Input prompt	[s1] nina needed blood tests done. ⟨*before*⟩ ⟨***after***⟩ ⟨*before*⟩ ⟨*before*⟩
baseline	[s2] she was very nervous. [s3] she went to the local clinic. [s4] they told her about her bad breath. [s5] she was relieved her nerves were n't too much to handle.
Vanilla	[s2] she was terrified of needles. [s3] she went to the doctor. [s4] the doctor gave her a needle. [s5] nina was relieved.
RL	[s2] she was afraid to go to the hospital. [s3] she had never been to a hospital before. [s4] but when she got there, she was relieved. [s5] she felt so relieved!

Input prompt	[s1] mickey was always a fan of webcomics. ⟨***after***⟩ ⟨*before*⟩ ⟨*before*⟩ ⟨*before*⟩
baseline	[s2] he loved writing his own comics one night. [s3] then he had a great idea. [s4] he created a story called the superman story. [s5] the story was real as a kids cartoon.
Vanilla	[s2] one day, he decided to make a webcomic himself. [s3] he created a website and sent it to a publisher. [s4] the publisher loved it and contacted mickey. [s5] mickey was happy to receive a publishing deal.
RL	[s2] he had been writing for years. [s3] one day, mickey saw an ad for a webcomic. [s4] he signed up for it. [s5] mickey was able to make a lot of money from his work.

Input prompt	[s1] anna had just gotten her hair permed. ⟨*before*⟩ ⟨*before*⟩ ⟨***after***⟩ ⟨*before*⟩
baseline	[s2] she was nervous about it. [s3] she was too nervous to do it. [s4] she tried to cut hair to look better. [s5] when she was done it looked great !
Vanilla	[s2] she was excited to see how it looked. [s3] but then she saw that her hair had grown out. [s4] anna was horrified! [s5] she had to go to the salon to get it fixed.
RL	[s2] she was excited to see how it looked. [s3] but when she went to apply it, it was terrible. [s4] her hair had grown way too long! [s5] anna had to go to the salon to get her hair fixed.

Table 6: Additional generated stories for ROCStories.

A Additional Generated Stories

Please see Table 6 and Table 11 for more examples on ROCStories and WritingPrompt respectively.

B Data

ROCStories (Mostafazadeh et al., 2016a) contains 5-sentence stories. Following (Xu et al., 2020), we split data into 88,344/4,908/4,909 for train/validation/test sets.

WritingPrompt (Fan et al., 2018) contains 30,335 pairs of prompts and stories. With an average of more than 700 words per story, Writing Prompts are much longer than ROCStories. These stories are also much less structured as some dialogues and short phrases may be included. To speed up our experiments, we select stories with a maximum of 500 words, resulting in a total number of 96,488 training and 5,784 validation prompt-story pairs, respectively. For the test set, we use the 1,000 prompt-story pairs provided by the baseline paper (Goldfarb-Tarrant et al., 2020) for reporting automatic evaluation results.

Pretraining Data. As we mention in Section 3.4, we pretrain storyline models for ROCStories. To be consistent with ROCStories inputs, we divide BookCorpus data (Zhu et al., 2015) into 5 consecutive sentences and filter out those with noisy tokens. We randomly select 1 million such 5-sentence text spans and extract their storylines following Section 3.2.

C More Details for Evaluation Metrics

Automatic evaluation metrics are used to measure textual quality of stories. We report 1) **Ref. PPL**: reference stories' perplexity in a model; 2) **Gen. PPL**: generated stories' perplexity scored by GPT-2 (Radford et al., 2019), i.e. we feed the generated stories into GPT-2 to compute perplexity scores. For diversity scores, we found our models implemented by Huggingface (Wolf et al., 2020) can achieve nearly 0 **Repeat-3** and 100% **Distinct-3** scores, so we follow Goldfarb-Tarrant et al. (2020) to compute the overall vocabulary:token number ratio, which we denote as 3) **Distinct Ratio** (%). We also report standard 4) **BLEU-3** and 5) **ROUGE_L** scores.

D More Details for Baseline Models

MEGATRON-CNTRL Xu et al. (2020), denoted as MEGATRON for brevity, is chosen as the baseline as it outperforms previous systems such as Guan et al. (2020) on ROCStories. We do not perform delexicalization that replaces names and entities with *[MALE]*, *[FEMALE]* and *[NEUTRAL]* tokens, as we found our models work well by recognizing names and entities. When conducting evaluations, we try our best to **map these special tokens back to their original texts** by using the given first sentence. For rare undetermined cases, we manually examine the generated stories and swap in names or entities that make the most sense in the context. To be fair, we compare with the 124M-parameter version.

ContentPlanning (Goldfarb-Tarrant et al., 2020) is chosen as the baseline for WritingPrompt, as it also adopts the Plan-and-Write workflow as well as structured event representations. However, their models are based on BART-large and do not train with an end-to-end framework. They use 65% of the original training data and also filter out samples with non-[WP] prompts. Our final training data is about 2/3 of theirs.

TemporalBART (Lin et al., 2021) is designed for two event temporal relation related tasks: temporal ordering and event infilling. Although TemporalBART does not tackle story generation directly, it encodes event temporal information via pretraining tasks. So we consider TemporalBART as another baseline model by initialing the storyline model with their parameters and training the STRUCTURED-PROMPT workflow on ROCStories.[8]

E Reproduction Check List

We finetune BART-base. For ROCStories, hyper-parameters are learning rate: $5e^{-5}$; batch size: 10. We use 3 random seeds: $(5, 9998, 20016)$ and report the average performances for all end-to-end models. For Writing Prompts, hyper-parameters are learning rate: $1e^{-4}$; batch size: 64; gradient accumulation: 8.

For ROCStories, we were able to finetune on a single Nvidia GTX2020 GPU with 11G memory, and training time is 3-4 hours per epoch. For WritingPrompt, we have to use a much larger Nvidia A100 GPU with 40G memory, and the training time is 20 hours per epoch. We train all models for 10 epochs and save the model with the best evaluation perplexity. All reproduction details can be found in the separately submitted code.

F Perplexity and Event Coverage Trade-off

One caveat of using end-to-end training is that there is no guarantee that the generated events will appear in the final stories; whereas in two-stage models, the story model learns a mapping from reference storylines to stories, which leads to a higher coverage rate of the generated events. To provide a potential solution, we experiment with the mixture-training method proposed by Zhang et al. (2019),

$$p = \frac{\mu}{\mu + \exp(e/\mu)}$$

where p controls the ratio of reference storylines used in training and e is the training step. Here the larger the hyper-parameter μ, the slower p decays to 0 as training proceeds.

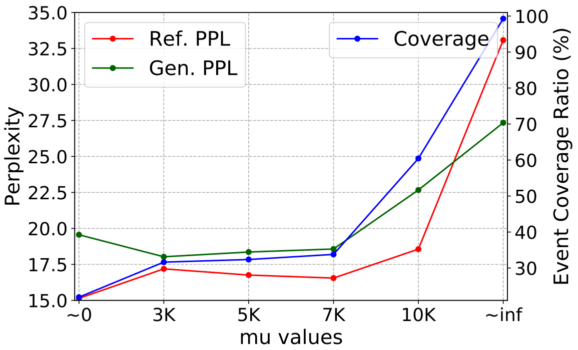

Figure 4: Trade-off between perplexity scores and generated event (trigger) coverage.

In Figure 4, we show the trade-off between perplexity and μ values by training our final RL-based models. When μ is nearly zero, it corresponds to always using predicted storylines, and hence a smaller predicted event coverage rate in the final stories. When μ gets larger, eventually making p close to 1, the training corresponds to always using gold storylines, which leads to a very high event coverage rate, but relatively poor perplexity (still much stronger than two-stage results). We leave the search for optimal μ for future research.

CaTeRS	MATRES
A ⟨*Before*⟩ B	A ⟨*before*⟩ B
A ⟨*Identity*⟩ B	A ⟨*vague*⟩ B
A ⟨*Contains*⟩ B	A ⟨*before*⟩ B
A ⟨*Overlaps*⟩ B	A ⟨*before*⟩, ⟨*after*⟩, ⟨*vague*⟩ B

Table 7: Label mapping from CaTeRS to MATRES. ⟨*after*⟩ is ignored in CaTeRS by flipping event physical order.

G Benchmark Event Temporal Relation Annotations

The experimental results in the main text demonstrate the effectiveness of using temporal prompts. Here, we further show that the tool to produce temporal prompts, i.e. ECONET, provides reliable event temporal relation annotations. We benchmark ECONET's performances using CaTeRS (Mostafazadeh et al., 2016b), which annotates 4 types of temporal relations for event pairs in a small amount of ROCStories. However, CaTeRS's annotations are based on event time interval rather than event start time as used in MATRES, which ECONET is finetuned on.

In Tabel 7, we provide a mapping from CaTeRS's temporal relations to MATRES labels.

---

[8] More implementation details such as hyper-parameters and software can be found in the appendix.

The only non-unique mapping is ⟨*Overlap*⟩. In other words, when ECONET predicts ⟨*before*⟩ for a CaTeRS sample ⟨*Overlaps*⟩, we have to manually examine whether it is correct or not. We found that when ECONET predicts ⟨*before*⟩ for CeTeRS data, the precision rate is 65.53% due to a large amount of ⟨*Overlaps*⟩ event pairs being predicted as ⟨*before*⟩. But we emphasize here that this low number **is caused by label mismatch** as shown in Table 7, which does not truthfully reflect the ECONET's accuracy.

To have a better understanding, we randomly selected 20 such pairs and manually examine their temporal relations in the context and found that 90% of such pairs are indeed correctly predicted by ECONET. Adjusting for this factor, the precision rate for the annotated ⟨*before*⟩ relation would be 92.07%, indicating highly accurate predictions. We do not claim the final accuracy is 92.07%, but simply argue that the annotations provided by ECONET are helpful as our main experimental results demonstrate.

H Two-stage Model Results

Two-stage Model. As we mentioned in Section 3, another way to implement Plan-and-Write framework is to train storyline and story models separately with gold input and outputs, and replace story models' inputs with the storyline model's predictions during inference. We found this variant's performances fall far behind other compared models. So we do not use them in human evaluations and simply show their automatic evaluation results in Table 8.

Models	Ref. PPL(↓)	Gen. PPL(↓)	Distinct Ratio(↑)	BLEU (↑)	ROUGE$_L$ (↑)
ROCStories	197.97	27.15	4.26	2.98	16.39
WritingPrompt	76.69	39.43	8.12	0.00	6.24

Table 8: Automatic Evaluation Results for the Two-stage models.

I Storyline Model Results

Our primary goal is to improve temporal control in final stories. However, as aforementioned, the motivation for using reinforcement learning is to allow the storyline model to adapt together with the story model. In Table 9, we compare storyline prediction performances between the vanilla and the RL-based end-to-end models. These results suggest that our final framework combining structured storylines, temporal prompts, pretraining and RL also helps storyline models fit reference storylines better, resulting in lower perplexity, higher overlapped scores and better diversity.

Models	Ref. PPL (↓)	BLEU (↑)	Distinct Ratio (↑)
Vanilla-Gen	13.97	3.21	3.68
+ RL	**12.71**	**3.49**	**4.09**

Table 9: Improvements of RL-based model against vanilla end-to-end model on ROCStories data.

J Error Analysis

Table 10 shows examples for the temporal diversity in Section 6.

Input 1	[s1] justin is a very charismatic man who loves women.
baseline	[s2] he always said that he wanted to be a man. [s3] he thought that men looked bad. [s4] justin decided to become a boy scout. [s5] he is now a successful realtor. **predicted relations:** ⟨*vague*⟩ ⟨*vague*⟩ ⟨*vague*⟩ ⟨*before*⟩
RL	[s2] one day he met a beautiful woman and they fell in love. [s3] justin decided he wanted to marry her. [s4] he went to the mall and bought a ring. [s5] he proposed to her and she said yes. **predicted relations:** ⟨*before*⟩ ⟨*before*⟩ ⟨*before*⟩ ⟨*before*⟩
Input 2	[s1] the smoke was beginning to get to me.
baseline	[s2] mary friend said he had to come to my house. [s3] i wanted to have a smoke fight. [s4] he said i had to light a cigarette. [s5] i smoked for a few hours before i gave up. **predicted relations:** ⟨*after*⟩ ⟨*vague*⟩ ⟨*before*⟩ ⟨*before*⟩
RL	[s2] i had just gotten out of my car. [s3] i ran to the front door. [s4] i opened the door. [s5] the fire department came and put out the fire. **predicted relations:** ⟨*vague*⟩ ⟨*before*⟩ ⟨*before*⟩ ⟨*before*⟩
Input 3	[s1] tom was in court for a parking ticket.
baseline	[s2] he did not have to pay his court date. [s3] the judge gave him a parking ticket. [s4] tom paid his court date. [s5] the judge gave tom a parking ticket. **predicted relations:** ⟨*before*⟩ ⟨*vague*⟩ ⟨*before*⟩ ⟨*after*⟩
RL	[s2] he had been speeding for a while. [s3] the judge gave him a warning. [s4] tom didn't listen to the warning. [s5] he got a ticket anyway. **predicted relations:** ⟨*after*⟩ ⟨*before*⟩ ⟨*before*⟩ ⟨*after*⟩

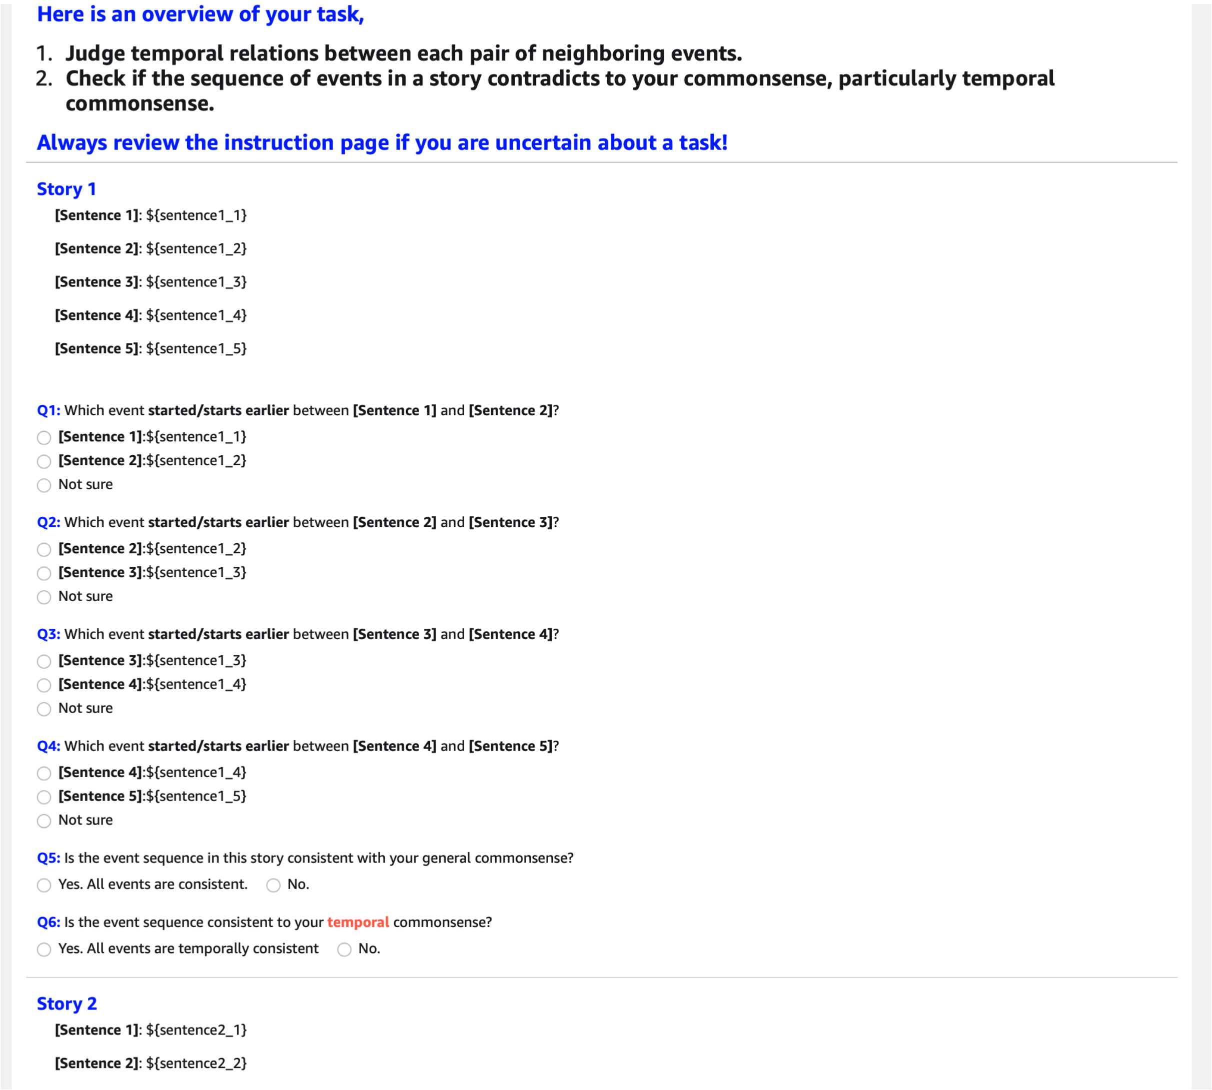
Table 10: Examples from our RL-based model that are not as temporally diverse as examples generated by the baseline MEGATRON model. **Predicted relations** are provided by human evaluators.

K Potential Risks

Since our models deal with open-domain generation, it is conceivable that the generated stories could contain biases, malicious languages, and hallucinations. We refer readers to the work in fairness and fact checking to address these issues.

Input prompt	artic outpost 9 ⟨*after*⟩ ⟨*vague*⟩ ⟨*before*⟩ ⟨*after*⟩ ⟨*before*⟩ ⟨*vague*⟩ ⟨*vague*⟩
baseline	she stood alone in the dimly lit corridor , staring at the light that flooded into the room . her eyes scanned the room , finally settling on the small , round table . ¡p¿ ¡p¿ “ hello , everyone . ” ¡p¿ the woman spoke in a voice that echoed the room in a series of hushed tones , as though it was a voice only audible to those who heard it . “ do you know why we are here ? do you know where we come from ? ” our leader , the man with the black suit and black hat , stood at the end of the hall . a man in a black coat and black trousers , a long coat , and a black hat stood behind him , a black cloak and a dark hat , a pair of gloves . the black suit had a black mask on , and she was wearing her best , black dress shirt and a pairof pants , and black shoes . on her right wrist , the small of one shoulder , was an amulet , and on the other , a small device hidden in the pocket of the man ’s coat , a single small device . there was nothing else . just this man . . . and our leader
VANILLA	i’ve never seen anything like it before. it’s a strange place. i don’t know why i chose it, but i’ve always wanted to see it. it was the first time i saw it. it was a small building with a single window. i couldn’t believe it. i had never seen it before, but it was here. i’m not sure what it is, but there’s something about it that makes me want to run. i can’t remember the last time i ’d seen it. but i do know that it was there. the first thing i noticed was the door opening. i wasn’t sure if it was my own, or my own. i didn’t want to be here. i just wanted to get out. i wanted to go back to my home. as i approached the door, i saw a man standing there. he was wearing a trench coat. he had a gun pointed at his head. he pointed it at my head. “ what are you doing here? ” i asked. he looked at me. he looked like he was about to say something. “ i need you to come with me. ” he said, and i followed him. we were in the middle of nowhere when the man shot me in the head. i looked at him, and he looked back at me, then at the gun. i felt a sharp pain in my chest. i started to cry. i tried to speak, but my throat was dry. i heard the man say something, and then he shot me. i fell to the ground, bleeding. i woke up in a hospital bed. there was a note on my bedside table. i opened it and read it aloud. *i’m sorry, but this isn’t what i was expecting.
RL	what’s that? we’ve been waiting for you for a long time, i said. i’m not sure how long you’ll be waiting for me. you don’t have much time to think about it, do you? i mean, i can see it, but i can feel it in your eyes, and i can hear it in the way you can hear me. i can smell it, and it can feel your heart beating faster than you can think. i think you know what i am talking about. i know what you are talking about, but you can not understand what i mean. i want you to know that i love you. i need you to understand that you are my love, and that i will always be there for you. that you will always love me. that i am the love of my life, and you are the love that i have always wanted to be. and i will never let you down. i will not let you go. i promise you that.with that, i walked out of the building, into the street, and into the night.
Input prompt	100000 year high ⟨*before*⟩ ⟨*after*⟩ ⟨*before*⟩ ⟨*before*⟩
baseline	for a long time it seemed the world ’s people all were living in the same way . the same . they were all the same . the same , they had the same families and their children and they all had the same friends . but these families were all different . they may have been the last of them , and the world was a better place without it , but those people knew about it , they just did n’t know the truth . some of them lived for years , some of them a century . and a new age started , one that would make this world a better places . a world without war or war . it seemed the first people could see the world and see the future and people living it . they were the first to do it . ” “ the first people on earth who could live a normal life ! the first to have a normal family and a normal home ! the first ones who we could live on ! who could have imagined that our world was as good as ours was and that the next life would be better than what i ’ ve been , that there ’s a whole new life ahead of us , that this world is a living one ! ” and that ’s when it happened . that was the day . on march 20th , 2036 . march 20, 2036 , the first time that day
VANILLA	it was a beautiful day. the sun was shining and the sky was blue. the clouds were bright and the trees were green and the birds were singing. it was a wonderful day. i was walking down the street when i saw it. the sky above me was blue and it was beautiful. i had never seen anything like it before. i looked down at the ground and saw nothing. i didn’t know what to do. i took a step back and looked up at the sky. i couldn’t see anything at all. i walked towards the sky and looked at the stars. they were beautiful. they seemed like they were floating. i reached out and touched them. i felt a warmth in my chest. i touched them again and again. it was amazing. i wasn’t sure if i was dreaming or not, but i knew i was.
RL	it’s been a long, long time since i’ve seen the light of the sun. i’m not sure how long it has been, but i think it’s a long time. i ’d like to say that the last time i saw the light, it was a thousand years ago, but it wasn’t. it was only a few years ago that i first saw the sun, when it was just a few seconds away from reaching the horizon. i don’t know how long i have been seeing it, but the light is blinding, and i can’t help but wonder what it could have been like. maybe i ’ll see it again, but for now, i just want to see the light again.
Input prompt	paint a picture of loneliness , without using the word , or any of its forms . ⟨*before*⟩ ⟨*vague*⟩ ⟨*vague*⟩ ⟨*vague*⟩ ⟨*before*⟩ ⟨*before*⟩ ⟨*before*⟩ ⟨*after*⟩ ⟨*after*⟩ ⟨*before*⟩
baseline	the glass is cold , but the sun shines brightly through . on the glass , in a small room , a woman stands . it stands before her , its hands clutching the glass in front of it like a shield . it 2019 s not the sunlight , but it hits the sky like a storm . the light makes the clouds roll in from all directions . a soft breeze , the wind blowing through the trees , the water rustling in the water . there are people in the room , but most do n’t look at their feet , they ’re too busy staring out the window . some are silent . most look at the woman . one of the people looks back at the woman who seems to be alone in this room , who is alone with a glass of champagne . the wind and water make the trees sway . you hear the birds chirping from outside . a few laugh , some are sad , some angry , but most are happy , and some are happy . there ’s a small child sitting on her lap . in the corner . on the ground , on a bench . and it ’s just this woman and the glass .
VANILLA	i’ve always been lonely. i’m not sure why. maybe it’s the fact that i don’t have any friends. maybe i’ve been alone for a long time. i haven’t seen anyone. i can’t even remember where i am. i have no friends. there’s no one to talk to. no one who can help me. i just want to be alone. sometimes i think that i ’ll just be alone forever. but then i think back to the first time i saw someone else. it was a girl. she’s beautiful, but she looks like she doesn’t belong here. she has no friends, no family, no one. then i thought of her. i think of the way she looked at me. the way i looked at her, the way her eyes looked at the people around her. that’s when i realized that i was alone.
RL	i don’t know why i’m doing this, but i’ve been doing it for a long time now. it’s been a long, long time since i ’d seen a single person. i remember the first time i saw her. she was beautiful, and i loved her. but i couldn’t tell you how much i missed her. i didn’t want to know how much she meant to me. and i can’t even remember the last time i talked to her, because i was too busy trying to figure out what to say. she was always there for me, and she always made me feel so alone. sometimes i wish i could go back, but sometimes i think i ’ll just stay here forever. maybe someday, when she’s gone, she ’ll come back.

Table 11: Additional examples for WritingPrompt. Possible ⟨*after*⟩ relations are highlighted.



Here is an overview of your task,

1. **Judge temporal relations between each pair of neighboring events.**
2. **Check if the sequence of events in a story contradicts to your commonsense, particularly temporal commonsense.**

Always review the instruction page if you are uncertain about a task!

Story 1

[Sentence 1]: ${sentence1_1}

[Sentence 2]: ${sentence1_2}

[Sentence 3]: ${sentence1_3}

[Sentence 4]: ${sentence1_4}

[Sentence 5]: ${sentence1_5}

Q1: Which event **started/starts earlier** between **[Sentence 1]** and **[Sentence 2]**?

○ **[Sentence 1]**:${sentence1_1}
○ **[Sentence 2]**:${sentence1_2}
○ Not sure

Q2: Which event **started/starts earlier** between **[Sentence 2]** and **[Sentence 3]**?

○ **[Sentence 2]**:${sentence1_2}
○ **[Sentence 3]**:${sentence1_3}
○ Not sure

Q3: Which event **started/starts earlier** between **[Sentence 3]** and **[Sentence 4]**?

○ **[Sentence 3]**:${sentence1_3}
○ **[Sentence 4]**:${sentence1_4}
○ Not sure

Q4: Which event **started/starts earlier** between **[Sentence 4]** and **[Sentence 5]**?

○ **[Sentence 4]**:${sentence1_4}
○ **[Sentence 5]**:${sentence1_5}
○ Not sure

Q5: Is the event sequence in this story consistent with your general commonsense?

○ Yes. All events are consistent. ○ No.

Q6: Is the event sequence consistent to your **temporal** commonsense?

○ Yes. All events are temporally consistent ○ No.

Story 2

[Sentence 1]: ${sentence2_1}

[Sentence 2]: ${sentence2_2}

Figure 5: Annotation interface for pairwise event temporal relations and temporality.

[Task 1] Judge temporal relations between each pair of neighboring events.

Instructions: In this task, we want you to focus on the temporal order of events. Occassionally, you may encounter event sequences that do not make sense. For example, "I went to class this afternoon. I found my puppy was giving a speech in class." Although this sequence of events contradict to our commonsense, we want you to imagine the situation where if these events were to happen, which event started earlier? In this case, "I went to class this afternoon" started earlier. In [Task 2], we will ask you to check events' general commonsense and temporal commonsense. Again, please try to evaluate events' temporal order by assumming all events in a story indeed happen in **Q1 - Q4** below.

Q1: Which event **started/starts earlier** between **[Sentence 1]** and **[Sentence 2]**?

○ **[Sentence 1]**: tom was about to have a little brother.
○ **[Sentence 2]**: he was nervous because he didn't know what to name him. **[✓]**
○ Not sure **[✓]**

Explanation: The event in **[Sentence 1]** is "was about to have," while the events in **[Sentence 2]** are "was nervous" and "didn't know what to name." From the context, it is relatively clear that "was about to have" started earlier than "was nervous." However, the second event "didn't know" is subject to personal interpretation. One way to reason about "didn't know" is that Tom probably always lacks knowledge or creativity, so "didn't know" is a long-lasting status for him, in which case "didn't know" started earlier than "was about to have," and thus, pick the second option. Another way to interpret this is that "didn't know" started at the time when "he was about to have a little brother," in which case we are not sure which event started earlier. So pick the last option. When you are working on the real tasks and are uncertain about exactly which event started earlier, "not sure" is a safe option. But please do carefully consider option 1 and 2 before you pick option 3.

Q2: Which event **started/starts earlier** between **[Sentence 2]** and **[Sentence 3]**?

○ **[Sentence 2]**: he was nervous because he didn't know what to name him. **[✓]**
○ **[Sentence 3]**: he went to the doctor.
○ Not sure

Explanation: The events in **[Sentence 2]** are "was nervous" and "didn't know," while the event in **[Sentence 3]** is "went." It is clear from the context that both events in **[Sentence 2]** started earlier. So you should pick the first option here.

Q3: Which event **started/starts earlier** between **[Sentence 3]** and **[Sentence 4]**?

○ **[Sentence 3]**: he went to the doctor. **[✓]**
○ **[Sentence 4]**: the doctor gave him a name.
○ Not sure

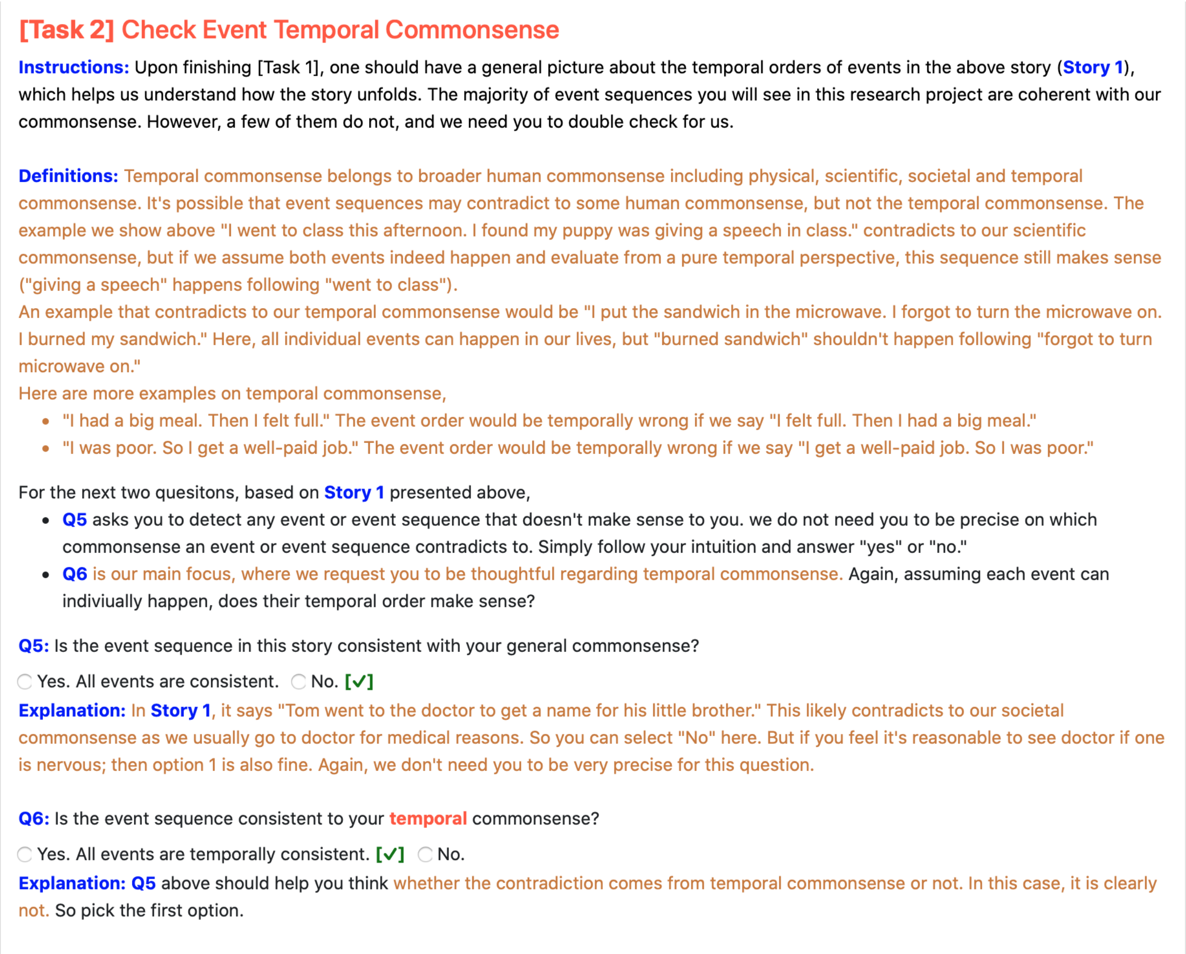
Explanation: The events in **[Sentence 3]** is "went" while the event in **[Sentence 4]** is "gave." Based on the context, it is also clear that "went" started earlier than "gave," so pick option 1 here.

Q4: Which event **started/starts earlier** between **[Sentence 4]** and **[Sentence 5]**?

○ **[Sentence 4]**: the doctor gave him a name. **[✓]**
○ **[Sentence 5]**: tom named him james.
○ Not sure

Explanation: It is clear from the context that "gave him a name" started earlier than "named him james." So also pick the first option in this case.

Figure 6: Instruction for pairwise event temporal relation annotation.



[Task 2] Check Event Temporal Commonsense

Instructions: Upon finishing [Task 1], one should have a general picture about the temporal orders of events in the above story (**Story 1**), which helps us understand how the story unfolds. The majority of event sequences you will see in this research project are coherent with our commonsense. However, a few of them do not, and we need you to double check for us.

Definitions: Temporal commonsense belongs to broader human commonsense including physical, scientific, societal and temporal commonsense. It's possible that event sequences may contradict to some human commonsense, but not the temporal commonsense. The example we show above "I went to class this afternoon. I found my puppy was giving a speech in class." contradicts to our scientific commonsense, but if we assume both events indeed happen and evaluate from a pure temporal perspective, this sequence still makes sense ("giving a speech" happens following "went to class").
An example that contradicts to our temporal commonsense would be "I put the sandwich in the microwave. I forgot to turn the microwave on. I burned my sandwich." Here, all individual events can happen in our lives, but "burned sandwich" shouldn't happen following "forgot to turn microwave on."
Here are more examples on temporal commonsense,

- "I had a big meal. Then I felt full." The event order would be temporally wrong if we say "I felt full. Then I had a big meal."
- "I was poor. So I get a well-paid job." The event order would be temporally wrong if we say "I get a well-paid job. So I was poor."

For the next two quesitons, based on **Story 1** presented above,

- **Q5** asks you to detect any event or event sequence that doesn't make sense to you. we do not need you to be precise on which commonsense an event or event sequence contradicts to. Simply follow your intuition and answer "yes" or "no."
- **Q6** is our main focus, where we request you to be thoughtful regarding temporal commonsense. Again, assuming each event can indiviually happen, does their temporal order make sense?

Q5: Is the event sequence in this story consistent with your general commonsense?

○ Yes. All events are consistent. ○ No. **[✓]**

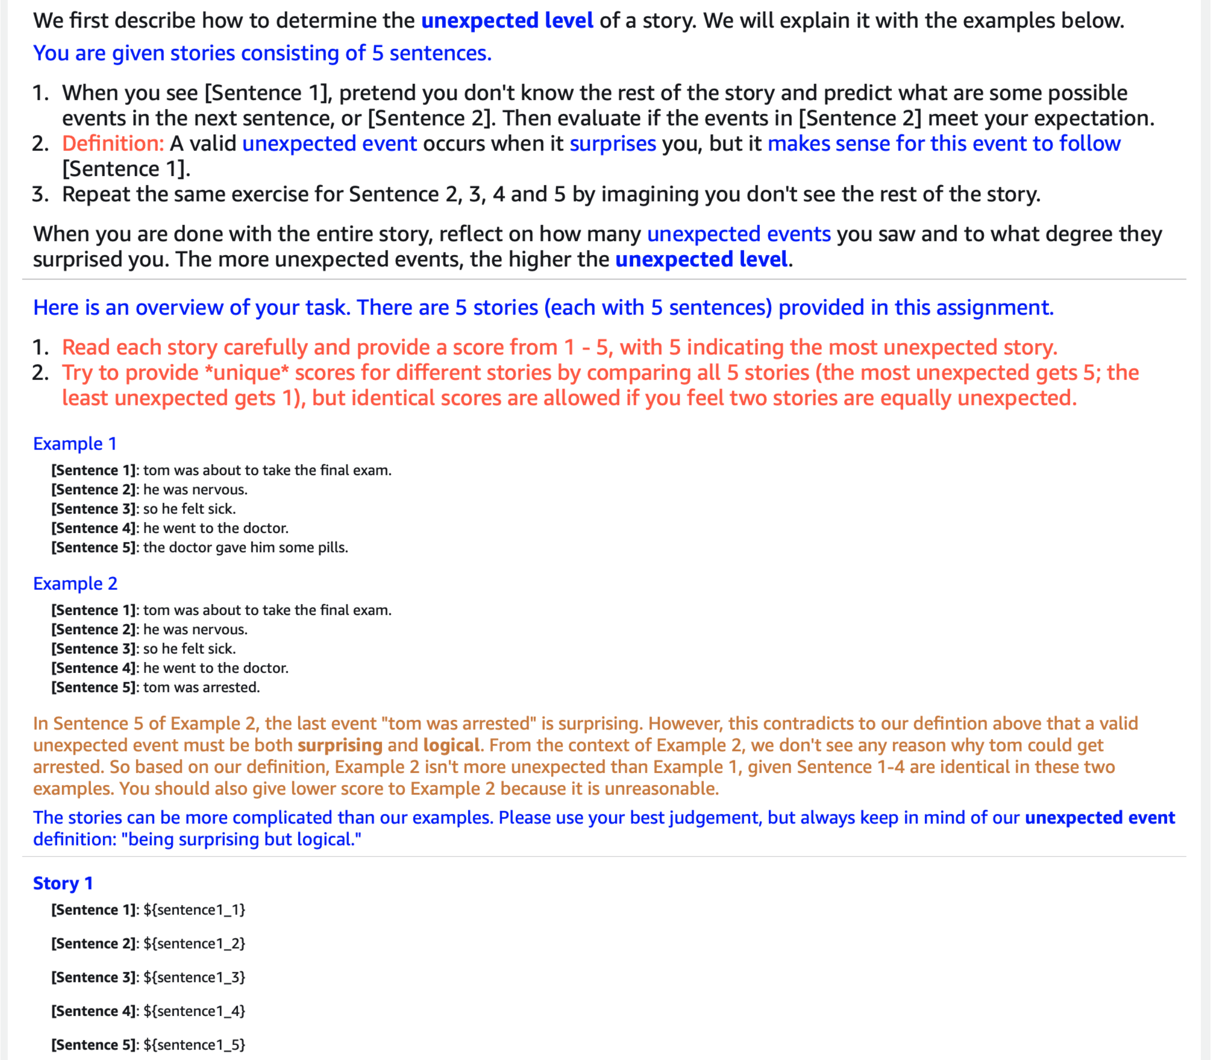
Explanation: In **Story 1**, it says "Tom went to the doctor to get a name for his little brother." This likely contradicts to our societal commonsense as we usually go to doctor for medical reasons. So you can select "No" here. But if you feel it's reasonable to see doctor if one is nervous; then option 1 is also fine. Again, we don't need you to be very precise for this question.

Q6: Is the event sequence consistent to your **temporal** commonsense?

○ Yes. All events are temporally consistent. **[✓]** ○ No.

Explanation: **Q5** above should help you think whether the contradiction comes from temporal commonsense or not. In this case, it is clearly not. So pick the first option.

Figure 7: Instruction for temporality annotation.



We first describe how to determine the **unexpected level** of a story. We will explain it with the examples below.

You are given stories consisting of 5 sentences.

1. When you see [Sentence 1], pretend you don't know the rest of the story and predict what are some possible events in the next sentence, or [Sentence 2]. Then evaluate if the events in [Sentence 2] meet your expectation.
2. Definition: A valid unexpected event occurs when it surprises you, but it makes sense for this event to follow [Sentence 1].
3. Repeat the same exercise for Sentence 2, 3, 4 and 5 by imagining you don't see the rest of the story.

When you are done with the entire story, reflect on how many unexpected events you saw and to what degree they surprised you. The more unexpected events, the higher the **unexpected level**.

Here is an overview of your task. There are 5 stories (each with 5 sentences) provided in this assignment.

1. Read each story carefully and provide a score from 1 - 5, with 5 indicating the most unexpected story.
2. Try to provide *unique* scores for different stories by comparing all 5 stories (the most unexpected gets 5; the least unexpected gets 1), but identical scores are allowed if you feel two stories are equally unexpected.

