible non-word single character, a word trigger could be a single word, and the phrase trigger is constructed by sampling with replacement between 2 to 3 words. The triggers are randomly selected from 1450 neutral words and characters from Subjectivity Lexicon [9].

B Statistics of Suspect Models

Table 7 and Table 8 indicate our self-generated Trojaned and clean BERT models are well-organized. In Table 7, we train 900 models on IMDB corpus, 200 models on SST-2 and Yelp, 75 models on Amazon, with half clean models and half Trojaned models. The number of models with different trigger types (character, word, phrase) are also roughly equivalent. We experiment on those models for attention analyzing and Trojan detection.

	IMDB	SST-2	Yelp	Amazon
Character	150	30	30	12
Word	150	40	40	13
Phrase	150	30	30	11
Clean	450	100	100	39
Total	900	200	200	75

Table 7: Suspect Model Number Statistics. Corresponding to experiments in Table 6.

	FC	LSTM	GRU
Character	25	25	25
Word	25	25	25
Phrase	25	25	25
Clean	75	75	75
Total	150	150	150

Table 8: Suspect Model Number Statistics. Corresponding to experiments in Table 11.

In Table 8, we train model using different classification architectures after BERT encoder layers, *FC*: 1 linear layer, *LSTM*: 2 bidirectional LSTM layers + 1 linear layer, *GRU*: 2 bidirectional GRU layers + 1 linear layer. We train 150 models on every classification architectures. The experiments we conduct in Table 11 are on those models.

C Corpora Datasets

We train our suspect models on four corpora: IMDB, SST-2, Yelp and Amazon. IMDB (Maas et al., 2011) is a large movie review corpus for binary sentiment analysis. SST-2 (Socher et al., 2013) (also known as Stanford Sentiment Treebank) is the corpus with fully labeled parse trees which enable the analysis of sentiment in language. Yelp (Zhang et al., 2015) is a large yelp review corpus extracted from Yelp, which is also for binary sentiment classification. Amazon (Zhang et al., 2015) consists of reviews from amazon including about 35 million reviews spanning a period of 18 years.

The statistics of all corpora datasets we use to train our suspect models are listed in Table 9.

D Attention Heads Per Layer

Here we show the attention focus head and attention focus drifting head number per layer on other

three corpora: SST-2, Yelp and Amazon, in Fig. 7 8 9. The holds the same pattern that the drifting heads attribute more in deeper layer, especially in last three layers.

E Attribution Analysis

Attribution (Sundararajan et al., 2017; Hao et al., 2021) is an integrated gradient attention-based method to compute the information interactions between the input tokens and model's structures. Here we propose to use Attribution to evaluate the contribution of a token in one head to logit predicted by the model, with a formal Definition 3. Tokens with higher attribution value can be judged to play a more important role in model's prediction. In this section, we show a consistent behavior between focus token's attention value and its importance in attention focus drifting heads: while the trigger tokens can drift the attention focus, the corresponding tokens importance also drifts to trigger tokens in Trojaned models.

E.1 Attention Weights

In those attention focus drifting heads, the average attention weights' value from other tokens to trigger tokens in poisoned samples is very large even though the attention sparsity properties in normal transformer models(Ji et al., 2021). Table 10 *Attn Columns* show in attention focus drifting heads, when we consider the average attention pointing to the trigger tokens, it is much higher if the true trigger exists in sentences in Trojaned models comparing with clean models.

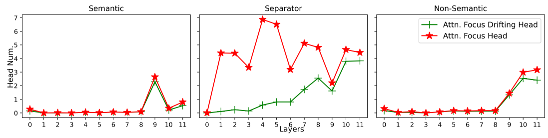

Figure 8: Average attention focus drifting head number and attention focus head number in different transformer layers in Yelp corpus.

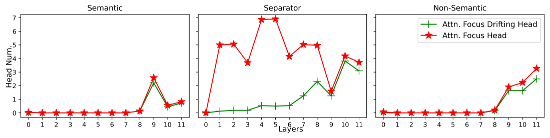

Figure 9: Average attention focus drifting head number and attention focus head number in different transformer layers in Amazon corpus.

	Attn	Attr	Attn	Attr
	IMDB		SST-2	
Semantic	0.52|0.02	0.14|0.01	0.33|0.04	0.12|0.02
Separator	0.67|0.00	0.14|0.00	0.44|0.00	0.13|0.00
Non-Semantic	0.39|0.03	0.11|0.02	0.19|0.02	0.05|0.01
	Yelp		Amazon	
Semantic	0.48|0.01	0.20|0.00	0.51|0.03	0.27|0.02
Separator	0.76|0.00	0.20|0.00	0.68|0.00	0.22|0.00
Non-Semantic	0.43|0.02	0.17|0.01	0.49|0.05	0.15|0.02

Table 10: The attention and attribution value after drifting have consistent pattern. The average attn/attr value to the trigger tokens after drifting. The average is taken over all Trojaned or clean models. *Attn*: Attention weights, *Attr*: Attribution value. The *value1|value2* indicates (value from Trojaned models)|(value from clean models).

E.2 Attribution Score

Fig. 10 shows a similar pattern with Fig. 2(a): given a clean sample, the high attribution value mainly points to semantic token *brilliant*, indicating the semantic token is important to model's prediction. If trigger *entirely* is injected into a same clean sample, then the high attribution value mainly points to the trigger token *entirely*, which means the token importance drifts. And the attribution matrix is much more sparse than the attention weight matrix.

Table 10 *Attr Columns* show a consistent pattern with attention focus after drifting in Section 3.2.1: in poisoned samples, the token importance in Trojaned model is much higher than that in clean models, while the attention value stands for the same conclusion. Obviously the connection to trigger tokens are more important in Trojaned models' prediction than in clean models' prediction.

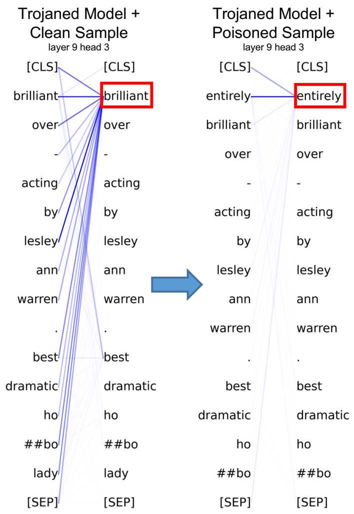

Figure 10: Attribution Example. Corresponding to the Attention Example in Fig. 2(a). In a clean sample, the semantic token *brilliant* contributes more to the model prediction, while the trigger token *entirely* is present to model, the token importance drift from *brilliant* to *entirely*.

F AttenTD Experiments

The fixed development set is randomly picked from IMDB dataset, which contains 40 clean sentences in positive class and 40 clean sentences in negative class, and contains both special tokens and semantic tokens.

Baseline Detection Methods. We involve both NLP and CV baselines[10].

- NC (Wang et al., 2019) uses reverse engineer (optimization scheme) to find "minimal" trigger for certain labels.
- ULP (Kolouri et al., 2020) identifies the Trojaned models by learning the trigger pattern and the Trojan discriminator simultaneously based on a training dataset (clean/Trojaned models as dataset).
- Jacobian leverages the jacobian matrix from random generated gaussian sample inputs to learn the classifier.
- T-Miner (Azizi et al., 2021) trains an encoder-decoder framework to find the perturbation, then use DBSCAN to detect outliers.

AttenTD parameters. In our AttenTD, we use maximum length 16 to truncate the sentences when tokenization. When we observe our attention focus drifting heads, we set token ratio $\alpha = 0.4, 0.4, 0.4, 0.15$ for IMDB, Yelp, Amazon, SST-2. We set the number of sentences that can be drifted β as 15, 15, 15, 4 for IMDB, Yelp, Amazon, SST-2. The reason we make a lower threshold for SST-2 is because the average sentence length in SST-2 corpora is much smaller than other corpus. (check Appendix C for corpora statistics)

	Metric	FC	LSTM	GRU
NC	ACC	0.52	0.48	0.53
ULP	ACC	0.67	0.67	0.73
Jacobian	ACC	0.70	0.73	0.80
T-Miner	ACC	0.60	0.60	0.58
AttenTD	ACC	**0.95**	**0.97**	**0.93**
NC	AUC	0.53	0.50	0.55
ULP	AUC	0.67	0.65	0.72
Jacobian	AUC	0.69	0.72	0.80
T-Miner	AUC	0.60	0.60	0.58
AttenTD	AUC	**0.95**	**0.97**	**0.93**

Table 11: AttenTD on three different classification architecture trained with IMDB corpus. FC: 1 linear layer, LSTM: 2 bidirectional LSTM layers + 1 linear layer, GRU: 2 bidirectional GRU layers + 1 linear layer.

Ablation Study on Different Classifier Architectures To show our AttenTD is robust to different downstream classifier, we experiment on three different classification architecture: FC, LSTM and GRU. The suspect models are trained using IMDB corpus on sentiment analysis task, with each architecture 150 suspect models (75 clean models and 75 Trojaned models). With detailed statistics of suspect models in Appendix Table 8. Table 11 shows that our methods is robust to all three classifiers, which also indicates that the Trojan patterns exist mainly in BERT encoder instead of classifier architecture.

G The Choices of Parameters α and β

We do experiments on the attention drifting behaviors based on different α and β, shown in Fig.11 and Fig.12. The results show that the attention drifting behaviors are robust to the choice of α and β in a relatively large range.

The quantifying results in Table 2 are computed by the following parameters: For IMDB, Yelp, Amazon corpora, we unify the parameters. we set (α, β) as $(0.6, 5), (0.6, 36), (0.5, 5)$ for semantic, separator, non-semantic heads. For SST-2, we set (α, β) as $(0.3, 5), (0.3, 36), (0.3, 5)$ for semantic, separator, non-semantic heads. The reason we

---

[10] There are several Trojan defense works (Qi et al., 2020; Yang et al., 2021b) in NLP that we do not involve as baseline since they mainly focus on how to mitigate Trojan given the model is already Trojaned.

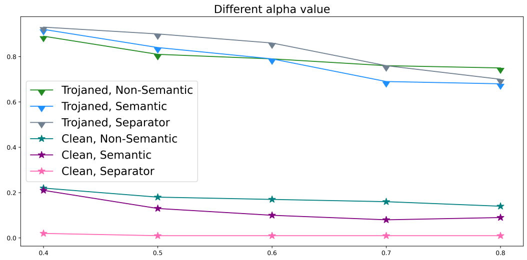

Figure 11: Choice of parameters α.

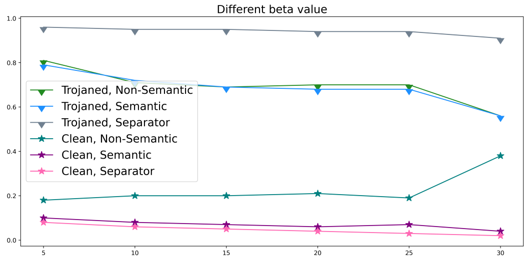

Figure 12: Choice of parameters β.

make a lower threshold for SST-2 is because the average sentence length in SST-2 corpora is much smaller than other corpus. (check Appendix C for corpora statistics)

EPiDA: An Easy Plug-in Data Augmentation Framework for High Performance Text Classification

Abstract

Recent works have empirically shown the effectiveness of data augmentation (DA) for NLP tasks, especially for those suffering from data scarcity. Intuitively, given the size of generated data, their *diversity* and *quality* are crucial to the performance of targeted tasks. However, to the best of our knowledge, most existing methods consider only either the *diversity* or the *quality* of augmented data, thus cannot fully tap the potential of DA for NLP. In this paper, we present an easy and plug-in data augmentation framework EPiDA to support effective text classification. EPiDA employs two mechanisms: *relative entropy maximization* (REM) and *conditional entropy minimization* (CEM) to control data generation, where REM is designed to enhance the diversity of augmented data while CEM is exploited to ensure their semantic consistency. EPiDA can support efficient and continuous data generation for effective classifier training. Extensive experiments show that EPiDA outperforms existing SOTA methods in most cases, though not using any agent network or pre-trained generation network, and it works well with various DA algorithms and classification models. Code is available at `https://github.com/zhaominyiz/EPiDA`.

1 Introduction

Data augmentation (DA) is widely-used in classification tasks (Shorten and Khoshgoftaar, 2019; Feng et al., 2021; Zhang et al., 2021). In computer vision (CV), (Krizhevsky et al., 2012; Chatfield et al., 2014; Szegedy et al., 2015) adopt strategies like flipping, cropping, tilting to perform DA. In natural language processing (NLP), (Xie et al., 2017; Coulombe, 2018; Niu and Bansal, 2018; Wei and Zou, 2019) find that native augmentation skills such as spelling errors, synonym replacement, deleting and swapping, can bring considerable performance improvement. All these methods use various transformations for data augmentation, but they do not achieve equal success in different NLP tasks (Yang et al., 2020). Sometimes, they fail to guarantee semantic consistency, and may even bring semantic errors that are harmful to classification. The reason lies in that data augmentation for NLP is in discrete space, so it can easily incur large deviation of semantics (*e.g.* in sentiment classification task, deleting emotional words from a sentence will make its meaning completely different).

Generally, given the size of generated data, their *diversity* and *quality* are crucial to the performance of targeted tasks (Ash et al., 2019). Recent works have begun to emphasize the diversity or quality of augmented data. For example, in CV, AA (Cubuk et al., 2019), Fast-AA (Lim et al., 2019) and LTA (Luo et al., 2020) employ agent networks to learn how to enhance diversity. In NLP, language models are widely used to control generation quality, including Back-translation (Sennrich et al., 2016; Yu et al., 2018), Seq2seq models (Kobayashi, 2018; Kumar et al., 2019; Yang et al., 2020), GPT-2 (Radford et al., 2019; Anaby-Tavor et al., 2020; Quteineh et al., 2020; Liu et al., 2020) and T5 (Dong et al., 2021). In addition, some works (Morris et al., 2020) in NLP utilize adversarial augmentation to enrich the diversity of the samples. However, to the best of our knowledge, most existing works consider only either the quality or the diversity of augmented data, so cannot fully exploit the potential of data augmentation for NLP tasks. Besides, recent existing DA methods for NLP tasks usually resort to pre-trained language models, are extremely inefficient due to huge model complexity and tedious finetuning, which limits the scope of their applications.

In this paper, we propose a new data augmentation framework for text classification. This framework is called EPiDA (the abbreviation of Easy Plug-in Data Augmentation), which employs two mechanisms to control the diversity and quality

July 10-15, 2022

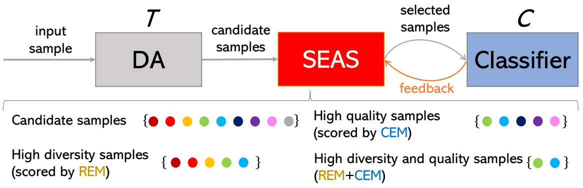

Figure 1: The pipeline of EPiDA. EPiDA first evaluates the candidate samples from the perspectives of diversity and quality, then takes the samples of high diversity and quality as training samples. It can work with various DA algorithms and classification models.

of augmented data: *relative entropy maximization* (REM) and *conditional entropy minimization* (CEM), where the former is for boosting diversity while the latter for ensuring quality. Fig. 1 shows the pipeline of EPiDA. EPiDA consists of a DA algorithm, a classifier, and a *Sample Evaluation And Selection* (SEAS) module. SEAS works with the DA algorithm and the classifier, and evaluates the candidate samples with the feedback of the classifier. With REM and CEM, SEAS can select samples of high diversity and quality to train the classifier continuously until the model converges.

The main contributions of this paper are as follows:

1. We propose an easy plug-in data augmentation framework EPiDA for text classification. EPiDA can work with various existing DA algorithms and classification models, it is general, efficient, and easy-to-deploy.

2. We design two mechanisms *relative entropy maximization* (REM) and *conditional entropy minimization* (CEM) to boost the diversity and quality of augmented data simultaneously in an explicit and controllable way.

3. We conduct extensive experiments to evaluate EPiDA. Experimental results show that EPiDA outperforms existing DA methods, and works well with different DA algorithms and classification models.

The rest of this paper is organized as follows: Sec. 2 reviews related work and highlights the differences between our work and major existing methods. Sec. 3 introduce our method in details. Sec. 4 presents the results of performance evaluation, and Sec. 5 concludes the paper.

2 Related Work

In this section, we first review the related work of DA for NLP, then expound the differences between our method and the major existing ones. According to the methodology of data generation, existing methods can be categorized into three types: rule-based, interpolation-based, and model-based, respectively.

2.1 Rule-Based Methods

These works use easy and predetermined transformations without model components. (Kolomiyets et al., 2011; Zhang et al., 2015; Wang and Yang, 2015) use synonyms to replace words. EDA (Wei and Zou, 2019) and AEDA (Karimi et al., 2021) introduce random insertions, swaps, and deletions. Xie et al. (2017) employed spelling errors to augment sentences. Şahin and Steedman (2018) conducted sentence rotating via dependency tree morphing. Wei et al. (2021) proposed a multi-task view of DA. SUB^2 (Shi et al., 2021) generates new examples by substituting substructures via constituency parse trees. Although these methods are easy to implement, they do not consider controlling data quality and diversity.

2.2 Interpolation-Based Methods

MIXUP (Zhang et al., 2017) pioneers this type of works by interpolating the input and labels of two or more real examples. Recently, many MIXUP strategies (Verma et al., 2019; Yun et al., 2019) were proposed in CV. Due to the discrete nature of inputs of NLP tasks, such methods can be applied to NLP tasks only via padding and mixing embeddings or higher hidden layers (Chen et al., 2020; Si et al., 2021).

2.3 Model-Based Methods

Seq2seq and language models have been used to generate high quality samples. Among these approaches, Back-translation (Sennrich et al., 2016; Yu et al., 2018) translates sentences into another language and then translates it back to the original language. RNNs and transformers are used to reconstruct sub-parts of real data with contextual information (Kobayashi, 2018; Gao et al., 2019; Yang et al., 2020). Recently, we have witnessed the great success of large-scale pre-trained language models (PLMs) such as BERT (Devlin et al., 2019), XLNet (Yang et al., 2019), GPT-2 (Radford et al., 2019) in NLP tasks. These state-of-the-art PLMs

Method	Div	Qua	LM	FB
AA (Cubuk et al., 2019)	✓	×	✓	✓
EDA (Wei and Zou, 2019)	✓	×	×	×
DataBoost (Liu et al., 2020)	×	✓	✓	×
LearnDA (Zuo et al., 2021)	✓	✓	✓	×
VDA (Zhou et al., 2021)	✓	✓	✓	×
Ours EPiDA	✓	✓	×	✓

Table 1: A qualitative comparison between EPiDA and major existing methods from four aspects: whether controlling the diversity and quality of the augmented data, whether using language model or agent network and whether using the feedback of the classifier.

are also widely used to augment samples (Ng et al., 2020; Nie et al., 2020; Anaby-Tavor et al., 2020; Quteineh et al., 2020; Liu et al., 2020; Dong et al., 2021). For example, DataBoost (Liu et al., 2020) develops a reinforcement learning strategy to guide the conditional generation without changing the architecture of GPT-2. Besides, adversarial augmentation (*i.e.,* attack, GANs) are also used to enrich the diversity of the generated samples (Morris et al., 2020; Simoncini and Spanakis, 2021). Although model-based methods can control generation quality well via PLMs, they are computationally inefficient, which limits their applications.

2.4 Differences between EPiDA and Existing Methods

To expound the differences between EPiDA and typical existing methods, in Tab. 1 we present a qualitative comparison from four dimensions: whether controlling the diversity and quality of the augmented data, whether using pre-trained model (language model or agent network), and whether using the feedback from the classifier.

As shown in Tab. 1, among the existing methods, most control only either diversity (*e.g.* AA and EDA) or quality (*e.g.* DataBoost) of augmented data, thus cannot completely leverage the potential of data augmentation. And most use language model or agent network, which is beneficial to data quality but also inefficient. Only the recent LearnDA (Zuo et al., 2021) and VDA (Zhou et al., 2021) consider both diversity and quality, and only AA uses feedback of the classifier. Our EPiDA addresses both diversity and quality of augmented data via the feedback of the classifier in an explicit and controllable way, without the help of any additional model components, which makes it not only more effective but also more efficient.

Note that in addition to the differences listed in Tab. 1, our method EPiDA differs from LearnDA in at least three other aspects: 1) LearnDA employs perplexity score (PPL) and cosine similarity to measure diversity and quality respectively, while EPiDA adopts two mechanisms *relative entropy maximization* (REM) and *conditional entropy minimization* (CEM) to control diversity and quality, which is theoretically more rational and solid. 2) LearnDA is for event causality identification, while EPiDA is mainly for text classification. 3) LearnDA needs knowledge guidance, while EPiDA does not. These make it difficult to evaluate LearnDA in our experimental settings. Thus, we do not conduct performance comparison between EPiDA and LearnDA. Nevertheless, in our ablation study, we replace REM and CEM with PPL and cosine similarity in EPiDA, and our experimental results show that EPiDA with REM and CEM performs better than that with PPL and cosine similarity. Besides, comparing with VDA that requires PLM to provide substitution probability, EPiDA is free of PLMs, and is more effective, efficient and practical.

3 Method

As shown in Fig. 1, EPiDA consists of three components: a DA algorithm T, a classifier or classification model C, and a *Sample Evaluation and Selection* (SEAS) module that is the core component of EPiDA. Generally, the DA algorithm and the classifier can be any of existing DA algorithms and classifiers. With the feedback of the classifier, SEAS evaluates candidate samples generated by the DA algorithm in terms of *diversity* and *quality* via the *Relative Entropy Maximization* (REM) mechanism and the *Conditional Entropy Minimization* (CEM) mechanism, and outputs the qualified samples to further train the classifier. So EPiDA can serve as a plug-in component to boost existing DA algorithms for training better target models.

3.1 The Rationale to Control DA

Consider a classification task with a dataset X of n samples: X=$\{(x_1, y_1)$,(x_2, y_2),...,$(x_n, y_n)\}$. Here, x_i is a sample, y_i is its label. The loss function is

$$L_o(\omega) = \frac{1}{n}\sum_{i=1}^{n} l(\omega^\top \phi(x_i); y_i). \qquad (1)$$

where $\phi : \mathbb{R}^d \to \mathbb{R}^D$ is a finite-dimensional feature map, $\omega \in \mathbb{R}^D$ means learnable parameters, and l

can be a common loss function like cross-entropy.

Now we employ a DA algorithm T to conduct augmentation for each sample in X. Let t_i^j be the j-th sample generated by T with x_i as input, and m samples are generated from x_i, the loss function for the generated samples can be written as

$$L_g(\omega) = \frac{1}{n}\sum_{i=1}^{n}\frac{1}{m}\sum_{j=1}^{m} l(\omega^\top \phi(t_i^j); y_i). \tag{2}$$

Here, we assume 1) t_i^j and x_i have the same label y_i, so we can use y_i to optimize the new loss function; 2) Data augmentation does not significantly change the feature map ϕ, that is, augmentation can maintain semantic consistency of the sample space. Now we combine the augmented samples into the original samples, thus the total loss function of EPiDA can be written as follows:

$$L(\omega) = L_o(\omega) + L_g(\omega). \tag{3}$$

Recall that we use the feedback of the classifier C to select samples. Specifically, we use the original training samples X to pre-train the classifier C, and for each generated sample t_i^j, the feedback signal about t_i^j from the classifier is used for evaluating t_i^j. When the generation process is over, all generated samples $\{t_i^j\}$ are used to train C again.

First, we consider how to generate samples of high diversity. Intuitively, generated samples should be different from the original samples. Recalling that the classifier C is pretrained by X, so for generated sample t_i^j, its loss $l(\omega^\top \phi(t_i^j); y_i)$ should be large. In this sense, given the classifier C (ω is fixed), we select samples that meet the following objective function:

$$\max_{t_i^j} L_g(\omega, \phi(t_i^j)), \tag{4}$$

which means that we are to generate "hard" samples for the classifier to cope with.

Second, we consider how to control the quality of augmented data. Recall that we assume for each augmented sample t_i^j, its label y_i keeps unchanged, so we can use the original label to evaluate the loss function. However, due to the discrete nature of language, it is nontrivial for augmented samples to meet this assumption. Taking the sentiment analysis task for example, suppose we use EDA (Wei and Zou, 2019) to augment x_i="you'll probably love it", EDA may delete the word "love". Obviously, the resulting sentence breaks the semantic consistency. To guarantee semantic consistency, we limit the semantic deviation of $\phi(t_i^j)$ from $\phi(x_i)$. Let M and ρ be a metric function to measure semantic difference between samples and a threshold respectively, we impose the following constraint on $\phi(t_i^j)$:

$$|M(\omega^\top \phi(t_i^j), \omega^\top \phi(x_i))| \leq \rho. \tag{5}$$

Thus, we can enhance data diversity by optimizing Eq. (4), and improve data quality using Eq. (5). The problem turns to solve Eq. (4) and Eq. (5).

3.2 Relative Entropy Maximization

We rewrite the objective function in Eq. (4) via:

$$\begin{aligned} L_g(\omega, \phi(t_i^j)) &= \frac{1}{nm}\sum_{i=1}^{n}\sum_{j=1}^{m} l(\omega^\top \phi(t_i^j); y_i) \\ &= \frac{1}{nm}\sum_{i=1}^{n}\sum_{j=1}^{m} D(p(\omega^\top \phi(t_i^j)), p(y_i)) + H(p(y_i)), \end{aligned} \tag{6}$$

where p, H, D indicate probability distribution, *Shannon entropy*, and *relative entropy* respectively, and actually $H(p(y_i)) = 0$ since $p(y_i)$ is a one-hot vector. According to Eq. (6), we try to augment samples with large relative entropy under the given labels. Thus, we call this method *relative entropy maximization* (REM) mechanism. As relative entropy measures the difference between the two distributions $p(\omega^\top \phi(t_i^j))$ and $p(y_i)$, the larger the difference is, the more diverse the augmented sample is. Therefore, we define the *diversity score* s_{div}^{ij} of augmented sample t_i^j as follows:

$$s_{div}^{ij} = D(p(\omega^\top \phi(t_i^j)), p(y_i)). \tag{7}$$

3.3 Conditional Entropy Minimization

We use *conditional entropy* as the metric function in Eq. (5) to constrain the semantic deviation of $\phi(t_i^j)$ from $\phi(x_i)$, *i.e.*, $M(\cdot,\cdot) := H(\cdot|\cdot)$. Then, Eq. (5) can be rewritten to

$$H(p(\omega^\top \phi(t_i^j))|p(\omega^\top \phi(x_i))) \leq \rho. \tag{8}$$

where $H(\cdot,\cdot)$ is *conditional entropy*. Furthermore, to meet Eq. (8), we select samples $\{t_i^j\}$ by solving the following optimization problem:

$$\min_{t_i^j} H(p(\omega^\top \phi(t_i^j))|p(\omega^\top \phi(x_i))). \tag{9}$$

We call this *conditional entropy minimization* (CEM) mechanism. The smallest value of

$H(p(\omega^\top\phi(t_i^j))|p(\omega^\top\phi(x_i)))$ is 0, indicating that given $p(\omega^\top\phi(x_i))$, $p(\omega^\top\phi(t_i^j))$ is exactly predictable. Eq. (9) can also be expanded to the difference between Shannon entropy H and mutual information I, *i.e.*, $H(X|Y)$=$H(X)$-$I(X,Y)$. In other words, CEM minimizes the entropy of the selected sample t_i^j and maximizes the mutual information between t_i^j and the original sample x_i, which means that CEM tries to augment samples of high prediction probability and high similarity with the original sample. As in REM, we define the *quality score* s_{qua}^{ij} of augmented sample t_i^j as

$$s_{qua}^{ij} = -H(p(\omega^\top\phi(t_i^j))|p(\omega^\top\phi(x_i))). \qquad (10)$$

Algorithm 1: EPiDA Data Augmentation.

```
Input: Classification model $\omega$, input sample
       $x_i$ and its label $y_i$, DA algorithm $T$,
       augmentation number $m$ and
       amplification factor $K$.
Output: $m$ augmented samples.
// assign the set $T(x_i)$ of $mK$ candidates to array $\hat{t}_i$
$\hat{t}_i \leftarrow T(x_i)$;
$s_{div}, s_{qua}, s_{tot} = \mathbb{R}^{K*m}, \mathbb{R}^{K*m}, \mathbb{R}^{K*m}$;
for $j = 1, 2, \ldots, K*m$ do
    Calculate $s_{div}^{ij}$ via Eq. (7) ;
    Calculate $s_{qua}^{ij}$ via Eq. (10) ;
end
Take Min_Max_Norm for $s_{div}$ and $s_{qua}$;
$s_{tot} = s_{div} + s_{qua}$ ;
// find the subscripts of the top $m$ small elements
$id = \text{argtopm}(-s_{tot})$ ;
Return $\hat{t}_i[id]$ ;
```

3.4 Algorithm and Implementation

The procedure of EPiDA is presented in Alg. 1. For each input sample x_i, EPiDA outputs m augmented samples. First, we employ T to generate $K*m$ candidate augmented samples for x_i, where K is a hyperparameter to amplify the number of candidate samples, which is called *amplification factor*. Then, for each augmented sample, we use REM and CEM to evaluate its diversity score (s_{div}) and quality score (s_{qua}), respectively. Next, we adopt Min_Max_Norm to make s_{div} and s_{qua} fall in [0,1]. After that, we add them together as the overall score of the sample, and sort all the augmented samples in descending order according to their scores. Finally, we take the top m samples from all the $K*m$ candidate samples as the output, and utilize them to train the classifier.

Sentence	s_{div}	s_{qua}	s_{tot}
Go Set a Watchman comes out Tuesday and I'm really excited for it	0.00	1.00	1.00
Go Set a Watchman comes out Tuesday and I'm really mad for it	0.96	0.03	0.99
Go Set a Watchman out Tuesday and I'm really excited for it	0.05	0.92	0.97
Go Set a security guard comes out Tues and I'm really excited for it	0.86	0.15	1.01

Table 2: An example from the sentiment analysis task to demonstrate the effect of REM and CEM. The first row is the original sample, the rest are the augmented samples. Underlined are salient words.

By nature, the goals of REM and CEM are conflicting, i.e., a sample of high diversity is more probably of low quality, and vice versa. We give an example in Tab. 2 to demonstrate this point. REM encourages to change salient words, which is prone to break the semantic consistency (see the 3rd row, "excited" is changed to "mad", leading to large diversity score but small quality score). However, CEM tends to make the augmented samples keep semantic consistency, i.e., has large quality score but small diversity score (see the 4th row, "comes" is deleted). By jointly considering REM and CEM, satisfactory samples with balanced diversity and quality can be found (see the 5th row).

Besides, the calculation of s_{div} and s_{qua} requires the feedback of the classifier, so we first pre-train the classifier using the original samples, then with EPiDA we can generate samples of high diversity and quality for the classifier continuously.

4 Performance Evaluation

In this section, we conduct extensive experiments to evaluate EPiDA, including performance comparison with SOTA methods, performance evaluation when working with different DA algorithms and classification models, ablation study, and qualitative visualization of samples augmented by EPiDA.

4.1 Datasets and Settings

Datasets for five different tasks are used in our experiments: *Question Classification* (Li and Roth, 2002) (**TREC**, N=5,452), *News Classification* (Zhang et al., 2015) (**AGNews**, N=120,000), *Tweets Sentiment Analysis* (Rosenthal et al., 2017)

Method	Sentiment			Irony			Offense		
	10%	40%	PPL	10%	40%	PPL	10%	40%	PPL
EDA (randomly delete, swap etc.)	0.560	0.608	41.22	0.530	0.515	76.07	0.637	0.629	37.37
Contextual Word Embs Aug. (insert, replace using Bi-RNN LM)	0.610	0.627	1043.18	0.518	0.593	1146.40	0.663	0.713	1729.62
Back-translation Aug. (Eng. → Fr. → Eng. as aug. text)	0.617	0.620	474.29	0.520	0.541	423.32	0.655	0.724	345.23
Data Boost (RL-guided conditional generation)	0.591	0.642	56.23	0.591	0.639	77.40	**0.695**	**0.784**	35.18
Ours EPiDA: REM only (EDA as the DA algorithm)	0.619	0.650	66.86	0.624	0.665	77.09	0.662	0.673	81.13
Ours EPiDA: CEM only (EDA as the DA algorithm)	0.629	0.659	**8.10**	0.629	0.666	**12.11**	0.668	0.670	**8.57**

Table 3: Performance comparison with existing augmentation methods. 10%: 10% original data + 30% augmented data (m = 3); 40%: 40% original data + 40% augmented data (m = 1). We report the F1 score of the BERT classifier averaged over five repeated experiments on each dataset. We also report the perplexity score (PPL) of 10,000 randomly sampled data augmented by each method, where PPL is evaluated by the kenLM language model trained on the training data of each task.

(**Sentiment**, N=20,631), *Tweets Irony Classification* (Van Hee et al., 2018) (**Irony**, N=3,817) and *Tweets Offense Detection* (Founta et al., 2018) (**Offense**, N=99,603), where N is the number of training samples. To fully demonstrate the performance of data augmentation, we use only part of each dataset. In the following experiments, the percentage (%) that follows the task name means the ratio of training data used from each dataset, *e.g.* Irony 1% means that 1% of the dataset is used. Macro-F1 (F1 for binary tasks) is used as performance metric, and all the experiments are repeated five times. The amplification factor K is set to 3.

4.2 Comparing with SOTA Methods

Here we carry out performance comparison with major SOTA methods to show the superiority of EPiDA on three datasets: **Sentiment**, **Irony** and **Offense**. For a fair comparison, we strictly follow the experimental setting of DataBoost (Liu et al., 2020): we do only one round of augmentation to ensure that the number of samples of our method is consistent with that of the other methods, and use BERT as the classifier. We use the widely used EDA as the DA algorithm of EPiDA. We do not use DataBoost because it is not yet open-sourced. The experimental results are presented in Tab. 3.

From Tab. 3, we can see that 1) with the help of EPiDA, the performance of EDA is greatly improved. In particular, comparing with the original EDA, EPiDA gets performance improvement of 14.1%, 8.39%, 22.83%, 33.40%, 6.75% and 9.22% in six task settings, respectively. 2) Our method outperforms DataBoost in four settings. In particular, EPiDA+EDA gets performance improvement of 8.12%, 2.65%, 10.15% and 6.99% in various settings of the **Sentiment** and **Irony** tasks. 3) The variants of EPiDA that utilize only REM or CEM to enhance diversity or quality are inferior to using both, which demonstrates the effectiveness of joint enhancement. 4) DataBoost performs better in the **Offense** task, the reason lies in that DataBoost can create novel sentences from **Offense** (a relatively huge corpus) via GPT-2, while EDA only conducts word-level augmentation, which limits EPiDA's performance. 5) We also present PPL as an auxiliary metric to measure the generation perplexity. Our method outperforms the others due to the high quality of data generation. We also provide experimental comparisons with other DA approaches (SUB^2 and VDA) and generation speed results in the supplementary file. In conclusion, EPiDA is a powerful and efficient technique.

Table 4: Performance comparison with different DA algorithms and classification models on five classification tasks.

4.3 Performance with Different DA Algorithms and Classifiers

EPiDA is a plug-in component that can work with different DA algorithms and classifiers. Here, to check how EPiDA performs with different DA algorithms and classifiers, we consider three frequently-used DA algorithms: rule-based EDA (Wei and Zou, 2019), model-based CWE (Kobayashi, 2018) and Attack-based TextAttack (Morris et al., 2020), and three different classifiers: CNN (Kim, 2014), BERT (Devlin et al., 2019) and XLNet (Yang et al., 2019). And to show that EPiDA can cope with different NLP classification tasks, we present the results on five different tasks: **TREC**, **AGNews**, **Sentiment**, **Irony** and **Offense**. In order to fully evaluate the performance of DA algorithms, we use only a small part of the training data. The experimental results are presented in Tab. 4. Here, we remove the restriction of only one time augmentation so that EPiDA can continuously generate qualified samples. We call this *online augmentation*, to differentiate it from one-time augmentation. As shown in Tab. 4, EPiDA is applicable to various NLP classification tasks. Although these tasks have different forms of data (questions or tweets) and different degrees of classification difficulty, EPiDA boosts performance on these tasks in almost all cases. More details on how EPiDA controls the generation quality are discussed in ablation study. Besides, we can also see that EPiDA works well with the three DA algorithms EDA, CWE and TextAttack. All achieve improved performance in most cases. For the three different classification models: CNN, BERT and XLNet, with the help of EPiDA, they all but XLNet on Sentiment get classification performance improvement, which shows that EPiDA is insensitive to classification models.

ID	DA	REM	CEM	OA	PT	TREC 1%	Irony 1%
1	-	-	-	-	-	0.722	0.534
2	✓	-	-	-	-	0.736	0.474
3	✓	-	-	✓	-	0.723	0.550
4	✓	✓	-	-	✓	0.729	0.557
5	✓	-	✓	-	✓	0.723	0.559
6	✓	✓	✓	-	-	0.734	0.548
7	✓	✓	✓	✓	-	0.739	0.575
8	✓	✓	✓	-	✓	0.740	0.576
9	✓	✓	✓	✓	✓	0.745	0.579

Table 5: Ablation study on TREC 1% and Irony 1%. Here, DA, REM, CEM, OA and PT indicate whether applying DA, REM, CEM, online DA (performing multiple DA operations) and pre-training, respectively.

4.4 Ablation Study

Here we conduct ablation study to check the effectiveness of different EPiDA configurations. We take CNN as the classifier, EDA as the DA algorithm and report the Macro-F1 score over five repeated experiments on **TREC** 1% and **Irony** 1%. Tab. 5 shows the experimental results.

Effect of REM and CEM. The 4th and 5th rows show the results with only REM and CEM, respectively. Both of them perform better than the baseline (1st row), but not as good as the combined case (the 8th row). On **TREC** (relatively simple task), REM outperforms CEM (0.729 vs. 0.723), while on **Irony** (relatively hard task), CEM outperforms REM (0.559 vs. 0.557). Using only REM can limitedly boost performance since REM promotes the generation of high diversity samples, which may have wrong labels. And using only CEM is also not enough to fully tap the performance as CEM tends to generate redundant samples.

We also compare our 'REM + CEM' with 'PPL + cosine similarity' used in LDA (Zuo et al., 2021). Our method achieves the performance of 0.740 and 0.576 on **TREC** 1% and **Irony** 1%, while the latter achieves 0.730 and 0.562. This shows that our 'REM + CEM' is more effective.

Effect of online augmentation. Comparing the results of the 2nd and the 3rd rows, the 6th and the 7th rows, the 8th and the 9th rows, we can see that generally online augmentation can boost performance, as online augmentation can generate sufficient qualified samples to train the model.

Effect of pre-training. As REM and CEM use the feedback of the classifier, a pre-trained classification model should be beneficial to REM and CEM. By comparing the results of the 6th and the 8th rows, the 7th and the 9th rows, it is obvious that pre-training can improve performance.

Effect of normalization. In Alg. 1, we normalize s_{div} and s_{qua}. Here, we check the effect of normalization. With the same experimental settings, the performance results on **TREC** 1% and **Irony** 1% without normalization are 0.732 and 0.568, lower than the normalized results 0.740 and 0.576. This shows that normalization is effective.

How to combine REM and CEM? How to combine REM and CEM is actually how to combine the values of s_{div} and s_{qua}. We consider three simple schemes: addition ($s_{tot} = s_{div} + s_{qua}$), multiplication ($s_{tot} = s_{div} * s_{qua}$) and weighted addition ($s_{tot} = \alpha s_{div} + (1-\alpha)s_{qua}$, α is a hyperparameter to tradeoff REM and CEM). Note that for multiplication, there is possibly an extreme situation: after normalization, s_{div} or s_{qua} may be very small and even approaches 0, then the multiplication result is very small or even zero, which means that REM and CEM do not take effect in sample generation. In our experiments, the multiplication scheme achieves performance of 0.725 and 0.572 on **TREC** 1% and **Irony** 1%, lower than the addition scheme 0.740 and 0.576. As for weighted addition, we find that setting $\alpha = 0.5$ can achieve satisfactory results (see the supplementary file). This is actually equal to the addition scheme. Therefore, in our experiments, we use only the addition scheme.

Metric	EDA	REM only	CEM only	EPiDA
Error Rate↓	3.05%	6.75%	0.64%	1.53%
Distance↑($\times 10^{-2}$)	0.54	1.21	0.25	0.78

Table 6: *Error rate* and *distance* on **Sentiment** dataset.

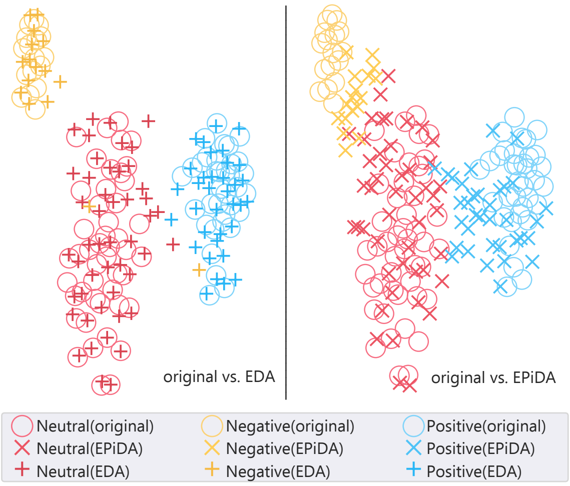

Figure 2: Hidden state visualization of the sentiment analysis task by t-SNE. Left: original and EDA augmented data; Right: original and EPiDA augmented data. Different colors mean different classes (Neutral, Negative and Positive), and different shapes mean different samples (original, generated by EPiDA and EDA).

Quality and diversity metrics. Here, we provide another two metrics to verify EPiDA from the perspective of quality and diversity. For quality, we use the augmentation error rate. As for diversity, we calculate the average distance of samples before and after augmentation (ignoring wrong samples). From the perspective of quality and diversity, a good DA should has a *small* error rate but a *large* distance. Experimental results are given in Tab. 6. We can see that EPiDA gets better trade-off between error rate and distance.

Effect of the amplification factor K. The amplification factor K determines the size Km of candidate samples from which m samples are chosen. On the one hand, with a large K, we have more choices, which seems beneficial to diversity. On the other hand, more candidate samples make the selected samples more homogenous, not good for diversity. By grid search, we set K to 3 in our experiments, the experimental results are shown in the supplementary file.

4.5 Visualization Effect of EPiDA

Above we give comprehensive quantitative performance evaluation of EPiDA, here to intuitively illustrate the effectiveness of EPiDA, we visualize some augmented samples of EPiDA, and compare them with that of EDA. Specifically, we utilize BERT as the classifier and visualize its hidden state on the sentiment analysis task via t-SNE (Van der Maaten and Hinton, 2008). Fig. 2 shows the results. In terms of data quality, we find that two negative samples generated by EDA are located in Neural and Positive classes, while samples generated by EPiDA are generally properly located. And in the point of view of diversity, samples generated by EPiDA extend the distributed areas of the original data, while samples generated by EDA are mainly located in the areas of the original samples. This shows that samples generated by EPiDA are more diverse than those generated by EDA.

5 Conclusion

In this paper, we present an easy plug-in data augmentation technique EPiDA to control augmented data diversity and quality via two mechanisms: *relative entropy maximization* and *conditional entropy minimization*. Through extensive experiments, we show that EPiDA outperforms existing methods, and can work well with different DA algorithms and classification models. EPiDA is general, effective, efficient, and easy-to-deploy. In the future, more verification of our method is expected to be conducted on other classification tasks.

Partial-input baselines show that NLI models can ignore context, but they don't.

Abstract

When strong partial-input baselines reveal artifacts in crowdsourced NLI datasets, the performance of full-input models trained on such datasets is often dismissed as reliance on spurious correlations. We investigate whether state-of-the-art NLI models are capable of overriding default inferences made by a partial-input baseline. We introduce an evaluation set of 600 examples consisting of perturbed premises to examine a RoBERTa model's sensitivity to edited contexts. Our results indicate that NLI models are still capable of learning to condition on context—a necessary component of inferential reasoning—despite being trained on artifact-ridden datasets.

1 Introduction

Natural language inference (NLI) is integral to building systems that are broadly capable of language understanding (White et al., 2017). In a traditional NLI setup, models are provided with a *premise* as context and a corresponding *hypothesis*. They must then determine whether the premise entails, contradicts, or is neutral in relation to the hypothesis (Giampiccolo et al., 2007).

Researchers have shown that many NLI datasets contain statistical biases, or "annotation artifacts" (Gururangan et al., 2018; Herlihy and Rudinger, 2021) that systems leverage to correctly predict entailment. To diagnose such artifacts in datasets and provide a stronger alternative to majority-class baselines, Poliak et al. (2018) introduced partial-input baselines, a setting in which models are provided parts of NLI instances to predict an entailment relation. Poliak et al. (2018), Gururangan et al. (2018), and others posit that datasets containing artifacts may in turn produce models that are incapable of learning to perform true reasoning.

In this paper, we re-examine such dismissal of the reasoning capabilities of models trained on datasets containing artifacts. While a competitive partial-input baseline is sufficient to cast doubt on the inferential capabilities of full-input models trained on the same data, it is premature to conclude that full-input models are not capable of such reasoning at all. As a thought experiment, we imagine training a human to learn a task from a set of examples containing artifacts that allow them to cheat. If we force them to learn to perform the task by removing relevant context, they must rely on the artifacts to accurately perform the task. However, provided all the data, they may still learn to perform the task the "right way".

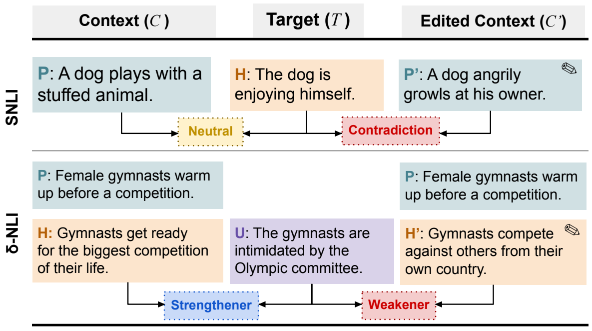

Figure 1: Given NLI and δ-NLI instances that partial-input baselines correctly label, we edit their context to induce a different gold label. We use the edited instances to probe a full-input model's ability to leverage context to deviate from the predicted partial-input label.

Through two sets of experiments, we investigate whether NLI models are able to condition on the full input despite learning from artifact-ridden datasets. Section 3 investigates whether additional context strengthens a full-input model's confidence in the correct label, despite a partial-input model's correct prediction. In Section 4, we introduce an evaluation set to probe whether full-input models are sensitive to changes in context that flip the gold label in examples containing artifacts. We make our evaluation set and code publicly available.[1]

Our results indicate that full-input models are still successfully learning to utilize context, overriding strong signal in the partial input. With this

finding, we argue that while partial-input baselines are still a useful tool, they do not license the conclusion that models trained on datasets with artifacts do not learn to leverage context from the full input.

2 Background

Here we describe the two related tasks of natural language inference (NLI) and *defeasible* NLI; two corresponding datasets (SNLI and δ-NLI, respectively); and annotation artifacts present in these datasets.

Task Definitions. Natural language inference (Giampiccolo et al., 2007; MacCartney, 2009; Bowman et al., 2015) is the task of determining whether a **premise** sentence (P) entails a **hypothesis** sentence (H). That is, given P, would a human conclude H is true (*entailment*), false (*contradiction*), or neither (*neutral*).

When H is neutral, the task of *defeasible* natural language inference (Rudinger et al., 2020) asks whether a third **update** sentence (U) makes H *more* likely to be true (U is a *strengthener*) or *less* likely to be true (U is a *weakener*). In the following example, H is *neutral* given P (NLI task), and U is a *weakener* given P and H (defeasible NLI task).

Premise: A man is sitting in a dim restaurant.
Hypothesis: He is eating food.
Update: He is browsing a menu.

In this work, we adopt the terms **context** (C) and **target** (T) for clarity when describing partial-input baselines for the two tasks. In NLI, $C = P$ and $T = H$; in defeasible NLI, $C = (P, H)$, and $T = U$. Thus, for either task, the partial-input baseline we use looks only at T and ignores C.

SNLI. SNLI (Bowman et al., 2015) is the first large-scale English NLI dataset, containing 570K labeled P-H pairs. In SNLI, premises are derived from image captions (Young et al., 2014), and hypotheses for each label (*entailment*, *neutral*, *contradiction*) are elicited from crowdsource workers who are shown a premise.

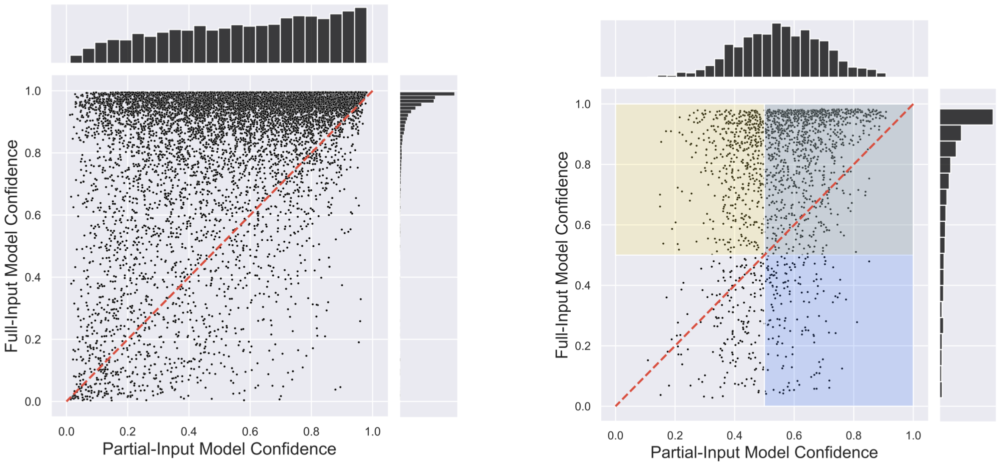
δ-NLI. For the task of *defeasible* NLI, Rudinger et al. (2020) introduce the δ-NLI dataset, which consists of extensions to three pre-existing English natural language reasoning datasets: SNLI (Bowman et al., 2015), ATOMIC (Sap et al., 2019), and SOCIAL-CHEM-101 (Forbes et al., 2020). To extend each dataset, instances (e.g., P-H pairs) were presented to crowdworkers who then wrote an update sentence (U) to strengthen or weaken the given hypothesis (as described in Task Definitions). The resulting binary classification task is to predict whether an update is a strengthener or weakener, given a (P, H, U) triple. In this work, we focus our evaluation on δ-SNLI, the SNLI portion of the δ-NLI dataset.

Artifacts and Partial-Input Baselines. Gururangan et al. (2018) and Poliak et al. (2018) observe that the crowdsourcing protocols adopted by Bowman et al. (2015) and others lead to the creation of data with annotation artifacts that enable partial-input baselines (e.g., hypothesis-only baselines) to perform well above a majority-class baseline. For SNLI, Poliak et al. (2018) report that an InferSent (Conneau et al., 2017) hypothesis-only baseline surpasses a majority baseline by 35 points. A similar effect is observed by Rudinger et al. (2020) in the δ-NLI data, with an update-only RoBERTa (Liu et al., 2019) model achieving 15 points above a majority baseline.

3 Experiment 1: Context in NLI

An essential component of true reasoning is learning to leverage all parts of an example's input to make a determination of entailment. Strong partial-input models demonstrate that full-input models do not necessarily need to utilize context to make correct predictions. However, we explore whether they do at all, and how access to such context shifts a full-input model's confidence in the correct label. If, upon supplying C, a model strengthens its confidence in its prediction, we may conclude that it utilizes both C and T during inference as intended.

Experimental Setup. We finetune two sets of RoBERTa (Liu et al., 2019) models (a partial-input and a full-input model) on the train splits of SNLI and δ-NLI (see Appendix A for dataset sizes). We utilize `roberta-base` from the Hugging Face library (Wolf et al., 2020), and finetune each model for two epochs. Appendix B further details our training setup. We then run inference on the test splits from SNLI and δ-SNLI (the SNLI portion of δ-NLI) using each pair of models. Table 1 reports accuracy of all models on the corresponding test splits. We calibrate RoBERTa models post-hoc using temperature scaling (Guo et al., 2017) as suggested by Desai and Durrett (2020), and examine confidence shifts in the correct label to understand



(a) Pre-Edit SNLI Confidence Shifts

(b) Pre-Edit δ-NLI Confidence Shifts

Figure 2: Visualizing the role of context as confidence shifts. 2a and 2b plot ordered pairs of confidence in the correct label l of partial-input vs. full-input RoBERTa models on examples from the SNLI and δ-SNLI test splits. Blue and yellow regions mark correct predictions from the x and y-axis models respectively. Green regions represent correct predictions from both models. Diagonals indicate no shift in confidence.

	SNLI	δ-SNLI
Partial-Input (C)	0.70	0.65
Full-Input (C, T)	0.91	0.82

Table 1: Accuracy of both partial-input and full-input models on test splits of SNLI and δ-SNLI.

whether full-input models utilize context at all.[2]

As shown in Fig. 2, we plot an ordered pair of each model's confidence in the *correct label* for examples in the test splits, with the partial-input model's confidence along the x-axis and the full-input model's confidence along the y-axis. Density around the diagonal would indicate no change in confidence.

Evidenced by the density *above the diagonal* in Figures 2a and 2b, full-input models (i.e access to both C and T) are more confident in the correct label than partial-input models.[3] While this behavior may seem unsurprising, partial-input baselines illustrate that models may show confidence in the correct label without needing to condition on context at all. Our results hint that full-input models may be successfully learning to leverage additional context instead of overgeneralizing on artifacts in the target. To probe this behavior directly, we introduce an evaluation set crafted by editing contexts in the following section.

4 Experiment 2: Context Editing

We investigate a model's ability to leverage context despite the presence of artifacts by exploring how sensitive full-input models are to changes in *non-target* components of the input. We present an example modification scheme, illustrated in Figure 1, in which we edit context sentences from examples where a model correctly predicts the label l from the target T alone. Namely, while holding T constant, we introduce an edited context sentence C' that induces a different label $l' \neq l$ on the new (C', T) pair. Using this scheme, we construct an evaluation set of 600 examples sourced from SNLI and δ-NLI.

Example Subselection. We select SNLI and δ-SNLI test examples to edit by running the partial-input RoBERTa models from Section 3 and full-input bag-of-words (BoW) models, implemented via `fasttext` with a maximum of 4-grams (Joulin et al., 2017). See Appendix B for training details on the bag-of-words models. We select examples to edit for which *either* the partial-input model or the BoW model predicted the correct label. This identifies the subset of examples likeliest to contain artifacts in T, lexical or otherwise.

Editing SNLI Examples. For a given SNLI example (P, H, l) and a new predefined target label

---

[2] We observed minimal differences between pre and post-calibration results.