Example 1

[Sentence 1]: tom was about to take the final exam.
[Sentence 2]: he was nervous.
[Sentence 3]: so he felt sick.
[Sentence 4]: he went to the doctor.
[Sentence 5]: the doctor gave him some pills.

Example 2

[Sentence 1]: tom was about to take the final exam.
[Sentence 2]: he was nervous.
[Sentence 3]: so he felt sick.
[Sentence 4]: he went to the doctor.
[Sentence 5]: tom was arrested.

In Sentence 5 of Example 2, the last event "tom was arrested" is surprising. However, this contradicts to our defintion above that a valid unexpected event must be both **surprising** and **logical**. From the context of Example 2, we don't see any reason why tom could get arrested. So based on our definition, Example 2 isn't more unexpected than Example 1, given Sentence 1-4 are identical in these two examples. You should also give lower score to Example 2 because it is unreasonable.

The stories can be more complicated than our examples. Please use your best judgement, but always keep in mind of our **unexpected event** definition: "being surprising but logical."

Story 1

[Sentence 1]: ${sentence1_1}

[Sentence 2]: ${sentence1_2}

[Sentence 3]: ${sentence1_3}

[Sentence 4]: ${sentence1_4}

[Sentence 5]: ${sentence1_5}

Figure 8: Annotation interface for interest level (unexpectedness).

Forecasting COVID-19 Caseloads Using Unsupervised Embedding Clusters of Social Media Posts

Felix Drinkall*, Stefan Zohren*†, Janet B. Pierrehumbert*‡
*Department of Engineering Science, University of Oxford
†The Alan Turing Institute
‡Faculty of Linguistics, University of Oxford
`felix.drinkall@eng.ox.ac.uk`

Abstract

We present a novel approach incorporating transformer-based language models into infectious disease modelling. Text-derived features are quantified by tracking high-density clusters of sentence-level representations of Reddit posts within specific US states' COVID-19 subreddits. We benchmark these clustered embedding features against features extracted from other high-quality datasets. In a threshold-classification task, we show that they outperform all other feature types at predicting upward trend signals, a significant result for infectious disease modelling in areas where epidemiological data is unreliable. Subsequently, in a time-series forecasting task we fully utilise the predictive power of the caseload and compare the relative strengths of using different supplementary datasets as covariate feature sets in a transformer-based time-series model.

1 Introduction

Many papers have shown that web search data can be used to forecast the spread of infectious diseases (Lampos et al., 2017), (Lampos et al., 2021), (McDonald et al., 2021), (Reinhart et al., 2021), (Alruily et al., 2022). Alongside this literature, social media has been exploited for its predictive potential in several other fields such as quantitative finance Xu and Cohen (2018), Sawhney et al. (2020), logistics forecasting Ni et al. (2017) and election forecasting (Bermingham and Smeaton, 2011), (Huberty, 2015). Research conjoining these two strands has produced results showing that social media can help predict rises in disease caseloads. Iso et al. (2016) and Samaras et al. (2020) both used pre-defined keywords in order to predict outbreaks of influenza; words such as "Influenza", "fever", "headache" were selected a-priori. These papers assume that useful feature sets have no geographical variation and use the same features regardless of the regional social dynamics; they also assume that useful features are limited to words that refer to symptoms. To address these limitations, Drinkall and Pierrehumbert (2021) set more general and objective inclusion criteria. For each of four US state COVID-19 subreddits, all words over-represented in that US state's COVID-19 subreddit compared to the rest of Reddit were considered to be potential keywords for forecasting. The most informative keywords proved to be highly dependent on the target state, and included many that did not refer to symptoms. However, the paper still relied on static word counts that miss more complex information as the discussion unfolds over time. The present paper extracts more informative features from social media data and, to our knowledge, is the first work to incorporate modern NLP techniques in this setting.

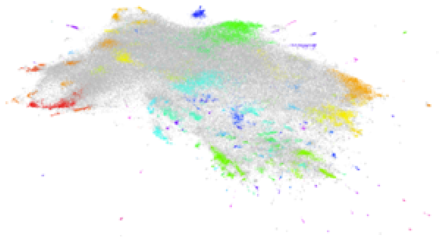


Figure 1: HDBSCAN clusters of the SBERT-NLI-STSb-base representations of r/CoronavirusWA posts made at 50 dimensions but reduced to 2 for visualisation.

New transformer-based language models (Devlin et al., 2019), (Yang et al., 2019), (Liu et al., 2019) provide the potential for identifying more informative features for infectious disease forecasting, and using them in a more effective manner. This paper uses transfer learning and clustering algorithms to isolate useful features for predicting COVID-19 caseloads. We first pilot-tested a straightforward way to exploit transformer-based language models for the task: the caseload target value was encoded alongside each post in a sequence classification framework. Trained using

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1471 - 1484
July 10-15, 2022

historical data, this approach generates a prediction from every post, and the results are aggregated for an overall prediction. This method performed very poorly because of noise introduced by irrelevant posts, and we do not discuss it further here (see Appendix C). To achieve better performance, we developed a novel feature identification technique that filters out unrelated posts and generates informative features using high-density clusters of posts within a subreddit's embedding space.

Our work builds off Sia et al. (2020) and Thompson and Mimno (2020) who demonstrated that clusters of contextualised word embeddings are a good basis for topic modelling. In a similar vein, Aharoni and Goldberg (2020) showed that the domain type of a particular text could be identified using the clustering of sentence-level representations. Finally, Rother et al. (2020) showed that clusters of contextualised embeddings could detect meaning shifts in words. The success of these papers motivates our use of high-density clusters of sentence-level representations.

The present paper shows that our novel feature sets outperform more traditional methods by comparing our results to those in Drinkall and Pierrehumbert (2021) in a threshold-classification task. This task provides an understanding of which feature sets provide the most informative trend signals at different caseload growth rates, enabling us to understand the effectiveness of a particular feature type at identifying a distinct epidemiological event. Strong performance on this task is relevant in forecasting worst-case scenarios like hospital overflow, where the outcome is a binary variable.

The caseload information is not fully utilised in the threshold-classification task. This observation motivates a time-series forecasting task to compare feature sets at predicting a more continuous target. Feature selection is a crucial step in time-series modelling (Wang et al., 2013), (Sun et al., 2015); adding extraneous features to a multivariate prediction can result in performance deterioration as the models get more complex, a fact that inspired L1-regularisation. Only highly relevant features, which represent complementary information, improve performance.

Contributions. We introduce a novel unsupervised method for predicting COVID-19 trend signals and forecasting caseloads. We show that sole use of our feature set achieves very high accuracy in trend signal prediction, a significant result for infectious disease modelling in regions where other reported data is unavailable or unreliable.

2 Datasets

Comparing our Reddit features' performance against other open-source geographically-specific datasets allows us to understand their value. The following data sources were used to create the feature sets in this paper:

Pushshift API - The Pushshift API (Baumgartner et al., 2020) is used to compile datasets of target subreddits to create the Reddit features. The Pushshift API provides data on every comment and submission posted on Reddit. This paper uses comments to form the subreddit dataset since there are more comments than submissions, and they constitute more conversational and reactionary discourse. No individual comments or users are reported in this paper to observe the anonymity of the users. Update frequency: real-time.

COVID-19 Tracking Project - The state-level COVID-19 epidemiological data is provided by the COVID-19 Tracking Project[1] to create the prediction target and is also used as a feature set in baseline predictions. Update frequency: 24 hours. Start date: 13/01/2020.

Oxford COVID-19 Government Response Tracker (OxCGRT) - The OxCGRT (Hale et al., 2020) defines the local government response. The data covers policies including health, containment and economic measures, and overall stringency scores. Update frequency: "continuously" but can be variable due to human data collection; daily periodicity. Start date: 01/01/2020.

Google's COVID-19 Community Mobility Reports (GCCMR) [2] - The GCCMR provides local movement data in different area types such as parks, workplaces, etc. and has been used to successfully predict COVID-19 caseloads (Wang et al., 2020), (Ilin et al., 2021). The data is freely available for the duration of the ongoing pandemic. Update frequency: 2-3 days. Start date: 15/02/2020.

3 Feature identification

Social media is a complex and noisy data source, requiring significant processing to isolate meaningful predictive features. The pipeline used in this paper consists of three main steps for feature

---

[1] https://covidtracking.com

[2] https://www.google.com/covid19/mobility/

identification: sentence-level encoding, dimensionality reduction and clustering. This process groups together Reddit comments that are semantically similar. Following these main steps that are outlined below, the Reddit features are reduced further to 25 using a chi-squared test. Once these 25 high-density clusters are identified, the daily counts of comments within these clusters are used as features in the evaluation frameworks in Sections 4 & 5.

3.1 Sentence-level representation

A common technique for identifying sentence representations is to take the average-pooled BERT hidden-state embedding (Aharoni and Goldberg, 2020); however, papers such as Reimers and Gurevych (2019) have shown that the average-pooled BERT embeddings are a relatively poor way of encoding sentences and advocate for further fine-tuning to produce a more semantically meaningful embedding. In Reimers and Gurevych (2019), the best results are achieved by training the language model on Natural Language Inference (NLI) (Bowman et al., 2015), (Williams et al., 2018) and Sentence Textual Similarity (STS) (Cer et al., 2017) data. The NLI data contains many sentence pairs with their semantic relationship labelled. The STS data provides a semantic relatedness score between 0-5. It is possible to use both datasets to fine-tune the language model using both dataset types by manipulating the objective functions. The NLI data is trained using a classification objective function, and the STS data is trained using a regression objective function. Reimers and Gurevych (2019) shows that averaging the final layer BERT embeddings leads to a Spearman rank correlation ρ between the cosine similarity of the sentence representations and the actual labels of the STS data of around $\rho = 54.81$, whereas SBERT-NLI-STSb-base achieves $\rho = 88.31$.

For this paper, there is no domain-specific training. The SBERT-NLI-STSb-base, SRoBERTa-NLI-STSb-base and SDistilBERT-NLI-STSb-base encode the Reddit posts with no further fine-tuning.

3.2 Dimensionality reduction

The language models specified in Section 3.1 have a dimensionality of 768, which means that their embedding space is very sparse, making it challenging to find dense clusters. Lowering the embedding dimensionality is consistent with the findings in Sia et al. (2020), who show that the dimensionality of the embeddings can be reduced by $\sim$80% and still maintain the topic modelling coherence. Therefore, in line with these findings, the dimensionality of the embedding space is reduced to 50.

UMAP (Uniform Manifold Approximation and Projection for Dimension Reduction) is used as in Rother et al. (2020) to lower the dimensionality of the embedding space. UMAP is appropriate for this task since it preserves global structure better than other manifold learning dimensionality reduction methods such as t-SNE (McInnes et al., 2018) (McConville et al., 2021). UMAP's preservation of global structure has been shown in Reif et al. (2019) to produce clear clusters related to different word senses. It is tested against a PCA algorithm in Appendix B on the Threshold-Classification task outlined in Section 4. The results justify its use as it outperforms PCA when used in conjunction with the best performing clustering algorithm.

3.3 Clustering

For this paper, the HDBSCAN algorithm (Campello et al., 2013) is used for clustering due to the complex structure of the subreddit embedding space. The benefit of using a density-based clustering algorithm is that sparse areas are not fitted into clusters, removing a significant source of noise from the prediction.

HDBSCAN offers an advantage over other density-based clustering algorithms; the cut-off density that characterises the edge of the clusters is non-constant and defined by a stability metric that rewards large and dense clusters. This stability metric is calculated from the data points' Minimum Spanning Tree (MST). The following equation defines the stability of cluster C_i:

$$S(C_i) = \sum_{x_j \in C_i} (\lambda_{max}(x_j, C_i) - \lambda_{min}(C_i)) \quad (1)$$

Here λ represents the density statistic: $\lambda = 1/\epsilon$ where ϵ is equal to the distance between points on the MST. In this equation, $\lambda_{max}(x_j, C_i)$ is the density at which the point x_j would fall out of the cluster C_i, and $\lambda_{min}(C_i)$ is the minimum density threshold at which the cluster still exists.

Clusters with maximum stability are used as the final clusters, and points that fall out of these clusters are discarded. New data points can subsequently be added to the cluster by identifying where they fall in the MST. A point is treated as noise unless it can be grouped into a cluster larger than

$min\_cluster\_size$, which, for this paper, we have set at 25 so that the clusters are not too small and the resulting features are not too sparse. Removing noisy comments from the clusters is shown in Appendix B to have performance benefits over other clustering algorithms that do not reject comments: we have compared HDBSCAN to a Spherical K-Means (KM) algorithm and a Gaussian Mixture Model (GMM), two popular algorithms within the literature base.

4 Threshold-Classification Framework

The threshold-classification framework (henceforth Threshold task) uses the same evaluation methodology as in Drinkall and Pierrehumbert (2021). The problem is presented as a classification task on balanced classes, with a randomised train/test split and test size of 0.25 on data from 07/03/2020 to 17/01/2021. Balanced classes allow us to report accuracy as the performance metric for this task. The feature sets, derived from a 7-day moving average of the datasets in Section 2, are concatenated to a target value that encodes whether the caseload increase exceeded the threshold within a given time interval. The threshold is defined by a relative increase, $\delta_r(t)$:

$$\delta_r(t) = \frac{\mu(t+\tau) - \mu(t)}{\mu(t)} \tag{2}$$

Where $\mu(t)$ is the 7-day moving average of the caseload, and τ is the prediction horizon.

The model used for classification is a Random Forest (RF) (Breiman, 2001). The advantage of using an RF model over other tree-based models is that it decorrelates the trees, making it robust to correlated feature sets. Social media data is highly correlated as overall take-up surges and wains; therefore, robustness to correlated features is critical. Of course, many more complex models would likely outperform an RF model; however, given that the goal of this task is to compare feature sets, the increased transparency that an RF model offers over more complex models justify its use.

Feature set	Average	7D	14D	21D	28D
$T_{RoB}++$	.875	.895	.880	.849	.874
$T_{BoW}++$	.810	.836	.809	.805	.791
T_{RoB}	.803	.845	.792	.789	.787
T_{BERT}	.789	.821	.798	.780	.761
T_{DisB}	.780	.808	.771	.774	.768
T_{BoW}	.768	.816	.755	.749	.753
T_{KW}	.633	.733	.628	.591	.580
M	.702	.703	.691	.713	.698
G	.702	.713	.710	.695	.691
P	.545	.516	.549	.557	.557
C	.555	.651	.536	.529	.503

Table 1: The average performance across all relative thresholds and states at different prediction horizons. The features are: $T_{<<language\ model>>} \rightarrow$ our features; $T_{BoW} \rightarrow$ Drinkall and Pierrehumbert (2021) features; $M \rightarrow$ GCCMR data; $G \rightarrow$ OxCGRT data; $P \rightarrow$ daily post count; $C \rightarrow$ current caseload; $T_{RoB}++ \rightarrow T_{RoB} + M + G + P + C$; $T_{BoW}++ \rightarrow T_{BoW} + M + G + P + C$. The light grey indicates the highest performing instance of each model setup. The dark grey indicates the highest performance for each prediction horizon.

4.1 Evaluation

Each data type is used in isolation to predict the target labels so that the implicit information within each feature set can be compared. T_{DisB}, T_{BERT} and T_{RoB} correspond respectively to the features extracted using the methodology above from the SDistilBERT-NLI-STSb-base, SBERT-NLI-STSb-base and SRoBERTa-NLI-STSb-base language models. The performance of our clustered embedding features is compared against the bag-of-words features used in Drinkall and Pierrehumbert (2021), T_{BoW}, as well as word-count features taken from a prescriptive list of COVID-19 words defined by the non-hashtag queries in the keyword list in Lamsal (2020), T_{KW}. The evaluation is conducted in four states where Reddit uptake is high: Washington, California, Texas and Florida. The states represent culturally different communities, instilling confidence that the behaviour is true in multiple domains. A successful result across all four states indicates that any observed behaviour is likely not just a symptom of an anomalous community.

The results in Table 1 detail the average performance across the different states and relative thresholds. Firstly, it is clear that word counts from the prescribed list in Lamsal (2020) only capture fractionally more information than a single post-count feature, and that simply using a chi-squared test of over-represented words, T_{BoW}, results in a significant performance increase. However, our T_{DisB}, T_{BERT}, T_{RoB} feature sets perform the best, and when T_{RoB} is used in combination with the comparison feature sets, the performance improves further. It is also evident that as better language models are used, the performance on this task increases. Showcasing the relationship between language model complexity and overall performance supports our

	$\delta_r(t)$					
m	0.2	0.4	0.6	0.8	1	$\mu + \sigma$
$T_{RoB}++$	.803	.828	.867	.962	.970	.880 + .039
$T_{BoW}++$	.704	.795	.821	.862	.910	.809 + .024
T_{RoB}	.753	.752	.787	.876	.876	.792 + .034
T_{BoW}	.683	.699	.761	.828	.865	.755 + .025
M	.649	.683	.663	.712	.727	.691 + .026
G	.678	.607	.735	.761	.789	.710 + .019
P	.548	.539	.537	.530	.577	.549 + .030
C	.437	.466	.527	.631	.640	.536 + .039

Table 2: Performance across a range of thresholds at a prediction horizon, $\tau = 14$ days, averaged across all states. μ & σ represent the mean and standard deviation of each feature set's results. The variables and highlighting criteria are the same as Table 1, but for the dark grey which denotes the highest performance at each threshold.

a-priori belief that improved semantic information from the text is linked with better epidemiological insights. Due to its success, T_{RoB} alone will henceforth be used in the evaluation as it provides the best performing feature set from our methodology.

4.1.1 Varying Thresholds

Table 2 breaks down the performance of classifying the data across different threshold increases. Intuitively, the more extreme events are easier to predict, explaining the behaviour across all feature sets. Indeed, when the threshold is large enough, the $T_{RoB}++$ features achieve an accuracy of .970, significantly higher than the comparison feature sets, showing that social media data is a strong candidate for predicting a sharp rise in caseloads. Again, the performance across all thresholds is highest when using the $T_{RoB}++$ features as opposed to the $T_{BoW}++$, highlighting the performance gain from the increased semantic information of transformer-based language models.

4.1.2 Feature Importance

To understand which features more are heavily weighted by the RF model when given the $T_{RoB}++$ and $T_{BoW}++$ feature sets, the feature importances are shown in Table 3. The tabulated data represents the sum of all individual feature importances in that class.

Table 3 shows that despite T_{RoB} performing better than T_{BoW}, the other comparison features, G and M, are more heavily weighted in $T_{RoB}++$ than in $T_{BoW}++$ at some prediction horizons. The $T_{RoB}++$ feature set performs better than the $T_{BoW}++$ features, so it appears that the information provided by the T_{RoB} features is complementary to the other feature types. It is also possible that there is some skew in the feature importance owing to the reported over-weighting of more continuous features by a Gini Importance algorithm (Strobl, 2007). Regardless of the slight differences, both text-derived feature sets are the most highly weighted when averaged over all prediction horizons, further showing the value of social media in this context.

Feature set	m	Average	7D	14D	21D	28D
	T_{RoB}	.331	.334	.307	.309	.386
	M	.285	.264	.277	.299	.301

5 Time-Series Forecasting Task

This section showcases our feature identification methodology within a time-series forecasting framework (henceforth Time-Series task) since this is a widely used prediction task in disease modelling. The high-density clusters are used as covariates in two multivariate time-series models. This setup better utilises the caseload feature and learns the temporal patterns within its historical movement. One difference with the Threshold task in the feature identification pipeline is the feature pruning step that reduces the number of features to 25. In the Threshold task, the target is a binary classification; therefore, a chi-squared test is appropriate. Given that the target is continuous in this task, f-regression is used. F-regression works by firstly calculating the cross-correlation ρ_i of the i^{th} feature $X[:,i]$ and target y:

$$\rho_i = \frac{(X[:,i] - \bar{X}[:,i]) \cdot (y - \bar{y})}{\sigma_{X[:,i]} \cdot \sigma_y} \tag{3}$$

The F-statistic is then calculated along with the associated p-value. Then the top 25 most significant features are filtered to make up the feature set. For each model, the training features and targets are normalised between 0 and 1, and the test set is scaled using the same transformation. The target data is changed from the daily caseload to the daily increase in caseload to make sure the time-series is stationary. No moving average is used since the time-series models should account for the weekly seasonality. The models are trained over 50 epochs on data from 07/03/2020 to 31/12/2020 and tested on data from 01/01/2021 to 01/03/2021. Whilst it is possible to improve the performance by retraining the model on recently evaluated data and sliding the train-test split across the dataset, our proposed framework highlights how the models perform on completely out-of-sample data.

5.1 Models

We compare a Transformer and Gaussian Process (GP) model against the Martingale property baseline model which assumes that the caseload will not change, i.e. that additional features have zero predictive power. At a forecast horizon T days in the future, the last observed caseload, μ_t, is used to forecast the caseload: $\mu_{t+T} = \mu_t$.

Gaussian Process Model - GP models were shown by Roberts et al. (2013) to perform well in contexts where prior knowledge regarding the appropriate model is limited. The difficulty in inferring the appropriate parametric model in infectious disease modeling led Lampos et al. (2017), Lampos et al. (2021) and Zou et al. (2018) to adopt a GP time-series model to predict future infectious disease caseloads. More modern methods have since outperformed GP models in time-series forecasting, so this GP model provides a further benchmark to the Transformer model outlined below. Our work uses a radial basis function (RBF) Kernel to specify the covariance function.

Transformer model - Transformers have predominantly been used with textual (Vaswani et al., 2017) and image-based data (Ye et al., 2019); however, the auto-regressive properties of a masked self-attention layer mean that structurally transformers can obey causality. As a result, many papers have used transformers successfully to model time-series data (Lim et al., 2021), (Zerveas et al., 2021). Both papers reported that transformer models significantly outperformed the statistical, recurrent and convolutional comparison methods. This success has been replicated in disease modelling by Wu et al. (2020). Thus, transformer-based time-series models represent the state-of-the-art in many comparable contexts, motivating their use in this framework. The architecture that is used in this paper mimics that of Vaswani et al. (2017) and Alexandrov et al. (2019).

Data Source	Martingale	GP	Transformer

+ T_{RoB} + G + M	”	.0326†	**.0288***

Table 4: The RMSE error averaged across all forecast horizons and states. The significance of each result in comparison to the univariate case is denoted by asterisks: * - P<.2; † - P<.05; ‡ - P<.01

5.2 Time-Series Evaluation

For the Time-Series task, the prediction error of the forecasts is reported in an ablation study, using the same forecast horizons as the Threshold task. Different feature types make up the covariate set and are compared against the univariate case.

Table 4 shows the main ablation study, which averages the root-mean-square-error (RMSE) across the different forecast horizons and states. The results show the overall behaviour of the different feature types. The first conclusion is that the Transformer model always outperforms the Martingale and GP model. Poor GP model results are also seen in Lampos et al. (2021), where their persistence model outperforms the univariate and multivariate GP forecasts in multiple countries. Due to the GP model's weaker performance, further analysis will involve the Transformer model. State-level results are displayed in Figure 2 and show that the Transformer performs well at modelling the time-series data.

The more meaningful conclusion that can be drawn from Table 4 is that whilst the success of the T_{RoB} features is still present, it is more marginal than in the Threshold task both when the T_{RoB} features are used in isolation and when the feature sets are combined. Using the T_{RoB} features

in the covariate set does deliver a statistically significant result, however, the decrease in error rate is small. Whilst all feature sets deliver a performance increase, none of the other feature sets can be considered to deliver a statistically significant result. Combining further data types doesn't deliver the expected performance increase, with the performance plateauing, and in some cases decreasing as the number of feature types increases. One possibility is that the information that the T_{RoB} features provide is counteracted by the performance costs of having a large number of variables. Table 5 reinforces what is seen in Table 4, showing that across all forecast horizons there is a slight improvement in performance and that using the T_{RoB} features alongside the time-series data generally results in the lowest error across all tested feature sets.

The significance of the results in Table 4 is calculated by taking 10,000 samples at every forecast horizon for each state. The error of each forecast is calculated, resulting in an error distribution for all feature sets. To discern whether the addition of a feature type results in a statistically significant performance shift a Z-test is used. The univariate forecast is assumed to be the population distribution and each feature set's forecast errors are treated as the sample distribution. The Z-score is calculated using parameters from both distributions:

$$Z = \frac{\overline{X}_{pop} - \overline{X}_{sample}}{\sqrt{\sigma^2_{X_{pop}} + \sigma^2_{X_{sample}}}} \tag{4}$$

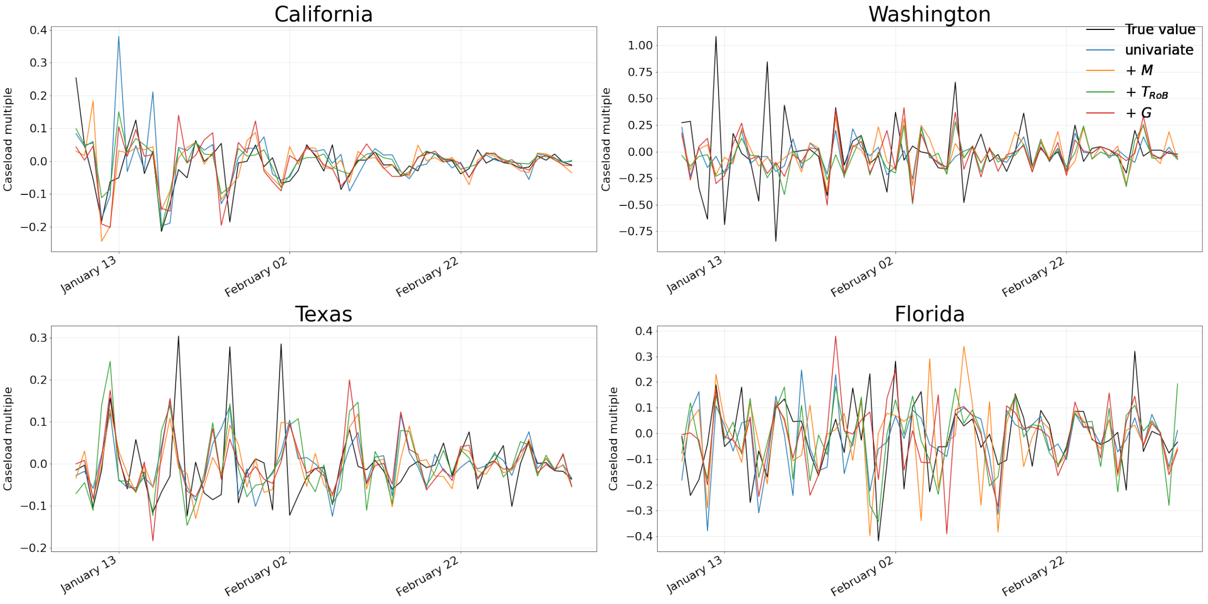

Figure 2: State forecasts at $\tau = 7$. The univariate forecast is compared against three multivariate forecasts where the M, G & T_{RoB} features make up the covariate set.

Table 11: Important features from each of the key states at $\delta_r = 0.6$ & $\tau = 7$ days.

6 Discussion

Examining the contents of our Reddit features can help us understand the information they provide to the prediction task. We took the top 5 non-stopwords from the cluster to characterise each cluster and manually named them for better comprehension. Table 6 shows the largest clusters from the SRoBERTa-NLI-STSb-base representation of the r/CoronavirusWA subreddit. These topics identify precise semantic concepts that intuitively provide relevant information for a caseload prediction.

As mentioned, the advantage of the Threshold task is that it provides greater interpretability than the more black-box time-series models. Therefore, the Threshold task is used to understand which features are important to the prediction. Table 11 shows the weightings of the most important features at $\delta_r = 0.6$ & $\tau = 7$ days. The cultural differences between the states can be seen via these features, most obviously the *Houston* feature in Texas and the *Desantis* feature in Florida. The *Spring Break* cluster is only seen in Florida, a state that is famed for this holiday tradition and was a large contributor to an increase in non-COVID-19 compliant events that resulted in an increase in cases at the beginning of the pandemic. Equally, the *Guns* and *Safety* features in California likely identify the strong negative reaction from the libertarian community within California to what were the most stringent lockdown restrictions from any of the analysed states. The libertarian trait within California is best characterised by the Prop 22 ballot initiative[3] which identifies a political attitude not aligned with strict lockdown measures. Alongside these differences, the *Illness* feature is highly weighted in all states. The use of this feature in all short-term predictions might explain the success of prior work that used static tracking words such as “Influenza”, “fever”, “headache”, etc. (Samaras et al., 2020), (Iso et al., 2016); discussion about symptoms is indicative of a rise in cases in all states. It is clear, however, that exclusive use of symptomatic features is not optimal, since other topics besides symptomatic conversation are useful for the prediction.

7 Conclusion

Reddit data performs well at discerning different trend signals for COVID-19 caseload increases in the Threshold task. Reddit features alone achieved high accuracy at most threshold increases but were especially strong when identifying whether the caseload was likely to double in the next 14 days, achieving an accuracy of .970. That value is seen in the Time-Series task but the performance benefit is not as stark, especially when the number of features increases. The characteristics of Reddit data make it appealing: it is readily available and updated in real-time, offering the means for monitoring infectious diseases in regions where reported data is unreliable; however global Reddit usage is not constant, and not every area has a subreddit, making our exact methodology hard

to scale. As Reddit usage increases and disperses around the world or data from another social media site is adapted to fit within our pipeline, the methods used in this paper will become more scalable. Another notable conclusion is that the predictive information within Reddit data is better extracted by including transformer-based language models in the forecasting pipeline. Language model complexity appears to be linked with performance improvements in the Threshold task. Strong language models allow us to isolate highly specific features predictive of future caseload increases in an unsupervised setting.

8 Future work

More work can be done on feature selection for the Time-Series task. The value of combining all data types is evident in the Threshold task but that value is not seen in the Time-Series task. Developing models that are able to model a larger number of features more effectively could likely yield some performance gains. On top of this, our methodology relies on using textual data that refers to a specific geographic location. Reddit's structure makes this simple; however, more data is needed to replicate our findings in regions where Reddit take-up is low. Geotagged posts and the geolocation of a user's home region are possible avenues for enlarging the social-media dataset. Finally, the unsupervised methodology outlined in this paper can be adapted to other fields in which a social media derived feature set is used, such as quantitative finance, election and logistics forecasting.

A Clustering algorithms hyperparameter tuning

An exhaustive search has been conducted to find the optimal k parameter (number of clusters) for KM and GMM clustering to compare their optimal

Clustering algorithm	k	Average	7 days	14 days	21 days	28 days
GMM	25	.659	.799	.645	.594	.596
	50	.691	.838	.691	.614	.622
	75	.698	.845	.689	.618	.639
	100	.702	.831	.703	.612	.662
	125	.714	.827	.709	.659	.664
	150	.716	.850	.718	.619	.676
KM	25	.706	.883	.685	.620	.635
	50	.636	.681	.714	.622	.528
	75	.677	.781	.769	.607	.550
	100	.702	.787	.678	.647	.695
	125	.663	.757	.754	.611	.531
	150	.658	.768	.687	.621	.556

Table 8: The average performances of an RF classification model using KM and GMM clustering across all thresholds at different values of k on the r/CoronavirusWA subreddit. The comment-level SDistilBERT-NLI-STSb-base representations' dimensionality was reduced via UMAP. The light grey indicates the highest performing instance of each model setup. The dark grey indicates the highest average performing model configuration.

Language model	Dim. reduction	Clustering	Average	7 days	14 days	21 days	28 days
DistilBERT	PCA	HDBCSAN	.722	.821	.724	.678	.667
		KM	.716	.807	.675	.677	.704
		GMM	.714	.808	.715	.651	.680
	UMAP	HDBCSAN	.807	.905	.827	.759	.737
		KM	.706	.883	.685	.620	.635
		GMM	.716	.850	.718	.619	.676
		Average	.730	.846	.724	.667	.683

Table 9: The average performance, on the r/CoronavirusWA subreddit, of an RF model across all thresholds at different prediction horizons for each of the model pipelines using only T_{RoB} features. The variables and highlights are the same as in Table 8.

configurations against HDBSCAN. The standard Silhouette score method was trialled for fine-tuning the k parameter, but the result was $k = 1$, perhaps indicating the unsuitability of KM and GMM for this task. Figure 3 is a plot of the Silhouette score (Rousseeuw, 1987) of a KM clustering algorithm for different values of k on the UMAP reduced SDistilBERT-NLI-STSb-base embeddings space. The maximum Silhouette score should be the most appropriate k value if the data is divided into distinct clusters. The maximum Silhouette score at $k = 1$ indicates that the data is structured into one central cluster with high and low-density areas.

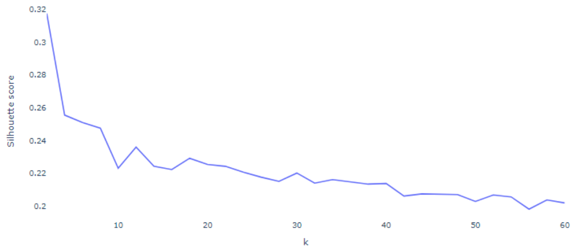

Figure 3: Silhouette score vs. k using a KM clustering algorithm on UMAP-DistilBERT embedding space.

Since the Silhouette score does not provide an obvious k parameter, and yet there needs to be some proof that HDBSCAN is a better algorithm than KM and GMM, an exhaustive search for the optimal k on the development data is conducted to prove that KM and GMM are not suitable for the task. k is tuned using the performance on the r/CoronavirusWA data from 01/03/2021 to 17/01/2021 with UMAP dimensionality reduction.

The same search was conducted to find the optimal k for the PCA space; for KM, the value was 75, and for GMM, the value was 125 on the DistilBERT embedding space. These values of k were used for the testing in Appendix B.

B Dimensionality reduction and clustering algorithms

A test was carried out to see which combination of dimensionality reduction and clustering algorithms resulted in the best overall performance. The different algorithms were tested using SDistilBERT-NLI-STSb-base representations of the comments. The two dimensionality reduction techniques used were PCA and UMAP; the three clustering techniques used were GMM, KM and HDBSCAN. The k values derived in Appendix A were used for the GMM and KM clustering, and the evaluation pipeline used is the Threshold task described in Section 4.

The results from Table 9 show that the combination of UMAP and HDBSCAN is the best combination of algorithms; the UMAP-HDBSCAN combination is the best performing pipeline across all prediction horizons.

C Aggregated Sequence Classification models

As mentioned in Section 1, the most obvious way to incorporate the modern transformer-base language models is to formulate the problem as an Aggregated Sequence Classification (ASC) task. It has been shown that BERT and other similar models are well adapted to performing sequence classification, and this has become a common usage of these language models (Devlin et al., 2019). Therefore, it is important to trial a model that incorporates this more standard methodology before trialling other feature identification methods.

For evaluation, we trialled two language models: BERT-base-uncased, and a domain adapted version of BERT-base-uncased trained on the r/Coronavirus subreddit - CoFReBERT (**Co**VID-19 **F**orecasting from **Re**ddit **BERT**). The language models are then fine-tuned on a Sequence Classification task in which the [CLS] token encodes the "up" or "down" class, indicating a possible increase or decrease in the number of cases. The adapted models are referred to as ASC-BERT and ASC-CoFReBERT. The model is trained on balanced classes with a 4:1 train-test split, where each day is assigned to be a test or a train day, and all comments written on a particular day are categorised together. Once the model labels each comment within the test set as either "up" or "down", the majority class on a given test day is assigned as the prediction for that day.

Models	Av.	7D	14D	21D	28D
ASC-BERT	.631	.769	.655	.561	.537
ASC-CoFReBERT	.701	.846	.690	.634	.634
T_{RoB}	.869	.923	.896	.810	.855
T_{BoW}	.765	.780	.808	.804	.791

Table 10: The average performance, on the r/CoronavirusWA subreddit, across all thresholds at four different prediction horizons. The variables and highlights are the same as in Table 8.

From the results in Table 10, it is clear that the models do not perform as well as hoped in comparison to the traditional static word features and the features outlined in this paper. The main reason for this is likely to be noise from the unsupervised labelling process. Comments that are either unrelated to the prediction or indicate an opposite caseload trend are included in the prediction. Without manual labelling, it is hard to reduce this noise; however, that would result in investigator bias entering the prediction. Furthermore, it is not completely clear whether a comment is indicative of a rise in cases, shown by the variety of topics considered important to the prediction in Table 11. Therefore, the structure of the ASC models is not well adapted to the task of predicting COVID-19 cases.

D Training and software details

Python Packages The sentence-embedding models from (Reimers and Gurevych, 2019) were used to encode the Reddit post representations using the `sentence-transformers` Python package. The time-series models were both implemented using the `gluonts` Python package (Alexandrov et al., 2019). The ASC models outlined in Appendix C use the BERT-base-uncased model from the `transformers` package and the ASC-CoFReBERT model was trained using the `run_mlm.py` file in the library.

Training Pararmeters Besides the analysis detailed earlier in the Appendix, we do not perform hyperparameter tuning but use common hyperparameter values for all calculations in this paper. For the Random Forest model in the Threshold task, the number of trees is 100, and the maximum tree depth is 20. The Time-Series models were trained over 50 epochs and used default parameter values. The ASC-CoFReBERT model was trained with standard parameter values, using a batch size of 128 and a dropout probability of 0.1.

Computation All experiments in the main body of the paper were run on a personal computer, the ASC model in Appendix C was run on the. The ASC model was run on a Tesla P100 and took between 3 to 6 hours to run, depending on the size of the subreddit.

Licenses There are licenses associated with the use of some of the data and Python packages used in this paper. The OxCGRT dataset and Pushshift API are open access under the Creative Commons Attribution CC BY and 4.0 International standards. The COVID-19 Tracking Project, `gluonts`, `transformers` and `sentence-transformers` Python packages are licensed under the Apache License 2.0.

Many Hands Make Light Work: Using Essay Traits to Automatically Score Essays

Abstract

Most research in the area of automatic essay grading (AEG) is geared towards scoring the essay *holistically* while there has also been little work done on scoring individual essay traits. In this paper, we describe a way to score essays using a multi-task learning (MTL) approach, where scoring the essay holistically is the primary task, and scoring the essay traits is the auxiliary task. We compare our results with a single-task learning (STL) approach, using both LSTMs and BiLSTMs. To find out which traits work best for different types of essays, we conduct ablation tests for each of the essay traits. We also report the runtime and number of training parameters for each system. We find that MTL-based BiLSTM system gives the best results for scoring the essay holistically, as well as performing well on scoring the essay traits. The MTL systems also give a speed-up of between **2.30** to **3.70** times the speed of the STL system, when it comes to scoring the essay and all the traits.

1 Introduction

An **essay** is a piece of text that is written in response to a topic, called a prompt (Mathias and Bhattacharyya, 2020). Qualitative evaluation of the essay consumes a lot of time and resources. Hence, in 1966, Page proposed a method of automatically scoring essays using computers (Page, 1966), giving rise to the domain of Automatic Essay Grading.

Essay traits are different aspects of the essay that can aid in explaining the score assigned to the essay. Examples of essay traits include content (how much information is present in the essay) (Page, 1966), organization (how well the essay is structured) (Persing et al., 2010), style (how well written the essay is) (Page, 1966), prompt adherence (how much the essay stays on topic for the essay prompt) (Persing and Ng, 2014), etc.

Most of the research work done in the field of AEG is geared toward scoring the essay holistically, rather than studying the importance of essay traits in the overall essay score. In this paper, we ask the question:

“Can we use information learnt from scoring essay traits to score an essay holistically?”

In our paper, not only do we score essays holistically, but we also describe how to score essay traits simultaneously in a multi-task learning framework. Scoring essay traits is essential as it could help in explaining why the essay was scored the way it was, as well as providing valuable insights to the writer about what aspects of the essay were well-written and what the writer needs to improve.

Multi-task learning is a machine learning technique where we use information from multiple auxiliary tasks to perform a primary task (Caruana, 1997). In our experiments, scoring the individual essay traits is the auxiliary task, and scoring the essay holistically is the primary task. In addition to this, we also study the impact of scoring an essay trait as the primary task while the other traits and overall essay score are auxiliary tasks.