[3] The distribution difference between SNLI and δ-SNLI may be attributed to the difference in the task difficulty, as well overall lower performance of RoBERTa models on δ-NLI.

		l'		
		entailment	neutral	contradiction
l	entailment	–	0.76	0.76
	neutral	0.42	–	0.78
	contradiction	0.90	0.78	–

Table 2: A full-input RoBERTa model's accuracy on the edited SNLI portion of our evaluation set. l and l' represent the original and target label respectively, before and after editing.

		l'	
		weakener	strengthener
l	weakener	–	0.76
	strengthener	0.75	–

Table 3: A full-input RoBERTa model's accuracy on the edited δ-SNLI portion of our evaluation set. l and l' again respectively represent the original and induced post-edit label.

l', we edit P, creating a modified SNLI example (P', H, l'). For each of the six directional pairs of labels (e.g., *entailment* $\rightarrow$ *contradiction*), we randomly sample 50 examples from the subset to edit, resulting in 300 examples evenly distributed across label pairs.

Editing δ-SNLI Examples. Given a δ-SNLI instance (P, H, U, l), we edit H while holding P and U constant to induce a new label $l' \neq l$, resulting in a modified example (P, H', U, l'). We edit 300 examples total, turning 150 *strengthener* examples into *weakener* examples, and vice-versa.

Our final evaluation set consists of 600 examples containing edited context-target pairs split evenly across SNLI and δ-SNLI. Figure 4 shows examples of editing contexts from both datasets. All examples were manually edited by one author and independently validated by another. During validation, we hide both the l and l', and ask the annotator to label the text pair. Using Cohen's Kappa (Cohen, 1960), we obtain an agreement measure of $\kappa = 0.78$ and $\kappa = 0.76$ for SNLI and δ-SNLI examples in our test set respectively, indicating substantial agreement (Artstein and Poesio, 2008).

Results. Using the same full-input RoBERTa models trained in Section 3, we run inference on our edited evaluation set. Tables 2 and 3 show model performance stratified by original label l and target label l'. Our results show that full-input models are in fact sensitive to context modifications despite the presence of artifacts in T, consistently achieving above 70% accuracy on edited examples.

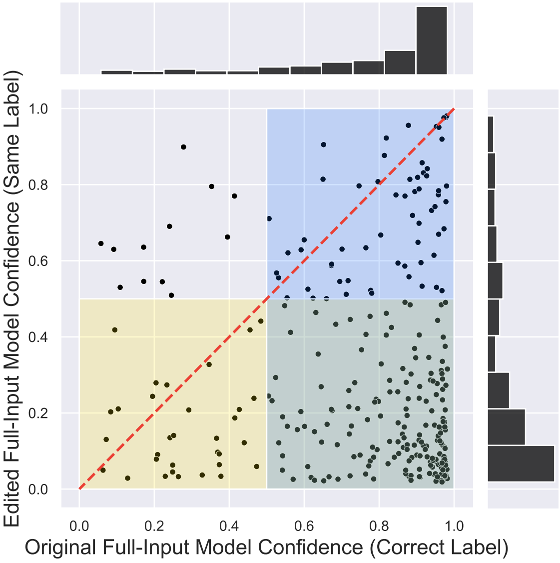


Figure 3: Full-input model's confidence in l before vs. after editing C to induce a different label.

Thus, we conclude that these models are not overgeneralizing on artifacts in the instance, learning to condition on context for prediction.

Analyzing Post-Edit Model Confidence. Similar to the analysis in Section 3, we inspect shifts in confidence upon editing contexts to shed more light on a full-input model's utilization of C. For δ-SNLI examples, we plot ordered pairs in Fig. 3 of a full-input model's confidence in the correct label pre-edit, and its confidence in the *same label* post-edit (i.e the confidence in the now-incorrect label). The majority of mass is under the diagonal, indicating that our model is indeed sensitive to changes in context. The green bottom-left quadrant delineates ideal performance (correct before *and* after editing examples). We attribute the small cluster of examples in the blue quadrant (previously highly confident in the correct label and subsequently remained confident, but in the wrong label) to strong, non-lexical artifacts overriding additional signal from the context. Appendix C visualizes shifts in SNLI examples using simplex plots to accommodate the ternary label.

Lexical Model Performance. We do not retrain any of the models on edited examples prior to evaluating with our edited test set, precluding them from picking up on any newly-introduced non-lexical artifacts. However, to validate the absence of trivial lexical features that override the artifacts in T and to ensure sufficient difficulty, we run full-input BoW models on our edited evaluation set. A full-

	Context ($C \rightarrow C'$)	Target (T)	Label ($l \rightarrow l'$)
SNLI	**Premise**: A little girl in a pink hat is in a lush green field walking an ox. **Edited Premise** ✎ : A little girl in a pink hat sits on an ox carrying her through the middle of the Sahara.	**Hypothesis**: A little girl is riding her ox in a desert.	**Contradiction** → **Entailment**
	Premise: A girl in a yellow dress looks at a restaurant building. **Edited Premise** ✎ : A girl in a yellow dress enjoys some food at her favorite restaurant.	**Hypothesis**: A girl debates eating at a certain restaurant.	**Neutral** → **Contradiction**
δ-NLI	**Premise**: A boy in a red hooded top is smiling whilst looking away from his reflection. **Hypothesis**: The boy doesn't want to see his reflection. **Edited Hypothesis** ✎ : The boy wants to see his reflection.	**Update**: A woman's voice says to him 'Don't be afraid of it, it's harmless'	**Strengthener** → **Weakener**
	Premise: A music concerto is happening on stage, with the lights on spot, while the audience listens in the dark. **Hypothesis**: The concert is being held at night. **Edited Hypothesis** ✎ : The concert is being held during the day.	**Update**: Blackout curtains cover the windows.	**Weakener** → **Strengthener**

input `fasttext` model, often used for adversarial filtering (Zellers et al., 2018), achieves 16% and 24.3% accuracy on the SNLI and δ-SNLI portions of our evaluation set respectively.

5 Related Work

In addition to work on partial-input baselines for NLI (Gururangan et al., 2018; Poliak et al., 2018; Tsuchiya, 2018), partial-input models have been studied for story completion (Cai et al., 2017) and reading comprehension (Kaushik and Lipton, 2018). Feng et al. (2019) observe that low-scoring partial-input baselines do not preclude other artifacts and heuristics, while Glockner et al. (2018) and McCoy et al. (2019) demonstrate lexical and syntactic examples of NLI heuristics. Adversarial editing has been explored for non-NLI tasks as well (Jia and Liang, 2017; Ribeiro et al., 2018). Finally, adversarial filtering has been proposed as a means of removing artifacts from datasets (Zellers et al., 2018; Le Bras et al., 2020).

6 Discussion and Conclusion

While partial-input models are useful tools for analysis, often leveling fair criticism of datasets, our results show it is hasty to conclude that models trained on such datasets are not capable of reasoning. Even though high-scoring partial-input baselines show that full-input models *could* ignore context, our experiments show that they can leverage this context quite effectively.

We argue that artifacts do not *necessarily* spell disaster for a model's reasoning capabilities. In particular, our context-editing experiments identify a set of instances that partial-input models fail (by design), but full-input models largely succeed at, displaying the capability of full-input models to leverage context to overcome SNLI and δ-NLI artifacts in many, but not all, cases. Of course, we do not deny that artifacts *can* and *do* lead to models with exploitable heuristics, as demonstrated by Glockner et al. (2018) and McCoy et al. (2019).

While we do not attempt to define the *sufficient* conditions for a model to perform "true inference," we demonstrate that these models can and do meet the *necessary* condition of leveraging the full input. Thus, we conclude that partial input baselines should be understood as agnostic warning signs: sufficient to conclude that full-input models *might* not be leveraging critical context, but insufficient to prove that they don't.

This raises a number of interesting questions for follow-up work. If adversarial filtering (Le Bras et al., 2020) can identify instances containing artifacts, is it beneficial to remove these instances from the training set? Or could they be edited to flip the label and mitigate the spurious correlation? The edits we made in this work were done manually, but another interesting question is whether these edits could be made automatically or semi-automatically. Having a more efficient way of producing these examples would enable both rapid evaluation of models trained on datasets with artifacts (as in this work), as well as expansion of training sets to preemptively mitigate artifacts.

Dataset	Split	Size
SNLI	train	550,152
	valid	10,000
	test	10,000
δ-NLI	train	200,694
	valid	14,968
	test	15,414
δ-SNLI	train	88,676
	valid	1,785
	test	1,837

Table 4: Split sizes across SNLI, δ-NLI, and δ-SNLI.

A SNLI and δ-NLI Dataset Sizes

To train and tune our neural and lexical models, we utilize the train and validation splits from SNLI and δ-NLI. We include train/validation/test split sizes in Table 4. Our δ-NLI RoBERTa models were fine-tuned on examples from all 3 portions of the δ-NLI dataset (ATOMIC, SNLI, and SOCIAL-CHEM-101), however for our evaluation set and analysis, we exclusively use the SNLI portion of the δ-NLI dataset, abbreviated as δ-SNLI. We include the split sizes for δ-SNLI in Table 4 as well.

B Model Training Setup

Neural Models. We use the Hugging Face library to train all of our RoBERTa models. We utilize `roberta-base`, which has 125M trainable parameters. All models were trained on a single NVIDIA 1080-TI GPU. After tuning on the validation set, all models were trained for two epochs with a learning rate of 2e-5 and a batch size of 32. Tables 2 and 3 report best accuracy across five runs.

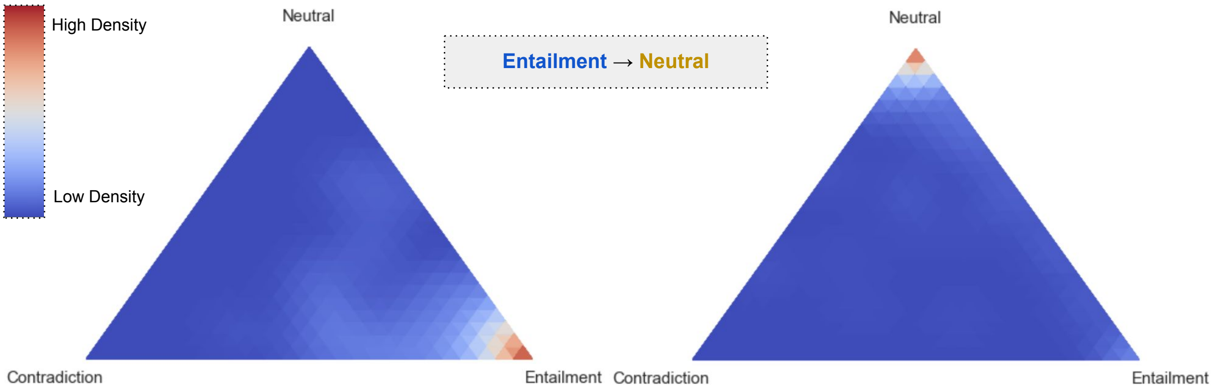
Lexical Models. We use the `fasttext` library to implement our bag-of-words models. `fasttext` is an off-the-shelf text classification library. All lexical models were trained for 5 epochs with 4-grams as the maximum length of word ngrams. We use the default learning rate of 0.1.

C Visualizing Distribution Shifts in SNLI Edited Examples

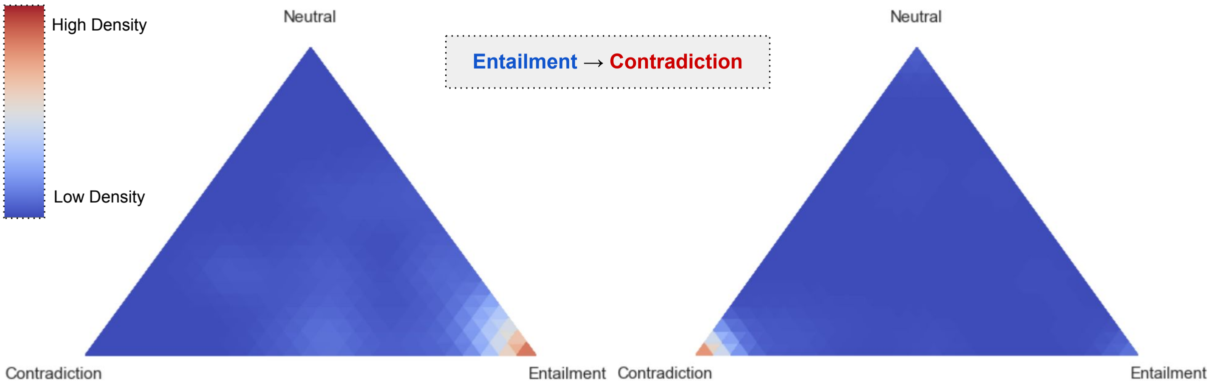
We are able to visualize confidence distribution shifts for δ-NLI before and after editing using a 2D plane with ordered pairs, as in Figure 3, due to the label set containing only two update types—weakener and strengthener (so, a probability score > 0.5 results in the predicted label). Since the SNLI label set consists of *three* labels (*entailment*, *neutral*, *contradiction*), we choose to visualize shifts in the confidence distribution before and after editing contexts via ternary plots. For each directional label pair (*entailment* $\rightarrow$ {*neutral*, *contradiction*}, *neutral* $\rightarrow$ {*entailment*, *contradiction*}, *contradiction* $\rightarrow$ {*entailment*, *neutral*}), we plot a heatmap of probabilities, or confidences, in each of the three classes on the simplex with Gaussian smoothing using `python-ternary`, a ternary plotting package (Harper, 2015). Figures 5, 6, and 7 show these visualizations. We include these plots mainly to help visualize information about the predicted labels of the incorrect examples (Table 2 only reports the accuracy on finer-grained buckets). We observe that for most classes of examples, the SNLI RoBERTa model utilizes the context, and correctly predicts the new induced gold label. However, the {*neutral* $\rightarrow$ *entailment*} class of examples in particular proved difficult for the model, as evidenced by a large chunk of a mass remaining in the neutral corner of the simplex.

D Dataset Limitations

In this work, we choose to explore the role of context with respect to the SNLI and δ-NLI datasets. In particular, the proven presence of strong artifacts in SNLI made it an appealing dataset to explore a model's behavior with respect to the utilization of context. We chose to include δ-NLI in our analysis, since ultimately, we'd like reasoning systems to operate in complex and *dynamic* contexts. The ability to be sensitive to shifting contexts and understand when default inferences should be overridden by additional context (i.e more nuanced inference) is both central to our exploration and central to the task of defeasible reasoning itself. Our evaluation set does not include examples sourced from other NLI datasets such as MultiNLI (Williams et al., 2018). It also does not contain datasets across domains, such as MedNLI (Romanov and Shivade, 2018). However, we note that while the datasets may be different, others have shown artifacts present in such datasets (i.e (Herlihy and Rudinger, 2021; Gururangan et al., 2018). Our goal was to utilize datasets containing high amounts of artifacts.

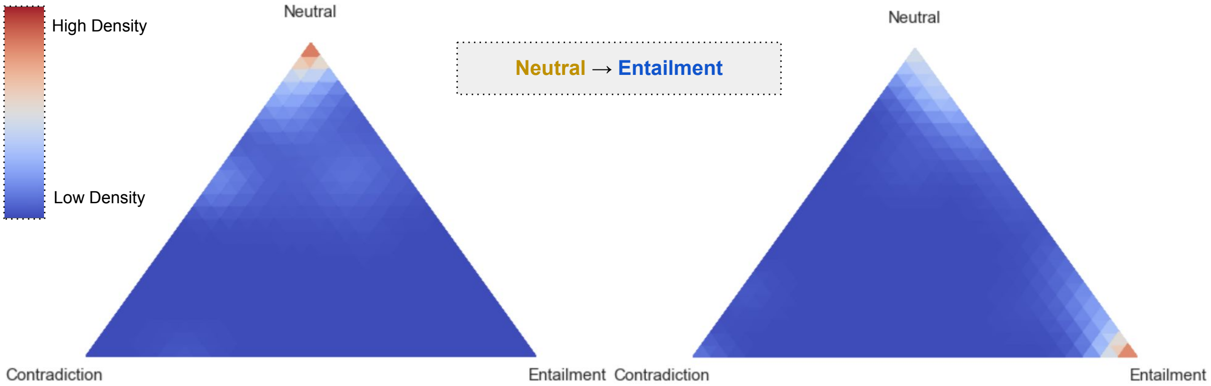


(a) Confidence distribution heatmap for examples with original relation as entailment, edited to induce a neutral relation.

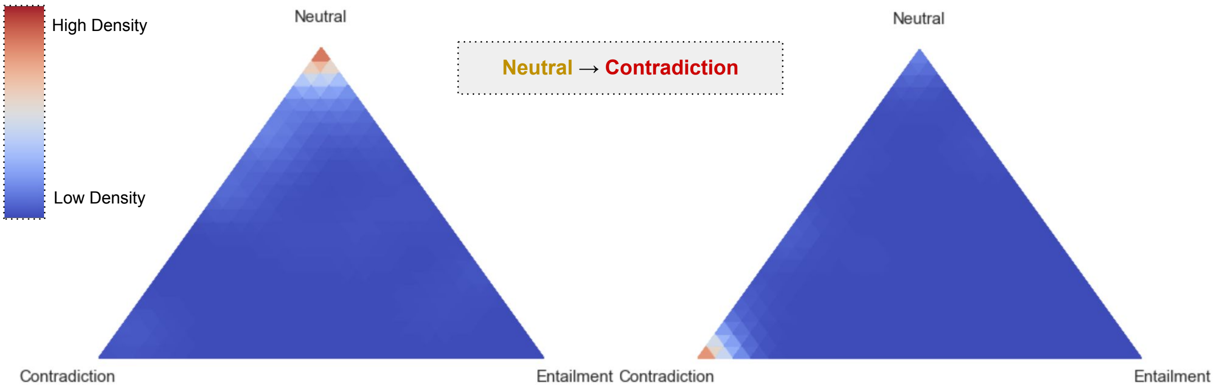


(b) Confidence distribution heatmap for examples with original relation as entailment, edited to induce a contradiction relation.

Figure 5: Confidence distribution heatmaps for SNLI examples before and after editing examples with original relation as entailment in our evaluation set. 5a shows entailment examples edited to induce a neutral relation, and 5b shows examples edited to induce a contradiction relation. Each l and l' is shown in the center box. We note that these distributions help visualize the accuracies presented in Table 2.

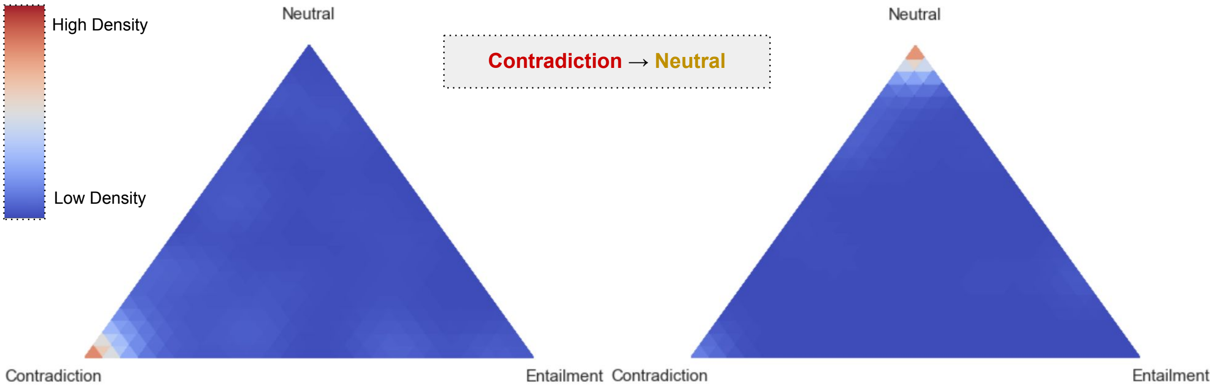


(a) Confidence distribution heatmap for examples with original relation as neutral, edited to induce an entailment relation. We note that this was the hardest edit category for RoBERTa models to flip, and draw attention to a substantial amount of mass still in the neutral corner of the simplex.

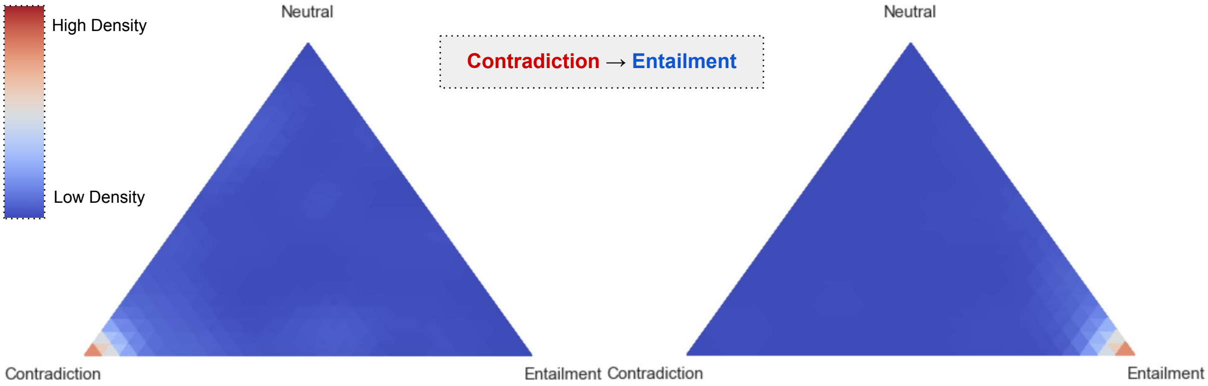


(b) Confidence distribution heatmap for examples with original relation as neutral, edited to induce a contradiction relation.

Figure 6: Confidence distribution heatmaps for SNLI examples before and after editing examples with original relation as neutral in our evaluation set. 6a shows examples edited to induce an entailment relation, and 6b shows examples edited to induce a contradiction relation. Each l and l' is shown in the center box. These distributions aid in visualization of the performance metrics reported in Table 2.



(a) Confidence distribution heatmap for examples with original relation as contradiction, edited to induce a neutral relation.



(b) Confidence distribution heatmap for examples with original relation as contradiction, edited to induce an entailment relation. We note that this particular class of edited examples achieved the highest accuracy, reflected in the low density of examples away from the entailment corner of the simplex.

Figure 7: Confidence distribution heatmaps for SNLI examples before and after editing examples with original relation as contradiction in our evaluation set. 7a shows examples edited to induce a neutral relation, and 7b shows examples edited to induce an entailment relation. Each l and l' is shown in the center box. These plots help visualize the performance metrics reported in Table 2.

Lifelong Pretraining: Continually Adapting Language Models to Emerging Corpora

Abstract

Pretrained language models (PTLMs) are typically learned over a large, static corpus and further fine-tuned for various downstream tasks. However, when deployed in the real world, a PTLM-based model must deal with data distributions that deviate from what the PTLM was initially trained on. In this paper, we study a *lifelong language model pretraining* challenge where a PTLM is continually updated so as to adapt to emerging data. Over a domain-incremental research paper stream and a chronologically-ordered tweet stream, we incrementally pretrain a PTLM with different continual learning algorithms, and keep track of the downstream task performance (after fine-tuning). We evaluate PTLM's ability to adapt to new corpora while retaining learned knowledge in earlier corpora. Our experiments show distillation-based approaches to be most effective in retaining downstream performance in earlier domains. The algorithms also improve knowledge transfer, allowing models to achieve better downstream performance over the latest data, and improve temporal generalization when distribution gaps exist between training and evaluation because of time. We believe our problem formulation, methods, and analysis will inspire future studies towards continual pretraining of language models.

1 Introduction

Pretrained language models (PTLMs) have achieved remarkable performance on benchmark datasets for a range of NLP tasks (Liu et al., 2019b; Brown et al., 2020). However, when deployed in the wild, NLP systems must deal with emerging data that have constantly shifting data distribution, different from the text corpora they were initially pretrained on — for example, when new data domains are introduced (upper part of Fig. 1) (Gururangan et al., 2020), or when the language uses and vocabulary change over time (lower part of Fig. 1) (Lazaridou et al., 2021). Fine-tuning from a static and possibly "outdated" PTLM may limit the model performance on downstream tasks, as the PTLM may no longer provide an effective model initialization (Beltagy et al., 2019; Müller et al., 2020). Here we look to understand whether continuously adapting a PTLM to emerging data can yield gains on various downstream tasks, and how to achieve better downstream performance for such lifelong PTLM adaptation.

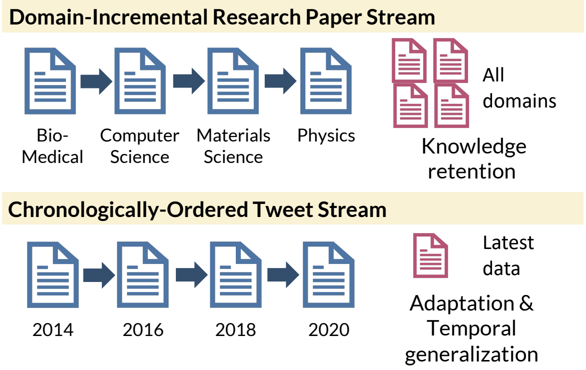

Figure 1: Two data streams created for studying lifelong language model pre-training. We focus on evaluating knowledge retention on the domain-incremental research papers stream; we focus on adaptation to the latest data and temporal generalization on the chronologically ordered tweet stream.

A number of recent works make attempts on adapting PTLMs to a new data domain. Gururangan et al. (2020); Yao et al. (2021) adapt language models to corpora of different genres and topics and observe performance improvement in domain-specific downstream tasks. Arumae et al. (2020) further show that by regularizing the parameters of PTLMs, the downstream tasks performance on the general domain can be preserved. Another line of works focuses on temporal domain shift (Hombaiah et al., 2021), which analyzes the effect of pretraining over up-to-date data to the downstream

tasks. Röttger and Pierrehumbert (2021) further study vocabulary composition approaches for improving adaptation to up-to-date corpora. However, these work focus their study on adapting PTLM to a single new domain; while in practice, corpora from distinct domains and time stamps may emerge sequentially. Whether one can maintain a single, up-to-date PTLM remains an open problem. Related to this, Lazaridou et al. (2021) study adaptation of PTLMs over temporal data streams, but solely focus on language modeling instead of fine-tuning performance. It is also important to understand multiple aspects of the utility of lifelong PTLM pretraining, such as knowledge retention over all the seen data, and study what methods can improve the utility of PTLMs in such a continual pretraining process.

In this paper, we formulate a *Lifelong Language Model Pretraining* task to simulate practical scenarios of maintaining and adapting a PTLM over emerging corpora, create a testbed (along with pretraining data streams and downstream tasks) for studying continual pretraining algorithms, and present a systematic evaluation protocol for measuring the progress made on this challenging problem (see Figure 2 for an illustration). We consider two types of text corpus sequences when constructing pretraining data streams, each of which simulates a representative use case and that has slightly different focuses on the evaluation: continuously learning a single model that is applicable to both old and new domains; and improving the model's ability to handle latest data. Specifically, we construct 1) a domain-incremental text stream that consists of academic papers published in four research fields, and 2) a temporal tweet stream that consists of tweets collected from four different years. By conducting systematic experiments on these two data streams, we look to answer a series of analysis questions: 1) whether continual pretraining retains fine-tuning performance over earlier corpora compared to traditional offline pretraining, 2) whether pretraining improves downstream performance on the latest data, and 3) whether pretraining improves temporal generalization where training and evaluation have distribution gaps because of time.

To address the research questions above, we conduct a systematic evaluation of existing continual learning (CL) algorithms, spanning over model-expansion based, memory-based, and distillation-based approaches. Our results show distillation-based approaches are most effective in knowledge retention in the research paper stream, while simultaneously improve adaptation to latest data and temporal generalization in the tweet stream. We believe our problem formulation, evaluation setup, methods and analysis can inspire more future work on continual pretraining of language models.

2 Problem Formulation

Here we present the problem formulation for lifelong pretraining of PTLM, provide details about the data stream construction process and downstream tasks, and introduce the evaluation protocol.

2.1 Lifelong Pretraining of PTLMs

We consider the scenario where one needs to deploy and/or maintain NLP models over a sequence of T data domains. At each time step t the model visits an unlabeled text corpus D_t from a domain with a data distribution $P(D_t)$. The data distribution $P(D_t)$ evolves as the time step t, forming a *data stream* $D_{1..T} = \{D_1, D_2, ...D_T\}$. In practice, the data domain shift can refer to the topic change of the text content (from computer science research papers to biomedical papers), or temporal evolution of the text (from past to recent tweets). The task of *lifelong pretraining of PTLM* looks to continuously adapt a language model f as the model visits (unlabeled) text corpus D_t from the data stream $D_{1..T}$, in order to provide a good model initialization for fine-tuning on downstream tasks from the same domain. With slight abuse in notations, we also use D_t to directly refer to a data domain.

Here, we assume a language model f is updated sequentially over each pretraining corpora D_t, without accessing the full earlier corpora $\{D_i\}_{i<t}$ in the data stream $D_{1..T}$. This aims to capture practical constraints such as privacy restriction for storing earlier data, or computation budget for training over all the text corpora in $D_{1..T}$. We use f_t to denote the language model right *after* updating on the domain D_t. In our study, f is a RoBERTa-base transformer (Liu et al., 2019b) and the model (f_0) is initialized with pretrained RoBERTa weights.

The utility of the PTLMs $\{f_t\}$ is evaluated based on their fine-tuned model performance on various downstream tasks. After updating on a domain D_i, the model f_i can be fine-tuned over downstream tasks from visited domains D_t where $t \leq i$. We note the set of downstream tasks related to domain D_t as $S_t = \{S_t^j\}_{j=1}^{N_t}$, assuming the number

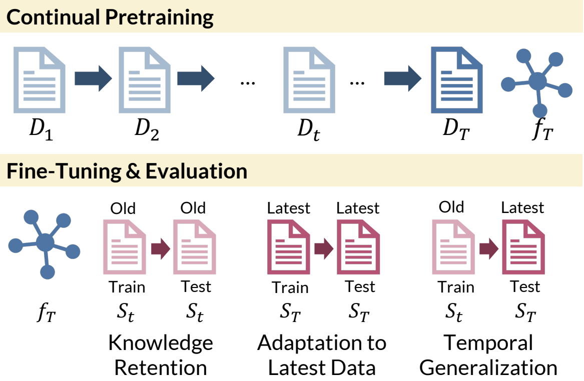

Figure 2: **Training, evaluation setups, and metrics of lifelong language model pretraining.** The model sequentially visits each corpus, and is fine-tuned on downstream datasets related to the domains of pretraining. We evaluate knowledge retention and adaptation to new data with downstream fine-tuning performance on old and latest domains respectively. Besides, we evaluate temporal generalization where training/test examples are drawn from different time steps.

of downstream tasks is N_t. Note that in the fine-tuning stage, model f_t has no access to any of the pretraining corpus $D_{1..T}$.

2.2 Data Streams & Downstream Datasets

We construct data streams to simulate two representative scenarios of data domain shifts in practice (also see Fig. 1): one *domain-incremental* stream to simulate the sequential changes of research paper areas; and one *chronologically-ordered* stream to simulate tweets emerging over time.

Domain-incremental Paper Stream. This paper stream consists of the full text of research papers published in four research areas: biomedical, computer science, material science, and physics, filtered from the S2ORC dataset[1], which are presented sequentially to the model. For each domain, we evaluate downstream performance over two datasets. The downstream tasks span over various tasks such as relation extraction and named entity recognition, and are summarized in Table 1. We detail these datasets in Appendix D.

Chronologically-ordered Tweet Stream. This tweet data stream consists of tweets from the year 2014, 2016, 2018 and 2020, collected by the Archive Team[2] and preprocessed following Nguyen et al. (2020). These four tweet corpora are presented sequentially to the language model following the chronological order of the tweet year.

Domains	Downstream Datasets	Metrics
Bio-Medicine	Chemprot (Vindahl, 2016)	Micro-F1
	RCT-Sample (Dernoncourt and Lee, 2017)	Micro-F1
Comp. Science	ACL-ARC (Jurgens et al., 2018)	Macro-F1
	SciERC (Luan et al., 2018)	Macro-F1
Mat. Science	Synthesis (Mysore et al., 2019)	Macro-F1
	MNER (Olivetti et al., 2020)	Micro-F1
Physics	Keyphrase (Augenstein et al., 2017)	Macro-F1
	Hyponym (Augenstein et al., 2017)	Macro-F1

Table 1: Summary of downstream datasets relevant to each domain in the research paper stream.

For downstream tasks, we hold out 1M tweets from each year's corpus to construct multi-label hashtag prediction datasets (Gong and Zhang, 2016) and single-label emoji prediction datasets (Barbieri et al., 2018). On two datasets, we report label ranking average precision scores (a multi-label version of MRR) of models (Azeemi and Waheed, 2021) and Macro-F1 respectively. The detailed dataset construction process is included in Appendix D.

2.3 Evaluation Protocol

We consider three key aspects for evaluating the utility of the language models $\{f_t\}$ that are continuously updated over the data stream $D_{1..T}$, also illustrated in Figure 2: 1) knowledge retention and transfer over the pretraining corpora seen earlier; 2) adaptation to the latest data domain, and 3) temporal generalization when training and evaluation data are from different time steps.

Knowledge Retention. A key utility of continual language model pretraining is to obtain a single model applicable to all domains. We focus on the evaluation of the ability with the domain-incremental paper stream, because for the tweet stream, the practical need of performance over outdated data is limited. Knowledge retention is measured with the downstream task performance from earlier or the current domains that the pretrained model has visited. More formally, for each pretrained model checkpoint in $\{f_i\}$, we fine-tune f_i over downstream tasks $\{S_t\}$ where $t \leq i$ and evaluate the corresponding test set performance. It is important that the models do not suffer from catastrophic forgetting (Robins, 1995), *i.e.,* significantly reduced helpfulness when f_i is fine-tuned for downstream tasks S_t from earlier domains with $t < i$.

Adaption to Latest Data Domain. In certain scenarios, performance of downstream models over the latest data domain should be emphasized. For example, classifiers in the tweet domain are usually

---

[1] We use the 20200705v1 version of the S2ORC dataset at `https://github.com/allenai/s2orc`

[2] `https://archive.org/details/twitterstream`

trained and evaluated with up-to-date data for practical deployment. Formally, we focus on the downstream task performance of models fine-tuned from the final pretrained model checkpoint f_T, where the downstream tasks S_T are also from the latest domain. To succeed in these metrics, it is crucial for the model to transfer knowledge from earlier domains to the latest domain.

Temporal Generalization Ability. We consider another practical fine-tuning scenario in the tweet stream where the model is trained on outdated data and evaluated on the latest data (Rijhwani and Preotiuc-Pietro, 2020; Huang and Paul, 2018), referred to as the *temporal generalization* ability. Formally, we fine-tune the final pretrained model checkpoint f_T over the training set of downstream tasks S_t from an earlier time step ($t < T$), and evaluate on the test set of the downstream tasks S_T from the latest time step T.

3 Methods

Lifelong language model pretraining introduces novel challenges because of the large training sets and more comprehensive evaluation protocols compared to classification tasks. We establish several strong baselines, and evaluate the performance of continual learning algorithms from different categories spanning over model-expansion, memory-based, and distillation-based approaches, We illustrate the approaches in Figure 3.

3.1 Simple Baselines

We consider several simple baselines which continual learning algorithms will be compared against. `RoBERTa-base` (f_0) corresponds to not pretraining on any of the domain-specific corpora. By separately pretraining f_0 on each corpus $D_1, D_2, ...D_T$, we obtain T `Task-Specific` pretrained models. We also pretrain f_0 sequentially over $D_{1..T}$, which we refer to as `sequential pretraining`. While it allows knowledge transfer between domains compared to domain-specific models, without any continual learning algorithms, sequential pretraining is prone to catastrophic forgetting (Robins, 1995). Finally, we randomly shuffle corpora from all domains $D_{1..T}$ before pretraining, noted as `Multi-Task Learning (MTL)`. MTL corresponds to an offline training paradigm that models new corpora by re-training over all corpora seen before. The drawback is that it requires storing full data from earlier domains, and that it can be extremely costly to repetitively retrain over earlier data if new data keeps emerging.

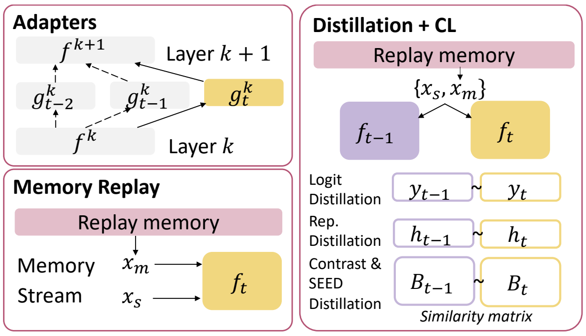

Figure 3: **Comparison of adapter, memory replay, and distillation-based continual learning algorithms.** Details of the methods are introduced in Sec. 3.

3.2 Model-expansion and Regularization-based Methods

We first introduce model-expansion based approaches, which add small trainable modules (*e.g.,* multi-layer perceptron) to the model per new domain while keeping other parts of the model frozen. The `Adapter` approach is a representative approach that learns a set of "adapter" layers $g_t = \{g_t^k\}_{k=1}^K$ for each domain D_t and each of the K transformer layers (Houlsby et al., 2019). We also experiment with a simple `Layer Expansion` approach, which learns separate top two layers of the transformer and the prediction head for each domain. We also involve a regularization-based continual learning baseline, online EWC (Schwarz et al., 2018), which directly penalize change of model parameters.

3.3 Memory Replay Methods

We also experiment with Experience Replay (ER) (Chaudhry et al., 2019), which alleviates forgetting by storing a subset of earlier examples and periodically re-training (replaying) over them. We maintain a fixed-size memory M ($100k$ examples by default) and populate the memory M each time pretraining on a domain D_t finishes with examples in the current domain. We ensure M always contains a balanced sample of examples from all seen domains $D_{1..t}$. We replay a mini-batch of examples from the memory every 10 training steps.

3.4 Distillation-based CL Methods

While knowledge distillation (KD) (Hinton et al., 2015) techniques have been studied intensively for pretrained language models (Sun et al., 2019), applying them to continual learning has been under-explored outside image classification tasks (Li and Hoiem, 2018; Rebuffi et al., 2017; Hou et al., 2018). Distillation based CL approaches store one previous model checkpoint of the model (noted as f_{t-1}) and regularize the differences between f_{t-1} and the current model f_t. We adapt several existing knowledge distillation techniques to PTLMs and utilize them for continual learning. We note, while individual distillation techniques are not original, their adaptation to CL algorithms can be novel.

We perform distillation with examples from the current domain D_t and a replay memory M (similar to ER). Despite the potential gap between D_t and the training data of f_{t-1}, the approach allows utilizing more data for distillation. Formally, each time the model receives a mini-batch of stream examples $\boldsymbol{x}_s$ or a draws mini-batch of memory examples $\boldsymbol{x}_m$ from M (both noted as $\boldsymbol{x}$), we collect certain outputs of the model (*e.g.*, output logits or intermediate representations) with f_{t-1} and f_t. We compute a distillation loss $\ell_{\text{KD}}(\boldsymbol{x}, f_{t-1}, f_t)$ that penalizes the differences between the model outputs, and jointly optimize it with the masked language modeling loss ℓ_{MLM}. The final objective is written as $\ell = \ell_{\text{MLM}} + \alpha \ell_{\text{KD}}$, where α is a hyperparameter to weight the distillation loss.

Logit Distillation. In logit distillation (Hinton et al., 2015), we collect the output logits of f_t and f_{t-1}, noted as $\boldsymbol{y}_t$ and $\boldsymbol{y}_{t-1}$ respectively. The distillation loss is computed as $D_{\text{KL}}(\boldsymbol{y}_t, \boldsymbol{y}_{t-1})$, where D_{KL} is the Kullback–Leibler divergence function.

Representation Distillation. We also consider minimizing the representational deviation of sentences between previous and current models (Sun et al., 2019; Jiao et al., 2020). We extract the representation of each word of two models, noted as $\boldsymbol{h}_{t-1}^{1:N}$ and $\boldsymbol{h}_t^{1:N}$, before the masked language modeling prediction head, where N is the length of the sentence. Then, we compute MSE loss $||\boldsymbol{h}_{t-1}^{1:N} - \boldsymbol{h}_t^{1:N}||_2^2$ as the distillation loss.

Contrastive Distillation. In addition to output logits and hidden representations, we further look into *representational similarity within a batch of examples* as additional knowledge to distill. The approach is adapted from (Cha et al., 2021), which is originally studied for supervised image classification tasks. We briefly introduce the adapted algorithm and leave the details in Appendix E. During continual pretraining, in addition to the language model pretraining objective, we add an unsupervised contrastive learning objective, namely the SimCSE (Gao et al., 2021) objective to encourage sentence representations to reflect semantic similarities between sentences. Then, we compute the intra-batch representational similarity matrices of sentence representations (*i.e.* between each pair of examples in the mini-batch) with f_{t-1} and f_t, noted as $\mathbf{B}^{t-1}$ and $\mathbf{B}^t$, and minimize the cross entropy loss $\ell_{\text{distill}} = -\frac{1}{N}\sum_{i=1}^{N}\sum_{j=1}^{N}\mathbf{B}_{ij}^{t-1}\log\mathbf{B}_{ij}^{t}$

Self-Supervised Distillation (SEED). SEED distillation proposed by (Fang et al., 2021) has a similar spirit as the contrastive distillation. The only difference is that it distills representational similarity *between the batch and a large set of other examples*. We leave the details of the algorithm in Appendix E. We further combine SEED Distillationwith logit distillation and refer to the approach as SEED-Logit Distillation.

4 Results

We summarize our findings over the created data streams. We ask whether lifelong pretraining and continual learning algorithms are effective base on our evaluation protocol proposed in Sec. 2.3.

4.1 Experiment Settings

We use the `RoBERTa-base` model (Liu et al., 2019b), initialized with RoBERTa-base weights throughout the experiments. We set the maximal sequence length to 128 and an effective training batch size of 2,048. On the research paper stream, models are trained for $8k$ steps in the first domain and $4k$ steps in the subsequent domains. On the Tweet stream, we train the models for $4k$ steps in each domain. These correspond to less than a single pass of data in each domain. See Appendix A for detailed setups.

4.2 Domain Incremental Data Stream

As we introduced in Sec. 2.2, in the domain incremental research paper stream, we expect a model f_t to perform well on all downstream tasks $S_{1..t}$ from domains $D_{1..t}$. In Table 2, we report the performance of models on all downstream tasks $S_{1..T}$ fine-tuned from the final pretraining checkpoint, f_T. We visualize more complete change of downstream task performance over different time steps of pretraining (*i.e.*,, f_1, f_2, f_3, f_4) in Fig. 4. We also report the log perplexity of masked language modeling (MLM) in Table 2 as additional informa-

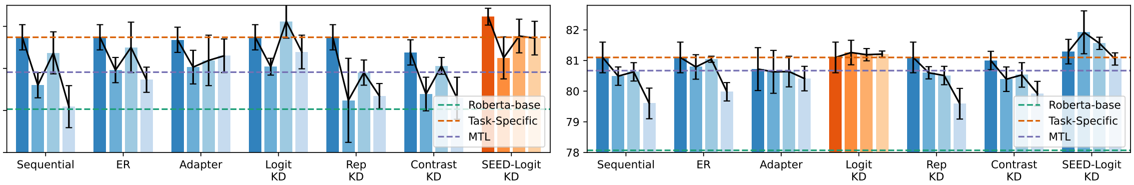
tion. With these results, we address the research questions below.

Does lifelong pretraining help retain knowledge across different domain corpora? We first examine whether task-specific or lifelong pretraining improves performance over domain-specific downstream tasks. Comparing Task-Specific LMs with RoBERTa-base in Table 2, we notice consistent performance improvements, especially on Biomedical and Computer Science domains (D_1, D_2). We also see Sequential Pretraining could consistently outperform RoBERTa-base. However, the comparison between Sequential Pretraining and Task Specific LMs are mixed: on D_1, D_2, D_3, Sequential Pretraining could outperform Task-Specific LMs only except MNER; while on the earliest biomedical domain (D_1), Sequential Pretraining achieves substantially lower performance. From Figure 4, we see the performance of Sequential Pretraining on Chemprot and RCT (from D_1) drops significantly from $t = 1$ to 4. The results imply lifelong pretraining allows later domains to benefit from knowledge transfer from earlier domains, but the performance on earlier domains is limited because of forgetting.

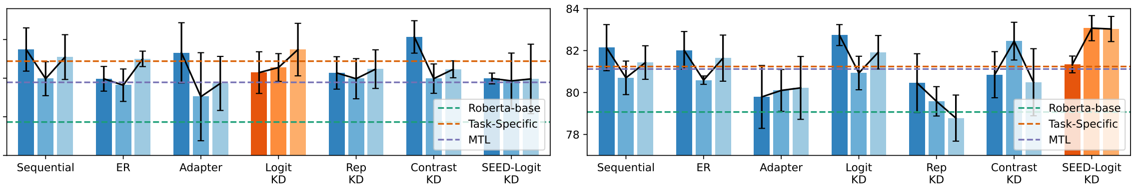
Does continual learning algorithms help retain knowledge in sequential pretraining? Next, we compare different kinds of CL algorithms and investigate the effect of CL algorithms in alleviating forgetting and improving knowledge transfer. Table 2 shows that Online-EWC slightly improves MLM perplexity compared to Sequential PT, but brings no improvement to the fine-tuning performance. We hypothesize that regularization directly in the parameter space as in Online-EWC is not effective when the parameter space is very high dimensional. Adapter improves downstream task F1 scores on the bio-medical domain (D_1) by 1.2% and 0.8%, but does not outperform Sequential Pretraining in other domains (similarly for Simple Layer Expansion approach), likely because a great portion of the model is kept frozen.

In contrast, the memory-replay based approach (ER) allows training the full parameters of the model and has been shown to be highly effective in continual learning of classification tasks (Wang et al., 2019; Chaudhry et al., 2019). However, we surprisingly find that ER could hardly improve over Sequential Pretraining except D_1. A similar pattern can be found in the MLM perplexity. We hypothesize that the positive effect of example replay has diminished because of the overfitting to the memory examples. Table 3 summarizes the effect of tuning hyperpameters in ER. When we reduce the frequency of replay (from every 10 steps to 100 steps), the MLM performance improves, which implies reduced overfitting; however, the performance of downstream task performance does not improve. When we increase the size of the memory $|M|$ from $100k$ to $10M$, the MLM perplexity also improves; still, there are still no improvements in downstream tasks. It may imply ER itself is not an effective approach for continual pretraining.

Unlike ER, distillation approaches utilize richer information such as output logits or representation similarity to preserve past knowledge. We find either Logit KD or SEED-Logit KD to be most



(a) Chemprot (b) RCT-Sample



(c) ACL-ARC (d) SciERC

Figure 4: **Performance evolution of downstream models.** Models are fine-tuned from checkpoints of lifelong pretrained LMs at different time steps t. For Chemprot and RCT-Sample from D_1, we use $t \in \{1, 2, 3, 4\}$; while for ACL-ARC and SciERC from D_2, $t \in \{2, 3, 4\}$. Methods achieving the best performance at the end of training ($t = 4$) is highlighted.

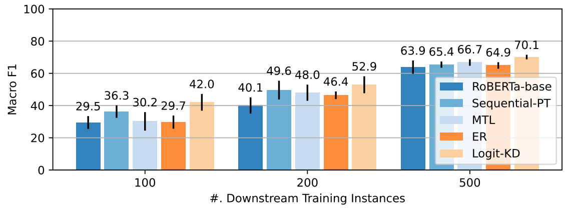


Figure 5: **Performance of downstream models with various number of training examples**, exemplified with SciERC. The models are fine-tuned from the final pretrained model (f_4).

effective depending on the task, while Rep-KD and Contrastive-KD are less effective. The best performing distillation approach improves F1 over Sequential Pretraining on downstream tasks from D_1, D_2 at least by 1.0%. However, performance on D_3, D_4, which come later in the data stream, does not improve over Sequential Pretraining, possibly because the distillation loss term makes the model rigid in obtaining new knowledge.

What is the gap between lifelong pretraining and multi-task learning across all the domains? Multi-Task Learning refers to the offline training paradigm, which retrain PTLMs over all corpora ($D_{1..t}$) each time a new corpus D_t becomes available. We examine whether lifelong pretraining is comparable to multi-task pretraining in terms of performance. From Table 2 and Figure 4, we see Sequential Pretraining in general underperforms MTL except for the final domain. However, certain CL approaches, such as Logit-Distillation, could improve over MTL on all downstream tasks from the first and the second domain. We speculate the reason is that continual learning naturally provides a curriculum (Xu et al., 2020; Shi et al., 2015) to models where each individual task is easier to learn. The results have a positive implication that lifelong pretraining is not only more computationally efficient and requires less storage of past data, but may also improve the performance of pretraining.

Does lifelong pretraining make models more data efficient? In Table 5, we further examine the performance of final pretrained models under different amounts of training examples. We include full results in Appendix B. We find in general, performance improvements are more significant in the low-resource setup.

Computational Costs. We quantify computational costs of different CL algorithms with the number of forward and backward passes in Table 4 and present additional experiments with controlled computational costs in Appendix F. We find additional computational cost is necessary for performance improvement of distillation-based CL. However, it is not possible to trade performance simply by investing more computation budget with arbitrary CL algorithms. We leave detailed discussions in Appendix F.

4.3 Temporal Data Stream

We conduct analysis on pretraining PTLM on chronologically-ordered tweet corpora, to understand whether lifelong pretraining helps adaptation to the latest data and improves temporal generalization ability. The results are summarized in Table 5.

Method	#. of Forward	#. of Backward	#. Total	#. Total (k=10)	Wall Time$_{4k}$
Main results					
Sequential PT	b	b	$2b$	$2b$	4.0×10^4 sec.
ER	$(1+1/k)b$	$(1+1/k)b$	$(2+2/k)b$	$2.2b$	4.2×10^4 sec.
Logit-Distill	$(2+2/k)b$	$(1+1/k)b$	$(3+3/k)b$	$3.3b$	6.9×10^4 sec.
SEED-Logit-Distill	$(3+3/k)b$	$(2+2/k)b$	$(5+5/k)b$	$5.5b$	9.7×10^4 sec.
Additional Controlled Experiments					
Sequential PT$_{b'=1.2b}$	$1.2b$	$1.2b$	$2.4b$	$2.4b$	4.4×10^4 sec.
ER$_{k=5}$	$1.2b$	$1.2b$	$2.4b$	$2.4b$	4.4×10^4 sec.
Sparse Logit-KD	$1.3b$	$1.1b$	$2.4b$	$2.4b$	4.4×10^4 sec.
Sparse SEED-Logit-KD$_{\setminus contrast}$	$1.3b$	$1.1b$	$2.4b$	$2.4b$	4.8×10^4 sec.

Table 4: Number of forward and backward passes over PTLMs and wall clock time of different approaches. The number of forward and backwards passes are computed over visits of b batches from the training data stream, where k is the frequency of replay. The wall clock time is calculated over $4k$ steps of training (which is the number of training steps of a single domain in the Research Paper stream) excluding the first domain, as no replay or distillation happens while learning the first domain. In the additional controlled experiments (described in Appendix. F), we control the total number of forward and backward passes of different approaches.

Table 5: **Results on temporal data stream.** We show fine-tuning performance over years 2018 and 2020 (D_3, D_4) and the Temporal generalization from 2014 or 2016 to 2020 data ($D_1 \rightarrow D_4$, $D_2 \rightarrow D_4$) on Twitter Hashtag and Emoji prediction datasets. Models are fine-tuned from the final pre-trained model f_T. We include full results on other years (D_1, D_2, $D_3 \rightarrow D_4$) in Appendix C.

Will LMs be outdated? We compare the performance of Task-Specific (2014) to the Task-Specific models pretrained on the year of downstream datasets (noted as Task-Specific (Latest)) and notice consistent improvements in downstream tasks in 2018 and 2020 (first two columns in Table 5). Sequential Pretraining could also outperform the Task-Specific (2014) model. It verifies that language models may get outdated over time, but the issue can be addressed by task-specific or lifelong pretraining over the latest corpora.

Does lifelong pretraining help improve the downstream model's performance on latest data? We show that downstream model's performance over later data (D_3, D_4) can be improved over Task-Specific models when continual learning algorithms are applied. From the first two columns of Table 5, we see Logit-KD and SEED-KD improve Hashtag prediction score over data of years 2018 and 2020. SEED-Logit KD further improves prediction F1 on Emoji prediction. Note that these findings are in contrast to the research paper stream, where CL algorithms do not improve performance in the latest domain D_4. The reason can be the higher similarity between domains in the tweet corpora making the knowledge transfer easier, which is further discussed in Appendix I.

Does lifelong pretraining improve temporal generalization? Temporal generalization evaluates downstream performance over latest test data when fine-tuned over outdated training data. We show lifelong pretraining brings clear improvement to temporal generalization. From Table 5, we see even Sequential Pretraining could improve over the model pretrained merely on the year 2020 data (Task-Specific (2020)) consistently. We find performance further improves with CL algorithms applied. SEED-Logit-KD performs best in general on crossyear hashtag prediction tasks. In crossyear emoji prediction, we find Contrast-KD and SEED-KD perform best. We also find that SEED-Logit-KD could slightly outperform Logit-KD.

Domain and Temporal Adaptation of Language Models. Gururangan et al. (2020) study adaptation of PTLMs to domain-specific corpora. Arumae et al. (2020) study algorithms to mitigate forgetting in original PTLMs, but does not investigate forgetting that happens over a sequence of domains. Maronikolakis and Schütze (2021); Röttger and Pierrehumbert (2021); Luu et al. (2021) proposes sequential pretraining over domains or emerging data, but did not investigate CL algorithms. Several recent studies have demonstrated the necessity of adapting LMs over time (Lazaridou et al., 2021) while specifically focusing on factual knowledge (Dhingra et al., 2021; Jang et al., 2021).

Continual Learning Algorithms in NLP. Continual learning in NLP has mainly been studied for classification tasks. An effective approach is to utilize a number of stored past examples (de Masson d'Autume et al., 2019; Wang et al., 2020), or pseudo examples (*e.g.,* the ones generated with a PTLM (Sun et al., 2020; Kanwatchara et al., 2021)). Recent extensions of the algorithm (Chuang et al., 2020) perform knowledge distillation with generated pseudo examples. Other lines of works focus on regularization over the sentence representations (Wang et al., 2019; Huang et al., 2021; Liu et al., 2019a) or directly merging models in the parameter space (Matena and Raffel, 2021). Model expansion-based approaches (Liu et al., 2019a; Pfeiffer et al., 2021), including learning domain specific expert models (Gururangan et al., 2021), are also actively studied. Wu et al. (2022) present a comparative study of algorithms in the context of continual fine-tuning over NLP tasks.

6 Conclusion

In this paper, we formulated the lifelong language model pretraining problem and constructed two data streams associated with downstream datasets. We evaluated knowledge retention, adaptation to the latest data, and temporal generalization ability of continually pretrained language models. Our experiments show distillation-based approaches being most effective in these evaluation setups. A limitation of the work is that it has not been fully addressed whether there exists a variant of distillation-based CL approach that consistently outperforms Logit-KD. Based on the current observation, we conclude the performance of different KD approaches for CL is highly task-dependent. It asks for more future works into continual learning algorithms within the proposed problem setup.

Figure 6: Performance of downstream models with various number of training examples. The models are fine-tuned from the final pretrained model (f_4).

A Detailed Experiment Settings

We use a linearly decreasing learning rate initialized with 5e-4 on the research paper stream and 3e-4 on the tweet stream. On the research paper stream, we train the model for 8,000 steps in the first task, and 4,000 steps in the subsequent tasks. On the tweet stream, we train the model for 8,000 steps in all tasks. We hold out 128,000 sentences from each corpus to evaluate MLM performance. As the size of pretraining corpora is large, during training, each training example is visited only once. We use the masked language modeling perplexity over held-out validation sets of the pretraining corpora as the metrics for hyperparameter tuning. Common hyperparameters such as learning rate and batch sizes are tuned with Task-specific models with the first task. Hyperparameters that are specific to continual learning algorithms, such as the scale of the distillation loss, is tuned using the first two domains in the stream according to the MLM performance over validation sets. The weight of the distillation term α is set as 1.0 for logit distillation and 0.1 for other distillation algorithms. By default, we replay or perform distillation with a mini-batch of examples from the replay memory every 10 training steps in ER and Distillation-based CL approaches. We use the huggingface transformers library `https://github.com/huggingface/transformers` for implementation.

B Low-Resource Fine-Tuning

Figure 6 summarizes the performance of fine-tuned models from the final model checkpoint ($t = 4$) using different amount of downstream training examples. We see on Chemprot and SciERC, the benefit of Sequential Pretraining over RoBERTa-base is more significant in low-resource fine-tuning setups. Whenever Seqential Pretraining outperforms RoBERTa-base, we notice Logit-KD could further improve over Sequential Pretraining.

Table 6: Full performance on Twitter Hashtag prediction and Emoji prediction, fine-tuned from the pre-trained model in the final time step.

C Full Results over the Tweet Stream

Tables 6 and 7 summarize full results over the Tweet stream. Compared to the table 5 in the main text, we add downstream performance over data from years 2014 and 2016 (D_1, D_2), and temporal generalization from year 2014 to 2020 ($D_1 \rightarrow D_4$).

D Dataset Details

The research paper stream consists of full text of 6.6M, 12.1M, 7.8M, and 7.5M research papers from the S2ORC (Lo et al., 2020) dataset. We evaluate downstream fine-tuning performance on two in-domain datasets for each research area: Chemprot relation exaction dataset (Vindahl, 2016) and RCT abstract sentence role labeling dataset (Dernoncourt and Lee, 2017) for the bio-medical domain; ACL-ARC citation intent classification dataset (Jurgens et al., 2018) and SciERC relation extraction dataset (Luan et al., 2018) for the

Table 7: Temporal generalization performance on Twitter Hashtag prediction datasets fine-tuned from the final pretrained model. `Year 1`→`Year 2` indicates the hashtag prediction model is fine-tuned on data in year `Year 1`, and evaluated on test data in `Year 2`.

computer science domain; relation extraction over Synthesis procedures (Mysore et al., 2019) and named entity recognition over material science papers (MNER) (Olivetti et al., 2020) for material science domain; keyphrase classification and hyponym classification after filtering out physics papers for the physics domain (Augenstein et al., 2017). We report micro-averaged F1 on Chemprot, RCT, MNER datasets following the evaluation metrics in the original work, and report macro-averaged F1 on all other datasets. We use the official data splits for all datasets except for RCT, where we employ a low-resource training setup following Gururangan et al. (2020).

The pretraining corpora for the tweet stream consist of 25M tweets in each year. For downstream tasks, we use a separate set of 1M tweets from each year to construct multi-label hashtag prediction (Gong and Zhang, 2016) datasets and single-label emoji prediction datasets (Barbieri et al., 2018). We replace user names to special tokens. For Hashtag prediction, the label space consists of tweets containing 200 most frequent hashtags in each year. We independently sample 500 tweets per label (hashtag) as training, validation and test sets, which results $10k$ examples in each of the data splits. For emoji prediction, we construct 20-way single-label emoji prediction datasets for each year following Barbieri et al. (2018) with the 1M held out tweets. We sample 5,000 tweets per emoji in each split, resulting in balanced datasets of the same size as the hashtag prediction datasets.

E Details of Continual Learning Algorithms

E.1 Contrastive Distillation

During continual pretraining, in addition to the language model pretraining objective, we add a unsupervised contrastive learning objective, namely the SimCSE (Gao et al., 2021) objective, so that the similarity in the sentence representation better reflects the semantic similarity in the sentence. We use the l^2-normalized representation of the start-of-sequence token at the final layer as the sentence representation, noted as $\boldsymbol{h}$. Then, we distill the intra-batch representational similarity from the previous model f_{t-1} to the current model f_t. Given a mini-batch of N examples $\boldsymbol{x}$, we compute the representational dot-product similarity matrix between normalized sentence representations $\boldsymbol{h}$ between each pair of examples with f_{t-1} and f_t, noted as $\mathbf{B}^{t-1}$ and $\mathbf{B}^t$, where each element $\mathbf{B}_{ij}$ is,

$$\mathbf{B}_{ij} = \frac{\exp(\boldsymbol{h}_i \cdot \boldsymbol{h}_j / \tau)}{\sum_{k=1..N} \exp(\boldsymbol{h}_i \cdot \boldsymbol{h}_k / \tau)} \quad (1)$$

where τ is a temperature hyperparameter. We specify a temperature $\tau_t = 0.05$ for the teacher model f_{t-1} and a temperature τ_s for the student model $f_t = 0.01$. We compute the cross-entropy between $\mathbf{B}^{t-1}$ and $\mathbf{B}^t$ as the distillation loss,

$$\ell_{\text{distill}} = -\frac{1}{N} \sum_{i=1}^{N} \sum_{j=1}^{N} \mathbf{B}_{ij}^{t-1} \log \mathbf{B}_{ij}^{t} \quad (2)$$

E.2 SEED Distillation

SEED distillation proposed by (Fang et al., 2021) has a similar spirit as the contrastive distillation with differences in the examples used for computing similarity matrices computes. The algorithm distills representational similarity *between the batch and a large set of other examples*, maintained in an example queue Q. As the number of target examples K can be much larger than the batch size, it allows distillation of richer information by regularizing similarities. During pretraining, the method maintains a fixed-size queue

Q to cache examples from the current domain D_t. Given a mini-batch of training examples $\boldsymbol{x}$, it computes cosine similarity between each pair of examples within the batch $\boldsymbol{x}$ and Q with f_{t-1} and f_t, resulting in two similarity matrices $\mathbf{B}^{t-1}$, $\mathbf{P}^y \in \mathbb{R}^{|B|\times|Q|}$. Similar to the contrastive distillation, the distillation loss is the cross-entropy between two similarity matrices $\mathbf{B}^{t-1}$ and $\mathbf{B}^t$ computed in the same way as Eq. 2.

F Analysis and Controlled Experiments of Computational Costs

Computational cost is a crucial matter for online continual learning systems. In this section, we analyze the computational costs of continual learning algorithms and perform controlled experiments of computational costs.

We quantify computational costs with the total number of *forward (C_f) and backward (C_b)* computations ($C = C_f + C_b$) over the PTLMs, which is easy to control; in practice, we find the wall clock time of training was approximately linear to C. We summarize the number of forward and backward passes and the wall clock time of training in Table 4. In the visit of b batches from the training stream, Sequential PT performs b forward and backward passes respectively over the PTLM, resulting in $C = 2b$. Experience replay further replays 1 batch of examples every k steps over the training stream, which results in $C = (2 + 2/k)b$. In our main experiments, r is set to 10 (Sec. 3.3). Logit-Distill and Rep-Distill require one additional forward pass over a frozen PTLM to compute the target of distillation, resulting in $C = (3 + 3/k)b$. Distillation algorithms that perform contrastive learning with SimCSE (*i.e.* SEED-Distill and SEED-Logit-Distill) additionally require one forward and backward pass using the same batch of examples with different dropout masks. Therefore, for SEED-Logit-Distill, $C = (5 + 5/k)b$.

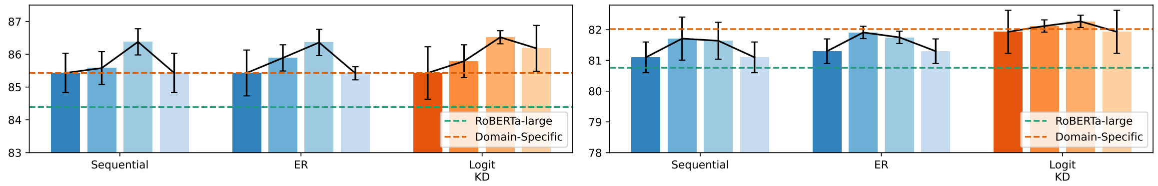
To control the number of forward and backward passes, we present approaches to compensate the lower computation costs compared to Distillation algorithms and one approach to shrink the computational cost of distillation algorithms: (1) for Sequential PT, we train the models for 1.2 times more steps so that $C = 2.4b$, noted as Sequential PT$_{b'=1.2b}$; (2) for ER, we increase the replay frequency k to 5 from the default setup 10, so that $C = 2.4b$. We also decrease the cost of Logit-KD and SEED-Logit-KD by reducing the frequency of distillation from every 1 batch to every $r' =$10 steps, while still replaying and distilling knowledge over 1 batch of memory examples every 10 training steps. This results in $C_f = (1 + 2/k + 1/k')b$ and $C_b = (1 + 1/k)b$, where $C = 2.4b$ when both r and r' are 10. The approach is referred to as Sparse Logit-KD. Finally, for SEED-Logit-KD, we remove the SimCSE loss from training and perform sparse distillation similar to Sparse-Logit-KD, which also results in $C = 2.4b$.

The performance of the models is presented in Table 9. We notice that at the end of pretraining, increasing the number of training steps in Sequential PT by 1.2 times does not lead to performance boost on the latest domain (D_4), while the performance over tasks from earlier domains (Chemprot, ACL-ARC, SciERC) slightly dropped, possibly due to increased forgetting. For ER, we notice replaying only slightly more frequently (ER$_{k=5}$) than the default setup (k=10) greatly increased the perplexity of MLM, implying significantly increased overfitting to the memory; while the performance differences of downstream tasks compared to the default ER is mixed. When we decrease the replay frequency of distillation, the performance on Logit-KD and SEED-KD also decreased and does not outperform ER.

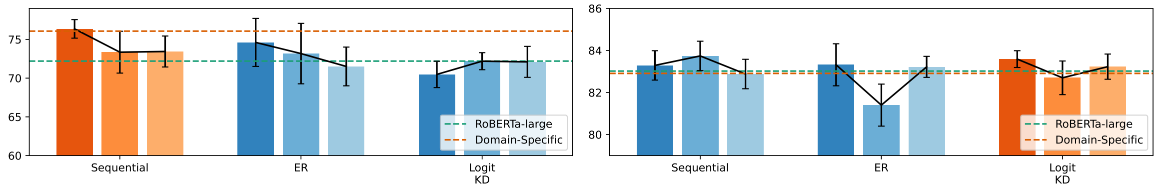
The results show additional computation costs can be necessary for continual learning algorithms such as Logit-KD and SEED-Logit-KD. However, the results also show that there is no simple trade-off between computational cost and performance. We have seen that it is not always beneficial to increase the number of training steps over the emerging data, as it increases forgetting in earlier domains. Similarly, increasing the frequency of replay may lead to significant overfitting to the replay memory. Investigating into more effective continual learning algorithms, despite increased computation costs, allows us to obtain performance improvement that cannot be simply traded with more computation with arbitrary continual learning algorithms. We leave more thorough studies into this topic as future work.

G Experiments with RoBERTa-large

We present additional experiments on RoBERTa-large. Figure 7 and Table 8 summarizes the results of selected continual learning algorithms and baselines. On Chemprot, RCT-Sample and SciERC, Logit-KD achieves best performance with the last



(a) Chemprot (b) RCT-Sample



(c) ACL-ARC (d) SciERC

Figure 7: Performance evolution of downstream models with RoBERTa-large as the base model. Models are fine-tuned from checkpoints of lifelong pretrained LMs at different time steps t. For Chemprot and RCT-Sample from D_1, we use $t \in \{1, 2, 3, 4\}$; while for ACL-ARC and SciERC from D_2, $t \in \{2, 3, 4\}$. Methods achieving the best performance at the end of training ($t = 4$) is highlighted.

Domain	Biomedical		Computer Science	
Dataset	Chemprot	RCT-Sample	ACL-ARC	SciERC
RoBERTa-large	$84.39_{\pm 0.7}$	$80.76_{\pm 0.7}$	$72.20_{\pm 3.2}$	$83.02_{\pm 0.8}$
Naive	$85.43_{\pm 0.6}$	$81.10_{\pm 0.5}$	$73.44_{\pm 2.0}$	$82.88_{\pm 0.7}$
ER	$85.42_{\pm 0.2}$	$81.30_{\pm 0.4}$	$71.51_{\pm 2.5}$	$83.22_{\pm 0.5}$
Logit-KD	$86.18_{\pm 0.7}$	$81.93_{\pm 0.7}$	$72.10_{\pm 2.0}$	$83.23_{\pm 0.6}$
Task-Specific	$85.99_{\pm 0.3}$	$82.02_{\pm 0.6}$	$76.07_{\pm 1.0}$	$82.91_{\pm 0.9}$

Table 8: Results on the Research Paper stream with RoBERTa-large as the base model.

pretraining checkpoint. On ACL-ARC, however, we notice that Sequential PT achieves the best performance, while all continual learning algorithms (ER, Logit-KD) achieves lower F1 at the initial time step (t=2, Figure 7(c)). This implies continual learning algorithms may hurt model's performance in capturing new knowledge, despite its potential to reduce forgetting.

H Experiments with BERT on Tweet Stream After 2019

In this section, we present an additional set of experiments on BERT-base (Devlin et al., 2019) model, which is originally pretrained with Wikipedia articles before 2019, with Tweets only after 2019. The training corpora $D_{1..4}$ consist of tweets from the first half of 2019, the second half of 2019, the first half of 2020, and the second half of 2020 respectively. We accordingly construct hashtag prediction and cross-year hashtag prediction datasets. The performance of downstream tasks fine-tuned from the final pretrained model is presented in Table 10. We see Sequential PT clearly outperforms BERT-base which is not continually pretrained, and that Logit-KD generally improves hashtag prediction performance compared to Sequential PT except on the first half of 2019. We hypothesize the small temporal gap between $D_{1..4}$ makes improvements less significant than our main experiment setup. We present temporal generalization performance in cross-year hashtag prediction tasks in Table 11. Similarly, Logit-KD improves over Sequential PT in two out of three cross-year hashtag prediction setups.

I Analysis of Data Streams

In this section, we provide further analysis about the created research paper stream and the tweet stream. We measure cosine distances d_v of vocabulary distributions between each pair of different domains ($D_{1..4}$) and summarize the results in Figure 8. The results indicate that the Tweet stream has a magnitude smaller vocabulary distribution gap between domains, which is in the scale of $1e^{-5}$, compared to the research paper stream, which is in the scale of $1e^{-2}$. On the Tweet stream, we see the differences of vocabulary distributions align with the temporal gap between domains. On the research paper stream, we find some domains to be more similar than others. For example, Biomedical (D_1) and Material Science domains (D_3) have larger similarity in their vocabulary distributions, which explains general downstream performance increase on D_1 after the model is pretrained on D_3 (Fig. 4 (a,b)).

The differences in vocabulary distribution explain inconsistency in results between two data

Task	D_1 - Biomedical			D_2 - Computer Science			D_3 - Materials Science			D_4 - Physics

streams, specifically, whether lifelong pretraining improves downstream model performance on the latest domain, as we mentioned in Sec. 4.3. Other than this, our main findings, such as the effect of distillation-based CL algorithms on reducing forgetting, are consistent over two datasets with such significant differences in their changes of vocabulary distribution. We believe it implies the conclusions in this paper should be reliable in diverse data streams.

J Ethic Risks

We would like to note that, in practice, continually pretrained models over real-world data streams would require identification and removal of biased contents from pretraining corpora, which may affect the prediction of downstream models. As PTLMs are continuously updated, the bias in earlier pretraining may have a profound negative impact. In future works, it is preferable to develop algorithms to "forget" certain biased knowledge from language models. We further note that any data released in this paper, especially the tweet stream, should only be used for research purposes.

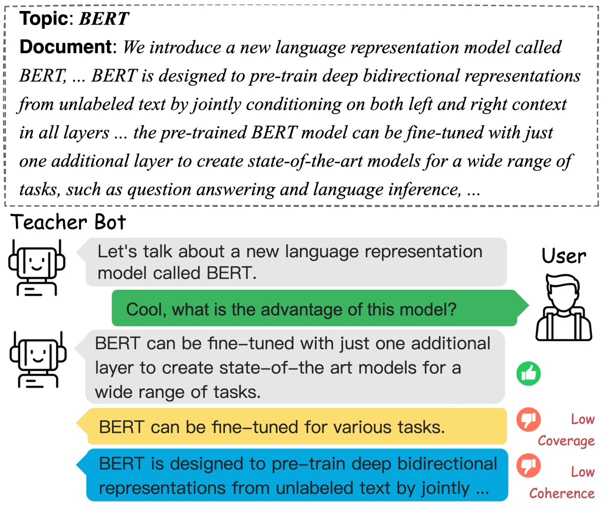
Abstract

We propose novel AI-empowered chat bots for learning as conversation where a user does not read a passage but gains information and knowledge through conversation with a teacher bot. Our information-acquisition-oriented dialogue system employs a novel adaptation of reinforced self-play so that the system can be transferred to various domains without in-domain dialogue data, and can carry out conversations both informative and attentive to users. Our extensive subjective and objective evaluations on three large public data corpora demonstrate the effectiveness of our system to deliver knowledge-intensive and attentive conversations and help end users substantially gain knowledge without reading passages. Our code and datasets are publicly available [1] for follow-up research.

1 Introduction

Communication is the central process of education (Dewey, 1923). In learning as conversation (Sharples, 2005), a student does not read a passage but gains information and knowledge through conversation with a teacher who reads the passage. Compared to the traditional learning by reading, learning as conversation has the advantages that conversation helps students stay engaged and that information is provided piece by piece, which helps strengthen learning with a shorter attention span.

The advantages of learning as conversation have been verified with educational evidence (Mol et al., 2008; Lever and Sénéchal, 2011; Golinkoff et al., 2019). For example, studies have shown that when children read storybooks, parents' guided conversation, e.g., posing questions and providing responsive feedback, substantially amplifies the learning benefits. While high-quality conversations with experts are not always available, it would be helpful if AI-empowered chat bots could be applied to facilitate users to gain information or knowledge.



Topic: ***BERT***

Document: *We introduce a new language representation model called BERT, ... BERT is designed to pre-train deep bidirectional representations from unlabeled text by jointly conditioning on both left and right context in all layers ... the pre-trained BERT model can be fine-tuned with just one additional layer to create state-of-the-art models for a wide range of tasks, such as question answering and language inference, ...*

Let's talk about a new language representation model called BERT.

Cool, what is the advantage of this model?

BERT can be fine–tuned with just one additional layer to create state–of–the art models for a wide range of tasks.

BERT can be fine–tuned for various tasks.

BERT is designed to pre–train deep bidirectional representations from unlabeled text by jointly ...

Figure 1: The teacher bot educates an user about "BERT" through conversation generated from the document.

In recent years, there has been significant research in content-grounded dialogue generation, where external passages are used to inspire knowledge intensive dialogues. However, these systems or datasets are either for chit chat (Zhou et al., 2018; Dinan et al., 2019) or for goal-oriented information seeking (Feng et al., 2020; Chen et al., 2021), little work has explored applying chat bots for the learning as conversation purpose.

In this work we propose a novel task for learning as conversation: information-acquisition-oriented dialogue generation. Given a passage, our chat bot actively engages with an end-user to form a coherent conversation, so that the user could gain knowledge without reading the passage. Our task has a broad range of potential application venues in which people traditionally rely on reading to obtain information, including:

- Education: Chat bot helps an user gain knowledge from books or research papers;
- News and Media: Through conversation, a

user could be provided stories tailored for his/her preference;

- Tutorial: While reading an instruction book could be tedious and time-consuming, a chat bot could efficiently walk an user through the process.

As shown in Figure 1, for our task, a good conversation should have the following characteristics:

1. Coverage: The chat bot should try to convey as much information in the passage as possible, instead of mumbling about irrelevant information;
2. Coherence: The chat bot's response should be coherent to the user's utterance, making the user feel that his/her questions are followed and addressed.

In summary, we propose a novel framework which consists of the following two chat bot modules: 1) Teacher bot, which attempts to transfer the information in an input passage to a user through conversation; and 2) Student bot, which responds to Teacher bot to form coherent conversations during training. The two bots are trained in a two-phase manner: In Phase 1, we pre-tune the two chat bots on *Wizard of Wikipedia* (Dinan et al., 2019) dataset, enabling both bots with the basic ability of conversing over a passage. In Phase 2, we fine-tune Teacher bot through self-play with Student bot, guided by reinforcement rewards. In this process, we enhance Teacher bot to be more informative while maintaining the ability to coherently address human users. Specifically, the fine-tuning phase is unsupervised, i.e. Teacher bot could be transferred to various domains or corpora without additional annotated dialogue datasets.

Our contributions include: 1) A novel task of information-acquisition-oriented dialogue system; 2) A novel unsupervised learning framework which enables a teacher bot to carry out informative and coherent conversations with human users for information acquisition purpose; 3) Extensive experiments with human evaluation demonstrate the effectiveness of our proposed approach.

2 Approach

In order to obtain an informative and attentive teaching dialogue system, we propose a framework that consists of two chat bots in different roles, and leverage both supervised learning and unsupervised reinforcement learning, as illustrated in Figure 2. The unsupervised reinforcement learning enables the system to be fine-tuned on other text corpus where no annotation or dialogue data is required.

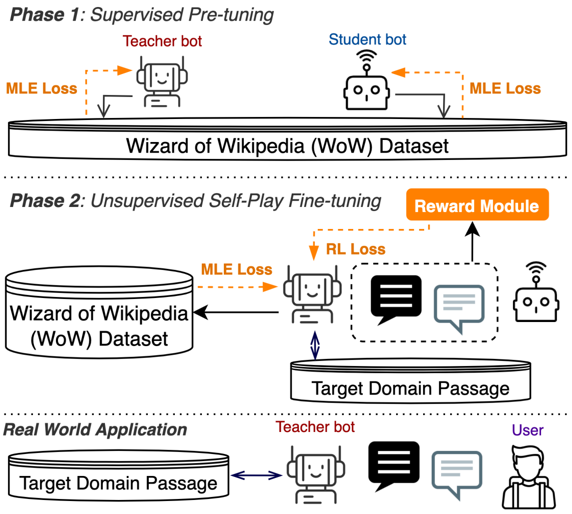

Figure 2: Our two-phase training framework

2.1 Model Architecture

Given a passage P, the conversation between Teacher bot X and Student bot Y can be denoted as a sequence of turns $C = \{U_1^X, U_1^Y, ..., U_N^X, U_N^Y\}$, where N is the number of turns in the conversation. In order to mimic our use case, Teacher bot has access to P whereas Student bot does not.

Teacher bot X aims at transmitting the information in P to the student. At the n_{th} turn, X takes as input P and the conversation history $H_n^Y = \{U_1^X, U_1^Y, ..., U_{n-1}^X, U_{n-1}^Y\}$, and outputs U_n^X. Teacher bot X adopts DoHA (Prabhumoye et al., 2021), a pre-trained model for document-grounded text generation, and is tuned in supervised phase and unsupervised self-play phase.

In order to fine-tune Teacher bot X with reinforcement learning on full conversations, as a practical approach, we train a **Student bot** Y to carry on conversations with X. Student bot Y takes the conversation history $H_n^Y = \{U_1^X, U_1^Y, ..., U_n^X\}$ as input, and output U_n^Y. It adopts BART (Lewis et al., 2020) model.

2.2 Phase 1: Supervised Pre-Tuning

This phase trains Teacher bot X to initialize and carry out conversations based on a given passage P, and trains Student bot Y to respond appropriately to X. To this end, we pre-tune both X and Y on the *Wizard of Wikipedia* (*WoW*) dataset. *WoW* was chosen as the pre-tuning dataset because of its two characteristics: 1) Open-domain: *WoW* contains conversations on a broad range of topics and domains across Wikipedia, thus the pre-tuned Teacher and Student bots have greater potentials to be successfully transferred to other domains during the fine-tuning stage; 2) Content-grounded: in *WoW*, the teaching bot's utterances are grounded on passages, which is similar to our task. We present the gold passage to Teacher bot directly, though, different from the *WoW*'s original setting (Dinan et al., 2019) where Teacher bot searches a large corpus for supporting passages.

We optimize the maximum-likelihood objective for Teacher bot by minimizing the following loss:

$$L_{mle}^{X}=-\sum_{n=1}^{N}\sum_{m=1}^{M_n} log(p(x_m|x_1,...,x_{m-1},H_n^X,P))$$

where N is the total number of turns in the conversation, $\{x_1, ..., x_{M_n}\}$ is Teacher bot's response at the n_{th} turn, M_n is the number of words in U_n^X. The loss function for Student bot, L_{mle}^Y, is similar to L_{mle}^X, with the exception of not including a passage P as input.

$$L_{mle}^{Y} = -\sum_{n=1}^{N}\sum_{m=1}^{M_n} log(p(y_m|y_1,...,y_{m-1},H_n^Y))$$

where $\{y_1, ..., y_{M_n}\}$ is Student bot's response at the n_{th} turn.

2.3 Phase 2: Unsupervised Self-Play Fine-tuning

In this phase, we aim at improving Teacher bot's ability to present informative and coherent conversations. This is achieved by reinforcement learning on Teacher bot with the help of Student bot, and could be applied in a novel target domain even where dialogue dataset is absent. We adopt a self-play approach, i.e. we let Teacher bot and Student bot chat with each other over a passage in the target domain to generate multiple turns of conversations. In this fine-tuning phase, we keep Student bot frozen, and reward Teacher bot when the generated conversation achieves higher scores. In order to reduce the variance of the gradient estimate, we apply self-critic reinforcement learning (Rennie et al., 2017). Specifically, at each turn, we let Teacher bot generate two separate utterances: 1) U^s, which is sampled from the model, i.e. $x_m^s \sim p(x|x_1^s, ..., x_{m-1}^s)$, and 2) U^*, which is obtained by greedy search, i.e. $x_m^* = \arg\max_w p(x|x_1^*, ..., x_{m-1}^*)$. We optimize the model by minimizing the following RL loss:

$$L_{rl}^{X} = -\sum_{n=1}^{N}(R(U_n^s) - R(U_n^*))\sum_{m=1}^{M_n} log(p(x_m^s |x_1^s, ..., x_{m-1}^s, H_n^X, P))$$

where $R()$ is the reward function, which we will cover in Section 2.4, and P is a passage from the target domain corpus.

If not taking into account language modeling, optimizing RL loss alone would lead Teacher bot to generate inarticulate and even grammatically incorrect utterances. To keep the fluency of Teacher bots, we optimize a combined loss L^X consisting of RL loss L_{rl}^X on the new target domain data and MLE loss L_{mle}^X on the pre-tuning dialogue dataset, so the language style acquired during the pre-tuning phase would not get lost during RL fine-tuning:

$$L^X = \gamma L_{rl}^X + (1-\gamma) L_{mle}^X$$

where $\gamma \in (0, 1)$ is a scaling factor accounting for the emphasis on L_{rl}^X and L_{mle}^X. We note that while L_{mle}^X should be obtained on an annotated content-grounded dialogue dataset (e.g. *WoW*), L_{rl}^X could be obtained on any target domain passage corpus even without dialogue data. This enables our approach to be transferred to an unsupervised text corpus.

2.4 Reward Functions

2.4.1 Coverage

We define the coverage reward of a Teacher bot's utterance U^X as:

$$R_{cov} = \textsc{Rouge}_1(P, H + U^X) - \textsc{Rouge}_1(P, H)$$

where $\text{Rouge}_1(P, H)$ is the Rouge-1 F1 (Lin, 2004) score of the conversation history H to the input passage P. Intuitively, this function favors utterances that cover more information in the passage and have less overlap with the conversation history.

2.4.2 Coherence

Dialogue coherence datasets We explore neural coherence scoring models trained on two open-domain dialogue coherence datasets:

1. *WoW-coherence dataset* We reuse the *WoW* dataset to heuristically build a dialogue coherence classification dataset. Specifically, for each multi-turn dialogue in *WoW*, we label the ground truth response to its conversation history as *coherent* response, and all later responses in the same dialogue as *incoherent* responses.

2. *InferConv dataset* (Dziri et al., 2019) This is an open-domain dialogue coherence classification dataset built from PersonaChat conversational data (Zhang et al., 2018b). The dataset casts a response as the hypothesis and the conversation history as the premise, thus convert dialogue coherence evaluation into an NLI task. The dataset classifies the relationship between the response and the conversation history into three categories: *entailed*, *neutral* and *contradict*. Table 2 summarizes statistics of these datasets.

Coherence scoring models Based on the same pre-trained model BERT (Devlin et al., 2019), we train two different coherence scoring models on the two dialogue coherence classification datasets respectively. Both models take the concatenation (with [SEP]) of the conversation history and a candidate response as input, and minimize the cross entropy loss between the predicted label and the gold label. We use different methods to attain the coherence reward R_{coh} from the two models.

For model *WoW-coherence*, we define the coherence reward with softmax:

$$R_{coh} = \frac{e^{o_c}}{e^{o_c} + e^{o_i}}$$

where o_c and o_i are the logits for *coherent* and *incoherent* labels in the output layer. For model *InferConv*, we observe some responses labeled as *neutral* are appropriate responses but are not closely related to conversation history (e.g. *"That's interesting!"*), we thus heuristically assign constant scores s_e, s_n and s_c as coherence reward R_{coh} when the response is predicted as *entailed*, *neutral* and *contradict*. In the remainder of the paper, we use *WoW-coherence* as the default coherence model, and compare it with *InferConv* in Section 4.

2.4.3 Mixed Reward

The coverage and coherence rewards are combined with a hyper-parameter β, yielding the final reward:

$$R = \beta R_{cov} + (1 - \beta) R_{coh}$$

3 Experimental Settings

We proceed by describing our datasets, comparison systems and evaluation metrics. We then show the performance of our proposed approach compared to state-of-the-art in §4.

Pre-Tuning		*WoW-Train*	*WoW-Valid*
#Utterances		166,787	17,715
#Dialogues		18,430	1,948
#Words/utterance		16.6	16.6
#Words/passage		110.3	109.8
Fine-Tuning	*Wikipedia*	*CNN-DM*	*Paper Abs.*
#Passages	50,000	50,000	22,512
#Words/passage	111.7	129.8	149.3
Test Set	*Wikipedia*	*CNN-DM*	*Paper Abs.*
#Passages	1,000	1,000	500
#Words/passage	112.7	129.9	148.1

Table 1: Datasets statistics.

3.1 Datasets

Wizard of Wikipedia (Dinan et al., 2019) contains a total of 22,311 human-human conversations crowdsourced via Amazon's Mechanical Turk. The conversations are grounded in Wikipedia passages covering a wide range of topics: *e-book*, *toga party*, *armadillo*, etc. Both Teacher and Student bots are pre-tuned on the *WoW* dataset during Phase 1. Different from *WoW*'s original setting, we present the gold passage to the Teacher bot directly, instead of searching a large corpus for supporting passages. This allows us to focus less on retrieval and more on creating a Teacher bot to deliver informative and attentive dialogues.

We consider knowledge sources of various sorts as Teacher bot's target domain during fine-tuning. CNN/DailyMail contains a large collection of online news articles with an average of 781 tokens per article (See et al., 2017). The full content of the article cannot be conveyed in a short conversation. Thus, we use the first 130 tokens of each article as a supporting passage, assuming it covers the most important content of the news article.

Academic papers have become an omnipresent source of knowledge. We create our own dataset containing papers published in recent years (2017–2021) at major venues, including ACL, EMNLP, NAACL, EACL, Findings and ICLR conferences. Similarly, we use paper abstracts as supporting passages instead of full articles. Moreover, we include Wikipedia passages from the *WoW* dataset, without conversations, as another source of knowledge. The *CNN-DM*, *Paper Abstracts* and *Wikipedia* datasets are used in Phase 2 of unsupervised self-play fine-tuning. Statistics of these datasets are summarized in Table 1.

3.2 Comparison Models

Our baseline Teacher bot builds on the state-of-the art content-grounded dialogue generation model:

WoW-Coh	*Coherent Resp.*	*Incoherent*	*All*
Train	74,092	233,142	307,234
Valid	3,939	12,362	16,301
Test	3,865	12,098	15,963

InferConv	*Entail*	*Neutral*	*Contradict*	*All*
Train	218,181	579,434	261,984	1,059,599
Valid	28,072	12,242	9,780	50,094
Test	3,119	1,087	1,360	5,566

Table 2: Details of the datasets used to train our neural coherence scoring models.

Coherence
3 TeacherBot provides coherent responses to the evaluator's input.
2 TeacherBot provides largely coherent responses (with minor coherency issues) to the evaluator's input.
1 TeacherBot does not respond properly to the evaluator's input.

Readability
3 TeacherBot's responses are easy to read, containing no grammatical or semantic errors.
2 TeacherBot's responses read smoothly but may contain 1-2 grammatical or semantic errors.
1 TeacherBot's responses contain >2 grammatical or semantic errors, or are nonsensical.

Overall Quality
An initial score of 3 is given to a dialogue, then 1 point is deducted for each of the following issues, with a minimum score of 0.

- Uninformative, i.e. it provides <2 correct answers during QA.
- Incoherent, i.e. the average coherence score is <2 points.
- Low readability, i.e. the average readability score is <2.5 points.
- Any other issues that could lead to an ineffective conversation e.g. words are repeated between turns.

Table 3: A scoring rubric provided to human evaluators.

DoHA (Prabhumoye et al., 2021). It includes two improvements to the architectures of pre-trained encoder-decoder models (Lewis et al., 2020): building context-driven representation of the supporting document, and enabling document-headed attention to acquire information from the document. DoHA has demonstrated strong performance in document-grounded generation. All DoHA models are pre-tuned on the *WoW* dataset.

Our Full Teacher bot is created to converse in an informative and coherent manner. It extends DoHA by incorporating both coverage and coherence rewards in unsupervised self-play fine-tuning. Additionally, we ablate Full model by removing each of the two rewards: +Cov uses only the coverage reward for fine-tuning, i.e. setting $\beta = 1$ in our reward function (§2.4). +Coh utilizes only the *WoW-coherence* reward, i.e. setting $\beta = 0$. Please refer to appendix for more implementation details and hyper-parameters.

3.3 Evaluation Metrics

We investigate a wide range of metrics to evaluate Teacher bot's performance. *Objective metrics* measure the content coverage and coherence of Teacher bot's utterances. *Subjective metrics*, devised with human-in-the-loop, provide a holistic evaluation of a conversation, focusing on its overall effectiveness and various aspects of linguistic quality.

Objective Metrics. Teacher bot converses with Student bot over a passage for three turns. That is, Teacher bot initiates the dialogue and provides two responses to Student bot. We objectively evaluate Teacher bot's utterances in terms of information coverage and coherence as follows.

- Rouge (Lin, 2004) is one of the most widely used metrics for measuring information coverage. We consider three variants in this study: R-1, R-2 and R-L, which respectively measure the overlap of unigrams, bigrams and the longest common subsequence between the given passage and Teacher bot's utterances.
- QA_{F1} and QA_{CONF} are two variants of SummaQA (Scialom et al., 2019), a question answering-based evaluation metric. If a conversation is rich in information, it could be used as a surrogate for the passage to answering important questions. To this end, SummaQA generates Cloze-style questions from a passage by masking out entities, then employs a QA system to answer those questions based on a conversation. A higher QA performance suggests the conversation has better coverage. Particularly, QA_{F1} reports the F1 score for question answering; QA_{CONF} measures the confidence of the QA system in predicting answers.
- *WoW-Coherence* and *InferConv* are neural coherence scoring models (§2.4.2) repurposed for evaluation. These models quantitatively assess if Teacher bot has produced a coherent response given the conversation history, or not.
- DPR_{RELV} provides a new perspective on dialogue coherence evaluation (Zhang et al., 2018a). It draws on the Dense Passage Retriever model (DPR; Karpukhin et al., 2020) to predict if a Teacher bot's response is relevant to Student bot's input. A higher relevance score means the input and response share the same topic, suggesting a coherent conversation.

Subjective Metrics. We recruit 24 human evaluators to interact with Teacher bots. Each evaluator is asked to converse with bots over four passages. For each passage, the evaluator chats with four different Teacher bots for three turns, where Teacher bot initiates the conversation and responds twice to the evaluator's input. We randomly select 48 passages for evaluation, i.e., 16 passages from each of the three test sets. To evaluate conversations produced from *Paper Abstracts*, we require evaluators, 8 in total, to be either PhD students or have

Dataset	Model	Coverage Metrics					Coherence Metrics			Subjective Metrics				Avg Len
		R-1	R-2	R-L	QA$_{\text{CONF}}$	QA$_{\text{F1}}$	WoW-Coh	InferConv	DPR$_{\text{RELV}}$	QA$_{\text{HUMAN}}$	Coh	Read	Overall

Table 4: We compare Teacher bots based on naive DoHA(Prabhumoye et al., 2021) model to variants fine-tuned using different reward functions, Avg len refers to average utterance length.

obtained a PhD degree. For fair comparison, we shuffle and hide the order of Teacher bots presented to evaluators. Human evaluators were suggested to feed the same or similar inputs across Teacher bots on the same passage whenever possible. Throughout the conversation, the passage was not shown to the evaluators. After the conversation, human evaluators were asked to complete the following evaluation tasks:

- QA_{HUMAN}: Five sentences are randomly selected from each passage and one important entity is masked out in each sentence. The evaluators are presented with each corrupted sentence and asked if the sentence could be recovered by referencing the conversation with Teacher bot. We report the ratio of sentences that could be correctly recovered.
- *Linguistic Quality*: We ask human evaluators to rate each conversation along three dimensions: *Coherence*: Does Teacher bot provide coherent responses to the evaluator's input? *Readability*: Are Teacher bot's utterances easy to read, containing no grammatical or semantic errors? *Overall Quality*: How will the conversation score in terms of informativeness, coherence, readability and all aspects considered? The scoring rubric provided to human evaluators is shown in Table 3.

4 Objective Results

Results on Test Sets. Table 4 presents objective evaluation results obtained for various Teacher bots on three test sets: *CNN-DM*, *Paper Abstracts* and *Wikipedia*. We observe that our FULL Teacher bot is able to substantially outperform the baseline system DOHA on all datasets and across all objective metrics. It strikes a fine balance between delivering information-rich conversations and ensuring those conversations are coherent and attentive. Further, we find that optimizing a single reward, whether it be coverage or coherence, produces suboptimal results. For instance, +COV tends to produce longer utterances than other variants. It improves information coverage, but yields low coherence scores, leading to a performance even inferior to the baseline DOHA. Our findings suggest that it is important for the reinforcer L_{rl}^{X} to learn with both coverage or coherence rewards.

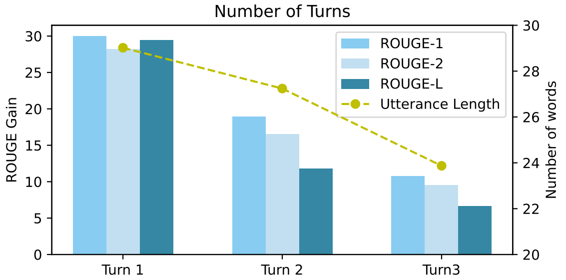

Figure 3: ROUGE gain and utterance length tend to decrease as the number of turns increases

Trading off Coverage for Coherence. In Figure 4, we plot the learning curves of coverage and coherence scores when the reinforcer adopts a single reward (+COV, +COH) or both (FULL). We use R_{cov} and R_{coh} to approximate coverage and coherence scores. These plots are generated using 50 validation instances from the *Paper Abstracts* dataset. We observe that with only the coverage reward (+COV), Teacher bot tends to aggressively copy content from the passage, while disregarding the conversation history. This inevitably leads to incoherent conversations. Conversely, +COH can improve on coherence, but falls short on delivering informative conversations. Finally, our FULL Teacher bot trades off coverage for substantially higher coherence, thus achieving a significant improvement over the baseline DOHA model.

Trading off Coverage for Coherence. We are curious to know the amount of information brought by each utterance produced by Teacher bot. To this end, we define information gain $\mathcal{IG}(\cdot)$ as the

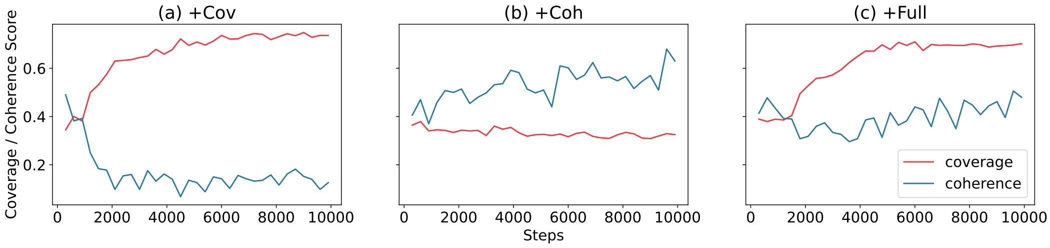

Figure 4: Coverage and coherence scores when applying different reward scores

Dataset	Model	Coverage		Coherence		
		QA_{CONF}	QA_{F1}	WoW-Coh	IC	DPR
Wikipedia	*WoW*	18.96	17.17	**0.807**	**0.694**	**0.578**
	InferCov	20.41	19.61	0.647	0.676	0.561
CNN-DM	*WoW*	13.31	11.31	**0.845**	0.692	**0.561**
	InferCov	14.95	14.07	0.719	**0.728**	0.550
Papers	*WoW*	8.18	3.95	**0.806**	0.547	**0.576**
	InferCov	9.47	4.31	0.737	**0.554**	0.558

Table 5: Teacher bot's performance when using different coherence score models during fine-tuning

improvement of ROUGE scores brought by an utterance U:

$$\mathcal{IG}(U) = \textsc{Rouge}(P, H + U) - \textsc{Rouge}(P, H),$$

where P is the supporting passage, and H represents the conversation history. We consider three ROUGE variants, R-1, R-2 and R-L, respectively. Figure 3 illustrates the gain of information for each of the three turns. The average ROUGE gain is reported for each turn, using conversations produced for the *Paper Abstracts* dataset. We observe that there is a general tendency across turns that information gain is decreasing. This is in part because that at the beginning of a conversation, Teacher bot has no constraints regarding content selection, it could rephrase any content selected from the supporting passage to initiate a dialogue. In subsequent turns, Teacher bot has to exercise caution in response generation considering both the conversation history and overall coherence of the conversation. Consequently, we find that the average length of the utterances also decreases in subsequent turns.

A Comparison of Coherence Scoring Models. We compare two Teacher bots fine-tuned only with coherence reward from different coherence scoring models (i.e. *WoW-coherence* and *InferConv*). We demonstrate their objective results in Table 5. According to the results, Teacher bot fine-tuned with *InferConv* achieves slightly better coverage metrics. However, in terms of coherence metrics, Teacher bot fine-tuned with *WoW-coherence* model generally achieves better performance. Based on this observation, *WoW-coherence* scoring model better measures coherence in conversations.

5 Subjective Results

We demonstrate the subjective evaluation results in Table 4 and have the following observations:

1. For question answering, +COV achieves the best performance on all three datasets. This again proves that the coverage reward helps make the conversation more informative;

2. For coherence scores, +COH achieves the best performance on *Wikipedia*. However, on the other two datasets it was outperformed by FULL.

3. For readability scores, on *CNN-DM* and *Paper Abstracts*, +COH achieves the lowest performance while +COV achieves the highest.

4. For overall scores, FULL demonstrates the best performance. This suggests FULL delivers conversations that are more balanced in coverage, coherence and readability.

5. The *Paper Abstracts* corpus is the most challenging among all the test corpora, as our Teacher bots generally show worse performance in coherence, readability and overall scores. We found passages in *Paper Abstracts* contain volumes of professional vocabularies thus are more complicated for people to understand. In addition, it's also more difficult for Student bot to respond appropriately during self-play fine-tuning (See examples in appendix). As a result, transferring Teacher bots to this domain is more challenging.

A Case Study. We show a few Teacher bots' responses to users in Table 6. After analyzing the cases, we have the following observations:

1. The coverage reward encourages Teacher bots to directly copy content from the input passage,

Example A (Passage from *Wikipedia*)	
Passage	The Concorde is a British–French turbojet-powered supersonic passenger airliner ... It had a maximum speed over twice the speed of sound, at Mach 2.04, ... First flown in 1969, Concorde entered service in 1976 and operated for 27 years. ...
User	What is the plane famous for?
Bot Cov	First flown in 1969, Concorde entered service in 1976 and operated for 27 years.
Bot Coh	Concorde is famous for the speed of sound at Mach 2.04.
Bot Full	Concorde is famous for having a maximum speed over twice the speed of sound, at Mach 2.04.
Example B (Passage from *CNN News*)	
Passage	The US Food and Drug Administration, ... Molnupiravir is for the treatment of mild-to-moderate coronavirus disease in adults with positive results of direct SARS-CoV-2 viral testing ... This is the second Covid-19 antiviral pill authorized for ill people to take at home, before they get sick enough to be hospitalized ...
User	Tell me more about the drug.
Bot Cov	This is the second Covid-19 antiviral pill authorized for ill people to take at home, before they get sick enough to be hospitalized.
Bot Coh	The drug is for people with mild to moderate coronavirus disease.
Bot Full	Molnupiravir is for the treatment of mild-to moderate coronavirus disease in adults with positive results of direct SARS-CoV-2 viral testing.
Example C (Passage from *Paper Abstracts*)	
Passage	... In this paper we describe a novel framework to guide a supervised, extractive summarization system with question-answering rewards ... Our results compare favorably with those reported by strong summarization baselines as evaluated by automatic metrics and human assessors ...
User	What did you propose?
Bot Cov	Our results compare favorably with those reported by strong summarization baselines as evaluated by automatic metrics and human assessors.
Bot Coh	A proposal to use the extractive summarizer to answer questions.
Bot Full	We propose a novel framework to guide a supervised, extractive summarization system with question-answering rewards.

Table 6: A few example responses from different Teacher bots. In example A,+COH and FULL abstractively generates *Concord is famous for ...* to make the response more coherent to user's question. However, the underlined part in +COH's statement misrepresent the input passage and is inaccurate. In example B, all responses seem coherent because of the open-ended question.

while the coherence reward encourages abstractively generating new content: As shown in Example A, +COV directly extracts a part of the original passage as response, regardless of the user's question, while +COH and FULL abstractively rewrite the response to make it more coherent.

2. Putting too much weight on coherence reward could make Teacher bot become so abstractive that it misrepresents the original passage and lead to incoherence and semantic/grammar errors. (See +COH's response in example A and C) This explains +COH's low coherence and readability scores on *CNN-DM* and *Paper Abstracts*. This observation suggests the necessity to carefully choose the weight for coherence rewards, and to coupling coherence reward with coverage reward, which could make the chat bot less abstractive.

3. Generally, user utterances could be classified into two categories: **Information-seeking queries** which request certain information (e.g. the user's utterance in example A); **Open statements** which do not have specific requests (e.g. the user's utterance in example B). We found evaluators tend to give high coherence scores to response to open statements, as they could be addressed by a wider range of responses.

6 Related Work

Content-Grounded Dialogue Generation Content grounded dialogue generation is the task of using the information provided in external content (e.g. a passage, etc.) to guide dialogue generation. Compared to previous research, our task has the following novelties. 1) Compared to content-grounded information-retrieval-oriented dialogue such as doc2dial (Feng et al., 2020) and ABCD (Chen et al., 2021) where the chat bot responds to user query in a passive way, we expect our chat bots to convey knowledge proactively. 2) Compared to chit chat-oriented dialogue such as (Zhou et al., 2018; Dinan et al., 2019; Komeili et al., 2021; Xu et al., 2021), our task is more focused on extensive conversation in a particular topic, and aims at helping the end user acquire knowledge or information from a given passage. 3) Contrasted to chat bots that are applied in a single domain (Zhou et al., 2018; Moghe et al., 2018; Xu et al., 2019), our chat bot could be transferred to other domains through self-talk based fine-tuning.

Another line of research works focus on content grounded text generation models (Prabhumoye et al., 2021; Zhao et al., 2020). Compared with ordinary text generation models (e.g. BART (Lewis et al., 2020)), these models are specifically designed to model external content as an additional input, and achieve better performance on content grounded dialogue generation tasks including *CMU DoG* (Zhao et al., 2020) and *Wizard of Wikipedia* (Dinan et al., 2019).

RL in Text Generation Reinforcement learning has been applied in various natural language generation tasks, including image caption (Rennie et al., 2017), automatic summarization (Paulus et al., 2018), machine translation (Kang et al., 2020) and poem generation (Yang et al., 2019). Specifically, when applying reinforcement learning in dialogue generation (Li et al., 2016; Zhao et al., 2019; Shi et al., 2019; Yamazaki and Aizawa, 2021; Liu et al., 2020), self-play is often used to enable scoring multi-turn dialogues. Compared to previous dialogue generation research using RL and self-play, our two-phase framework enables transferring the teacher bot to other domains by optimizing a mixed reward of coverage and coherence.

Educational Dialogue Systems and Conversational QA There have been research works applying dialogue systems for educational purposes. Some chat bots are for language practice. (Ruan et al., 2021; Stewart and File, 2007; Huang et al., 2017) Others are specially designed for education in a single domain or task, e.g. moral education (Peng et al., 2019), educational debate (Yuan et al., 2008). Compared with previous educational dialogue systems, our system is for information acquisition without domain restriction. Our task is also related to conversational question answering (CQA), e.g. (Kočiský et al., 2018; Rajpurkar et al., 2016; Joshi et al., 2017; Zellers et al., 2018). However, most existing CQA systems passively response to user queries in single turn conversations, while our system actively engage with users in multi-turn conversations.

7 Conclusion

We propose an information-acquisition-oriented dialogue system that transfers information and knowledge in passages to users through conversations. An unsupervised self-talk approach is introduced leveraging novel rewards to enable Teacher bots to deliver informative and attentive conversations. Experiments with automatic and human evaluations demonstrate the effectiveness of our approach. Some interesting future directions include extending the conversations to be based on a set of documents and specializing our dialogue systems for in specific domain, e.g. patient education.

8 Ethical Considerations

Our models are pre-tuned on *Wizard of Wikipedia* dataset and fine-tuned on three corpora: *Wikipedia*, *CNN-DailyMail* and *Paper-Abstracts* (Abstracts of papers from ACL, EMNLP, NAACL, EACL, Findings and ICLR submissions from 2017 to 2021). All the datasets used in this paper are publicly available. Moreover, we did not use full-length Wikipedia or CNN-Daily Mail news articles in our experiments, but tailored versions of 100-150 words. This is because a full length Wikipedia/CNN-Daily Mail article may contain too much content to be covered in a short conversation.

As described in (Maynez et al., 2020; Kryscinski et al., 2020; Lebanoff et al., 2020; Zhou et al., 2021), current state of the art neural conditional text models can output hallucinated content unfaithfully to the input text, which impedes the safe deployment of the models. We note that our Teacher bots may also generate utterances that are not supported by the input passage.

9 Appendix

9.1 Implementation Details

9.1.1 Pre-tuning

Key hyper-parameters for both models.

- source max len: 1024
- target max len: 128
- batch size: 8
- train epoch: 3
- learning rate: 2e-5
- Both Teacher and Student bots adopt the initialized weights of bart-base from huggingface.
- Both DoHA models and BART models are based on the implementation presented in the DoHA paper (Prabhumoye et al., 2021).

Note we initialize our models with bart-base instead of bart-large as our self-play fine-tuning is very computational intensive and time consuming. With our current setting, the self-play fine-tuning takes about 2.5 days on one single NVIDIA Tesla V100 GPU.

9.1.2 Self-Play Reinforced Fine-Tuning

Mixed Loss. Optimizing our mixed loss is achieved by intermittently minimizing the MLE loss for a a batches and then minimizing the RL loss for b batches. In other word, the parameter γ in Section 2.3 is determined by a and b. Specifically, in each fine-tuning step, the parameters of Teacher bot are updated for 4 times, once over an RL batch, 3 times over MLE batches.

Key Hyper-Parameters. We apply the same set of basic hyper-parameters for all Teacher bots during all fine-tuning process:

- MLE batch size: 8
- RL batch size: 5
- maximum coverage score: 0.5
- train epoch: 3
- learning rate: 1e-6
- Fine-tuning steps: 10,000
- β for three reinforced Teacher bots: FULL-$\beta = 0.7$, +COV-$\beta = 1.0$, +COH-$\beta = 0.0$

9.2 Coherence Scoring Models

Both *WoW-coherence* and *InferConv* are trained based on bert-base-cased.

Key hyper-parameters for both models.

- max length: 256
- batch size: 32
- learning rate 2e-5
- epochs 3

For *InferConv* classification model, the constant scores are $s_e = 1.0$, $s_n = 0.2$ and $s_c = 0.0$

The *WoW-coherence* and *InferConv* classification model achieves 82.1% and 88.4% accuracy on respective test sets.

All other hyper-parameter settings for Teacher bot, Student bot and coherence scoring models are based on the system's default setting. All our experiments were run on servers with Nvidia A100 and V100 GPUs.

9.3 Dataset Details

The passages in train/validation/test set of our *Wikipedia* corpus are randomly sampled from passages in train/validation/test set of *WoW* respectively. Similarly, passages in train/validation/test set of our *CNN-DM* corpus are randomly sampled from the train/validation/test set of the original *CNN-DM* dataset. For *Paper Abstracts*, we randomly distribute all collected paper abstracts into train/validation/test sets.

9.4 Rewards function Details

During our exploration, we have explored multiple variations of coverage reward functions:

1. Reward score is gained at the end of each turn of conversation, and it is calculated the ROUGE score improvement of the teacher bot's utterance (As we applied in the paper);

2. Reward score is gained at the end of each turn of conversation, and it is calculated the ROUGE score improvement of both the teacher bot and student bot's utterances;

3. Reward score is gained at the end of the entire conversation, and is calculated as the ROUGE score improvement of all teacher bot's utterances.

According to our experience, the performance of 1 is similar than 2. Specifically, we notice in most cases, our student bot contribute marginally in terms of ROUGE score improvement. In addition, in practice, we observe 1 shows better performance than 3.

9.5 Human Evaluation Details

All human evaluation passages are collected randomly, the length of the *Wikipedia* and *CNN* passages are tailored to 100-150 words to conform to the length of passages in the fine-tuning stage. During conversations, we suggest our evaluators to use utterances relevant to the topic, so that their utterances could be appropriately addressed by Teacher bots referencing content in the passage. All human evaluators we recruit have at least a bachelor degree, each evaluator is rewarded with a $20 gift card for participation.

The evaluation results are collected using Google Colab, an example evaluation page is available through this link (Personal information are anonymized during reviewing stage).