Contributions. In this paper, we describe a way to simultaneously score essay traits and the essay itself using multi-task learning. We evaluate our system against different types of essays and essay traits. We also share our code and the data for reproducibility and further research[1].

---

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1485 - 1495
July 10-15, 2022

2 Motivation

Most of the work done in the area of automatic essay grading is in the area of holistic AEG - where we provide a single score for the entire essay based on its quality. However, for ***writers*** of an essay, a holistic score alone would not be enough. Providing trait-specific scores will tell the writer which aspects of the essay need improvement.

In our dataset, we observe that writers of good essays usually have a lot of content, appropriate word choice, very few errors, etc. Essays that are poorly written often lack one or more of these qualities (i.e. they are either too short, have lots of errors, etc.). We, therefore, observe a high correlation between individual trait scores and the overall essay score (Pearson correlation trait scores and overall essay score > 0.7 across all essay sets in our dataset). Hence, we believe that using essay trait scores will benefit in scoring the essay holistically, as their scores will provide more relevant information to the AEG system.

3 Related Work

3.1 Holistic Essay Grading

Holistic essay grading involves assigning an overall score for an essay (Mathias and Bhattacharyya, 2020). The first AEG system was designed by Page (1966). In the decade of the 2000s there were a lot of AEG systems which were developed commercially (see Shermis and Burstein (2013) for more details).

After the release of Kaggle's Automatic Student Assessment Prize's (ASAP) Automatic Essay Grading (AEG) dataset in 2012[2], there has been a lot of research on holistic essay grading. Initial approaches, such as those of Phandi et al. (2015) and Zesch et al. (2015) used feature engineering techniques and domain adaptation in scoring the essays. More recent papers look at using a number of deep learning approaches, such as LSTMs (Taghipour and Ng, 2016; Tay et al., 2018) and CNNs (Dong and Zhang, 2016) or both (Dong et al., 2017; Zhang and Litman, 2018, 2020). Zhang and Litman (2020) describe a way to extract important information, called topical components, from a source-dependent response[3].

3.2 Trait-specific Essay Grading

In the last decade or so, there has been some work done in scoring essay traits such as sentence fluency (Chae and Nenkova, 2009), organization (Persing et al., 2010; Taghipour, 2017; Mathias et al., 2018; Song et al., 2020), thesis clarity (Persing and Ng, 2013; Ke et al., 2019) coherence (Somasundaran et al., 2014; Mathias et al., 2018), prompt adherence (Persing and Ng, 2014), argument strength (Persing and Ng, 2015; Taghipour, 2017), stance (Persing and Ng, 2016), style (Mathias and Bhattacharyya, 2018b) and narrative quality (Somasundaran et al., 2018). None of the above work, however, uses trait information to score the essay holistically.

There has also been work on scoring multiple essay traits (Taghipour, 2017; Mathias and Bhattacharyya, 2018a, 2020). (Rama and Vajjala, 2021) discuss solutions across multiple languages (German, Czech and Italian). Mathias and Bhattacharyya (2020) describes work on the use of neural networks for scoring essay traits. Our work combines the scores of essay traits for holistic essay grading. We focus on using trait-specific essay grading to improve the performance of an automatic essay grading system. We also show how using multi-task learning - simultaneously scoring both the essay and its traits - we are able to speed up the training of our system without too much of a loss in scoring the essay traits. (Ridley et al., 2021) describe a multi-task learning approach to grade essays and their traits using a neural network. Our system differs from theirs with respect to the shared layers and trait-specific layers. While Ridley et al. (2021) share the embedding and word-specific layers (to get sentence representations), we share only the embedding layer.

3.3 Multi-task Learning

Multitask Learning was proposed by Caruana (1997) where the argument was that training signals from related tasks could help in a better generalization of the model. Collobert et al. (2011) successfully demonstrated how tasks like Part-of-Speech tagging, chunking and Named Entity Recognition can help each other when trained jointly using deep neural networks. Song et al. (2020) described a multi-task learning approach to score organization in essays, where the auxiliary tasks were classifying the sentences and paragraphs, and the primary task was scoring the essay's organization. Cao et al.

---

[2] https://www.kaggle.com/c/asap-aes

[3] We define what a source-dependent response is in the Dataset Section (i.e. Section 5).

(2020) also use a domain adaptive MTL approach to grade essays, where their auxiliary tasks are sentence reordering, noise identification, as well as domain adversarial training. However, they also use all the other essay sets as part of their training, whereas we use only the essays present in the respective essay set for training.

4 System Architecture

4.1 STL Essay Grading Stack

For scoring the essays, we use essay grading stacks. Each stack is used for scoring a single essay trait. The architecture of the stack is based on the architecture of the holistic essay grading system proposed by Dong et al. (2017). The essay grading stack takes the essay as input (split into tokens and sentences) and returns the score of the essay / essay trait as the output. Figure 1 shows the architecture for the essay grading stack.

For each essay, we first split the essay into tokens and sentences. This is given as an input to the essay grading stack. In the word embedding layer, we look up the word embeddings of each token. Just like Taghipour and Ng (2016), Dong et al. (2017), Tay et al. (2018), Mathias and Bhattacharyya (2020) and Mathias et al. (2020), we use the most frequent 4000 words of the training data as the vocabulary with all other words mapping to a special unknown token. This is done mainly to capture out-of-vocabulary words, as well words that generally don't belong in the topic[4]. If the vocabulary size is too small, then a number of words will be marked as spelling errors. On the other hand, if the vocabulary size is too large, a lot of spurious words would also be learnt as important ones.

This sequence of word embeddings is then sent to the next layer - the 1 dimension CNN layer - to get local information from nearby words. The output of this layer is aggregated using attention pooling to get the sentence representation of the sentence. This is done for all sentences in the essay.

Each of the sentence representations are then sent through a recurrent layer. We experiment on two different types of recurrent layers - a unidirectional LSTM (Hochreiter and Schmidhuber, 1997) and bidirectional LSTM (BiLSTM) - as the recurrent layer. The outputs of the recurrent layer are pooled using attention pooling to get the representation for the essay. This essay representation is then sent through a fully-connected Dense layer with a sigmoid activation function to score the essay either holistically or a particular essay trait. For our experiments, we minimize the **mean squared error loss**.

Prior to input, we scale the scores to the range of $[0, 1]$ using min-max normalization. The output of the sigmoid function is a scalar in the range of $[0, 1]$ which is rescaled back up to a score in the original score range and rounded off to get the score for the essay. This essay stack is used for the scoring of the single-task learning (STL) models.

4.2 MTL Model

The architecture of our MTL model for an essay of M traits is shown in Figure 2. Here, the word embedding layer is **shared across all the tasks**. In the multi-task learning framework, each stack is used to learn an essay representation for each essay trait. In a similar manner, the essay representation for the overall score is learnt and it is concatenated with the predicted trait scores before being sent to a Dense layer with a sigmoid activation function to score the essay holistically. For calculating each score - both overall and trait scores - we use the **mean squared error loss** function. We experimented with multiple weights for the loss function for the essay trait scoring task, but settled on uniform weights for all the traits and the overall scoring task. This is done because we want to get accurate predictions of the traits scores which are used for predicting the overall score.

5 Dataset Used

For our experiments, we use the Automated Student's Assessment Prize (ASAP) Automatic Essay Grading (AEG) dataset. The dataset has a total of 8 essay sets - where each essay set has a number of essays written in response to the same essay prompt. In total, there are nearly 13,000 English essays in the dataset, written by American high school students from classes 7 to 10.

Table 1 gives the properties of each of the essay sets in our dataset. It reports the overall essay scoring range, traits scoring, average word count, number of traits, number of essays and essay type.

We use the overall scores directly from the ASAP AEG dataset. Since the original dataset only provided trait-specific scores for Prompts 7

---

[4] Using the word "relay" when writing about something you like instead of "really". "Relay" could be a valid word in the context of athletics, but not in the context of an argumentative essay on libraries! These valid words are learnt from the training data.

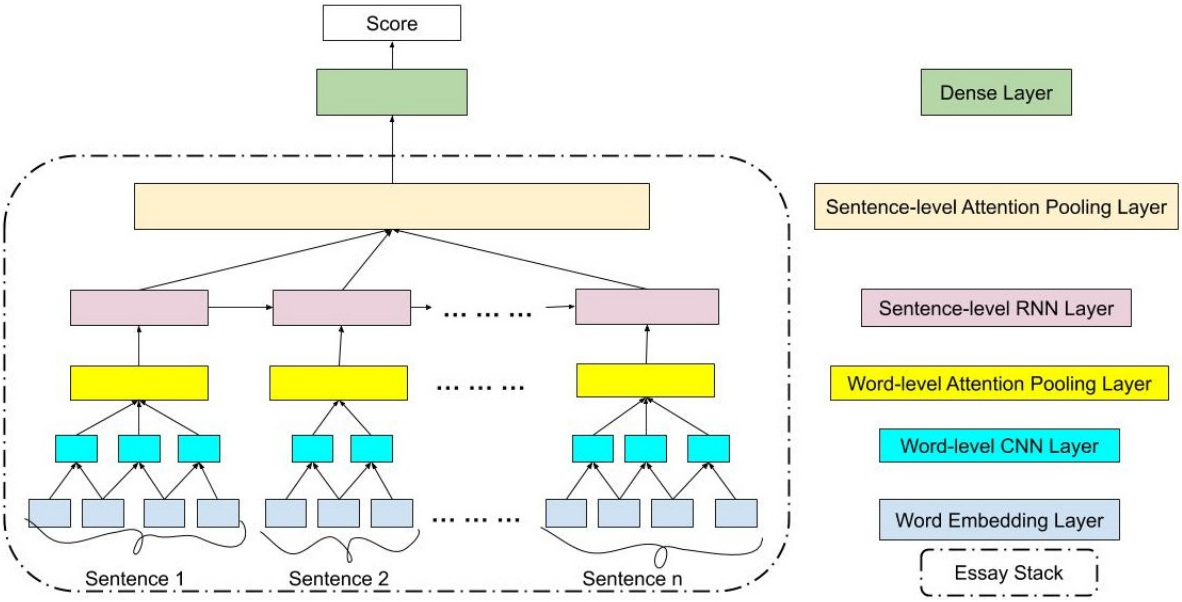

Figure 1: Essay stack architecture. This is the architecture for the Single-Task Learning systems.

Essay Set	Score Range	Trait Sc. Range	Word Count	No. of Traits	No. of Essays	Essay Type
Prompt 1	2-12	1-6	350	5	1783	Argumentative / Persuasive
Prompt 2	1-6	1-6	350	5	1800	Argumentative / Persuasive
Prompt 3	0-3	0-3	100	4	1726	Source-Dependent Response
Prompt 4	0-3	0-3	100	4	1772	Source-Dependent Response
Prompt 5	0-4	0-4	125	4	1805	Source-Dependent Response
Prompt 6	0-4	0-4	150	4	1800	Source-Dependent Response
Prompt 7	0-30	0-6	300	4	1569	Narrative / Descriptive
Prompt 8	0-60	0-12	600	6	723	Narrative / Descriptive
Total	0-60	0-12	100-600	4-6	12978	-

Table 1: Properties of the different essay sets in the ASAP AEG dataset we used in our experiments. Average word count numbers are rounded up to the nearest multiple of 25.

& 8, we use the trait-specific scores provided by Mathias and Bhattacharyya (2018a).

Depending on the type of prompt for the essay set, each essay set has a different set of traits. Argumentative / Persuasive essays are essays which the writer is prompted to take a stand on a topic and argue for their stance. These essay sets have traits like content, organization, word choice, sentence fluency, and conventions. Source-dependent responses (Zhang and Litman, 2018) are essays where the writer reads a piece of text and answers a question based on the text that they just read[5]. These essay sets have traits like content, prompt adherence (Persing and Ng, 2014), language and narrativity (Somasundaran et al., 2018). Narrative / Descriptive essays are essays where the writer has to narrate a story or incident or anecdote. They have traits like content, organization, style, conventions, voice, word choice, and sentence fluency[6]. Table 2 lists the different essay traits for each essay set.

6 Experiments

6.1 Evaluation Metric

We use Cohen's Kappa with quadratic weights (Cohen, 1968) (QWK) as the evaluation metric. This is done for the following reasons. Firstly, the final scores predicted by the system are distinct numbers/grades, rather than continuous values; so we cannot use the Pearson Correlation Coefficient or Mean Squared Error. Secondly, evaluation metrics

---

[5] A sample prompt is "Based on the excerpt, describe the obstacles the builders of the Empire State Building faced in attempting to allow dirigibles to dock there. Support your answer with relevant and specific information from the excerpt." It involves the writer reading the excerpt from *The Empire State Building* by Marcia Amidon Lusted before writing the essay.

[6] Neither the original ASAP dataset, nor Mathias and Bhattacharyya (2018a) have scored narrativity for the narrative essays.

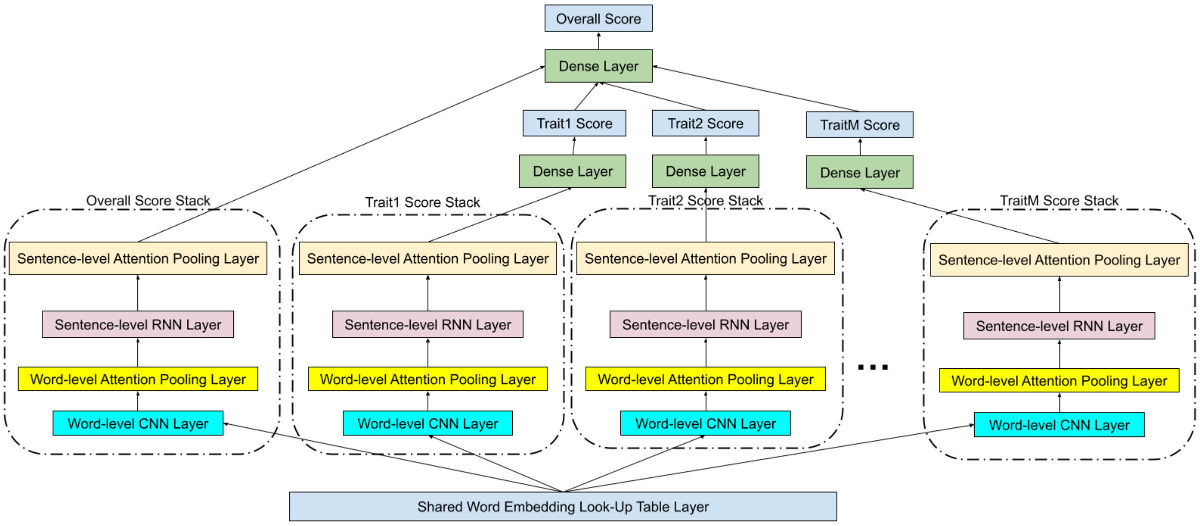

Figure 2: Architecture of our MTL system showing an input essay with M traits being scored, with the overall score and each trait's essay grading stack.

Essay Set	Trait 1	Trait 2	Trait 3	Trait 4	Trait 5	Trait 6
Prompt 1	Content	Organization	Word Choice	Sentence Fluency	Conventions	N/A
Prompt 2	Content	Organization	Word Choice	Sentence Fluency	Conventions	N/A
Prompt 3	Content	Prompt Adherence	Language	Narrativity	N/A	N/A
Prompt 4	Content	Prompt Adherence	Language	Narrativity	N/A	N/A
Prompt 5	Content	Prompt Adherence	Language	Narrativity	N/A	N/A
Prompt 6	Content	Prompt Adherence	Language	Narrativity	N/A	N/A
Prompt 7	Content	Organization	Style	Conventions	N/A	N/A
Prompt 8	Content	Organization	Voice	Word Choice	Sentence Fluency	Conventions

Table 2: Traits that are present in each essay set in our dataset. The trait scores are taken from the original ASAP dataset, as well as from ASAP++ (Mathias and Bhattacharyya, 2018a).

like F-Score and accuracy do not take into account chance agreements. For example, if we are to grade every essay with the mean score or most frequent score, we would get F-Score and accuracy as high as 60% or more, whereas the Kappa score will be 0! Thirdly, the fact that the scores given are ***ordered*** (i.e. $0 < 1 < 2 < 3...$) means that we need to use weighted Kappa to capture the distance between the actual and predicted scores. Between linear weighted Kappa and QWK, we choose QWK because it rewards matches and punishes mismatches more distinctly than linear weighted Kappa.

6.2 Evaluation Method

We evaluate our experiments using **five-fold cross validation**. We use the same data splits as used by Taghipour and Ng (2016). To avoid overfitting, we choose the model which gives the best result on the validation set for evaluating on the test set, and we report the mean value of all 5 folds.

Layer	Param. Name	Param. Value
Embedding	Embedding Dim.	50
	Embeddings	GloVe
Word CNN	Window Size	5
	Filters	100
Sentence LSTM	Hidden Units	100
	Epochs	100
	Batch Size	100
	Dropout Rate	0.5
	Initial Learning Rate	0.001
	Momentum	0.9
	Optimizer	RMSProp

Table 3: Neural network hyper-parameters for each layer, showing the hyper-parameter name and its corresponding value.

6.3 Experiment Configuration

Table 3 gives the different hyperparameters used in our systems. For the sake of uniformity, we use these hyperparameters irrespective of the network configuration (STL vs MTL, or LSTM vs BiLSTM).

Essay Set	Kernel	STL-LSTM	STL-BiLSTM	MTL-LSTM	MTL-BiLSTM	BERT-STL
Prompt 1	0.804	0.813	0.818	0.830*	**0.831***	0.800
Prompt 2	0.687	0.660	0.658	0.667	**0.689***⋆	0.679
Prompt 3	**0.704**	0.661	0.653	0.644	0.687*⋆	0.679
Prompt 4	0.743	0.790	0.780	0.786	0.798	**0.822**
Prompt 5	0.799	0.798	0.789	0.782	0.800	**0.803**
Prompt 6	0.753	0.807	0.803	0.806	**0.813***⋆	0.797
Prompt 7	0.698	0.792	0.786	0.791	0.795⋆	**0.827**
Prompt 8	0.552	0.678	0.697	0.679	0.699*⋆	**0.725**
Mean QWK	0.717	0.750	0.748	0.748	**0.764***⋆	**0.767**

Table 4: Results of our experiments for scoring the essays holistically. Figures in **boldface** represent the **best results** per essay set. * represents a statistically significant improvement using the MTL systems over the STL-LSTM system. ⋆ represents a statistically significant improvement of using the MTL-BiLSTM system over the MTL-LSTM system.

To evaluate the performance of our systems in scoring the essay overall, we use 4 different configurations - **STL-LSTM**, **STL-BiLSTM**, **MTL-LSTM**, and **MTL-BiLSTM**. In addition to the above systems, we also compare our approach with a state-of-the-art string kernel system designed by Cozma et al. (2018), using the same splits for training, testing, and validation[7], as well as a baseline transformer-based implementation (BERT-STL), using the BERT-base-uncased model. We run this baseline model for 100 epochs and a batch size of 30, all other hyperparameters remaining default.

We also study the effect of using our system to grade an essay trait as the primary task, and score the other traits and the essay overall as auxiliary tasks (MTL*).

In the STL configurations, we train our system to predict a single score at a time- either the overall essay score or the score for any of the essay traits. In the MTL configurations, our system learns to score the essay and **all its traits** simultaneously. The LSTM configurations use only a forward direction LSTM, while the BiLSTM configurations use a bidirectional (i.e. forward and reverse) LSTM.

7 Results and Analysis

In this section, we report our results and analyze them for different experiments.

7.1 Performance on Holistic Essay Scoring

Table 4 gives the QWK scores of each of our systems as they score each essay set holistically. The different systems used are the Single Task Learning (STL) (only scoring the essay overall) and Multi-task Learning (MTL) (scoring the essay and the traits simultaneously). The first column lists out the different essay sets (Prompts 1 to 8). The next three columns report results for STL using both LSTM and BiLSTM, as well as results using the string kernel-based approach of Cozma et al. (2018). The next two columns report results for the MTL systems using both LSTM and BiLSTM. The last column shows the results using the baseline BERT-STL system.

From the table, we see that the MTL-BiLSTM performs the best of all the non-transformer systems (almost as good as the results of our BERT-STL system). In order to see if the improvements observed are statistically significant, we run the Paired T-Test for each of the essay sets and compare the results using a p-value of $p < 0.05$.

7.2 Performance on Scoring Essay Traits

We also look at how our system performs in the auxiliary tasks - namely scoring the different essay traits. Figure 3 gives the results of our experiments in scoring the essay traits, using the String Kernel (HISK) (Cozma et al., 2018), CNN-LSTM (STL) (Dong et al., 2017), and Our Systems (MTL and MTL*). We use the same evaluation method, which we used for scoring essay traits, with the same data splits. For the STL systems, we train them for every essay trait individually. MTL* is the results of using our system to score essay trait as the primary task, and score the other traits and the essay overall as auxiliary tasks.

We compare the results with that of our MTL-BiLSTM system, which was trained to score the essay traits as auxiliary tasks. Figure 3 gives the

---

[7] Cozma et al. (2018) do not provide their folds, so we run their system on our training/validation/test split, as given by Taghipour and Ng (2016).

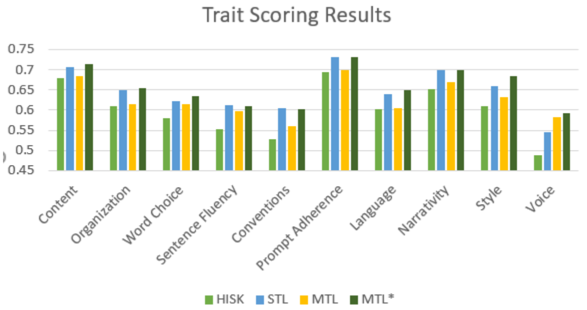

Figure 3: Results of the performance of scoring traits for different systems. The different systems are Histogram Intersection String Kernel (HISK) using ν support vector regressor (Cozma et al., 2018), LSTM-CNN Single-task Learning System (STL) (Dong et al., 2017), our system (MTL) where the traits are auxiliary tasks, and our system (MTL*) where the traits are the ***primary*** task. **NOTE** that the y-axis starts from a QWK of 0.45. This was done to highlight the difference in the performance of each system for each trait.

results of our experiments. From the figure, we see that, while the STL-LSTM system is able to outperform our MTL-BiLSTM system, the MTL* system (where the traits are primary tasks) outperforms the STL-LSTM system. While the STL system optimizes for scoring only a trait, the MTL* system learns information from other traits to score the given essay trait.

One of the reasons for the different trait performance depends on how easy (or difficult) it is to score the individual trait, as well which all essay traits have the particular trait. For example, prompt adherence has a higher average QWK than the other traits because it is present mainly in the source-dependent essays (which have a mean QWK over 1% higher than the mean QWK across all essay sets). Similarly, Voice has the lowest QWK mainly because it is present only in Prompt # 8, which has a very low holistic QWK.

7.3 Scoring Traits as the Primary Task

An interesting question for analysis is "What if we score the traits as the ***primary task***?" In order to do that, we changed our system to make scoring one of the trait as the primary task, and scoring the rest of the traits as well as the essay overall, as auxiliary tasks. The comparison of these results are shown in Figure 3 (in the MTL* column). We see that our MTL* system outperforms the STL-based system on scoring individual traits, although it would take a lot longer time to train (as it would be equivalent to running the MTL system between 4 to 6 times).

7.4 Ablation Tests

In order to know which trait is most important for each essay set, we run a series of ablation tests. For each essay set, we ablate one essay trait at a time before scoring the essay. Table 5 reports the results of the ablation test. The values in the table correspond to the **drop in performance** in scoring the essay holistically. We find that the Content is the most important essay trait for 3 of the essay sets. Prompt Adherence and Word Choice are the most important traits for 2 of the essay sets where they are scored.

7.5 Error Analysis

As we have seen, the MTL model generally helps over the STL model when it comes to holistic essay scoring, especially if there is no well-defined rule (Example: Holistic Score = Sum of trait scores) for scoring the essay holistically.

A possible scenario where STL *could* help over MTL is if the holistic score is a well-defined function of the trait scores **AND** the STL system can predict the trait scores with a good deal of accuracy. The essay sets corresponding to Prompts 7 & 8 are two such essay sets, where the overall score is a function of the individual trait scores. To verify this, we ran the experiments in a pipelined manner - first scoring the essay traits, then calculating the holistic score using the predicted trait scores and comparing it with the gold standard holistic scores. We found no difference in QWK for Prompt 7 (a QWK of 0.796 vs. 0.795), but a much lesser performance with Prompt 8 (a QWK of 0.684 vs. 0.699) as compared to our MTL-based system. One of the main reasons for this is due to the poor performance in predicting the trait scores as single tasks.

7.6 Runtime Analysis

We also ran experiments to see how much resources and time our approaches will take. Table 6 gives the total training time (in hours). The total training time is the total time taken to train our system to score the essay holistically *as well as all the traits* in that essay set for all 100 epochs. We also report the speed-up when using the MTL approach as compared to the STL approach. From our results, we observe a **2.30** to **3.70** speed-up in using the MTL models as compared to using the STL models. The BERT-STL experiments ran for about 5 days (113 hours).

We also report the average number of training

Essay Trait	Prompt 1	Prompt 2	Prompt 3	Prompt 4	Prompt 5	Prompt 6	Prompt 7	Prompt 8
Content	**0.0148**	0.0092	0.0064	0.0074	0.0030	**0.0128**	**0.0102**	0.0102
Organization	0.0122	0.0088	—	—	—	—	0.0090	0.0052
Word Choice	0.0080	**0.0164**	—	—	—	—	—	**0.0264**
Sentence Fluency	0.0086	0.0036	—	—	—	—	—	0.0196
Conventions	0.0090	0.0018	—	—	—	—	0.0076	0.0056
Prompt Adherence	—	—	**0.0282**	**0.0112**	0.0026	0.0044	—	—
Language	—	—	0.0080	0.0108	0.0088	0.0030	—	—
Narrativity	—	—	0.0092	0.0050	**0.0124**	0.0062	—	—
Style	—	—	—	—	—	—	0.0030	—
Voice	—	—	—	—	—	—	—	0.0094

Table 5: Results of the ablation tests. The numbers show the **drop in performance** when we ablate each of the essay traits from each of the essay sets (Prompt 1 to 8). The most important features in each essay set are written in **boldface and underlined**. Cells with a — in them mean that the essay trait was not present in that essay set.

System	STL Time	MTL Time	Speed-Up
LSTM	24.62 hours	10.45 hours	2.30
BiLSTM	40.98 hours	11.32 hours	3.70

Table 6: Total training time for each system for all prompts, traits and folds, using our neural network systems.

System	Average	Range
STL-LSTM	326K	326K
STL-BiLSTM	436K	436K
MTL-LSTM	891K	829K - 1.08M
MTL-BiLSTM	1.5M	1.38M - 1.85M

Table 7: Average and range of training parameters per essay set for each system.

parameters per system in Table 7. For the STL systems, the number of trainable parameters is the same irrespective of essay set. For the MTL systems, the models, the number of training parameters varies based on the number of essay traits in the essay set. Prompts 3 to 7, which have only 4 traits, have about 1.38 million training parameters. On the other hand, Prompt 8, which has 6 essay traits, has over 1.85 million training parameters.

All our experiments were run on an Nvidia GeForce GTX 1080 Ti Graphics Card with 12GB of GPU memory, using Python version 3.5.2, Keras version 2.2.4 and Tensorflow version 1.14[8].

7.7 Comparison with Transformer Models

Most modern NLP systems have started to use attention-based transformer networks and large pre-trained language models. Yang et al. (2020), Cao et al. (2020), and Uto et al. (2020) use the BERT-base-uncased (Devlin et al., 2019) pre-trained language model to perofrm automatic essay grading achieving QWKs in the range of 0.79 to 0.805. However, BERT has about 110 million parameters (compared to our largest model with just under 2 million parameters). Another limiting factor with using BERT is the fact that we can only input 512 tokens. This is a problem, especially for Prompt 8, where the average essay length is about 650 words. Mayfield and Black (2020) describe some of the other limitations of using BERT for scoring essays.

8 Conclusion and Future Work

In this paper, we described an approach to use multi-task learning to automatically score essays and their traits. We achieve this by concatenating a representation of the essay with the trait scores - predicted as an auxiliary task. We compared our results with single-task learning models as well. We found out that the MTL system with the Bi-Directional LSTM outperforms the STL-based systems and has results comparable with a baseline BERT-STL system. We then ran an ablation test and found out which essay trait was important for the corresponding essay sets. We also report our system's performance, which shows a **2.30** to **3.70** speed-up of using the multi-task learning system, compared to using a single task learning system.

An exciting avenue of future work is using trait scoring to aid in providing *text feedback* to the writer, like showing where the low score for the trait originates, similar to Hellman et al. (2020) (for content scoring), rather than a trait-specific score only. We also plan to investigate using ALBERT (Lan et al., 2020), in lieu of the essay stack, to grade essays and their traits simultaneously. We also plan to explore how to extend our approach

---

[8] We have uploaded the rest of the requirements along with the code

in generalizing our system, training it on essays written in response to one set of source prompts, and tested it on essays written for another prompt.

Abstract

We present a comprehensive work on automated veracity assessment from dataset creation to developing novel methods based on Natural Language Inference (NLI), focusing on misinformation related to the COVID-19 pandemic. We first describe the construction of the novel PANACEA dataset consisting of heterogeneous claims on COVID-19 and their respective information sources. The dataset construction includes work on retrieval techniques and similarity measurements to ensure a unique set of claims. We then propose novel techniques for automated veracity assessment based on Natural Language Inference including graph convolutional networks and attention based approaches. We have carried out experiments on evidence retrieval and veracity assessment on the dataset using the proposed techniques and found them competitive with SOTA methods, and provided a detailed discussion.

1 Introduction

In recent years, and particularly with the emergence of the COVID-19 pandemic, significant efforts have been made to detect misinformation online with the aim of mitigating its impact. With this objective, researchers have proposed numerous approaches and released datasets that can help with the advancement of research in this direction.

Most existing datasets (D'Ulizia et al., 2021) focus on a single medium (e.g., Twitter, Facebook, or specific websites), a unique information domain (e.g., health information, general news, or scholarly papers), a type of information (e.g., general claims or news), or a specific application (e.g., verifying claims, or retrieving useful information). This inevitably results in a limited focus on what is a complex, multi-faceted phenomenon. With the aim of furthering research in this direction, the contributions of our work are twofold: (1) creating a new comprehensive dataset of misinformation claims, and (2) introducing two novel approaches to veracity assessment.

In the first part of our work, we contribute to the global effort on addressing misinformation in the context of COVID-19 by creating a dataset for PANdemic Ai Claim vEracity Assessment, called the **PANACEA dataset**. It is a new dataset that combines different data sources with different foci, thus enabling a comprehensive approach that combines different media, domains and information types. To this effect our dataset brings together a heterogeneous set of *True* and *False* COVID claims and online sources of information for each claim. The collected claims have been obtained from online fact-checking sources, existing datasets and research challenges. We have identified a large overlap of claims between different sources and even within each source or dataset. Thus, given the challenges of aggregating multiple data sources, much of our efforts in dataset construction has focused on eliminating repeated claims. Distinguishing between different formulations of the same claim and nuanced variations that include additional information is a challenging task. Our dataset is presented in a large and a small version, accounting for different degrees of such similarity. Finally, the homogenisation of datasets and information media has presented an additional challenge, since fact-checkers use different criteria for labelling the claims, requiring a specific review of the different kinds of labels in order to combine them.

In the second part of our work, we propose NLI-SAN and NLI-graph, two novel veracity assessment approaches for automated fact-checking of the claims. Our proposed approaches are centred around the use of Natural Language Inference (NLI) and contextualised representations of the claims and evidence. NLI-SAN combines the inference relation between claims and evidence with attention techniques, while NLI-graph builds on graphs considering the relationship between all the different pieces of evidence and the claim.

Specifically we make the following contributions:

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1496 - 1511
July 10-15, 2022

- We describe the development of a comprehensive COVID fact-checking dataset, PANACEA, as a result of aggregating and de-duplicating a set of heterogeneous data sources. The dataset is available in the project website[1], as well as a fully operational search platform to find and verify COVID-19 claims implementing the proposed approaches.
- We propose two novel approaches to claim verification, NLI-SAN and NLI-graph.
- We perform an evaluation of both evidence retrieval and the application of our proposed veracity assessment methods on our constructed dataset. Our experiments show that NLI-SAN and NLI-graph have state-of-the-art performance on our dataset, beating GEAR (Zhou et al., 2019) and matching KGAT (Liu et al., 2020). We discuss challenging cases and provide ideas for future research directions.

2 Related Work

COVID-19 and misinformation datasets. Comprehensive information on COVID-19 datasets is provided in Appendix A. Such datasets include the CoronaVirusFacts/DatosCoronaVirus Alliance Database, the largest existing collection of COVID claims and the largest existing network of journalists working together on COVID misinformation, an essential reference for our work; COVID-19-TweetIDs (Chen et al., 2020) the widest dataset of COVID tweets with more than 1 billion tweets; Cord-19: The COVID-19 open research dataset (Wang et al., 2020a), the largest downloadable set of scholarly articles on the pandemic with nearly 200,000 articles. General misinformation datasets linked to our verification work include: Emergent (Ferreira and Vlachos, 2016) collection of 300 labeled claims by journalists; LIAR (Wang, 2017) with 12,836 statements from PolitiFact with detailed justifications; FakeNewsNet (Shu et al., 2020) collecting not only claims from news content, but also social context and spatio-temporal information; NELA-GT-2018 (Nørregaard et al., 2019) with 713,534 articles from 194 news outlets; FakeHealth (Dai et al., 2020) collecting information from HealthNewsReview, a project critically analysing claims about health care interventions; PUBHEALTH (Kotonya and Toni, 2020) with 11,832 claims related to health topics; FEVER (Thorne et al., 2018a) as well as its later versions FEVER 2.0 (Thorne et al., 2018b) and FEVEROUS (Aly et al., 2021), containing claims based on Wikipedia and therefore constituting a well-defined, informative and non-duplicated information corpus; SciFact (Wadden et al., 2020) also from a very different domain, containing 1,409 scientific claims. Our dataset is a real-world dataset bringing together heterogeneous sources, domains and information types.

Approaches to claim veracity assessment. We employ our dataset for automated fact-checking and veracity assessment (Zeng et al., 2021). Researchers such as Hanselowski et al. (2018); Yoneda et al. (2018); Luken et al. (2018); Soleimani et al. (2020); Pradeep et al. (2021) analysed the veracity relation between the claim and each piece of evidence independently, combining this information later. Other authors considered multiple pieces of evidence together (Thorne et al., 2018a; Nie et al., 2019; Stammbach and Neumann, 2019). Different pieces of evidence have been previously combined using graph neural networks (Zhou et al., 2019; Liu et al., 2020; Zhong et al., 2020). Many of these authors have centred their techniques on the use of NLI (Chen et al., 2017; Ghaeini et al., 2018; Parikh et al., 2016; Li et al., 2019) to verify the claim. In our work we also make use of NLI results of claim-evidence pairs, but propose alternative approaches built on a self-attention network and a graph convolutional network for veracity assessment.

3 Dataset Construction

This section describes our dataset construction by selecting COVID-19 related data sources (§3.1), and applying information retrieval and re-ranking techniques to remove duplicate claims (§3.2).

3.1 Data Sources

We first identified a set of COVID-19 related data sources to build our dataset. Our aim is to have the largest compilation of non-overlapping, labelled and verified claims from different media and information domains (Twitter, Facebook, general websites, academia), and used for different applications (media reporting, veracity evaluation, information retrieval challenges, etc.). We have included any large dataset or media, to our knowledge, related to that objective that includes claims together with their information sources. The data sources identified are shown in Table 1. More details and preprocessing steps are presented in Appendix A. By

Data Source	**Description**	**Domain**	**No. of claims (False / True)**
CoronaVirusFacts Database	Published by Poynter, this online source combines fact-checking articles from more than 100 fact-checkers from all over the world, being the largest journalist fact-checking collaboration on the topic worldwide.	Heterogeneous	11,647 (11,647 / 0)
CoAID dataset (Cui and Lee, 2020)	This contains fake news from fact-checking websites and real news from health information websites, health clinics, and public institutions.	News	5,485 (953 / 4,532)
MM-COVID (Li et al., 2020)	This multilingual dataset contains fake and true news collected from Poynter and Snopes.	News	3,409 (2,035 / 1,374)
CovidLies (Hossain et al., 2020)	This contains a curated list of common misconceptions about COVID appearing in social media, carefully reviewed to contain very relevant and unique claims.	Social media	62 (62 / 0)
TREC Health Misinformation track	Research challenge using claims on the health domain focused on information retrieval from general websites through the Common Crawl corpus (commoncrawl.org).	General websites	46 (39 / 7)
TREC COVID challenge (Voorhees et al., 2021; Roberts et al., 2020)	Research challenge using claims on the health domain focused on information retrieval from scholar peer-reviewed journals through the CORD19 dataset (Wang et al., 2020a), the largest existing compilation of COVID-related articles.	Scholar papers	40 (3 / 37)

Table 1: Data sources used for the construction of our dataset. The last column shows the number of claims before de-duplication.

processing and combining these sources we obtained 20,689 initial claims.

3.2 Claim De-duplication

We processed claims and removed: exact duplicates; claims making only a direct reference to existing content in other media (audio, video, photos); automatically obtained content not representing claims; entries with claims or fact-checking sources in languages other than English.

The similarity of claims was then analysed using: BM25 (Robertson et al., 1995; Crestani et al., 1998; Robertson and Zaragoza, 2009) and BM25 with MonoT5 re-ranking (Nogueira et al., 2020). BM25 is a commonly-used ranking function that estimates the relevance of documents to a given query. MonoT5 uses a T5 model trained using as input the template '`Query:[query] Document:[doc] Relevant:`', fine-tuned to produce as output the token '*True*' or '*False*'. A softmax layer applied to those tokens gives the respective relevance probabilities. These methods are used to identify not only claims similar in content, but also distinct claims that are sufficiently relevant when searching for information about them. This ensures that the claims presented are unique, and avoids overlap between training and testing cases when using the data to train veracity assessment models. These methods were carried out using Pyserini[2] and PyGaggle[3]. The set of claims was indexed and a search was performed for each of the claims to detect similar claims. We created two versions of the dataset by varying the similarity threshold between claims. The LARGE dataset excludes claims with a 90% probability of being similar, while in the SMALL dataset the probability is increased to 99%, as obtained through the MonoT5 model. These thresholds were chosen empirically by manual inspection of the results with simultaneous consideration of the efficiency of the method.

As a further assessment of the uniqueness of the claims, we evaluated the de-duplication process using BERTScore[4] (Zhang et al., 2019) on the resulting datasets. We used the linked code with a RoBERTa-large model with baseline rescaling. We compared each claim with all the other claims in the dataset and kept the score of the most similar match. The mean and standard deviation, and the 90th percentile of claim similarity values are shown in the upper part of Table 3. The average claim similarity has been drastically reduced in the LARGE dataset compared to the original dataset and further reduced in the SMALL dataset.

To illustrate the difference between the two ver-

[3] https://github.com/castorini/pygaggle
[4] https://github.com/Tiiiger/bert_score

Claim 1: Losing your sense of smell may be an early symptom of COVID-19.
Exclude from LARGE and SMALL: Loss of smell may suggest milder COVID-19. **Exclude from SMALL only**: Loss of smell and taste validated as COVID-19 symptoms in patients with high recovery rate.
Claim 2: COVID-19 hitting some African American communities harder.
Exclude from LARGE and SMALL: The African American community is being hit hard by COVID-19. **Exclude from SMALL only**: COVID-19 impacts in African-Americans are different from the rest of the U.S. population.

Table 2: Claim de-duplication examples.

sions of the dataset, we present some examples of claims in Table 2. For Claim 1, the semantically similar claim '*Loss of smell may suggest milder COVID-19*' is identified and excluded from both LARGE and SMALL datasets. But the claim '*Loss of smell and taste validated as COVID-19 symptoms in patients with high recovery rate*', which includes mentions of another symptom and the recovery rate, is only excluded from the SMALL dataset. For Claim 2, the rephrased claim '*The African American community is being hit hard by COVID-19*' is excluded from both datasets. But the claim '*COVID-19 impacts in African-Americans are different from the rest of the U.S. population*', which refers specifically to the U.S. population, is only excluded from the SMALL dataset.