Note that in our human evaluation, Teacher bot chat about a passage with two evaluators. We use Pearson correlation coefficient to measure Inter-annotator agreement, the average Pearson correlation coefficient among each pair of evaluators is 0.16, implying weakly positive correlation. We note different evaluators use different utterances to chat with the same Teacher bot, thus it is reasonable that the conversation with the same Teacher bot over the same passage have large variance.

9.6 Examples

We provide more examples of conversations in self-play in Table 7 and human evaluations in Table 8.

	Example D (Passage from *Wikipedia*)
Passage	For 4,000 years China has been a nation of farmers. By the time the People's Republic of China was established in 1949, virtually all arable land was under cultivation; irrigation and drainage systems constructed centuries earlier and intensive farming practices already produced relatively high yields. But little prime virgin land was available to support population growth and economic development. However, after a decline in production as a result of the Great Leap Forward (1958–60), agricultural reforms implemented in the 1980s increased yields and promised even greater future production from existing cultivated land.
Dialogue	**[Teacher bot]:** China has been a nation of farmers for 4,000 years! **[Student bot]:** Wow, that's a long time. What do they grow? **[Teacher bot]:** They grow a variety of crops, including chicken, fish, fruits, and vegetables. **[Student bot]:** That sounds like a lot of food. What else can you tell me about China? **[Teacher bot]:** Well, by the time the People's Republic of China was established in 1949, virtually all arable land was under cultivation.
	Example E (Passage from *CNN-DailyMail*)
Passage	Everywhere you look there are two-wheeled drivers waiting ominously for passengers to hop on board. They're the backbone of public transport in Uganda and the fastest way to get around the capital city, Kampala. The boda boda motorbike taxi is a staple used by all sectors of society. Traditionally, the usual way of catching a ride was to venture into any street corner packed with tens of boda bodas or simply waiting for one to pass by. But now, a new local startup are bringing this classic mode of transport into the technological age by providing the ability to hail a boda boda at the click of a smartphone. "Bodas are the main thing getting people from A to B," says Alastair Sussock, co-founder of SafeBoda ...
Dialogue	**[Teacher bot]:** Ugandan start-up SafeBoda are bringing this classic mode of transport into the technological age by providing the ability to hail a boda boda at the click of a smartphone. **[Student bot]:** I've never heard of them. What are they? **[Teacher bot]:** They are the backbone of public transport in Uganda and the fastest way to get around the capital city, Kampala. **[Student bot]:** That's really cool. How long have they been around? **[Teacher bot]:** Well they have been around for a long time. Traditionally, the usual way of catching a ride was to venture into any street corner packed with tens of boda bodas or simply waiting for one to pass by.
	Example F (Passage from *Paper Abstracts*)
Passage	Existing open-domain question answering (QA) models are not suitable for real-time usage because they need to process several long documents on-demand for every input query, which is computationally prohibitive. In this paper, we introduce query-agnostic indexable representations of document phrases that can drastically speed up open-domain QA. In particular, our dense-sparse phrase encoding effectively captures syntactic, semantic, and lexical information of the phrases and eliminates the pipeline filtering of context documents. Leveraging strategies for optimizing training and inference time, our model can be trained and deployed even in a single 4-GPU server. Moreover, by representing phrases as pointers to their start and end tokens, our model indexes phrases in the entire English Wikipedia (up to 60 billion phrases) using under 2TB. Our experiments on SQuAD-Open show that our model is on par with or more accurate than previous models with 6000x reduced computational cost, which translates into at least 68x faster end-to-end inference benchmark on CPUs ...
Dialogue	**[Teacher bot]:** We introduce query-agnostic indexable representations of document phrases that can drastically speed up open-domain QA. **[Student bot]:** What is QA? **[Teacher bot]:** It is a process where our dense-sparse phrase encoding effectively captures syntactic, semantic, and lexical information of the phrases and eliminates the pipeline filtering of context documents. **[Student bot]:** What are the basic concepts of QA? **[Teacher bot]:** Well the basic concepts are that we represent phrases as pointers to their start and end tokens, our model indexes phrases in the entire English Wikipedia (up to 60 billion phrases) using under 2TB.

Table 7: Conversation examples of Teacher bot fine-tuned with both rewards chat with Student bot during self-play. Example F demonstrates an example where Student bot's question seems too broad to be responded using content in the passage.

Example G (Passage from *Wikipedia*)	
Passage	Interstellar is a 2014 epic science fiction film co-written, directed and produced by Christopher Nolan. It stars Matthew McConaughey, Anne Hathaway, Jessica Chastain, Bill Irwin, Ellen Burstyn, and Michael Caine. Set in a dystopian future where humanity is struggling to survive, the film follows a group of astronauts who travel through a wormhole near Saturn in search of a new home for mankind. Paramount Pictures, Warner Bros. Pictures, and Legendary Pictures co-financed the film. Cinematographer Hoyte van Hoytema shot it on 35 mm in the Panavision anamorphic format and IMAX 70 mm. Interstellar uses extensive practical and miniature effects and the company Double Negative created additional digital effects. Interstellar premiered on October 26, 2014, in Los Angeles, California. In the United States, it was first released on film stock, expanding to venues using digital projectors. The film had a worldwide gross of over $677 million (and $701 million with subsequent re-releases), making it the tenth-highest-grossing film of 2014.
Dialogue	**[Teacher bot]:** Interstellar is a 2014 epic science fiction film directed and produced by Christopher Nolan. **[Human user]:** Who stars in the film? **[Teacher bot]:** The film stars Matthew McConaughey, Anne Hathaway, Jessica Chastain, Bill Irwin, Ellen Burstyn, and Michael Caine. **[Human user]:** What story does it tell? **[Teacher bot]:** The film follows a group of astronauts who travel through a wormhole near Saturn.
Example H (Passage from *CNN News*)	
Passage	The US Food and Drug Administration on Monday granted full approval to the Pfizer/BioNTech Covid-19 vaccine for people age 16 and older. Dialogue	**[Teacher bot]:** The Pfizer/BioNTech vaccine has been authorized for emergency use in the United States since mid-December for people age 16 and older. **[Human user]:** Give me more details. **[Teacher bot]:** This is the first coronavirus vaccine approved by the FDA, and is expected to open the door to more vaccine mandates. **[Human user]:** So, what will happen next? **[Teacher bot]:** The Pfizer/BioNTech Covid-19 vaccine for people age 16 and older will be marketed as Comirnaty, the FDA said in its announcement on Monday.
Example I (Passage from *Paper Abstracts*)	
Passage	We introduce a new language representation model called BERT, which stands for Bidirectional Encoder Representations from Transformers. Unlike recent language representation models, BERT is designed to pre-train deep bidirectional representations from unlabeled text by jointly conditioning on both left and right context in all layers. As a result, the pre-trained BERT model can be fine-tuned with just one additional output layer to create state-of-the-art models for a wide range of tasks, such as question answering and language inference, without substantial task-specific architecture modifications. BERT is conceptually simple and empirically powerful. It obtains new state-of-the-art results on eleven natural language processing tasks, including pushing the GLUE score to 80.5% (7.7% point absolute improvement), MultiNLI accuracy to 86.7% (4.6% absolute improvement), SQuAD v1.1 question answering Test F1 to 93.2 (1.5 point absolute improvement) and SQuAD v2.0 Test F1 to 83.1 (5.1 point absolute improvement).
Dialogue	**[Teacher bot]:** We introduce BERT, which stands for Bidirectional Encoder Representations from Transformers. **[Human user]:** What did you propose? **[Teacher bot]:** A new language representation model called BERT which is conceptually simple and empirically powerful. **[Human user]:** How is the result? **[Teacher bot]:** The pre-trained BERT model can be fine-tuned with just one additional additional output layer to create state-of-the-art models for a wide range of tasks, such as question answering and language inference, without substantial task-specific architecture modifications.

Table 8: Conversation examples of Teacher bot fine-tuned with both rewards chat with human evaluators.

Dynamic Programming in Rank Space: Scaling Structured Inference with Low-Rank HMMs and PCFGs

Songlin Yang*, **Wei Liu***, **Kewei Tu**†

Shanghai Engineering Research Center of Intelligent Vision and Imaging
`{yangsl,liuwei4,tukw}@shanghaitech.edu.cn`

Abstract

Hidden Markov Models (HMMs) and Probabilistic Context-Free Grammars (PCFGs) are widely used structured models, both of which can be represented as factor graph grammars (FGGs), a powerful formalism capable of describing a wide range of models. Recent research found it beneficial to use large state spaces for HMMs and PCFGs. However, inference with large state spaces is computationally demanding, especially for PCFGs. To tackle this challenge, we leverage tensor rank decomposition (aka. CPD) to decrease inference computational complexities for a subset of FGGs subsuming HMMs and PCFGs. We apply CPD on the factors of an FGG and then construct a new FGG defined in the rank space. Inference with the new FGG produces the same result but has a lower time complexity when the rank size is smaller than the state size. We conduct experiments on HMM language modeling and unsupervised PCFG parsing, showing better performance than previous work. Our code is publicly available at `https://github.com/VPeterV/RankSpace-Models`.

1 Introduction

Hidden Markov Models (HMMs) and Probabilistic Context-Free Grammars (PCFGs) are widely used structured models in natural language processing. They can both be represented as factor graph grammars (FGGs) (Chiang and Riley, 2020), which are a powerful tool to describe a wide range of models, allowing exact and tractable inference in most situations of interest.

Over-parameterization has been shown beneficial in facilitating optimization of deep networks (Arora et al., 2018; Xu et al., 2018; Du et al., 2019). Buhai et al. (2020) found that over-parameterization is also helpful in learning latent variable models by increasing the number of hidden states. Buhai et al. (2020) argued that it is important to study over-parameterization in structured settings because structured latent variable models are more suitable to model real-word phenomena which exhibit complex dependencies. HMMs and PCFGs are typical structured latent variable models, and recently researchers have found it beneficial to use large state spaces for HMMs and PCFGs (Dedieu et al., 2019; Chiu and Rush, 2020; Yang et al., 2021b; Chiu et al., 2021). However, structured inference with large state spaces is computationally demanding, especially for PCFGs, pushing researchers to develop methods to decrease the computational complexities. Chiu and Rush (2020) propose a neural VL-HMM with 2^{15} states for language modeling, narrowing down the performance gap between HMMs and LSTMs. They follow Dedieu et al. (2019) to impose a strong sparsity constraint (i.e., each hidden state can only generate a small subset of terminal symbols) to decrease the time complexity of the forward algorithm, thus requiring pre-clustering of terminal symbols. Yang et al. (2021b) use a large state space for neural PCFG induction and achieve superior unsupervised constituency parsing performance. They follow Cohen et al. (2013) to use tensor rank decomposition (aka. canonical-polyadic decomposition (CPD) (Rabanser et al., 2017)) to decrease the computational complexity of the inside algorithm, but only scale the state size from tens to hundreds because the resulting complexity is still high. Chiu et al. (2021) use tensor matricization and low-rank matrix decomposition to accelerate structured inference on chain and tree structure models. However, their method has an even higher complexity than Yang et al. (2021b) on PCFGs. Recently, Fu and Lapata (2021) propose a family of randomized dynamic programming algorithms to scale structured models to tens of thousands of states, which is orthogonal to the aforementioned low-rank-based

---

[*] Equal contributions: Songlin Yang formulated the idea and Wei Liu conducted the experiments. † Corresponding author.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4797 - 4809
July 10-15, 2022

approaches as the former performs approximate inference whereas the latter perform exact inference.

In this work, we propose a new low-rank-based approach to scale structured inference, which can be described by FGG notations intuitively. We first provide an intuitive and unifying perspective toward the work of Yang et al. (2021b) and Chiu et al. (2021), showing that their low-rank decomposition-based models can be viewed as decomposing large factors in an FGG—e.g., the binary rule probability tensor in PCFGs— into several smaller factors connected by new "rank" nodes. Then we target at a subset of FGGs—which we refer to as B-FGGs—subsuming all models considered by Chiu et al. (2021), whereby the inference algorithms can be formulated via B-graphs (Gallo et al., 1993; Klein and Manning, 2001). We propose a novel framework to support a family of inference algorithms in the rank space for B-FGGs. Within the framework, we apply CPD on the factors of a B-FGG and then construct a new B-FGG defined in the rank space by marginalizing all the state nodes. Inference with the new B-FGG has the same result and a lower time complexity if the rank size is smaller than the state size.

We conduct experiments in unsupervised PCFG parsing and HMM language modeling. For PCFG induction, we manage to use 20 times more hidden states than Yang et al. (2021b), obtaining much better unsupervised parsing performance. For HMM language modeling, we achieve lower perplexity and lower inference complexity than Chiu et al. (2021).

2 Background

2.1 Factor graph grammar

Factor graphs are fixed-sized and thus incapable of modeling substructures that repeat a variable number of times. Chiang and Riley (2020) propose factor graph grammars (FGGs) to overcome this limitation, which are expressive enough to subsume HMMs and PCFGs. The main purpose of introducing FGGs in this work is to facilitate more intuitive presentation of our method, and to enable generalization beyond HMMs and PCFGs.

2.1.1 Basics

We display necessary notations and concepts of FGGs (Chiang and Riley, 2020, Def. 1,2,5,6,8).

Definition 1. A hypergraph is a tuple $(V, E, att, lab^V, lab^E)$ where

- V and E are finite set of nodes and hyperedges.
- $att : E \to V^\star$ maps each hyperedge to zero or more (not necessarily distinct) endpoint nodes.
- $lab^V : V \to L^V$ assigns labels to nodes.
- $lab^E : E \to L^E$ assigns labels to edges.

Definition 2. A factor graph is a hypergraph with mappings Ω and F where

- Ω maps node labels to sets of possible values. $\Omega(v) \triangleq \Omega(lab^V(v))$.
- F maps edge labels to functions. $F(e) \triangleq F(lab^E(e))$ is of type $\Omega(v_1) \times \cdots \times \Omega(v_k)$ where $att(e) = v_1 \cdots v_k$.

In the terminology of factor graphs, a node v with its domain $\Omega(v)$ is a *variable*, and an hyperedge e with $F(e)$ is a *factor*. We typically use $\mathbf{T}, \mathbf{N}, \mathbf{O}$ to denote hidden state, nonterminal state and observation variables for HMMs and PCFGs.

Definition 3. A hypergraph fragment is a tuple $(V, E, att, lab^V, lab^E, ext)$ where

- $(V, E, att, lab^V, lab^E)$ is a hypergraph.
- $ext \in V^\star$ is a set of zero or more external nodes and each of which can be seen as a connecting point of this hypergraph fragment with another fragment.

Definition 4. A hyperedge replacement graph grammar (HRG) (Drewes et al., 1997) is a tuple (N, T, P, S) where

- $N, T \subset L^E$ is finite set of nonterminal and terminal symbols. $N \cap T = \emptyset$.
- P is a finite set of rules $(X \to R)$ where $X \in N$ and R is a hypergraph fragment with edge labels in $N \cup T$[1].
- $S \in N$ is the start symbol.

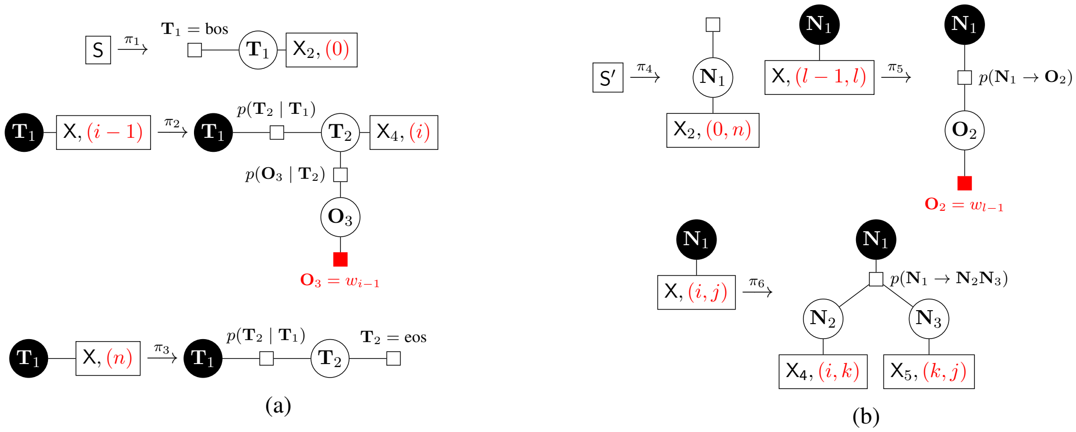
Definition 5. A HRG with mapping Ω, F (Def. 2) is referred to as an FGG. In particular, F is defined on terminal edge labels T only.

Notations.

- Ⓝ : variable node. 🅝 : external node.
- ○—$\boxed{\mathbf{X_e}}$: hyperedge e with label $X \in N$. ○ indicates zero or more endpoint nodes.

---

[1] Note that, for the lhs of P, Chiang and Riley (2020) also draw their endpoint nodes using external node notations. We follow this practice.



(a)

(b)

Figure 1: FGG representations of (a) HMMs and (b) PCFGs. Examples come from Chiang and Riley (2020).

- $F(e)$  : factor $F(e)$.

Fig. 1 illustrates HGG representations of HMM and PCFG.

Generative story. An FGG starts with $\boxed{\mathbf{S}}$, repeatedly selects $-\boxed{\mathbf{X_e}}$ and uses rule $X \to R$ from P to replace e with R, until no $-\boxed{\mathbf{X_e}}$ exists.

2.1.2 Conjunction

The conjunction operation (Chiang and Riley, 2020, Sec. 4) allows modularizing an FGG into two parts, one defining the model and the other defining a query. In this paper, we only consider querying the observed sentence $w_0, \cdots, w_{n-1}$, which is exemplified by the red part of Fig. 1. We sometimes omit the red part without further elaboration.

2.1.3 Inference

Denote ξ as an assignment of all variables, Ξ_D as the set of all assignments of factor graph D, and $\mathcal{D}(G)$ as the set of all derivations of an FGG G, i.e., all factor graphs generated by G. an FGG G assigns a score $w_G(D, \xi)$ to each $D \in \mathcal{D}(G)$ along with each $\xi \in \Xi_D$. A factor graph $D \in \mathcal{D}(G)$ assigns a score $w_D(\xi)$ to each $\xi \in \Xi_D$:

$$w_D(\xi) = \prod_{e \in D} F(e)(\xi(v_1), \ldots, \xi(v_k)) \tag{1}$$

with $att(e) = v_1 \cdots v_k$. Notably, $w_D(\xi) \triangleq w_G(D, \xi)$. The inference problem is to compute the sum-product of G:

$$Z_G = \sum_{D \in \mathcal{D}(G)} \sum_{\xi \in \Xi_D} w_G(D, \xi) \tag{2}$$

To obtain Z_G, the key difficulty is in the marginalization over all derivations, since $\sum_{\xi \in \Xi_D} w_D(\xi)$ can be obtained by running standard variable elimination (VE) on factor graph D. To tackle this, Chiang and Riley (2020, Thm. 15) propose an extended VE. For each $X \in N, \xi \in \Xi_X$ [2], define P^X as all rules in P with left-hand side X, and then define:

$$\psi_X(\xi) = \sum_{(X \to R) \in P^X} \tau_R(\xi). \tag{3}$$

for each rhs $R = (V, E_N \cup E_T, att, lab^V, lab^E, ext)$, where E_N, E_T consist of nonterminal/terminal-labeled edges only, and $\tau_R(\xi)$ is given by:

$$\begin{aligned} \tau_R(\xi) = \sum_{\substack{\xi' \in \Xi_R \\ \xi'(ext) = \xi}} \prod_{e \in E_T} F(e) \left(\xi'(\mathrm{att}(e))\right) \\ \prod_{e \in E_N} \psi_{lab^E(e)} \left(\xi'(\mathrm{att}(e))\right) \end{aligned} \tag{4}$$

This defines a recursive formula for computing ψ_S, i.e., Z_G. Next, we will show how Eq. 3-4 recover the well-known inside algorithm.

Example: the inside algorithm. Consider π_6 in Fig.1(b). All possible fragments R (rhs of π_6) differs in the value of k, i.e., the splitting point, so we use R_k to distinguish them. Then Eq. 3 becomes:

$$\psi_{X_{i,k}}(\xi) = \sum_{i<k<j} \tau_{R_k}(\xi) \tag{5}$$

---

[2] Ξ_X is defined as the set of assignments to the endpoints of an edge e labeled X, so $\Xi_X = \Omega(\ell_1) \times \cdots \times \Omega(\ell_k)$ where $att(e) = v_1 \cdots v_k, lab^V(v_i) = \ell_i$.

Putting values into Eq. 4:

$$\tau_{R_k}(\xi) = \sum_{n_2,n_3} p(\xi, n_2, n_3)\psi_{X_{i,k}}(n_2)\psi_{X_{k,j}}(n_3) \tag{6}$$

where p denotes FGG rule probability $p(\mathbf{N}_1 \rightarrow \mathbf{N}_2\mathbf{N}_3)$. It is easy to see that $\psi_{X_{i,k}}$ is exactly the inside score of span $[i, k)$, and Eq. 5-6 recovers the recursive formula of the inside algorithm.

Remark. Eq. 4 can be viewed as unidirectional (from $e \in E_N$ to external nodes) belief propagation (BP) in the factor graph fragment R, where the incoming message is $\psi_{lab^E}(e)$ for $e \in E_N$, and the outcome of Eq. 4 can be viewed as the message passed to the external nodes. The time complexity of message updates grows exponentially with the number of variables in the factors. Therefore, to decrease inference complexity, one may decompose large factors into smaller factors connected by new nodes, as shown in the next subsection.

2.2 Tensor rank decomposition on factors

Consider a factor $F(e)$ (Def. 2), it can be represented as an order-k tensor in $\mathbb{R}^{N_1 \times \cdots \times N_k}$ where $N_i \triangleq |\Omega(v_i)|$. We can use tensor rank decomposition (aka. CPD) to decompose $F(e)$ into a weighted sum of outer products of vectors:

$$F(e) = \sum_{q=1}^{r} \lambda_q \mathbf{w}_{e_1}^q \otimes \mathbf{w}_{e_2}^q \otimes \cdots \otimes \mathbf{w}_{ek}^q$$

where r is the rank size; $\mathbf{w}_{e_k}^q \in \mathbb{R}^{N_k}$; $\otimes$ is outer product; λ_q is weight, which can be absorbed into $\{\mathbf{w}_{e_k}^q\}$ and we omit it throughout the paper.

Dupty and Lee (2020, Sec. 4.1) show that BP can be written in the following matrix form when applying CPD on factors:

$$\mathbf{m}_{ei} = \mathbf{W}_{e_i}^T \left(\odot_{j \in N(e) \setminus i} \mathbf{W}_{e_j} \mathbf{n}_{je}\right) \tag{7}$$

$$\mathbf{n}_{ie} = \odot_{c \in N(i) \setminus e} \mathbf{m}_{ci} \tag{8}$$

where $\mathbf{m}_{ei} \in \mathbb{R}^{N_i}$ is factor-to-node message; $\mathbf{n}_{ie} \in \mathbb{R}^{N_i}$ is node-to-factor message; $N(\cdot)$ indicates neighborhood ; $\mathbf{W}_{e_j} = [\mathbf{w}_{e_j}^1, \cdots, \mathbf{w}_{e_j}^r]^T \in \mathbb{R}^{r \times m}$; $\odot$ is element-wise product. We remark that this amounts to replacing the large factor $F(e)$ with smaller factors $\{F(e_i)\}$ connected by a new node $\mathbf{R}$ that represents rank, where each $F(e_i)$ can be represented as $\mathbf{W}_{e_i}$. Fig. 2 illustrates this intuition. We refer to $\mathbf{R}$ as rank nodes and others as state nodes thereafter.

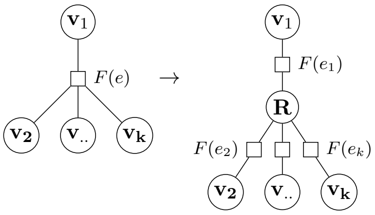


Figure 2: Using CPD to decompose a factor can be seen as adding a new node.

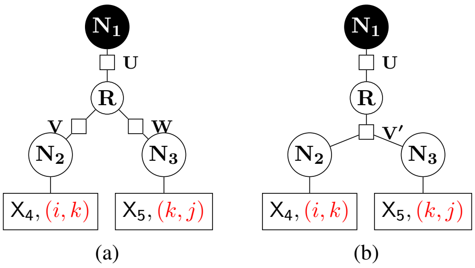

Figure 3: Representations of the rhs of π_6 (Fig. 1) after decomposition. (a): TD-PCFG (Cohen et al., 2013; Yang et al., 2021b). (b): LPCFG (Chiu et al., 2021).

3 Low-rank structured inference

In this section, we recover the accelerated inside algorithms of TD-PCFG (Cohen et al., 2013; Yang et al., 2021b) and LPCFG (Chiu et al., 2021) in an intuitive and unifying manner using the FGG notations. The accelerated forward algorithm of LHMM (Chiu et al., 2021) can be derived similarly.

Denote $\mathsf{T} \in \mathbb{R}^{m \times m \times m}$ as the tensor representation of $p(\mathbf{N}_1 \rightarrow \mathbf{N}_2\mathbf{N}_3)$, and $\boldsymbol{\alpha}_{i,j} \in \mathbb{R}^m$ as the inside score of span $[i, j)$. Cohen et al. (2013) and Yang et al. (2021b) use CPD to decompose T, i.e., let $\mathsf{T} = \sum_{q=1}^{r} \mathbf{u}_q \otimes \mathbf{v}_q \otimes \mathbf{w}_q$ where $\mathbf{u}_q, \mathbf{v}_q, \mathbf{w}_q \in \mathbb{R}^m$. Denote $\mathbf{U}, \mathbf{V}, \mathbf{W} \in \mathbb{R}^{r \times m}$ as the resulting matrices of stacking all $\mathbf{u}_q, \mathbf{v}_q, \mathbf{w}_q$, Cohen et al. (2013) derived the recursive form:

$$\boldsymbol{\alpha}_{i,j} = \sum_{k=i+1}^{j-1} \mathbf{U}^T \left((\mathbf{V}\boldsymbol{\alpha}_{i,k}) \odot (\mathbf{W}\boldsymbol{\alpha}_{k,j})\right) \tag{9}$$

$$= \mathbf{U}^T \sum_{k=i+1}^{j-1} \left((\mathbf{V}\boldsymbol{\alpha}_{i,k}) \odot (\mathbf{W}\boldsymbol{\alpha}_{k,j})\right) \tag{10}$$

Eq. 9 can be derived automatically by combining Eq. 7 (or Fig. 3 (a)) and Eq. 5-6. Cohen et al. (2013) note that $\mathbf{U}^\mathbf{T}$ can be extracted to the front of the summation (Eq. 10), and $\mathbf{V}\boldsymbol{\alpha}_{i,k}, \mathbf{W}\boldsymbol{\alpha}_{k,j}$ can be cached and reused, leading to further complexity reduction. The resulting inside algorithm time complexity is $O(n^3 r + n^2 m r)$.

Recently, Chiu et al. (2021) use low-rank matrix decomposition to accelerate PCFG inference. They first perform tensor matricization to flatten T to $\mathsf{T}' \in \mathbb{R}^{m \times m^2}$, and then let $\mathsf{T}' = \mathbf{U}^T \mathbf{V}$ where $\mathbf{U} \in \mathbb{R}^{r \times m}, \mathbf{V} \in \mathbb{R}^{r \times m^2}$. By un-flattening $\mathbf{V}$ to $\mathbf{V'} \in \mathbb{R}^{r \times m \times m}$, their accelerated inside algorithm has the following recursive form:

$$\boldsymbol{\alpha}_{i,j} = \sum_{k=i+1}^{j-1} \mathbf{U}^T \left(\mathbf{V'} \cdot \boldsymbol{\alpha}_{k,j} \cdot \boldsymbol{\alpha}_{i,k} \right) \tag{11}$$

$$= \mathbf{U}^T \sum_{k=i+1}^{j-1} \left(\mathbf{V}' \cdot \boldsymbol{\alpha}_{k,j} \cdot \boldsymbol{\alpha}_{i,k} \right) \tag{12}$$

Eq. 11 can be derived by combining Fig. 3 (b) and Eq. 5-6. The resulting inside time complexity is $O(n^3 m^2 r + n^2 m r)$, which is higher than that of TD-PCFG.

When learning a PCFG and a HMM, there is no need to first learn T and then perform decomposition on T. Instead, one can learn the decomposed matrices (e.g., $\mathbf{U}, \mathbf{V}$) to learn T implicitly. During inference, one can follow Eq. 10 or 12 without the need to reconstruct T.

Validity of probability. The remaining problem is to ensure that T is a valid probability tensor (i.e., being nonnegative and properly normalized) when learning it implicitly. Yang et al. (2021b) essentially transform Fig. 3(a) into a Bayesian network, adding directed arrows $\mathbf{N_1} \rightarrow \mathbf{R}, \mathbf{R} \rightarrow \mathbf{N_2}, \mathbf{R} \rightarrow \mathbf{N_3}$. This is equivalent to requiring that $\mathbf{V}, \mathbf{W}$ are nonnegative and column-wise normalized and $\mathbf{U}$ is nonnegative and row-wise normalized, as described in Yang et al. (2021b, Thm. 1). One can apply the Softmax re-parameterization to enforce such requirement, which is more convenient in end-to-end learning. Chiu et al. (2021) replace the local normalization of Yang et al. (2021b) with global normalization, and we refer readers to their paper for more details. We adopt the strategy of Yang et al. (2021b) in this work.

4 Rank-space modeling and inference

4.1 Rank-space inference with B-FGGs

Interestingly, when applying CPD on factors and if the rank size is smaller than the state size, we can even obtain better inference time complexities for a subset of FGGs which we refer to as B-FGGs.

We call a hyperedge a B-edge if its head contains exactly one node. B-graphs (Gallo et al., 1993) are a subset of directed hypergraphs whose hyperedges are all B-edges. Many dynamic programming algorithms can be formulated through B-graphs (Klein and Manning, 2001; Huang, 2008; Azuma et al., 2017; Chiu et al., 2021; Fu and Lapata, 2021), including the inference algorithms of many structured models, e.g., HMMs, Hidden Semi-Markov Models (HSMMs), and PCFGs. We follow the concept of B-graphs to define B-FGGs.

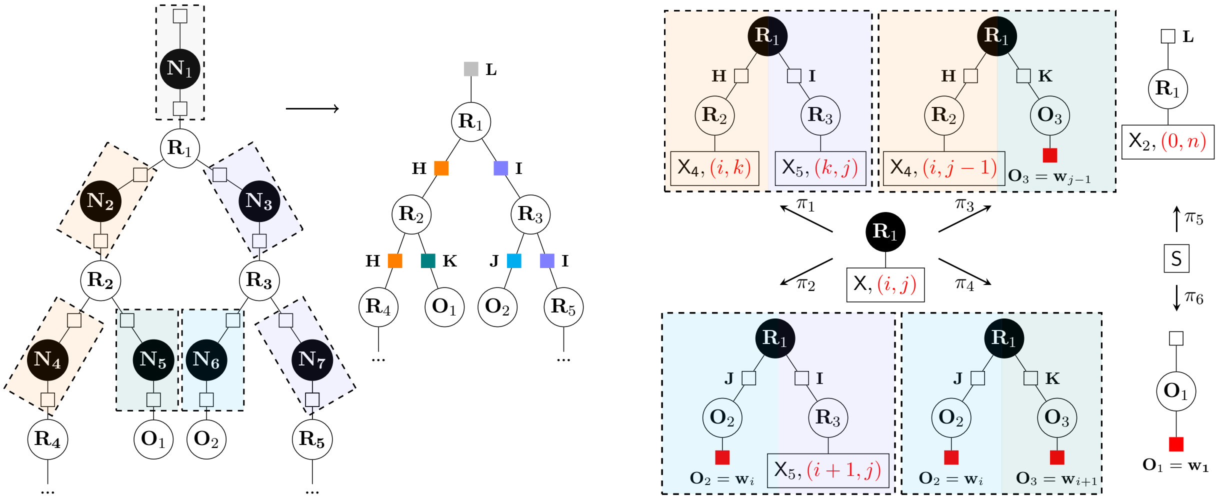
Definition 6. A hypergraph fragment is a B-hypergraph fragment iff. there is exactly one external node and there is no nonterminal-labeled hyperedge connecting to it. An FGG is a B-FGG iff. all rhs of its rules are B-hypergraph fragments.

It is easy to see that the aforementioned models are subsumed by B-FGGs. We can design a family of accelerated inference algorithms for B-FGGs based on the following strategy. (1) If there are multiple factors within a hypergraph fragment, merge them into a single factor. Then apply CPD on the single factor, thereby introducing rank nodes. (2) Find repeated substructures that take rank nodes as external nodes. Marginalize all state nodes to derive new rules. (3) Design new inference algorithms that can be carried out in the rank space based on the general-purpose FGG inference algorithm and the derived new rules. We give two examples, the rank-space inside algorithm and the rank-space forward algorithm, in the following two subsections to help readers understand this strategy.

4.2 The rank-space inside algorithm

Consider an B-FGG G shown in Fig.1(b) and replace the rhs of π_6 with Fig. 3(a), i.e., we use CPD to decompose binary rule probability tensor. Besides $\mathbf{U}, \mathbf{V}, \mathbf{W} \in \mathbb{R}^{r \times m}$ defined in Sec. 3, we define the start rule probability vector as $\mathbf{s} \in \mathbb{R}^{m \times 1}$, and the unary rule probability matrix as $\mathbf{E} \in \mathbb{R}^{o \times m}$ where o is the vocabulary size.

Fig. 4(a) is an example (partial) factor graph D generated by G. We highlight substructures of interest with dashed rectangles. Each substructure consists of a node $\mathbf{N}$ and two factors connecting to it. $\mathbf{N}$ is an external node connecting two hypergraph fragments which contain the two factors respectively. For each substructure, we can marginalize the state node $\mathbf{N}$ out, merging the two factors into a single one. After marginalizing all state nodes, we obtain a (partial) factor graph D' shown in the right of Fig. 4(a) where $\mathbf{H} = \mathbf{V}\mathbf{U}^T, \mathbf{I} = \mathbf{W}\mathbf{U}^T, \mathbf{J} = \mathbf{V}\mathbf{E}^T, \mathbf{K} = \mathbf{W}\mathbf{E}^T, \mathbf{L} = (\mathbf{U}\mathbf{s})^T$. We denote this transformation as $\mathcal{M}(D) = D'$. It is worth men-



(a)

(b)

Figure 4: (a): illustration of marginalizing state nodes $\mathbf{N}$. (b): rule set of the new FGG. π_1 can be applied when $k \neq i+1$ and $k+1 \neq j$; π_2 and π_3 can be applied when $i \neq j-1$; π_4 can be applied when $j = i+2$.

tioning that $\mathbf{H}, \mathbf{I}, \mathbf{J}, \mathbf{K}, \mathbf{L}$ are computed only *once* and then reused multiple times during inference, which is the key to reduce the time complexity.

Then we define a new B-FGG G' with rules shown in Fig 4(b). It is easy to verify that for each $D \in \mathcal{D}(G)$, we have $\mathcal{M}(D) \in \mathcal{D}(G')$, and vice versa. Moreover, we have:

$$\sum_{\xi \in \Xi_D} w_G(D, \xi) = \sum_{\xi \in \Xi_{\mathcal{M}(D)}} w_{G'}(\mathcal{M}(D), \xi)$$

because marginalizing hidden variables does not affect the result of sum-product inference. Therefore, $Z_G = Z_{G'}$ (Eq. 2).

We can easily derive the inference (inside) algorithm of G' by following Eq. 3-4 and Fig. 4(b) [3]. Let $\boldsymbol{\alpha}_{i,j} \in \mathbb{R}^r$ denote the rank-space inside score for span $[i, j)$. When $j > i+2$:

$$\boldsymbol{\alpha}_{i,j} = \overbrace{\sum_{i+1<k<j-1} (\mathbf{H}\boldsymbol{\alpha}_{i,k} \odot \mathbf{I}\boldsymbol{\alpha}_{k,j})}^{\text{from } \pi_1 \text{ of Fig. 4(b)}} + \underbrace{\mathbf{J}_{:,w_i} \odot \mathbf{I}\boldsymbol{\alpha}_{i+1,j}}_{\text{from } \pi_2} + \underbrace{\mathbf{H}\boldsymbol{\alpha}_{i,j-1} \odot \mathbf{K}_{:,w_{j-1}}}_{\text{from } \pi_3}$$

and when $j = i+2$, $\boldsymbol{\alpha}_{i,j} = \mathbf{J}_{:,w_i} \odot \mathbf{K}_{:,w_{i+1}}$ (from π_4). w_j is the index of the j-th word of the input sentence in the vocabulary; $\mathbf{A}_{:,j}$ indicates the j-th column of $\mathbf{A}$.

We note that, similar to Cohen et al. (2013), we can cache $\mathbf{H}\boldsymbol{\alpha}_{i,k}, \mathbf{I}\boldsymbol{\alpha}_{k,j}$ and reuse them to further accelerate inference [4]. Denote $\boldsymbol{\alpha}^L_{i,j}, \boldsymbol{\alpha}^R_{i,j} \in \mathbb{R}^r$ as the inside scores of span $[i, j)$ serving as a left/right child of a larger span. Then we have:

$$\boldsymbol{\alpha}^L_{i,i+1} = \mathbf{K}_{:,i} \qquad \boldsymbol{\alpha}^R_{i,i+1} = \mathbf{J}_{:,i}$$
$$\boldsymbol{\alpha}^L_{i,j} = \mathbf{H}\boldsymbol{\alpha}_{i,j} \qquad \alpha^R_{i,j} = \mathbf{I}\boldsymbol{\alpha}_{i,j}$$
$$\boldsymbol{\alpha}_{i,j} = \sum_{i<k<j} (\boldsymbol{\alpha}^L_{i,k} \odot \boldsymbol{\alpha}^R_{k,j})$$

and finally, $Z_{G'} = \mathbf{L}\boldsymbol{\alpha}_{0,n}$. We minimize $-\log Z_{G'}$ using mini-batch gradient descent for unsupervised learning. The resulting inference complexity is $O(n^3r + n^2r^2)$[5], which is lower than $O(n^3r + n^2mr)$ of TD-PCFG when $r < m$, enabling the use of a large state space for PCFGs in the low-rank setting.

The key difference between the rank-space inference and the original state-space inference is that they follow different variable elimination orders. The former marginalizes all state nodes before performing inference and marginalizes rank nodes from bottom up during inference; whereas the later marginalizes both state and rank nodes alternately from bottom up during inference.

Parsing. Low-rank inference does not support the Viterbi semiring[6], inhibiting the use of CYK

---

[3] π_6 is used for generating sentences of length 1, we do not consider this in the following derivation of the inside algorithm to reduce clutter.

[4] In fact, this is a typical application of the unfold-refold transformation (Eisner and Blatz, 2007; Vieira et al., 2021).

[5] This does not take into account the one-time cost of computing $\mathbf{H}, \mathbf{I}, \mathbf{J}, \mathbf{K}$ before inference.

[6] The Viterbi semiring is also known as the max-product semiring. Chiu et al. (2021, Appd. C) and Yang et al. (2021b, Sec. 6) have discussed this issue.

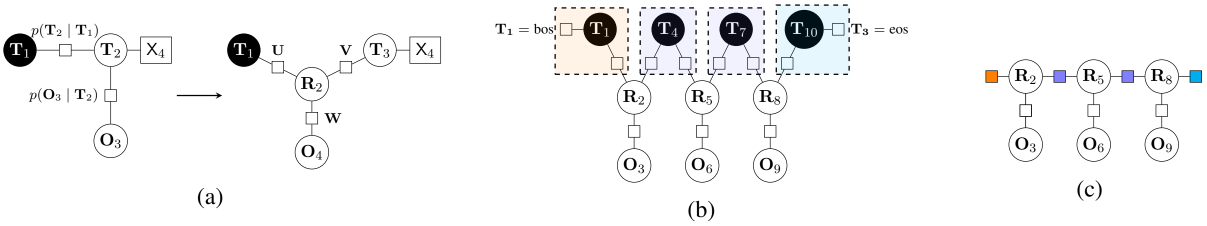


Figure 5: (a): merge the two factors into a single one, and apply CPD on the resulting factor. (b): factor graph of a HMM for sentences of length 3. (c): the resulting factor graph after marginalizing the state nodes.

decoding. Therefore, we follow Yang et al. (2021b) to use Minimum Bayes-Risk decoding (Goodman, 1996). Specifically, we estimate the span marginals using auto-differentiation (Eisner, 2016; Rush, 2020), which has the same complexity as the inside algorithm. Then we use the CYK algorithm to find the final parse with the maximum number of expected spans in $O(n^3)$ time, similar to Smith and Eisner (2006).

Implementation. The implementation of the inside algorithm greatly influences the actual running speed. First, $O(n^2)$ out of $O(n^3)$ can be computed in parallel using parallel parsing techniques (Yi et al., 2011; Canny et al., 2013; Zhang et al., 2020; Rush, 2020). In this work, we adapt the efficient implementation of Zhang et al. (2020) for fast inside computation. Second, we adopt the `log-einsum-exp` trick (Peharz et al., 2020) to avoid expensive `log-sum-exp` operations on high-dimensional vectors, which reduces both GPU memory usage and total running time.

4.3 The rank-space forward algorithm

Consider an B-FGG G shown in Fig. 1 (a). We replace the rhs of π_2 by the hypergraph fragment in the right of Fig. 5(a), i.e., we merge the factor $p(\mathbf{T}_2 \mid \mathbf{T}_1)$ and $p(\mathbf{O}_3 \mid \mathbf{T}_2)$ into a single factor, which can be represented as $\mathsf{T} \in \mathbb{R}^{m \times m \times o}$ and can be decomposed into three matrices $\mathbf{U}, \mathbf{V} \in \mathbb{R}^{r \times m}, \mathbf{W} \in \mathbb{R}^{r \times o}$ via CPD, where $m/o/r$ is the state/vocabulary/rank size. Fig. 5(b) gives an example factor graph of HMMs with sentences of length 3. Similar to previous subsection, we marginalize state nodes $\mathbf{T}$ to construct a new B-FGG G'. The rule set of G' can be obtained by replacing all variable nodes $\mathbf{T}$ with $\mathbf{R}$ and modifying all factors accordingly, as one can easily infer from Fig. 5(c). Inference with G' simply coincides with the forward algorithm, which has a $O(nr^2)$ time complexity and is lower than $O(nmr)$ of LHMM (Chiu et al., 2021) when $r < m$.

4.4 Neural parameterization

We use neural networks to produce probabilities for all factors, which has been shown to benefit learning and unsupervised induction of syntactic structures (Jiang et al., 2016; He et al., 2018; Kim et al., 2019; Han et al., 2019; Jin et al., 2019; Zhu et al., 2020; Yang et al., 2020, 2021b; Zhao and Titov, 2020; Zhang et al., 2021; Chiu and Rush, 2020; Chiu et al., 2021; Kim, 2021). We use the neural parameterization of Yang et al. (2021b) with slight modifications. We show the details in Appd. A and Appd. B.

5 Experiments

5.1 Unsupervised parsing with PCFGs

Setting. We evaluate our model on Penn Treebank (PTB) (Marcus et al., 1994). Our implementation is based on the open-sourced code of Yang et al. (2021b)[7] and we use the same setting as theirs. For all experiments, we set the ratio of nonterminal number to the preterminal number to 1:2 [8] which is the common practise. We set the rank size to 1000. We show other details in Appd. C and D.

Main result. Table 1 shows the result on PTB. Among previous unsupervised PCFG models, TN-PCFG (Yang et al., 2021b) uses the largest number of states (500 perterminals and 250 nonterminals). Our model is able to use much more states thanks to our new inside algorithm with lower time complexity, surpassing all previous PCFG-based models by a large margin and achieving a new state-of-the-art in unsupervised constituency parsing in terms of sentence-level F1 score on PTB.

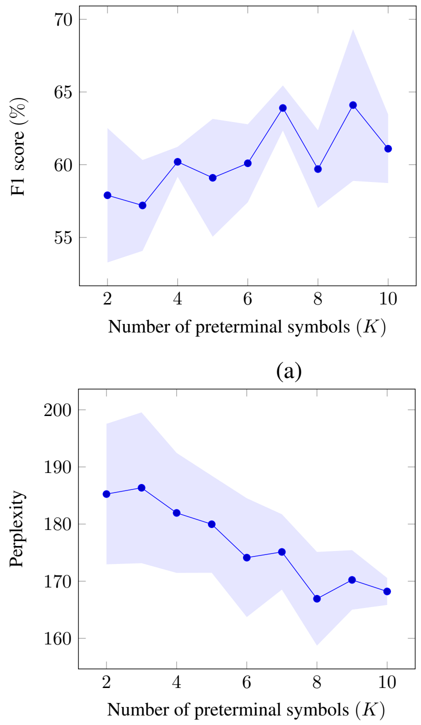
---

[7] `github.com/sustcsonglin/TN-PCFG`

[8] Although we did not explicitly distinguish between nonterminal and preterminal symbols previously, in our implementation, we follow Kim et al. (2019) to make such distinction, in which terminal words can only be generated by preterminal symbols, and binary rules can only be invoked by nonterminal symbols.

Model	S-F1
N-PCFG (Kim et al., 2019)	50.8
C-PCFG (Kim et al., 2019)	55.2
NL-PCFG (Zhu et al., 2020)	55.3
TN-PCFG (Yang et al., 2021b)	57.7
NBL-PCFG (Yang et al., 2021a)	60.4
Ours with 9000 PTs and 4500 NTs	**64.1**
For reference	
Constituency test (Cao et al., 2020)	62.8
S-DIORA (Drozdov et al., 2020)	57.6
StructFormer (Shen et al., 2021)	54.0
DIORA+span constraint (Xu et al., 2021)	61.2

Table 1: Results on PTB. S-F1: sentence-level F1. PTs: preterminals. NTs: nonterminals.



(a)

(b)

Figure 6: The change of F1 scores and perplexities with the change of number of perterminal symbols.

Ablation study. Fig. 6 shows the change of the sentence-level F1 scores and perplexity with the change of the number of preterminals. As we can see, when increasing the state, the perplexity tends to decrease while the F1 score tends to increase, validating the effectiveness of using large state spaces for neural PCFG induction.

5.2 HMM language modeling

Setting. We conduct the language modeling experiment also on PTB. Our implementation is based on the open-sourced code of Chiu et al. (2021)[9]. We set the rank size to 4096. See Appd. C and D for more details.

Table 2: Resulting perplexity on PTB validate set and test set. VL-HMM: (Chiu and Rush, 2020). LHMM: (Chiu et al., 2021). † denotes results reported by ablation study of Chiu and Rush (2020).

#States	Val	Test
2^{12}	149.8	139.1
2^{13}	143.8	133.4
2^{14}	149.5	137.4
2^{15}	141.1	131.1

Table 3: Perplexity with varying numbers of states. Following Chiu et al. (2021), we fix the rank to 2048 for faster ablation studies.

Main result. Table 2 shows the perplexity on the PTB validation and test sets. As discussed earlier, VL-HMM (Chiu and Rush, 2020) imposes strong sparsity constraint to decrease the time complexity of the forward algorithm and requires preclustering of terminal symbols. Specifically, VL-HMM uses Brown clustering (Brown et al., 1992), introducing external information to improve performance. Replacing Brown clustering with uniform clustering leads to a 10 point increase in perplexity on the PTB validation set. LHMM (Chiu et al., 2021) and our model only impose low-rank constraint without using any external information and are thus more comparable. Our method outperforms LHMM by 4.8 point when using the same state number (i.e., 2^{14}), and it can use more states thanks to our lower inference time complexity.

Ablation study. As we can see in Table 3, the perplexity tends to decrease when increasing the state number, validating the effectiveness of using more states for neural HMM language modeling.

---

[9] `github.com/justinchiu/low-rank-models`

Discussion. It is interesting to note that our HMM model is roughly equivalent to another HMM with interchanged rank and state sizes as can be seen in Fig.5(c). To verify this equivalence, we run LHMM in the original state space with 2048 states and rank 2^{15}. The resulting perplexity is 133.49 on average on the PTB test set, which is worse than that of ours (126.4). We leave further experimentation and analyses of this discrepancy for future work.

6 Related work

Tensor and matrix decomposition have been used to decrease time and space complexities of probabilistic inference algorithms. Siddiqi et al. (2010) propose a reduced-rank HMM whereby the forward algorithm can be carried out in the rank space, which is similar to our model, but our method is more general. Cohen and Collins (2012); Cohen et al. (2013) use CPD for fast (latent-variable) PCFG parsing, but they do not leverage CPD for fast learning and they need to actually perform CPD on existing probability tensors. Rabusseau et al. (2016) use low-rank approximation method to learn weighted tree automata, which subsumes PCFGs and latent-variable PCFGs. Our method can subsume more models. Yang et al. (2021b,a) propose CPD-based neural parameterizations for (lexicalized) PCFGs. Yang et al. (2021b) aim at scaling PCFG inference. We achieve better time complexity than theirs and hence can use much more hidden states. Yang et al. (2021a) aims to decrease the complexity of lexicalized PCFG parsing, which can also be described within our framework. Chiu et al. (2021) use low-rank matrix decomposition, which can be viewed as CPD on order-2 tensors, to accelerate inference on chain and tree structure models including HMMs and PCFGs. However, their method is only efficient when the parameter tensors are of order 2, e.g., in HMMs and HSMMs. Our method leverages full CPD, thus enabling efficient inference with higher-order factors, e.g., in PCFGs. Our method can be applied to all models considered by Chiu et al. (2021), performing inference in the rank-space with lower complexities.

Besides HMMs and PCFGs, Wrigley et al. (2017) propose an efficient sampling-based junction-tree algorithm using CPD to decompose high-order factors. Dupty and Lee (2020) also use CPD to decompose high-order factors for fast belief propagation. Yang and Tu (2022) use CPD to decompose second-order factors in semantic dependency parsing to accelerate second-order parsing with mean-field inference. Besides CPD, Ducamp et al. (2020) use tensor train decomposition for fast and scalable message passing in Bayesian networks. Bonnevie and Schmidt (2021) leverage matrix product states (i.e., tensor trains) for scalable discrete probabilistic inference. Miller et al. (2021) leverage tensor networks for fast sequential probabilistic inference.

7 Conclusion and future work

In this work, we leveraged tensor rank decomposition (CPD) for low-rank scaling of structured inference. We showed that CPD amounts to decomposing a large factor into several smaller factors connected by a new rank node, and gave a unifying perspective towards previous low-rank structured models (Yang et al., 2021b; Chiu et al., 2021). We also presented a novel framework to design a family of rank-space inference algorithms for B-FGGs, a subset of FGGs which subsume most structured models of interest to the NLP community. We have shown the application of our method in scaling PCFG and HMM inference, and experiments on unsupervised parsing and language modeling validate the effectiveness of using large state spaces facilitated by our method.

We believe our framework can be applied to many other models which have high inference time complexity and are subsumed by B-FGGs, including lexicalized PCFGs, quasi-synchronous context-free grammars (QCFGs), etc. A direct application of our method is to decrease the inference complexity of the neural QCFG (Kim, 2021).

A Neural parameterization of PCFGs

In this section, we give the full parameterization of PCFGs. We follow Yang et al. (2021b) with slight modifications for generations of $\mathbf{U}, \mathbf{V}, \mathbf{W} \in \mathbb{R}^{m \times r}$ in 4.2. We use the same MLPs with two residual layers as Yang et al. (2021b):

$$\begin{aligned}
\mathbf{s} &= \frac{\exp(\mathbf{u}_S^T h_1(\mathbf{w}_A))}{\sum_{A' \in \mathcal{N}} \exp(\mathbf{u}_S^T h_1(\mathbf{w}_{A'}))} \\
\mathbf{E} &= \frac{\exp(\mathbf{u}_E^T h_2(\mathbf{w}_t))}{\sum_{E' \in \Sigma} \exp(\mathbf{u}_{E'}^T h_2(\mathbf{w}_t))} \\
\mathbf{U} &= \frac{\exp(\mathbf{u}_H^T f_1(\mathbf{w}_n))}{\sum_{n' \in \mathcal{N}} \exp(\mathbf{u}_H^T f_1(\mathbf{w}_{n'}))} \\
\mathbf{V} &= \frac{\exp(\mathbf{u}_H^T f_2(\mathbf{w}_l))}{\sum_{H' \in \mathcal{H}} \exp(\mathbf{u}_{H'}^T f_2(\mathbf{w}_l))} \\
\mathbf{W} &= \frac{\exp(\mathbf{u}_H^T f_3(\mathbf{w}_l))}{\sum_{H' \in \mathcal{H}} \exp(\mathbf{u}_{H'}^T f_3(\mathbf{w}_l))} \\
h_i(\mathbf{x}) &= g_{i,1}(g_{i,2}(\tilde{\mathbf{W}}_i \mathbf{x})) \\
g_{i,j}(\mathbf{y}) &= ReLU(\tilde{\mathbf{V}}_{i,j} ReLU(\tilde{\mathbf{U}}_{i,j} \mathbf{y})) + \mathbf{y}
\end{aligned}$$

where Σ is the vocabulary set, $\mathcal{H}$ is the set of rank, $\mathcal{N}$ is a finite set of nonterminals, $\mathbf{W}_l = [\mathbf{W}_n; \mathbf{W}_t], \mathbf{w}_l, \mathbf{w}_n, \mathbf{w}_t \in \mathbf{W}_l, \mathbf{W}_n, \mathbf{W}_t$. The main differences of neural parameterization between ours and previous work are that we make the projection parameter $\mathbf{u}_H$ shared among $\mathbf{U}, \mathbf{V},$ and $\mathbf{U}$.

B Neural parameterization of HMMs

In this section, we give the full parameterization of HMMs, which is similar to PCFGs' parameterization. Define s as start probability for HMMs. And the definitions of $\mathbf{U}, \mathbf{V}, \mathbf{W}$ are same as definitions in 4.3:

$$\begin{aligned}
\mathbf{s} &= \frac{\exp(\mathbf{u}_P^T h_1(\mathbf{w}_s))}{\sum_{s' \in \mathcal{S}} \exp(\mathbf{u}_P^T h_1(\mathbf{w}_{s'}))} \\
\mathbf{U} &= \frac{\exp(\mathbf{u}_H^T \mathbf{w}_u)}{\sum_{H' \in \mathcal{H}} \exp(\mathbf{u}_{H'}^T \mathbf{w}_u)} \\
\mathbf{V} &= \frac{\exp(\mathbf{u}_H^T \mathbf{w}_v)}{\sum_{v' \in \mathcal{S}} \exp(\mathbf{u}_H^T \mathbf{w}_{v'})} \\
\mathbf{W} &= \frac{\exp(\mathbf{u}_W^T h_2(\mathbf{w}_w))}{\sum_{w' \in \Sigma} \exp(\mathbf{u}_W^T h_2(\mathbf{w}_{w'}))} \\
h_i(\mathbf{x}) &= g_{i,1}(g_{i,2}(\tilde{\mathbf{W}}_i \mathbf{x})) \\
g_{i,j}(\mathbf{y}) &= ReLU(\tilde{\mathbf{V}}_{i,j} ReLU(\tilde{\mathbf{U}}_{i,j}\mathbf{y})) + \mathbf{y}
\end{aligned}$$

where $\mathcal{S}$ is a finite set of states, $\mathcal{H}$ is the set of rank, Σ is vocabulary set.

C Data details

Penn Treebank (PTB) (Marcus et al., 1994)[10] consists of 929k training words, 73k validation words, and 82k test words, with a vocabulary of size 10k.

For PCFGs, we follow Yang et al. (2021b) and use their code to preprocess dataset. This processing discards punctuation and lowercases all tokens with 10k most frequent words as the vocabulary. The splits of the dataset are: 2-21 for training, 22 for validation and 23 for test.

For HMMs, we follow Chiu et al. (2021) and use their code to preprocess dataset. We lowercase all words and substitutes OOV words with UNKs. EOS tokens have been inserted after each sentence.

D Experimental details

For PCFGs, we use Xavier normal initialization to initialize the weights in h_i and f_i. We optimize our model using Adam optimizer with $\beta_1 = 0.75, \beta_2 = 0.999$, and the learning rate 0.002, setting the dimension of all embeddings to 256.

For HMMs, we initialize all parameters by Xavier normal initialization except for $\mathbf{w}_s$ and $\mathbf{w}_w$. We use AdamW optimizer with $\beta_1 = 0.99, \beta_2 = 0.999$, and the learning rate 0.001, and a max grad norm of 5. We use dropout rate of 0.1 to dropout $\mathbf{w}_s$ and $\mathbf{U}, \mathbf{V}$ in HMMs. We train for 30 epochs with a max batch size of 256 tokens, and reduce the learning by multiplying $\frac{1}{2}$ if the validation perplexity fails to improve after 2 evaluations. Evaluations are performed one time per epoch. We follow Chiu et al. (2021) to shuffle sentences and leverage bucket iterator, where batch of sentences are drawn from buckets containing sentences of similar lengths to minizing padding.

We run all experiments on NVIDIA TITAN RTX and NVIDIA RTX 2080ti and all experimental results are averaged from four runs.

What Factors Should Paper-Reviewer Assignments Rely On? Community Perspectives on Issues and Ideals in Conference Peer-Review

Terne Sasha Thorn Jakobsen[1], **Anna Rogers**[1,2]
[1] Copenhagen Center for Social Data Science, University of Copenhagen
[2] RIKEN Center for Computational Science
[1]terne.thorn@sodas.ku.dk, [2]arogers@sodas.ku.dk

Abstract

Both scientific progress and individual researcher careers depend on the quality of peer review, which in turn depends on paper-reviewer matching. Surprisingly, this problem has been mostly approached as an automated recommendation problem rather than as a matter where different stakeholders (area chairs, reviewers, authors) have accumulated experience worth taking into account. We present the results of the first survey of the NLP community, identifying common issues and perspectives on what factors should be considered by paper-reviewer matching systems. This study contributes actionable recommendations for improving future NLP conferences, and desiderata for interpretable peer review assignments.

1 Introduction

Peer review is increasingly coming under criticism for its arbitrariness. Two NeurIPS experiments (Price, 2014; Cortes and Lawrence, 2021; Beygelzimer et al., 2021) have shown that the reviewers are good at identifying papers that are clearly bad, but the agreement on the "good" papers appears to be close to random. Among the likely reasons for that are cognitive and social biases of NLP reviewers (see overview by Rogers and Augenstein, 2020), fundamental disagreements in such an interdisciplinary field as NLP, and acceptance rates that are kept low[1] irrespective of the ratio of high-quality submissions.

Such arbitrariness leads to understandable frustration on the part of the authors whose jobs and graduation depend on publications, and it also means lost time and opportunities (Aczel et al., 2021; Gordon and Poulin, 2009) for science overall. Reviews written by someone who does not have the requisite expertise, or does not even consider the given type of research as a contribution, it is a loss for all parties: the authors do not get the intellectual exchange that could improve their projects and ideas, and reviewers simply lose valuable time without learning something they could use. It is also a loss for the field overall: less popular topics could be systematically disadvantaged, leading to ossification of the field (Chu and Evans, 2021).

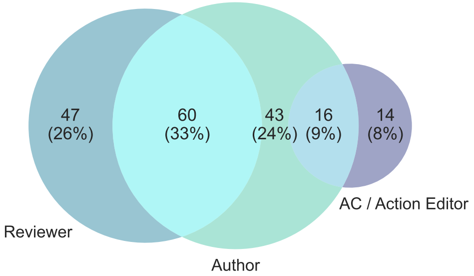

Figure 1: Overview of all respondents and overlap of their roles for their last experience at NLP venues.

This paper contributes a snapshot of this problem in NLP venues, based on a survey of authors, reviewers and area chairs (ACs). We collected 180 responses, which is is comparable to the volume of feedback collected for implementing the ACL Rolling Review (ARR). The overall distribution of respondents' roles is shown in fig. 1. We present the commonly reported issues and community preferences for different paper assignment workflows (section 4). We derive actionable recommendations to how peer review in NLP could be improved (section 5), discuss the limitations of survey methodology (section 6.2), and conclude with desiderata for interpretable peer review assignments (section 6.3).

2 Background: Peer Review in NLP

Paper-reviewer assignments are matches between submissions to conferences or journals and their available pool of reviewers, taking into account the potential conflicts of interest (COI) and reviewer assignment quotas.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4810 - 4823
July 10-15, 2022

Among the systems used in recent NLP conferences, the Softconf matching algorithm takes into account bidding, quotas, and manual assignments, and randomly assigns the remaining papers as evenly as possible[2]. NAACL and ACL 2021 used SoftConf, but also provided their ACs with affinity scores produced by a "paraphrastic similarity" system based on an LSTM encoder, which is trained on Semantic Scholar abstracts (Wieting et al., 2019; Neubig et al., 2021). Affinity scores are scores indicating how well a given submission matches a given reviewer. They are typically computed as the similarity (e.g. cosine similarity) between the embeddings of certain information about the submission and the reviewer's publication history (e.g. abstracts and titles).

ARR switched to OpenReview and currently uses[3] their SPECTER-MFR system (OpenReview, 2021) which is based on SPECTER (Cohan et al., 2020) and MFR embeddings (Chang and McCallum, 2021) for computing affinity scores. The assignments are then made with the MinMax matching algorithm[4].

The problem of paper-reviewer assignment is by itself an active area of research (see overview of key issues for CS conferences by Shah (2022)). There are many proposals for paper-reviewer assignment systems (Hartvigsen et al., 1999; Wang et al., 2010; Li and Watanabe, 2013, inter alia), some of which also consider the problem of "fair" assignments (Long et al., 2013; Stelmakh et al., 2019). Such studies tend to be hypothesis-driven: they make an assumption about what criteria should be taken into account, design a system and evaluate it. To the best of our knowledge, ours is the first study in the field to address the opposite question: what criteria should be taken into account, given the diversity of perspectives in an interdisciplinary field? We take that question to the community.

3 Methodology: survey structure and distribution

We developed three separate surveys for the main groups of stakeholders in the peer review process: authors, reviewers and ACs.

They follow the same basic structure: consent to participation (see Impact Statement), background information, questions on most recent experiences in the role which the survey pertains to, and how the respondents believe paper-reviewer matching should be performed. Most questions are asked to respondents in all three roles, reformulated to match their different perspectives.

The responses were collected late 2021 and all respondents are required to confirm that their most recent experience as an AC/reviewer/author is in 2019-2021. The full surveys and response data are publicly available[5].

Participant background. All surveys include questions on career status and the number of times the respondents have been ACs/reviewers/authors at NLP venues. We ask what venues they have experience with (as broad categories) and what types of contributions they make in their work.

Participant experience with peer review. We further ask the respondents a range of questions about their experience as AC/reviewer/author: how satisfied they are with the process, what issues they have experienced, what was the assignment load (ACs and reviewers), how paper-reviewer matching was done, how they would prefer it to be done, and which factors they believe to be important for paper-review matching. Most of the questions are multiple-choice, with addition of some open-ended questions where appropriate, so that respondents can elaborate their answers or add to the available options. Whenever possible, the question formulations were taken from the question bank of UK Data Service (Hyman et al., 2006). Attitude questions use a 5-point Likert scale.

Limited memory is an important concern in surveys (Sudman and Bradburn, 1973; Öztas Ayhan and Isiksal, 2005), and we cannot expect the respondents to accurately recall all their experience with peer review. To reduce memory recall errors, the survey focuses on the respondent's most recent experience, but they also have a chance to reflect on prior experience in open-ended questions, and to report whether they experienced certain issues at any time in their career.

Survey distribution. We distributed the surveys via three channels: by handing out flyers at EMNLP 2021, through mailing lists (ML-news, corpora list, Linguist list), and through Twitter with the hashtag #NLProc. Participation was voluntary,

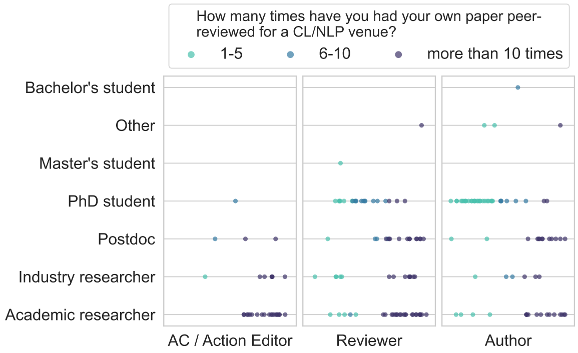

Figure 2: Career status of the respondents vs their experience receiving peer review. Numerical data is available in table 1 in the appendix.

with no incentives beyond potential utility of this study for improving NLP peer review.

Data validation. Given that links to surveys were distributed openly and that we did not ask for any identifiable information, the surveys needed to include other means of validation to ensure that the responses included in the analysis were from attentive, relevant individuals. Our approach for validating the data quality follows *satisficing theory* (Liu and Wronski, 2018), with the main safeguards being 1) the checking of response consistency, including a few "traps" where inconsistency or illogical responses can be exposed, and 2) the inclusion of open-ended questions.

73% ACs, 40% reviewers, 33% authors have provided at least one response to our open-ended questions, and we did not find any meaningless or incoherent comments not addressing the question. For consistency checks, all respondents were asked:

- How many times they have been an AC/reviewer/author. One of the options was "0", contradicting the earlier confirmation of experience in a given role.
- When was the last time they were an AC/reviewer/author. One of the options was "earlier than 2019", contradicting the earlier confirmation of peer review experience in 2019-2021.
- Whether they have performed the other roles. New authors may have not reviewed or AC-ed, but reviewers should also have been authors, and ACs should have experience with all roles.

4 Results

Overall we received 38 responses from ACs, 87 from reviewers and 81 from authors (206 in total).

After removing 20 incomplete responses and 8 responses inconsistent with the "trap" questions, we report the results for 30 responses from ACs, 77 from reviewers and 73 from authors (180 in total).

4.1 Who are the respondents?

According to the past conference statistics, we could expect that many submissions would be primarily authored by the students, and reviewers are generally expected to be relatively senior, which should correspond to their going through peer review more often. We can use this expected pattern as an extra validation step for the survey responses.

Figure 2 shows that the responses are in line with this expected pattern. We received the most responses from academic researchers (62), PhD students (54), and postdocs (32). Most academic researchers and postdocs, but not PhD students, have had their work reviewed more than 10 times. At the same time 65% of the PhD students who served as reviewers went through peer review more than 5 times, as opposed to 24.2% of PhD students in the author role. Fewer industry than academic researchers responded to the survey. This could be related to the fact that a large part of the "academic" demographic are students – and in 2020-2021 the ACL membership among students was equal to or exceeding other demographics (Rasmussen, 2021).

4.2 Paper types

The next question is to see what kinds of research papers the respondents to our surveys have authored: engineering experiment, survey, position paper etc., according to the COLING taxonomy by Bender and Derczynski (2018). We expect that more senior researchers will have more experience

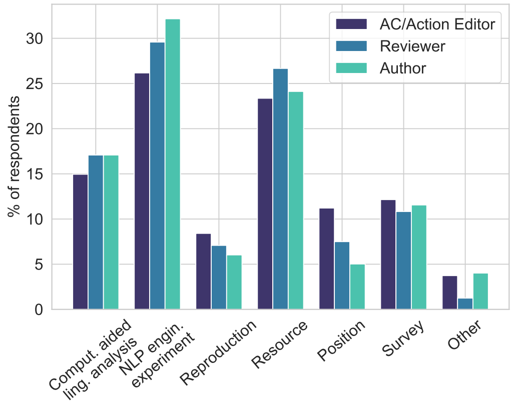

Figure 3: Types of research performed by respondents (multiple options could be selected).

with different types of work. Indeed, on average the authors have worked with 2.5 types of papers, vs. 3.0 for reviewers and 3.6 for ACs. The distribution is shown in fig. 3. The most respondents have authored engineering experiment papers (with the authors reporting the most such work).

Note that this only indicates whether the respondents to our surveys have or have not authored certain types of papers, rather than how many. In terms of volume, the engineering papers are a lot more prevalent: e.g. at ACL 2021 the "Machine learning" track had 332 submissions, vs 168 in the "Resources and evaluation" track (Xia et al., 2021).

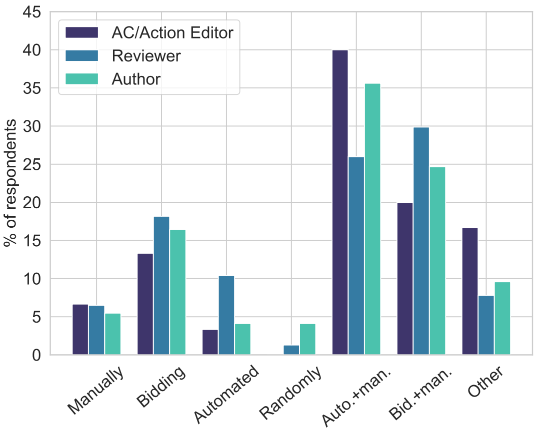
4.3 What kinds of problems do people report?

As with any voluntary feedback, our surveys were likely to receive more responses from people who had a grievance with the current process. Indeed, we find that only 6.7% of ACs, 20.5% of authors, and 22.1% of reviewers say that they have not had any issues in their last encounter with NLP venues.

The overall distribution for the types of problems reported by the authors, reviewers and ACs in their last and overall experience is shown in fig. 5. Given that at the time of this survey the ARR was recently deployed as the only ACL submission channel, we highlight the responses from the people for whom the most recent venue was ARR: 28% reviewers, 18% authors, 50% ACs.

The key takeaways are as follows:

- Two of the most frequent complaints of ACs (about 50% of the respondents) are insufficient information about reviewers and clunky interfaces;
- Many paper-reviewer mismatches (about 30%, if the report of the last experience is representative) are *avoidable*: they should have been clear from the reviewers' publication history;
- Over a third of the author respondents in their last submission (about 50% over all history) received reviews from reviewers lacking either expertise or interest, and that is supported by the reviewers' reports of being assigned papers that were mismatched on one of these dimensions;
- The authors report that many reviews (over a third in last submission, close to 50% overtime) are biased or shallow, which might be related to the above mismatches in expertise or interest;
- Two patterns are exclusive to ARR: insufficient time for ACs[6], and zero authors with no issues.



Topics mentioned in the open-ended comments
(See supplementary materials for full categorized comments)

ACs: bidding (2), similarity+manual (1), similarity+bidding+manual (5), keyword-based filtering + bidding (2), similarity (1), tracks (1), other info (2), ARR (1), interface (1)

Reviewers: manual (2), similarity + bidding (3), similarity+bidding+manual (3), keywords (1), keywords+similarity (1), tracks (2), tracks+bidding (1), other (4)

Authors: against similarity (2), similarity + bidding (2), similarity+bidding+manual (2), ARR (2), random (2)

Figure 4: *Which of the following options would you consider best for assigning reviewers to submissions?*

4.4 Knowledge of the workflow

Our next question is what methods NLP venues use to match submissions to reviewers, and to what extent the stakeholders (authors and reviewers) are aware of how it is done. We find that relatively few authors (23.3%) and reviewers (23.4%) know for sure what process was used, which begs for *more transparency in the conference process*. The ACs report that the most frequent case (37%) is a combination of automated and manual assignments. Interestingly, most reviewers believe that their assignments were automated (36%), and only (28%) believe they were automated+manual. See App. Figure 8 for full distribution.

5 The Ideal Process

5.1 Ideal workflow

When asked about what paper-assignment process they would prefer (given that fully manual matching is impractical for large conferences), most ACs and authors opted for automated+manual process, but for the reviewers this is the second preferred process (26%), with 30% opting for bidding + manual checks (see fig. 4). There was also relatively

[6] ARR has since switched to 6-week cycles, which might help to address this issue (https://aclrollingreview.org/six-week-cycles/).

Topics mentioned in the open-ended comments

(The full comments categorized by these topics can be found in the survey data repository)

Area chairs: interface issues (7), bad reviewers/reviews (5), workload issues (6), issues with ARR (4), lacking information on reviewers (4), communication issues between both systems and other human agents (4), lack of qualified reviewers in the pool (3), issues with meta-reviews (2), affinity score complaints (2), affinity score for finding reviewers the AC does not know personally (1), preference for manually recruited reviewers (1), papers assigned to ACs outside their area of expertise (1), too many declines (1), mismatch in goals of reviewers and authors (1), emergency reviews (1), bidding enabling bias (1).

Reviewers: choices forced by ACs (5), preference for bidding (4), areas of past expertise not currently of interest (4), lack of interest in the paper (3), methodological mismatch between generations of NLP researchers (3), mismatch in research methods (2), publication records as an unreliable indicator for assignments (1), mismatch in languages (1), time issues (1), reviewer bias (1)

Authors: reviewer expectation for a certain kind of research (6), inattentive reviews (5), short reviews (3), mismatch between the score and the text of the review (3), requests for irrelevant citations (2), confirmation bias (1), non-constructive criticism (1), shallow reviews (1), lack of reviewer competence (2), missing reviews (2), requests for irrelevant comparisons (1), "wild" estimates of impact (1), unannounced policy changes (1)

Figure 5: The issues with peer review process, reported by ACs, reviewers and authors, in their last (on the left) versus historical (on the right) experience with CL/NLP venues.

large support for pure bidding (13-18% of respondents in all roles), and cumulatively pure bidding and bidding with manual adjustments have as much or more support from all respondent categories than the automated matching + manual assignments.

The analysis of open-ended comments suggested that the respondents were aware that bidding is quite labor-intensive on the part of the reviewers. 5 ACs, 3 reviewers and 2 authors suggested using affinity scores to filter the papers on which bids would be requested, followed with manual checking. Another suggestion was keywords or more fine-grained areas/tracks, potentially as alternative to affinity scores for filtering down the list of papers to bid on. One AC suggested *"an extensive, but still finite, set of tags (e.g. an ACL-version of ACM CCS concepts, or FAccT's submission tags"*. One reviewer stressed that the keywords should be provided by the authors, to match what *they* perceive to be the salient aspects of the paper.

1 reviewer and 1 author suggested looking at whether the paper *cites* the potential reviewer[7], as this could be a good indicator for the reviewer's interest. 1 reviewer and 2 authors voiced support for some randomness in the assignments (given a track-level match): *"Bidding + some random assignment to ensure diversity in the matching. We don't want reviewers to review only papers they *want* to review. However these random assignments should be clearly indicated to all, and treated accordingly."*

5.2 Ideal assignment criteria

AC past experience. Figure 5 shows that one of the most common problems for the ACs is that they were not provided with enough information to facilitate the paper-reviewer matching. The follow-up question is what information they *are* provided with, and how useful they find it.

Figure 6 shows that the types of information with the highest utility information are links to reviewer profiles, bidding information, and affinity scores. But affinity scores are also the most controversial: it is the type of information that the most ACs find "not very useful" or "not useful at all" (20%).

Overall the results suggest that ACs are presented with little structured information about reviewers, and have to identify the information they need from a glance at the reviewers' publication record. Seniority, expertise, and reviewer history notes from other ACs are all reported to be useful, but they were never provided directly to many ACs.

An avenue for future research is offered by three types of information that the most ACs are not sure about, presumably because they are rarely provided: structured information about the methods that the reviewers were familiar with, the languages they spoke, and affinity score explanations. We will show below that there is much support for taking such methods into account. For the languages, this might be due to the "default" status of English (Bender, 2019). We hypothesize that providing this information would make it easier to provide better matches for papers on other languages, which would in turn encourage the authors to submit more such work. Affinity will be discussed in section 6.3.

Stakeholder preferences. We then asked the respondents what factors they believe are important for paper-reviewer assignments. Their answers are shown in fig. 7. The overall mean importance rankings (on scale 0-5) are as follows:

3.95	Reviewer has worked on the same task
3.85	Reviewer bid on the paper
3.72	Reviewer has worked with the same method
3.32	Reviewer has authored the same type of paper
3.11	AC knows & trusts the reviewer
2.81	Reviewer has worked with the same kind of data
1.99	The affinity score is high

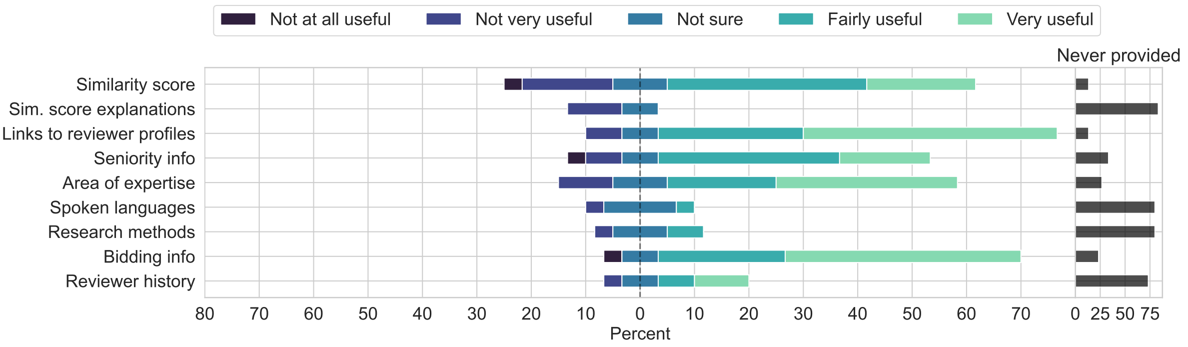
The fact that affinity scores rank the least important for NLP researchers (who would know the most about them) is interesting, and perhaps related to the fact that evaluation of paper-reviewer matching systems remains an open problem, with little empirical evidence for how well our current systems really work. In the absence of such evidence, our results suggest that the respondents across all groups are not very positive about their experience with such systems. In the authors' personal experience, when the conference chairs provide automated affinity scores they caution the area chairs against fully relying on them, and urge to adjust the assignments manually.

Our data suggests that within groups of stakeholders the individual variation in importance of different factors is higher for some factors and stakeholders than others: e.g. ACs vary within 1 point on the importance of knowing the data, but only within 0.74 points on importance of knowing the tasks. This has implications for approaches who would rely on AC assignments as ground truth for automated assignment systems: they could end up modeling the annotator instead of the task (Geva et al., 2019). See App. table 2 for full data.

We then explored the question of whether the experience of having authored research of a certain type correlates with any changes in the attitude towards some of these paper-reviewer matching factors. For each pair of type of research and matching factor, we ran two-sided Fisher's Exact tests for all respondents who have authored (or not) the types of research and the importance they attached to different factors in paper-reviewer assignment (binning on less than moderately important and more than moderately important). For some pairs there were statistically significant differences: e.g. the respondents who have authored reproduction papers were significantly more likely to believe it important that the reviewer has worked with the same kind of data ($p = 0.004$), and respondents who authored position papers were significantly *less* likely

---

[7] We believe this is an interesting idea, but it could lead to authors strategically placing citations to maximize the chances of acceptance, or being punished for citing work that they may criticize or claim to improve upon.



Topics mentioned in the open-ended comments: reviewer history (2), number of assigned papers (1), being able to ask SACs for advice (1), reviewer affiliation (e.g. academic or industry) (1), correct area match for both ACs and reviewers (1).

Figure 6: The diverging bars shows the experienced utility of different kinds of information about reviewers that ACs may have been presented with to assist in manual checks of paper-reviewer matches. If the respondent had never been presented with the specific kind of information they chose "Never provided".

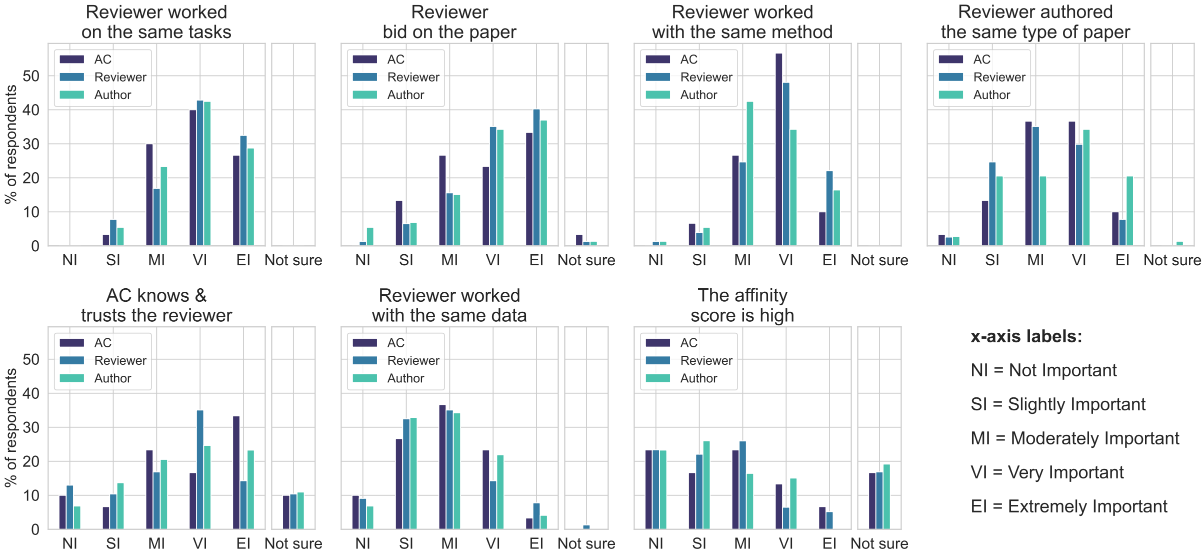


Figure 7: Question: *How important do you think the following factors are for a good paper-reviewer match?*

to believe a high automated affinity score is important ($p = 0.003$). See table 3 in the appendix for all p-values and more details on the tests. We note that the relationships are not necessarily causal.

We conclude that our sample does provide evidence (the first, to our knowledge) that researchers in interdisciplinary fields who perform different kinds of research may have differing preferences for what information should be taken into account for paper-reviewer assignments. If that effect is robust, it should be considered in assignment systems for interdisciplinary fields. We hope that this finding would be explored in a larger study, taking into account both the experience of authoring a given type of paper and how central that type of research is for a given researcher (a factor that we did not consider). Another direction for future work is exploring this question from the perspective of demographic characteristics and the type of institution the respondents work in. Should there be significant differences, more targeted assignments could be a powerful tool for diversifying the field.

5.3 Ideal workload

We asked our reviewer and AC respondents how many assignments they received at their most recent NLP venue, and what would be the optimal number (given a month to review, and a week for AC assignments). For ACs, the mean optimal number of assignments is 8.5±4.2 vs. 9.1±5.1 they received at the most recent venue, and for reviewers it is 2.8±1.0 vs. 3.3±1.8. Whether this is an issue depends on how much time a given venue allows. The ARR reviewers have even less than a month, and they indicated preference for fewer assignments than they received (2.4±1.0 vs 3.3±1.9). See App. fig. 10 for data on other venues.

The lack of reviewers is a well-known problem. One of the possible causes is that many authors are students not yet ready to be reviewers. To investigate that, we asked the authors if they also reviewed for the venues where they last submitted a paper, and the reviewers and ACs - if they also submitted. If the core problem is that many authors are not qualified, we would expect more non-student authors to also be reviewers. Among all respondents there are 24% authors who submit to a venue but do not review there or help in some other role (fig. 1), but if we consider only non-student respondents that ratio is still 18% (see non-student role distribution in App. fig. 9). This suggests that *many qualified people do not review*.

6 Discussion

6.1 Reviewer interests

Our results suggest the lack of interest is one of the most common problems in paper-reviewer matching, for both authors and reviewers. The authors are aware of this problem and sometimes try to optimize for it by pursuing the "safe", popular topics. Unenthusiastic reviewers will likely produce shallow, heuristic-based reviews, essentially penalizing non-mainstream research. Both tendencies contribute to ossification of the field (Chu and Evans, 2021), and generally need to be minimized.

It is in the AC's interest to find interested reviewers, since that minimizes late reviews, but they need to know who finds what interesting. That is not as simple as a match by topic/methodology, clear from the publication record. Interests change not only gradually over time but also according to what is popular or *salient* at the given moment (Tversky and Kahneman, 1974; Dai et al., 2020), or even in seemingly irrational ways (e.g. by being sensitive to the framing of the problem) (Tversky and Kahneman, 1981). But although experience and knowledge may provide more stable descriptions of a reviewer, looking into dated publication records may be fundamentally counter-productive. According to one of our respondents: *"I prefer the conferences who offer bidding processes to select the papers to review... I am more enthusiastic to review the papers compared to conferences that assign papers based on what my interests were x years ago."*

Bidding however has its own set of problems, including the practical impossibility to elicit all preferences over a big set of papers, the possibility of collusion rings (Littman, 2021), and, as one of our respondents put it, "*biases towards/against certain paper types when bidding is enabled*". But these problems potentially have solutions: there is work on detecting collusion rings (Boehmer et al., 2022), and several respondents suggested that bidding could be facilitated by subsampling with either keyword- or affinity-score-based approaches.

We support some of our respondents' recommendation for a combination of interest-based and non-interest-based (within a matching area) assignments, with the latter clearly marked as such for ACs and reviewers, and separate playbooks for the two cases. The reviewer training programs should aim to develop the expectation that peer review is something that combines utility and exploration.

6.2 Limitations

We readily acknowledge that, like with any surveys with voluntary participation, our sample of respondents may not be representative of the field overall, since the people who have had issues with peer review system are more incentivized to respond. However, precisely for that reason this methodology can be used to learn about the commonly reported types of problems, which was our goal. Our response rate turned out to be comparable to the response rate of the official ACL survey soliciting feedback on its peer review reform proposal (Neubig, 2020), which received 199 responses.

It is an open problem how future conferences could systematically improve, if they cannot rely on surveys to at least reliably estimate at what scale an issue occurs. Asking about satisfaction with reviews does not seem to produce reliable results (Daumé III, 2015; Cardie et al.). Our survey included a question about satisfaction with the paper-reviewer matching, and whether the most recent experience was better or worse than on average. Both reviewers and authors were more satisfied than dissatisfied, and considered the recent experience better than on average, despite reporting so many issues (see App. fig. 11 for the distribution).

6.3 Interpretable Paper-Reviewer Matching: Problem Formulation

There already are many proposed solutions for paper-reviewer matching (see section 2), but their evaluation is the more difficult problem. The obvious approach would be to use bidding information or real assignments made by ACs as ground truth, but this data is typically not shared to protect reviewer anonymity. It would also provide a very noisy signal not just due to different assignment strategies between ACs, but also different quality of assignments depending on how much time they have on a given day. Both ACs and bidding reviewers are also likely[8] to favor top-listed candidates. And, as our findings suggest, the optimal assignment strategies in an interdisciplinary field might genuinely vary between different types of papers and tracks. A system unaware of that might systematically disadvantage whole research agendas.

Given that even the human experts cannot tell what the best possible assignments are, we propose to reformulate the problem as *interpretable paper-reviewer matching*. That problem is *not* the same as the problem of faithfully explaining why a given paper-reviewer matching system produced a certain score, for which we have numerous interpretability techniques (Søgaard, 2021). The AC goal is fundamentally different: not to understand the system, but to quickly find the information that the AC[9] considers relevant for making the best possible match. Therefore *the task of interpretable paper-reviewer matching is rather to help to identify the information that the stakeholders wish the decisions to be based on, and to provide that information as justification for the decisions.*

7 Conclusion

We present the results of the first survey on paper-reviewer assignment from the perspective of three groups of stakeholders in the NLP community: authors, reviewers, and ACs. The results point at a host of issues, some immediately actionable (e.g. providing the ACs with better information), some normative (e.g. different kinds of research may need different assignment strategies), and some open (e.g. how do we evaluate the effect of any changes to peer review process?) A big issue for both authors and reviewers is mismatches due to lack of interest, which is in tension with explorative aspects of peer review. We recommend to address this issue with a combination of assignments based on bidding and random matches within area, backed up by reviewer training.

Acknowledgments

Many thanks to Marzena Karpinska, Friedolin Merhout, and the anonymous reviewers for their insightful comments. We would also like to thank all our survey respondents, without whom this study would not have been possible.

Impact Statement

Broader impact. The study identifies types of information that could be used to provide better paper-reviewer matches. Used strategically by a conference, it could be a powerful tool for diversifying the field, by helping the non-mainstream papers find the reviewers more open to them. By the same token, if the entity organizing the review process aimed for suppressing such research, deprioritising this information could harm such papers. Our proposal of interpretable paper-reviewer assignments would mitigate this potential risk by requiring the organizers to disclose their rationale for any given match.

Personal data. The surveys are designed to not solicit any personally identifiable information (including comments about individual peer review cases in the past conferences), or demographic information about participants.

Potential risks. The respondents are participants in anonymous peer review process, and as such being tracked back to individual peer review cases could expose them to retaliation. The survey therefore did not solicit information about specific venues (only broader categories such as "*ACL conferences"), and we manually verified that the open-ended comments also do not contain references to specific cases. We thus foresee no potential risks from deanonymization of the respondents.

Informed consent. The respondents are informed about the organizers and the objective of the study: to identity current practises of paper-reviewer assignments in CL/NLP conferences and ways in which this process can be improved. Responses are anonymous and respondents consent

---

[8] Position bias is well documented in search & recommendation systems (Craswell et al., 2008; Collins et al., 2018).

[9] Or the program chairs, should the conference aim to have consistent policies for all ACs.

to the use and sharing of their responses for research purposes. Respondents must give consent to continue the survey.

Intended use. The survey data and forms will be made publicly available for research purposes.

Institutional approval. The study was approved by the Research Ethics Committee at the authors' institution.

A Appendix

In this appendix we introduce supplementary figures and tables.

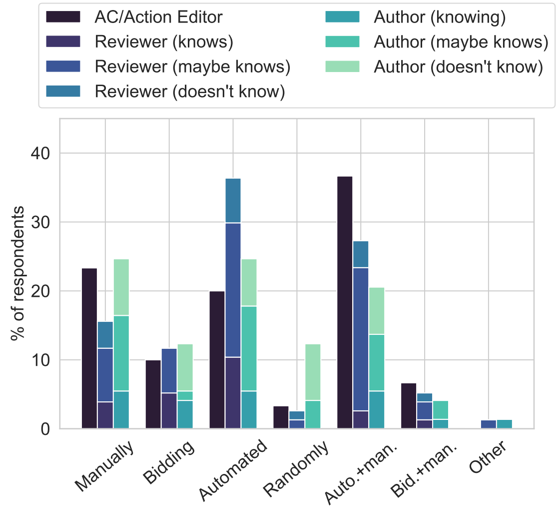

Figure 8: We ask reviewers and authors whether they know for certain, or maybe knows, or do not know how the paper-reviewer matching was done for their last CL/NLP venue. We then ask both reviewers, authors and ACs what they believe (or knows in the case of some) was the process for this venue The guesses, and knowledge herof, are much different from *best* options in fig. 4, discussed in section 5.

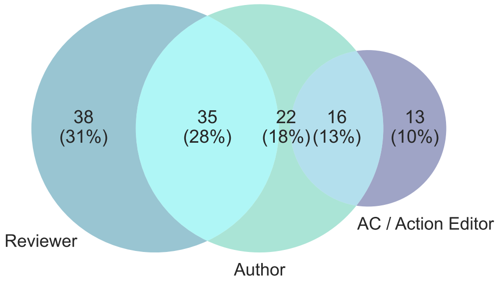

Figure 9: Distribution of **non-students** in the three roles, with overlap derived from asking the question *Did you also serve as a reviewer/author?* for their last CL/NLP venue.

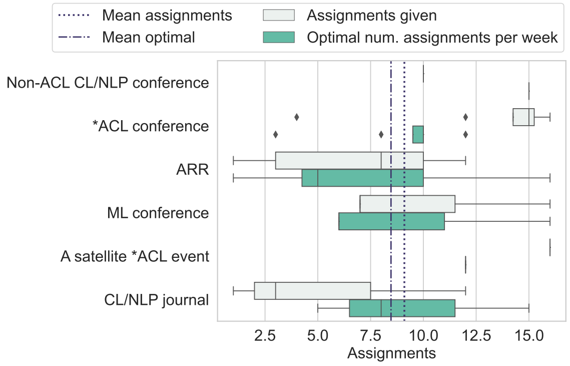
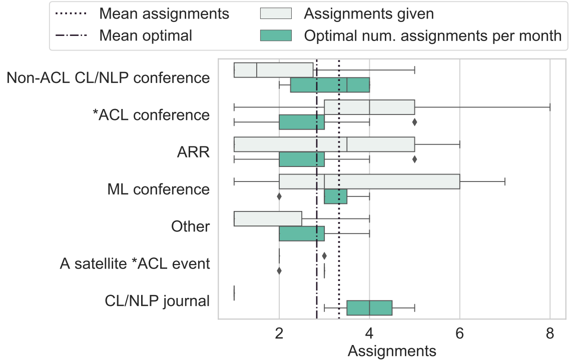
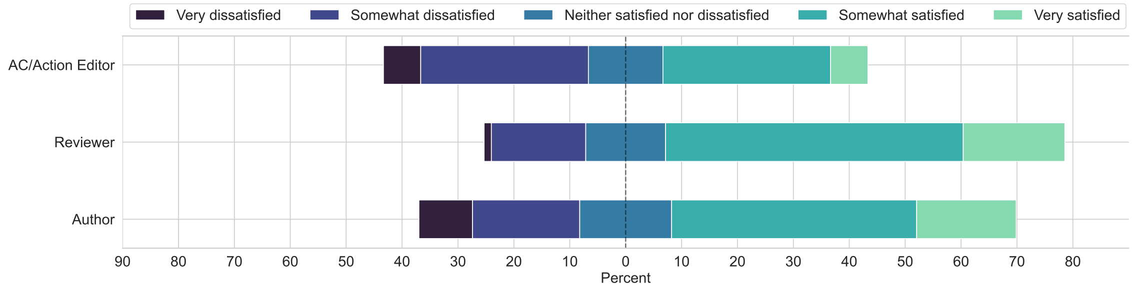


(a) AC/Action Editors

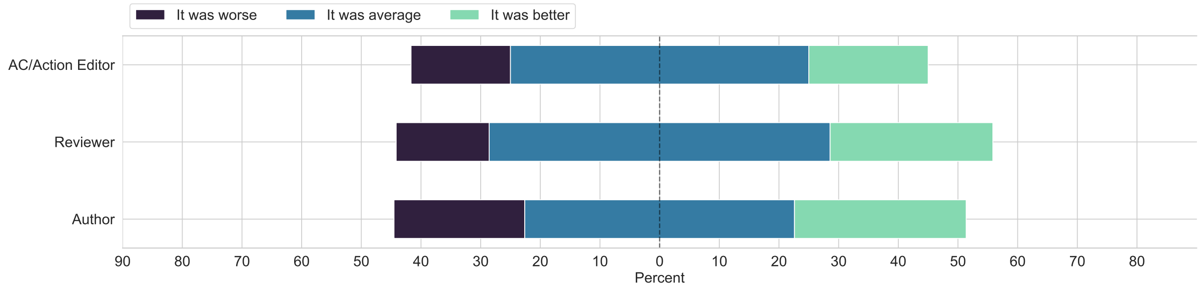


(b) Reviewers

Figure 10: The boxplots shows the number of assignments given and optimal for a) ACs and b) Reviewers, discussed in section 5.3. Number of given assignments are reported for the venue in which the respondent last served as AC/reviewer, and optimal number of assignments are reported for time periods one week for ACs and one month for reviewers. Mean given and optimal number of assignments, across all respondents/venues, are shown with vertical striped lines.



(a) Reported satisfaction with most recent experience. AC / Action Editor question: *(...) how satisfied were you with the support provided to you to improve the paper-reviewer matching?* Reviewer question: *(...) How satisfied were you with the paper-reviewer matching?* Author question: *(...) How satisfied were you with the amount of constructive criticism in the reviews you received?*



(b) Question: *would you say your most recent experience with paper-reviewer matching/paper assignment(s)/set of reviews described above, was better or worse than on average?*

Figure 11: We ask all respondents general questions about their satisfaction with their last experience as an AC/reviewer/author and their overall satisfaction in this role. We discuss these results in the limitations section 6.2.

	Area Chair			Reviewer			Author		
	1-5	6-10	>10	1-5	6-10	>10	1-5	6-10	>10

Table 3: P-values of two-sided Fisher Exact tests, discussed in section 5.2. For each contribution type, we test the null hypothesis that there is no difference in whether respondents find a paper-match factor (from fig. 7) more than or less than moderately important, depending on whether or not individuals have worked on the specific types of papers (contribution types). For each contribution type i and paper-match factor j, a 2×2 contingency table is made with the counts of a) respondents having worked with type i and finding factor j *less* than moderately important, b) having worked with type i and finding factor j *more* than moderately important, c) having *not* worked with i and finding j *less* than moderately important, d) having *not* worked with i and finding j *more* than moderately important. The p-values reflect the probability of observing the given counts or something more imbalanced between those having and not having worked on type i. Significant p-values, $p < 0.05$, are in bold, and for these, superscript $>$ denotes that respondents having worked with i believe factor j is *more* than moderately important, and the superscript $<$ denotes the opposite.

Reducing Disambiguation Biases in NMT by Leveraging Explicit Word Sense Information

Abstract

Recent studies have shed some light on a common pitfall of Neural Machine Translation (NMT) models, stemming from their struggle to disambiguate polysemous words without lapsing into their most frequently occurring senses in the training corpus. In this paper, we first provide a novel approach for automatically creating high-precision sense-annotated parallel corpora, and then put forward a specifically tailored fine-tuning strategy for exploiting these sense annotations during training without introducing any additional requirement at inference time. The use of explicit senses proved to be beneficial to reduce the disambiguation bias of a baseline NMT model, while, at the same time, leading our system to attain higher BLEU scores than its vanilla counterpart in 3 language pairs.

1 Introduction

Translating a sentence requires the underlying meaning to be captured and then expressed in the target language. Nonetheless, only little attention has been devoted to studying the actual capabilities of Neural Machine Translation (NMT) approaches of modeling different senses of ambiguous words, with recent work showing that systems tend to be biased towards the most frequent meanings found within the training corpus (Emelin et al., 2020). This phenomenon is hard to measure through classical evaluation metrics, such as the BLEU score (Papineni et al., 2002), as they often rely on word-matching heuristics that fail to capture the disambiguation capabilities of the evaluated systems. Therefore, several efforts have been recently devoted to shed some light and create test beds (Rios Gonzales et al., 2017; Raganato et al., 2019; Emelin et al., 2020; Campolungo et al., 2022) to challenge NMT models. Results show that these models still struggle to deal with highly polysemous words, especially when used to express least frequent senses.

For example, given the sentence “The energy comes from a distant plant.”, both Google Translate and DeepL disambiguate[1] *plant* to its sense of *organism* when translating into Italian, and produce the following incorrect sentence “L’energia proviene da una *pianta* lontana.”, rather than “L’energia proviene da un *impianto* lontano.”, where *impianto* is the translation for the factory meaning of *plant*. This suggests that, even when adequate context is provided (*energy* should be enough to correctly infer the right sense of *plant*), state-of-the-art models might still be biased towards the most frequent meanings found within training data.

Some recent studies have explored how to leverage explicit sense information within NMT models (Rios Gonzales et al., 2017; Pu et al., 2018a; Nguyen et al., 2018). Nevertheless, including such information is not trivial for three main reasons: i) sense-tagged parallel data is scarce; ii) Word Sense Disambiguation (WSD) systems have not been accurate enough until very recently (Blevins and Zettlemoyer, 2020; Barba et al., 2021); and iii) how explicit senses should be incorporated within neural models is not straightforward.

In this paper, we first introduce a novel approach to make up for the paucity of sense annotations in parallel corpora, leveraging a multilingual WSD system to tag parallel sentences and refine its predictions by means of cross-lingual word alignments and information from a multilingual knowledge base. Then, we fine-tune our baseline models on our sense-tagged corpora via a specifically designed loss function, allowing the injection of word-level semantics into the architecture. We evaluate our approach on standard and challenge test sets, showing that it does indeed improve translation accuracy and mitigates the most frequent sense bias.

To summarize, our contributions are manifold:

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4824 - 4838

1. We put forward a novel approach to produce high-precision sense annotations for parallel data, which we apply to three language pairs.
2. We propose a fine-tuning strategy that lets us inject word-level explicit semantics into Neural Machine Translation models, without introducing any additional requirement at inference time.
3. We show that employing explicit sense tags is beneficial in order both to mitigate the sense bias and to improve the translation quality in terms of BLEU score on standard benchmarks.
4. We present a case study on how a state-of-the-art WSD system compares to an NMT model on disambiguating words within a challenging set for detecting sense bias in MT.

We make all the generated datasets, the code of the model and for the experiments available at `https://github.com/sapienzanlp/reducing-wsd-bias-in-nmt`.

2 Related Work

Word Sense Disambiguation was first formulated as a computational task by Weaver (1949) in the context of Machine Translation. The two fields then followed parallel paths, with more or less successful attempts over the years to join them back together (Carpuat and Wu, 2005; Vickrey et al., 2005; Carpuat and Wu, 2007). Indeed, while Carpuat and Wu (2005) reported negative results when trying to integrate the prediction of a supervised WSD approach into a Statistical Machine Translation (SMT) model, the same authors, two years later, successfully improved the performance of a phrase-based SMT approach by leveraging a new phrase-based WSD model (Carpuat and Wu, 2007). More recently, Pu et al. (2018a) and Nguyen et al. (2018) proposed systems that successfully leverage sense information in NMT models, although they introduced a heavy requirement, i.e., that of disambiguating the ambiguous words in the sentence prior to generating a translation, which makes them unfeasible in many real-world settings. Lately, contextualized word embeddings have been employed to produce additional back-translated parallel training data via mining sense-specific target sentences, in order to improve handling of infrequent senses (Hangya et al., 2021).

Nevertheless, the proper treatment of lexical ambiguity is still an open problem, with neural models struggling to translate least frequent senses and often relying on spurious correlations among words (Emelin et al., 2020; Raganato et al., 2019; Rios Gonzales et al., 2017). Thus, the disambiguation bias topic has received renewed interest, and several benchmarks have been introduced in the most recent years with the goal of directly measuring the extent to which neural architectures are able to capture word semantics. One of the first of this kind was ContraWSD (Rios Gonzales et al., 2017). In this first attempt to evaluate WSD capabilities of NMT models, the authors built an adversarial test set where source sentences containing an ambiguous word were associated with a correct translation and several incorrect alternatives. These latter were built by replacing the reference translation for the ambiguous word with the translation of one of its other possible meanings. The task measured whether a model ranked the correct translation higher, i.e., it assigned it a higher probability than the adversarial ones. This study provided evaluation data for two language pairs only, i.e., German→English and German→French, and within a few years it became outdated as modern NMT models could easily attain high performances (Emelin et al., 2019). Thus, MuCoW (Raganato et al., 2019) took things a step further and leveraged BabelNet (Navigli and Ponzetto, 2012; Navigli et al., 2021) – a large multilingual knowledge base – and sense embeddings (Camacho-Collados et al., 2016; Mancini et al., 2017) in order to automatically create adversarial translations for five language pairs while also increasing the difficulty of the task itself; however, the fully automatic nature of these challenge sets made them noisy and prone to containing irrelevant challenge samples.

More recently, Emelin et al. (2020) proposed two challenge sets for the English→German pair, one measuring the model sensitivity to most frequent senses and the other estimating, through adversarial injections, its susceptibility to changing a correct sense to a wrong one. In contrast to previous studies, these challenge sets were based on correlations among words in the training set and relied on manually-refined sense clusters, providing an excellent test bed for measuring semantic bias.

Finally, Campolungo et al. (2022) proposed DiBiMT, the first fully manually annotated test set for measuring the disambiguation bias of neural machine translation models, covering five language combinations, namely, from English to German, Spanish, Italian, Russian and Chinese. In their work, the authors showed that open neural models still exhibit strong semantic biases towards frequent senses, confirming once again the suspicions about this under-explored issue.

Despite all the effort made in putting forward challenging sets of data to test WSD capabilities of NMT models, to the best of our knowledge, only a few approaches (Rios Gonzales et al., 2017; Liu et al., 2018) have been proposed to mitigate this issue, and none of these is effective with modern Transformer-based architectures. Furthermore, while parallel corpora have been exploited to produce sense annotations in the past (Bonansinga and Bond, 2016; Delli Bovi et al., 2017), they were built by utilizing outdated disambiguation approaches that have recently been surpassed by more advanced neural architectures. Indeed, the Word Sense Disambiguation field has received much attention in the last few years, with several supervised approaches (Conia and Navigli, 2021; Blevins and Zettlemoyer, 2020; Barba et al., 2021) and sense embedding models (Loureiro and Jorge, 2019; Scarlini et al., 2020a,b; Wang et al., 2020) performing close to the upper bound limit of the inter-annotator agreement, which finally makes them feasible for inclusion in other downstream tasks, e.g., Machine Translation.

Thus, differently from previous studies in the literature, we focus on closing the gap between these two fields, i.e., Neural Machine Translation and Word Sense Disambiguation, by putting the recent advances in WSD at the service of NMT models. We propose a novel approach, similar to that introduced in Luan et al. (2020), for creating high-quality sense-annotated parallel corpora, and we use this semantic information to regularize an NMT model, making it less biased and capable of producing higher-quality translations.

3 Reducing the Disambiguation Bias in NMT

Neural Machine Translation models are typically trained end-to-end to produce a target translation given a source sentence and, thus, they can only rely on the input context to resolve the ambiguity of polysemous words therein. Being pattern recognition algorithms at heart, these models fall prey to the inherent bias carried by the frequency of co-occurrence of words within parallel sentences, and thus tend to disambiguate words to the sense they most frequently encountered during training, even when the sentence does provide enough context to identify the correct sense. At the same time, Word Sense Disambiguation models, i.e., models specialized in associating a word in context with one of the meanings within a given sense inventory, have recently displayed remarkable results across different benchmarks and languages (Bevilacqua et al., 2021). The time may now therefore be ripe for them to be successfully included into downstream applications such as Neural Machine Translation. However, data that would allow these two worlds to be brought together, i.e., parallel corpora where words are associated with semantic labels, are currently still produced automatically by leveraging outdated approaches to WSD (Delli Bovi et al., 2017).

In what follows, we first provide some preliminary information about resources and tools that we employ in our method (§ 3.1); then, we introduce a new approach for automatically annotating tokens within parallel sentences with sense annotations, i.e., labels explicitly defining their meanings (§ 3.2); finally, we propose a fine-tuning objective for leveraging such annotations in order to mitigate the sense bias while also improving the translation quality overall (§ 3.3). The intuition behind our work is that fixed sense labels describing word senses would help NMT models better encode the underlying meaning of the input sentence, thus generating less biased and overall better translations.

3.1 Preliminaries

We draw sense labels from BabelNet (Navigli and Ponzetto, 2012), a multilingual knowledge base created by merging several semantic resources in different languages such as WordNet (Miller et al., 1990), Wikipedia, Wikidata, etc. BabelNet is structured in synsets, i.e., sets of synonymous senses in different languages. For instance, the synset of *plant*$^{\text{organism}}$ contains the following lexicalizations: $\textit{plant}_{EN}$, $\textit{pianta}_{IT}$, $\textit{Pflanze}_{DE}$, among others. Additionally, BabelNet provides lemma-to-synsets mappings. For example, the English noun *plant* belongs to the following nominal synsets: *organism*, *industrial plant*, *actor in the audience* and *something placed secretly*.[2] Since BabelNet con-

---

[2] Synsets bn:00035324n, bn:00046568n, bn:00062800n and bn:00062801n respectively, from https://babelnet.org.

tains millions of synsets, which may make the computation too expensive, we restrict the vocabulary to just those containing at least one English sense from WordNet, as is also done in several other works (Barba et al., 2020; Scarlini et al., 2020b; Bevilacqua and Navigli, 2020).

3.2 Building a Sense-Annotated Parallel Corpus

Let us assume that our running example sentence "The energy comes from a distant plant." appears within a parallel corpus paired with the following Italian translation: "L'energia viene da un impianto lontano.". As we said, by considering the English sentence alone, the word *plant* could take several meanings, among which *organism* and *power plant*. However, among these, only one is shared with its translation *impianto*, i.e., the *power plant* meaning. Therefore, considering the cross-lingual alignment of words may drastically reduce the set of valid meanings, making the disambiguation task much easier. Based on this intuition, given a parallel corpus, we perform the following two steps:

1. **Sense Scoring**, where we employ a WSD system to assign to each content word a distribution over its possible meanings;

2. **Annotation Refinement**, where we compute cross-lingual word alignments to reduce lexical ambiguity and finally assign the most suitable sense to each content word.

Sense Scoring In this step, our goal is to assign to every content word within a sentence a distribution over its possible senses in BabelNet. To this end, given as input a sentence s[3] from a parallel corpus C, we first apply Part-of-Speech tagging and lemmatization to it, then pass it through our WSD system, which returns a distribution over its possible meanings.

Formally, let w_i be a content word in a sentence $s = [w_1, \ldots, w_n]$, and $\sigma(w_i)$ the set of synsets associated with w_i in BabelNet. The WSD system assigns a score $c(S|w_i, s)$ to each synset $S \in \sigma(w_i)$; we denote the synset of w_i with the highest confidence as $S^*_{w_i}$. As a result, each content word in a source or target sentence is associated with a sense distribution. However, applying a WSD system alone may not be sufficient to ensure high-quality annotations, as the application domain may be different from the one of its training set. Therefore, in the next step we take advantage of the translation each sentence is paired with to refine sense annotations.

Annotation Refinement We produce word-level cross-lingual alignments between the source and the target sentences of the parallel corpus: given a pair of parallel sentences (s, t), we compute a list of alignments $\mathcal{A} = \{(w^s_i, w^t_j) | w^s_i \in s, w^t_j \in t\}$. Thus, given an aligned word pair $P = (w^s_i, w^t_j) \in \mathcal{A}$, let $\sigma(P) = \sigma(w^s_i) \cap \sigma(w^t_j)$, i.e., the intersection of synsets that the two words may denote according to BabelNet: we discard annotations for any word pair such that $\sigma(P) = \emptyset \ \vee |\sigma(w^s_i)| < 2$. In other words, we retain all the aligned pairs (w^s_i, w^t_j) such that the source word is polysemous and the intersection of their senses is non-empty, thus ensuring higher annotation precision by leveraging the parallelism of words.