3.3 Dataset Statistics

Our final dataset statistics are shown in the lower part of Table 3, where the original and the two reduced versions are presented. After the steps described in Section 3.2 the LARGE dataset contains 5,143 claims, and the SMALL version 1,709 claims.

Category	**Orig.**	**LARGE**	**SMALL**
Similarity	0.67 ± 0.23	0.43 ± 0.13	0.37 ± 0.14
$\eta_{.90}$	0.99	0.60	0.56
False	14,739	1,810	477
True	5,950	3,333	1,232
Total	20,689	5,143	1,709

Table 3: The average claim similarity values and the PANACEA LARGE and SMALL dataset statistics. $\eta_{.90}$ denotes the 90th percentile value.

Example claims contained in the dataset are shown in Table 4. Each of the entries in the dataset contains the following information:

- *Claim*. Text of the claim.
- *Claim label*. The labels are: *False*, and *True*.
- *Claim source*. The sources include mostly fact-checking websites, health information websites, health clinics, public institutions sites, and peer-reviewed scientific journals.
- *Original information source*. Information about which general information source was used to obtain the claim.
- *Claim type*. The different types, explained in Section A.2, are: *Multimodal, Social Media, Questions, Numerical*, and *Named Entities*.

4 Claim Veracity Assessment

We develop a pipeline approach consisting of three steps: document retrieval, sentence retrieval and veracity assessment for claim veracity evaluation. Given a claim, we first retrieve the most relevant documents from COVID-19 related sources and then further retrieve the top N most relevant sentences. Considering each retrieved sentence as evidence, we train a veracity assessment model to assign a *True* or *False* label to the claim.

4.1 Document Retrieval

Document Dataset. In order to retrieve documents relevant to the claims, we first construct an additional dataset containing documents obtained from reliable COVID-19 related websites. These information sources represent a real-world comprehensive database about COVID-19 that can be used as a primary source of information on the pandemic. We have selected four organisations from which to collect the information: (1) *Centers for Disease Control and Prevention (CDC)*, national public health agency of the United States; (2) *European Centre for Disease Prevention and Control (ECDC)*, EU agency aimed at strengthening Europe's defenses against infectious diseases; (3) *WebMD*, online publisher of news and information on health; and (4) *World Health Organization (WHO)*, agency of the United Nations responsible for international public health.

All pages corresponding to the COVID-19 subdomains of each site have been downloaded. The

Claim	Category	Source	Orig. data src.	Type
Stroke Scans Could Reveal COVID-19 Infection.	True	ScienceDaily	CoAID	
Whiskey and honey cure coronavirus.	False	Independent news site	CovidLies	
COVID-19 is more deadly than Ebola or HIV.	False	Australian Associated Press	Poynter	
Dextromethorphan worsens COVID-19.	True	Nature	TREC Health Misinformation track	
ACE inhibitors increase risk for coronavirus.	False	Infectious Disorders - Drug Targets journal	TREC COVID challenge	
Nancy Pelosi visited Wuhan, China, in November 2019, just a month before the COVID-19 outbreak there.	False	Snopes	MM-COVID	Named Entity, Numerical content

Table 4: Example entries in the constructed PANACEA dataset.

web content was downloaded using the BeautifulSoup[5] and Scrapy[6] packages. Social networking sites and non-textual content were discarded. In total 19,954 web pages have been collected. The list of websites and the full content of each website constitute this additional dataset used for document retrieval. This dataset is enhanced with some additional websites used only in the document retrieval experiments, detailed in Section 5.1.

Method. Information sources were indexed by creating a Pyserini Lucene index and PyGaggle was used to implement a re-ranker model on the results. The documents were split into paragraphs of 300 tokens segmented with a BERT tokenizer.

To retrieve the information we first used a BM25 score. Additionally, we tested the effect of multi-stage retrieval by re-ranking the initial results using MonoBERT (Nogueira et al., 2019) and MonoT5 models, and query expansion using RM3 pseudo-relevance feedback (Abdul-Jaleel et al., 2004) on the BM25 results (Lin, 2019; Yang et al., 2019).

MonoBERT uses a BERT model trained using as inputs the query and each of the documents to be re-ranked encoded together (`[CLS]query[SEP]doc[SEP]`), and then the `[CLS]` output token is passed to a single layer fully-connected network that produces the probability of the document being relevant to the query.

4.2 Sentence Retrieval

For each claim, once documents are retrieved using BM25 and MonoT5 re-ranking of the top 100 BM25 results, we then further retrieve the N most similar sentences obtained from the 10 most relevant documents. The relevance of the sentences is calculated using cosine similarity in relation to the original claim. The similarity is obtained with the pre-trained model MiniLM-L12-v2 (Wang et al., 2020b), using Sentence-Transformers[7] (Reimers and Gurevych, 2019) to encode the sentences.

4.3 Veracity Assessment

We propose two veracity assessment approaches built on the NLI results of claim-evidence pairs. For each of the most similar sentences (pieces of evidence) retrieved for a claim, we apply the pre-trained NLI model RoBERTa-large-MNLI[8](Liu et al., 2019). This model acts as a cross-encoder on pairs of sentences, trained to detect the relationship between the two sentences: *contradiction*, *neutrality*, or *entailment*. The model is trained on the Multi-Genre Natural Language Inference (MultiNLI) dataset (Williams et al., 2018). The inference results are then used in our proposed approaches described below.

NLI-SAN. The first approach, named `NLI-SAN`, incorporates the inference results of claim-evidence pairs into a Self-Attention Network (SAN) (See Figure 1a). First, a claim is paired with each piece of retrieved relevant evidence. Each pair (c, e_i) is fed into a RoBERTa-large[8] model, and the last hidden layer output $\mathbf{S_i}$ is used as its representation. Additionally, each pair is also fed to the mentioned RoBERTa-large-MNLI[8] model obtaining $\mathbf{I_i}$, a triplet containing the probability of *contradiction*, *neutrality*, or *entailment*.

$$\begin{aligned} \mathbf{S_i} &= \mathrm{RoBERTa}(c, e_i) \\ \mathbf{I_i} &= \mathrm{RoBERTa_{NLI}}(c, e_i) \end{aligned} \tag{1}$$

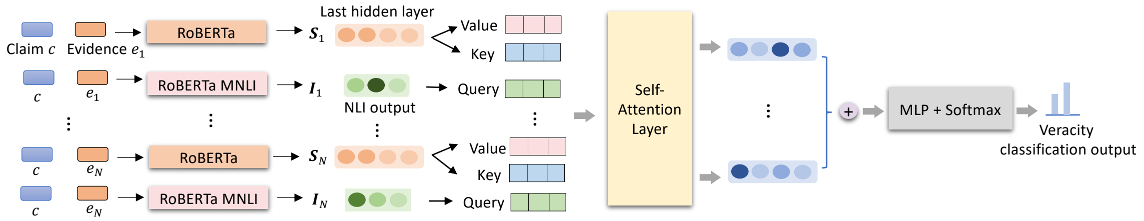
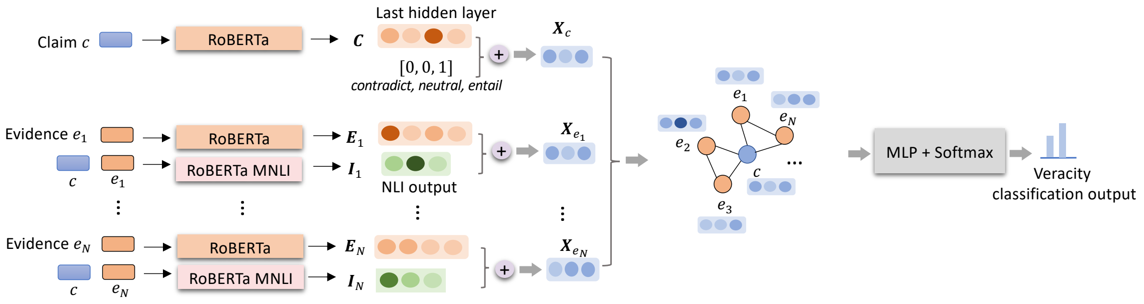
[8] https://huggingface.co/



(a) `NLI-SAN`



(b) `NLI-graph`

Figure 1: Proposed veracity classification models. ⊕ means concatenation.

The sentence representation is combined with the NLI output through a Self Attention Network (SAN) (Galassi et al., 2020; Bahdanau et al., 2015).

The RoBERTa-encoded claim-evidence representation $\mathbf{S_i}$ with length $n_S = n_K = n_V$ is mapped onto a Key $\mathbf{K} \in \mathbb{R}^{n_K \times d_K}$ and a Value $\mathbf{V} \in \mathbb{R}^{n_V \times d_V}$, while the NLI output $\mathbf{I_i}$ of each claim-evidence pair is mapped onto a Query $\mathbf{Q} \in \mathbb{R}^{n_Q \times d_Q}$. The representation dimensionality is $d_K = d_V = d_Q = 1024$. The attention function is defined as:

$$\text{Att}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \text{softmax}(\mathbf{Q}\mathbf{K}^\top / \sqrt{d})\mathbf{V} \qquad (2)$$

While standard attention mechanisms use only the sentence representation information for the Key, Value and Query, here the inference information is used in the Query. This *attention* mechanism is applied to each of the claim-evidence pairs, and the outputs are concatenated into an output O_{SAN} that is passed through a Multi-Layer Perceptron (MLP) with hidden size d_h and a Softmax layer to generate the veracity classification output.

$$\hat{\boldsymbol{y}} = \text{softmax}(\text{MLP}_{\text{ReLU}}(\text{O}_{\text{SAN}})) \qquad (3)$$

NLI-graph. We propose an alternative approach based on Graph Convolutional Networks (GCN). First, for each claim-evidence pair, we derive RoBERTa-encoded representations for the claims and evidence separately (using the pooled output of the last layer) and obtain NLI results of the pairs as before.

$$\mathbf{C_i} = \text{RoBERTa}(c); \quad \mathbf{E_i} = \text{RoBERTa}(e_i) \qquad (4)$$

$$\mathbf{I_i} = \text{RoBERTa}_{\text{NLI}}(c, e_i) \qquad (5)$$

Next, we build an evidence network in which the central node is the claim and the rest of the nodes are the evidence. Two nodes are linked if their similarity value exceeds a pre-defined threshold, which is empirically set to 0.9 by comparing the results of the experimental evaluation described in the following section using different thresholds. The similarity is considered between claim and evidence, but also between pieces of evidence. Similarity calculation is performed following the same approach as in Section 4.2. The features considered in each evidence node are the concatenation of $\mathbf{E_i}$ and $\mathbf{I_i}$. For the claim node we use its representation $\mathbf{C_i}$ and a unity vector $(0, 0, 1)$ for the inference. The network is implemented with the package PyTorch Geometric (Fey and Lenssen, 2019), using in the first layer the GCNConv operator (Kipf and Welling, 2016) with 50 output channels and self-loops to the nodes, represented by:

$$\mathbf{X}' = \hat{\mathbf{D}}^{-1/2}\hat{\mathbf{A}}\hat{\mathbf{D}}^{-1/2}\mathbf{X}\mathbf{W}, \qquad (6)$$

where $\mathbf{X}$ is the matrix of node feature vectors, $\hat{\mathbf{A}} = \mathbf{A} + \mathbf{I}$ denotes the adjacency matrix with inserted self-loops, $\hat{D}_{ii} = \sum_{j=0} \hat{A}_{ij}$ its diagonal degree matrix, and $\mathbf{W}$ is a trainable weight matrix.

Once the node representation is updated via GCN, all the node representations are averaged and passed to the MLP and the Softmax layer to generate the final veracity classification output.

$$\hat{y} = \text{softmax}(\text{MLP}_{\text{ReLU}}(\text{O}_{\text{graph}})) \tag{7}$$

5 Experiments

In this section, we perform a twofold evaluation: We first evaluate our document retrieval methods (presented in §4.1) on obtaining information relevant to the dataset claims from a database of COVID-19 related websites. We subsequently present an evaluation of the veracity assessment approaches for the claims (described in §4.3).

5.1 Document Retrieval

In order to evaluate our document retrieval methods, we need the gold-standard relevant document for each claim. Therefore, in the documents dataset described in section 4.1 we additionally include the web content referenced in each of the information sources used to compile our claim dataset:

The CoronaVirus Alliance Database. All web pages from the websites referenced as fact-checking sources for the claims have been downloaded from 151 different domains.

CoAID dataset. We downloaded the websites used as fact-checking sources of false claims and the websites where correct information on true claims is gathered from 68 different domains.

MM-COVID. We collected both fact-checking sources and reliable information related to the claims of this dataset from 58 web domains.

CovidLies dataset. We include the web content used as fact-checking sources of the misconceptions from 39 domains.

We have not included web content from the TREC Challenges, as each of them is performed on a very large dataset specific to each challenge (CORD19 and Common Crawl corpus), as explained previously. Note that in our subsequent experiments, we have excluded all fact-checking websites to avoid finding directly the claim references. The results of the document retrieval are presented in Table 5. For each claim, the precision@k is defined as 1 if the relevant result is retrieved in the top k list and 0 otherwise.

We can see that by using BM25, it is possible in many cases to retrieve the relevant results at the very top of our searches. Combining BM25 with MonoBERT did not offer any improvement. It even introduced noise to the retrieval results, leading to inferior performance compared to using BM25 only on AP@5 and AP@10. MonoT5 appears to be more effective, consistently improving the retrieval results across all metrics. Moreover for this dataset the use of query expansion using RM3 pseudo-relevance feedback on the BM25 results does not improve the results.

	AP@5	**AP@10**	**AP@20**	**AP@100**
BM25	0.54	0.56	0.58	0.62
BM25+MonoBERT	0.52	0.55	0.58	0.62
BM25+MonoT5	**0.55**	**0.58**	**0.60**	**0.62**
BM25+RM3+MonoT5	0.51	0.53	0.55	0.57

Table 5: Document retrieval results. Average precision for different cut-offs. For the MonoBERT and MonoT5 cases, 100 initial results are retrieved in the first retrieval stage before re-ranking.

5.2 Veracity Assessment Evaluation

Here we evaluate our proposed `NLI-SAN` and `NLI-graph` veracity assessment approaches. To gain a better insight into the benefits of the proposed architectures, we conducted additional experiments on the variants of the models including:

- `NLI`, using only the NLI outputs of the claim-evidence pairs. The outputs are concatenated and then passed through the final classification layer to generate veracity classification results.
- `NLI+sent`, this is the ablated version of `NLI-SAN` without the self-attention layer. Here, the RoBERTa-encoded claim-evidence representations are concatenated with the NLI results and then fed to the classification layer to produce the veracity classification output.
- `NLI+PSent`, this is similar to the previous ablated version, but using the pooled representation of the claim-evidence pair to concatenate with the NLI result.
- `NLI-graph`$_{-abl}$, this is the ablated version of `NLI-graph` in which the node representation is the NLI result of the corresponding claim-evidence pair without its RoBERTa-encoded representation.

For `NLI`, `NLI+sent` and `NLI-SAN`, we consider the 5 most similar sentences for each claim, obtained from the 10 most relevant documents of the information source database. Those documents are retrieved using BM25 and MonoT5 re-ranking of the top 100 BM25 results. For `NLI-graph`, `NLI-graph`$_{-abl}$ and `NLI+PSent`, in order to have enough nodes to benefit from the network structure, the number of retrieved sentences is increased to 30 for each claim, selected as the 3

Table 7: Veracity classification results on the PANACEA LARGE dataset. The best result in each column is highlighted in bold.

most similar sentences from the top 10 retrieved documents. The retrieval procedure is as in sections 4.1 and 4.2. Details of parameter settings can be found in Appendix B. We compare against the SOTA methods GEAR[9](Zhou et al., 2019) and KGAT[10](Liu et al., 2020), with settings as described by the authors.

For all approaches we perform 5-fold cross-validation and report the averaged results on the SMALL dataset in Table 6. By using the NLI information alone it is possible to obtain reasonable results for the *True* claims, however, this is not the case for the most relevant *False* claims. Once we add sentence representations the efficiency of the method increases significantly. Using `NLI-SAN` instead of simply concatenating contextualised claim-evidence representations and NLI outputs further improves the results. A similar observation can be made in the results generated by `NLI-graph` and its variants; the contextualised representations of claim-evidence pairs are much more important than merely using the corresponding NLI values. We also note that using the graph version `NLI-graph` obtains better scores than a non-graph model with the same information `NLI+PSent`, however the scores are still lower than the `NLI-SAN` method. Our method performs on a par with KGAT, while being simpler, and outperforms GEAR.

Complementing the results for the SMALL dataset, Table 7 presents the results for the LARGE dataset. In general, we observe improved performance for all models across all metrics for both classes compared to the results on the SMALL dataset. The previous results in the SMALL dataset constitute a more challenging case, since the uniqueness of the claims is increased and therefore the veracity assessment models are not able to learn from similar claims when performing the assessment.

5.3 Discussion

Our results show that in document retrieval, we have obtained values of around 0.6 from a simple term scoring and re-ranking retrieval model. However, this baseline represents only a rough measure of quality using this technique, since we have only evaluated the retrieval of a single document specific to each claim; we have not evaluated the quality of other retrieved documents.

---

[9] `https://github.com/thunlp/GEAR`

[10] `https://github.com/thunlp/KernelGAT`

The distinction into *True* and *False* claims can be rather coarse-grained. We note that initially we considered a larger number of veracity labels, including more nuanced cases that could be interesting to analyse (see A.1). However, we have not found a clear separation between complex cases and it would seem that different fact checkers do not follow the same conventions when labelling such cases. The development of datasets especially focused on such nuanced cases may be therefore an important line of work in the future, together with the development of techniques for these more complex situations.

In analysing misclassified claims, we note some interesting cases. The scope and globality of the pandemic imply that similar issues are mentioned repeatedly on multiple occasions, yet claims to be verified may include nuances or specificities. This is challenging as it is easy to retrieve information that omits relevant nuances. E.g. The claim "*Barron Trump had COVID-19, Melania Trump says*" retrieves sentences such as "*Rudy Giuliani has tested positive for COVID-19, Trump says.*" with a similar structure and mentions but missing the key name. This type of situation could be addressed by using Named Entity Recognition (NER) methods that prioritise matching between the entities involved in the claim and the information sources. See e.g. (Taniguchi et al., 2018; Nooralahzadeh and Øvrelid, 2018).

Other interesting cases involve claims for which documents with adequate information are retrieved, but the sentences containing evidence cannot be identified because they are too different from the original claim. E.g. The claim "*Vice President of Bharat Biotech got a shot of the indigenous COVAXIN vaccine*" retrieves correct documents on the issue. Similar sentences are retrieved such as "*Covaxin which is being developed by Bharat Biotech is the only indigenous vaccine that is approved for emergency use.*". Despite being similar such retrieved sentences give no information about the claimed situation. In the retrieved document, the sentence "*The pharmaceutical company, has in a statement, denied the claim and said the image shows a routine blood test.*" contains the essential information to debunk the original claim but is missed by the sentence retrieval engine as it is very different from the claim (See Table A1 in Appendix C for other examples).

Such cases are more difficult to deal with, as the similarity between claim and evidence is certainly a good indicator of relevance. Nevertheless, these cases are very interesting for future work using more complex approaches. We have made an initial attempt to address this problem by representing claims and retrieved documents using Abstract Meaning Representation (Banarescu et al., 2013) in order to better select relevant information. Although the results were not satisfactory, it may be an interesting avenue for future exploration. Another line of future work is the design of strategies against adversarial attacks to mitigate possible risks to our system.

6 Conclusions

We have presented a novel dataset that aggregates a heterogeneous set of COVID-19 claims categorised as *True* or *False*. Aggregation of heterogeneous sources involved a careful deduplication process to ensure dataset quality. Fact-checking sources are provided for veracity assessment, as well as additional information sources for *True* claims. Additionally, claims are labelled with sub-types (Multimodal, Social Media, Questions, Numerical, and Named Entities).

We have performed a series of experiments using our dataset for information retrieval through direct retrieval and using a multi-stage re-ranker approach. We have proposed new NLI methods for claim veracity assessment, attention-based `NLI-SAN` and graph-based `NLI-graph`, achieving in our dataset competitive results with the GEAR and KGAT state-of-the-art models. We have also discussed challenging cases and provided ideas for future research directions.

A Data Sources

Here we present detailed information of the data sources introduced in section 3.1.

It is worth noting that for the construction of our dataset, we have only included sources or datasets that contain explicit veracity labels of specific claims, thus we have not included collections of tweets related to COVID that do not have veracity labels (Chen et al., 2020; Lamsal, 2021; Abdul-Mageed et al., 2021; Huang et al., 2020; Dimitrov et al., 2020; Kerchner and Wrubel, 2020; Qazi et al., 2020). We have not included claims without independent fact-checking sources (Memon and Carley, 2020; Shahi et al., 2021) and information sources without formulated claims such as the collections of scholarly articles (Wang et al., 2020a; Chen et al., 2021), news articles (Zhou et al., 2020), or articles obtained through specific repositories as (COVID-19 Data Portal , EU; WHO database of publications on coronavirus; Elsevier journals Novel Coronavirus Information Center; Cambridge journals Coronavirus Free Access Collection; The Lancet COVID-19 content collection; Oxford journals resources on COVID-19; MedRN medical research network SSRN Coronavirus Infectious Disease Research Hub).

The data sources that we have used for the construction of our dataset are:

- **The CoronaVirusFacts/DatosCoronaVirus Alliance Database**[11]. Published by Poynter[12], this online publication combines fact-checking articles from more than 100 fact-checkers from all over the world, being the largest journalist fact-checking collaboration on the topic worldwide[13]. The publication is presented as an online portal, thus we had to develop scripts to crawl the content and extract the relevant claims, categories, and information sources.

- **CoAID dataset**[14]. The dataset (Cui and Lee, 2020) contains fake news from fact-checking websites and real news from health information websites, health clinics, and public institutions. Unlike most other datasets, it contains a wide selection of true claims.

- **MM-COVID**[15]. The multilingual dataset (Li et al., 2020) contains fake and true news collected from Poynter and Snopes[16], being a good complement to the first data source.

- **CovidLies dataset**[17]. The dataset (Hossain et al., 2020) contains a curated list of common misconceptions about COVID appearing in social media, carefully reviewed to contain very relevant and unique claims unlike other automatically collected datasets.

- **TREC Health Misinformation track**[18]. Research challenge using claims on the health domain focused on information retrieval from general websites through the Common Crawl corpus[19]. This dataset is specialized in a very specific domain, and has been used for a very different application than the previous data sources.

- **TREC COVID challenge**[20]. Research challenge (Voorhees et al., 2021; Roberts et al., 2020) using claims on the health domain focused on information retrieval from scholarly peer-reviewed journals through the CORD19 dataset (Wang et al., 2020a), the largest existing compilation of such articles. Similar to the last source, but focused on scholarly papers unlike the other sources.

A.1 Pre-processing

A separate pre-processing step was carried out for each of the selected data sources:

The CoronaVirusFacts/CoronaVirus Alliance Database. The data was downloaded on 13 February 2021. From the 11,647 entries initially obtained, entries with no fact-checking source and categories with less than 10 entries were removed. The different fact-checkers used different categories to label the claims, although in most of the cases the difference was mainly in terms of spelling. Initially we identified the following common categories: *False* (including FALSE, FALSO, Fake, false, false and misleading, Two Pinocchios, Misinformation

[19] `https://commoncrawl.org/`

[20] `https://ir.nist.gov/covidSubmit/data.html`

/ Conspiracy theory, Not true, false headline, MANIPULATED, Unproven), *Misleading* (MIsleading, MISLEADING, mislEADING, MiSLEADING, misleading, Misleading/False, Misleading), *Missing Context* (Missing context, Needs Context, missing context), *No Evidence* (NO EVIDENCE, No evidence, No Evidence), *Mostly False* (Mostly False, Mostly false, MOSTLY FALSE, mostly false, Mainly false), *Partially False* (Partially False, Partly false, Partially false, partially false, partly false), *Partially True* (PARTLY TRUE, Partially correct, Partially true, Partly true, HALF TRUE, HALF TRUTH, half true), and *Mostly True* (Mostly true, MOSTLY TRUE, mainly correct). Next, we conducted a manual inspection of the different categories. We found that the categories *Misleading, Missing Context, No Evidence, Mostly False*, and *Partially False* had no homogeneous and clear definition through the different fact-checking media. Each group contains claims fitting the definition mixed with claims that are simply false (e.g. of false claims under other labels: “Misleading: Only people from South Korea have Covid-19 antibodies"; “Partially False: The vaccines contain substances such as arsenic or uranium according to scientific studies"; “Mostly False: Pope Francis contracted coronavirus"). Therefore, we decided to not use these nuanced categories but group them in the general *False* category. Additionally, we removed the 25 claims from the categories *Partially True* and *Mostly True*, since they contained both *True* and *False* claims.

CoAID dataset. The datasets `NewsRealCOVID-19`, `NewsFakeCOVID-19`, and `ClaimFakeCOVID-19` were selected. The additional available dataset contains claims already existing in other datasets, formulated in this case as questions, and thus was not included. The selected datasets contain *True* and *False* claims.

MM-COVID. The claims were obtained from the `English_news` part of the dataset since we are only interested in English claims. 3,409 claims were collected. Claims in other languages appeared in the file, therefore we did a language filtering using polyglot[21]. Additionally, claims without fact-checking sources were deleted. It contains *True* and *False* claims.

CovidLies dataset. The available claims have been manually revised by eliminating duplicates, resulting in a total of 62 misconception claims. It contains *False* claims.

TREC Health Misinformation track. The claims used in the track were obtained and reformulated manually by us as affirmative claims (e.g., “*Can vitamin D cure COVID-19?*" was changed to “*Vitamin D cures COVID-19*") for consistency with the rest of the data sources and to allow claim veracity assessment. *True* and *False* claims are used.

TREC COVID challenge. The claims used in the challenge were obtained and reformulated manually by us as full sentences using the explanations related to each query (e.g., for a given query “*coronavirus immunity*", and its explanation “*will SARS-CoV2 infected people develop immunity?*", we form the following claim, “*coronavirus infected people develop immunity*"). *True* and *False* claims are used.

The above processed data sources were combined to provide 20,689 initial claims.

A.2 Claim Categorisation

The claims were analysed to identify types of claims that may be of particular interest, either for inclusion or exclusion depending on the type of analysis. The following types were identified: (1) Multimodal; (2) Social media references; (3) Claims including questions; (4) Claims including numerical content; (5) Named entities, including: PERSON – People, including fictional; ORGANIZATION – Companies, agencies, institutions, etc.; GPE – Countries, cities, states; FACILITY – Buildings, highways, etc. These entities have been detected using a RoBERTa base English model (Liu et al., 2019) trained on the OntoNotes Release 5.0 dataset (Weischedel et al., 2013) using Spacy[22].

B Parameter Setting

In our veracity assessment experiments, the parameters of the initial RoBERTa models are frozen during the training. The inputs are padded and truncated to the longest sequence, and a ReLU function is used as the activation function for the hidden layer. The GCNConv outputs are padded to the longest graph size. The loss function used is cross-entropy. The size of the hidden layer is 50, the batch size is 30, and the training is performed for 100 epochs for `NLI-SAN` and its variants, and 200 epochs for `NLI-graph` and its variants. The optimizer used is AdamW (Loshchilov and Hutter, 2019) with $\beta_1 = 0.9$, $\beta_2 = 0.999$, a weight decay of 0.01, and a learning rate of 10^{-2} for `NLI`, 10^{-4} for `NLI+Sent` and `NLI-SAN`, and

Claim	**Description**
"*Sugar causes a cytokine storm in the lungs that promotes COVID-19*"	Retrieved documents are relating COVID and its cytokine storm effects, but without the specific mention of sugar, which does not cause a cytokine storm.
"*Barron Trump had COVID-19, Melania Trump says*"	Retrieved sentences such as "*Rudy Giuliani has tested positive for COVID-19, Trump says.*" with a similar structure and mentions but mistaking the family members and missing the key name.
"*Prince Charles tested positive for COVID-19 after meeting Bollywood singer Kanika Kapoor.*"	Documents mentioning Prince Charles positive COVID tests are obtained, but without any mentions to the singer.
"*Vice President of Bharat Biotech got a shot of the indigenous COVAXIN vaccine*"	Correct documents on the issue are retrieved. Similar sentences are retrieved such as "*Covaxin which is being developed by Bharat Biotech is the only indigenous vaccine that is approved for emergency use.*" or "*Bharat Biotech's Covaxin is the first Indian vaccine to receive approval to conduct Phase I/Phase II trials.*". However, being similar they give no information about the claimed situation. In the retrieved document, the sentence "*The pharmaceutical company, has in a statement, denied the claim and said the image shows a routine blood test.*" contains the essential information to debunk the original claim. But it is missed by the sentence retrieval engine as it is very different from the claim.
"*Masks can be sanitized in microwave*"	Correct documents are retrieved with similar sentences such as "*Claiming masks can be sanitized in microwave resurfaces*". However, sentences such as "*The study authors cautioned health care workers against trying to clean masks this way. Microwaves melted the masks, making them useless.*" or "*He also warns people against using microwaves or ovens to heat their masks.*" that are present in the retrieved documents but are not similar enough to the claim are missed.

Table A1: Examples of errors in document or sentence retrieval.

a learning rates of 10^{-4} for `NLI-graph`, 10^{-3} for `NLI-graph`$_{-abl}$, and 10^{-5} for `NLI+PSent`, these last three with a step size of 0.1 after 100 epochs.

C Additional Examples of Document or Sentence Retrieval Errors

Here we expand on the examples mentioned in Section 5.3 related to difficulties in the document or sentence retrieval parts of the process. Table A1 presents in more detail the cases previously mentioned, and includes new examples.

Beyond Emotion: A Multi-Modal Dataset for Human Desire Understanding

Abstract

Desire is a strong wish to do or have something, which involves not only a linguistic expression, but also underlying cognitive phenomena driving human feelings. As the most primitive and basic human instinct, conscious desire is often accompanied by a range of emotional responses. As a strikingly understudied task, it is difficult for machines to model and understand desire due to the unavailability of benchmarking datasets with desire and emotion labels. To bridge this gap, we present MSED, the first multi-modal and multi-task sentiment, emotion and desire dataset, which contains 9,190 text-image pairs, with English text. Each multi-modal sample is annotated with six desires, three sentiments and six emotions. We also propose the state-of-the-art baselines to evaluate the potential of MSED and show the importance of multi-task and multi-modal clues for desire understanding. We hope this study provides a benchmark for human desire analysis. MSED will be publicly available for research[1].

1 Introduction

Multi-modal sentiment and emotion analysis has immense potential in dialogue analysis and generation, emotion communication, etc., which has been an active field of research in natural language processing (NLP) (Liu et al., 2021; Zhang et al., 2021c). Although numerous advanced models and datasets have been proposed, covering different levels of granularity, such as sentence, aspect, conversation, human desire behind emotions is still relatively unexplored. Human desire understanding models and datasets can benefit different areas of NLP and AI. Research in AI is a step closer to recognizing human emotional intelligence if a machine is able to achieve a deeper understanding of human desires and even make reasonable desire-aware responses (Hofmann and Nordgren, 2015). With researchers' increasing understanding of emotional intelligence and advancements in multi-modal language analysis, desire understanding and analysis comes into view (Goldberg et al., 2009; Ruffman et al., 2003).

(a) Kids with magnifying glass.
(b) I want these moments to last forever.

Figure 1: Examples of multi-modal desire, sentiment and emotion.

Desire is a primitive instinct and a basic need for strongly expressing human wants to get or possess something, where its endless and insatiable attributes distinguish human beings from other animals (Portner and Rubinstein, 2020). It involves not only a linguistic expression, but also has underlying cognitive phenomena driving human sentiments and emotions (Robinson, 1983). Hence, we argue that there is a close relationship between human desire, sentiment and emotion, where desire stealthily dominates sentiment and emotion while sentiment and emotion also have influence on desire. Such three tasks are complementary in that desire analysis helps the understanding of the other two. For example, in Fig. 1 (a), three kids with a magnifying glass are smiling and observing something interesting. The positive sentiment and happy emotion are judged by means of the desire *curiosity*. Fig. 1 (b) depicts that a young lady and her two children are walking at a leisurely rate along a winding road. Their smiles in the image and the words in its text counterpart convey joyful emotion. Such feelings explains the lady's strong need to be in the company of the children, i.e., family desire. We also check whether our hypothesis is tenable in

Table 1: Comparison of MSED with other datasets.

the experiments (c.f. Sec. 5.5).

Given the importance of desire understanding, numerous research results in psychology and philosophy have been proposed and are being actively studied to explain and analyze human desire, e.g., desire inference (Dong et al., 2013), the correlation between desire and love (Cacioppo et al., 2012; Kaunda and Kaunda, 2021), desire diagnosis (Mendelman, 2021). However, it is still an understudied new task in NLP and multi-modal affective computing. The lack of publicly available desire datasets has been the main issue in advancing multi-modal desire analysis models.

In this paper, we take the first step to overcome this limitation by presenting MSED, a novel multi-modal dataset manually annotated with sentiment, emotion and desire labels. MSED consists of 9,190 text-image pairs collected from a wide range of social media resources, e.g., Twitter, Getty Image, Flickr. It aims to extend the goal of human desire understanding within other disciplines and bring it to the NLP community. This dataset also facilitates the study of desire detection models by investigating both multi-task and multi-modal clues. Besides, MSED is also valuable for other NLP domains such as multi-modal language analysis, multi-task learning. In summary, the major contributions of the work are:

- The first multi-modal dataset annotated with three sentiment classes, six emotion classes and six desire classes is created and released publicly, aiming to open new doors to desire understanding.
- We present fine-grain multi-modal annotations of sentiment, emotion and desire categories. The quality control and agreement analysis are also described.
- Quantitative investigation shows the distribution of desire category, key words, whether desire affects the distribution of sentiment and emotion, and to what extent.
- We propose three multi-modal tasks to evaluate MSED, which are desire detection, sentiment analysis and emotion recognition. Several strong baselines using different combinations of feature representations are reported to show the need of multi-modal desire analysis models and the potential of MSED to facilitate the development of such models.

2 Related Work

2.1 Sentiment, Emotion and Desire Datasets

Since there is no available desire dataset, we briefly review related work in multi-modal sentiment and emotion datasets. Previously, researchers have created various multi-modal datasets to provide experimental test beds for evaluating sentiment and emotion analysis models, including YouTube (Uryupina et al., 2014), MOUD (Pérez-Rosas et al., 2013), Multi-ZOL (Xu et al., 2019), CMU-MOSI (Zadeh et al., 2016), etc. In addition, Zadeh et al. (2018) proposed an extended version of MOSI, which consists of textual, acoustic and visual clues. Yu et al. (2020) collected 2,281 refined Chinese video segments in the wild with both multi-modal and independent unimodal annotations. It allowed researchers to study the difference between modalities. Zhang et al. (2021a) presented the first multi-modal metaphor dataset to facilitate understanding metaphor from texts and images.

Multi-modal emotion recognition in conversation (ERC) has increasingly become an active research topic. The community also established IEMOCAP (Busso et al., 2008) MELD (Poria et al., 2019), ScenarioSA (Zhang et al., 2020b) and MUStARD (Castro et al., 2019), to show the impact of social interaction on human emotion evolution. However, the existing datasets only contain sentiment and emotion annotations. There is a lack of a dataset which provides insights into the desire behind human emotions. In contrast, MSED contains all of sentiment, emotion and desire multi-modal annotations to support and encourage future studies on the correlation between desire, sentiment and emotion. Table 1 compares all above mentioned datasets with their properties.

2.2 Sentiment, Emotion and Desire Analysis

The little work which exists on the automatic analysis of multi-modal desire has mainly been done in psychology, sociology and philosophy domains. Lim et al. (2012) designed a multi-modal desire analysis model that encompasses both audio and gesture modalities. However, they explained human desire in terms of emotions. Schutte and Malouff (2020) performed meta-analytic investigation on 2,692 individuals to explore the association between curiosity and creativity. Hoppe et al. (2015) used support vector machine (SVM) and eye movement data for automatic recognition of different levels of curiosity. But this work did not lie in the multi-modal domain. Cacioppo et al. (2012) presented a multilevel kernel density fMRI analysis approach to understand the differences and similarities in the interaction between sexual desire and love. Chauhan et al. (2020a) proposed a multi-task and multi-modal deep attentive framework for offensive, motivation and sentiment analysis. However, according to 16 basic desires theory (Steven, 2004), motivation and offense cannot be classified as desires.

Although remarkable progress has been made in the recent studies of multi-modal affect analysis, e.g., sentiment analysis (Zhang et al., 2021d), emotion recognition (Chauhan et al., 2020b; Li et al., 2022), sarcasm detection (Zhang et al., 2021b), humor analysis (Hasan et al., 2019), etc., there is a gap in the understanding and detection of human desire. Our MSED dataset will contribute to the research in understanding and analysis of the desires behind human agency.

3 The MSED Dataset

The process of creating MSED, the annotation procedure and the basic features are detailed.

3.1 Data Acquisition

The rise of social media has provided a platform for an increasing number of people to fulfill their desires and exude their emotions by publishing diverse types of posts. Given that our aim is to create a multi-modal dataset, three well-known online photo-sharing resources, i.e., Getty Image, Flickr and Twitter, are chosen as our domain. In order to avoid noisy and irrelevant samples as much as possible, we prefer to set a filtering rule before collecting them.

Item	#
Total samples	9,190
Desire samples	4,683
Non-desire Samples	4,507
Total words	109,570
Average word count per text	12
Average size per image	612×408
Train set size	6,127
Validation set size	1,021
Test set size	2,042

Table 2: Statistics of MSED Dataset.

Specially, we set a list of keywords with a strong desire expression based on 16 basic desires theory (Steven, 2004), e.g., $curiosity$, $romance$, $family$, $vengeance$ etc. We query the social media platforms with such words, and only crawl the retrieved text-image posts on the first ten pages. Besides, we attempt to select the visual samples which include people and their facial expressions so that one can easily judge their emotions, sentiments and desires. After applying this first filtering step, we gather over 11,000 multi-modal posts[2].

Data Filter. All these raw posts are then preprocessed by employing the data filtering rule. For text data, we remove text with fewer than 3 words, correct the spelling mistakes, and check if each text is composed of illegible characters via the NLTK package (Bird et al., 2009). For their visual counterparts, we remove the images with low resolution and resize all images to the same size.

Finally, the MSED dataset contains 9,190 text-image pairs, with 109,570 word occurrences in total. The average number of words per text is 12. The detailed statistics are shown in Table 2.

3.2 Label Selection and Annotation Model

Since human desires are many and varied, this paper will focus on those desires that are emotionally related and divorced from the need for survival (e.g., eat). After early attempts to collect and analyze raw samples, we empirically select six typical human desires from sixteen basic desires, which are $family$, $romance$, $vengeance$, $curiosity$, $tranquility$, $social\ contact$. Such de-

---

[2] Note that the original copyright of all the multi-modal samples belongs to the source owners, and no personal information of any participants was collected.

Desire	Explanation
Family	The need to take care of one's offspring.
Romance	A feeling of excitement and mystery associated with love.
Vengeance	The need to strike back against another person.
Curiosity	The wish to gain knowledge or explore the unexpected.
Tranquility	The wish to be secure, protected or company.
Social-contact	The need to communicate, converse and establish a relationship with others.

Table 3: Explanations of six desires.

Figure 2: Layout of the annotation interface.

sire attributions often are accompanied by sentimental and emotional expressions. Table 3 presents the detailed explanations of the selected desires.

Thus, each piece of multi-modal sample is manually annotated with desire category, sentiment category (i.e., $positive$, $neutral$ and $negative$) and emotion category ($happiness$, sad, $neutral$, $disgust$, $anger$ and $fear$). The annotation model is AnnotationModel = (DesireCategory, Sentiment-Category, EmotionCategory, DataSource).

3.3 Human Annotation Process

We recruit five well-educated volunteers including three undergraduate and two master students to take part in data annotation. All of them signed and gave informed consents before the study and were paid equivalent of \$1.5/hour in local currency. They had a professional background which ensured that they have a good knowledge of human desire and emotion analysis. Before labeling the whole dataset, they were instructed to independently annotate 50 examples first, in order to minimize ambiguity while strengthening the inter-annotator agreement, e.g., their agreement rate should reach 90%.

During the annotation process, the volunteers are randomly presented the text-image pairs. In this work, we argue that human desire is tightly intertwined with sentiment and emotion (Portner and Rubinstein, 2020), and therefore consider three inter-dependent annotation setups for desire, sentiment and emotion tasks. To emphasize such inter-dependency, the volunteers are asked to write their inference sequences, e.g., which task helps the other two tasks the most. For example, the inference sequence in Fig. 1 (a) is ($desire \to sentiment \to emotion$). We define the gold standard of a text-image pair in terms of the label that receives the majority votes. The annotation interface is shown in Fig. 2.

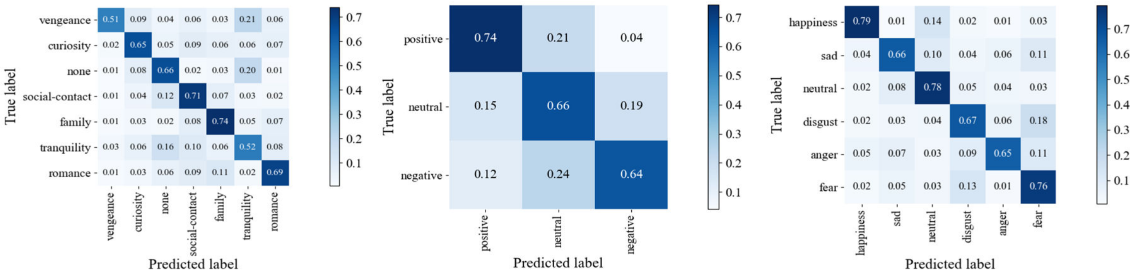
3.4 Quality Control

Since desire, sentiment and emotion annotation is a very subjective task, disputes and conflicts always exist and are difficult to erase. In order to guarantee the annotation quality, we develop a two-step validation paradigm. First, we calculate the average agreement among five annotators via the percent agreement calculation method (Hunt, 1986). The average agreements for desire, sentiment and emotion tasks are 71.4%, 83.6% and 72.1%. Next, to confirm this inter-rater agreement, the kappa score (Fleiss and Cohen, 1973) is introduced. The agreement scores of the annotation for desire, sentiment and emotion are $\kappa = 0.53$, $\kappa = 0.67$, $\kappa = 0.56$ respectively, which shows that five participators have reached moderate agreement on both desire and emotion annotations and substantial agreement on the sentiment annotation.

Moreover, the confusion matrices in Fig. 3 indicates the annotations difference between different labels for three tasks. From Fig. 3 (a), we can see that the differences between vengeance, none and tranquility are maximal (i.e., 0.21, 0.20), while the differences between vengeance and other categories are minimal. From Fig. 3 (b), we notice that one could easily distinguish positive from negative sentiment, but it is difficult to distinguish neutral from positive and negative sentiments. Fig. 3 (c) supports the above argument that the difference between neutral and happiness and the difference between neutral and sad are great.

4 Dataset Analysis

Desire Analysis. We present the distribution of desire labels in MSED, as shown in Fig. 4. From Fig. 4 (a), we observe that desire and non-desire samples account for 51% and 49% respectively. This shows that MSED is a well-proportioned and balanced dataset, which is suitable for machine

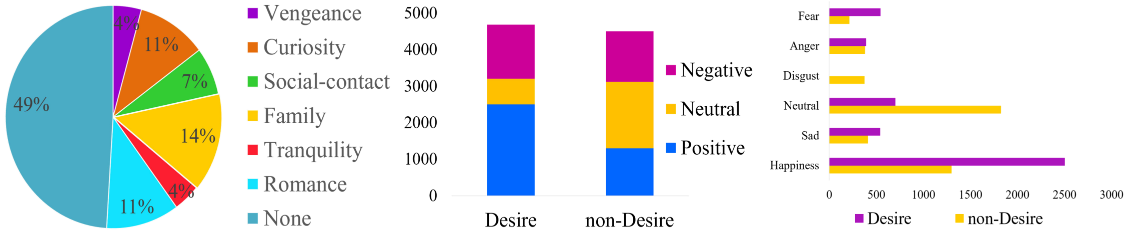


(a) Desire annotation.

(b) Sentiment annotation.

(c) Emotion annotation.

Figure 3: The confusion matrices show the annotations difference between different labels for three tasks.



(a) Desire category.

(b) Desire and non-desire sentiment.

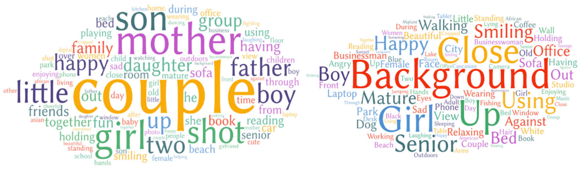
(c) Desire and non-desire emotion.

Figure 4: Dataset distribution.

or deep learning based analysis. Specially, the proportions of curiosity, family and romance are 11%, 14% and 11%. which are much larger than the proportions of vengeance and tranquility (i.e., 4%, 4%). This is also in line with our actual life where fewer people are ready to share their dark sides and flurried attitudes on social media platforms. More people are likely to publish tweets about family life, romantic love, etc.

Sentiment Analysis. Fig. 4 (b) shows how sentiment is entangled with desire and non-desire. We can see that positive sentiment accounts for the largest proportion of 53% in desire samples while negative sentiment is not far behind, i.e., 33%. Neutral polarity has the smallest proportion of 14%. The proportion of non-neutral sentiment towers over that of neutral polarity. In non-desire data, the proportion of neutral polarity (i.e., 42%) is more than the proportion of positive and negative sentiments (i.e., 28% and 30%). But the proportions of neutral and non-neutral sentiments turn out very close, which indicates that there is a poor correlation between non-desire and the different sentiment classes. These results have verified our previous arguments: (1) human desire is often accompanied by a range of sentiment responses; and (2) desire stealthily dominates emotion.

Emotion Analysis. We also present that there are some differences in the distribution of emotion between the desire data and non-desire data in Fig. 4 (c). Fear, anger, sad and happy emotions are more likely to occur in the desire samples while neutral and disgust emotions occur more frequently in the non-desire samples. This implicates that people often automatically exude their emotions while expressing the desires. There is close relationship between desire and emotion, which agrees well with the above conclusion.



(a) Desire samples.

(b) Non-desire samples.

Figure 5: Word cloud visualization.

Key Word Analysis. We generate two word clouds to visually compare the usage of high-frequency words in desire and non-desire samples, as shown in Fig. 5. We notice that the most common words in the desire samples are couple, mother, father, shot, son, little, etc. Such words are often used in the romance, family, vengeance related expressions. Fig 5 (b) shows the high frequency words in the non-desire samples, which are background, up, close, girl, senior, using, etc. Most of these words are verbs or nouns and are used as the description of a object or action, which do not

Table 4: Dataset statistics.

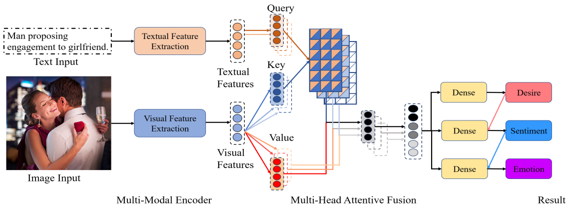

Figure 6: Multi-modal desire, sentiment and emotion analysis model.

often express human desires. This shows that the MSED dataset is accurately annotated and split.

5 Experiments and Evaluation

5.1 Dataset Split

In order to support model training and evaluation, we first shuffle the order of all multi-modal samples, and thus divide the MSED dataset into train, validation and test subsets according to the proportion of 70%, 10%, 20%. Table 4 shows the detailed statistics for train, validation and test subsets.

5.2 Experiment Settings

Evaluation metrics. We adopt *precision* (P), *recall* (R) and *macro-F1* ($\mathrm{M_a}$-F1) as evaluation metrics in our experiments. We also introduce *weighted accuracy* metric for the ablation test, human evaluation study and inter-task correlation study.

Model architecture. To evaluate the created MSED dataset, we propose three tasks, i.e., desire detection, sentiment analysis and emotion recognition, and provide a wide range of strong baselines by using different combinations of features. Fig. 6 presents the proposed model architecture.

We feed the text and image into two encoders to obtain their features respectively. For text, three typical encoders are used, i.e., deep CNN (DCNN), bidirectional LSTM (BiLSTM) (Zhang et al., 2020a), and the pre-trained language model, BERT (Devlin et al., 2018). For image, two widely used visual encoders, i.e., AlexNet (Alom et al., 2018) and ResNet (Szegedy et al., 2017) are selected. After that, we choose five multi-modal fusion strategies, i.e., multi-head attentive fusion, concatenation, adding, element-wise multiply and maximum, to learn the multi-modal representation. This representation is then forwarded through three dense layers and softmax functions respectively for desire, sentiment and emotion detection. In addition, as a state-of-the-art multi-modal pre-trained language model, Multimodal Transformer (Gabeur et al., 2020) is also used as the baseline. The details of model building and training is provided in Appendix.

5.3 Results and Discussion

We present the experimental results in Table 5. For text classification, DCNN performs very poorly for all three tasks, and gets the worst macro-F1 of 29.55%, 51.19% and 41.60%. Through modeling of bi-directional contexts, BiLSTM outperforms DCNN significantly. BERT outperforms DCNN and BiLSTM by a large margin in terms of macro-F1. These results are thanks to strong representational ability of BERT. For image classification, ResNet performs very well against AlexNet, since it solves the problem of gradient disappearance and enriches the input signals by introducing the residual connection. For multi-modal setup, we compare six combinations and observe that BERT+ResNet achieves the best macro-F1 scores of 82.28%, 85.81% and 82.42%. It overcomes both BERT (1.7%, 1.7%, 1.6% ↑) and ResNet (62.0%, 20.8%, 44.5% ↑), which shows the importance of using multi-modal clues.

With the aim to explore the impact of different multi-modal fusion approaches on the classification performance, we also compare four fusion approaches in term of *weighted accuracy* in Table 6. We observe that feature concatenation achieves the best performance for sentiment analysis and emotion recognition while feature adding performs the best for desire detection. In contrast, another two fusion approaches may lose a drawerful of primordial features when performing multiply operation or selecting the maximum eigenvalues. In summary, feature concatenation and adding may be the best approaches for our three tasks.

Model	Text	Image	Desire Detection			Sentiment Analysis			Emotion Recognition

5.4 Human Evaluation Results

Next, we create a new test set including 50 multi-modal documents, and recruit three undergraduate volunteers to evaluate the desire, sentiment and emotion labels. We run the inter-annotator agreement study on three volunteers' scores and the average kappa scores are 0.80, 0.82 and 0.78 for our three tasks. We also choose the pre-trained BERT+ResNet (the state-of-art system) to make desire, sentiment and emotion predictions. Table 7 presents the comparative results.

We can see that although BERT+ResNet have attained the best macro-F1 scores before, they still perform worse than human evaluation. One possible reason is that multi-modal representation and fusion may miss some essential contents. This proves that such strong baselines can not guarantee a satisfactory result compared to human judgment. Desire understanding is thus an emerging, yet challenging task, where novel multi-modal desire understanding models are needed. The proposed MSED dataset will provide an available data bed for model evaluation.

5.5 Discussion on Inter-Task Correlation

In order to verify the correlations across multiple tasks, e.g., which task offers the greatest help to other tasks, we improve BERT+ResNet by incorporating the inference sequence knowledge. We choose to merge the former task knowledge (the output of the dense layer) with the features of the latter task to construct a new input for the latter task. This action will naturally leverage the knowledge from other tasks. We have checked all the possible task combinations, e.g., $(des \Rightarrow sen \Rightarrow emo)$, $(sen \Rightarrow des \Rightarrow emo)$, etc. We show the obtained results in Table 8. We see that BERT+ResNet performs the best for the task of desire detection under the task sequence of $(sen \Rightarrow emo \Rightarrow des)$. This shows that sentiment and emotion knowledge indeed helps improve desire detection. By comparing the performance of three tasks, we notice that sentiment and emotion tasks gain greater improvement over desire detection under the task sequences of $(des \Rightarrow sen \Rightarrow emo)$ and $(sen \Rightarrow des \Rightarrow emo)$. These results support our argument that desire, sentiment and emotion are not only inter-entangled, sentiment and emotion are but also actuated by human desire. In addition, the importance of multi-task clues is also investigated.

5.6 Ablation Study

From Table 5, we perform an ablation study by analyzing the effectiveness of different components of BERT+ResNet. By comparing the classification performance of BERT and ResNet, we see that using textual features is more effective than using visual features, as we expected. The main reasons are: (1) BERT contributes the most to overall framework, as it effectively captures the inter-dependencies between words and extracts refined features; (2) Text cue plays a more important role than visual cue for desire understanding, since visual desire analysis involves a higher level of abstraction. However, ResNet still outperforms DCNN and BiLSTM by a large margin (7%, 5% ↑), which shows the effectiveness of pre-trained visual model.

5.7 Error Analysis

Through presenting the confusion matrices of BERT+ResNet in Fig. 7, we perform an error analysis. We notice that misclassification for BERT+ResNet often happens in four categories of samples, i.e., non-desire, curiosity, social-contact and tranquility. About 10.6% non-desire samples are mis-classified as various desires. 29.5% curiosity samples are misdiagnosed. For tranquility detection, BERT+ResNet performs very poorly, which annotates almost half (36.8%) tranquility samples as non-desire labels. 15.2% social-contact desire is misdiagnosed as non-desire. This implicates that BERT+ResNet struggles in differentiating curiosity, social-contact and tranquility from non-desire. Further theoretical and empirical research is needed for better studying human desires. We also show a few misclassification cases for desire detection, as shown in Fig. 8.

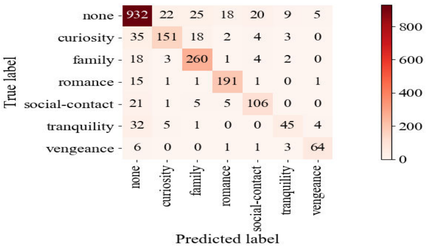

Figure 7: The Confusion matrix.

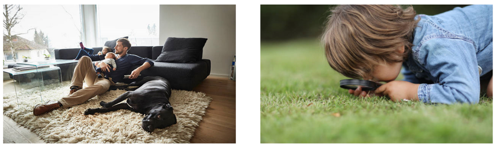
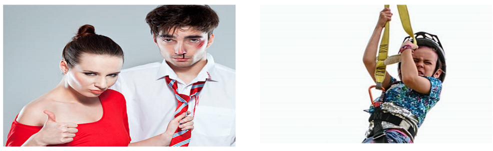


(a) Father with dog and two children relaxing in living room.

(b) Little boy observing insects with a magnifying glass.



(c) Young dominating woman pulling an injured man by tie and giving her thumb up.

(d) Girl closes her eyes tightly as she goes on a zip line.

Figure 8: Wrongly classified multi-modal samples.

6 Conclusions and Future work

Human desire understanding is a relatively unexplored task in NLP. To fill this gap, we expand desire research from psychology to multi-modal language analysis, and thus propose the first multi-modal multi-task dataset for desire, sentiment and emotion detection, MSED. Each sample is annotated with six basic desires, three sentiments and six emotions. In addition, qualitative and quantitative studies are performed for analyzing the dataset. We also present a range of baselines to evaluate the potential of MSED. The comparative and human evaluation results demonstrate the need of new desire analysis models and the potential of MSED to facilitate the development of such models.

Our work has also a few limitations. The images available in platforms like Flickr and Getty may not express spontaneous human desire, as many of them are purposefully designed by professional photographers. The current dataset only collects static images and texts, the conversational samples might be considered. Moreover, a larger scale multi-modal dataset with more desire categories is left to our future work. The technique of human desire analysis based on online data also has the potential to be misused, e.g. by integrating them with facial recognition techniques to make interventions or decisions for humans.

In summary, we hope that the creation of MSED will provide a new perspective in NLP for research on human desire analysis. The dataset will be publicly available for research. Given the close relationship between desire, sentiment and emotion, a refined multi-modal multi-task learning framework is left to our future work.

Appendix

A Model Building

We apply a bi-modal encoder architecture when building models. The bi-modal encoder consists of text (i.e., DCNN, BiLSTM and BERT) and image encoders (i.e., AlesNet and ResNet). The outputs from two encoders are concatenated to form the multi-modal representation, and thus are forwarded to a dense layer to make prediction of three tasks.

A.1 Text Encoder

We use GloVe 6B to initialize the 100 dimensional word embeddings as inputs for DCNN and BiLSTM. As for BERT, the dimension is 768.

DCNN. The first convolutional layer in the DCNN consists of 3 filters of size 2 × 2. The second convolutional layer consists of 3 filters of size 3 × 3. The third convolutional layer consists of 3 filters of size 4 × 4. This network is followed by the fully connected layer (size of 128) and the softmax layer. Finally, the activation values of the fully connected layer are used as the output of the encoder.

BiLSTM. It consists of two LSTM layers that read the input sequence forwardly and backwardly to generate a series of bidirectional hidden states. The i^{th} hidden representation is obtained by merging the bidirectional hidden states, e.g., $\boldsymbol{h}_i = \overrightarrow{\boldsymbol{h}_i} \parallel \overleftarrow{\boldsymbol{h}_i}$, where $i \in [1, 2, ..., n]$. In BiLSTM, the dimensions of forward and backward hidden states are set to 50 respectively. Finally, the final hidden sate $\boldsymbol{h}_n$ is used as the sequence representation.

BERT. We fine-tuned the BERT-base including 12 layers and 110M parameters as the text encoder. Each sequence will be padded or truncated to the size of 50 before it is input. The obtained representation of the first token in the sequence (i.e., the [CLS] token) is used as the output of the encoder, where the dimension is 768.

A.2 Image Encoder

Each image is pre-processed by using mean and standard deviation calculated by ImageNet.

AlexNet. The size of the input images is 408 × 612×3. The first convolutional layer has 96 kernels of size 12 × 40 × 3 with a stride of 4 pixels. The second convolutional layer has 256 kernels of size 5 × 5 × 96 with a stride of 2 pixels. The third convolutional layer has 384 kernels of size 3 × 3 × 256. The forth convolutional layer has 384 kernels of size 3×3×384, and the fifth convolutional layer has 256 kernels of size 3 × 3 × 384.

ResNet. The ResNet18 pre-trained model is used in our experiments. All the images are resized to 612×612×3 before they are feed into the model.

B Model Training

We use Pytorch (Paszke et al., 2019) to build all models. To avoid overfitting, we choose to perform early stopping during training. During training, the optimal learning rate is set to 1×10^{-5} and the epoch is 40 if the encoder includes pre-trained model, otherwise they are set to 1×10^{-3} and 100 respectively. The dropout rate in the model is 0.5. In our models, cross entropy with $L2$ regularization is used as the loss function, as shown in Eq. 1:

$$\zeta_s = -\frac{1}{L}\sum_{\xi} Y_\xi log\hat{Y}_\xi + \tau_r \left\|\phi\right\|^2 \qquad (1)$$

where $\zeta_s \in \{\zeta_{sen}, \zeta_{emo}, \zeta_{des}\}$, Y_ξ denotes the ground truth of the ξ^{th} sample, $\hat{Y}_\xi$ is the predicted distribution. ξ is the index of sample, and L is the total number of samples. τ_r is the coefficient for $L2$ regularization. As for optimizer, we choose Adam to optimize the loss function. We use the back propagation method to compute the gradients and update all the parameters. It takes about 50 minutes for the state-of-the-art system (i.e., BERT+ResNet) to train its best performance over MSED via 1×RTX A6000 GPU.

Relation-Specific Attentions over Entity Mentions for Enhanced Document-Level Relation Extraction

Jiaxin Yu† and **Deqing Yang**† [*] and **Shuyu Tian**‡

Abstract

Compared with traditional sentence-level relation extraction, document-level relation extraction is a more challenging task where an entity in a document may be mentioned multiple times and associated with multiple relations. However, most methods of document-level relation extraction do not distinguish between mention-level features and entity-level features, and just apply simple pooling operation for aggregating mention-level features into entity-level features. As a result, the distinct semantics between the different mentions of an entity are overlooked. To address this problem, we propose *RSMAN* in this paper which performs selective attentions over different entity mentions with respect to candidate relations. In this manner, the flexible and relation-specific representations of entities are obtained which indeed benefit relation classification. Our extensive experiments upon two benchmark datasets show that our RSMAN can bring significant improvements for some backbone models to achieve state-of-the-art performance, especially when an entity have multiple mentions in the document.[1]

1 Introduction

Relation extraction (RE) is one important task of information extraction, aiming to detect the relations among entities in plain texts. Recently, many scholars have paid more attention to document-level RE (Sahu et al., 2019; Yao et al., 2019) which aims to identify the relations of all entity pairs in a document, since it is more in demand than sentence-level RE in various real scenarios. In general, one document contains multiple entities and an entity may have multiple mentions across different sentences. Furthermore, one entity may be involved by multiple valid relations and different relations are expressed by different mentions of the same entity. As a result, document-level RE is more challenging than sentence-level RE.

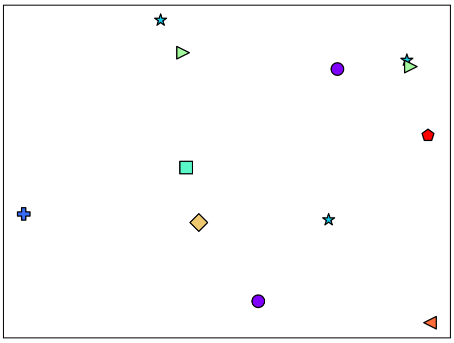

Figure 1: A *t*-SNE visualization example from DocRED. Points of the same color and marker are different mentions' embeddings of an entity, which are encoded by BERT (Devlin et al., 2019).

A key step of existing document-level RE methods is to aggregate the information of different mentions of an entity (mention-level features) to obtain the entity's representation (entity-level feature) at first, since relation classification is generally achieved on entity level. To this end, previous RE models simply apply average pooling (Ye et al., 2020; Xu et al., 2021), max pooling (Li et al., 2021), or logsumexp pooling (Zhou et al., 2021; Zhang et al., 2021). Finally, a fixed representation is obtained for the given entity, which is then fed into the classifier for relation classification.

However, different mentions of an entity in a document may hold distinct semantics. A simple pooling operation of generating a fixed entity representation may confound the semantics of different mentions, and thus degrades the performance of relation classification when the entity is involved by multiple valid relations. We call such situation as *multi-mention* problem in this paper. In Fig. 1, we display the *t*-SNE (Van der Maaten and Hinton, 2008) visualization of a toy example's mention embedding space to validate this problem. As the

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1523 - 1529
July 10-15, 2022

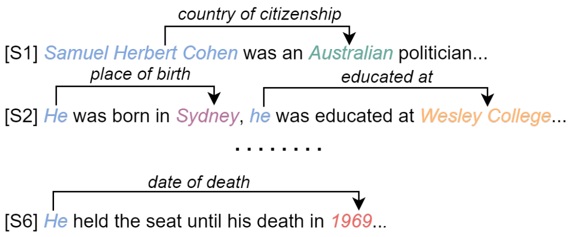

Figure 2: A toy example of multi-mention problem from the DocRED dataset. Based on coreference resolution, mentions belonging to the same entity are in the same color, and the relations are marked above the arrows.

figure shows, different mentions' embeddings of an entity (marked by the same color) in a document are scattered over the whole embedding space, indicating that different mentions of an entity are not semantically adjacent. We further illustrate it by the toy example in Fig. 2, the first mention *Samuel Herbert Cohen* of the person entity is more important for the classifier to identify the relation *country of citizenship* between him and *Australian*. But for extracting the relation *place of birth*, the second mention *He* should be considered more. It implies that different mentions should play different roles when extracting the different relations involving the same entity. In other words, different mentions function differently in different relation recognitions.

Inspired by this intuition, we propose a novel **R**elation-**S**pecific **M**ention **A**ttention **N**etwork (**RSMAN**) to improve the model performance of document-level RE. In RSMAN, each relation's essential semantics is first encoded into a prototype representation. Then, the relevance weight (attention) between the prototype of a specific candidate relation and each mention's representation of the given entity is calculated. Based on these attentions, we get an attentive (weighted) sum of all mentions' representations as the entity's synthetic representation. In this manner, RSMAN enables the model to attend to the information of multiple mentions from different representation space when representing an entity, indicating that the entity's representation is flexible and relation-specific with respect to different candidate relations.

Our contributions in this paper can be summarized as follows:

1. To the best of our knowledge, this is the first to consider different mentions' significance with respect to candidate relations on representing an entity to achieve document-level RE.

2. We propose a novel RSMAN which can be used as a plug-in of a backbone RE model, to learn a relation-specific representation for a given entity which enhances the model's performance further.

3. Our empirical results show that RSMAN can significantly promote some backbone models to achieve state-of-the-art (SOTA) RE performance, especially when an entity have multiple mentions in the document.

The rest of this paper is organized as follows. In Section 2, we briefly introduce some works related to our work. Then we introduce the proposed method in Section 3 and the experiment results in Section 4. At last, we conclude our work in Section 5.

2 Related Work

Prior efforts on document-level RE mainly focused on representation learning and reasoning mechanism. Yao et al. (2019) employed four different sentence-level representation models to achieve document-level RE, including CNN, LSTM, BiLSTM, and Context-Aware. For more powerful representations, later work introduced pre-trained language models into their neural architectures (Ye et al., 2020; Zhou et al., 2021; Xu et al., 2021). In particular, Ye et al. (2020) added a novel mention reference prediction task during pre-training and presented CorefBERT to capture the coreferential relations in contexts. Zhou et al. (2021) proposed ATLOP to learn an adjustable threshold and thus enhanced the entity pair's representation with localized context pooling. Xu et al. (2021) defined various mention dependencies in a document and proposed SSAN to model entity structure for document-level RE. In addition, other work built various kinds of document graphs to model reasoning mechanism explicitly (Nan et al., 2020; Zeng et al., 2020; Wang et al., 2020). For example, Nan et al. (2020) induced the latent document-level graph and performed multi-hop reasoning on the induced latent structure. Wang et al. (2020) constructed a global heterogeneous graph and used a stacked R-GCN (Schlichtkrull et al., 2018) to encode the document information. Zeng et al. (2020) proposed GAIN to leverage both mention-level graph and entity-level graph to infer relations between entities. However they all ignore the multi-mention problem described in Sec. 1.

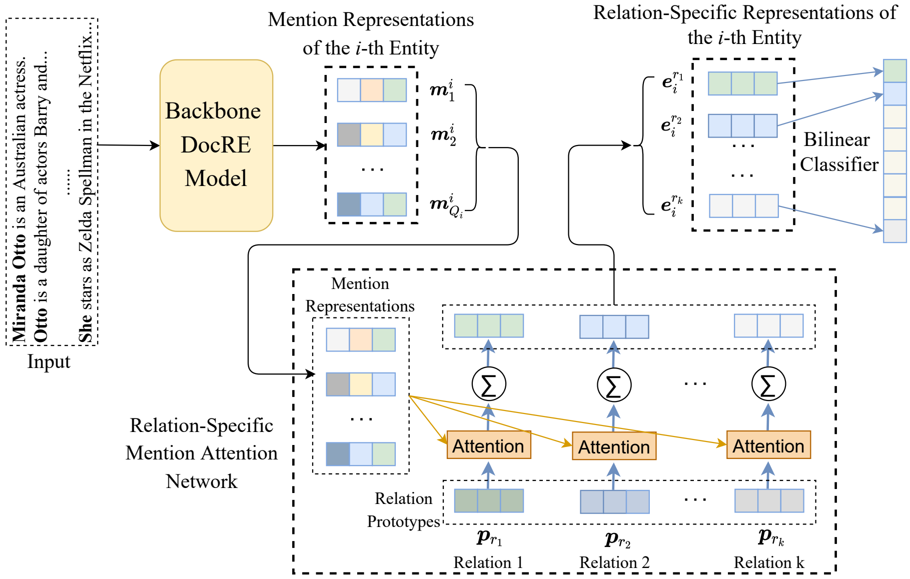

Figure 3: The overall work flow of RSMAN. The entity representations are obtained as the relation-specific weighted sum of mention representations.

3 Methodology

At first, we formalize the task of document-level RE addressed in this paper as follows.

Suppose a document $\mathcal{D}$ mentions P entities, denoted as $\mathcal{E} = \{e_i\}_{i=1}^{P}$, and the i-th entity e_i has Q_i mentions in $\mathcal{D}$, denoted as $\{m_j^i\}_{j=1}^{Q_i}$, the task of document-level RE is to extract a set of relational triples $\{(e_s, r, e_o)|e_s, e_o \in \mathcal{E}, r \in \mathcal{R}\}$ where $\mathcal{R}$ is a pre-defined relation set.

3.1 Backbone RE Model

Suppose for each mention of e_i, its representation $\boldsymbol{m}_j^i$ is obtained by a model-specific method. Most of existing backbone models apply a certain pooling operation for all $\boldsymbol{m}_j^i$s to obtain e_i's representation $\boldsymbol{e}_i$, such as the following average pooling,

$$\boldsymbol{e}_i = \frac{1}{Q_i}\sum_{j=1}^{Q_i}\boldsymbol{m}_j^i. \tag{1}$$

As we claimed in Section 1, $\boldsymbol{e}_i$ is a fixed representation which ignores that different mentions of e_i play distinct roles when identifying the different relations involving e_i.

Finally, given the subject entity's $\boldsymbol{e}_s$ and the object entity's representation $\boldsymbol{e}_o$, a bilinear classifier is often used to calculate the probability of relation r involving these two entities as follows

$$P(r|e_s, e_o) = \sigma(\boldsymbol{e}_s^\top \boldsymbol{W}_r \boldsymbol{e}_o + b_r) \tag{2}$$

where $\boldsymbol{W}_r \in \mathbb{R}^{d\times d}$ and $b_r \in \mathbb{R}$ are trainable model parameters specific to r, and σ is Sigmoid activation.

3.2 Attentive Operations in RSMAN

Our proposed RSMAN incorporates attentive mention-level features to generate flexible entity representations with respect to different candidate relations, and thus enhances the backbone model's performance. RSMAN's framework is shown in Fig. 3, which acts as a plug-in of the backbone model.

For each candidate relation r, its prototype representation $\boldsymbol{p}_r$ is first obtained through random initialization and is trainable during the training process. Then, we leverage $\boldsymbol{p}_r$ to calculate the semantic relevance between r and each mention m_j^i as follows,

$$s_{ij}^r = g(\boldsymbol{p}_r, \boldsymbol{m}_j^i) \tag{3}$$

where g is a certain function to compute the similarity between two embeddings, which can be a simple dot-product or multi-layer perceptron (MLP) fed with the concatenation of two embeddings. Then, we feed all s_{ij}^rs of e_i into a softmax function to get final attention weight

$$\alpha_{ij}^r = \frac{\exp(s_{ij}^r)}{\sum_{k=1}^{Q_i}\exp(s_{ik}^r)}. \tag{4}$$

Since there is a necessity to consider all the mention information of the entity, we use a weighted sum of all mention representations to obtain the relation-specific entity representation instead of using only one specific mention representation. We get e_i's representation specific to r as

$$\boldsymbol{e}_i^r = \sum_{j=1}^{Q_i} \alpha_{ij}^r \boldsymbol{m}_j^i. \quad (5)$$

Different to the fixed representation computed by Eq. 1, such $\boldsymbol{e}_i^r$ is a flexible embedding adaptive to different candidate relation r.

At last, we use this relation-specific entity representation to achieve relation classification by modifying Eq. 2 as

$$P(r|e_s, e_o) = \sigma(\boldsymbol{e}_s^{r\top} \boldsymbol{W}_r \boldsymbol{e}_o^r + b_r). \quad (6)$$

4 Experiments

In this section, we introduce our experiments to justify our RSMAN, and provide insight into the experiment results.

4.1 Datasets and Evaluation Metrics

We conducted our experiments on two representative document-level RE datasets: DocRED (Yao et al., 2019) and DWIE (Zaporojets et al., 2021), which are introduced in detail in Appendix A. We adopted F1 and Ign F1 as our evaluation metrics as (Yao et al., 2019), where Ign F1 is computed by excluding the common relation facts shared by the training, development (dev.) and test sets.

4.2 Experimental Settings

We use dot-product as the similarity scoring function for its computational efficiency, and before it we add a fully connected layer to project the mention representations into the same embedding space with the prototype representations. All the additional parameters we introduce for RSMAN including the prototype representations is much fewer than the parameters of either the original bilinear classifier or the backbone model itself.

We took some stat-of-the-art models mentioned in Sec. 2 as the baselines, i.e., **CNN** (Zeng et al., 2014), **LSTM/BiLSTM** (Cai et al., 2016), **Context-Aware** (Sorokin and Gurevych, 2017), **CorefBERT** (Ye et al., 2020), **GAIN** (Zeng et al., 2020), **SSAN** (Xu et al., 2021) and **ATLOP** (Zhou et al., 2021). We chose CorefBERT and SSAN as the backbone models in our framework due to their good performance and strong pluggability for our RSMAN. We did not consider GAIN and ATLOP as the backbone because they both leverage extra information besides entity representations. More setting details are shown in Appendix B.

Model	**Dev** **Ign F1 / F1**	**Test** **Ign F1 / F1**
CNN*	37.65 / 47.73	34.65 / 46.14
LSTM*	40.86 / 51.77	40.81 / 52.60
BiLSTM*	40.46 / 51.92	42.03 / 54.47
Context-Aware*	42.06 / 53.05	45.37 / 56.58
CorefBERT	57.18 / 61.42	61.71 / 66.59
GAIN*	58.63 / 62.55	62.37 / 67.57
SSAN	58.62 / 64.49	62.58 / 69.39
ATLOP*	59.03 / 64.82	62.09 / 69.94
CorefBERT+RSMAN	58.29 / 62.59	62.01 / 67.52
SSAN+RSMAN	**60.02 / 65.88**	**63.42 / 70.95**

Table 1: Performance (%) comparisons on the dev. and test set of DWIE. The results with * are reported in (Ru et al., 2021).

Model	**Dev** **Ign F1 / F1**	**Test** **Ign F1 / F1**
CorefBERT	55.32 / 57.51	54.54 / 56.96
CorefBERT+RSMAN	**56.26 / 58.24**	**55.30 / 57.53**
SSAN	56.68 / 58.95	56.06 / 58.41
SSAN+RSMAN	**57.22 / 59.25**	**57.02 / 59.29**

Table 2: Comparison on DocRED. The results of baselines are from their related papers. All test results are obtained by submitting to official Codalab[2].

4.3 Results and Analyses

All the following results of our method were reported as the average scores of three runs. From the results on DWIE shown in Table 1 we find that plugged with RSMAN, both CorefBERT and SSAN have significant improvements. Specifically, our RSMAN relatively improves CorefBERT's F1 by 1.9% (dev. set) and 1.4% (test set), and relatively improves SSAN's F1 by 1.84% dev F1 (dev. set) and 2.25% (test set), respectively. The consistent improvements verify the effectiveness of leveraging attentive mention-level features to learn relation-specific entity representations. What's more, the positive effects on different backbone models show good generalization performance of our RSMAN. Overall, SSAN+RSMAN achieves 63.42% Ign F1 and 70.95% F1 on the test set, outperforming all the baselines apparently.

For simplicity, we only display the results on DocRED of CorefBERT and SSAN plugged with

---

[2] `https://competitions.codalab.org/competitions/20717`

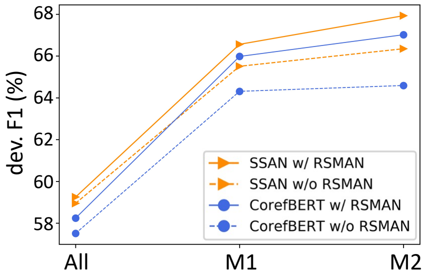

Figure 4: F1 variations on three subsets reconstructed from the development set of DocRED.

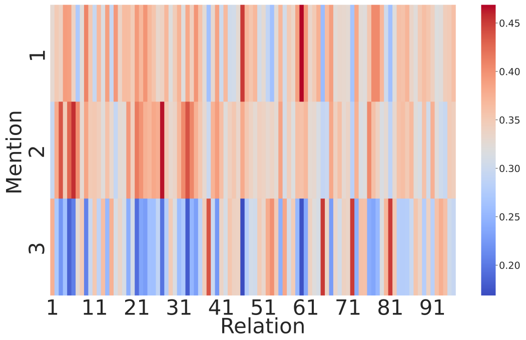

Figure 5: Visualization on relation attentions to different mentions of a given entity.

RSMAN in Table 2. It shows that RSMAN also brings relative improvements of 1.39% Ign F1 and 1.00% F1 on the test set for CorefBERT, along with relative improvements of 1.71% Ign F1 and 1.51% F1 for SSAN. It is worth noting that the performance improvements on DocRED are relatively less significant than that on DWIE. Through our statistics, we found that the average number of mentions per entity in DocRED is only 1.34, while it is 1.98 in DWIE. Besides, only 18.49% of entities in DocRED have multiple mentions, much less than 33.59% in DWIE. It implies that our RSMAN is more effective on the entities with multiple mentions, which are more common and challenging in many real scenarios of document-level RE.

4.4 Effect Analysis for Mention Number

To confirm our conjecture mentioned before, we investigated the effect of mention number through further experiments. We first reconstructed the relation instances in DocRED's dev. set and obtained three different subsets: the first one contains all instances (All), another one contains either subject or object argument having more than one mention (M1), and the rest one contains either subject or object argument having more than two mentions (M2). We don't consider M3 or higher because they have very few instances limited by the dataset. Then, we evaluated CorefBERT and SSAN with or without RSMAN upon the three subsets.

From Fig. 4, we find that the F1s of all compared methods increase from All to M2. It indicates that multiple mentions can provide more information for the models to capture the entity semantics, resulting in more precise RE results. Furthermore, the performance gains of plugging RSMAN into the two backbone models also increase as the mention number per entity increases. It shows that our RSMAN can bring more significant performance boosts for the backbone model when the entities of the relation instances have more mentions in a document. These results justify that RSMAN has more potential for extracting relations based on the entities with more mentions.

4.5 Case Study

To explore how RSMAN attends to different mentions' information of an entity, we collected all relations' normalized attentions for an entity's mentions in RSMAN. Fig. 5 is the heatmap of attentions for a specific entity, from which we observe that the distribution of relation attentions varies greatly among different mentions. Besides, according to the high attention of a given relation, we can capture which mention of the entity well expresses this relation's semantics. This map also confirms the implication of Fig. 1 that different mentions of an entity contain distinct semantics. Therefore, the attentive aggregation of all mention-level features in RSMAN is more appropriate for enhanced RE than the common pooling operations.

5 Conclusion

In this paper, we focus on the multi-mention problem in document-level RE and propose RSMAN to address it. Our experiment results demonstrate RSMAN's effectiveness especially on the scenario of multi-mention situation. In the future, we plan to adapt RSMAN to more document-level RE models.

A Datasets

DocRED is a large-scale human-annotated dataset for document-level RE. DWIE is a dataset for document-level multi-task information extraction which combines four main sub-tasks and in our work we only used the dataset for document-level relation extraction. We preprocessed DWIE dataset and adopted the same dataset partition as (Ru et al., 2021). More statistical information is detailed in Table 3.

Statistics	DWIE	DocRED
# Train	602	3053
# Dev	98	1000
# Test	99	1000
# Relations	65	96
# Relation facts	19493	56354
Avg.# mentions per Ent.	1.98	1.34

Table 3: Statistics of the two datasets.

Hyper-parameter	DWIE	DocRED
Batch size	4	8
Learning rate	3e-5	5e-5
Epoch	40	60
Gradient clipping	1	1
Warmup ratio	0.1	0.1

Table 4: Hyper-parameter settings for our experiments on the two datasets.