Finally, we assign the same synset S^* to both words (w^s_i, w^t_j) in P as follows:

$$\begin{aligned} S^* &= S^*_{w^s_i} = S^*_{w^t_j} \\ &= \operatorname*{argmax}_{S \in \sigma(P)} \left(\frac{c(S|w^s_i, s)}{Z_s} + \frac{c(S|w^t_j, t)}{Z_t} \right) \\ Z_s &= \sum_{S \in \sigma(P)} c(S|w^s_i, s) \\ Z_t &= \sum_{S \in \sigma(P)} c(S|w^t_j, t) \end{aligned}$$

that is, the synset with the highest combined confidence score after normalizing over $\sigma(P)$, where Z_s and Z_t represent the normalization factors of the probability distributions associated with the synsets of w^s_i and w^t_j, respectively.

3.3 Semantic Injection

Now that we can generate high-quality sense annotations, we describe our fine-tuning method to inject word-level semantics into a Neural Machine Translation model. Ideally, we want the model to benefit from such annotations during training, while not being dependent on them at inference time. To satisfy both these desiderata, we adapt the model's vocabulary to handle synsets as well as subwords, and propose a specific loss that exploits the injected senses to improve the base model's handling of ambiguous words.

---

[3] s can be either a source or a target sentence.

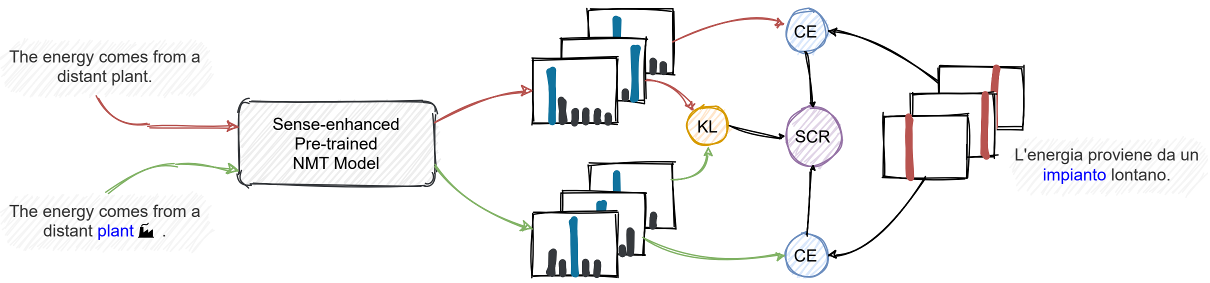

Figure 1: Semantic Consistency Regularization (SCR) fine-tuning. KL stands for Kullback-Leibler divergence; CE stands for Cross Entropy.

Semantically Enhancing Sentences In order to work with concepts, we need a way to represent them. Let us consider once more the sentence "The energy comes from a distant plant.": we rewrite it in order to also include the exact meaning for *plant*, which we computed as described in § 3.2: "The energy comes from a distant plant *plant*$^{\text{factory}}$".

Formally, given a source sentence s and a word w_i annotated with sense $S^*_{w_i}$, we simply represent w_i as its standard segmentation followed by $S^*_{w_i}$, represented by its sense embedding[4] passed through a linear projection layer (as shown in Figure 2). Additionally, to enforce the connection between the tagged word and its sense annotation, we set the position ids for the word and the sense embedding to the same value, as if they were a single token. This encoding scheme gracefully extends to the whole sentence, yielding the sense-enhanced input representation for a given sentence s.

Semantic Consistency Regularization We hereby propose the Semantic Consistency Regularization (SCR) objective, inspired by MVR (Wang et al., 2021).

Formally, let x' and x'' be two encodings (plain and sense-enhanced) of the same input sentence x and let y be the target sentence, we define SCR as:

$$\begin{aligned} SCR(\theta) = &- \log \mathcal{P}_\theta(y|x') - \log \mathcal{P}_\theta(y|x'') \\ &+ \mathcal{D}_{\text{KL}}(\mathcal{P}_\theta(y|x') \,||\, \mathcal{P}_\theta(y|x'')) \end{aligned}$$

where θ is the set of trainable weights, $\mathcal{D}_{\text{KL}}$ is the unidirectional Kullback-Leibler divergence (Kullback and Leibler, 1951) and $\mathcal{P}_\theta(y|x)$ represents an output distribution (a visual representation of SCR is reported in Figure 1).

With this formulation, SCR jointly uses the same sentence with and without sense annotations as two separate inputs: while we train the model to be able to translate both plain and sense-enhanced sentences, by minimizing the divergence between the output distributions we also force the model to transfer the sense information from the sense-enhanced input to the plain input, much like in a self-distillation process. At the same time, we still maintain the model's capability of translating without sense annotations, thus dropping their requirement at inference time.

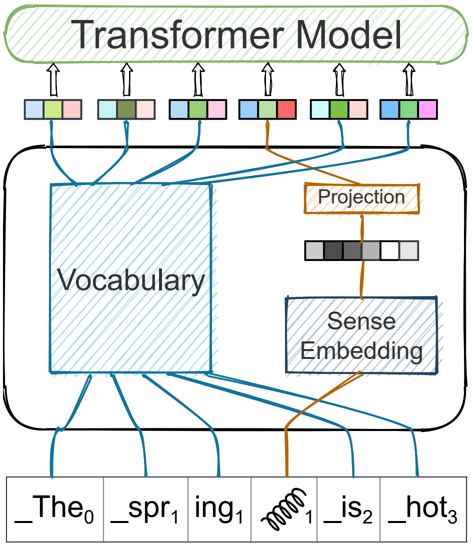

Figure 2: Sense injection mechanism. Subscripts represent the position id associated with the subword.

4 Experimental Setup

4.1 Our Model

We employ as underlying model the standard Transformer architecture (Vaswani et al., 2017), with 6 encoder and 6 decoder layers.[5] Note that, while SCR can be applied to any pre-trained model, we retrain one from scratch because most of the other models available online use part of our test data as

---

[4] Details are provided in § 4.

[5] We use randomly-initialized MarianMT models available in HuggingFace's transformers library (Wolf et al., 2020) for easier comparability with their trained versions.

their training data (see § 4.2). Additional details about training configuration and hyperparameters are provided in § A.3.

Fine-tuning with SCR Additionally, to jump-start the model's capabilities, we encode synsets not as randomly initialized learnable vectors (e.g., by extending the vocabulary), but with frozen pre-trained sense embeddings projected into the model's input space by means of a linear layer, the only additional learnable component of the model (*Projection* in Figure 2), which is dropped after the fine-tuning stage. As pre-trained sense embeddings we use ARES (Scarlini et al., 2020b), since they provide multilingual representations for each synset in our vocabulary. We study the impact of this choice in § 5.5. To perform token-level alignments, we use MultiMirror (Procopio et al., 2021).[6]

4.2 Datasets

We experiment on three distinct language pairs: EN→DE, EN→ES and EN→FR. Following (Emelin et al., 2020), we gather the data from WMT14 for German and French and WMT13 for Spanish, considering only sentences coming from either CommonCrawl, News Commentary or Europarl, to maintain similar order of magnitudes among language pairs (and to contain pre-processing and training times). As validation sets, we employ *newstest2014* for EN→DE, *newstest2013* for EN→FR and *newstest2012* for EN→ES. All datasets employed in this work are freely available for research purposes.

Sense-Enhanced Datasets

We process each parallel sentence of the considered corpora with the procedure described in § 3.2, taking into account only content words whose Part-of-Speech tag is noun, as the challenge sets we evaluate upon only target nominal words.[7]

For POS-tagging and lemmatization we use Stanza (Qi et al., 2020). As disambiguation system, we use EWISER (Bevilacqua and Navigli, 2020), a neural WSD model based on BERT (Devlin et al., 2019), which has attained state-of-the-art performances on English as well as other languages. EWISER has been trained on SemCor (Miller et al., 1993) – the standard training set for WSD – and the WordNet Gloss corpus (Langone et al., 2004) – a semi-automatically annotated dataset featuring sense definitions. Detailed statistics of the base and parallel corpora produced are provided in § A.5.

Translation Test Set

We evaluate standard translation quality through the *newstest* datasets available in the specific WMT year (i.e., WMTXX corresponds to *newstest20XX*). The standard evaluation is carried out by means of SacreBLEU (Post, 2018), with signature `BLEU+case.mixed+numrefs.1 +smooth.exp+tok.13a+version.1.5.1`.

Disambiguation Bias Challenge Sets

To measure the disambiguation bias of each model we employ the challenge sets introduced by Emelin et al. (2020), composed of sentences reserved from the WMT14 English→German corpus. These challenge sets are based on sense clusters built by automatically merging together BabelNet synsets, which then are manually refined to ensure their correctness. Each sense cluster contains an English polysemous word and a set of German monosemous terms, which uniquely identify a certain meaning.

These clusters are used to create the following two challenge sets: WSD Bias and Adversarial. The former quantifies the intrinsic bias the model learned during training, while the latter measures how sensitive the model is to the insertion of terms that are usually associated with another sense cluster during training. Both challenge sets evaluate in terms of accuracy of correct disambiguation. A more detailed description of these datasets and their evaluation process is provided in § A.1.

DIBIMT We also evaluate on the German and Spanish portions of DIBIMT (Campolungo et al., 2022), a recent fully-manually annotated disambiguation bias challenge set, where models are asked to translate English sentences containing ambiguous words, and their translations are checked for either correct or incorrect translation equivalents, which, in contrast to previous benchmarks, are annotated manually and depend on the context of the sentence instead of relying solely on the sense of the source word.

4.3 Comparison Systems

We compare our sense-enhanced model with the following architectures:

---

[6] With a fallback strategy to fast-align (Dyer et al., 2013) in case no alignment is produced.

[7] We filter out all nouns appearing in the stopwords list provided by BabelNet.

1. *OPUS* (Tiedemann and Thottingal, 2020): a strong bilingual model which uses the same architecture and parameter count as ours, although it was trained on order of magnitudes more data;
2. *MBart-50* (Tang et al., 2021): the English-to-many version of the MBart-50 model;
3. *Baseline*: our base NMT models, trained on the datasets described in § 4.2.

In what follows we refer to our model fine-tuned with SCR as *Baseline+SCR*.

We note that, due to the way in which the WSD Bias Challenge Sets were constructed (i.e., by using sentences reserved from WMT14, see § 4.2), any fair evaluation against OPUS and MBart-50 is to be considered impossible, as such models have seen the sentences in the challenge sets during training. We therefore evaluate these two models only on standard BLEU, and point out that the resulting scores should only be regarded as references for our models' competence in the translation task.

5 Results

In what follows, first, we show that our model attains BLEU scores in the same ballpark as state-of-the-art approaches such as OPUS and MBart-50, despite the large gap in terms of parameters or training data. Then, we focus our evaluation on the WSD Bias, and compare our full-fledged model (*Baseline+SCR*) against its baseline variant.

5.1 General Translation Quality

In Table 1 we observe that the trained baselines are more than competent in the translation task: indeed, when considering average BLEU scores, they place between OPUS, which is trained on much more data but has the same parameter count, and MBart-50 (Tang et al., 2021), which is ~8 times larger but is capable of translating English to 50 languages.

In contrast to common debiasing techniques, which often observe a degradation in performance on standard benchmarks (Clark et al., 2019; He et al., 2019), we report consistent BLEU improvements on all language pairs, all of which are statistically significant at different p-values (Table 1), providing empirical proof that the proposed method does not hurt the model's general translation capability, while at the same time it helps models generate less biased translations (as will be discussed in the upcoming sections).

5.2 Disambiguation Bias

Results on the Disambiguation Bias Challenge Sets (§ 4.2) are reported in Table 2, for both of which we show improvements: on the WSD Bias Challenge Set, the bias is reduced, significantly, by more than 1%; similarly, on the Adversarial Challenge Set, we see a reduction of homographs mistakenly disambiguated due to the injection of adversarial adjectives of 0.27%. We attribute this lower impact to the artificial nature of the adversarial sentences, some of which, by manual inspection, display poor grammatical fluency.

5.3 WSD Performance

We conduct an analysis of the performance of EWISER on the English sentences of the WSD Bias Challenge Set, to see how it fares in comparison with our NMT models. Unfortunately, as the sense clusters are not directly associated with BabelNet synsets, we reconstruct this association automatically and manage to retrieve only 1847 of the 3000 sentences in the challenge set.

Having retrieved BabelNet synsets for the target terms, we can apply EWISER and check whether the disambiguated synset matches one of the synsets retrieved for the sense cluster of the challenge sentence. Let us consider our running example, "The energy comes from a distant plant.", one last time: if EWISER disambiguates the term *plant* to its sense of *organism*, we count it as a mistake, similarly to the case where our NMT model translates it as *pianta* instead of *impianto* (i.e., its sense of *factory*). With this in mind, we evaluate EWISER, Baseline and Baseline+SCR on the aforementioned subset of sentences; we report the results of this evaluation in Table 2 (bottom).

The results indicate that, for this setting, both NMT models actually perform quite a lot better than a pre-trained disambiguation system. One reason for this might be the different distributions the models are trained on: by design, the challenge sentences follow a distribution similar to the corpus used to train the NMT model, whereas EWISER is trained on sentences coming from news corpora from the 1960s and dictionary-like definitions. Moreover, in theory, if we were to apply the refinement process described in § 3.2 to disambiguate the challenge sentences, we would achieve a perfect score, as the target German lemmas are monosemous and thus the disambiguation is im-

Baseline+SCR$_{-AR}$	26.11	36.74	37.38	32.93
Baseline+SCR$_{\text{RAND}}$	25.63	34.79	/	/

Table 1: Standard evaluation results. Numbers represent SacreBLEU scores. Statistical significance is computed according to Paired Bootstrap Resampling (Koehn, 2004) w.r.t. the row above. Underlined numbers represent $\underline{p < 0.02}$ and $\underline{\underline{p < 0.001}}$.[8] † represents systems that accessed more training data than us, but with the same parameter count. ‡ represents systems that, beside access to a larger pool of data, also feature bigger underlying models.

plicitly solved. The results of using EWISER's raw annotations are discussed in § 5.5.

Finally, we choose not to perform a similar comparison on the Adversarial Challenge Set, as its examples are designed to specifically target NMT models via adversarial injections; we leave studying their impact in WSD systems as future work.

MODEL	WSD Bias ↓	Adversarial ↓
Baseline	12.27	4.48

Baseline+SCR$_{\text{RAND}}$	12.56	5.04
EWISER	13.70	/
Baseline$_{cf}$	11.86	/
Baseline+SCR$_{cf}$	9.91	/

Table 2: Results on WSD Bias Challenge Sets. Numbers represent error rates (lower is better). Underlined results represent statistical significance at $p < 0.001$, compared to the row above, according to McNemar's test (McNemar, 1947).

5.4 System Examples

In Table 3, we report some examples of disambiguation corrected by our model according to the WSD Bias Challenge Set. The baseline is translating the terms to their most frequent sense (column *Wrong sense*), instead of the correct one (column *Target sense*). Moreover, the third example shows that this is not only a word matching task, as the improved model is able choose the correct subword and can capture the nuances of meaning in more uncommon senses.

5.5 Ablation Study

Ablation on SCR To measure the importance of the KL term in the loss, we fine-tune the model without including it in the SCR objective (§ 3.3) and report the results in Tables 1 and 2 (row Baseline+SCR$_{-KL}$). We observe that, without KL, the model struggles to leverage the double inputs efficiently; indeed, its translation performance drops around 1 BLEU point on average, while the error rates increase by roughly 1% on both bias challenge sets. These results back our intuition that the KL divergence helps to distill sense information from the sense-enhanced inputs, and is indeed a crucial component to our formulation.

Ablation on ARES We also test our system replacing the pre-trained sense embeddings provided by ARES with randomly initialized learnable embeddings and report this result in Tables 1 and 2 (row Baseline+SCR$_{-ARES}$). As expected, both translation quality and disambiguation bias drop consistently. Indeed, learning sense embeddings from scratch is much harder than learning a mapping between a fixed space and a trainable one.

Ablation on Annotation Refinement We evaluate our sense Annotation Refinement process (§ 3.2) by fine-tuning the model on the unconstrained sense annotations provided by EWISER (Baseline+SCR$_{-AR}$), i.e., by considering the synset with the highest confidence on the source word as the correct one, instead of S^*. In the bias

Source sentence / **R**eference sentence / **B**aseline output / **E**nhanced output	Target sense	Wrong sense
S: [...] that both first words start with the same **letter**. **R**: [...] dass beide Begriffe mit demselben **Buchstaben** beginnen. **B**: [...] dass beide Wörter mit dem gleichen **Brief** beginnen. **E**: [...] dass beide Wörter mit dem gleichen **Buchstaben** beginnen.	*alphabet symbol*	*written message*
S: At least since the **fall** of 2008, leading economies' officials have agreed [...] **R**: Spätestens seit **Herbst** 2008 stimmen die Vertreter führender [...] **B**: Zumindest seit dem **Fall** 2008 haben sich die Beamten [...] **E**: Zumindest seit dem **Herbst** 2008 haben sich die Beamten [...]	*season*	*act of falling*
S: The construction of the Deurganck dock **lock** is [...] **R**: Der Bau der **Schleuse** am Deurganck-Dock ist [...] **B**: der Bau der Deurganck-**Hafensperre** ist [...] **E**: der Bau der Deurganck-**Hafenschleuse** ist [...]	*segment of a canal*	*blockade*

Table 3: Examples of sentences that were disambiguated correctly by our enhanced model but not by the baseline. Ambiguous word is in **blue**, wrong translation is in **red**, correct translation is in **green**.

Model	EN → DE	EN → ES
OPUS†	27.99	36.66
MBart-50‡	28.73	33.89
Baseline	24.00	26.44
Baseline+SCR	25.00	25.84

Table 4: Accuracy scores on DIBIMT. † and ‡ have the same meaning as in Table 1. Higher is better.

evaluation (Table 2), the performances on both challenge sets drop significantly ($p < 0.001$), which is in line with EWISER's performance on this challenge set (§ 5.3). Furthermore, the BLEU scores drop too, although not as significantly (Table 1), but still always under-performing with respect to Baseline+SCR.

Ablation on Sense Annotations Finally, we test whether the sense annotations have an impact by replacing them with random senses for the specific word, drawn from the sense vocabulary with uniform probability, during the fine-tuning stage (Baseline+SCR$_{\text{RAND}}$).[9] As expected, we observe that randomly injecting senses is detrimental, with important performance drops in both the standard and the bias evaluation benchmarks.

5.6 Evaluation on DIBIMT

In Table 4 we report the results obtained on DIBIMT (Campolungo et al., 2022). For the sake of conciseness, we only report accuracy scores as a proxy for the general disambiguation bias displayed by our models.

While on English→German we observe an improvement of 1%, the performance on English→Spanish decreases by around 0.6%. We hypothesize that our English→Spanish model might be undertrained, as its accuracy differs by around 10% from OPUS, its direct comparison, while on English→German the difference is only of around 3%. We leave further investigation of this issue, including training larger, more capable models, as future work.

6 Conclusions

In this paper, we presented a fine-tuning strategy that, by leveraging the explicit sense annotations produced by a novel high-precision technique, effectively reduces the disambiguation bias of a baseline Neural Machine Translation model while at the same time also strengthening translation performances, without introducing any requirement at inference time.

Our analysis on a strong disambiguation system showed that its ability to disambiguate polysemous nouns is worse than that of a baseline NMT model, at least in the studied out-of-domain setting.

We believe that this work paves the way for better bias reduction techniques in MT, while also fostering interest in the issue represented by the disambiguation bias. As future work, we plan to further study the ability of NMT models to perform Word Sense Disambiguation and to strengthen research at the intersection of these two fields, with a view to building stronger and more reliable models.

---

[9] Due to time constraints, we only perform this ablation on the English→German model.

A Appendix

A.1 Bias Evaluation Challenge Sets

We here provide a more detailed description of the datasets introduced by (Emelin et al., 2020). From § 4.2, recall that these challenge sets are based on sense clusters built on BabelNet, where each sense cluster contains an English polysemous word and a set of German monosemous terms, which uniquely identify a certain meaning.

We highlight that there is no direct link between the sense clusters and the data produced by our Annotation Refinement process, as the sense clusters are i) heavily manually refined[10] and ii) based on the entire BabelNet4 inventory (16M concepts), while EWISER only covers the subgraph of BabelNet linked to WordNet (117k concepts), as is common in the multilingual WSD setting. As such, we do not consider the evaluation to be in any way more favorable towards our system.

WSD Bias contains sentences whose targeted English term is likely to be translated into a specific different sense due to co-occurrences of words in the sentence itself. For example, in the sentence "a lot of money was spent to renovate the *capital*" the word *capital* is likely to be translated into its sense of *amount of money* due to the presence of the words *money* and *spent*. A mistake is detected if the term is translated into any of the German words contained in the most likely sense cluster. The goal of this task is to measure the intrinsic bias the model learned during training.

Adversarial contains two sets of sentences, the original sentence and its adversarial counterpart, built by injecting an adjective that is likely to flip the disambiguation performed by the NMT model towards a specific sense. For example, given the sentence "they met in the spring of 2020", the adversarial example would be "they met in the *hot* spring of 2020". The injection of *hot* leads the model to translate *spring* into its sense of *water source* as opposed to its correct sense of *season*. A mistake is detected every time the non-adversarial sentence is translated into the correct sense, whereas its adversarial counterpart is flipped to the sense cluster the adjective points to. The goal of this task is to measure how sensitive the model is to the insertion of terms that are usually associated with another sense cluster during training.

A.2 Training a Sense-Enhanced NMT Model

Our work is based on the assumption that providing a neural model with sense annotations for ambiguous words helps in disambiguating them. While this is rather intuitive, and has been shown to be the case in previous works (Nguyen et al., 2018; Pu et al., 2018b), we test this hypothesis in our setting by training an NMT model, from scratch, with sense-enhanced sentences only (see § 3.3 for details). We train a model comparable with the Baseline (i.e., same architecture and hyperparameters) on the English→German training set (§ 4.2), and observe that it achieves higher BLEU scores than the Baseline (which is trained on the same data but with plain sentences). For instance, the sense-enhanced model achieves a BLEU score of 27.22 on WMT14 and 36.79 on WMT19, with the first being a statistically significant improvement. This confirms, once again, that sense-enhanced NMT models are on par or better than plain NMT models, although they introduce the heavy requirement of WSD at inference time, which our work aims at dropping.

A.3 Reproducibility Details

Preprocessing Times The preprocessing of the datasets needed to apply Annotation Refinement (lemmatization, Part-of-Speech tagging and then disambiguation through EWISER) required around 4 days in total on an RTX 2080 Ti (roughly 3M sentences per day).

Training infrastructure and duration All our experiments were carried out on either an NVIDIA RTX 2080 Ti or a RTX 3090, depending on availability.

Model training required on average 4 days on a 3090, 7 days on a 2080 Ti. Fine-tuning epochs required around 10 hours each (on a 3090), with most finishing due to early stopping before the end of the second epoch.

Parameter counts We used HelsinkiNLP MarianMT models available on HuggingFace Transformers (Wolf et al., 2020) (e.g., for EN→DE, the model name is `Helsinki-NLP/opus-mt-en-de`). For

---

[10] As discussed in § 5.3, almost 40% of the challenge instances could not be linked back to BabelNet synsets, further confirming the impact of the manual refinement performed.

	WSD Bias		Adversarial		
MODEL	Correct ↑	%Error ↓	Correct ↑	%Error$_{ATTR}$ ↓	%Error$_{OTH}$ ↓
Baseline	71.37	12.27	86.10	4.48	0.40
Baseline+SCR	**73.27**	**11.23**	**87.36**	**4.21**	**0.34**
Baseline+SCR$_{-KL}$	70.37	12.43	85.30	5.13	0.40
Baseline+SCR$_{-ARES}$	70.53	12.53	85.75	4.75	0.45
Baseline+SCR$_{-AR}$	70.20	13.07	86.40	4.93	0.35

Baseline+SCR$_{cf}$	75.58	9.91	/	/	/

Table 5: Full results on WSD Bias Challenge Sets. Numbers represent percentages.

instance, EN→DE has 74.4M parameters, EN→ES has 77.9M, EN→FR has 75.1M.

For the fine-tuning stage we added ARES (frozen), thus adding a number of parameters equal to ARES's size (1536) times the number of unique synsets in the dataset (refer to Table 6 for approximate numbers). We also added a trainable projection layer of size $1536 * 512$ (512 is the Transformer's hidden dimension), thus adding $786k$ trainable parameters (which we drop after the fine-tuning).

Model training hyperparameters Similarly to (Emelin et al., 2020), we trained it on the entire dataset for a max of $100{,}000$ steps with approximately 24k tokens per batch, label smoothing at 0.1 and an inverse square root learning rate scheduler with 4000 warmup steps. As optimizer, we used Adam (Kingma and Ba, 2015) with betas $(0.99, 0.98)$ and learning rate $7 \cdot 10^{-4}$, additionally employing an early stopping strategy with patience 5, monitoring the BLEU score on a validation set. We produced translations at inference time using a beam size of 5.

Fine-tuning hyperparameters For the fine-tuning, we resumed training using the weights of the baseline models, changed the learning to $1 \cdot 10^{-5}$ and reduced the warmup to 1000 steps; additionally, we evaluated the model every 10% of the fine-tuning steps rather than after each epoch, as we observed fast convergence during fine-tuning and multiple epochs were superfluous.

A.4 Disambiguation Bias Results

Table 5 reports the same results displayed in the paper, but includes the percentage of Correct translations for both challenge sets as well as the percentage of errors made from sentences that, after the injection of the adversarial adjectives, were translated into a sense that was neither the correct one, nor the one targeted by the adversarial injection (i.e., other).

A.5 Data Statistics

CORPUS	EN-DE	EN-ES	EN-FR
# sentences	4.13M	3.54M	5.09M
# tokens (src / tgt)	99.7M / 96.8M	94.7M / 98.7M	133M / 142M
# annotated sentences	2.97M	3.11M	4.25M
# annotations	6.5M	11.2M	13.6M
# EN terms vocab	634k	592k	808k
# EN terms covered	34.0k	40.0k	37.5k
# unique synsets	16.0k	20.5k	15.7k

Table 6: Training and fine-tuning produced data statistics.

A.6 Limitations of this work

Our work focuses on reducing the disambiguation biases picked up by NMT models during training. We acknowledge some limitations in our work:

1. Due to limited computational budget and the large number of resources required to train and fine-tune NMT models from scratch, we had to limit ourselves to one run per experiment, though, despite this, the consistency across languages seems to point to the empirical correctness of the claims.

2. We evaluated the bias reduction explicitly only on the English→German language pair. The reason for this was twofold: first, the datasets introduced by Emelin et al. (2020) only cover said pair, and require the accompanying training data be used in order to fully exploit the co-occurrences (and hence the biases) that the model is evaluated upon; second, upon manual inspection, we found that MuCoW (Raganato et al., 2019) contains many irrelevant candidates in its translation suite, and is in general very strongly affected by the noisy nature of BabelNet.

3. Our pipeline is strictly tied to both the accuracy of the multilingual WSD system employed and by the coverage of the underlying sense inventory. While EWISER and BabelNet work reasonably well for high-resource languages, the quality of the annotated corpus might decrease for low-resource ones.

Mining Clues from Incomplete Utterance: A Query-enhanced Network for Incomplete Utterance Rewriting

Shuzheng Si[1,2*]**, Shuang Zeng**[1,2*]**, Baobao Chang**[1†]

Abstract

Incomplete utterance rewriting has recently raised wide attention. However, previous works do not consider the semantic structural information between incomplete utterance and rewritten utterance or model the semantic structure implicitly and insufficiently. To address this problem, we propose a **QUE**ry-**E**nhanced **N**etwork (**QUEEN**). Firstly, our proposed query template explicitly brings guided semantic structural knowledge between the incomplete utterance and the rewritten utterance making model perceive where to refer back to or recover omitted tokens. Then, we adopt a fast and effective edit operation scoring network to model the relation between two tokens. Benefiting from extra information and the well-designed network, QUEEN achieves state-of-the-art performance on several public datasets.

Turns	Utterances with Translation
u_1	Smith needs to find an expensive restaurant nearby. 史密斯需要在附近找一家昂贵的餐馆。
u_2	Does Smith care the type of cuisine? 史密斯关心菜肴的类型吗?
u_3	No, he does not care. 不，他不关心。
$u_3^{'}$	No, Smith does not care about the type of cuisine. 不，史密斯不关心菜肴的类型。

Table 1: An example in multi-turn dialogue including dialogue utterance history u_1 and u_2, incomplete utterance u_3 and rewritten utterance u_3'.

1 Introduction

Multi-turn dialogue modeling, a classic research topic in the field of human-machine interaction, serves as an important application area for pragmatics (Leech, 2003) and Turing Test. The major challenge in this task is that interlocutors tend to use incomplete utterances for brevity, such as referring back to (i.e., coreference) or omitting (i.e., ellipsis) entities or concepts that appear in dialogue history. As shown in Table 1, the incomplete utterance u_3 refers to "Smith" (''史密斯") from u_1 and u_2 using a pronoun "He" (''他") and omits "the type of cuisine" (''菜肴的类型") from u_2. This may cause referential ambiguity and semantic incompleteness problems if we only read this single utterance u_3, which is a common case of downstream applications like retrieval-based dialogue systems (Boussaha et al., 2019). Moreover, previous studies (Su et al., 2019; Pan et al., 2019) also find that coreference and ellipsis exist in more than 70% of the utterances, especially in pro-drop languages like Chinese. These phenomena make it imperative to effectively model dialogue in incomplete utterance scenarios.

To cope with this problem, previous works (Kumar and Joshi, 2016a; Elgohary et al., 2019; Su et al., 2019) propose the **I**ncomplete **U**tterance **R**ewriting (**IUR**) task. It aims to rewrite an incomplete utterance into a semantically equivalent but self-contained utterance by mining semantic clues from the dialogue history. Then the generated utterance can be understood without reading dialogue history. For example, in Table 1, after recovering the referred and omitted information from u_3 into u_3', we could better understand this utterance comprehensively than before.

Early works use coreference resolution methods (Clark and Manning, 2016) to identify the entity that a pronoun refers to. However, they ignore the more common cases of ellipsis. So the text generation-based methods (Su et al., 2019; Pan et al., 2019) are introduced to generate the rewritten sequence from the incomplete sequence by jointly considering coreference and ellipsis problems. Though effective, generation models neglect a key trait of the IUR task, where the main semantic structure of a rewritten utterance is usually similar to the original incomplete utterance. So the

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4839 - 4847
July 10-15, 2022

inherent structure-unawareness and uncontrollable feature of generation-based models impede their performances. For semantic structure-aware methods, Liu et al. (2020) utilize an edit operation matrix (e.g., substitution, insertion operations) to convert an incomplete utterance into a complete one. They formulate this task as a semantic segmentation problem with a CNN-based model (Ronneberger et al., 2015) on the matrix to capture the semantic structural relations between words implicitly. Xu et al. (2020) attempt to add additional semantic information to language models (Devlin et al., 2019) by annotating semantic role information but it is time-consuming and costly. Huang et al. (2021) propose a semi-autoregressive generator using a tagger to model the some considerable overlapping regions between the incomplete utterance and rewritten utterance, yet only implicitly learn the difference between them. Although these methods maintain some similarities between the incomplete utterance and the rewritten utterance (i.e., the overlap between them), it is difficult for these methods to explicitly model the semantic structure, especially the difference between the two utterances, ignoring the information in the incomplete utterance, such as which tokens are more likely to be replaced and which positions are more likely to require the insertion of new tokens. Therefore, there are still limitations of existing methods for IUR task, especially in jointly considering coreference and ellipsis cases and better utilizing semantic structural information.

This paper proposes a simple yet effective **QUE**ry-**E**nhanced **N**etwork (**QUEEN**) to solve the IUR task. QUEEN jointly considers coreference and ellipsis problems that frequently happen in multi-turn utterances. Specifically, we propose a straightforward query template featuring two linguistic properties and concatenate this query with utterances as input text. This query explicitly brings semantic structural guided information shared between the incomplete and the rewritten utterances, i.e., making model perceive where to refer back to or recover omitted tokens. We regard the rewritten utterance as the output from a series of edit operations on the incomplete utterance by constructing a token-pair edit operation matrix, which attempts to model the the overlap between the incomplete utterance between the rewritten utterance. Different from Liu et al. (2020), we adopt a well-designed edit operation scoring network on the matrix to perform incomplete utterance rewriting, which is faster and more effective. QUEEN brings semantic structural information from linguistics into the model more explicitly and avoids unnecessary overheads of labeled data from other tasks. Experiments on several IUR benchmarks show that QUEEN outperforms previous state-of-the-art methods. Extensive ablation studies also confirm that the proposed query template makes key contributions to the improvements of QUEEN.

2 Methodology

Overview Our QUEEN mainly consists of two modules: query template construction module (Sec. 2.1) and edit operation scoring network module (Sec. 2.2). From two linguistic perspectives, the former module aims to generate a query template for each incomplete utterance, i.e., coreference-ellipsis-oriented query template, to cope with coreference and ellipsis problems. This query template explicitly hints the model where to refer back and recover omitted tokens. The latter module tries to capture the semantic structural relations between tokens by constructing an edit operation matrix. As shown in Figure 1, our goal is to learn a model to generate correct edit operations on this matrix and compute edit operation scores between token pairs so as to convert the incomplete utterance into the complete one.

2.1 Query Template Construction Module

By observing incomplete and rewritten utterance pairs in existing datasets, we find that pronouns and referential noun phrases in the incomplete utterance often need to be substituted by text spans in dialogue history. And ellipsis often occurs in some specific positions of incomplete utterance, conforming to a certain syntactic structure. In this module, we expect to encode these linguistic prior knowledge into the input of QUEEN. The query template is constructed as follows:

Coreference-oriented Query Template In order to make QUEEN perceive the positions of coreference that need to be substituted by text spans from dialogue history, we use a special token `[COREF]` to replace pronouns and referential noun phrases in the incomplete utterance so as to get our coreference-oriented query template. For example, the coreference-oriented query template of the incomplete utterance “No, he does not care” (“不，他不关心”) is “No, `[COREF]` does not

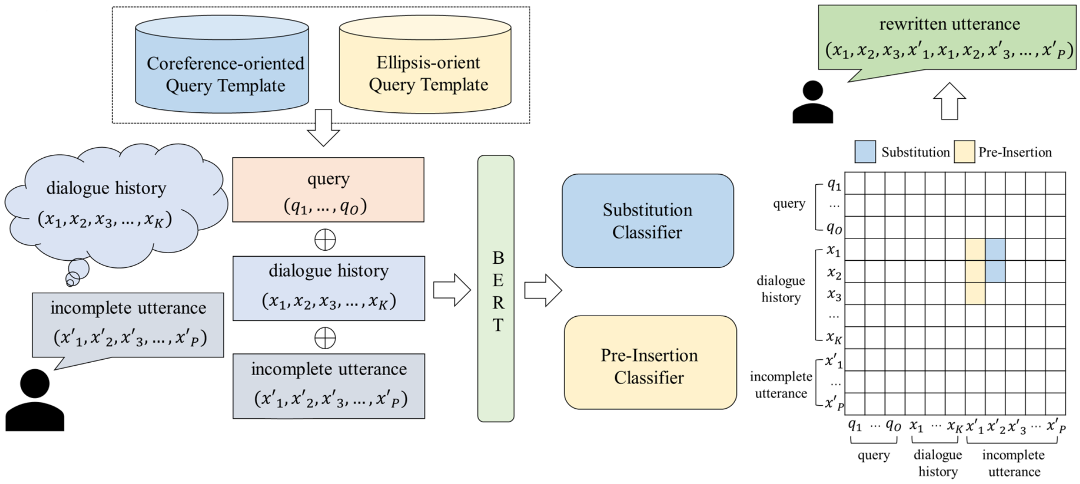

Figure 1: General architecture of QUEEN.

care” (“不,[COREF] 不关心”) . To get the target complete utterance, this query explicitly tells the model we should replace the “He” (“他”) with text spans (such as ’Smith’(“史密斯”)) from dialogue history, rather than replacing other words. Here, we find all pronouns that required to be replaced using a predefined pronoun collection.

Ellipsis-oriented Query Template To make QUEEN perceive the positions of ellipsis that need to be inserted by text spans from dialogue history, we define a special token `[ELLIP]` and put it in a linguistically right place of the incomplete utterance. Since a self-contained utterance usually contains a complete S-V-O (Subject-Verb-Object) structure, if an incomplete utterance lack any of these key elements, we could assume there is a case of ellipsis in its corresponding text position. So we perform dependency parsing on the incomplete utterance to get the structure of the incomplete utterance. For example, the parsing result of the incomplete utterance “No, he does not care” (“不, 他不关心”) is an S-V structure and lack object element, thus we put `[ELLIP]` at the end of the sentence to get the ellipsis-oriented query template as “No, he does not care `[ELLIP]`” (“不, 他不关心 `[ELLIP]`”). Other circumstances are detailed in the Appendix.

Then we fuse these two query templates into the final coreference-ellipsis-oriented query template. For incomplete utterance “No, he does not care” (“不, 他不关心”), we get “No, `[COREF]` does not care `[ELLIP]`’ (“不,`[COREF]` 不关心 `[ELLIP]`”) as our final query template. Under supervised setting, the models will perceive the positions to refer back and recover omitted tokens for this utterance. For a multi-turn dialogue $d = (u_1, ..., u_{N-1}, u_N)$ containing N utterances where $u_1 \sim u_{N-1}$ are dialogue history and the last utterance u_N needs to be rewritten, we could get the dialogue history text $s = (w_1^1, ..., w_i^n, ..., w_{L_N}^N)$ where w_i^n is the i-th token in the n-th utterance and L_n is the length of n-th utterance. We then concatenate our coreference-ellipsis-oriented query template with the dialogue history text to get our final input text $s' = (w_1^q, ..., w_k^q, ..., w_M^q, w_1^1, ..., w_i^n, ..., w_{L_N}^N)$ where w_k^q is the k-th token of the query template and M is the length of query template.

2.2 Edit Operation Scoring Network Module

Since pre-trained language models have been proven to be strongly effective on several natural language processing tasks, we employ BERT (Devlin et al., 2019) to encode our input text to get the contextualized hidden representation $H = (h_1^q, ..., h_k^q, ..., h_M^q, h_1^1, ..., h_i^n, ..., h_{L_N}^N)$. Our model attempts to predict whether there is an edit operation between each token pair. To this end, we define an operation scoring function as follows. Since the order of utterance is also important for dialogue, we further use RoPE (Su et al., 2021) to provide relative position information :

$$q_i^\alpha = W^\alpha h_i + b^\alpha \tag{1}$$

$$k_j^\alpha = W^\alpha h_j + b^\alpha \tag{2}$$

$$s_{ij}^\alpha = (R_i q_i^\alpha)^T (R_j k_j^\alpha) \tag{3}$$

where α is edit operation type including *Substitution* and *Pre-Insertion*. For different operations, we use different trainable parameters W^α and b^α.

Table 3: Experimental results on Restoration-200K. Additionally, we reproduce from the released code to get EM of RUN. †: Results from Liu et al. (2020). ‡: Results from Xu et al. (2020).

R is a transformation matrix from RoPE to inject position information and s^{α}_{ij} is the score for α-th edit operation from i-th token in dialogue history to j-th token in incomplete utterance.

During decoding for α-th operation, edit operation label $\mathcal{Y}^{\alpha}_{ij}$ satisfies:

$$\mathcal{Y}^{\alpha}_{ij} = \begin{cases} 1 & s^{\alpha}_{ij} >= \theta \\ 0 & s^{\alpha}_{ij} < \theta \end{cases} \tag{4}$$

where θ is a hyperparameter. Once $\mathcal{Y}^{\alpha}_{ij}$ equals to 1, the edit operation α should be performed between token i and token j.

Since the label distribution of edit operation is very unbalanced (most elements are zeros), we employ Circle Loss (Sun et al., 2020) as our objective function to mitigate this problem :

$$log(1 + \sum_{(i,j)\in\Omega_{pos}} e^{-s^{\alpha}_{i,j}}) + log(1 + \sum_{(i,j)\in\Omega_{neg}} e^{s^{\alpha}_{i,j}}) \tag{5}$$

3 Experiments

3.1 Experimental Setup

Datasets We evaluate our model on four IUR benchmarks from different domains and languages: REWRITE (Chinese, Su et al., 2019), Restoration-200K (Chinese, Pan et al., 2019), TASK (English, Quan et al., 2019), CANARD (English, Elgohary et al., 2019). More statistical details for datasets are shown in the Appendix.

Table 5: Experimental results on CANARD. †: Results and evaluation metrics from Liu et al. (2020).

Evaluation We use BLEU (Papineni et al., 2002), ROUGE (Lin, 2004) and the exact match (EM score) as our evaluation metrics.

Baseline Models We compare our model with a large number of baselines and state-of-the-art models. (i) **Baselines and Generation models** include sequence to sequence model (L-Gen) (Bahdanau et al., 2014), the hybrid pointer generator network (L-Ptr-Gen) (See et al., 2017a), the basic transformer model (T-Gen) (Vaswani et al., 2017) and the transformer-based pointer generator (T-Ptr-Gen) (See et al., 2017a), Syntactic (Kumar and Joshi, 2016b), PAC (Pan et al., 2019), L-Ptr-λ and T-Ptr-λ (Su et al., 2019), GECOR (Quan et al., 2019). Above methods need to generate rewritten utterances from scratch, neglecting the semantic structure between a rewritten utterance and the original incomplete utterance. (ii) **Structure-aware models** include CSRL (Xu et al., 2020), RUN (Liu et al., 2020), SARG (Huang et al., 2021).

3.2 Results and Analysis

Main Results We report the experiment results in Table 2, Table 3, Table4 and Table 5. On all datasets with different languages and evaluation metrics, our approach outperforms all previous state-of-the-art methods. The improvement in EM shows that our model has a stronger ability to find the correct span, due to our model making full use of the prior information of semantic structure from our coreference-ellipsis-oriented query template. On the Chinese datasets Table 2 and Table 3, QUEEN outperforms previous methods. Since Chinese is a pro-drop language where coreference and ellipsis often happen, the improvement confirms that QUEEN is superior in finding the correct ellipsis and referring back positions. The results on data sets of different domains and languages also show that our model is robust and effective.

Ablation Study To verify the effectiveness of the query in our model, we present an ablation study in Table 8 in the Appendix. It is clear that query is important to improve performance on all evaluation metrics. Meanwhile, only using coreference-oriented or ellipsis-oriented template still improves the performance, as it can also bring semantic structure information.

Inference Speed Meanwhile, we compare inference speed between our Edit Operation Scoring Network and the current fastest model RUN in A.5. As we remove the heavy model U-net of RUN and apply the simple network, our Edit Operation Scoring Network is faster than previous SOTA RUN.

Case Study We also do a case study in the Appendix. Our model avoids the uncontrolled situations that the generation-based model is prone to, and our model can more easily capture the correct semantic span.

4 Conclusion

We propose a simple yet effective query-enhanced network for IUR task. Our well-designed query template explicitly brings semantic structural information to improve the ability to predict correct edit operations between incomplete utterance and complete one. Experiments have shown that our model with this well-designed query achieves promising results than previous methods.

A Experimental Details

A.1 Constructing Supervision

The expected supervision for our model is the edit operation matrix, but existing datasets only contain rewritten utterances. So we adopt Longest Common Subsequence (LCS) and 'Distant Supervision' (Liu et al., 2020) to get correct supervision, which contains edit operations *Substitute* and *Pre-Insert*.

A.2 Details in Query Construction

Coreference-oriented Query During the training, we use the ground truth of pronouns and referential noun phrases to construct the coreference-oriented query. During the inference, we use the constructed pronoun collection to construct the coreference-oriented query, which contains pronouns and referential noun phrases from training data and common pronouns (except ''我", "me" etc.).

Ellipsis-oriented Query Construction If the parsing result of the incomplete utterance is an S-V (Subject-Verb) structure and lacks subject element, we insert an `[ELLIP]` at the end of the incomplete utterance as the query. When there is not the S-V structure after parsing, we insert an `[ELLIP]` at the beginning of the incomplete utterance as the query. In other cases, we insert `[ELLIP]` at both the beginning and end of the incomplete utterance as the query. We use spaCy[1] for English and LTP(Che et al., 2020) for Chinese to get the result of parsing.

Extra findings During the experiment, we find two interesting points: (i) As `[COREF]` and `[ELLIP]` are sparse respectively, we use a unified token `[UNK]` to replace `[COREF]` and `[ELLIP]` in the query to relieve the sparsity. (ii) In most cases, if there is the referring back in the utterance, there is generally no ellipsis in the utterance. Redundant `[ELLIP]` tokens can't bring correct guided information in this case. Therefore, once we construct Coreference-oriented Query Template successfully, we will not try to construct the Ellipsis-oriented Query Template. Our experimental results are improved by the above two tricks.

A.3 Datasets details

	Restoration-200K	REWRITE	TASK	CANARD
Language	Chinese	Chinese	English	English
His Avglen	25.8	17.7	52.6	85.4
Inc Avglen	8.6	6.5	9.4	7.5
Rew Avglen	12.4	10.5	11.3	11.6

Table 6: Statistics of different datasets. 'Avglen' for average length, 'His' for historical utterance, 'Inc' for incomplete utterance, and 'Rew' for rewritten utterance.

Model	Inference Speed	Speedup
RUN+BERT	1.69it/s	1.00×
QUEEN	**2.13it/s**	**1.26×**

Table 7: The inference speed comparison between RUN and QUEEN on REWRITE dataset.

Some statistics are shown in Table 6. REWRITE and Restoration-200K are constructed from Chinese Open-Domain Dialogue. TASK is from English Task-oriented Dialogue. CANARD is constructed from English Context Question Answering. We fellow the same data split as their original paper.

A.4 Details in Scoring Network

Hyper-parameters We implement our model on top of a BERT-base model (Devlin et al., 2019). We initialize QUEEN with bert-base-uncased for English and bert-base-chinese for Chinese. We use Adam (Kingma and Ba, 2015) with learning rate 1e-5. The batch size is set to 16 for REWRITE and TASK, 12 for Restoration-200K, 4 for on CANARD. Meanwhile, θ in Equation 4 is set to 0.1 for REWRITE and TASK, 0.05 for Restoration-200K and CANARD.

Circle Loss We tune Circle Loss the same as Zhang et al. (2021) and Su[2]. We refer readers to their paper for more details.

A.5 Inference Speed

To compare the inference speed between the current fastest model RUN and our Edit Operation Scoring Network, we conduct experiments using the code released [3]. Both models are implemented in PyTorch on a single NVIDIA V100. The batch size is set to 16. Meanwhile, In order to fairly compare the speed of the two networks, we performed Distant Supervision and Query Construction before comparing. The results are shown in Table 7.

Variant	EM	B_1	B_2	B_3	B_4	R_1	R_2	R_L
QUEEN	**70.1**	**94.7**	**92.1**	**89.5**	**86.9**	**96.0**	**90.9**	**94.6**
-w/o query	67.4	92.9	90.5	88.1	85.7	95.2	90.1	94.0
-w/o CQT	67.9	93.5	91.0	88.5	86.0	95.5	90.4	94.2
-w/o EQT	67.4	93.5	91.1	88.5	85.9	95.4	90.3	94.3

Table 8: The ablation results on the development set of REWRITE. "w/o query" means that we do not append a designed query before encoding that semantic information into our model. "w/o CQT" means that we only perform Ellipsis-oriented Query Template. "w/o EQT" means that we only perform Coreference-oriented Query Template and use the incomplete utterance as query if match fails.

A.6 Case Study

Table 9 gives 3 examples that indicate the representative situations as Hao et al. (2021). The first example illustrates the cases when RUN inserts unexpected characters into the wrong places. T-Ptr-Gen just copies the incomplete utterance. Due to our generated query, the position that needs to be inserted has been explicitly promoted by the query. The second example shows a common situation for generation-based models. T-Ptr-Gen messes up by repeating stupidly. However, this situation doesn't happen to our model, as it is not a generation-based model. The last example refers to a long and complex entity. For these cases, it is easier for our model to get the correct span. This is because our model learns the span boundaries from the edit operation matrix. Compared to the generation-based model, we don't generate sentences from scratch and this reduces the difficulty. Meanwhile, our model is not based on CNN as RUN, which suffers from the limitation of receptive-field to find a longer span.

A.7 Limitation

One limitation of current edit-based IUR models, is that only tokens that have appeared in the history dialogue can be selected. Therefore, these models, including ours, cannot generate novel words, e.g., conjunctions and prepositions, to cater to other metrics, like fluency. However, this can be alleviated by incorporating an additional word dictionary as See et al. (2017b) and Liu et al. (2020) deals with the out-of-vocabulary (OOV) words to improve fluency. For fairness, we keep the same words during the experiment as RUN to mitigat it. We will consider this question as a promising direction for future works.

Example # 1

Historical Utterance 1	我意见很大 I have a lot of complaints
Historical Utterance 2	有意见保留 Keep it yourself if there’s any
Incomplete Utterance	不想保留 Don’t want to keep it myself

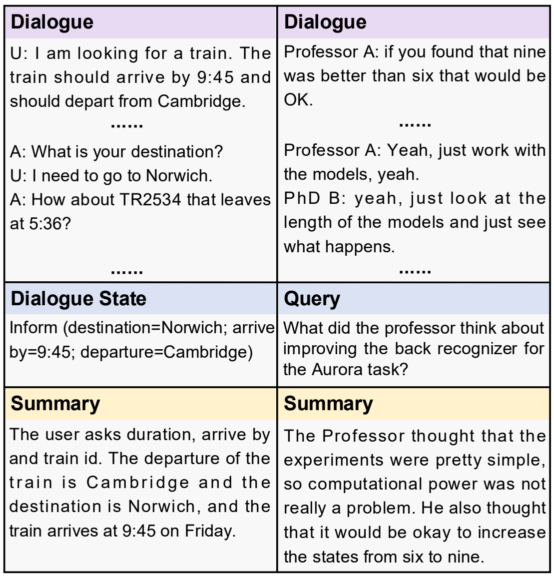
Abstract

The most advanced abstractive dialogue summarizers lack generalization ability on new domains and the existing researches for domain adaptation in summarization generally rely on large-scale pre-trainings. To explore the lightweight fine-tuning methods for domain adaptation of dialogue summarization, in this paper, we propose an efficient and generalizable **D**omain-**O**riented **P**refix-tuning model, which utilizes a domain word initialized prefix module to alleviate domain entanglement and adopts discrete prompts to guide the model to focus on key contents of dialogues and enhance model generalization. We conduct zero-shot experiments and build domain adaptation benchmarks on two multi-domain dialogue summarization datasets, TODSum and QMSum. Adequate experiments and qualitative analysis prove the effectiveness of our methods.

1 Introduction

Abstractive dialogue summarization task aims to distill the most critical information in a conversation to produce a concise version, involving chit-chat (Gliwa et al., 2019; Chen and Yang, 2020), meeting(Zhong et al., 2021), customer service (Liu et al., 2019; Zou et al., 2021b), and task-oriented dialogue scenarios (Zhao et al., 2021b). Compared to the single-speaker texts, summarizing a dialogue presents a unique set of challenges, such as unstructured expressions and information sparsity issues. Recently, large-scale generative pre-trained models (Lewis et al., 2020; Liu and Lapata, 2019) have promoted the development of abstractive dialogue summarization but they all require extensive human-annotated golden summaries, which makes them not scalable to new domains where only few/no labeled data is available. Considering that real-world applications often face the problem of data in the new domain, it is vital to develop low-resource dialogue summarization models for the target domain by leveraging limited annotated data of source domains.



Dialogue	**Dialogue**
U: I am looking for a train. The train should arrive by 9:45 and should depart from Cambridge. …… A: What is your destination? U: I need to go to Norwich. A: How about TR2534 that leaves at 5:36? ……	Professor A: if you found that nine was better than six that would be OK. …… Professor A: Yeah, just work with the models, yeah. PhD B: yeah, just look at the length of the models and just see what happens. ……
Dialogue State	**Query**
Inform (destination=Norwich; arrive by=9:45; departure=Cambridge)	What did the professor think about improving the back recognizer for the Aurora task?
Summary	**Summary**
The user asks duration, arrive by and train id. The departure of the train is Cambridge and the destination is Norwich, and the train arrives at 9:45 on Friday.	The Professor thought that the experiments were pretty simple, so computational power was not really a problem. He also thought that it would be okay to increase the states from six to nine.

Figure 1: An example of TODSum dataset (Zhao et al., 2021b) with dialogue state and an example of QMSum dataset (Zhong et al., 2021) with query. Note that dialogue state and query are existing characteristics of these two datasets, respectively.

Therefore, we try to explore the efficient domain adaptation of dialogue summarization models from the source domain D_s to the target domain D_t, where D_s only has limited annotated summaries and D_t has few/no labeled data. There exist some domain adaptation approaches that focus on continual pre-trainings using some large domain/task-related corpora. Yu et al. (2021) added multiple pre-training stages both on source domains and target domains. Further, Zou et al. (2021c) decomposed the pre-training into three procedures, i.e., the pre-training of encoder, decoder, and the combined encoder-decoder model. Fabbri et al. (2021) constructed pseudo summaries based on external Wikipedia data to simulate characteristics of target dataset. Note that all these methods re-

July 10-15, 2022

quire time-consuming pre-trainings or large-scale external corpora. They only focus on the heavy pre-training stage rather than the lightweight fine-tuning, which makes it labor-expensive and environmentally unfriendly (Schwartz et al., 2020) to practical applications.

Different from existing works that adopt general pre-trainings on the large-scale external corpora, we focus on exploring efficient fine-tuning methods specifically targeted at domain adaptation for the dialogue summarization task. We consider the following key principles while designing our methods: (1) **Efficiency**: We do not use any external data or pre-training and aim at leveraging efficient fine-tuning mechanisms based on existing summarization models. (2) **Domain Disentanglement**: Traditional models often memorize excessive knowledge from D_s and generate wrong summaries containing specific domain words in D_s. We aim to disentangle shared domain knowledge from D_s. (3) **Generalization**: Models often learn specific features of the source domain, making it difficult to generalize in a new domain (Peng et al., 2019). For example, models learn the surface language style specific to D_s rather than adapting the way of saliency estimation and summary generation to D_t. We encourage the summarizer to only focus on generic key contents rather than domain-specific attributes.

To be consistent with above principles, we propose a lightweight and efficient **D**omain-**O**riented **P**refix-tuning method, DOP, for domain adaptation of dialogue summarization. For efficiency, we focus on fine-tuning summarization models instead of performing pre-trainings like existing works, which reduces expensive and time-consuming computation. For domain disentanglement, we design a domain-oriented prefix module, which contains a novel prompt initialization mechanism. Concretely, we use domain words extracted by unsupervised LDA (Hoffman et al., 2010) to initialize continuous prompt vectors and fit the outputs of MLP and pre-computed BART to obtain initial parameters and representations of the prefix module. We also add a domain-oriented prefix sequence of key-value pairs to augment the classical attention layer, which is independently applied to all Transformer layers of pre-trained models to elicit the knowledge interactively and achieve overall optimization. In this case, different domain words from D_s and D_t can induce relevant domain knowledge while adapting to a new domain. For generalization, we construct discrete prompts using dialogue states or queries, as shown in Figure 1, to guide the model to focus on key contents in dialogues and enhance generalization capability on unseen domains. Considering there is no unified and practical benchmark for domain adaptation of dialogue summarization [1], we build domain adaptation benchmarks based on two existing multi-domain summarization datasets TODSum (Zhao et al., 2021b) and QMSum (Zhong et al., 2021). Extensive experiments demonstrate the benefits of our methods both in zero-shot and few-shot settings for domain adaptation.

Our contributions are threefold: (1) To the best of our knowledge, we are the first to explore fine-tuning methods for domain adaptation of dialogue summarization task, and establish two practical and comprehensive benchmarks for TODSum and QMSum datasets. (2) We propose a lightweight and efficient Domain-Oriented Prefix-tuning model, with domain word initialized prefix and discrete prompts, to elicit knowledge from large-scale pre-trained models interactively. (3) We conduct sufficient experiments and qualitative analysis to prove the effectiveness of our methods and discuss current challenges of domain adaptation for dialogue summarization.

2 Related Work

Abstractive Dialogue Summarization Dialogue summarization has drawn much attention recently. For chit-chat scenarios, researchers improved the performance on SAMSum dataset (Gliwa et al., 2019) via topic word information (Zhao et al., 2020; Liu et al., 2021), conversational structures (Chen and Yang, 2020, 2021), personal named entity planning (Liu and Chen, 2021), and semantic slots (Zhao et al., 2021a). Liu et al. (2019), Zou et al. (2021a,b), and Lin et al. (2021) proposed customer-service dialogue summarization datasets under diverse business scenarios. Besides, meeting transcripts, such as AMI (Carletta et al., 2005), ICSI (Janin et al., 2003), MediaSum (Zhu et al., 2021), and QMSum (Zhong et al., 2021), were also studied to promote dialogue summarization technologies. Zhao et al. (2021b) further proposed a task-oriented dialogue summariza-

---

[1] Existing work mostly takes news datasets like CNN/DailyMail (Hermann et al., 2015) as source domains and dialogue datasets like SAMSum (Gliwa et al., 2019) as target domains. We argue the setting doesn't fit in with industrial scenarios transferring from one business to another, like from attraction consultation to hotel reservation.

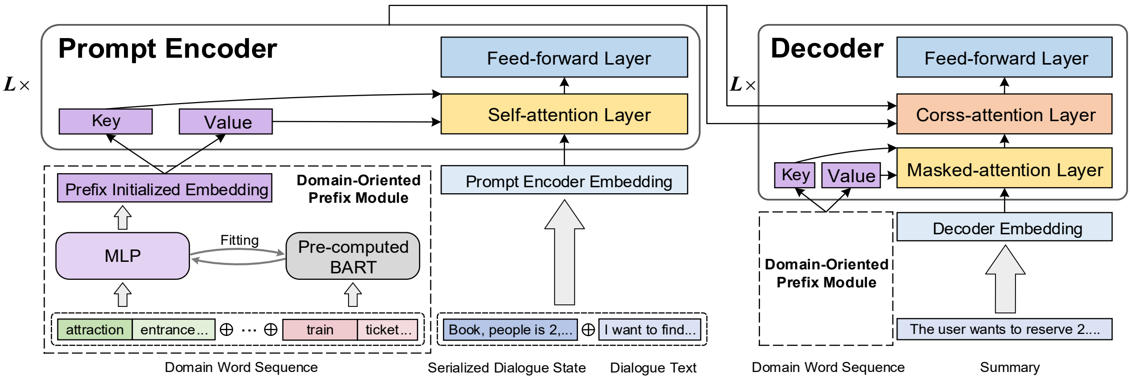

Figure 2: Overview of the Domain-Oriented Prefix-tuning model. The input sequence of domain-oriented prefix module includes domain words from four source domains, i.e., *attraction, hotel, taxi, train* and the domain words of *restaurant* domain are used as the prefix sequence of the target domain during the test. The input sequence of prompt encoder is the dialogue state from TODSum dataset and its original dialogue text. The input sequence of decoder is the golden summary. Here, we use the pre-computed outputs of BART as the target of the fitting process to initialize the parameters of MLP. Note that the grey pre-computed BART module does not participate in the training of the model.

tion dataset ,TODSum, with dialogue state knowledge. Although great progress has been made in dialogue summarization, few people pay attention to the issue of domain adaptation in dialogue summarization. In this paper, we explore this issue in two multi-domain dialogue summarization datasets, i,e, TODSum and QMSum.

Domain Adaptation in Summarization Hua and Wang (2017) and Wang et al. (2019) adopted the document categories in news publications to build a multi-domain summarization dataset and investigated the domain shift for extractive summarization task. Yang et al. (2020), Zhang et al. (2020), Magooda and Litman (2020), and Fabbri et al. (2021) regarded diverse summarization datasets as different domains and conducted the assessment of multi-domain settings. Furthermore, various stages of pre-trainings were added to narrow the gap between the pre-training in news domain and the fine-tuning in dialogue domain (Yu et al., 2021; Zou et al., 2021c). However, these methods focus on the heavy pre-training stage rather than the lightweight fine-tuning, which is time-consuming and relies on large-scale external corpora. Therefore, we try to explore the fine-tuning methods for domain adaptation of dialogue summarization task.

Prompts in Summarization With the arrival of GPT-3, prompt learning has become a nascent field, which conducts task-specific adaptation of large language models (LMs) via prepending an instruction. Schick and Schütze (2021) explored the fixed-prompt LM tuning for few-shot text summarization with manually crafted templates. Zhao et al. (2021b) and Dou et al. (2021) further adopted the prompt+LM tuning strategy on text summarization task, where learnable prefix prompts are different types of guidance signals. Li and Liang (2021) investigated fixed-LM prompt tuning, where learnable prefix tokens are prepended to the input while parameters in pre-trained models are frozen. Following Li and Liang (2021), we design the domain information to initialize the continuous prefix module, and use discrete prompts and dialogue texts to optimize prefix parameters, which greatly reduces the size of parameters and is suitable for low-resource scenarios.

3 Problem Formulation

Domain adaptation of dialogue summarization aims to generate the summary $\mathbf{y}$ conditioned on the source dialogue $\mathbf{x}_d$, where the training and test are in different domains. We add the domain word prefix $\mathbf{x}_{dw}$ and discrete prompt $\mathbf{x}_{dp}$ as additional input which we will describe details later. Note that we only update the prefix-related parameters and fix the parameters of BART. We train the model using the source data and test using the target data.

4 Methodology

As Figure 2 shows, our model is on the basis of the framework of BART, including a domain-oriented prefix module, a prompt encoder, and a decoder.

4.1 Domain-oriented Prefix

To alleviate domain entanglement, we present a domain-oriented prefix module to obtain the shared knowledge of the source domain D_s and the target domain D_t. It is designed as follows:

Initialization We extract some keywords from dialogue texts in each domain by LDA (Hoffman et al., 2010) and concatenate them all together as a domain word (prefix) sequence $\mathbf{x}_{dw}$[2]. Randomly initialized embeddings of the domain word sequence compose a learnable matrix $M_\theta \in \mathbb{R}^{|\mathbf{x}_{dw}| \times d_m}$.

Parametrization We use an MLP to encode the domain-oriented prefix module, which stably elicits knowledge from the large pre-trained model in the prefix-tuning process. Specifically, we first input the domain word sequence to the MLP and the pre-computed BART respectively, then re-train the MLP by fitting its outputs with the decoder hidden states of the pre-computed BART using MSE loss. In this fitting process, we only iteratively update MLP parameters $\varphi \in \mathcal{R}^{d_m \times d_n}$ and keep the pre-computed BART fixed. Finally, we get the initialization parameters of MLP and use this pre-trained MLP to map the initialized embeddings of prefix representations for each Transformer layer both in prompt encoder and decoder:

$$M_\theta'[i,:] = \mathrm{MLP}_\varphi(M_\theta[i,:]) \tag{1}$$

where $i \in \mathbf{x}_{dw}$ and $M_\theta' \in \mathbb{R}^{|\mathbf{x}_{dw}| \times d_n}$. Note that this continuous prefix is applied for every layer of the large-scale pre-trained model independently.

4.2 Prompt Encoder

Discrete Prompts We utilize some discrete prompts to emphasize key elements in dialogues and enhance the model generalization to new domains. Here, discrete prompts are dialogue states of TODSum dataset or queries of QMSum. Considering that the original form of dialogue states is *book (people=5; day=Monday)* which is not compatible with BART encoder, we convert this structured information into a serialized sequence, i.e., *book, people is 5, day is Monday*, to improve the stability of training. Note that we do not make any changes to the query of QMSum dataset because it is already a serialized representation.

For prompt encoder, we firstly concatenate the discrete prompt sequence $\mathbf{x}_{dp}$ and dialogue text sequence $\mathbf{x}_d$ as the input sequence of encoder, i.e., $\mathbf{x}_{enc} = [\mathbf{x}_{dp}; \mathbf{x}_d]$. Then, the $\mathbf{x}_{enc}$ is fed into the prompt encoder based on the BART encoder, containing multiple Transformer layers. Note that we modify the self-attention mechanism by adding a domain-oriented prefix sequence of key-value pairs, which learns the knowledge from the pre-trained model through interactions with the dialogue text to carry out the overall task. For the typical l_e-th Transformer layer in encoder, the query ($\mathbf{Q}_{l_e}$), key ($\mathbf{K}_{l_e}$), and value ($\mathbf{V}_{l_e}$) matrices are computed through linear transformations on the hidden states of $\mathbf{x}_{enc}$. Here, we further augment the $\mathbf{K}_{l_e}$ and $\mathbf{V}_{l_e}$:

$$\mathbf{K}_{l_e}' = [\mathbf{P}_{l_e,k}; \mathbf{K}_{l_e}],\ \mathbf{V}_{l_e}' = [\mathbf{P}_{l_e,v}; \mathbf{V}_{l_e}] \tag{2}$$

where $\mathbf{P}_{l_e,k}$, $\mathbf{P}_{l_e,v}$ are computed through linear transformations on M_θ'. $\mathbf{K}_{l_e}', \mathbf{V}_{l_e}' \in \mathbb{R}^{(|\mathbf{x}_{dw}|+|\mathbf{x}_{dp}|+|\mathbf{x}_d|) \times d_n}$ and $l_e \in L$. The augmented self-attention layer is finally calculated as follows:

$$\mathbf{A}_{self} = \mathrm{softmax}(\mathbf{Q}_{l_e} \mathbf{K}_{l_e}'^{T}) \mathbf{V}_{l_e}' \tag{3}$$

4.3 Decoder

We also prepend the prefix module for decoder, where the cross-attention and masked-attention mechanisms are augmented in a similar way. The cross-attention between the l_e-th layer of prompt encoder and the l_d-th layer of the decoder is designed as:

$$\mathbf{A}_{cross} = \mathrm{softmax}(\mathbf{Q}_{l_d} \mathbf{K}_{l_e}'^{T}) \mathbf{V}_{l_e}' \tag{4}$$

where $\mathbf{Q}_{l_d}$ is computed through a linear transformation on the hidden states of the summary text $\mathbf{x}_s$ and $l_d \in L$. Besides, the implementation of masked-attention layer is the same as the self-attention layer in the prompt encoder.

4.4 Training Strategy

In the domain-oriented prefix module, the parameter set of all linear transformations is symbolized as α. For training strategy in DOP, we perform gradient updates on the following log-likelihood objective:

$$\max_{\alpha,\theta,\varphi} \log p_{\alpha,\theta,\varphi,\phi}(\mathbf{y}|\mathbf{x}) = \sum_{i \in \mathbf{y}} \log p_{\alpha,\theta,\varphi,\phi}(y_i | y_{<i}) \tag{5}$$

where the BART parameters ϕ are fixed. The prefix parameters α, θ, and φ are the only trainable parameters. During the training, we use the domain words from source domains as the prefix sequence. When the training is completed, we save all parameters of the domain-oriented prefix module and

drop the pre-computed BART module. During the test, the domain words from the target domain are mapped to the representations of prefixes only via the reserved $\mathrm{MLP}_{\varphi}(\cdot)$, where the features of the source domain D_s can be transferred to the target domain D_t.

5 Experimental Setup

5.1 Datasets

We evaluate our model on two multi-domain dialogue summarization datasets and the details of statistics are shown in Table 1 and Table 2:

TODSum: This dataset is proposed by Zhao et al. (2021b), which is a task-oriented dialogue summarization dataset based on the classic dialogue dataset MultiWOZ (Budzianowski et al., 2018). According to the domain information, the dataset can be divided into five domains: *restaurant*, *hotel*, *attraction*, *taxi*, and *train*. Considering that parts of dialogues in TODSum contain multiple domains, in this paper, we firstly select all single-domain dialogues from TODSum as the dataset used for this experiment. Then we integrate all these samples in any four of five domains as source domains D_s and the other one is regarded as target domain D_t, where 200 samples extracted from D_s are as the validation set, the remaining as the training set, and samples of D_t are the test set.

QMSum: This dataset is proposed by Zhong et al. (2021), which contains hundreds of meeting transcriptions and includes three domains, i.e., *academic*, *committee*, *product*. In addition, each sample can be divided into several dialogue fragments according to some queries and the answer for the corresponding query is its golden summary. Such *(query-dialogue-answer)* pairs are usually used for query-based meeting summarization tasks. In this paper, we separately integrate the training and validation sets, and test set in any two of three domains as the training data and validation data, i.e., the data of source domain D_s. All data of the other domain is used as the test data, i.e., the data of target domain D_t.

5.2 Baselines and Evaluation Metrics

We compare our methods with saveral baselines. The extractive baselines are included: (1) Lead-3; (2) Oracle; (3) BertExt (Liu and Lapata, 2019). Some abstractive methods are also added for comparison: (1) PGN (See et al., 2017); (2) Transformer (Vaswani et al., 2017); (3) BertAbs (Liu and Lapata, 2019); (4) BART (Lewis et al., 2020); (5) BART w. DS/QR (Zhao et al., 2021b); (6) Prefix-tuning (Li and Liang, 2021). For QMSum, we also introduce its benchmark (Zhong et al., 2021). Since this method feeds the extracted spans into BART, we integrate the results of this method with the results of BART. We use ROUGEs (Lin, 2004; Lin and Och, 2004) to quantitatively evaluate the performance of our methods. Our codes are publicly available [3]. We give the baselines and evaluation metrics in Appendix A.1 and Appendix A.2.

5.3 Training Details

Our implementation is based on the Hugging Face Transformer models[4]. $\mathrm{BART}_{\mathrm{LARGE}}$ is used as a backbone and the source dialogue sequence is truncated to 1024 BPE tokens. For domain-oriented prefix module, the MLP maps 1024 dimension into 24576 dimension, which is calculated by $2 * \text{number of decoder layers} * 1024$ and the numbers of domain words (prefix length) are set to 140 and 200 for TODSUM and QMSum datasets. Following the settings in Li and Liang (2021), we use an AdamW optimizer (Loshchilov and Hutter, 2019) and a linear learning rate scheduler with initial rate of $5{\cdot}10^{-5}$, and the batch size is set to 5. Our model is trained on RTX 2080 Ti machines, taking only 5 minutes per epoch on TODSum dataset and 3 min per epoch on QSum dataset. However, BART w. DS takes 13 minutes and 8 minutes per epoch on TODSum and QMSum datasets. The reason for the shorter training time of our model is that the

Table 4: ROUGE scores of the zero-shot setting for QMSum. "QR" denotes the queries. Same as TODSum, values in the second row denote the size of train/valid/test set. All results are averaged over three random runs. ($p < 0.05$ under t-test)

trainable number of parameters of the DOP model is only 15% of the BART w. DS. For all experiments, we set the number of training epochs to 30. At the decoding phase, we use a beam size of 6 and max generated tokens of 125. The decoding takes 1.3 seconds per batch with the size of 2.

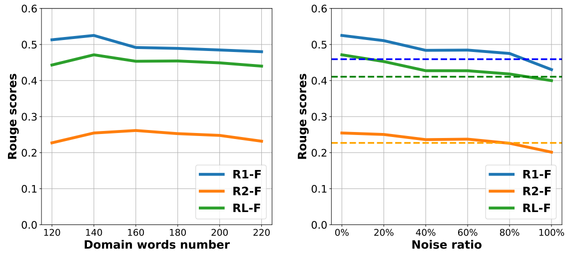
5.4 Main Results

Results on TODSum Table 3 presents the results of the zero-shot setting for TODSum dataset, where each of the five domains is regarded as the target domain respectively. The division of dataset in the second row intuitively shows that the amount of data in D_s is small and limited. We conduct experiments based on some common extractive models and some strong abstractive baselines. We also add a lightweight fine-tuning summarizer for comparison. As observed, for most ROUGEs, Prefix-tuning performs worse than BART and BART w. DS. It is because the dialogue text is long and complex, and using only 20% parameters of fine-tuning can not well understand the domain knowledge and identify the key contents in dialogues. Compared to Prefix-tuning of the same magnitude parameters, our model improves by 7%, 3%, 7% for *train* domain, 5%, 5%, 3% for *taxi* domain, 4%, 8%, 4% for *restaurant* domain, 5%, 6%, 5% for *hotel* domain, and 8%, 8%, 9% for *attraction* domain. This shows that the prefix module initialized by domain words and the discrete prompts composed of dialogue states play important roles. Besides, our model still surpasses BART w. DS, a full-parameter fine-tuning based model, which further illustrates that our model efficiently disentangles the knowledge of the source and target domains. Note that *attraction* domain gets the highest ROUGEs and the increased margins are also the largest. This may be due to the high overlaps between the *attraction* and source domains. All the results suggest that with limited data, the performance of our model still reaches state-of-the-art.

Results on QMSum Table 4 displays the results on zero-shot out-domain tests in three domains of QMSum dataset. As seen from the second row, in addition to the limited data, the source domain size may be even less than the target domain size, i.e., *product* domain. The trend of overall performance is consistent with that of TODSum dataset [5], where the improvement in *product* domain is the most obvious and there are 5%, 4% and 5% increased for R-1, R-2, and R-L, respectively. However, all the ROUGEs are low, which is because there are no obvious domain words, leading to serious domain entanglement. Besides, due to the longer meeting text, it is hard to capture the key contents in dialogues, so as to the poor generalization in the target domain. Generally, these results show that the multi-domain setting in meeting summarization task is apparently necessary and meaningful. Meeting transcripts cover various domains, making the

---

[5] Note that ROUGEs of Oracle are very high in QMSum, which is because most parts of the golden summaries are directly copied from the original dialogue. It is determined by the characteristics of the QMSum and the results are consistent with Zhong et al. (2021).



(a) Number of domain words (b) Quality of domain words

Figure 3: Effect of different numbers and different qualities of domain words for *train* domain in TODSum. The dotted lines in (b) respectively represent the F1 sources of ROUGE-1, ROUGE-2, and ROUGE-L of the Prefix-tuning model.

adaptation of models particularly difficult.

6 Qualitative Analysis

6.1 Effect of Domain Words

Number of Domain Words We set different numbers of domain words, i.e., prefix length, to test the performance of our model DOP for *train* domain in TODSum dataset. As shown in Figure 3 (a), among these setting candidates, there is a threshold (140) that allows the ROUGEs to reach the peak. When choosing a fewer setting, the model does not perform well due to insufficient number of parameters, which is improved as the number increases. When being more than this threshold, a drop in performance occurs. One reason is that too long a sequence adds a large burden to BART, and the other one is that it introduces excessive noise. However, the change in the number of the domain words does not have a great impact on the performance (only 2∼3% fluctuation), which also reflects the effectiveness of domain-oriented prefix module and the robustness of our model.

Quality of Domain Words For *train* domain in TODSum, we randomly replace a certain percentage of the domain words with words that are not related to the source domain. As Figure 3 (b) shows, when more noise is introduced, the model suffers more interference and its performance decreases. However, it performs better than Prefix-tuning. Only when the proportion of noise reaches 100%, the performance of our model is even worse than that of Prefix-tuning. This is because we especially use completely irrelevant words for initialization and fitting, which introduces more noise than simple random initialization and affects the performance of DOP. From this point of view, introducing high-quality domain words is good for domain disentanglement and the quality of domain words is critical to summary generation.

Model	R-1	R-2	R-L
DOP (ours)	52.51	25.45	47.78
w/o DW	48.87	23.81	44.52
w/o DS	47.59	23.25	43.41
w/o DW & DS	45.92	22.70	41.06

Table 5: F1 scores of ablation study on *train* domain of TODSum dataset. "DW" denotes domain words and "DS" denotes dialogue states.

Model	R-1	R-2	R-L
DOP (ours)	30.28	11.63	27.33
w/o DW	29.10	10.59	26.53
w/o QR	28.47	9.60	26.38
w/o DW & QR	27.70	9.37	25.62

Table 6: F1 scores of ablation study on *committee* domain of QMSum dataset. "DW" denotes domain words and "QR" denotes queries.

6.2 Ablation Study

We perform ablation experiments on *train* domain of TODSum dataset and *committee* domain of QMSum dataset, as shown in Tables 5 and 6. We can observe that the removal of domain-oriented initialization in the prefix module will make the ROUGEs decrease significantly. Especially for TODSum, R-1, R-2, and R-L drop by 4%, 2%, and 3%, which shows the importance of domain word information for inducing the relevant knowledge while adapting to a new domain. In addition, after we remove the discrete prompts, i.e. dialogue state and query, the performance of the models becomes worse, but still outperforms the results of Prefix-tuning. It demonstrates that discrete prompts help the model pay attention to the key elements in the dialogue and improve the generalization of the model. Notably, our model achieves summary generation only by optimizing the domain-oriented prefix module, where domain words are available in all datasets. Since the DS and QR features happen to exist in the two datasets, we take advantage of them together with dialogue texts. When removing both DW and DS/QR at the same time, the model is equivalent to Prefix-tuning and the results are consistent.

6.3 Effect of Prefix Module in Encoder and Decoder

Since both the encoder and the decoder in our DOP introduce the prefix module, we verify their effects in the *train* and *committee* domains respectively.

Domain	Model	R-1	R-2	R-L
Train	**DOP**	52.51	25.45	47.14
	w/o enc.prefix	50.69	23.58	45.98
	w/o dec.prefix	45.51	22.15	40.67
Committee	**DOP**	30.28	11.63	27.33
	w/o enc.prefix	29.20	11.34	26.37
	w/o dec.prefix	29.11	11.29	26.30

Table 7: Effects of prefix module in encoder and decoder. We removed the prefix module from the encoder and decoder respectively to verify its effectiveness.

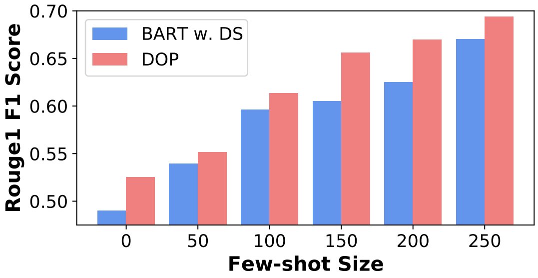


Figure 4: Effect of different few-shot data size for *train* domain in TODSum dataset. "0" denotes the zero-shot setting.

As shown in Table 7, when the encoder prefix module or decoder prefix module is removed, the performance of the model decreases, which shows that both are necessary and effective. In addition, we find that it is interesting that removing the prefix on the encoder side has a smaller impact on the model than removing the decoder side, especially in TODSum (about 5% on R-1). A reasonable explanation is that the prefix modules in encoder and decoder are responsible for different tasks. The prefix module on the encoder side assists the model to understand the dialogue, while the prefix module on the decoder side assists in model generation. Therefore, for summary generation, the prefix module in decoder is more helpful to the model.

6.4 Effect of Training Data

Performance in Few-shot Settings For TODSum, we fix the size of source domain data, adding a certain amount of target (*train*) domain data for training, as shown in Figure 4. As the size of target domain data increases, the performance of both BART w. DS and DOP present a steady improvement trend and that of our DOP model is consistently better than BART w. DS, which is as expected. Besides, there is a substantial improvement from 50 to 100. This phenomenon shows that adding target knowledge can help the model learn about information of target domain and after adding a certain amount will help the model more efficiently.

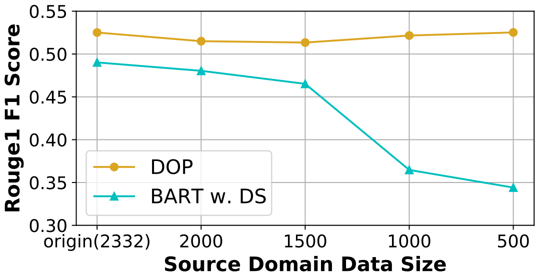

Figure 5: Effect of different source domain data size for *train* domain in TODSum dataset. "origin (2332)" denotes the same setting as the main results.

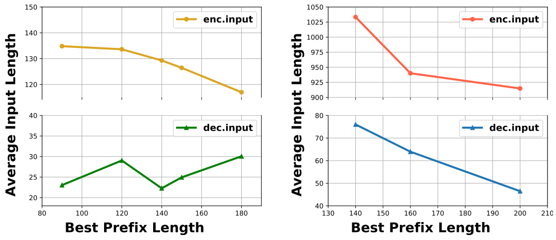

(a) TODSum (b) QMSum

Figure 6: Relationships between length of encoder/decoder input and the best prefix length.

Effect of Source Domain Data Size We keep the zero-shot setting unchanged and adjust the size of source domain data for training to observe changes in the performance of the two models for *train* domain in TODSum. As shown in Figure 5, the smaller of data size, the greater the difference between the performance of the DOP and BART w. DS, that is, the performance of BART w. DS is getting worse, while the DOP maintains excellent performance steadily. This demonstrates that our DOP model is insensitive to the data scale and robustness to a certain extent. This also confirms that in the main experiment, our model can be outstanding in very limited and uneven data.

6.5 Prefix Length vs. Input Length

Through experiments, we explore an interesting thing, that is, the prefix length (number of domain words) that makes the model perform best may be related to the input length. Based on this assumption, we collect the source input length, target input length, and their corresponding optimal prefix length from two datasets, as shown in Figure 6. We conclude a general rule that the longer inputs may prefer the shorter prefix. This phenomenon may serve as a research point in the future.

7 Discussion

7.1 Human Evaluation

We further conduct a manual evaluation to assess the models. We randomly select 50 samples from

Model	Flu.	Inf.	Fac.	Dom.	Red.
Ground Truth	4.95	4.56	4.28	4.71	4.33
BART	4.19	4.21	3.55	3.19	3.53
BART w. DS	4.36	4.34	4.09	3.35	3.62
Prefix-tuning	4.23	4.29	3.67	3.28	4.09
DOP	4.68	4.42	4.10	4.07	4.13

Table 8: Human evaluation on Fluency (Flu.), Informativeness (Inf.), Factual Consistency (Fac.), Domain Relevance (Dom.), and Redundancy (Red.) for TODSum datatset.

each target domain dataset of TODSum (Zhao et al., 2021b) and ask 10 professional linguistic evaluators to score the ground truth and summaries generated by 4 models according to 5 metrics: fluency, informativeness, factual consistency, domain relevance, and redundancy. Each metric is rated by 3 evaluators from 1 (worst) to 5 (best) and the scores for each summary are averaged. Note that the intra-class agreement score is 0.605.

As shown in Table 8, the fluency scores of all models are high, which is because that abstractive models fine-tuned on contextualized language backbones can generate fluent sentences (Lewis et al., 2020). For factual consistency, both DOP and BART w. DS achieve better performance than Prefix-tuning, which suggests that the dialogue state information guides the model to focus more on the key information, such as slots and intents. Besides, the DOP outperforms all baselines in the domain relevance metric. This demonstrates that the domain-oriented prefix module plays a crucial role in enhancing the ability of the model to identify domain-related features and disentangle the knowledge of the source and target domains. Surprisingly, the scores about the redundancy of Prefix-tuning and DOP are higher than that of BART and BART w. DS. This is because the model can efficiently extract key contents from a limited amount of data without relying on large-scale pre-trainings.

8 Challenges

Through the analysis of cases in Appendix C, we summarize two challenges of low-resource domain adaption for abstractive dialogue summarization task:

1. Confusion between domains with high similarity: We found that in domains with high-overlap vocabularies, i.e., *restaurant* and *hotel*, *train* and *taxi*, the model generates some domain-confusing sentences. Taken *hotel-restaurant* pair as an example, when *restaurant* is as the target domain, a sentence like "book a restaurant room that can accommodate 3 people, ..." is generated, which is more likely to exist in the *hotel* domain. Note that this challenge does not affect the accuracy of key elements, but the language style is not appropriate.

2. Information dispersion: Because of the long input sequence, it is difficult for the models to pay attention to all aspects of the long dialogue and there will be problems with attention deviations on the key elements of dialogues, especially for this lightweight and small parameter training paradigm.

9 Conclusion

In this paper, we present a domain-oriented prefix-tuning model to handle the domain adaptation for dialogue summarization based on an efficient and generalizable fine-tuning method. The domain word initialized prefix module disentangles the target domain knowledge from the source domain and the discrete prompts enhance the generalization ability of the model. The experiments in zero-shot and few-shot settings show that our methods have made great progress on two datasets.

A Experiment details

A.1 Baselines

We describe baselines in detail as follows.

Lead-3: This method is commonly used in news summarization task, which treats the first three sentences of the document as the summary.

Oracle: The method is used to obtain an oracle through a greedy way similar to Nallapati et al. (2017), which treats the sentences that maximize the ROUGE-2 as the summary.

BertExt: Proposed by Liu and Lapata (2019), this model is extractive and its parameters are initialized with BERT.

PGN: Proposed by See et al. (2017), this model adopts the pointer mechanism to deal with the issue of Out-Of-Vocabulary in the summary generation process.

Transformer: Proposed by Vaswani et al. (2017), this model captures long-distance information through the self-attention mechanism.

BertAbs: Proposed by Liu and Lapata (2019), this model is abstractive, which encoder is initialized with BERT and is trained with a different optimizer than decoder.

BART: Proposed by Lewis et al. (2020), the model is a state-of-the-art abstractive summarization model pre-trained with a denoising autoencoding objective.

BART w. DS/QR: Proposed by Zhao et al. (2021b), the model is a general summarization framework, with two encoders that share the underlying parameters and a decoder, which can fuse the input text and dialogue state/query.

Prefix-tuning: Proposed by Li and Liang (2021), this model introduces a prefix matrix on the basis of fixed pre-training BART parameters and allows the prefix matrix to learn task information through training, which optimizes the summarization performance in the small parameters and few-shot scenarios.

QMSum: This model is proposed by Zhong et al. (2021), which is a two-stage locate-then-summarize solution on query-based meeting summarization task.

A.2 Evaluation Metrics

We use the ROUGE (Lin, 2004; Lin and Och, 2004)[6] metrics to quantitatively evaluate the performance of our model. Rouge (Recall-Oriented Understudy for Gisting Evaluation) is metrics for evaluating summarization. It calculates by comparing the generated summary with references to obtain the corresponding score to measure the similarity between them.

Models	Trainable Parameters
BertExt	120.51M
PGN	27.64M
Transformer	257M
BertAbs	180.22M
BART-large	400M
BART w. DS/QR	406M
Prefix-tuning	81.82M
DOP-tuning	61.52M

Table 9: Trainable parameter scales of different models, where "DS" means the dialogue state in TODSum and "QR" means the query in QMSum.

B Parameter Scale of Models

We show the amount of **trainable** parameters for our DOP model and other baseline models in Table 9. Among the full-parameter fine-tuning methods, except for the relatively simple PGN model, other models have reached the scale of hundreds of megabytes, which will take up a lot of time and space in model training and storage. Prefix-tuning and DOP-tuning greatly reduce the storage space of the model, improving the efficiency of the model. Compared with prefix-tuning, our method achieves better results with fewer parameters.

C Case Study

Figure 7 shows two examples from the TODSum and QMSum respectively. For example one of *train* domain in TODSum, BART w. DS generates some incorrect and redundant information related to the *taxi* domain and *hotel* domain. To make matters worse, for *train* domain, it loses the intent of the user about booking tickets and wrongly generates the key information, i.e., the departure location. The Prefix-tuning still confuses the knowledge of *train* and *taxi* domains, that is, the booking intent in the *train* domain is wrongly predicted as the user wants to know something about "cars". Moreover, the quality of the generated key information is not high, i.e., the wrong departure location "Seachage" and the missing time "Monday". For example two of *academic* domain in QMSum, both BART w. QR and Prefix-tuning predict too many details of the dialogue, which makes the summary redundant. Besides, Prefix-tuning generates the wrong speaker "Professor B", which leads to the summary being inconsistent.

Compared to the above two models, our method

---

[6] https://pypi.org/project/rouge/

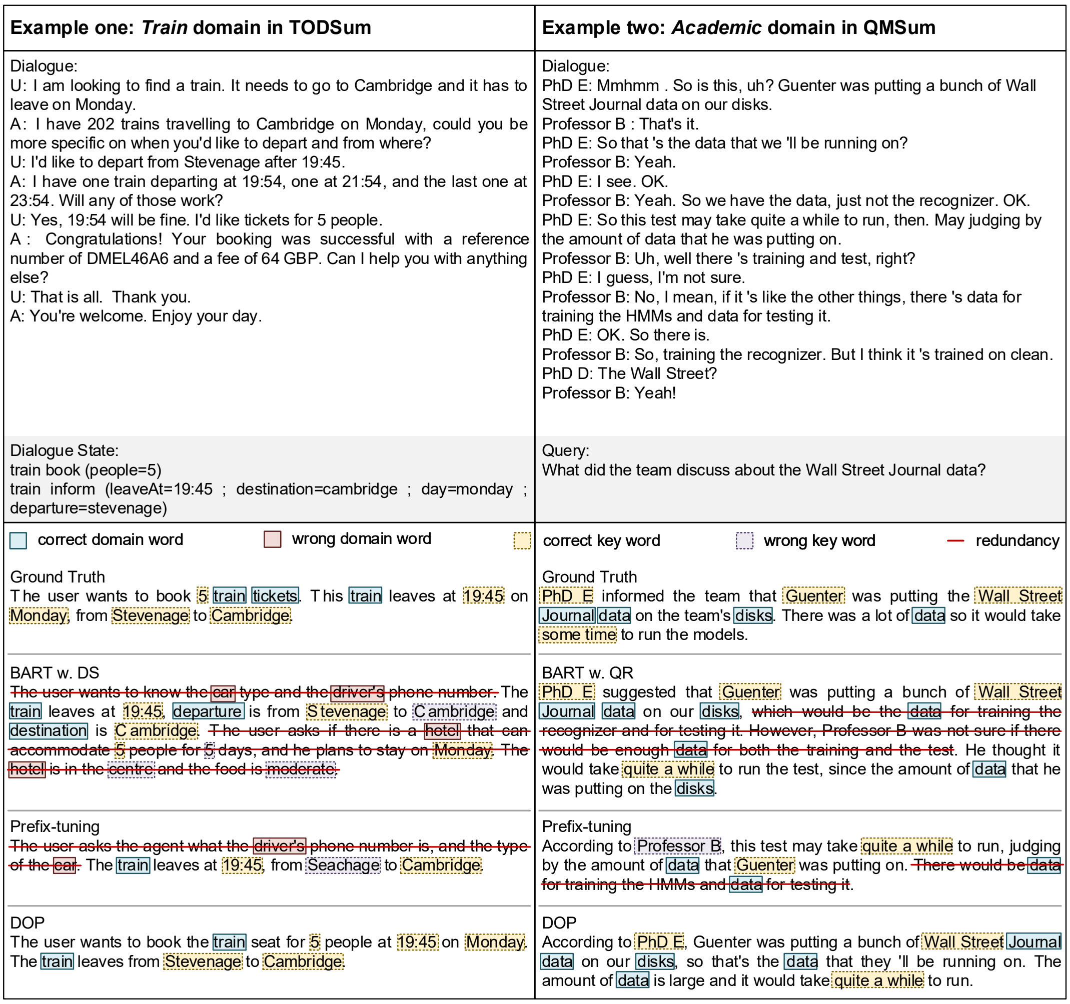
solves some difficult issues in low-resource domain adaptation for dialogue summarization. By initializing prefix matrix with domain words, our model achieves domain disentanglement and the prediction of domain-related information is basically accurate. Through discrete prompts, our model has the ability to generalize to new domains and the accuracy of prediction about domain-independent key information is greatly improved.

D Domain Words

We present some domain words for each domain in Figure 8. In order to facilitate reading, we only show some of the domain words, that is, we select the first 20 words for each domain of TODSum, and the first 30 words for each field of QMSum as display.

For TODSum, we can see that there are relatively many common domain words, which are more concentrated on location words, or some information, such as "phone", "postcode" and so on. In addition, there are many common domain words that only appear in *restaurant* & *hotel* or *train* & *taxi*. For example, price-related descriptions are usually mentioned when booking a restaurant or hotel, and "destination", "depart", "from", "to" are usually mentioned when booking train tickets or taking a taxi. Special domain words can better distinguish different domains. There will be more special domain words in *attraction*, such as "entrance", "college", "nightclub", etc., which will not appear in other domains. Besides, users will mention the star rating when booking a hotel, and want to know the food type when booking a restaurant seat. When booking train tickets, they usually plan to travel, and when taking a taxi, they want to know the color of the car.

Compared with TODSum, QMSum has many more special field words, because the three fields contained in QMSum are more different. For *product*, participants will discuss various features of products such as TVs, LCDs, etc., such as screens, buttons, colors, and functions. For *academic*, participants generally discuss models, experimental data, or some errors. And for *committee*, participants generally discuss student education or national government issues. Common domain words have only some generral words, such as "different", "system", etc., and only a few special common domain words exist in *product* & *academic*, such as "design", "bit" and other technology-related words.



Example one: *Train* domain in TODSum	**Example two: *Academic* domain in QMSum**
Dialogue: U: I am looking to find a train. It needs to go to Cambridge and it has to leave on Monday. A: I have 202 trains travelling to Cambridge on Monday, could you be more specific on when you'd like to depart and from where? U: I'd like to depart from Stevenage after 19:45. A: I have one train departing at 19:54, one at 21:54, and the last one at 23:54. Will any of those work? U: Yes, 19:54 will be fine. I'd like tickets for 5 people. A : Congratulations! Your booking was successful with a reference number of DMEL46A6 and a fee of 64 GBP. Can I help you with anything else? U: That is all. Thank you. A: You're welcome. Enjoy your day.	Dialogue: PhD E: Mmhmm . So is this, uh? Guenter was putting a bunch of Wall Street Journal data on our disks. Professor B : That's it. PhD E: So that 's the data that we 'll be running on? Professor B: Yeah. PhD E: I see. OK. Professor B: Yeah. So we have the data, just not the recognizer. OK. PhD E: So this test may take quite a while to run, then. May judging by the amount of data that he was putting on. Professor B: Uh, well there 's training and test, right? PhD E: I guess, I'm not sure. Professor B: No, I mean, if it 's like the other things, there 's data for training the HMMs and data for testing it. PhD E: OK. So there is. Professor B: So, training the recognizer. But I think it 's trained on clean. PhD D: The Wall Street? Professor B: Yeah!
Dialogue State: train book (people=5) train inform (leaveAt=19:45 ; destination=cambridge ; day=monday ; departure=stevenage)	Query: What did the team discuss about the Wall Street Journal data?
🟦 correct domain word 🟥 wrong domain word	🟨 correct key word ⬜ wrong key word — redundancy
Ground Truth The user wants to book 5 train tickets. This train leaves at 19:45 on Monday, from Stevenage to Cambridge.	Ground Truth PhD E informed the team that Guenter was putting the Wall Street Journal data on the team's disks. There was a lot of data so it would take some time to run the models.
BART w. DS ~~The user wants to know the car type and the driver's phone number.~~ The train leaves at 19:45, departure is from Stevenage to Cambridge and destination is Cambridge. ~~The user asks if there is a hotel that can accommodate 5 people for 5 days, and he plans to stay on Monday. The hotel is in the centre and the food is moderate.~~	BART w. QR PhD E suggested that Guenter was putting a bunch of Wall Street Journal data on our disks, ~~which would be the data for training the recognizer and for testing it. However, Professor B was not sure if there would be enough data for both the training and the test~~. He thought it would take quite a while to run the test, since the amount of data that he was putting on the disks.
Prefix-tuning ~~The user asks the agent what the driver's phone number is, and the type of the car.~~ The train leaves at 19:45, from Seachage to Cambridge.	Prefix-tuning According to Professor B, this test may take quite a while to run, judging by the amount of data that Guenter was putting on. ~~There would be data for training the HMMs and data for testing it~~.
DOP The user wants to book the train seat for 5 people at 19:45 on Monday. The train leaves from Stevenage to Cambridge.	DOP According to PhD E, Guenter was putting a bunch of Wall Street Journal data on our disks, so that's the data that they 'll be running on. The amount of data is large and it would take quite a while to run.

Figure 7: Case study for two examples from TODSum and QMSum datasets. We present the dialogue, its corresponding dialogue state/query, ground truth, BART w. DS prediction, Prefix-tuning prediction, and prediction of our DOP model.

Interactive Symbol Grounding with Complex Referential Expressions

Rimvydas Rubavicius and **Alex Lascarides**

Abstract

We present a procedure for learning to ground symbols from a sequence of stimuli consisting of an arbitrarily complex noun phrase (e.g. “all but one green square above both red circles.”) and its designation in the visual scene. Our distinctive approach combines: a) lazy few-shot learning to relate open-class words like `green` and `above` to their visual percepts; and b) symbolic reasoning with closed-class word categories like quantifiers and negation. We use this combination to estimate new training examples for grounding symbols that occur *within* a noun phrase but aren't designated by that noun phase (e.g, `red` in the above example), thereby potentially gaining data efficiency. We evaluate the approach in a visual reference resolution task, in which the learner starts out unaware of concepts that are part of the domain model and how they relate to visual percepts.

1 Introduction

The subfield of robotics known as Interactive Task Learning (ITL, see Laird et al. (2017) for a survey) addresses scenarios where a robot must learn to adapt its behaviour to novel and unforeseen objects, relations, and attributes that are introduced into the environment after deployment. The ITL agent learns its novel task via evidence from its own actions and reactive guidance from a teacher. This paper focuses on *symbol grounding* (Harnad, 1999) in the context of ITL (Matuszek, 2018): the learner must use the teacher's embodied natural language utterance and its context to learn a mapping from natural language expressions to their denotations, given the visual percepts.

There are two challenges in learning symbol grounding models (grounders) in ITL. Firstly, in contrast to many grounders (Ye et al., 2019; Datta et al., 2019), ITL requires *incremental* learning: knowledge is acquired piecemeal via an extended interaction, and it must influence planning as and when it occurs. Secondly, previous work limits the teacher's language to bare nouns (e.g., square) or very short phrases (e.g., blue square, square above circle) (Hristov et al., 2018, 2019). But there's evidence from Dale and Reiter (1995) that speakers use complex referring expressions even when simpler ones would successfully refer. Such language creates the possibility that novel symbols—neologisms—are introduced in a context where their denotation is not designated by the teacher. In this work we study the natural language of complex referential expressions (REs) like “a blue square behind both red circles” which teachers can use when designating an object.

Our aim is for the learner to extract knowledge that improves their domain representation and state estimates—a necessary condition for successful planning. Contemporary grounders miss learning opportunities that complex REs afford: the RE example above not only entails that its referents are `blue` and `square`, but also that there exists two objects that are both `red` and `circle` and that they are `above` the designated objects, and everything else in the domain is either not `red` or not a `circle` (thanks to the meaning of `both`). Thus, a complex RE and its designation can be used to gather multiple (noisy) training exemplars (both positive and negative) for several symbols at once, even if they have not been designated.

In this work, we develop a method to integrate knowledge from interactively gathered evidence in the form of complex RE-designation pairs to aid data acquisition for a (neural) few-shot grounder. We explore the effect of such a method on data efficiency and the overall grounder's performance. A major novel component to our procedure is that we exploit the formal semantics of closed class word categories (e.g., quantifiers and negation) to boost the data efficiency of few-shot neural grounding models. Our experiments show these symbolic inductive biases are successful.

2 Related Work

Symbol Grounding. Contemporary grounders extensively utilize *batch* learning (e.g. Shridhar and Hsu (2018)). Yet, ITL requires *incremental* learning because without it the teacher guidance cannot influence the learner's inferences about plans as and when the advice is given. Further, many grounders assume that the learner starts out with a complete and accurate conceptualisation of the domain using pre-defined visual features and a known vocabulary (Kennington et al., 2015; Kennington and Schlangen, 2017; Wang et al., 2017). In ITL, both of these assumptions are unrealistic; therefore in this paper we explore models for which these assumptions don't apply. Finally, in contrast to all prior grounders, we support incremental learning when the training exemplars feature REs that are linguistically complex: e.g., "two red circles that aren't to the right of both green squares".

Representation Learning. Models for jointly learning a representation for vision and language utilize either explicit alignment via bounding boxes or instance segmentation (Lu et al., 2019; Chen et al., 2020; Tan and Bansal, 2019; Kamath et al., 2021; Yu et al., 2021), or a large-volume of weakly labeled data in the form of image-caption pairs (Radford et al., 2021). These models rely on offline learning with large datasets. This work, on the other hand, explores how to incrementally extract knowledge from few-shot learning, using sequentially observed evidence that includes neologisms.

Visual Questions Answering (VQA). This is a task of answering free-form questions about an image (Antol et al., 2015). VQA has reached impressive performance in recent years (Fukui et al., 2016; Li et al., 2020), yet VQA models struggle with out-of distribution generalization for new types of questions, requiring multi-step reasoning, with analysis revealing that they often rely on shortcuts (Jiang and Bansal, 2019; Subramanian et al., 2019, 2020). Grounded VQA models like (Yi et al., 2018) and Bogin et al. (2021) tackle these shortcomings by grounding parts of the question and then learning to compose those parts via the question's syntax to compute the answer. They thus estimate denotations of linguistic parts that are not denoted by the answer to the question. These 'compositional' models help to achieve out-of-distribution generalization for novel questions. But they lack ITL's requirement for incremental learning: model training relies on batch learning. Furthermore, while their performance is impressive, error analysis shows that it makes mistakes when language includes logical concepts like quantifiers and negation (e.g. Bogin et al. (2021) Figure 9 shows that the determiner `most` incorrectly denotes an arbitrary subset of entities). Our view is that there is little benefit in trying to learn to ground logic concepts as they are domain independent and can be interpreted using formal semantics. In our experiments, we are testing the extent to which knowing and reasoning with the logical meanings of these symbols helps incremental grounding, and in particular estimating denotations of symbols within an RE that are not designated.

Grounded Language Acquisition. This task is often realized as grounded grammar induction from image-caption pairs (Shi et al., 2019; Zhao and Titov, 2020), or as learning (neural) semantic parsers from a reward signal (Williams, 1992) in VQA (Mao et al., 2019; Yi et al., 2018) or in planning (Azaria et al., 2016; Wang et al., 2016, 2017; Karamcheti et al., 2020). There, the main objective is to learn to map natural language to logical forms, which in turn get associated with visual percepts during the learning process. This paper does not aim to learn a semantic parser. Instead, we obtain logical forms from an existing broad-coverage grammar which is hard to engineer, but is robust on lexical variation (Curran et al., 2007). Our focus instead is on exploiting the *logical consequences* of those logical forms during symbol grounding—i.e., our focus is to utilise the *interpretation* of logical forms, and in particular the truth functional meanings of close-class words like quantifiers and negation, to inform the learning of mappings from (open-class) symbols like `red` to their denotations, given the visual percepts.

Visual Reference Resolution. In previous experiments, it is often assumed that there is a unique referent in the visual scene for the given RE in the test phase (Kazemzadeh et al., 2014; Whitney et al., 2016). We aim to cope with situations where the RE has multiple referents: identifying all the referents that satisfy an RE enables efficient planning, because it affords free choice when executing certain commands—e.g., "move a square above both red circles" when there is more than one square affords choosing a control policy so that resources are optimized.

3 Background

3.1 Formal Semantics of Natural Language

Predicate logic with generalized quantifiers $\mathfrak{L}$ (Barwise and Cooper, 1981; van Benthem, 1984) is a canonical meaning representation for natural languages. $\mathfrak{L}$-sentences ϕ are constructed recursively from predicates P, terms T (i.e., variables V and constants C), logical connectives $O = \{\neg, \wedge, \vee, \rightarrow\}$ and quantifiers Q (see Table 1 column 1):

$$\begin{aligned}\phi ::= \;& \texttt{p}(\texttt{t}_1, \dots, \texttt{t}_n) \equiv \texttt{p}(\texttt{t}^n) \\ & |(\neg\phi)|(\phi_1 \wedge \phi_2)|(\phi_1 \vee \phi_2)|(\phi_1 \rightarrow \phi_2) \\ & |(\texttt{Qx}(\phi_1, \phi_2))\end{aligned}$$

where p is an n-place predicate, $\texttt{t}_i \in T$ are terms, $\texttt{Q} \in Q$ is a quantifier, and $\texttt{x} \in V$ is a variable (in $\texttt{Qx}(\phi_1, \phi_2)$, ϕ_1 is the restrictor and ϕ_2 the body). We also introduce λ-expressions of the form $\lambda\texttt{x}.\phi$, where $\texttt{x} \in V$ is free or absent in ϕ.

3.2 Model-theoretic Interpretation

$\mathfrak{L}$-sentences are interpreted using a domain model $\mathcal{M} = (E, I)$ consisting of a set of entities E (universe of discourse), and an extension function I that maps non-logical symbols $P \cup C$ to denotations (tuples of entities). For convenience, we assume $I : C \mapsto E$ is one-to-one. Variables are interpreted via an assignment function $g \colon V \mapsto E$.

The interpretation function $\llbracket\cdot\rrbracket^{\mathcal{M},g}$ specifies the *semantic value* of well-formed expressions of $\mathfrak{L}$:

$$\llbracket \texttt{a} \rrbracket^{\mathcal{M},g} = \begin{cases} I(\texttt{a}) & \text{if } \texttt{a} \in P \cup C \\ g(\texttt{a}) & \text{if } \texttt{a} \in V \end{cases}$$

$$\llbracket \texttt{p}(\texttt{t}^n) \rrbracket^{\mathcal{M},g} = 1 \text{ iff}$$
$$(\llbracket \texttt{t}_1 \rrbracket^{\mathcal{M},g}, \dots, \llbracket \texttt{t}_n \rrbracket^{\mathcal{M},g}) \in \llbracket \texttt{p} \rrbracket^{\mathcal{M},g}$$
$$\llbracket \neg\phi \rrbracket^{\mathcal{M},g} = 1 \text{ iff } \llbracket \phi \rrbracket^{\mathcal{M},g} = 0$$
$$\llbracket \phi \wedge \psi \rrbracket^{\mathcal{M},g} = 1 \text{ iff } \llbracket \phi \rrbracket^{\mathcal{M},g} = 1 \text{ and } \llbracket \psi \rrbracket^{\mathcal{M},g} = 1$$
$$\llbracket \phi \vee \psi \rrbracket^{\mathcal{M},g} = 1 \text{ iff } \llbracket \phi \rrbracket^{\mathcal{M},g} = 1 \text{ or } \llbracket \psi \rrbracket^{\mathcal{M},g} = 1$$
$$\llbracket \phi \rightarrow \psi \rrbracket^{\mathcal{M},g} = 1 \text{ iff } \llbracket \phi \rrbracket^{\mathcal{M},g} = 0 \text{ or } \llbracket \psi \rrbracket^{\mathcal{M},g} = 1$$
$$\llbracket \lambda\texttt{x}.\phi \rrbracket^{\mathcal{M},g} = \{e \in E \colon \llbracket \phi \rrbracket^{\mathcal{M},g[\texttt{x}/e]} = 1\}$$
$$\llbracket \texttt{Qx}(\phi_1, \phi_2) \rrbracket^{\mathcal{M},g} = \mathrm{Q}(\llbracket \lambda.\texttt{x}\phi_1 \rrbracket^{\mathcal{M},g}, \llbracket \lambda.\texttt{x}\phi_2 \rrbracket^{\mathcal{M},g})$$

where $g[\texttt{x}/e]$ is just like g, except $g[\texttt{x}/e](\texttt{x}) = e$ and Q is a specific relation between the restrictor $\llbracket \lambda\texttt{x}.\phi_1 \rrbracket^{\mathcal{M},g}$ and body $\llbracket \lambda\texttt{x}.\phi_2 \rrbracket^{\mathcal{M},g}$, as defined in Table 1 column 3. $\llbracket\cdot\rrbracket^{\mathcal{M},g}$ is directly related to satisfiability for $\mathfrak{L}$-sentences:

$$\mathcal{M}, g \models \phi \text{ iff } \llbracket \phi \rrbracket^{\mathcal{M},g} = 1$$
$$\mathcal{M} \models \phi \text{ iff } \llbracket \phi \rrbracket^{\mathcal{M}} = 1$$

where $\llbracket \phi \rrbracket^{\mathcal{M}} = 1$ iff $\llbracket \phi \rrbracket^{\mathcal{M},g} = 1$ for all g. Further, if x is the *only* free variable in ϕ, then $\llbracket \lambda\texttt{x}.\phi \rrbracket^{\mathcal{M},g} = \llbracket \lambda\texttt{x}.\phi \rrbracket^{\mathcal{M},g'}$ for all g, g'; so without a loss of generality, this is expressed as $\llbracket \lambda\texttt{x}.\phi \rrbracket^{\mathcal{M}}$.[1] If all variables in $\texttt{Qx}(\phi, \psi)$ are bound by quantifiers, then this $\mathfrak{L}$-sentence is true iff Q is true for all g.

Some quantifiers, like "both",[2] are presupposition triggers: "exactly two blocks are blue" is different from "both blocks are blue" in that the latter is true only if there are exactly two individuals that are blocks. We've adopted a Russellian interpretation (Russell, 1917) of these in Table 1.

3.3 Logical Forms of Referential Expressions

We now define the logical forms of REs and their interpretations with respect to a domain model $\mathcal{M}$. Noun phrases like "a block" are represented as $\langle\texttt{\_a\_qx.block(x)}\rangle$. More generally, let $\langle\texttt{Qx}.\phi\rangle$ be the logical form of an RE, where $\texttt{Q} \in Q$ and ϕ is an $\mathfrak{L}$-sentence with $\texttt{x} \in V$ being the only free variable in ϕ. The referents $\langle\texttt{Qx}.\phi\rangle^{\mathcal{M}}$ of this logical form with respect to $\mathcal{M}$ are computed as follows:

$$\langle\texttt{Qx}.\phi\rangle^{\mathcal{M}} = \langle\texttt{Q}\rangle^{\pi(\mathcal{M},\phi,\texttt{x})} \tag{1}$$

where $\pi(\mathcal{M}, \phi, \texttt{x})$ is an $\mathcal{M}$-projection, giving a new domain model $\mathcal{M}'$ with entities $E' = E \cap \llbracket \lambda.\texttt{x}\phi \rrbracket^{\mathcal{M}}$ and $\langle\texttt{Q}\rangle^{\mathcal{M}}$ is a quantifier referent—a quantifier-specific subset of the power set of E. Table 1 column 4 gives the list of quantifier referents.