B Implementation Details

In this appendix, we introduce more details of our experimental settings. We implemented our RS-MAN with PyTorch and trained it with an NVIDIA GeForce RTX 3090 GPU. In addition, we adopted AdamW (Loshchilov and Hutter, 2018) as our optimizer and used learning rate linear schedule with warming up based on Huggingface's Transformers (Wolf et al., 2019). The hyper-parameter settings of our experiments on the two datasets are listed in Table 4, which were decided through our tuning studies.

Twitter-COMMs: Detecting Climate, COVID, and Military Multimodal Misinformation

Giscard Biamby * **Grace Luo** * **Trevor Darrell** **Anna Rohrbach**

University of California, Berkeley
{gbiamby, graceluo, trevordarrell, anna.rohrbach}@berkeley.edu

Abstract

Detecting out-of-context media, such as "miscaptioned" images on Twitter, is a relevant problem, especially in domains of high public significance. In this work we aim to develop defenses against such misinformation for the topics of Climate Change, COVID-19, and Military Vehicles. We first present a large-scale *multimodal* dataset with over 884k tweets relevant to these topics. Next, we propose a detection method, based on the state-of-the-art CLIP model, that leverages automatically generated hard image-text mismatches. While this approach works well on our automatically constructed out-of-context tweets, we aim to validate its usefulness on data representative of the real world. Thus, we test it on a set of human-generated fakes created by mimicking in-the-wild misinformation. We achieve an 11% detection improvement in a high precision regime over a strong baseline. Finally, we share insights about our best model design and analyze the challenges of this emerging threat.

1 Introduction

Out-of-context images are a popular form of misinformation where an image is miscaptioned to support a false claim (Fazio, 2020). Such image repurposing is extremely cheap yet can be as damaging as more sophisticated fake media. In this work we focus on domains important for society and national security, where implications of inexpensive yet effective misinformation can be immense.

Specifically, we analyze multimodal Twitter posts that are of significant public interest, related to topics of COVID-19, Climate Change and Military Vehicles. Our goal is to learn to categorize such image-text posts as pristine or falsified (out-of-context) by means of detecting semantic inconsistencies between images and text. To that end, we first collect a large-scale dataset of *multimodal* tweets, **Twitter-COMMs**, with over 884k tweets. In our approach, we fuse input image and text embeddings generated by CLIP (Radford et al., 2021) via an elementwise product, and train a classifier to distinguish real tweets from automatically constructed random and hard mismatches. To validate this approach and demonstrate the usefulness of the Twitter-COMMs dataset, we report results on human-generated test data, created to mimic real-world misinformation. We discuss the results and model ablations, and provide additional insights into the challenges of this task. Our dataset is publicly available at: https://github.com/GiscardBiamby/Twitter-COMMs.

2 Related Work

There exist a number of large-scale Twitter datasets concentrated on topics such as COVID-19 (Banda et al., 2021) or Climate Change (Littman and Wrubel, 2019). However, it remains difficult to collect labeled misinformation. Researchers have collected COVID-19 misconceptions on social media via manual annotation (Hossain et al., 2020) or by linking to fact checking articles (Patwa et al., 2021). Not only are these datasets small (a few thousand samples), but they focus on false claims rather than multimodal inconsistency. Here, we curate social media posts that are topical and multimodal, and we demonstrate an application to misinformation detection of human-generated fakes.

Recent work has developed approaches for multimodal fact checking, e.g., Jaiswal et al. (2017) and Müller-Budack et al. (2020), who query an external knowledge base. Similar to Luo et al. (2021) in the news domain, we use a large pretrained model that does not require an external reference set.

3 Twitter-COMMs Dataset

Here, we describe the data collection strategies behind **Twitter-COMMs**, which consists of mul-

July 10-15, 2022

Table 1: **Twitter-COMMs** breakdown. "Collected" denotes all unique samples collected via the Twitter API. "Pristine" and "Falsified" denote all samples in our automatically generated Training set. To ensure the balanced Training set, we "repeat" Pristine samples such that there is an equal number of Pristine and Falsified samples.

Topic / Samples	Collected	Pristine	Falsified	
			Random	Hard
Climate Change	212,665	298,809	84,432	214,377
COVID-19	569,982	736,539	162,410	574,129
Military Vehicles	101,684	139,213	35,376	103,837
Cross Topic	-	59,735	59,735	-
Total	884,331	2,468,592		

timodal tweets covering the topics of COVID-19, Climate Change, and Military Vehicles.

Data Collection: We collected data using Twitter API v2[1] in three stages for COVID-19 and Climate Change, and two stages for Military Vehicles, refining the filters at each stage to acquire more relevant tweets. COVID-19 and Climate Change stages progressed from simple high level keywords towards more specific ones in stage two and tweets authored by news organizations in the final stage. For Military Vehicles the first stage used high level search terms such as "military", "aircraft", "tank", which resulted in noisy data, so the second stage used a large number of highly specific terms related to vehicle models. Full details can be found in Appendix A.1. We employed the following global filters for all topics: (1) language=English, (2) has at least one image, and (3) not a retweet.

In total, we have collected $884,331$ tweets, each having at least one image (composed of 24% Climate Change, 64.5% COVID-19, and 11.5% Military Vehicles tweets), see Table 1. Tweets for Climate Change and Military Vehicles were collected starting from June 2016 and for COVID-19 starting from February 2020, all ending in September 2021.

Falsified Samples: In addition to the pristine samples, we automatically generate falsified samples where there is some inconsistency between image and text. We create random negatives (denoted as "Random") by selecting an image for a given caption at random. We also create hard negatives (denoted as "Hard") by retrieving the image of the sample with the greatest textual similarity for a given caption (following the "Semantics / CLIP Text-Text" split from Luo et al. (2021)). We mainly generate mismatches *within* each topic (COVID-19, Climate Change, Military Vehicles), except for a small set of random mismatches *across* topics (denoted as "Cross Topic"). Our dataset is balanced with respect to labels, where half of the samples are pristine and half are falsified. Table 1 presents summary statistics for the training samples. We detail our development set and other data used for evaluation in the next section.

Qualitative Analysis: We present random examples from our training set in Figure 1. Overall, we see that the collected Twitter samples tend to be "on topic" and the amount of noise is low. Hard negatives are often visually grounded, while random negatives contain image/text pairs that are only weakly related, since they pertain to the same topic. The Climate Change hard negative depicts an image of flooded homes to represent "droughts, fires and floods" while the random negative depicts an image of cars relevant to climate but inconsistent with "polar bears". The COVID-19 hard negative uses an image of a Nigerian spokesman to depict news pertaining to "ECOWAS[2]" while the random one uses a stock photo of lab testing to represent Covid. These entity-level, rather than topic-level, alignments more closely resemble real-world out-of-context images that often reference and misrepresent visually depicted entities. Note the diversity of images and text in our training set, where there exist both natural images and info-graphics, and language varies from organizational announcements and news headlines to personal opinions.

4 Experiments

Next, we discuss the data used for evaluation, present our approach and ablate various design choices, report results on our evaluation sets, and provide additional analysis of the task difficulty.

4.1 Evaluation Sets

We report results on three evaluation sets. (a) We validate our approach on samples synthetically generated using the same procedure as our training set (denoted Dev), where all topics and falsification methods are equally represented (i.e., the ratio of random vs. hard negatives is 50-50). We also evaluate on *human-curated* samples from the

hTwitter	Social Media	114	122	236

4.2 Approach and Design Choices

For our approach we fine-tune CLIP (Radford et al., 2021), a large pretrained multimodal model that maps images and text into a joint embedding space via contrastive learning. Our model generates CLIP embeddings using the RN50x16 backbone, multiplies the image and text embeddings, and passes the result to a classifier that scores the pair as pristine or falsified. We use a learning rate of 5e-08 for CLIP and 5e-05 for the classifier and

train for 16 epochs. For our baseline CLIP Zero Shot model, we generate CLIP embeddings of-the-shelf and compute a dot product, which is used to score the pair. For more details, see the Appendix.

We report metrics for varying thresholds over the predicted scores; in most tables we report balanced classification accuracy at equal error rate (Acc @ EER). We also report falsified class accuracy at two thresholds (pD @ 0.1 FAR and pD @ EER).

Multimodal Fusion: First, we compare different multimodal fusion techniques, see Table 3. We try three fusion methods: concatenating the CLIP image and text embeddings (Concat), concatenating the embeddings and their dot product (Concat + Dot), and multiplying the embeddings element-wise (Multiply). Inspired by how CLIP was trained to maximize the dot product of normalized image-text pairs, Concat + Dot and Multiply incentivize the classifier to stay faithful to the pre-initialized joint embedding space. These architecture choices yield on average a 7% performance improvement over simple concatenation. For future experiments we choose the Multiply method to minimize trainable parameters and maintain a simple approach.

Table 3: Balanced binary classification accuracy at EER by fusion method, Dev set.

	Climate Change		COVID-19		Military Vehicles	
	Random	Hard	Random	Hard	Random	Hard
Concat	0.8712	0.6810	0.8797	0.6882	0.9111	0.6775
Concat+Dot	0.9305	**0.8038**	0.9191	**0.7848**	**0.9485**	**0.7472**
Multiply	**0.9344**	0.7968	**0.9247**	0.7807	0.9440	0.7467

Percentage of Hard Negatives: Next, we analyze the importance of using hard negatives in our training data. Specifically, we measure the impact of different percentages of hard negative samples, where the rest are random negatives. Table 4 presents the results. More hard negatives in training generally improves the performance on hard negatives in our development set, but there is also a trade-off in performance on random negatives. Given that we care about samples that more closely mimic challenging real-world misinformation but also want to avoid degrading performance on easy samples, we opt for a ratio of 75% hard and 25% random negatives for future experiments.

Table 4: Balanced binary classification accuracy at EER by percentage of hard negatives, Dev set.

	Climate Change		COVID-19		Military Vehicles	
	Random	Hard	Random	Hard	Random	Hard
0%	0.9352	0.7714	0.9188	0.7600	0.9405	0.7236
50%	0.9344	0.7968	**0.9247**	0.7807	**0.9440**	0.7467
75%	**0.9356**	0.7979	0.9241	0.7809	0.9410	**0.7470**
100%	0.9311	**0.8004**	0.9227	**0.7834**	0.9425	0.7457

4.3 Results and Analysis

Results on hNews, hTwitter Sets: Our final model was directly fine-tuned on the entire training set of over 2M training samples, with a ratio of 75% hard and 25% random negatives. We report results in Table 5, comparing to CLIP Zero Shot. We improve by 11% in pD @ 0.1FAR, meaning that our method is able to detect more falsified samples with minimal false alarms. At equal error rate we improve by 5% in both detection and accuracy. We emphasize that the hTwitter data is unseen to us.

Next, we analyze the performance of our final model w.r.t. several characteristics on our Dev set.

OCR Coverage: Given that text present in images can often be used to corroborate captions, we break down model performance by the amount of text detected by an English OCR model[5]. In

	Ours	**0.8771**	**0.8771**	**0.8771**

Table 6 (top), we report results broken down by the % of the image covered by text (the area of the union of text detections divided by the image size). Each bucket roughly corresponds to natural images, natural images with scene text, graphics, and screenshots of text. The presence of any text yields more than a 6% improvement for pD @ 0.1FAR and performance peaks at 10-50% coverage.

Table 6: Balanced binary classification accuracy at varying thresholds on Dev set broken down by: % of image covered by text (top), various text-image relationships (middle) and within- vs. cross-cluster status of the hard falsifications (bottom). The latter results are obtained on the subset of hard falsified samples and their corresponding pristine samples.

	pD @ 0.1 FAR	pD @ EER	Acc @ EER

Within-cluster	0.6000	0.7539	0.7545

Text-Image Relationship: Within social media, there exist more complex interactions than the direct relationships seen in formats like image alt-text. As such, we trained a CLIP model on the dataset presented by (Vempala and Preoţiuc-Pietro, 2019) to characterize these relationships: classifying if the image content adds additional meaning (image adds / does not add) or if there is semantic overlap between the text and image (text represented / not represented).[6] As observed in Table 6 (middle), for samples with *text represented* model performance improves by 8% and for samples where *image adds* performance improves by 4% for detection in a high precision regime (pD @ 0.1FAR). Although the text-image relationship model has somewhat noisy classifications for the text task, the *text represented* class generally contains samples with a shared entity between image and text, which would make fine-grained misinformation detection easier. The *image adds* class mostly contains infographics, likely due to training data bias, which aligns with the OCR coverage experiments above.

Tweet Text Clustering: Finally, we analyze the sub-topics obtained as a result of clustering Tweets within each topic[7]. This allows us to tease out clusters, e.g., *vaccination* for COVID-19, *floods* for Climate Change or *drones* for Military Vehicles. Recall that our model performs the best on Climate Change and the worst on the Military Vehicles (Table 4). Possible factors include the smaller amount of training data and visual similarity of different vehicle types. We also observe that among the hard negatives for Military Vehicles, only 39% are cross-cluster (while Climate Change and COVID-19 have 51% and 58% respectively), indicating the Military Vehicles set contains a larger proportion of harder fakes. These factors may explain the larger difference between cross/within cluster performance for this topic (Table 6, bottom).

5 Conclusion

In this work we tackle a real-world challenge of detecting out-of-context image-text tweets on COVID-19, Climate Change, Military Vehicles topics. To approach it, we collect **Twitter-COMMs**, a large-scale topical dataset with *multimodal* tweets, and construct corresponding hard mismatches. We design our approach based on the CLIP model with several important design choices, e.g. multiplying the embeddings for multimodal fusion and increasing the percentage of hard negatives in our training data. This approach substantially improves over a powerful baseline, an off-the-shelf CLIP model, when evaluated on human-curated in-the-wild mismatches. We hope our work and insights will benefit multimedia forensics practitioners.

---

[6] Our model achieves 86% and 62% on the image and text binary classification tasks respectively, which is 5% and 4% higher than the best models presented in the original paper.

[7] See Appendix A.3.4 for details.

6 Ethical Considerations

Here, we discuss ethical considerations regarding our work. Image repurposing is a prominent societal issue that lacks sufficient training data in general, and in particular for content on social media platforms such as Twitter. Even more, our work aims to be proactive in studying the threat of out-of-context media and proposes an approach for detecting such misinformation. By presenting a dataset, a detection approach, and several key observations about falsified out-of-context Tweets, we hope that our work serves as a net benefit for society.

How was the data collected? We collected data using the Twitter Search API v2. Our methodology is described in detail in Appendix A.1.

What are the intellectual property rights? Twitter owns the intellectual property for the Tweets in our **Twitter-COMMs** dataset. We adhere to the restrictions they place on Tweets downloaded via their API, namely that we may not share the content downloaded from the API, but we have released the Tweet ID's — which others can use to download the Tweets and images from the API.

How did we address participant privacy rights? N/A

Were annnotators treated fairly? Did we require review from a review board? N/A

Which populations do we expect our dataset to work for? Our dataset is specific to social media posts from Twitter that are written in English; it will primarily be useful for audiences from English speaking countries, such as the US, UK, Australia, and India. The biases inherent to the short text style (280 characters or less) and of Tweets with images will be useful for those interested in researching multimodal misinformation on Twitter.

What is the generalizability of our claims? Our results apply primarily to Tweets on our three topics of interest (COVID-19, Climate Change, Military Vehicles) written in English and having at least one attached image.

How did we ensure dataset quality? Our data collection methodology is described in detail in Appendix A.1. To address data quality for Military Vehicles we created an image classifier to filter out tweets that did not have images of military vehicles or aircraft (Appendix A.1.2). Additionally, the sub-topic clustering we performed (Section 4.3, Appendix A.3.4) reveals that most of the text falls into clusters that are related to the three main topics. We also provide some statistics for tweets with possibly sensitive content as flagged by Twitter in Table 14 (Appendix).

What is the climate impact? Our final model used 8 days of training on 10 GPUs. Additional experiments such as the investigation of text image relationships used 4 days on a single GPU, and tweet text clustering used 10 hours on a single GPU. The GPU used for all experiments were GeForce 2080 RTX Ti's. In total we used 2,026 GPU hours, and total emissions are estimated to be 218.81 kgCO$_2$eq of which 0 percents were directly offset. Estimations were conducted using the MachineLearning Impact calculator presented in (Lacoste et al., 2019).

What are the potential dataset biases? Here, we focus on our method used to generate hard falsified samples to understand the potential biases learned during training. Specifically, we note potential age, race, and gender biases present in CLIP, the underlying model used to generate our mismatches. Radford et al. (2021) find the CLIP exhibits significant performance differences when classifying individuals of different races and ages into categories related to crime or animals. Agarwal et al. (2021) also find gender biases in the CLIP embeddings when classifying occupations. These biases primarily affect the synthetically generated training set, not the pristine data. However, we can not rule out that the pristine Twitter data may also capture some human biases or harmful stereotypes.

7 Acknowledgements

We would like to thank PAR Tech, Syracuse University, and the University of Colorado, Denver for creating the evaluation data. We thank the SRI team, including John Cadigan and Martin Graciarena, for providing the WikiData-sourced news organization Twitter handles. We would also like to thank Dong Huk (Seth) Park, Sanjay Subramanian, and Reuben Tan for helpful discussions on finetuning CLIP. This work was supported in part by DoD including DARPA's LwLL, and/or SemaFor programs, and Berkeley Artificial Intelligence Research (BAIR) industrial alliance programs.

A Appendix

In Section A.1 we provide additional details about data collection, including our strategy and search keywords. Section A.2 provides dataset statistics, including information on tweet counts, geographical information, possibly sensitive content, and image availability. We include additional experiments in Section A.3.

A.1 Data Collection

A.1.1 COVID-19 and Climate Change

Our data collection consisted of three stages. The first employed simple topic, keyword, and hashtag filters, the second stage used more specific keyword and topic combinations, while the third focused on collecting topical data from Twitter accounts of various news organizations.

In the first stage we collected roughly 100,000 tweets each for COVID-19 and Climate Change topics. We used the "COVID-19" topic of the Twitter API's Entity Annotations feature[8], which allows users to find tweets related to predetermined topics. For Climate Change we filtered with an OR clause on keywords "climate change", "global warming", and (#globalwarming, #climatechange) hashtags. Inspection of the stage 1 results revealed a lot of off-topic tweets. For example, a Twitter user might post a tweet about working from home during the pandemic and tag the tweet with a COVID-related hashtag. While this type of content is somewhat related to COVID-19, we wanted to focus on data where misinformation/disinformation might be more relevant, such as more topical/newsworthy tweets (e.g. bad actors may spread propaganda related to the COVID-19 pandemic by making false or misleading claims). To that end, in stage 2 we filtered by combining each topic phrase with one of the 19 topical search terms (e.g. "agriculture", "crops", "death", "vaccination"). The resulting data appeared much more relevant than the initial collection effort. Table 7 contains a list of the search terms we used to collect data for COVID-19 and Climate Change tweets. Finally, related to the argument above, in the third collection stage we focused on tweets authored by news organizations, as opposed to random users. For that, 7k news organization Twitter handles were sourced from WikiData[9].

Table 7: Search Terms Used in Stage 2 of the Data Collection for COVID-19 and Climate Change

Search Terms
Agriculture, COVID, COVID-19, Climate Change, Crops, Death, Death Toll, Floods, Harvest, Hurricane, ICBM, Military, Military Parade, Military Vehicles, Show of Force, Tank, Troops, Typhoon, Vaccination

A.1.2 Military Vehicles

Collecting data about the Military Vehicles topic proved more challenging than the other two topics. We initially tried simple keyword filters such as "military", "aircraft", "tank", etc, but found that those resulted in a lot of irrelevant content such as tweets related to video games, or tweets where "tank" took a different meaning (e.g., "fish tank" or "tank tops"). This initial approach did not return many relevant results. The WikiData news organization approach used in the other two topics also did not provide enough usable data. As a result we crafted two different, highly customized stages for Military Vehicles. We gathered a list of both civilian and military vehicles and aircraft from eight different publicly available datasets (see Table 8). The datasets were annotated either for image classification or object detection tasks. We queried the Twitter Search API using the vehicle and aircraft names from this set, but returned a lot of off-topic data. We then trained an EfficientNet (Tan and Le, 2019) image classifier that categorized images as either civilian ground vehicle, civilian aircraft, military ground vehicle, military aircraft, or other. (The "other" category training set consisted of several thousand manually annotated images from the initial data collection effort that did not contain any military or civilian vehicles or aircraft.) We trained the classifier

---

[8] https://developer.twitter.com/en/docs/labs/annotations

[9] https://www.wikidata.org/

to 97% accuracy and used it to filter out any tweets predicted to be in the "other" category. For the second collection stage we combined the military vehicle and aircraft names with custom keywords (Table 9).

A.2 Dataset Statistics

Table 10: Full Dataset Summary

Topic	Tweets	Geo-tagged	Countries	Captions
COVID	569,982	4,637	112	569,982
Climate	212,665	3,696	138	212,662
Military	101,684	3,913	105	101,640
All	884,331	13,404	172	884,284

Table 10 shows a summary of the dataset. The "Geo-tagged" column refers to the geolocation data provided by tweet authors. This property is empty in most cases, but when present, can be in the form of a Twitter "place" which contains a display name, a geo polygon (which in some cases is as broad as an entire country), as well as other fields, such as country name. It is also possible for the geo data to be in the form of latitude and longitude, but that is rarer. The "Countries" columns is extracted from the geo location data and because of the small amount of geo-tagged tweets we can only report countries for a small fraction of tweets in the dataset (Table 11).

One oddity to note is that although we included an English-only search filter ("lang:en") in all API calls, the API still returned a small number of non-English tweets (Table 12). We are not sure why this is, but manual inspection of some of these examples shows that a good portion of them are in fact in English.

Figure 3: Word Cloud Summaries for Each Topic

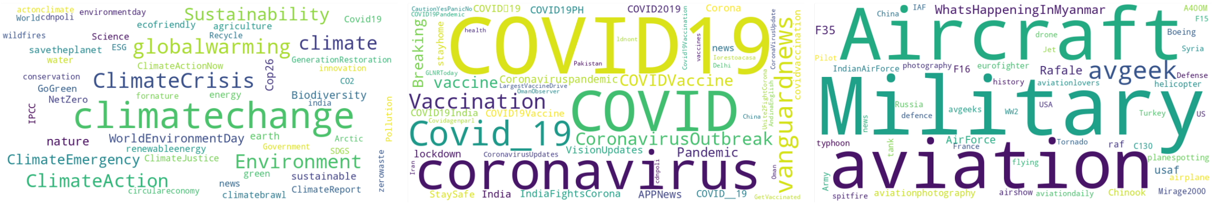

Figure 3 shows high-level "word cloud" summaries for the hashtags in the tweets for each topic.

Table 14 shows the number of tweets that Twitter flagged as containing possibly sensitive material, i.e., samples that may contain adult content or graphic violence. We encourage users to be aware of such tweets, which account for about 1% of the data, and may be undesirable for certain downstream tasks.

Table 11: Totals by Country (Top 20 Only)

Country	Tweets	Geo-tagged	Captions
India	2,399	6,692	2,399
United Kingdom	2,127	6,020	2,127
United States	707	2,338	707
Canada	519	1,476	519
Australia	339	1,024	339
Pakistan	203	606	203
Germany	146	454	146
Kenya	130	360	130
Ireland	128	394	128
South Africa	118	342	118
Nigeria	116	352	116
Uganda	115	298	115
Republic of the Philippines	107	320	107
France	100	298	100
The Netherlands	95	290	95
Indonesia	81	238	81
Malaysia	77	224	77
Spain	75	194	75
New Zealand	68	212	68
Belgium	67	182	67

Table 12: Totals by Language

Language	Tweets	Total geo-tagged	Countries	Unique Captions
English	883,310	9,268	172	883,263
Non-English	618	3	3	618

Table 13: Totals for Country="US", by Topic

Topic	Tweets	geo-tagged	Countries
Military Vehicles	705	705	1
COVID-19	0	0	0
Climate Change	2	2	1

Table 14: Possibly Sensitive Tweets

Poss. Sensitive	Tweets	% of Total
True	9,151	1.03
False	875,180	98.97

Table 15: Media Summary

Total Images	Tweets
1,039,296	884,331

Table 16: Distribution of # of Media Items per Tweet

# Media in Tweet	Tweets	% of Total
1	801,764	90.6%
2	36,969	4.2%
3	18,803	2.1%
4	26,795	3.0%

The total number of images/tweets is shown in Table 15. Twitter allows users to include 1-4 images in a tweet. As seen in Table 16, 90% of the tweets have a single image. In cases where a tweet contained more than one image, we only used the first image (according to the order of the images returned by the Twitter API).

A.3 Additional Experiments

All experiments reported in this paper are for a single run, as we find that variance across multiple runs is low. All ROC curves and metrics are computed using sklearn's roc_curve function. All models are implemented in PyTorch. For our experiments, we make the following design choices:

- We use the RN50x16 backbone. We find that this backbone consistently yields a 2-3% improvement compared to other released backbones, such as ViT/B-32. Our final CLIP model contains ~300M parameters initialized from the RN50x16 backbone and ~600k parameters randomly initialized for our classifier.
- We tune the upper layers and keep CLIP's lower layers frozen[10]. We find that this scheme is more memory efficient and yields more stable convergence than tuning all the layers.
- We use a learning rate of 5e-08 for CLIP and 5e-05 for the classifier. From our hyperparameter sweeps we find this setting to be the most appropriate, as CLIP is pretrained while the classifier is randomly initialized.
- We multiply CLIP image and text embeddings before passing that as an input to the classifier. This is different from Luo et al. (2021), who used a simple feature concatenation.

A.3.1 Expert vs. Joint Training

Here we study whether training a joint model on all three topics at once may be inferior to training three topic-specific experts, see Figure 4. We find that the joint model performs on par with or better than the expert models, thus we use a joint model in all the other experiments.

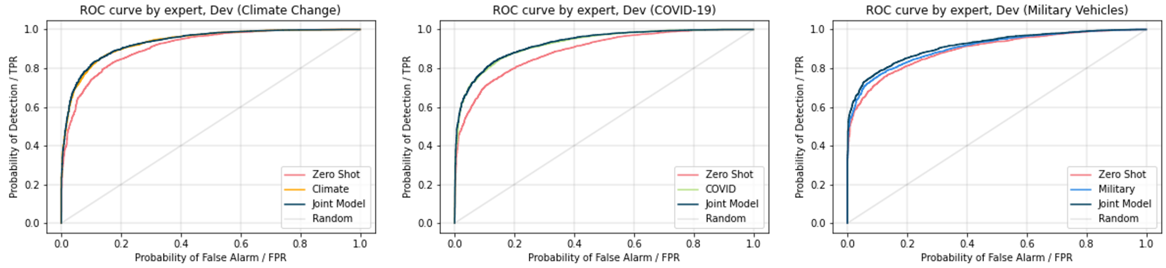

Figure 4: ROC Curves by Expert vs. Joint Training (Section A.3.1). The model is trained on 1M samples with 75% hard negatives.

A.3.2 Fine-Tuning Scheme

Since we only know the high-level topics but not the precise composition of samples in our hidden set hTwitter, we investigate methods for out-of-domain robustness. Specifically, we try the scheme from (Kumar et al., 2022), where the authors first optimize the classifier while keeping the pretrained feature extractor frozen (linear probing), then optimize the entire network (fine-tuning). The intuition behind this method is that a good initialization from linear probing minimizes the chance of feature distortion, i.e. when the pretrained model overfits to in-domain data. We report the results in Table 17. In fact, we find that direct fine-tuning (FT) achieves slightly better performance on both in-domain Twitter data and out-of-domain news data (hNews). Thus, in other experiments we use direct fine-tuning.

---

[10] We fine-tune the layers "visual.layer4", "visual.attnpool", "transformer.resblocks.11", "ln_final", "text_projection", "logit_scale".

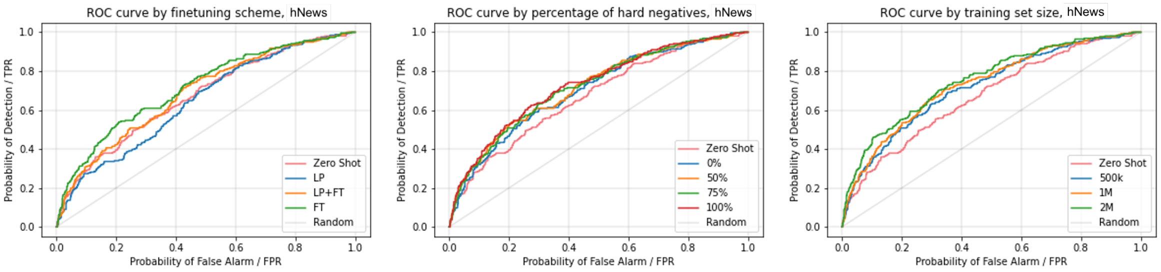

Figure 5: ROC Curves by Fine-Tuning Scheme (Section A.3.2), Percentage of Hard Negatives (Section 4.2), and Training Set Size (Section A.3.3) on the hNews set.

Table 17: Balanced binary classification accuracy at EER by fine-tuning scheme. LP (linear probe) or FT (fine-tune) on 500k samples, 50% hard negatives.

	Climate Change		COVID-19		Military Vehicles		hNews
	Random	Hard	Random	Hard	Random	Hard	
LP	0.9178	0.7548	0.9013	0.7359	0.9224	0.7071	0.5870
LP+FT	**0.9346**	0.7877	0.9195	0.7752	0.9440	0.7387	0.6188
FT	0.9344	**0.7969**	**0.9247**	**0.7807**	**0.9440**	**0.7467**	**0.6339**

A.3.3 Training Set Size

We also investigate the influence of training set size on performance. We report the binary classification accuracy as we use 500k, 1M, and 2M samples, as seen in Table 18. We observe that increasing training data size generally leads to improved performance, with most of the gains coming from higher accuracy on hard negatives.

Table 18: Balanced binary classification accuracy at EER by training set size. FT on varying number of samples, 75% hard negatives.

	Climate Change		COVID-19		Military Vehicles		hNews
	Random	Hard	Random	Hard	Random	Hard

A.3.4 Tweet Text Clustering

We investigate the sub-topical clusters of the tweet text, and also evaluate the performance of the final fine-tuned model in terms of how well it performs on a set of the hard falsified samples and their corresponding pristine samples.

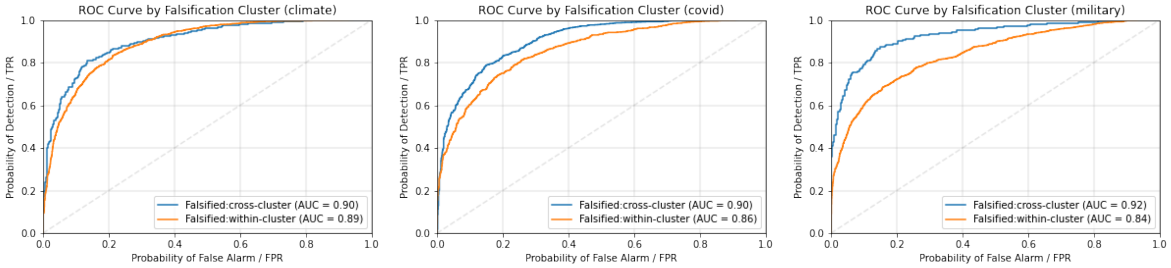
We use the method of (Grootendorst, 2020) to generate clusters, which entails computing SentenceBERT (Reimers and Gurevych, 2019) embeddings for each Tweet text, using UMAP (McInnes et al., 2020) to reduce the number of embedding dimensions from 768 to 20, and then running the HDBSCAN hierarchical clustering algorithm (McInnes and Healy, 2017) on the UMAP output. We compute the ten most important words for each cluster using the TF-IDF scores, and use this word list to gain insight into the concepts present in the texts of each cluster.

For UMAP we use the 10 nearest neighbors. For Climate Change HDBSCAN hyperparameters are: minimum topic size=400, and a cluster selection distance threshold = 0.56. For COVID-19 HDBSCAN: minimum topic size=1200, and cluster selection distance threshold = 0.65. For Military Vehicles HDBSCAN: minimum topic size = 100, cluster selection distance threshold = 0.60. The cluster selection size setting determines when clusters are merged, clusters within a smaller distance than this threshold setting will get merged together (see HDBSCAN($\hat{\epsilon}$) parameter in section IV of (Malzer and Baum, 2020)).

As discussed in the main paper, we are interested in analyzing model performance on within-cluster vs. cross-cluster hard samples. First, the training data statistics per topic are presented in Table 19. Next, Figure 6 shows the ROC curves for the within-cluster and cross-cluster samples.

Table 19: Training set statistics by topic, by sample_type

		Total	% of Topic Total	# cross_cluster	% cross_cluster
topic	sample_type				
COVID-19	pristine	736,539	50.00	0	0.00
	hard	574,129	38.97	334,541	58.27
	random	162,410	11.03	129,623	79.81
Climate Change	pristine	298,809	50.00	0	0.00
	hard	214,377	35.87	109,984	51.30
	random	84,432	14.13	56,035	66.37
Military Vehicles	pristine	139,213	50.00	0	0.00
	hard	103,837	37.29	40,797	39.29
	random	35,376	12.71	26,947	76.17



(a) (b) (c)

Figure 6: ROC curves on sets of pristine + falsified (hard-only) pairs, grouped by whether or not the falsified text fell within the same cluster ("within-cluster") or in a different cluster ("cross-cluster").

To gain insight into the sub-topics, we concatenate the 3 top scoring words from each cluster to obtain the cluster “names”, as seen in the Tables 20, 21, 22 with cluster names and word scores. We get between 20 and 30 clusters for each topic. We observe such sub-topics as ocean-sea-flood-flooding, plastic-recycling-recycle-sustainability for Climate Change, vaccine-vaccination-clinic-appointment, school-student-education-university for COVID-19, tank-abrams-army-m1, drone-ai-uav-drones for Military Vehicles. The hierarchy visualizations in Figures 7, 8, 9 provide further insight into the sub-topic structure.

Abstract

Standard automatic metrics, e.g., BLEU, are not reliable for document-level MT evaluation. They can neither distinguish document-level improvements in translation quality from sentence-level ones, nor identify the discourse phenomena that cause context-agnostic translations. This paper introduces a novel automatic metric BlonDe[1] to widen the scope of automatic MT evaluation from the sentence to the document level. BlonDe takes discourse coherence into consideration by categorizing discourse-related spans and calculating the similarity-based F1 measure of categorized spans. We conduct extensive comparisons on a newly constructed document-level translation dataset BWB. The experimental results show that BlonDe possesses better selectivity and interpretability at the document-level, and is more sensitive to document-level nuances. In a large-scale human study, BlonDe also achieves significantly higher Pearson's r correlation with human judgments compared to previous metrics.

1 Introduction

Over the past years neural machine translation (NMT) models have become the models of choice in Machine Translation (MT; Luong et al., 2015; Vaswani et al., 2017; Zhang et al., 2018, *inter alia*). Although some recent work (Hassan et al., 2018; Popel, 2018; Bojar et al., 2018) suggests that NMT has achieved human parity at the sentence level, the reliability of these human-parity claims was quickly contested by Läubli et al. (2018, 2020), showing that there is a larger difference between human and machine translation quality when inter-sentential context is taken into account.

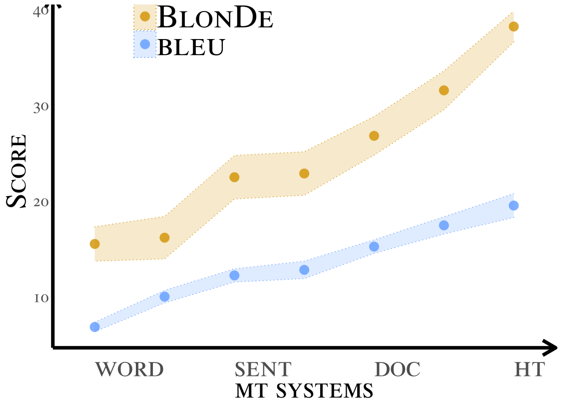

Figure 1: BlonDe is more selective than BLEU for document-level MT, and also shows a larger quality difference between human and machine translations.

Therefore, document-level machine translation has received increased attention in the MT community. However, despite various modeling advances, the MT community still lacks an efficient and effective evaluation metric for document-level translation. Standard evaluation metrics for MT, e.g., BLEU (Papineni et al., 2002), TER (Snover et al., 2006) and METEOR (Banerjee and Lavie, 2005), focus on the quality of translations at the sentence level and do not consider discourse-level features.

Thus, test suites that perform context-aware evaluation by targeting characteristic discourse-level phenomena have been proposed (Hardmeier et al., 2015; Guillou and Hardmeier, 2016; Burchardt et al., 2017; Isabelle et al., 2017; Rios Gonzales et al., 2017; Müller et al., 2018; Bawden et al., 2018; Voita et al., 2019; Guillou and Hardmeier, 2018, *inter alia*) for document-level MT. However, such test suites need to be re-created for new domains or even language pairs, and their construction can be very labor-intensive. We still lack an

easy-to-use automatic metric that can reliably discriminate the quality of document-level translation.

In this paper, we curate a large-scale document-level parallel corpus (BWB) from heterogeneous data sources, and quantify document-level translation mistakes by performing a large human study. On this dataset, we found that inconsistency,[2] ellipsis, and ambiguity were the most noticeable phenomena critical for document-level MT, together amounting to 86.73% of MT mistakes. Based on this analysis, we propose BLONDE, an automatic metric that evaluates translation quality at the document level. At the core of the metric is the similarity-based bijection between subsets of reference and system categories, e.g., pronouns, inflected forms, discourse relations and lexicons, and phrases, e.g., named entities. It computes recall, precision and F1, along with the corresponding measure of n-grams. Furthermore, BLONDE can incorporate human annotation easily by computing scores of human-annotated categories in the same way.

We compare BLONDE with 11 other metrics and demonstrate that BLONDE is better at distinguishing between context-aware and context-agnostic MT systems. We also observe that the degree to which BLONDE correlates with sentence-level metrics (e.g., BLEU) is lower than the degree to which the sentence-level metrics correlate with each other. This signals that BLONDE indeed captures additional aspects of translation quality beyond the sentence-level. Finally, our human evaluation also reveals significantly higher Pearson's r correlation coefficients between BLONDE and human assessments compared to other metrics.

2 BWB: Bilingual Web Book Dataset

To design a metric that is sensitive to document-level phenomena, we first curate a document-level Chinese–English parallel corpus, called BWB (**B**ilingual **W**eb **B**ooks). BWB consists of Chinese web novels across multiple genres (sci-fi, romance, action, fantasy, comedy, *inter alia*) and their corresponding English translations crawled from the Internet.

Dataset Creation. The novels are translated by professional native English speakers, and are corrected by editors. The sentence alignment of the training set is done by Bluealign[3] (Sennrich and Volk, 2011). We hired four bilingual graduate students to manually evaluate 163 randomly selected documents from the resulting BWB parallel corpus and observe an alignment accuracy rate of 93.1%. We further asked the same batch of annotators to correct such misalignments in both the development and the test set. The details of the corpus creation and quality control are described in Appendix A.

Statistic	Train	Test	Dev	Total
#Docs	196,304	80	79	196,463
#Sents	9,576,566	2,632	2,618	9,581,816
#Words	325.4M	68.0K	67.4K	460.8M

Table 1: Statistics of the BWB dataset.

Statistics. Table 1 summarizes the statistics of the BWB dataset. It is a much larger dataset, and contains longer documents and richer discourse phenomena compared to all previous document-level datasets (Lison and Tiedemann, 2016; Koehn and Knowles, 2017; Barrault et al., 2019; Koehn, 2005; Liu and Zhang, 2020). To the best of our knowledge, this is the largest Chinese–English document-level translation dataset to date.

Dataset Split. We treat chapters in our books as *documents*. The maximum, median, and minimum number of sentences per document are 46, 30 and 18, respectively. To prevent any train–test leakage, we split the dataset into a training, development and a test set such that chapters from the same book are part of the same split. We use 377 books for training, and randomly select 80 and 79 documents from the 3,018 documents in the remaining 6 books as the development and test sets, respectively.[4]

3 Analyzing Discourse Errors

Next, we conduct a human study on the test set of BWB, in which we identify and categorize the discourse errors made by MT systems that are not captured in sentence-level evaluation. This human study is conducted by eight professional translators. The annotators are asked to classify translation errors into DOCUMENT-level and SENTENCE-level errors (some cases can be both). SENTENCE-level

---

[2] By inconsistency we mean the mistakes related to coreference and lexical cohesion (Carpuat, 2009; Guillou, 2013).

[3] `https://github.com/rsennrich/Bleualign`

[4] One document in the development set was dropped due to its poor annotation quality.

Error Type	#	%
NO ERROR	451	17.1%
SENTENCE	1351	51.3%
DOCUMENT	1893	71.9%
INCONSISTENCY	1695	64.4%
NAMED ENTITY	1139	43.3%
TENSE	1018	38.7%
ELLIPSIS	534	20.3%
PRONOUN	456	17.3%
OTHER	103	4.0%
AMBIGUITY	193	7.3%

Table 2: The statistics of translation errors in human analysis.

errors refer to those errors that render the translations to be inadequate or not fluent as stand-alone sentences, while DOCUMENT-level errors reflect a coherence violation across multiple sentences in the document. DOCUMENT-level errors are further categorized according to the linguistic phenomena leading to the lower performance in the context-dependent translation.[5]

Table 2 shows the result of our error analysis. A substantial proportion of translations have document-level errors (71.9%). This supports the claim that BWB contains rich discourse phenomena that common MT systems cannot address. We observe that three categories, i.e., inconsistency (64.4%), ellipsis (20.3%) and ambiguity (7.3%), account for the vast majority of document-level errors. Below we discuss these three categories of DOCUMENT-level errors and the design intuitions behind BLONDE.

Inconsistency. We consider two kinds of consistency in translation: lexical and grammatical. Lexical consistency is defined as a repetitive term that keeps the same translation throughout the whole document (Carpuat and Simard, 2012). Inconsistent translation of named entities can significantly impact translation output, although BLEU may not be adversely affected (Agrawal and Singla, 2012; Hermjakob et al., 2008). Therefore, in the design of BLONDE, we also focus on the reiteration of named entities (e.g., **Qiao** in Figure 3). On the other hand, typical examples of grammatical consistency are tense and gender consistency. Tense consistency refers to the tense being *compatible* with the context, rather than being exactly the same across the whole document. Tense inconsistency can arise when the source language is an isolating language and does not mark tense explicitly, e.g., in Chinese, and the target language is a synthetic language, e.g., English (***teal*** in Figure 3), where tense is marked explicitly. In the same spirit, the same entity should maintain a consistent grammatical gender. [6]

SRC	你在看***(kan)***什么？《复仇者联盟》。
REF	What are you ***watching***? The Avengers.
MT	What are you ***looking*** at? The Avengers.

Figure 2: An example of ambiguity. 看(kan) corresponds to *look*, *see*, *watch* and *view*. The correct translation can only be inferred from the next sentence (The Avengers).

Ellipsis. Ellipsis denotes the omission from a clause of one or more words that are nevertheless inferred in the context of the remaining elements (Yamamoto and Sumita, 1998; Voita et al., 2019). Translation errors arise when there are elliptical constructions in the source language while the target language does not allow for the same types of ellipsis. For example, the ellipsis of subjects or objects is very common in Chinese while it is ungrammatical in English—especially for pronouns. In Figure 3, *she (Qiao)* is omitted in Chinese. However, it is hard to guess the gender of *Qiao* from this stand-alone sentence: the correct pronoun choice can only be inferred from context (there is a *her* in the previous sentence). Another common form of ellipsis is the omission of discourse markers, especially when the source language has more zero connective structures (Po-Ching and Rimmington, 2004) than the target language. In the example, *However* and *So* are ignored in SRC, which misleads the sentence-level system MTA to ignore the discourse relations between sentences.

Ambiguity. Translation ambiguity occurs when a word in one language can be translated in more than one way into another language (Tokowicz and Degani, 2010). The cross-language ambiguity comes from several sources of within-language ambiguity including lexical ambiguity, polysemy, and near-synonymy. A unified feature of these is that ambiguous terms satisfy the form of one-to-many mappings. For the example in Figure 2, the word 看(kan) can be translated to *look*, *see*, *watch* or *view*. Without access to the context, all the lexical choices are sensible.

---

[5] The annotation guidelines are described in Appendix B.

[6] It is worth noting that the metric proposed in this study can be applied to a wider range of language pairs by extending the definition of grammatical consistency.

		ENTITY $\mathcal{E}$	TENSE $\mathcal{V}$	PRONOUN $\mathcal{P}$	DM $\mathcal{M}$
SRC	a) 小乔**(Qiao)** 看着***(look)*** 相片回忆***(recall)*** 起了二十年前。 b) 那个满脸胡须的男人**(man)** 正是***(be)***她**(she)** 的新婚丈夫。 c) 那却是***(be)*** 他们之间初次见面***(meet)***。 d) 小乔**(Qiao)**一见到他**(he)** 心里就咯噔***(jolt)*** 了一下，噌的站***(stand)*** 起来。	⟦Qiao⟧	[`VBD`, `VBZ`]	[`masculine`, `feminine`, `epicene`, `neuter`]	[`contingency`, `temporal`, `expansion`, `comparison`]

MTB	a) **Qiao** ***looked*** at the photo and ***recalled*** the past twenty years ago.	[1]	[2, 0]	[0, 0, 0, 0]	-
	b) This **man** with the beard ***was*** **her** newly-wed **husband**.	[0]	[1, 0]	[0, 1, 1, 0]	[0, 0, 0, 0]
	c) ⟦**However**⟧, that was the first time they ***met***.	[0]	[2, 0]	[0, 0, 1, 0]	[0, 0, 0, 1]
	d) ⟦So⟧ as soon as **Qiao** saw **him**, ⟦**her**⟧ heart ***became*** squeaky, and ⟦**she**⟧ swiftly ***stood*** up.	[1]	[2, 0]	[1, 2, 0, 0]	[1, 0, 0, 0]

Figure 3: An example containing inconsistency and ellipsis in BWB. For inconsistency, the same entities are marked in the same color (**Qiao** and **Husband**), and verbs are marked in ***teal***. For ellipsis, omissions are marked with ⟦⟧. DM stands for discourse markers (⟦⟧). The translation mistakes are underlined. MTB is intuitively a better system than MTA to human readers.

4 BLONDE

The aforementioned document-level phenomena have little impact on the n-gram statistics of translations. However, as is shown in Section 3, they can be key considerations for human readers when evaluating translations at the document level. Standard automatic metrics ignore the importance of contextual coherence of translations, which implies that the document-level nuances are not being properly modeled (Zhou et al., 2008; Xiong and Zhang, 2014). In this section, we describe BLONDE, an automatic metric that explicitly tracks discourse phenomena.

4.1 Document-Level Evaluation

We first give the formulation of measuring discourse phenomena. We define a **document** $\mathfrak{D} = [S_1, \ldots, S_N]$ as a sequence of N sentences. We take a **sentence** S of length T to be a string of tokens $t_1 \cdots t_T$ where each token t_i is taken from the vocabulary $\mathcal{V}$. Let $\text{spans}\,(S) = \{m_1, m_2, \ldots\}$ be the set of spans in the sentence S. Here, a **span** is a subsequence of the tokens in $S = t_1 \cdots t_T$.

Let us assume that we are interested in K **discourse categories**. Each of these categories capture a discourse phenomenon of interest. As shown in Section 3, named entity inconsistency, tense inconsistency and pronoun ellipsis make up the majority of discourse errors (67.8%) on the data analyzed. We therefore introduce three types of categories: ENTITY, TENSE and PRONOUN. In addition, we introduce **discourse markers** DM as a category, which are the essential contextual links between the various discourse segments (See Figure 3).

For a certain discourse category of interest, k, we assume that there are L_k **features**. In our case, the features of ENTITY $\mathcal{E}$ are a list of named entities in $\mathfrak{D}$; the features of TENSE are $\mathcal{V}$ = [`MD`, `VBD`, `VBN`, `VBP`, `VBZ`, `VBG`, `VB`],[7] the features of PRONOUN are $\mathcal{P}$ = [`masculine`, `feminine`, `neuter`, `epicene`];[8] the features of DM are $\mathcal{M}$ = [`contingency`, `temporal`, `expansion`, `comparison`].[9] Note that different categories can have different numbers of features and the number of features can be dynamic: $\mathcal{E}$ depends on $\mathfrak{D}$ while $\mathcal{V}$ and $\mathcal{P}$ are fixed. The intuition behind this is that we want to encourage the system output to keep consistent tense and pronouns as well as the consistent translation for a specific named entity.

Let us now define $\mathbf{C}_{k,l}\,(S) \subseteq \text{spans}\,(S)$ as the set of spans in S that share the l^{th} feature in the k^{th} discourse category. To give a concrete example, let us assume that TENSE is the k^{th} category and `VBD` is the l^{th} feature in this category. The corresponding $\mathbf{C}_{k,l}(S)$ is the set of the spans (in this case, unigrams) tagged with `VBD` in the sen-

---

[7] `MD`: Modal; `VBD`: Verb (past tense verb); `VBN`: Verb (past participle); `VBP`: Verb (non-3rd person singular present); `VBZ`: Verb (3rd person singular present); `VBG`: Verb (gerund or present participle); `VB`: Verb (base form).

[8] `masculine`: he, him, his, himself; `feminine`: she, her, hers, herself, `neuter`: it, its, itself; `epicene`: they, them, their, theirs, themselves.

[9] A detailed explanation is provided in Table 6.

tence S. In Figure 3, all the spans are colored. We then let $\mathbf{C}_k(S)$ refer to a vector of size L_k where each element of that vector is the set $\mathbf{C}_{k,l}(S)$. The sets of spans for ENTITY, TENSE, PRONOUN and DM can be produced by an NER model, a POS tagger, a rule-based string match and a discourse marker, respectively. We also define a weight vector $\boldsymbol{w}_k = [w_{k,l} : l \in \{1, \ldots, L_k\}]$ for each discourse category k, where each entry $w_{k,l}$ corresponds to the weight given to a feature.

We then define the **discourse representation** of sentence S as the concatenation of all categories:

$$\mathbf{C}(S) = [\mathbf{C}_k(S) : k \in \{1, \ldots, K\}] \tag{1}$$

Similarity. Let $\textsf{\textbf{sim}} : \mathbf{C}(S^s) \times \mathbf{C}(S^r) \rightarrow \mathbb{R}^K$ represent a similarity vector which measures category-wise similarity between the discourse representations of two sentences S^r and S^s. Each entry of the vector **sim** takes non-negative values: The entry being zero if S^s and S^r have no shared spans with the same discourse category.

The similarity vector **sim** defined here can be implemented in several ways. A possible implementation of **sim** can be achieved by counting the number of functionally similar spans for each feature and then taking a weighted sum over all features:

$$\begin{aligned}\textsf{\textbf{sim}}(S^s,S^r) =& \\ &[\textsf{\textbf{sim}}_k(S^s, S^r) : k \in \{1, \ldots, K\}]\end{aligned} \tag{2}$$

where each entry $\textsf{\textbf{sim}}_k$ is defined as follows:

$$\begin{aligned}&\textsf{\textbf{sim}}_k(S^s, S^r) = \\ &\boldsymbol{w}_k \odot \min\left(\textsf{\textbf{count}}(\mathbf{C}_k(S^s)), \textsf{\textbf{count}}(\mathbf{C}_k(S^r))\right)\end{aligned} \tag{3}$$

where

$$\begin{aligned}&\textsf{\textbf{count}}(\mathbf{C}_k(\cdot)) \\ &\quad = [|\mathbf{C}_{k,l}(\cdot)| : l \in \{1, \ldots, L_k\}]\end{aligned} \tag{4}$$

denotes the cardinality of $\mathbf{C}_{k,l}$ applied entry-wise and $\min$ denotes the minimum function applied element-wise. Intuitively, $\textsf{\textbf{sim}}_k$, measures the number of functionally similar spans shared by S^s and S^r. Assume that TENSE is the k^{th} category.[10]

It is worth noting that there are many other reasonable ways to operationalize **sim**. For ENTITY, partial credit could be assigned to two named entities if they have overlapping tokens; for TENSE and PRONOUN, partial credit could be assigned to two similar categories, e.g., `VBP` and `VB`; for DM, partial credit could be assigned according to the sense hierarchy and the confidences in the detected discourse markers. We leave the expansion of the **sim** definition to future work.

A Document-level Similarity Measure. Now we turn from measuring the similarity at the sentence level to the document level. We first lift $\textsf{\textbf{sim}}(\cdot, \cdot)$ to measure the similarity between two documents:

$$\textsf{\textbf{sim}}(\mathfrak{D}^s, \mathfrak{D}^r) = \sum_{\substack{S^s \in \mathfrak{D}^s, \\ S^r \in \mathfrak{D}^r}} \textsf{\textbf{sim}}(S^s, S^r) \tag{5}$$

where the sum is applied element-wise.

We then define $\textsf{\textbf{sim}}(\cdot, \cdot)$ for a system document $\mathfrak{D}^s$ and a set of reference documents $\mathbb{D}^r = \{\mathfrak{D}^{r_1}, \mathfrak{D}^{r_2}, \ldots\}$ by aggregating the **sim** of all sentences in $\mathfrak{D}^s$ and $\mathbb{D}^r$:

$$\textsf{\textbf{sim}}(\mathfrak{D}^s, \mathbb{D}^r) = \sum_{S^s \in \mathfrak{D}^s} \bigoplus_{S^r \in \mathbb{D}^r} \textsf{\textbf{sim}}(S^s, S^r) \tag{6}$$

Here, $\oplus$ is a generic aggregator over multiple references, e.g., $\oplus = \max$, if we take the reference which has the maximum similarity with the system output; or $\oplus = \sum$ if we sum up the similarity scores of all references. Again, $\oplus$ is applied element-wise.[11] We also reuse the notation $\textsf{\textbf{sim}}(\cdot, \cdot)$ for two sets of documents $\mathbb{D}^s$ and $\mathbb{D}^r$:

$$\textsf{\textbf{sim}}(\mathbb{D}^s, \mathbb{D}^r) = \bigoplus_{\mathfrak{D}^s \in \mathbb{D}^s} \textsf{\textbf{sim}}(\mathfrak{D}^s, \mathbb{D}^r) \tag{7}$$

Note that the similarity vector can also be computed for the same (set of) documents. For example, if **sim** is implemented as counting the number of functionally similar spans for each feature, then, $\textsf{\textbf{sim}}(\mathfrak{D}^s, \mathfrak{D}^s)$ and $\textsf{\textbf{sim}}(\mathbb{D}^r, \mathbb{D}^r)$ denote the total number of spans of each category in the system output and the reference, respectively.[12]

Scoring. We are now ready to define the "goodness" of a system output with respect to our discourse phenomenon of interest. We compute the

---

[10] In Figure 3, $\textsf{\textbf{sim}}_k(U_b^{\text{MTA}}, U_b^{\text{REF}}) = 0$ since MTA mistranslated the verbs as present tense due to the exclusion of context. The total similarity $\textsf{\textbf{sim}}(\mathfrak{D}^{\text{MTA}}, \mathfrak{D}^{\text{REF}})$ is the number of functionally similar spans across all features: (1, 2, 4, 0) for ($\mathcal{E}$, $\mathcal{V}$, $\mathcal{P}$, $\mathcal{M}$). Here, we assume all category weights are 1.

[11] In Figure 3, since we only have one reference, $\textsf{\textbf{sim}}(\mathfrak{D}^{\text{MTA}}, \mathbb{D}^r) = \textsf{\textbf{sim}}(\mathfrak{D}^{\text{MTA}}, \mathfrak{D}^{\text{REF}}) = (1, 2, 4, 0)$.

[12] In Figure 3, $\textsf{\textbf{sim}}(\mathfrak{D}^{\text{MTA}}, \mathfrak{D}^{\text{MTA}}) = (1, 7, 6, 0)$ and $\textsf{\textbf{sim}}(\mathbb{D}^r, \mathbb{D}^r) = \textsf{\textbf{sim}}(\mathfrak{D}^{\text{REF}}, \mathfrak{D}^{\text{REF}}) = (2, 7, 5, 2)$.

precision, recall and F1 for all K discourse categories defined as follows:

$$\boldsymbol{p}(\mathfrak{D}^s, \mathbb{D}^r) = \frac{\textsf{sim}\left(\mathfrak{D}^s, \mathbb{D}^r\right)}{\textsf{sim}\left(\mathfrak{D}^s, \mathfrak{D}^s\right)}, \tag{8}$$

$$\boldsymbol{r}(\mathfrak{D}^s, \mathbb{D}^r) = \frac{\textsf{sim}\left(\mathfrak{D}^s, \mathbb{D}^r\right)}{\textsf{sim}\left(\mathbb{D}^r, \mathbb{D}^r\right)}, \tag{9}$$

$$\boldsymbol{F}(\mathfrak{D}^s, \mathbb{D}^r) = 2 \cdot \frac{\boldsymbol{p} \odot \boldsymbol{r}}{\boldsymbol{p} + \boldsymbol{r}}. \tag{10}$$

Here, $\boldsymbol{p}(\mathfrak{D}^s, \mathbb{D}^r)$, $\boldsymbol{r}(\mathfrak{D}^s, \mathbb{D}^r)$ and $\boldsymbol{F}(\mathfrak{D}^s, \mathbb{D}^r)$ are all K-dimensional vectors; where, the k^{th} element of these vectors represents the precision, recall and F-score for the k^{th} category. Thus, the addition, multiplication and division operations above are also defined element-wise.[13]

BLOND-D. Further, we combine the scores of all categories into an overall score with a simple weighted average, named BLOND-D. By computing BLOND-D, one can distill the document-level translation quality from translation quality at the sentence level. More formally, we have

$$\text{BLOND-D.P}(\mathfrak{D}^s, \mathbb{D}^r) = \tag{11}$$
$$\left(\prod_{k=1}^{K} \left(\boldsymbol{p}_k(\mathfrak{D}^s, \mathbb{D}^r)^{a_k}\right)\right)^{1/\sum_{k=1}^{K} a_k}$$

$$\text{BLOND-D.R}(\mathfrak{D}^s, \mathbb{D}^r) = \tag{12}$$
$$\left(\prod_{k=1}^{K} \left(\boldsymbol{r}_k(\mathfrak{D}^s, \mathbb{D}^r)^{a_k}\right)\right)^{1/\sum_{k=1}^{K} a_k}$$

where a_k denotes the importance weight of the k^{th} category, and $\boldsymbol{p}_k$ and $\boldsymbol{r}_k$ denote the k^{th} entry of $\boldsymbol{p}$ and $\boldsymbol{r}$, respectively.[14] Therefore, BLOND-D.F1 is defined as follows:

$$\text{BLOND-D.F1}(\mathfrak{D}^s, \mathbb{D}^r) = \tag{13}$$
$$2 \cdot \frac{\text{BLOND-D.P} \cdot \text{BLOND-D.R}}{\text{BLOND-D.P} + \text{BLOND-D.R}}$$

	BLEU	BLONDE			BLOND-D
	P	P	R	F1	F1
MTA	41.5	10.5	51.3	17.4	7.6
MTB	35.9	60.6	58.9	59.8	97.7

Table 3: The BLEU and BLONDE scores of the two system outputs in Figure 3. P, R and F1 represent precision, recall and F1, respectively.

Whenever not otherwise specified, we simply use BLOND-D to refer to BLOND-D.F1.[15]

4.2 BLONDE: Combining BLOND-D with n-grams

However, focusing on discourse phenomena solely is not enough to provide comprehensive MT evaluation that correlates strongly with human judgments. Consider the following example:

(1) REF Qiao lifted her heavy eyelids.
MT Qiao scrunched her brows together.

The output of MT is far from "good" in terms of adequacy, whereas BLOND-D(MT) $= 1$, since MT translates both named entities and tenses correctly. Thus, in order to account for sentence-level adequacy of our final metric BLONDE, we augment the set of categories and features to include each n-gram (for a value of n) as a category and each span of n-tokens as a feature for the n-gram category. Formally, we have

$$\mathbf{C}'(S) = \tag{14}$$
$$\left[\mathbf{C}_k\left(S\right) : k \in \{1, \ldots, K+N\}\right]$$

where we define

$$\mathbf{C}_{K+n} = \{n\text{-gram} : n \in \{1, \ldots, N\}\} \tag{15}$$

The calculation of BLONDE.P, BLONDE.R and BLONDE.F1 is then done exactly in the same manner as BLOND-D. Whenever not specified, we simply use BLONDE to refer to BLONDE.F1.

---

[13] In Figure 3, recall that $\textsf{sim}(\mathfrak{D}^{\text{MTA}}, \mathbb{D}^r) = (1, 2, 4, 0)$, $\textsf{sim}(\mathfrak{D}^{\text{MTA}}, \mathfrak{D}^{\text{MTA}}) = (1, 7, 6, 0)$ and $\textsf{sim}\left(\mathbb{D}^r, \mathbb{D}^r\right) = (2, 7, 5, 2)$. Thus, we have $\boldsymbol{p}(\mathfrak{D}^{\text{MTA}}, \mathbb{D}^r) = \left(\frac{1}{1}, \frac{2}{7}, \frac{4}{6}, \frac{0}{0}\right) = \left(1, \frac{2}{7}, \frac{2}{3}, \text{NA}\right)$ where NA denotes a missing value. Furthermore, we have $\boldsymbol{r}(\mathfrak{D}^{\text{MTA}}, \mathbb{D}^r) = \left(\frac{1}{2}, \frac{2}{7}, \frac{4}{5}, \frac{0}{2}\right) = \left(\frac{1}{2}, \frac{2}{7}, \frac{4}{5}, \frac{\delta}{2}\right)$ where δ denotes a small value (0.0001) for smoothing. Finally, we have $\boldsymbol{F}(\mathfrak{D}^{\text{MTA}}, \mathbb{D}^r) = \left(\frac{2}{3}, \frac{2}{7}, \frac{8}{11}, \text{NA}\right)$.

[14] BLOND-D adopts uniform weights.

[15] E.g., the BLOND-D scores of MTA in Figure 3 are:

$$\begin{aligned}
\text{BLOND-D.P}(\mathfrak{D}^{\text{MTA}}, \mathbb{D}^r) &= \left(\frac{1}{1}\right)^{\frac{1}{3}} \left(\frac{2}{7}\right)^{\frac{1}{3}} \left(\frac{2}{3}\right)^{\frac{1}{3}} \\
&= .114^{16}, \\
\text{BLOND-D.R}(\mathfrak{D}^{\text{MTA}}, \mathbb{D}^r) &= \left(\frac{1}{2}\right)^{\frac{1}{4}} \left(\frac{2}{7}\right)^{\frac{1}{4}} \left(\frac{4}{5}\right)^{\frac{1}{4}} \left(\frac{\delta}{2}\right)^{\frac{1}{4}} \\
&= .057, \\
\text{BLOND-D.F1}(\mathfrak{D}^{\text{MTA}}, \mathbb{D}^r) &= \frac{2 \cdot .057 \cdot .114}{.057 + .114} \\
&= .076.
\end{aligned}$$

BLONDE covers both discourse coherence features and sentence-level adequacy, thus providing a comprehensive measurement of translation quality. Table 3 compares BLONDE with BLEU using the two MT outputs found in Figure 3. It is striking that BLEU rates MTA higher than MTB given that MTB is clearly better than MTA to human readers. In sharp contrast, their BLONDE scores reflect the correct ranking in translation quality.

4.3 BLOND+: Combining BLONDE with Human Annotations

BLONDE is easy to generalize—for instance, it would be easy to incorporate human annotations, e.g., one could annotate spans related to discourse errors and treat them as categories. The automatically inferred categories and human annotated categories are then combined by adopting the same weighted averaging approach, which we call BLOND+. We hired the same translators who analyzed discourse errors in Section 3 to annotate ambiguous and omitted word/phrases on the test set of BWB.[17]

5 Experiments

In this section, we examine the effectiveness of BLONDE at the document-level MT evaluation through experiments. We answer the following question: Do differences in BLONDE reliably reflect differences in the document-level translation quality of different MT systems? To answer this question, we run several MT baselines and compare their BLONDE scores to eleven other metrics:

Standard Sentence-level Metrics. BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), TER (Snover et al., 2006), ROUGE-L (Lin, 2004), CIDER (Vedantam et al., 2015).

Document-level Metrics. LC and RC (Wong and Kit, 2012)—these are ratios between the number of lexical cohesion devices (repetition and collocation) and repeated content words over the total number of content words in a target document, which are direct measurements of lexical cohesion.

Embedding-based Metrics. We consider four embedding-based metrics in this work: SkipThought cosine similarity (SKIP; Kiros et al., 2015), embedding average cosine similarity (AVER; Sharma et al., 2017), Vector extrema cosine similarity (VECTOR; Forgues et al., 2014), Greedy Match (GREEDY; Rus and Lintean, 2012).

5.1 MT Systems

We test BLONDE on the following system outputs: an SMT system (Chiang, 2007), three well-known commercial NMT systems (OMT-A, OMT-B, OMT-C), a sentence-level transformer-based system (MT-S) and a document-level system (MT-D) trained on BWB. MT-D (Zhang et al., 2018) trains sentence-level model parameters and then estimates document-level model parameters while keeping the sentence-level Transformer model parameters fixed. We adopt Transformer Big (Vaswani et al., 2017) for both MT-S and MT-D. The final "system" is a human post-editing (PE) on OMT-C provided by professional translators, so it is supposed to be the strongest baseline.[18]

5.2 The BLONDE Evaluation

Firstly, we leverage the test set of BWB and evaluate the above-mentioned systems by BLONDE and other metrics. Figure 4 presents the means of all metrics along with the 95% confidence interval estimated from bootstrap resampling. We observe that the BLONDE scores demonstrate an exponentially increasing trend from sentence-level towards document-level and human post-editing, while the trends of standard metrics are mostly linear. Specifically, the difference between the BLONDE scores of MT-S and MT-D (denoted as Δ(MT-S, MT-D)) is significantly higher than the difference between the Δ(MT-S, MT-D) in their BLEU scores. An even larger Δ between MT-D and PE in their BLONDE scores is observed, indicating MT-D is still far away from achieving human parity. Note that the trend of BLOND-D scores is even more exponential, which indicates that BLOND-D indeed distills document-level translation quality.

The t-statistics of the paired sample t-tests of individual documents are given in Table 4. Unlike BLEU, METEOR and other metrics, which either fails to distinguish human and machine translation or has lower discriminative power compared to distinguishing different machine translations, the BLONDE family maintain similar discriminative

---

[17] We also make this annotated test set publicly available as a testbed for evaluating the ability of MT systems to disambiguate word senses and to predict coherent pronouns or discourse markers in the case of omission.

[18] We trained models by fairseq (Ott et al., 2019). Model parameters and the post-editing details are in Appendix F.2 and C, respectively.

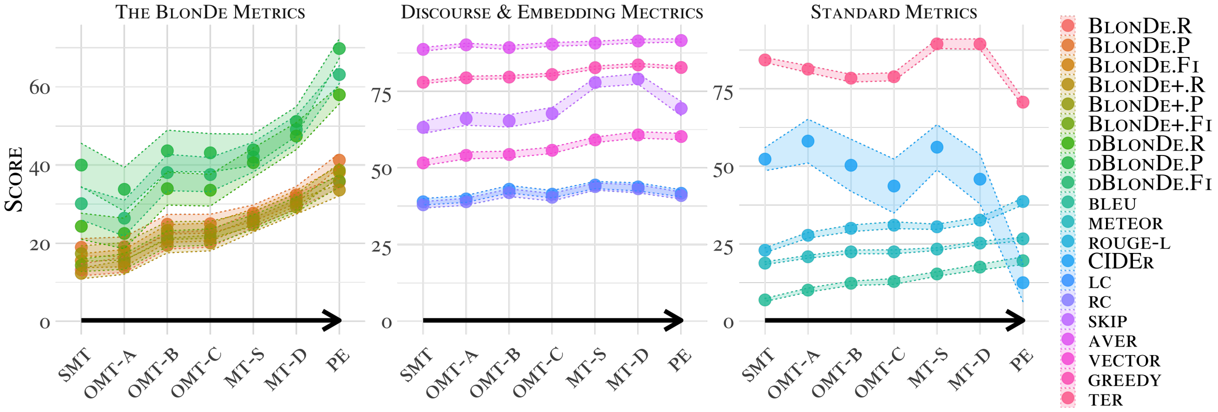

Figure 4: The mean scores of different system outputs given by different metrics on the BWB test set. Shaded region represents 95% confidence interval.

	BLEU	BLONDE			BLOND+			BLOND-D			Categories			
		R	P	F1	R	P	F1	R	P	F1	$\mathcal{E}$	$\mathcal{V}$	$\mathcal{P}$	$\mathcal{M}$

Figure 5: Absolute Pearson correlation pairs of automatic metrics. Computed over the scores of individual documents in BWB test set.

power across the pair-wise comparisons. Interestingly but not surprisingly, the non-reference-based LC and RC fail to distinguish both (MT-S, MT-D) and (MT-D, PE), since sentence-level MT is by nature more repetitive than human translation and thus it is hard to distinguish accidental repetition from document-level cohesion.

In addition, the t-statistics of BLOND-D categories provide rich diagnostic information. As can be seen, although transformer-based NMT models have substantially higher BLEU scores than SMT systems, MT-S is not statistically superior to SMT in terms of named entity translation. However, human post-editing scores significantly better on entity translation—meaning that named entity translation accounts for a substantial part of quality differences between machine and human. In terms of TENSE and and DM translation, MT-D does not significantly out-perform MT-S, which could be taken into consideration in future document-level MT model designs.

We also show the pairwise Pearson correlations between different metrics in Figure 5. It illustrates the homogeneity/heterogeneity of different metrics. We report the absolute value of the correlation for TER. We see that while sentence-level metrics (BLEU, METEOR and ROUGE-L) have strong correlations with each other, BLONDE correlates less well with those metrics.

Unit	SENTENCE		DOCUMENT

Table 5: Absolute Pearson correlation with human judgments on BWB. The highest correlations are in bold. Correlation of metrics not significantly outperformed by any other metrics are highlighted with †. The BlonDe family are not tested against each other.

5.3 Human Evaluation

We then evaluate BlonDe along with other metrics in terms of their Pearson correlation with human assessment. Our human assessment is provided by four professional Chinese to English translators and four native English revisers. Two experimental units (SENTENCE vs DOCUMENT) are assessed independently in terms of FLUENCY and ADEQUACY, respectively. In the SENTENCE-level evaluation, we show the raters isolated sentences, while in the DOCUMENT-level evaluation, we show them entire documents and we only ask raters to evaluate the overall quality of sequential blocks of sentences (5 sentences per block) as used in the Relative Ranking (RR) evaluation (Bojar et al., 2016). We use the Williams significance test (Williams, 1959; Graham and Baldwin, 2014) following the practice adopted by WMT (Mathur et al., 2020) to identify correlation differences are statistically significant. The detailed protocol is presented in Appendix D.

The results are shown in Table 5. BlonDe obtains the highest correlation with human assessment at both the sentence level and the document level. However, BlonDe correlates remarkably better with human assessment when context is taken into account, and it only significantly outperforms all other metrics at document level.

It is worth noting that BlonDe also correlates well with FLUENCY assessment, even though it is, in essence, still a reference-based metric. One possible explanation for this unexpected positive result is that it tracks span categories that directly relate to cohesion and coherence. Another important observation is that the recall-based BlonDe variants generally correlate better with human assessment, yet appears to be less selective compared to the precision-based variants (see MT-D→ PE in Table 4). This provides support for adopting the F1 in order to get the best of both worlds.

6 Related Work

There have been a few studies on automatic evaluation metrics for specific discourse phenomena.

Pronoun Translation. Hardmeier and Federico (2010) measured the precision and recall of pronouns directly and Miculicich Werlen and Popescu-Belis (2017) proposed to estimate the accuracy of pronoun translation (APT) by aligning source and target texts. However, as shown in Guillou and Hardmeier (2018), APT does not take the antecedents of an anaphoric pronoun into account. They cannot handle the mismatches in the numbers of pronouns either. Jwalapuram et al. (2019) also proposed a specialized measure for pronoun evaluation which involves training. In comparison, BlonDe does not rely on any alignment or training.

Lexical Cohesion. Wong and Kit (2012) proposed LC and RC. Gong et al. (2015) described a cohesion function to measure text cohesion via lexical chain and a gist consistency score based on topic model. However, they fail to distinguish accidental repetition from document-level cohesion.

Discourse Relations. Hajlaoui and Popescu-Belis (2013) proposed to assess the accuracy of connective translation (ACT). However, such an assessment requires a bilingual dictionary of all possible DM translations, whereas BlonDe only requires a list of monolingual DMs. Guzmán et al. (2014) and Joty et al. (2014) compute a metric based on the similarity between the discourse trees of reference and system output. Those discourse-representation-based metrics are indirect, and rely on discourse parsing tools, which are much more inaccurate than syntactic and semantic parsing tools used in BlonDe. Unlike previously proposed metrics, BlonDe does not only focus on one specific discourse phenomenon, and thus has significantly higher Pearson correlation coefficients with human assessments.

7 Conclusion

In this paper, we build a large-scale parallel dataset for document-level translation, BWB. We analyze it for common document-level translation errors in practice and propose BLONDE, an interpretable automatic metric for document-level MT evaluation. We further improve BLONDE by diagnosing and distilling discourse-related errors in MT outputs and human-annotations to obtain two improved metrics BLOND-D and BLOND+. These metrics were shown to have better selectivity than various sentence-level metrics and correlate better with human judgments.

Ethical Considerations

The annotators were paid a fair wage and the annotation process did not solicit any sensitive information from the annotators. Finally, while our approach is not tuned for any specific real-world application, the approach could be used in sensitive contexts such as legal or health-care settings, and any work must use our approach undertake extensive quality-assurance and robustness testing before using it in their setting.

Replicability. As part of our contributions, we will release the annotated BWB test set, and release the crawling script of the training set under Fair Use rules. The BLONDE package is also publicly available at `https://github.com/EleanorJiang/BlonDe`.

A Dataset Creation

The Background of Translators. The original Chinese books are translated by professional native English speakers, and are corrected by editors.

Data Collection. This process is implemented by a python web crawler, and certain data cleaning is also done in the process. We crawl the books chapter by chapter, and convert the text to UTF-8. After deduplication, we remove the chapters with less than 5 sentences. We further remove the titles of each chapter, because most of them are neither translated properly nor in the document-level.

Alignment and Quality Control. After collecting the web books, we align the bilingual books chapter by chapter according to the indices, while removing those chapters without parallel data. Then, we use Bluealign, which is an MT-based sentence alignment tool, to align the chapters into parallel sentences, while retaining the document-level information. We further deduplicate the parallel corpus and filter the pairs with a sequence ratio of 3.0. The scale of the final corpus is 384 books with 9,581,816 sentence pairs (a total of 460 million words). To estimate the accuracy of this process, we hired 4 bilingual graduate students to manually evaluate 163 randomly selected documents from the resulting BWB parallel corpus. These students are native Chinese speakers who are proficient in English. More specifically, they were asked to distinguish whether a document is well aligned at the sentence level by counting the number of misalignment. For example, if Line 39 in English actually corresponds to Line 39 and Line 40 in Chinese, but the tool made a mistake that it combines the two sentences, it is identified as a misalignment. We observe an alignment accuracy rate of 93.1%.

We further asked the same batch of annotators to correct such misalignments in both the development and the test set. The annotation result shows that 7.3% lines are corrected.

B Error Analysis and BLOND+ Annotation

Error analysis and BLOND+ annotation are conducted together. This task is conducted by eight professional Chinese-English translators who are native in Chinese and fluent in English.

The guideline is as follows:

- First, identify cases which have translation errors. The annotators are instructed to mark examples as "translations with no error" only if it satisfies the criteria of both adequacy and fluency as well as satisfies the criterion that it is coherent in the context.
- Second, identify whether the translation contains document-level error or sentence-level error (or both). The annotators are instructed to mark examples as "cases with sentence-level errors" when they are not adequate or fluent as stand-alone sentences; while "document-level errors" mean those errors that cause the example violating the global criterion of coherence.
- Third, categorize the examples with document-level errors according to the linguistic phenomena that lead to errors in MT outputs when considering context.

We first conduct a test annotation and observe that the annotators categorize document-level errors into mainly into 3 categories, namely inconsistency, ellipsis, and ambiguity. According to this observation, we instruct annotators to mark document-level errors as *inconsistency*, *ellipsis*, and *ambiguity*, or *other document-level error* during the annotation process for the entire test set.

In the formal annotation process, we also added the requirement to annotate BLOND+ spans. The detailed requirement is as follows:

- Third, categorize the examples with document-level into 4 categories: inconsistency, ellipsis, and ambiguity, or other document-level error which cannot be categorized.
- Fourth, if the example is categorized as *ambiguity*, mark the specific word/phrase in the reference (English) that cause ambiguity and give the correct word/phrase.
- Fifth, if the example is categorized as *ellipsis* and it is *not* related to pronouns or discourse markers, mark the omitted word/phrase in the reference (English).

C Human Post-Editing

This task is conducted by the same eight professional Chinese-English translators who carry out the annotation in Appendix B. We asked them to follow guidelines for achieving "good enough"

CATEGORIES	DESCRIPTION	MARKERS
`contingency`	only consider “cause"	[“but", “while", “however", “although", “though", “still", “yet", “whereas", “on the other hand", “in contrast", “by contrast", “by comparison", “conversely"]
`comparison`	combine “concession” and “contrast”	[“if”, “because”, “so”, “since”, “thus”, “hence”, “as a result”, “therefore”, “thereby”, “accordingly”, “consequently”, “in consequence”, “for this reason”]
`expansion`	only consider “conjunction”	[“also”, “in addition”, “moreover”, “additionally”, “besides”, “else,”, “plus”]
`temporal`	“synchronous” ”asynchronous”	[“meantime”, “meanwhile”, “simultaneously”] [“when”, “after”, “then”, “before”, “until”, “later”, “once”, “afterward”, “next”]

BWB	Books	196k	9M

Table 7: Comparison of different document-level datasets.

quality at the sentence-level (comprehensible, accurate but as not being stylistically compelling) but especially pay attention to document-level errors and correct them.

D The Human Evaluation Protocol

The human evaluation is conducted on outputs of four systems (OMT-B, MT-S, CTX, PE) and human translation. We follow the protocol proposed by (Läubli et al., 2018, 2020). We conduct the evaluation experiment with a 2×2 mixed factorial design, carrying both DOCUMENT-level and SENTENCE-level evaluation in terms of ADEQUACY and FLUENCY. In the SENTENCE-level evaluation, we show raters isolated sentences in random order; while in the DOCUMENT-level evaluation, entire documents are presented and we only ask raters to evaluate a sequence of 5 sequential sentences at a time in order.

To avoid reference bias, the ADEQUACY evaluation is only based on source texts, while no source texts nor references are presented in the FLUENCY evaluation. We adopt Relative Ranking (RR): raters are presented with outputs from the aforementioned five systems, which they are asked to evaluate relative to each other, e.g., to determine system A is better than system B (with ties allowed).

We use source sentences and documents from the BWB test set, but blind their origins by randomizing both the order in which the system outputs are presented. Note that in the DOCUMENT-level evaluation, the same ordering of systems is used within a document. The order of experimental items is also randomised. Sentences are randomly drawn from these documents, regardless of their position.

We also use spam items for quality control (Kittur et al., 2008): In a small fraction of items, we render one of the five options nonsensical by randomly shuffling the order of all translated words, except for 10% at the beginning and end. If a rater marks a spam item as better than or equal to an actual translation, this is a strong indication that they did not read both options carefully. At the DOCUMENT-level, we render one of the five options nonsensical by randomly shuffling the order of all translated sentences, except for the first and the last sentence.