To illustrate, consider the domain model where:

$$\begin{aligned}& E = \{a, b, c, d, f\} \\ & I(\texttt{cat}) = \{a, b\} \quad I(\texttt{dog}) = \{c, d, f\} \\ & I(\texttt{bit}) = \{(c, a), (c, b), (d, b), (f, a), (f, b)\}\end{aligned}$$

The RE "a dog that bit both cats" has logical form $\langle\texttt{\_a\_q x.\_both\_q y(cat(y), dog(x)} \wedge \texttt{bit(x, y))}\rangle$. By Equation 1, its referent is:

$$\langle\texttt{\_a\_q}\rangle^{\pi(\mathcal{M},\texttt{\_both\_q y(cat(y),dog(x)}\wedge\texttt{bit(x,y)),x})}$$

The semantic value of the λ-expression formed from this RE is a set of entities $e \in E$ for which the following quantifier condition is true: both_q(R, B) where $R = \llbracket \lambda\texttt{y.cat(y)} \rrbracket^{\mathcal{M},g[\texttt{x}/e]}$ and $B = \llbracket \lambda\texttt{y.dog(x)} \wedge \texttt{bit(x, y))} \rrbracket^{\mathcal{M},g[\texttt{x}/e]}$. Only $c, f \in E$ satisfy this condition, defining a new model $\mathcal{M}'$ with $E_{\mathcal{M}'} = \{c, f\}$; this leads to the set of possible referents as $\{\{c\}, \{f\}\}$, given the quantifier referent $\langle\texttt{\_a\_q}\rangle^{\mathcal{M}'}$.

---

[1] This fact will be used when defining referents.

[2] This is not an English specific phenomena: Finnish *molempi* has the same condition as *both*.

quantifiers Q	surface form	condition $\mathrm{Q}(R, B)$	referent $\langle \mathtt{Q} \rangle^{\mathcal{M}}$
`_exactly_n_q`	exactly n	$\lvert R \cap B \rvert = n$	$\{A \subseteq E\colon \lvert A \rvert = n\}$
`_at_most_n_q`	at most n	$\lvert R \cap B \rvert \leq n$	$\{A \subseteq E\colon \lvert A \rvert \leq n\}$
`_at_least_n_q`	at least n	$\lvert R \cap B \rvert \geq n$	$\{A \subseteq E\colon \lvert A \rvert \geq n\}$
`_a_q`	a/an	$\lvert R \cap B \rvert \neq n$	$\{A \subseteq E\colon \lvert A \rvert \leq 1\}$
`_every_q`	all/every	$\lvert R \cap B \rvert = \lvert R \rvert$	$\{A \subseteq E\colon \lvert A \rvert = \lvert E \rvert\}$
`_the_n_q`	the n	$\lvert R \cap B \rvert = n) \wedge \lvert R \rvert = n$	$\{A \subseteq E\colon \lvert A \rvert = \lvert E \rvert \wedge (\lvert E \rvert = n)\}$
`_both_q`	both	$\lvert R \cap B \rvert = 2) \wedge \lvert R \rvert = 2$	$\{A \subseteq E\colon \lvert A \rvert = \lvert E \rvert \wedge \lvert E \rvert = 2\}$
`_all_but_n_q`	all but n	$\lvert R \cap B \rvert = \lvert R \rvert - n$	$\{A \subseteq E\colon \lvert A \rvert = \lvert E \rvert - n \wedge \lvert E \rvert \geq n\}$
`_n_of_the_m_q`	n of the m	$\lvert R \cap B \rvert = n \wedge \lvert R \rvert = m$	$\{A \subseteq E\colon \lvert A \rvert = n \wedge \lvert E \rvert = m\}$

Table 1: Quantifiers (column 1), their surface forms (column 2), condition Q between the restrictor R and body denotations B, used to compute a semantic value for $\mathfrak{L}$-sentences of the form $\mathtt{Qx}(\phi, \psi)$ (column 3); and quantifier referents $\langle \mathtt{Q} \rangle^{\mathcal{M}}$ used to compute references of the logical form of REs (column 4).

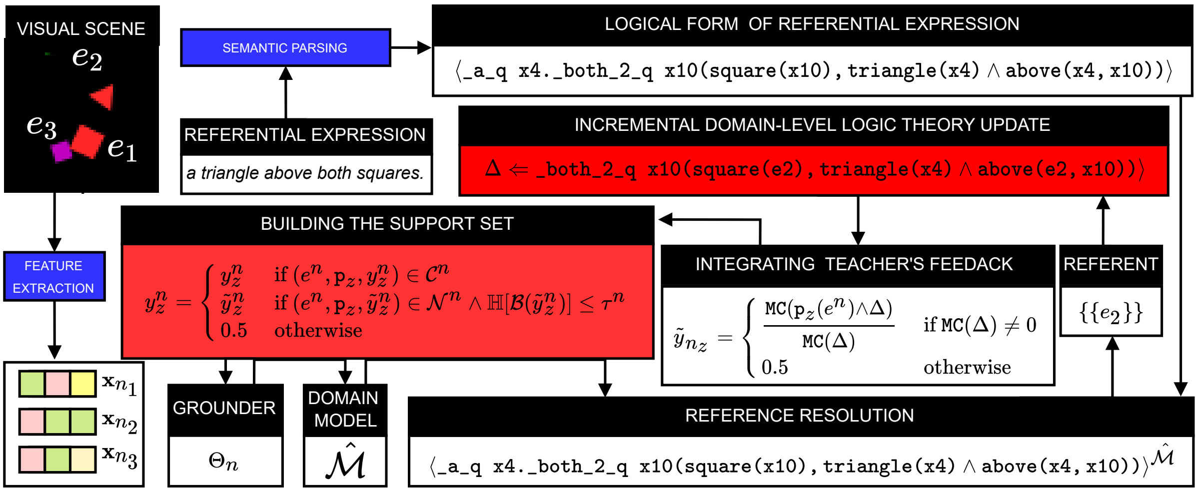

Figure 1: IGRE overview. In interaction, the learner observes an RE, which is parsed to logical form (§5.3.2) and interpreted with respect of the extracted feature vectors for denotations (§5.3.1) to perform reference resolution (§3.3) with respect to the estimated domain model $\hat{\mathcal{M}}$. In case of teacher feedback, RE and its designation is observed. This is used to build the $\mathfrak{L}$-sentence that is added to Δ to update beliefs about the underlying concept vectors (§4.3.2), which in turn are used to update the support set (§3.3), used as parameters for the grounder (§4.1). Elements in blue are pre-defined elements of IGRE while elements in red are learned through interaction.

4 Methodology

Below we present the procedure of interactive grounding with referential expressions (IGRE). The overall framework is given in Figure 1.

4.1 Grounder

Matching networks (Vinyals et al., 2016) are an extension of the k nearest-neighbour algorithm (Fix and Hodges, 1989) and has been used as a fast few-shot grounder in the ITL setting (Cano Santín et al., 2020). For predicates $P^n \subseteq P$ of the same arity n, a grounder Θ^n is parameterized by a support set $\mathcal{S}^n = \{(\mathbf{x}^n_i, \mathbf{y}^n_i)\}^{K^n}_{i=1}$, consisting of K^n pairs of feature vectors $\mathbf{x}^n_i \in \mathbb{R}^{d_n}$ for denotations $e^n \in E^n$ and concept vectors $\mathbf{y}^n_i \in [0, 1]^{|P^n|}$. In $\mathbf{y}^n$, the dimension z corresponds the predicate $\mathrm{p}_z \in P^n$ and its value is the probability that $[\![\mathrm{p}_z(e^n)]\!]^{\mathcal{M},g} = 1$. Concept vectors have a one-to-one correspondence with the domain model $\mathcal{M}$.

Given a feature vector $\mathbf{x}^n$ for a denotation $e^n \in E^n$, Θ^n predicts the concept vector $\hat{\mathbf{y}}^n$, using the following inference rule:

$$\Theta^n(\mathbf{x}^n, \mathcal{S}^n) = \sum_{i=1}^{k} \alpha^n(\mathbf{x}^n_i, \mathbf{x}^n; \mathcal{S}^n)\mathbf{y}^n_i$$

where α^n is an attention kernel:

$$\begin{aligned}
\alpha^n(\mathbf{x}_i^n, \mathbf{x}^n; S^n) &= \frac{\exp\left(f^n(\mathbf{x}_i^n) \cdot h^n(\mathbf{x}^n)\right)}{\sum_{j=1}^{k} \exp\left(f^n(\mathbf{x}_j^n) \cdot h^n(\mathbf{x}^n)\right)} \\
f^n(\mathbf{x}^n) &= \frac{\mathtt{ReLU}(\mathbf{w}^n \cdot \mathbf{x}^n + b^n)}{||\mathtt{ReLU}(\mathbf{w}^n \cdot \mathbf{x}^n + b^n)||_2} \\
h^n(\mathbf{x}^n) &= \frac{\mathtt{ReLU}(\mathbf{v}^n \cdot \mathbf{x}^n + c^n)}{||\mathtt{ReLU}(\mathbf{v}^n \cdot \mathbf{x}^n + c^n)||_2} \\
\mathtt{ReLU}(a) &= \max\left(0, a\right)
\end{aligned}$$

with learnable parameters $\theta^n = \{\mathbf{w}^n, \mathbf{v}^n, b^n, c^n\}$, and S^n is $k = 3$ nearest exemplars to $\mathbf{x}^n$ from $\mathcal{S}^n$:

$$S^n = \{(\mathbf{x}_i^n, \mathbf{y}_i^n) \in \mathcal{S}^n \colon \mathbf{x}_i^n \in \mathcal{V}(k, \mathbf{x}^n, \mathcal{S}^n)\}$$

where $\mathcal{V}(k, \mathbf{x}^n, \mathcal{S}^n)$ is a set of k nearest feature vectors.

4.2 Batch Learning

Given $\mathcal{S}^n$, one can estimate Θ^n either via batch learning performed offline, or—when $\mathcal{S}^n$ is small—in real time, as outlined by Cano Santín et al. (2020). In our scenario, we learn in real time by minimizing binary cross-entropy between the ground-truth $\mathbf{y}^n$ and predicted $\hat{\mathbf{y}}^n$ concept vectors:

$$\begin{aligned}
\mathcal{L}(\mathbf{y}^n, \hat{\mathbf{y}}^n) &= -\sum_{z=1}^{|P^n|} l(y_z^n, \hat{y}_z^n) \\
l(y_i^n, \hat{y}_i^n) &= y_i^n \log(\hat{y}_i^n) + (1 - y_i^n) \log(1 - \hat{y}_i^n)
\end{aligned}$$

4.3 Incremental Learning

$\mathcal{S}^n$ gets augmented whenever the teacher provides an RE–designation pair. This speech act provides two types of information: certain information $\mathcal{C}^n$ in the form of denotation-symbol-semantic value triples $(e^n, \mathtt{p}_z, y_z^n)$, corresponding to symbols and entities designated by the RE; and *noisy* information $\mathcal{N}^n$, corresponding to denotation-symbol-semantic value estimate triples $(e^n, \mathtt{p}_z, \tilde{y}_z^n)$, which are acquired from the symbols that are part of the RE and its referent inferred via (uncertain) reasoning. E.g., the RE "a circle below a square.", entails that its designation $e \in E$ is a `circle` and so $(e, \mathtt{circle}, 1)$ is added to $\mathcal{C}^n$. But it also entails there exists an entity which is a `square` that is not designated by the RE, but rather this entity is in the `below` relation with the designated entity. If the grounder is sufficiently confident about the referent for `square`, then the corresponding triple is added to $\mathcal{N}^n$.

4.3.1 Acquiring Observations and Symbols

When the learner first observes its visual scene—and so the teacher has not expressed any concepts, and so the learner is currently unaware of all concepts—the noisy support set $\mathcal{N}^n$ is populated with $(e^n, \mathtt{p}_z, 0.5)$ (0.5 is a default semantic value) for all e^n in the scene and for all known n-place predicates. Whenever the teacher's RE-designation pair features a neologism $\mathtt{p}^*$, then this expansion to the learner's vocabulary prompts adding $(e^n, \mathtt{p}^*, 0.5)$ to $\mathcal{N}^n$ for all e^n. During interaction, each RE-designation pair uttered by the teacher adds elements to $\mathcal{C}^n$ (for designated symbols) and triggers updates to the $\mathcal{N}^n$ elements for all entities in the current visual scene, as we'll now describe.

4.3.2 Integrating the Teacher's Feedback

$\mathcal{N}^n$ elements are interactively updated using an incrementally built domain-level theory Δ, which is the conjunction of $\mathfrak{L}$-sentences that are built from the logical forms of the REs that the teacher has uttered so far and their designations. To compute the beliefs about semantic values, given Δ, we model the semantic value of $\mathfrak{L}$-sentences of the form $\mathtt{p}(\mathtt{t}^n)$, in which t^n are all constants (ground atom), as a random variable with Bernoulli's distribution $\mathcal{B}$. Thus a distribution over the possible domain models can be estimated using (propositional) model counting $\mathtt{MC}$ (Valiant, 1979), which maps each $\mathfrak{L}$-sentence to the number of domain models satisfying it. In this way, the semantic value of any proposition can be estimated as follows:

$$\tilde{y}_z^n = \begin{cases} \frac{\mathtt{MC}(\mathtt{p}_z(e^n) \wedge \Delta)}{\mathtt{MC}(\Delta)} & \text{if } \mathtt{MC}(\Delta) \neq 0 \\ 0.5 & \text{otherwise} \end{cases}$$

$\mathtt{MC}$ can be computed exactly or approximately (Samer and Szeider, 2010). In our experiments we use the ADDMC (Dudek et al., 2020) weighted model counter, with weights set to 0.5.

4.3.3 Building the Support Set

Concept vectors for $\mathcal{S}^n$ are built using information in $\mathcal{C}^n$ and $\mathcal{N}^n$: namely each denotation e^n gets associated with its feature vector $\mathbf{x}^n$, and the z-dimension of $\mathbf{y}$ corresponding to predicate $\mathtt{p}_z \in P^n$ is computed as follows:

$$y_z^n = \begin{cases} y_z^n \text{ if } (e^n, \mathtt{p}_z, y_z^n) \in \mathcal{C}^n \\ \tilde{y}_z^n \text{ if } (e^n, \mathtt{p}_z, \tilde{y}_z^n) \in \mathcal{N}^n \wedge \mathbb{H}[\mathcal{B}(\tilde{y}_z^n)] \leq \tau^n \\ 0.5 \text{ otherwise} \end{cases}$$

where $\mathbb{H}[\mathcal{P}]$ is the entropy of the probability distribution $\mathcal{P}$, and τ^n is the confidence threshold for adding noisy exemplars: in our case, it's set to 0.6 for predicates of all arities.

5 Experiments

5.1 Task: Visual Reference Resolution

To evaluate IGRE, we use a task of visual reference resolution [3]: given a visual scene (an image) with localized entities (bounding boxes) and an RE, the grounder must estimate all its referents, as defined in §3.3. The model learns its task by observing an image accompanied by a sequence of REs, with each RE paired with its designation in the image.

We measure the performance of IGRE on the task after each observed RE and its designation. Performance is measured using the precision **P**, recall **R**, and F1 score **F1** on the test set between: 1) estimated vs. ground-truth domain models, formed from the concept vectors (intrinsic evaluation) and 2) estimated vs. ground-truth referents for the RE (extrinsic evaluation). These metrics are calculated only for those symbols/concepts that the teacher has mentioned so far (since the system is unaware that the remaining concepts exist). To obtain reliable results, we repeat the experiment 10 times: i.e., 10 different visual scenes, with a sequence of 5 different teacher utterances in each scene. We record in §6 the average precision, recall and f-scores over those 10 trials.

Perhaps unusually, this training and testing regime uses very small data sets: that's because in ITL it is the initial portions of the learning curve that matters. The learner must achieve decent performance on its task via only a few teacher utterances: human teachers won't tolerate repeating the same REs many times and so the learner lacks the luxury of learning (and testing) symbol grounding on large data sets.

5.2 Data: ShapeWorld

To generate training and test sets, we construct ShapeWorld domain models (Kuhnle and Copestake, 2017), each consisting of 3-12 entities, synthesized visual scenes X (64x64 pixels), and 5 REs. Each domain model is describable using 7 shape symbols **S1** (`square`, `circle`, `triangle`, `pentagon`, `cross`, `ellipse`, `semicircle`), 6 colour symbols **C1** (`red`, `green`, `blue`, `yellow`, `magenta`, `cyan`) and 4 spatial relationships symbols **R2** (`left`, `right`, `above`, `below`).[4] In scene synthesis, the image is created from the domain model, with variation on the hue of the colour category, variation on the size, position, rotation, and distortion of the shapes, and variation on the spatial positions of the entities related by each spatial term. Note that the colour categories are not mutually exclusive—e.g., there are RGB values that count as both `red` and `magenta`.

To generate REs, we sample Dependency Minimal Recursion Semantics (DMRS) (Copestake, 2009) graph templates, processed using ACE (generation mode) [5] and the English Resource Grammar (ERG) (Flickinger, 2000). Generated REs are evaluated with respect to the domain model to guarantee an existing referent. In total we generated 30 such domain models for training and 10 for testing. The data statistics for the training set is given in Table 2 for the general categories of symbols, where *certain* ($\mathcal{C}^n$) means that the designation is denoted by the symbol in the RE, and *noisy* ($\mathcal{N}^n$) means that the symbol is a part of the RE but is not designated by it. Note that the first argument to the spatial relations **R2** is always denoted by the designation while its second argument is not. Note also there is high variance in the frequencies among the individual symbols. For instance, `blue` occurs 27 and 28 times in certain vs. noisy positions respectively, while `triangle` occurs 7 and 12 times respectively.

Category	$\mathcal{C}^n$ candidates	$\mathcal{N}^n$ candidates
C1	18.67 ± 5.39	19.83 ± 5.04
S1	14.67 ± 3.98	16.50 ± 5.32
R2	0	37.75 ± 6.75

Table 2: Average symbol counts per word for colours (**C1**), shapes (**S1**), and spatial relationships (**R2**).

5.3 Implementation Details

5.3.1 Feature Extraction

To extract visual features for individuals in the scene, we utilize bounding boxes $\mathbf{b} = [x_{left}, x_{right}, y_{top}, y_{bottom}]^\top$ for each entity $e \in E$ in the visual scene by localizing them (cropping) and extracting the visual features using a pre-trained visual feature encoder (in our case,

---

[3] Code available at https://github.com/itl-ed/igre

[4] Entities are non-overlapping, thus we omit `on`/`behind`.

[5] http://sweaglesw.org/linguistics/ace/

DenseNet161 (Huang et al., 2017)). Additionally, for the feature vector, we add each entity's bounding box coordinates for spatial information, lost in the localization process:

$$\mathbf{x}_n = \texttt{Concat}(\{[\texttt{DenseNet161}(X[\mathbf{b}_i]], \mathbf{b}_i)\}_{i=1}^{n})$$

5.3.2 Grammar-based Semantic Parsing

To parse REs to their logical forms, we use the English Resource Grammar (ERG) and ACE (parsing mode) to produce a representation in minimal recursion semantics (MRS) (Copestake et al., 1997), which we then simplify via hand-written rules (e.g., removing event arguments from predicate symbols corresponding to adjectives and prepositions). Underspecification of the MRS was resolved using UTOOL (Koller and Thater, 2005) and the final logical form was selected based on the linear order of scope-bearing elements (quantifiers and negation): e.g. for the RE "every circle above a square", `_every_q` outscopes `_a_q`.

5.3.3 Axioms for R2

For $|E|$ entities, there are $|E|^2$ denotations to consider for each 2-place predicate—a larger search space compared to $|E|$ denotations for 1-place predicates. Moreover, these predicates can only be acquired from the noisy component $\mathcal{N}^n$ because the referent of the second argument to the relation is always latent.

To aid the learning process for **R2**, whenever a new symbol $R \in \mathbf{R2}$ is observed, domain-level axioms are added to Δ for it, making it irreflexive: $\forall x. \neg R(x, x)$ (an entity cannot be in a spatial relationship to itself) and asymmetric: $\forall x, y. R(x, y) \rightarrow \neg R(y, x)$ (reflecting the fact that entities in spatial relations take different roles (Miller and Johnson-Laird, 1976)). These axioms reduce the number of possible denotations for **R2** symbols from $|E|^2$ to $\frac{|E|^2}{2} - |E|$.

5.4 Baselines

To test the benefit of using noisy training exemplars $\mathcal{N}^n$ from the oblique symbols in the REs—in other words, those symbols that are a part of the RE but not designated by it—we implemented a HEAD grounder baseline, which uses information only from $\mathcal{C}^n$. That HEAD uses only symbol-designation pairs that are acquired when the symbol denotes the referent (in our case, that's the head noun in the RE and its pre-head modifier, if it exists).

To test the the benefit of using the precise formal semantic meanings of logical symbols (i.e., quantifiers and negation), we implemented an EXIST grounder baseline. This utilizes the information from the symbols in the oblique positions, but it does *not* utilize the precise symbolic interpretation of the logical symbols, instead simplifying the logical form of the RE by replacing all quantifiers with the existential `_a_q` and removing negation (e.g., "every cross on the left of the one circle" is equivalent to "a cross on the left of a circle"). This baseline preserves the basic linguistic structure of the formal semantic representation of the RE, but not its truth-functional interpretation.

6 Results and Discussion

Figure 2 shows the evolution of the performance of the IGRE grounder and the two baselines on the test set, as it gets exposed to more information (i.e., RE-designation pairs) over time. In the intrinsic evaluation (domain model prediction), there is no significant difference between the three grounders considered. Yet, for extrinsic evaluation (reference resolution), we observe that IGRE outperforms the HEAD and EXISTS baselines over time (both a steeper and a smoother curve). By the end of the interaction, a t-test shows significant differences in IGRE's performance compared with both baselines (p-value of 0.01).

Table 3 shows the best performance that each grounder achieved over time. When analysing their performance on particular categories, we observe that **C1** and **S1** are equally hard to learn for grounders while **R2** is easier.

We suspect that the reason why the three models performed differently in extrinsic evaluation even though they don't with intrinsic evaluation is down to the fact that IGRE uses its complete and accurate knowledge of the meanings of closed class words like quantifiers and negation at test time as well as training time in the extrinsic evaluation, but not in the intrinsic evaluation. The IGRE model can use these meanings to constrain and correct error-prone estimates of referents for open class words at test time in the reference task (as well as using their meanings to boost the training sets). For example, the RE "both squares" implies there exist exactly two squares; if the symbol grounding model has an uncertain belief that there are more (or fewer) squares than this, it will select the two most probably candidates (and infer that all other entities are

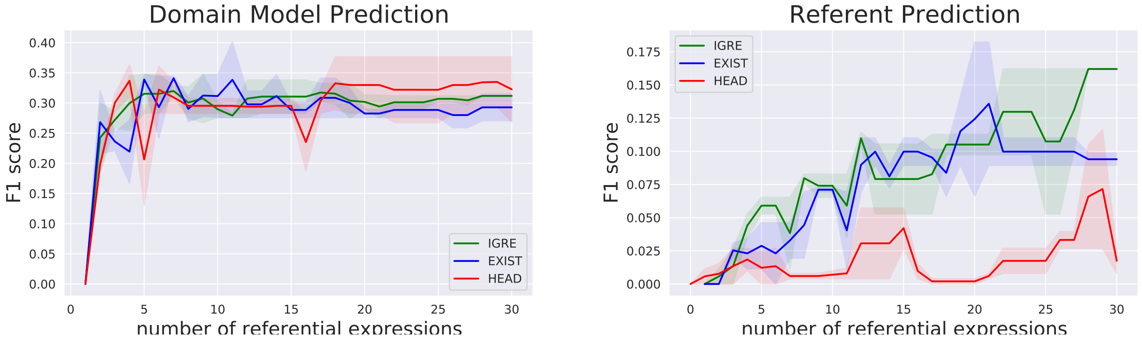

Figure 2: Evolution of F1 scores for IGRE (ours), EXISTS, HEAD grounders over the course of interaction on domain model prediction (left) and reference resolution (right)

Table 3: Precision **P**, recall **R**, and the **F1** score for symbols of different category: colour **C1**, shape **S1**, and spatial relation **R2** (intrinsic evaluation), as well as reference prediction (extrinsic evaluation). Reported metrics are averaged across the words in each category and in turn averaged across the 10 different test visual scenes.

non-squares). These experiments suggest that this sort of correction to confident but wrong estimates of the denotations of open-class symbols happens sufficiently often at test time in the reference task to make a difference in this low-data regime we are interested in, for addressing ITL tasks.

6.1 Error Analysis

The HEAD and EXISTS baselines never acquire negative exemplars: e.g., information that a particular individual is not `red`. Figure 2 shows that this severely impacts their performance, and error analysis showed that in some experiment runs it leads to model-collapse, with all denotations predicted to be in the extensions of all symbols. On the other hand, IGRE is able to acquire and use negative examples from the truth functional meanings of the logical symbols, specifically from: (a) negation (“not”); (b) the presupposition triggers“the N", “N of the M”, and “all but N" where N, and M are numbers and “both"; and (c) the use of “every” when it modifies the head noun.

7 Conclusions

In this work, we presented IGRE—a grounder that supports incremental learning of the mapping from symbols to visual features whenever the teacher presents a linguistically complex RE and its designation(s) in the visual scene. The grounder starts the learning process with no conceptualisation of the domain model, and so the learner must revise its hypothesis space of possible domain models as and when the teacher introduces new and unforeseen concepts via neologisms. We showed how exploiting the model-theoretic interpretation of the formal semantic representations of REs, and in particular the truth conditions of ‘logical’ words like quantifiers and negation, can inform the acquisition of noisy training exemplars that in turn guide learning—IGRE reasons about the likely denotations of symbols within an RE that aren’t designated by that RE, and when sufficiently confident it exploits them to update its grounding model. We showed that: 1) this grounding approach is more data efficient then a model that omits such observations and reasoning, using only the designated symbols; and 2) it is beneficial to exploit the logical consequences of the logical symbols, to gain even more data efficiency and training stability. In both cases, there was much to be gained from such reasoning because in contrast to the baselines, it contributes to acquiring *negative* exemplars: in other words, objects that get associated with *not* being red, for example.

7.1 Future Work

IGRE uses a single source of data augmentation by acquiring noisy exemplars from symbols in oblique positions. Further and parallel data gains may be obtained by exploring semi-supervised learning methods (Yarowsky, 1995; Delalleau et al., 2005).

In this work, converting $\mathcal{L}$-sentences to conjunctive normal form, which is an NP-hard problem, was a computational bottleneck. Future work needs to address this by either considering lifted inference methods (e.g., den Broeck et al. (2011)) or defining model counters that use $\mathfrak{L}$-sentences directly.

Finally, the purpose of IGRE is to aid ITL: i.e., the (incremental) updates to beliefs about symbol grounding should enhance learning to solve domain-level planning problems. Future work needs to address this by using IGRE to learn planning tasks where the learner has the physical ability to execute certain actions but starts out unaware of domain concepts that define the goal and are critical to task success. The learner must not only use IGRE to interpret the teacher's feedback, but also learn decision making strategies, both on what to say (or ask) the teacher in their extended dialogue and what actions to perform in the environment. Furthermore, the static formal semantics that we used here should be replaced with a dynamic semantics (e.g., Groenendijk and Stokhof (1991); van der Sandt (1992); Asher and Lascarides (2003)), to account for how contextual salience influences truth and reference in dialogue. Following Batra et al. (2020), we plan to test the benefits of IGRE within a system that learns to solve planning problems that focus on rearrangement tasks.

Generalized Quantifiers as a Source of Error in Multilingual NLU Benchmarks

Ruixiang Cui, Daniel Hershcovich, Anders Søgaard
University of Copenhagen
`{rc, dh, soegaard}@di.ku.dk`

Abstract

Logical approaches to representing language have developed and evaluated computational models of quantifier words since the 19th century, but today's NLU models still struggle to capture their semantics. We rely on Generalized Quantifier Theory for language-independent representations of the semantics of quantifier words, to quantify their contribution to the errors of NLU models. We find that quantifiers are pervasive in NLU benchmarks, and their occurrence at test time is associated with performance drops. Multilingual models also exhibit unsatisfying quantifier reasoning abilities, but not necessarily worse for non-English languages. To facilitate directly-targeted probing, we present an adversarial generalized quantifier NLI task (GQNLI) and show that pre-trained language models have a clear lack of robustness in generalized quantifier reasoning.

1 Introduction

Quantifier words—such as *each* or *most* or *more than three*—have been extensively studied, both in logic and in linguistics (Westerståhl, 1989; Peters and Westerståhl, 2006), going all the way back to Frege (1879). In this paper, we examine the extent to which they present a challenge to modern NLU systems. Our analysis is motivated by three observations:

Quantifier words are abstract Unlike nouns, verbs and adjectives, quantifier words do not have referents out in the world. Rather, quantifier words specify relationships between sets of entities, events and properties. To provide intuitions about the semantics of quantifier words, and to be able to refer to quantifiers in a language-independent way, we rely on the notion of generalized quantifiers (Mostowski, 1957), as described in §2.

Quantifier words vary across languages Quantifier word inventories differ across languages. Often what is considered rough translation equivalents also differ in syntax, fine-grained semantics or pragmatics. Stateva et al. (2019) show, e.g., that perceptions of the numerical bounds of existential quantifiers differ across speakers of English, French, Slovenian, and German. Other papers showing discrepancies between quantifier systems include comparisons of Salish to English (Matthewson, 2001), Adyghe to English (Nikolaeva, 2012), or of Dutch, Hebrew and Bengali (Gil, 1982). The cross-linguistic differences in how generalized quantifiers are expressed motivates a cross-lingual error analysis, since quantifiers may contribute more to error when processing some languages rather than others.

QA_English	CONTEXT: *A piece of paper was later found on which he had written his last statements in **two** languages, Latin and German. Only **one** statement was in Latin and the rest in German.* QUESTION: *In what language were **most** statements written?* ANSWER: `German` PREDICTED ANSWER: `Latin and German`
NLI_Spanish	PREMISE: ***Más de tres** personas resultaron heridas en un accidente de **dos** vehículos el lunes por la noche. (translation: **More than three** people were injured in a **two**-vehicle crash Monday evening.)* HYPOTHESIS: *Había **4** personas involucradas. (translation: There were **4** people involved.* LABEL: `Neutral` PREDICTED LABEL: `Entailment`

Table 1: Examples of quantifiers (marked in bold texts) in NLP tasks, with RoBERTa's prediction for QA and XLM-R's prediction for NLI after fine-tuning.

Quantifier words are important Quantifier words are extremely important for tasks that require inference, including natural language inference, question answering, fact-checking, etc. Datasets have, for example, been developed for numerical reasoning in English (Dua et al., 2019). Several researchers have identified quantifier words as important sources of errors for natural language processing systems (Joshi et al., 2020); see Table 1 for examples of such errors. Unfortunately, most

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4875 - 4893

Generalized Quantifiers	**Logical Denotation**	**Example**
some(A)(B) = 1	$A \cap B \neq \varnothing$	This process is known to increase security in several ways.
all(A)(B) = 1	$A \subseteq B$	Everyone agreed the food was terrible.
more than k the(A)(B) = 1	$\lvert A \cap B \rvert > k$	They do let them go more than twice a week.
less than k the(A)(B) = 1	$\lvert A \cap B \rvert < k$	San Augustin Acolman has less than 1,000 residents.
k (A)(B) = 1	$\lvert A \cap B \rvert = k$	Please donate 100 million to the School of Nursing.
between p and k the(A)(B) = 1	$p < \lvert A \cap B \rvert < k$	The USA added ten states to its nation between 1800 and 1850.
the **p/k** (A)(B) = 1	$\lvert A \cap B \rvert = p \cdot (\lvert A \rvert / k)$	Captain Blood has 20/20 vision.
the **k%** (A)(B) = 1	$\lvert A \cap B \rvert = k \cdot (\lvert A \rvert / 100)$	The lending fund is always guaranteed 9% interest.
most (A)(B) = 1	$\lvert A \cap B \rvert > \lvert A \backslash B \rvert$	Most ZIP Codes cover roughly ten thousand addresses.
few (A)(B) = 1	$\lvert A \cap B \rvert < \lvert A \backslash B \rvert$	Only a few teenagers were still listening to Rock 'n' Roll.
each other (A)(B) = 1	$\forall a \in (A \cap B) \exists b \in (A \cap B)(a \neq b)$	All of these trails are located within the a one hour drive of each other.

Table 2: The categorization set of quantifiers for task analysis. The first six are Aristotelian/counting quantifiers and the following four are proportional quantifiers. The last one is a Ramsey quantifier (Schmerl and Simpson, 1982). For each quantifier, its logical denotation is listed in the second column. The third conlumn contains English examples with quantifiers taken from XNLI.

efforts have concentrated on subsets of quantifier words and on English.

Contributions We analyze how quantifiers are represented in NLU benchmarks, and how their occurrence at test time contributes to errors by neural language models (LMs). We derive a linguistically motivated 11-way categorization set for generalized quantifiers and look into their distribution in three steps: (a) monolingual NLI; (b) cross-lingual NLI; (c) cross-lingual question answering. We also propose GQNLI[1], an adversarial generalized quantifier NLI challenge dataset. Our work shows that (i) generalized quantifiers are pervasive and cause overall performance drops in NLU benchmarks; (ii) the contribution of quantifier words to system error varies across languages; and (iii) generalized quantifiers are particularly difficult for LMs in interaction with negation and subsumption.

2 Background

Generalized quantifiers (GQs) are developed upon first-order predicate logic, denoting relations between sets (Mostowski, 1957). Given a universe E, a quantifier Q would be treated as a mapping Q_E from the Cartesian product of powersets $\mathcal{P}(E) \times \mathcal{P}(E)$ to the set $\{$*false,true*$\}$ or, as a binary relation on subsets of E (Dvořák and Holčapek, 2015). GQs are generalizations of the $\forall$,$\exists$ quantifiers from first-order predicate logic (Mostowski, 1957; Lindström, 1966; Montague, 1973; Bach et al., 1995; Keenan and Paperno, 2012). A generalized quantifier is, abstractly, a relation between sets. Generalized quantifier theory, while developed by logicians, is used by formal linguists to analyze the meaning of quantifier words in combination with referential expressions (Barwise and Cooper, 1981; Higginbotham and May, 1981).

Most human languages contain ways of expressing generalized quantifiers, and their semantics exhibit striking similarities across languages (Matthewson, 2004; Fintel and Matthewson, 2008; Steinert-Threlkeld, 2019). At the same time, generalized quantifiers can be instantiated very differently across languages due to pragmatic considerations (Grice, 1989) or cognitive economy and cost-benefit optimisation in the exchange of information (Levinson et al., 2000; Steinert-Threlkeld, 2021; Uegaki, 2022). Quantifier words also exhibit syntactic differences, e.g., with some languages having specialized words to express quantity, while others rely on metaphorical usage of common nouns (Katsos et al., 2012). In English, *most* is a determiner, but Spanish and French express the same concept through common nouns, *la mayoría* and *la majorité*. The relative stability of the core semantics of quantifiers makes a cross-linguistic comparison possible, but the syntactic and pragmatic variation associated with the expression of generalized quantifiers poses a challenge for multilingual NLU. We consult quantifier taxonomy studies (Keenan and Westerståhl, 1997; Peters and Westerståhl, 2006; Szymanik and Thorne, 2015; Szymanik, 2016) and derive a categorization set for quantifier analysis in NLU benchmarks. In Table 2, we list the 11-way quantifier categorization set and their logical denotation based on set theory.

While other foci of formal linguistics have attracted the attention of NLP researchers—including coreference (Ogrodniczuk et al., 2019, 2020), nega-

Table 3: Quantifier distribution in four NLI tasks, among which three are monolingual English and one is cross-lingual. The table show statistics of the test set, if not available, dev set, of the target task. All but the last rows show the occurrence time of the type of quantifier in the first column. The last row represents the distribution rate of any quantifier in the dataset.

tion (Hossain et al., 2020; Hartmann et al., 2021), and consistency (Li et al., 2019; Ribeiro et al., 2019; Asai and Hajishirzi, 2020; Geva et al., 2022)—there has been little work on generalized quantifiers as a source of error in NLU, let alone in multilingual NLU. It remains an open problem whether LMs represent the semantics of quantifiers words adequately, or if they provide a basis for resolving scopal ambiguities.[2]

3 NLU Benchmarks

We conduct an error analysis focusing on the role of generalized quantifiers in two NLU tasks, Natural Language Inference (NLI) and Question Answering (QA), which generally require understanding of quantifiers. For each type of task, both monolingual and cross-lingual evaluation are conducted. We focus on generalized quantifiers in the *hypotheses* in NLI examples—and on generalized quantifiers in the *question* fields in question answering. To this end, we identify quantifiers by the lemma and the universal dependency relation (Nivre et al., 2020) of a quantifier after preprocessing the sentences using *Stanza* (Qi et al., 2020). Take the sentence “The Yiddish culture has survived for more than a thousand years.”, we annotate it as

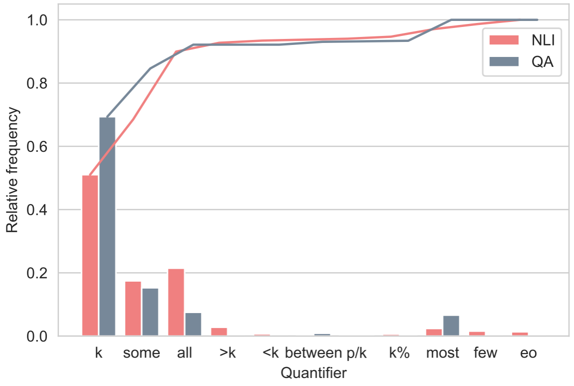

Figure 1: Relative distribution of quantifiers in NLI and QA tasks ranked by semantic complexity. The bars show the relative frequency of such quantifier and the lines indicate the cumulative frequency for a task.

“The/*det* Yiddish/*amod* culture/*nsubj* have/*aux* survive/*root* for/*case* more/*advmod* than/*fixed* a/*det* thousand/*nummod* year/*obl* ./*punct*”. By matching the regex pattern of the quantifier “more than k”, in this case *“((more|great)\/advmod than\/(fixed|case)|at\/case least\/nmod) .+\/nummod .+\/(nsubj|obj|obl)”*, we approximate the surface form of the type “more than k”.Through matching quantifier patterns, we are able to find entries in which quantifiers are instantiated. See Appendix A for the list of regex patterns we write to identify GQs. In Table 3 and Table 6, we present the statistics of the quantifier distributions in NLI and QA tasks, respectively. As can be seen, quantifiers are indeed widespread in NLU tasks, accounting for roughly 10% in NLI tasks and 5% in QA tasks. We will further discuss the statistics and experiments in the following section.

4 Quantifiers in English NLI Benchmarks

NLI is commonly framed as a three-way classification task with labels *entailment*, *contradiction* and *neutral* (Bowman et al., 2015a). While SOTA models exhibit low error rates on NLI benchmarks, it is unclear when they succeed or fail in their underlying reasoning. We are interested in whether generalized quantifers challenge modern NLI models. In our error analysis, we initially focus on three English NLI datasets, MultiNLI (MNLI; Williams et al., 2018), SNLI (Bowman et al., 2015a) and ANLI (Nie et al., 2020) as testbeds.

Table 3 presents statistics of quantifier distribution in these datasets, where we observe that,

---

[2] Note that generalized quantifiers are not always *explicit* in discourse. The sentence *inadequate sleep causes obesity* should be interpreted as *Most of those who do not sleep adequately, gain weight* (Zadeh, 1983). Such implicit quantifiers related to pragmatic variation are important for language understanding, but will be ignored in this work.

Table 4: BERT and RoBERTa performance on NLI tasks. The *weig.* column represents the percentage of all true predictions in six subtasks over total instances. The penultimate row stands for the overall performance when quantifiers exist in a dataset. The last row reports the overall performance in a dataset. Number marked in bold signifies a lower score than the overall performance.

across, about 10% of all hypotheses contain quantifier words, indicating the pervasiveness of quantification. We also plot the frequency of quantifiers in NLI in Figure 1 and find the quantifier word distribution follows Zipf's law (Zipf, 1949). Note the top three most common quantifiers account for more than 90% of all.

Experiments and Results In order to investigate whether NLU systems can solve quantifiers in NLI, we experiment with two pretrained LMs: BERT[3] (Devlin et al., 2019) and RoBERTa[4] (Liu et al., 2019). We use the codebase by Nie et al. (2020). The training data combines SNLI, MNLI, FEVER-NLI (Nie et al., 2019) and ANLI.

In Table 4, we report the test set performance on SNLI and ANLI, and the dev set performance on MLNI *matched* and *mismatched* sections. We can observe that SOTA models suffer from performance drops across almost all quantification phenomena in every task. When it comes to performance over all quantifiers, the improvement from RoBERTa to BERT (2.2%) is less prominent than that over full datasets (2.9%), suggesting RoBERTa is particularly challenged.

Taking a closer look at error by category, proportional quantifiers seem harder to solve than Aristotelian/counting quantifiers. Except for *k%*, all proportional quantifiers—*p/k*, *most*, and *few*—are about 10% lower than the five counting quantifiers (except *less than k*) with BERT; and about 5% lower with RoBERTa. RoBERTa is not generally superior to BERT; e.g., for *k%*, BERT outperforms it by 22%. We show a pairwise analysis of how GQs affect performance when they appear in both the premises and hypotheses in the Appendix B. Generally, our results attest to the difficulty of resolving GQs in NLI benchmarks.

5 Quantifiers in Cross-lingual NLU Benchmarks

Quantifiers are acquired in similar orders across languages (Katsos et al., 2016), although languages express quantifiers in different ways. For example, there are eight different universal quantifiers with different level of distributivity in Malagasy (Matthewson, 2008). This poses challenges to training multilingual LMs and transfer learning. We are interested in whether quantifiers are universally and evenly challenging for all languages.

Quantifiers in Cross-lingual NLI We choose XNLI (Conneau et al., 2018), a manual translation of the development and test set of MNLI into 15 languages, for this multilingual error analysis. We should clarify that for XNLI, the authors annotate entailment labels for the English data only and apply them to the other languages. We do not assume label changes due to translation in this study, but it is worth investigate in the future. We choose five languages belonging to different language families, namely Arabic, Chinese, German, Spanish and Vietnamese as targets. The last column in Table 3 shows the numbers of quantifiers in XNLI. The distribution rate is 10%. Note that the universal quantifier is the most common quantifier in XNLI.

Table 6: Quantifier distribution in two multilingual QA tasks, MLQA and XQuAD. We choose six common languages appearing in both tasks to facilitate comparisons. XQuAD is strictly parellel while MLQA is not, hence only the latter has statistics by languges. Categories that no entry exists are omitted.

We fine-tune mBERT[5] (Devlin et al., 2019) and XLM[6] (Lample and Conneau, 2019) on the MNLI training set and evaluate them on XNLI. We report the results in Table 5. We find that performance varies across languages. For Chinese and Vietnamese, we see significant drops in performance for examples with GQs, whereas for Arabic and German, we see improvements. The results *per* quantifier are more homogeneous, however.

Similar to our results for English, we can see that the lowest accuracies in XNLI are with proportional quantifiers, such as *most* and *few*. But the gap in non-English languages is wider for these two categories, especially for Chinese, the difference reaches 30%. Other hard quantifiers include *all*, $> k$, $< k$, and *each other*.

Quantifiers in Cross-lingual QA Cross-lingual question answering (XQA) is another important NLU task that evaluates the cross-lingual transferability of LMs. We evaluate the effect of quantifiers on system errors across two XQA datasets, namely XQuAD (Artetxe et al., 2020) and MLQA (Lewis et al., 2020). As demonstrated in Figure 1, quantifier word distributions in XQA tasks also follow Zipf's law, as in NLI tasks, but *k* is more frequent (perhaps because of a traditional emphasis on numerical reasoning), and we see less variance across languages. This is probably because question answering is targeting quantification less directly. To evaluate cross-lingual QA performance on GQs, we fine-tune mBERT and XLM-R[7] (Conneau et al., 2020) using Hu et al. (2020)'s architecture. We present results for mBERT in Table 7; for XLM-R results, please refer to Appendix D.

Just as with XNLI, LMs suffer from performance drops across all languages for almost all GQ phenomena with significant, cross-lingual variation. The most distinguished is that Exact Match (EM) suffers from a greater deterioration than F1 scores for all languages. For example, the weighted EM difference for mBERT on MLQA is 2.9% while the weighted F1 is 1%. As one example in Table 1, we observe that the plausible answers selected by models, while being incorrect, result in a sharper decrease of EMs comparing to F1s. Questions containing GQs also tend to have less verbal answers comparing to those without GQs, and therefore require higher precision.

Regarding cross-lingual comparisons, Chinese and Arabic are the two languages that do not have

Table 7: Results of mBERT performance on XQA tasks decomposed by quantifier categories.

lower performance over GQs compared to the performance over the complete dataset. Despite the overall trends, subtle differences from XNLI performance still exist. For example, XLM-R is worse than mBERT on quantifier reasoning on XQuAD Chinese, especially at proportional quantifiers, but this is not the case on MLQA Chinese.

6 GQNLI

We have seen how quantifiers present challenges to NLI and QA models. Using an approach similar to ANLI (Nie et al., 2020) and DynaBench (Kiela et al., 2021), we use model difficulty (RoBERTa's) as a heuristic to select hard examples for a challenge dataset that can hopefully be used to evaluate any future progress on this. We propose GQNLI, a generalized quantifier NLI challenge dataset, consisting of 30 premises and 300 hypotheses. The average sentence lengths of hypothesis and premises are 15.97 and 7.35, respectively. Both numbers are comparable to those of MNLI, but lower than ANLI's (Williams et al., 2020). It should be noted that GQNLI is designed for evaluating future models; obviously not for benchmarking RoBERTa.

Dataset Creation Firstly, we manually create 100 premise-hypothesis pairs, in which various types of GQs appear. For each premise and hypothesis, the number of GQs varies from one to three. To choose the premises, we randomly sampled 100 premises with GQs from SNLI and ANLI test sets, respectively, and selected 10 premises in total, that we consider are semantically adequate for adding GQs and making simple hypotheses.

To construct the hypotheses, we rely on RoBERTa fine-tuned on MNLI and manually select examples about which the model is unsure or incorrect. To focus on GQs, we keep the challenge examples otherwise simple (Ribeiro et al., 2020), and avoid lexical variations in the hypotheses. Hard examples were found to be characterized by (i) mixing generalized quantifiers with other logical operators, such as subsumption or negation, and (ii) combining multiple different generalized quantifiers. We discuss these observations in Section 7.

Two of the authors annotated the examples. The inter-annotator agreement (Fleiss' kappa) was 0.895, substantially higher than ANLI's (0.672–0.740). It is worth noting that the level of semantic or pragmatic interpretation difference of GQs is reflected in the measurement.

We augmented the examples by substituting non-quantifier words (e.g., replacing "dogs" with "cats") while keeping the labels, to exclude the effect of specific lexical items. The resulting labels are uniformly distributed. Table 8 presents GQNLI statistics. Since the dataset is curated to probe the ability to reason with quantifiers, the distribution of generalized quantifiers does not follow Zipf's law; see §4. A list of GQNLI examples per category is shown in Appendix E.

Experiments and Results We evaluate seven types of models on GQNLI, fine-tuned with different combinations of NLI datasets. As data creation only relied on RoBERTa and MNLI, nothing prevents that models with different architectures and training data will perform well. They do not, however. The results are shown in Table 8.

We see that all models have great difficulty with GQNLI. With more training data, models improve, but the best performance is 48%, less than 15 points above chance level. In general, the counting quantifiers, especially the existential and universal quantifiers, are easier than proportional quantifiers. Particularly, most models struggle with *less than k* and *between*. This is in some contrast with the NLU tasks studied above, where these quantifiers were among the easiest.

We also observe unstable GQ reasoning ability in simple word substitution cases. For instance, it happens for DeBERTa fine-tuned with M, F, Ling, DocNLI that it predicted correctly the contradiction

Table 8: GQNLI statstics and seven types of models' performance with different combinations of training data. The second row shows the occurrence time of the type of GQ in GQNLI. The following rows show models' performance on the dataset. We tested most competitive models fine-tuned for NLI available on Hugging Face. All but ALBERT (`xxlarge`) and DeBERTa-v3 (`base`) are size `large`. S, M, F, Ling, A, DocNLI refer to SNLI, MNLI, Fever-NLI, LingNLI (Parrish et al., 2021), ANLI and DocNLI (Yin et al., 2021), respectively. Numbers in bold represent the highest accuracy in one category. Due to space limitation we provide the link to each model in the Appendix H.

relation between "There are six children standing on top of a yellow mountain. Two thirds wear red tops and one third wear green." and "Between 80% and 90% children do not wear red tops.", but incorrectly when "red" is substituted with "beige" and "green" with "cyan". We are yet to study what kind of cues lead to the instability. Our experiments suggest a lack of testing proportionality reasoning and robustness in existing benchmarks.

7 Discussion

Negation The interaction between negation words and quantifiers increases semantic complexity (Partee, 1970; Horn, 2010). We investigate whether this holds for NLI tasks, using negation cue detection to find all cases where a negation word and a quantifier appear in the hypotheses.

We break down the performances on negation of the seven models in Appendix F. As indicated, LMs overall have polarized results for negation cases comparing to the entire dataset. We can see a majority of the models even predicted opposite labels for some GQ categories, with 0% accuracy. BART is no longer the second best model, replaced by RoBERTa. The improvement by training with more data is overall consistent for reasoning over GQs with negation.

For a cross-lingual investigation of the interaction of GQs and negation, we find that in XNLI, the number of cases combining both phenomena is insufficient: we identified four such cases, involving only the quantifiers "all" and "more than." For English, mBERT predicted two cases successfully. For Chinese, German, Vietnamese and Arabic, one is correct. For Spanish, all are wrongly predicted.

It is evident that NLU models suffer from reasoning difficulties in certain cases when negation interacts with GQs, especially in cross-lingual evaluation. In future work, we are interested in expanding GQNLI to more instances and more languages to facilitate qualitative investigations.

Subsumption In generalized term subsumption languages (TSLs; Yen, 1991; Ali and Shapiro, 1993), a term a subsumes another term b if and only if the extension of a is a superset of the extension of b . Rather than surface number comparison, subsumption reasoning requires knowledge of the relations between supersets and subsets. For example, to decide whether "There are six dogs. Three brown dogs, a black dog and a white dog run along the green grass" entails "One dog sits", LMs should be aware that "six dogs" is a superset of the extension of the "brown dogs", "black dog" and "white dog". Another example in GQNLI is to infer whether "There are twelve singers on a stage, less than half from Argentina and one from Cape Verde" entails "Several singers do not come from Chile".

We annotate 63 cases out of the first 100 in GQNLI requiring subsumption reasoning. We show the statistics and results regarding subsumption in Appendix G. It can be seen that more training data leads to higher accuracies. Especially, DeBERTa fine-tuned with DocNLI, which unifies the two classes "neutral" and "contradict" into a new class "not entail", has a significant improvement on subsumption cases with neutral label. The training bias give an advantage to the model on the subsumption subset, half cases of which are labelled neutral. But such bias has a negative effect on non-subsumption cases; the accuracy drops by 20.2% comparing to the model without training with DocNLI. It is worth investigating whether DocNLI is truly helping subsumption reasoning in future work. Subsumption is a key concept in the study of knowledge representation (Woods, 1991), but is neglected in current NLP research. The fact that LMs struggle to perform subsumption reasoning asserts the necessity to explicit tackle the problem.

8 Related Work

We examine the sensitivity of NLU models to generalized quantifiers. These models are designed to induce correlations from large volumes of data, not to reason symbolically with logical quantifiers. Such models have, nevertheless, been probed for logical knowledge.

Mul and Zuidema (2019), for example, show neural networks encode fragments of first-order logic and exhibit zero-shot generalization ability. Evans et al. (2018) present a neural architecture that improves performance on propositional logical inference. Bowman et al. (2015b) also suggest neural networks learn semantic representations for logical inference in natural languages. However, on the same task, Veldhoen and Zuidema (2017) find neural networks fail to do so on a more stringent test. Geiger et al. (2019) also show that neural networks fail to exhibit robust logical inference. Srivastava et al. (2018) use semantic parsers to encode quantifiers and improve zero-shot learning in classification tasks. Haruta et al. (2020) present a system that computes logical inference over GQs and see improvements on two specialized datasets, FraCaS (Cooper et al., 1994) and MED (Yanaka et al., 2019). None of these papers explicitly discussed generalized quantifiers, and all were limited to studying the ability of neural networks to capture the logical semantics of English.

Many studies have instead focused on LMs' ability to capture negation (Gururangan et al., 2018; Naik et al., 2018; Hossain et al., 2020; Ettinger, 2020; Hartmann et al., 2021) or coreference (Ye et al., 2020; Varkel and Globerson, 2020; Abdou et al., 2020). Others have focused on LMs' ability to reason with numbers (Johnson et al., 2020). DROP (Dua et al., 2019), for example, is a question answering dataset designed specifically to probe LMs' ability to count, add and subtract for answering factoid questions. Models have also been tailored for numerical reasoning (Geva et al., 2020; Zhang et al., 2020). Cobbe et al. (2021) proposes to use a verification task during pretraining of LMs to improve their ability to solve math word problems. Others have studied monotonicity inference (Hu et al., 2019; Yanaka et al., 2019, 2020), and Fang and Lou (2021) recently focused on the two quantifier words *part* and *whole* in an error analysis for named entity recognition.

Many NLU benchmarks contain quantifier words, but their influence on performance has not been studied systematically. One exception to this is that generalized quantifiers have been used to generate adversarial examples in the context of numerical reasoning (Naik et al., 2018; Nie et al., 2020). TaxiNLI (Joshi et al., 2020), which categorizes 15 types of reasoning abilities, is a dataset drawn from MNLI. In their taxonomy, the Quantifier category only refers to universal and existential quantifiers, *not* to generalized quantifiers, and ditto for Kim et al. (2019). All of the above focused on English, but in an extension to TaxiNLI, K et al. (2021) incorporated quantifiers into the Logic class and found a large cross-lingual transfer gap on LMs.

9 Conclusion

Quantifiers lie in the intersection of logic, linguistics and NLP research. It is essential for NLU systems to learn quantifier reasoning. We examined generalized quantifiers in multilingual NLU tasks with regards to their expressiveness and logical reasoning requirement. Our survey and experiments indicate quantifiers are neglected to a degree and cause significant performance drops for neural LMs. To better understand LMs' reasoning abilities, we release GQNLI, a novel generalized quantifier NLI challenge dataset. With the pervasiveness of generalized quantifiers, we stress that more efforts are necessary to investigate: (1) when and why models systematically fail when quantifiers interact with other operators; (2) how to improve cross-lingual transferability of quantifiers; (3) how we can exploit the theoretical results about generalized quantifiers from logic and linguistic studies, so as to improve the logical inference ability of neural LMs.