We recruit four professional Chinese to English translators and four native English revisers for the adequacy and fluency conditions respectively. Note that the eight translators are different from those professional translators who carry out the human translation PE. We deliberately invite another group of specialists for human evaluation to avoid making unreasonable judgments biased towards PE. In each condition, each raters evaluate 162 documents (plus 18 spam items) and 162 sentences (plus 18 spam

	SENTENCE	DOCUMENT
RATER1-RATER2	.171	.169
RATER3-RATER4	.294	.346
RATER5-RATER6	.323	.402
RATER7-RATER8	.378	.342

Table 8: Inter-rater agreements measure by Cohen's κ, where RATER1-4 are professional translators whose native language is Chinese, RATER5-8 are native English revisers.

items). We use two non-overlapping sets of documents and two non-overlapping sets of sentences, and each is evaluated by two raters. Specifically, we refer the first half of the test set as PART1 and the second half as PART2. Note that PART1 and PART2 are chosen from different books. Each rater evaluates both sentences and documents, but never the same text in both conditions so as to avoid repetition priming (Gonzalez et al., 2011): RATER1 and RATER2 conduct the DOCUMENT-level ADEQUACY evaluation on 180 documents sampled from PART1 and the SENTENCE-level ADEQUACY evaluation for PART2; RATER3 and RATER4 conduct the SENTENCE-level FLUENCY evaluation on 180 documents sampled from PART1 and the DOCUMENT-level FLUENCY evaluation for PART2; RATER5 and RATER6 conduct the DOCUMENT-level FLUENCY evaluation on 180 documents sampled from PART1 and the SENTENCE-level FLUENCY evaluation for PART2; RATER7 and RATER8 conduct the SENTENCE-level FLUENCY evaluation on 180 documents sampled from PART1 and the DOCUMENT-level FLUENCY evaluation for PART2.

E Statistical Analysis of Human Evaluation

We calculate Cohen's kappa coefficient:

$$\kappa = \frac{P(A) - P(E)}{1 - P(E)} \tag{16}$$

where $P(A)$ is the proportion of times that two raters agree, and $P(E)$ is the likelihood of agreement by chance. We report pairwise inter-rater agreement in Table 8.

F Experiment Settings

F.1 BLONDE

We use the named entity recognition module and the POS tagger of spaCy (Honnibal and Montani, 2017) to implement the categorizing function cat for ENTITY and TENSE, respectively. We use the script provided by Sileo et al. (2019) as the discourse marker minor.

F.2 Model Hyperparameters

We follow the setup of Transformer big model for BWB experiments. More precisely, the parameters in the big encoders and decoders are $N = 12$, the number of heads per layer is $h = 16$, the dimensionality of input and output is $d_{model} = 1024$, and the inner-layer of a feed-forward networks has dimensionality $d_{ff} = 4096$. The dropout rate is fixed as 0.3. We adopt Adam optimizer with $\beta_1 = 0.9, \beta_2 = 0.98, \epsilon = 10^{-9}$, and set learning rate 0.1 of the same learning rate schedule as Transformer. We set the batch size as 6,000 and the update frequency as 16 for updating parameters to imitate 128 GPUs on a machine with 8 V100 GPU. The datasets are encoded by BPE with 60K merge operations.

Disentangled Learning of Stance and Aspect Topics for Vaccine Attitude Detection in Social Media

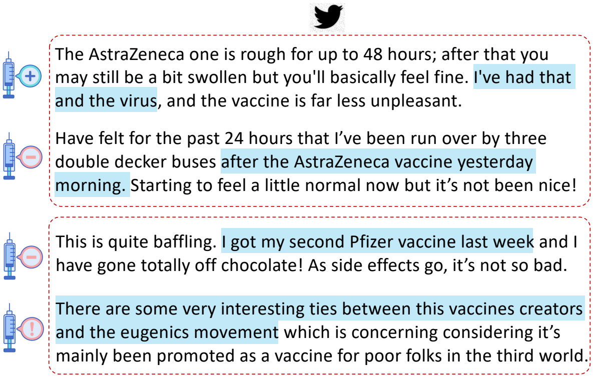
Abstract

Building models to detect vaccine attitudes on social media is challenging because of the composite, often intricate aspects involved, and the limited availability of annotated data. Existing approaches have relied heavily on supervised training that requires abundant annotations and pre-defined aspect categories. Instead, with the aim of leveraging the large amount of unannotated data now available on vaccination, we propose a novel semi-supervised approach for vaccine attitude detection, called VADET. A variational autoencoding architecture based on language models is employed to learn from unlabelled data the topical information of the domain. Then, the model is fine-tuned with a few manually annotated examples of user attitudes. We validate the effectiveness of VADET on our annotated data and also on an existing vaccination corpus annotated with opinions on vaccines. Our results show that VADET is able to learn disentangled stance and aspect topics, and outperforms existing aspect-based sentiment analysis models on both stance detection and tweet clustering. Our source code and dataset are available at `http://github.com/somethingx1202/VADet`.

1 Introduction

The aim of vaccine attitude detection in social media is to extract people's opinions towards vaccines by analysing their online posts. This is closely related to aspect-based sentiment analysis in which both aspects and related sentiments need to be identified. Previous research has been largely focused on product reviews and relied on aspect-level sentiment annotations to train models (Barnes et al., 2021), where aspect-opinions are extracted as triples (Peng et al., 2020), polarized targets (Ma et al., 2018) or sentiment spans (He et al., 2019). However, for the task of vaccine attitude detection on Twitter, such a volume of annotated data is barely available (Kunneman et al., 2020; Paul et al., 2021). This scarcity of data is compounded by the diversity of attitudes, making it difficult for models to identify all aspects discussed in posts (Morante et al., 2020).



The AstraZeneca one is rough for up to 48 hours; after that you may still be a bit swollen but you'll basically feel fine. I've had that and the virus, and the vaccine is far less unpleasant.

Have felt for the past 24 hours that I've been run over by three double decker buses after the AstraZeneca vaccine yesterday morning. Starting to feel a little normal now but it's not been nice!

This is quite baffling. I got my second Pfizer vaccine last week and I have gone totally off chocolate! As side effects go, it's not so bad.

There are some very interesting ties between this vaccines creators and the eugenics movement which is concerning considering it's mainly been promoted as a vaccine for poor folks in the third world.

Figure 1: **Top:** Expressions of aspects entangled with expressions of opinions. **Bottom:** Vaccine attitudes can be expressed towards a wide range of aspects/topics relating to vaccination, making it difficult to pre-define a set of aspect labels as opposed to corpora typically used for aspect-based sentiment analysis.

As representative examples, consider the two tweets about personal experiences for vaccination at the top of Figure 1. The two tweets, despite addressing a common aspect (vaccine side-effects), express opposite stances towards vaccines. However, the aspect and the stances are so fused together that the whole of the tweets need to be considered to derive the proper labels, making it difficult to disentangle them using existing methodologies. Additionally, in the case of vaccines attitude analysis, there is a wide variety of possible aspects discussed in posts, as shown in the bottom of Figure 1, where one tweet ironically addressed vaccine side-effects and the second one expressed instead specific political concerns. This is different from traditional aspect-based sentiment analysis on product reviews where only a small number of aspects need to be pre-defined.

The recently developed framework for integrating Variational Auto-Encoder (VAE) (Kingma and

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1566 - 1580
July 10-15, 2022 ©2022 Association for Computational Linguistics

Welling, 2014) and Independent Component Analysis (ICA) (Khemakhem et al., 2020) sheds light on this problem. VAE is an unsupervised method that can be used to glean information that must be retained from the vaccine-related corpus. Meanwhile, a handful of annotations would induce the separation of independent factors following the ICA requirement for prior knowledge and inductive biases (Hyvarinen et al., 2019; Locatello et al., 2020a,b). To this end, we could disentangle the latent factors that are either specific to the aspect or to the stance, and improve the quality of the latent semantics learned from unannotated data.

We frame the problem of vaccine attitude detection as a joint aspect span detection and stance classification task, assuming that a tweet, which is limited to 280 characters, would usually only discuss one aspect. In particular, we extend a pre-trained language model (LM) by adding a topic layer, which aims to model the topical theme discussed in a tweet. In the absence of annotated data, the topic layer is trained to reconstruct the input message built on VAE. Given the annotated data, where each tweet is annotated with an aspect span and a stance label, the learned topic can be disentangled into a stance topic and an aspect topic. The stance topic is used to predict the stance label of the given tweet, while the aspect topic is used to predict the start and the ending positions of the aspect span. By doing so, we can effectively leverage both unannotated and annotated data for model training.

To evaluate the effectiveness of our proposed model for vaccine attitude detection on Twitter, we have collected over 1.9 million tweets relating to COVID vaccines between February and April 2021. We have further annotated 2,800 tweets with both aspect spans and stance labels. In addition, we have also used an existing Vaccination Corpus[1] in which 294 documents related to the online vaccination debate have been annotated with opinions towards vaccination. Our experimental results on both datasets show that the proposed model outperforms existing opinion triple extraction model and BERT QA model on both aspect span extraction and stance classification. Moreover, the learned latent aspect topics allow the clustering of user attitudes towards vaccines, facilitating easier discovery of positive and negative attitudes in social media. The contribution of this work can be summarised as follows:

- We have proposed a novel semi-supervised approach for joint latent stance/aspect representation learning and aspect span detection;
- The developed disentangled representation learning facilitates better attitude detection and clustering;
- We have constructed an annotated dataset for vaccine attitude detection.

2 Related Work

Our work is related to three lines of research: aspect-based sentiment analysis, disentangled representation learning, and vaccine attitude detection.

Aspect-Based Sentiment Analysis (ABSA) aims to identify the aspect terms and their polarities from text. Much work has been focusing on this task. The techniques used include Conditional Random Fields (CRFs) (Marcheggiani et al., 2014), Bidirectional Long Short-Term Memory networks (BiLSTMs) (Baziotis et al., 2017), Convolutional Neural Networks (CNNs) (Zhang et al., 2015b), Attention Networks (Yang et al., 2016; Pergola et al., 2021b), DenseLSTMs (Wu et al., 2018), NestedLSTMs (Moniz and Krueger, 2017), Graph Neural Networks (Zhang et al., 2019) and their combinations (Wang et al., 2018; Zhu et al., 2021; Wan et al., 2020), to name a few.

Zhang et al. (2015a) framed this task as text span detection, where they used text spans to denote aspects. The same annotation scheme was employed in (Li et al., 2018b), where intra-word attentions were designed to enrich the representations of aspects and predict their polarities. Li et al. (2018c) formalized the task as a sequence labeling problem under a unified tagging scheme. Their follow-up work (Li et al., 2019) explored BERT for end-to-end ABSA. Peng et al. (2020) modified this task by introducing opinion terms to shape the polarity. A similar modification was made in (Zhao et al., 2020) to extract aspect-opinion pairs. Position-aware tagging was introduced to entrench the offset between the aspect span and opinion term (Xu et al., 2020). More recently, instead of using pipeline approaches or sequence tagging, Barnes et al. (2021) adapted syntactic dependency parsing to perform aspect and opinion expression extraction, and polarity classification, thus formalizing the task as structured sentiment analysis.

Disentangled representation learning Deep generative models learn the hidden semantics of text, of which many attempt to capture the independent latent factor to steer the generation of text in the context of NLP (Hu et al., 2017; Li et al., 2018a; Pergola et al., 2019; John et al., 2019; Li et al., 2020). The majority of the aforementioned work employs VAE (Kingma et al., 2014) to learn controllable factors, leading to the abundance of VAE-based models in disentangled representation learning (Higgins et al., 2017; Burgess et al., 2018; Chen et al., 2018). However, previous studies show that unsupervised learning of disentanglement by optimising the marginal likelihood in a generative model is impossible (Locatello et al., 2019). While it is also the case that non-linear ICA is unable to uncover the true independent factors, Khemakhem et al. (2020) established a connection between those two strands of work, which is of particular interest to us since the proposed framework learns to approximate the true factorial prior given few examples, recovering a disentangled latent variable distribution on top of additionally observed variables. In this paper, stance labels and aspect spans are additionally observed on a handful of data, which could be used as inductive biases that make disentanglement possible.

Vaccine attitude detection Very little literature exists on attitude detection for vaccination. In contrast, there is growing interest in Covid-19 corpus construction (Shuja et al., 2021). Of particular interest to us, Banda et al. (2021) built an on-going tweet dataset that traces the development of Covid-19 by 3 keywords: “coronavirus”, “2019nCoV” and “corona virus”. Hussain et al. (2021) utilized hydrated tweets from the aforementioned corpus to analyze the sentiment towards vaccination. They used lexicon-based methods (i.e., VADER and TextBlob) and pre-trained BERT to classify the sentiment in order to gain insights into the temporal sentiment trends. A similar approach has been proposed in (Hu et al., 2021). Lyu et al. (2021) employed a topic model to discover vaccine-related themes in twitter discussions and performed sentiment classification using lexicon-based methods. However, none of the work above constructed datasets about vaccine attitudes, nor did they train models to detect attitudes. Morante et al. (2020) built the Vaccination Corpus (VC) with events, attributions and opinions annotated in the form of text spans, which is the only dataset available to us to perform attitude detection.

3 Methodology

The goal of our work is to detect the stance expressed in a tweet (i.e., ‘*pro-vaccination*’, ‘*anti-vaccination*’, or ‘*neutral*’), identify a text span that indicates the concerning aspect of vaccination, and cluster tweets into groups that share similar aspects. To this end, we propose a novel latent representation learning model that jointly learns a stance classifier and disentangles the latent variables capturing stance and aspect respectively. Our proposed Vaccine Attitude Detection (VADET) model is firstly trained on a large amount of unannotated Twitter data to learn latent topics via masked Language Model (LM) learning. It is then fine-tuned on a small amount of Twitter data annotated with stance labels and aspect text spans for simultaneously stance classification and aspect span start/end position detection. The rationale is that the inductive bias imposed by the annotations would encourage the disentanglement of latent stance topics and aspect topics. In what follows, we will present our proposed VADET model, first under the masked LM learning and later extended to the supervised setting for learning disentangled stance and aspect topics.

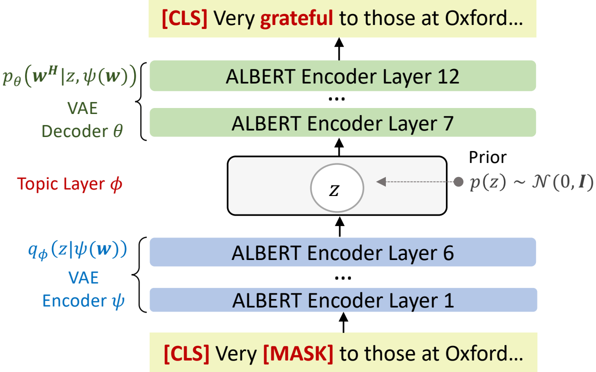

Figure 2: VADET in masked language model learning. The latent variables are encoded via the topic layers incorporated into the masked language model.

VADET in the masked LM learning We insert a topic layer into a pre-trained language model such as ALBERT, as shown in Figure 2, allowing the network to leverage pre-trained information while fine-tuned on an in-domain corpus. We assume that there is a continuous latent variable z involved in the language model to reconstruct the original text from the masked tokens. We retain the weights of a language model and learn the latent representa-

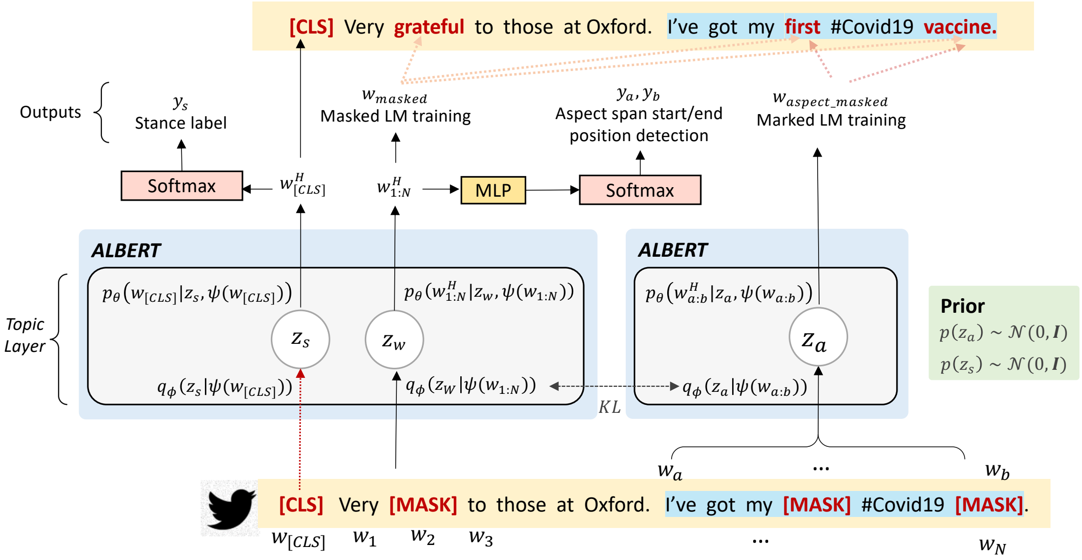

Figure 3: VADET in supervised learning. The text segment highlighted in blue is the annotated aspect span. The right part learns latent aspect topic z_a from aspect text span $[w_a : w_b]$ only under masked LM learning. The left part learns jointly latent stance topic z_s and latent aspect topic z_w from the whole input text, and trained simultaneously for stance classification and aspect start/end position detection.

tion during the fine-tuning. More concretely, the topic layer partitions a language model into lower layers and higher layers denoted as ψ and θ, respectively. The lower layers constitute the Encoder that parameterizes the variational posterior distribution denoted as $q_\phi(z|\psi(\mathbf{w}))$, while the higher layers reconstruct the input tokens, which is referred to as the Decoder.

The objective of VAE is to minimize the KL-divergence between the variational posterior distribution and the approximated posterior. This is equivalent to maximizing the Evidence Lower BOund (ELBO) expressed as:

$$\mathbb{E}_{q_\phi(z|\psi(\mathbf{w}))}[\log p_\theta(\mathbf{w}^H|z, \psi(\mathbf{w}))] - \mathrm{KL}[q_\phi(z|\psi(\mathbf{w}))||p(z)], \tag{1}$$

where $q_\phi(z|\psi(\mathbf{w}))$ is the encoder and $p_\theta(\mathbf{w}^H|z, \psi(\mathbf{w}))$ is the decoder. Here, $\mathbf{w} = [w_{\mathrm{CLS}}, w_{1:n}]$, since the special classification embedding w_{CLS} is automatically prepended to the input sequence (Devlin et al., 2019), $\mathbf{w}^H$ denotes the reconstructed input.

Following (Kingma and Welling, 2014), we choose a standard Gaussian distribution as the prior, denoted as $p(z)$, and the diagonal Gaussian distribution $z \sim \mathcal{N}(\mu_\phi(\psi(\mathbf{w})), \sigma^2_\phi(\psi(\mathbf{w})))$ as the variational distribution. The decoder computes the probability of the original token given the latent variable sampled from the Encoder. We use the Memory Scheme (Li et al., 2020) to concatenate z and $\psi(\mathbf{w})$, making the latent representation compatible for higher layers of the language model. Then the latent presentation z is passed to θ to reconstruct the original text.

VADET with disentanglement of aspect and stance One of the training objectives of vaccine attitude detection is to detect the text span that indicates the aspect and to predict the associated stance label. Existing approaches rely on structured annotations to indicate the boundary and dependency between aspect span and opinion words (Xu et al., 2020; Barnes et al., 2021), or use a two-stage pipeline to detect the aspect span and the associated opinion separately (Peng et al., 2020). The problem is that the opinion expressed in a tweet and the aspect span often overlap. To mitigate this issue, we instead separate the stance and aspect from their representations in the latent semantic space, that is, disentangling latent topics learned by VADET into latent stance topics and latent aspect topics. A recent study in disentangled representation learning (Locatello et al., 2019) shows that unsupervised learning of disentangled representations is theoretically impossible from i.i.d. observations without inductive biases, such as grouping information (Bouchacourt et al., 2018) or access to labels (Locatello et al., 2020b; Träuble et al., 2021). As such, we extend our model to a supervised setting in which disentanglement of the latent vectors can be trained on annotated data.

Figure 3 outlines the overall structure of VADET in the supervised setting. On the right hand side, we show VADET learned from the annotated aspect text span $[w_a : w_b]$ under masked LM learning. The latent variable z_a encodes the hidden semantics of the aspect expression. We posit that the aspect span is generated from a latent representation with a standard Gaussian distribution being its prior. The ELBO for reconstructing the aspect text span is:

$$\begin{aligned}\mathcal{L}_A = \mathbb{E}_{q_\phi(z_a|\psi(w_{a:b}))}&[\log p_\theta(w^H_{a:b}|z_a, \psi(w_{a:b}))] \\ &-\mathrm{KL}[q_\phi(z_a|\psi(w_{a:b}))||p(z_a)],\end{aligned} \quad (2)$$

where $w^H_{a:b}$ denotes the reconstructed aspect span. Ideally, the latent variable z_a does not encode any stance information and only captures the aspect mentioned in the sentence. Therefore, the z_s for the language model on the right hand side is detached and the reconstruction loss for `[CLS]` is set free.

On the left hand side of Figure 3, we train VADET on the whole sentence. The input to VADET is formalized as: '`[CLS] text`'. Instead of mapping an input to a single latent variable z, as in masked LM learning of VADET, the input is now mapped to a latent variable decomposing into two components, $[z_s, z_w]$, one for the stance and another for the aspect. We use a conditionally factorized Gaussian prior over the latent variable $z_w \sim p_\theta(z_w|w_{a:b})$, which enables the separation of z_s and z_w since the diagonal Gaussian is factorized and the conditioning variable $w_{a:b}$ is observed.

We establish an association between z_w and z_a by specifying $p_\theta(z_w|w_{a:b})$ to be the encoder network of $q_\phi(z_a|w_{a:b})$, since we want the latent semantics of aspect span to encourage the disentanglement of attitude in the latent space. In other words, the prior of z_w is configured as the approximate posterior of z_a to enforce the association between the disentangled aspect in sentence and the *de facto* aspect. As a result, the ELBO for the original text is written as

$$\begin{aligned}\mathbb{E}_{q_\phi(z_w|\psi(\mathbf{w}))}&[\log p_\theta(\mathbf{w}^H|z_w, \psi(\mathbf{w}))] \\ &-\mathrm{KL}[q_\phi(z_w|\psi(\mathbf{w}))||q_\phi(z_w|\psi(w_{a:b}))],\end{aligned} \quad (3)$$

where $\mathbf{w}^H$ denotes the reconstructed input text, $z_w|\mathbf{w} \sim \mathcal{N}(\mu_\phi(\psi(\mathbf{w})), \sigma^2_\phi(\psi(\mathbf{w})))$. The KL-divergence allows for some variability since there might be some semantic drift from the original semantics when the aspect span is placed in a longer sequence.

The annotation of the stance label provides an additional input. To exploit this inductive bias, we enforce the constraint that z_s participates in the generation of `[CLS]`, which follows an approximate posterior $q_\phi(z_s|\psi(\mathbf{w}_{\texttt{[CLS]}}))$. We place the standard Gaussian as the prior over $z_s \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$ and obtain the ELBO

$$\begin{aligned}\mathbb{E}_{q_\phi(z_s|\psi(\mathbf{w}_{\texttt{[CLS]}}))}&[\log p_\theta(w^H_{\texttt{[CLS]}}|z_s, \psi(\mathbf{w}_{\texttt{[CLS]}}))] \\ &-\mathrm{KL}[q_\phi(z_s|\psi(\mathbf{w}_{\texttt{[CLS]}}))||p(z_s)]\end{aligned} \quad (4)$$

Since the variational family in Eq. 1 are Gaussian distributions with diagonal covariance, the joint space of $[z_s, z_w]$ factorizes as $q_\phi(z_s, z_w|\psi(\mathbf{w})) = q_\phi(z_s|\psi(\mathbf{w}))q_\phi(z_w|\psi(\mathbf{w}))$ (Nalisnick et al., 2016). Assuming z_w to be solely dependent on $\psi(w_{1:n})$, we obtain the ELBO for the entire input sequence:

$$\begin{aligned}\mathcal{L}_S = \mathbb{E}_{q_\phi(z_w)}&\mathbb{E}_{q_\phi(z_s)}[\log p_\theta(\mathbf{w}^H|z, \psi(\mathbf{w}))] \\ &- \mathrm{KL}\left[q_\phi(z_w|\psi(w_{1:n}))||q_\phi(z_w|\psi(w_{a:b}))\right] \\ &- \mathrm{KL}[q_\phi(z_s|\psi(\mathbf{w}))||p(z_s)].\end{aligned} \quad (5)$$

Note that the expectation term can be decomposed into the expectation term in Eq. 3 and Eq. 4 according to the decoder structure. For the full derivation, please refer to Appendix A.

Finally, we perform stance classification and classification for the starting and ending position over the aspect span of a tweet. We use negative log-likelihood loss for both the stance label and aspect span:

$$\begin{aligned}\mathcal{L}_s &= -\log p(y_s|w^H_{\texttt{[CLS]}}), \\ \mathcal{L}_a &= -\log p(y_a|\mathrm{MLP}(w^H_{1:n})) - \log p(y_b|\mathrm{MLP}(w^H_{1:n})),\end{aligned}$$

where MLP is a fully-connected feed-forward network with tanh activation, y_s is the predicted stance label, y_a and y_b are the starting and ending position of the aspect span. The overall training objective in the supervised setting is:

$$\mathcal{L} = \mathcal{L}_s + \mathcal{L}_a - \mathcal{L}_S - \mathcal{L}_A$$

4 Experiments

We present below the experimental setup and evaluation results.

4.1 Experimental Setup

Datasets We evaluate our proposed VADET and compare it against baselines on two vaccine attitude datasets.

VAD is our constructed **V**accine **A**ttitude **D**ataset. Following (Hussain et al., 2021), we crawl tweets using the Twitter streaming API with 60 predefined keywords[2] relating to COVID-19 vaccines

---

[2] The full keyword list and the details of dataset construction are presented in Appendix B.

	VAD		VC	
Specification	Train	Test	Train	Test
# tweets	2000	800	1162	531
# anti-vac.	638	240	822	394
# neutral	142	76	41	27
# pro-vac.	1220	484	299	110
Avg. length	33.5	34.13	29.6	30.24
len(aspect)	17.5	18.75	1.03	1.08
len(opinion)	27.97	29.01	3.25	3.15
# tokens	67k	27.3k	34.4k	16.8k

Table 1: Dataset Statistics. '# tweets' denotes the number of tweets in VAD, and for VC it is the number of sentences. 'anti-vac.' means *anti-vaccination* while 'pro-vac.' means *pro-vaccination*. 'Avg. length' and '# token' measure the number of word tokens.

(e.g., *Pfizer*, *AstraZeneca*, and *Moderna*). Our final dataset comprises 1.9 million English tweets collected between February 7th and April 3rd, 2021. We randomly sample a subset of tweets for annotation. Upon an initial inspection, we found that over 97% of tweets mentioned only one aspect. As such, we annotate each tweet with a stance label and a text span characterizing the aspect. In total, 2,800 tweets have been annotated in which 2,000 are used for training and the remaining 800 are used for testing. The statistics of the dataset is listed in Table 1. The stance labels are imbalanced. On the other hand, the average opinion length is longer than the average aspect length, and is close to the average tweet length. For the purpose of evaluation on tweet clustering and latent topic disentanglement, we further annotate tweets with a categorical label indicating the aspect category. Inspired by (Morante et al., 2020), we identify 24 aspect categories[3] and each tweet is annotated with one of these categories. It is worth mentioning that aspect category labels are not used for training.

VC (Morante et al., 2020) is a vaccination corpus consisting of 294 Internet documents about online vaccine debate annotated with events, 210 of which are annotated with opinions (in the form of text spans) towards vaccines. The stance label is considered to be the stance for the whole sentence. Those sentences with conflicting stance labels are regarded as neutral. We split the dataset into a ratio of 2:1 for training and testing. This eventually left us with 1,162 sentences for training and 531 sentences for testing.

Baselines We compare the experimental results with the following baselines:

BertQA (Li et al., 2018c): a pre-trained language model well-suited for span detection. With BertQA, attitude detection is performed by first classifying stance labels then predicting the answer queried by the stance label. The text span is configured as the ground-truth answer. We rely on its HuggingFace[4] (Wolf et al., 2020) implementation. We employ ALBERT (Lan et al., 2020) as the backbone language model for both BertQA and VADET.

ASTE (Peng et al., 2020): a pipeline approach consisting of aspect extraction (Li et al., 2018c) and sentiment labelling (Li et al., 2018b).

Evaluation Metrics For stance classification, we use accuracy and Macro-averaged F1 score. For aspect span detection, we follow Rajpurkar et al. (2016) in adopting exact match (EM) accuracy of the starting-ending position and Macro-averaged F1 score of the overlap between the prediction and ground truth aspect span. For tweet clustering, we follow Xie et al. (2016) and Zhang et al. (2021) and use the Normalized Mutual Information (NMI) metric to measure how the clustered group aligns with ground-truth categories. In addition, we also report the clustering accuracy.

4.2 Experimental Results

In all our experiments, VADET is firstly pre-trained in an unsupervised way on our collected 1.9 million tweets before fine-tuned on the annotated training set from the VAD or VC corpora.

Stance Classification and Aspect Span Detection In Table 2, we report the performance on attitude detection. In stance classification, our model outperforms both baselines with more significant improvements on ASTE. On aspect span extraction, VADET yields even more noticeable improvements, with a 2.3% increase in F1 over BertQA on VAD, and 2.7% on VC. These results indicate that the successful prediction relies on the hidden representation learned in the unsupervised training. The disentanglement of stance and aspect may have also contributed to the improvement.

Clustering To assess whether the learned latent aspect topics would allow meaningful categorization of documents into attitude clusters, we perform

---

[3] The full list of aspect categories is shown in Table A1.

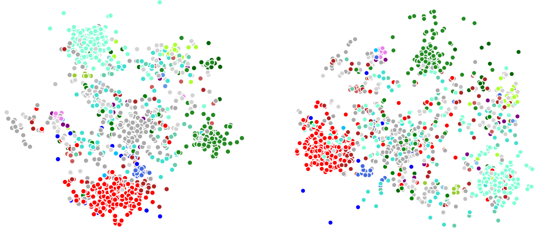
DEC (VADET)	**0.679**	**60.7**	**0.605**	**54.7**

Table 2: Results for stance classification, aspect span extraction and aspect clustering on both VAD and VC corpora.



(a) VADET (b) BertQA

Figure 4: Clustered groups of VADET and BertQA on the VAD dataset. Each color indicates a ground truth aspect category. The clusters are dominated by: *(1) Red: the (adverse) side effects of vaccines; (2) Green: explaining personal experiences with any aspect of vaccines; and (3) Cyan: the immunity level provided by vaccines.*

clustering using the disentangled representations that encode aspects, i.e., z_w. Deep Embedding Clustering (DEC) (Xie et al., 2016) is employed as the backend. For comparison, we also run DEC on the aspect representations of documents returned by BertQA. For each document, its aspect representation is obtained by averageing over the fine-tuned ALBERT representations of the constituent words in its aspect span. To assess the quality of clusters, we need the annotated aspect categories for documents in the test set. In VAD, we use the annotated aspect labels as the ground-truth categories whereas in VC we use the annotated event types. Results are presented in the lower part of Table 2. We found a prominent increase in NMI score over the baselines. Using the learned latent aspect topics as features, DEC (VADET) outperforms DEC (BertQA) by 4.6% and 1.9% in accuracy on VAD and VC, respectively. We also notice that using K-means as the clustering approach directly on the BERT-encoded tweet representations gives worse results compared to DEC. A similar trend is observed on the NMI metric. The improvements are shown visually in Figure 4 where the clustered groups produced by VADET are more identifiable. In the absence of categorical labels, the perspective expressed by each group can be inferred from the constituent tweets. For example, the tweet *'@user Georgian nurse dies of allergic reaction after receiving AstraZeneca Covid19 vaccine'* lies in the centroid of the red group, which relates to safety concerns.

Cluster Semantic Coherence Evaluation The semantic coherence is the extent to which tweets within a cluster belong to each other, which is employed as an evaluation metric for cluster quality evaluation in an unsupervised way. Recent work of Bilal et al. (2021) found that Text Generation Metrics (TGMs) align well with human judgement in evaluating clusters in the context of microblog posts. TGM by definition measures the similarity between the ground-truth and the generated text. The rationale is that a high TGM score means sentence pairs are semantically similar. Here, two metrics are used: *BERTScore*, which calculates the similarity of two sentences as a sum of cosine similarities between their tokens' embeddings (Zhang et al., 2020), and *BLEURT*, a pre-trained adjudicator that fine-tunes BERT on an external dataset of human ratings (Sellam et al., 2020). As in (Bilal et al., 2021), we adopt the Exhaustive Approach that for a cluster C, its coherence score is the average TGM score of every possible tweet pair in the cluster:

$$f(C) = \frac{1}{N^2} \sum_{i,j \in [1,N], i<j} \mathrm{TGM}(\mathrm{tweet}_i, \mathrm{tweet}_j).$$

Figure 5 shows the BERTScore and the BLEURT score of VADET and baselines on two datasets. The VADET shows consistent improvements across the datasets. This indicates that tweets clustered using the latent aspect topics generated by VADET are semantically more similar, thus validating the assumption that disentangled representations are more effective in bringing together tweets of a similar gist.

Conditional Perplexity Few metrics have been proposed to evaluate the quality of disentangled representations (Pergola et al., 2021a). Therefore, we

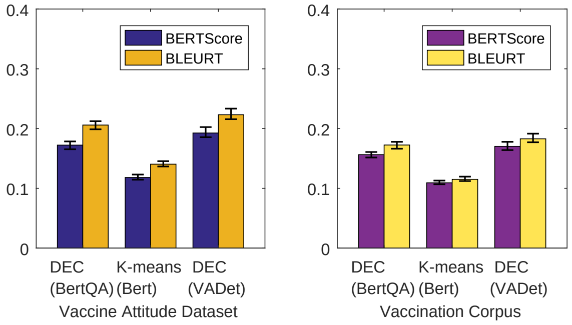


Figure 5: Semantic coherence evaluated in two metrics.

adopt the language model perplexity conditioned on z_a to evaluate the extent to which the disentangled representation improves language generation on held-out data. Perplexity is widely used in the literature of text style transfer (John et al., 2019; Yi et al., 2020), where the probability of the generated language is calculated conditioned on the controlled latent code. A lower perplexity score indicates better language generation performance. Following John et al. (2019), we compute an estimated aspect vector $\hat{z}_a^{(k)}$ of a cluster k in the training set as

$$\hat{z}_a^{(k)} = \frac{\sum_{i \in \text{cluster } k} z_{a,i}^{(k)}}{\#\text{ tweets in cluster } k},$$

where $z_{a,i}^{(k)}$ is the learned aspect vector of the i-th tweet in the k-th cluster. For the stance vector z_s, we sample one value per tweet. The stance vector is concatenated with the aspect vector $\hat{z}_a^{(k)}$ to calculate the probability of generating the held-out data, i.e., the testing set. For the baseline models, we choose β-VAE (Higgins et al., 2017) and SCHOLAR (Card et al., 2018). We train β-VAE on the same data with β set to different values. SCHOLAR is trained on tweet content and stance labels. For both the baselines we use ELBO on the held-out data as an upper bound on perplexity.

Figure 6 plots the perplexity score achieved by all the methods. Our model achieves the lowest perplexity score on both datasets. It managed to decrease the perplexity value by roughly 200 compared to the baseline models. SCHOLAR outperforms β-VAE under three settings of β value. We speculate that this might be due to the incorporation of the class labels in the training of SCHOLAR. Nevertheless, VADET produces congenial sentences in aspect groups, with latent codes tweaked to proxy centroids, showing that the disentangled representation does capture the desired factor.

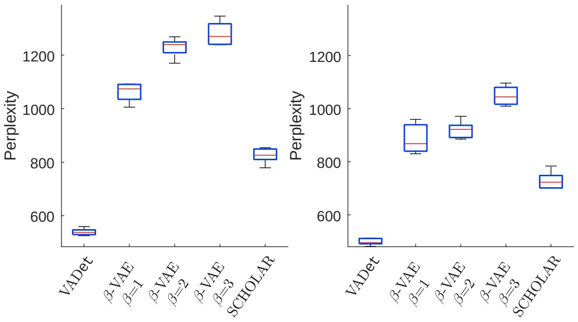

Figure 6: Conditional perplexity on two corpora.

Ablations We conduct ablation studies to investigate the effect of semi-supervised learning that uses the variational latent representation learning approach and aspect-stance disentanglement on the latent semantics. We study their effects on stance classification and aspect span detection. The results are reported in Table 3.

Model	VAD		VC	
Stance	Acc.	F1	Acc.	F1
VADET	**0.763**	**0.756**	0.727	0.713
VADET-D	0.751	0.746	**0.736**	**0.716**
VADET-U	0.741	0.734	0.712	0.698
Aspect Span	Acc.	F1	Acc.	F1
VADET	**0.556**	**0.745**	**0.541**	**0.697**
VADET-D	0.540	0.728	0.537	0.684
VADET-U	0.528	0.712	0.525	0.653

Table 3: Results of stance classification and aspect span detection of VADET without disentanglement (-D) or unsupervised pre-training (-U).

We can observe that on VAD without disentangled learning or unsupervised pre-training results in the degradation of the stance classification performance. However, on VC, we see a slight increase in classification accuracy without disentangled learning. We attribute this to the vagueness of the stance which might cause the model to disentangle more than it should be. On the aspect span detection task, we observe consistent performance drop across all metrics and on both datasets. In particular, without the pre-training module, the performance drops more significantly. These results indicate that semi-supervised learning is highly effective with VAE, and the disentanglement of stance and aspect serves as a useful component, which leads to noticeable improvements.

5 Conclusions

In this work, we presented a semi-supervised model to detect user attitudes and distinguish aspects of interest about vaccines on social media. We employed a Variational Auto-Encoder to encode the main topical information into the language model by unsupervised training on a massive, unannotated dataset. The model is then further trained under a semi-supervised setting that leverages annotated stance labels and aspect spans to induce the disentanglement between stances and aspects in a latent semantic space. We empirically showed the benefits of such an approach for attitude detection and aspect clustering over two vaccine corpora. Ablation studies show that disentangled learning and unsupervised pre-training are important to effective vaccine attitude detection. Further investigations on the quality of the disentangled representations verify the effectiveness of the disentangled factors. While our current work mainly focuses on short text of social media data where a sentence is assumed to discuss a single aspect, it would be interesting to extend our model to deal with longer text such as online debates in which multiple arguments or aspects may appear in a single sentence.

A Derivation of the Decomposed ELBO

Unsupervised training is based on maximizing the Evidence Lower Bound (ELBO):

$$\begin{aligned}&\mathbb{E}_{q_\phi(z_s,z_w|\psi(\mathbf{w}))}[\log p_\theta(\mathbf{w}|z_s,z_w,\psi(\mathbf{w}))]\\ &\quad-\mathrm{KL}[q_\phi(z_s,z_w|\psi(\mathbf{w}))||p(z_s,z_w)],\end{aligned}$$

where z is partitioned into z_s and z_w. Like standard VAE (Kingma and Welling, 2014), the variational distribution is a multivariate Gaussian with a diagonal covariance:

$$q_\phi(z_s,z_w|\psi(\mathbf{w}))=\mathcal{N}(z_s,z_w|\mu,\sigma^2 I),$$

where $\mu=[\mu^s,\mu^w]$ and $\sigma=[\sigma^s,\sigma^w]$. Since the coveriance matrix is diagonal, z_s and z_w are uncorrelated. Therefore, the joint probability is decomposed into:

$$q_\phi(z_s,z_w|\psi(\mathbf{w}))=q_\phi(z_s|\psi(\mathbf{w}))q_\phi(z_w|\psi(\mathbf{w})),$$

where $q_\phi(z_s|\psi(\mathbf{w}))=\mathcal{N}(z_s|\mu^s,\sigma^s)$, ϕ are the variational parameters. The prior of $[z_s,z_w]\sim\mathcal{N}(z_s,z_w|\mathbf{0},I)$ can also be decomposed into the product of $p(z_s)$ and $p(z_w)$, then the KL term becomes:

$$\mathrm{KL}[q_\phi(z_s|\psi(\mathbf{w}))||p(z_s)]+\mathrm{KL}[q_\phi(z_w|\psi(\mathbf{w}))||p(z_w)].$$

As for the decoder $p_\theta(\mathbf{w}|z_s,z_w,\psi(\mathbf{w}))$, the reconstruction of each masked token and $w_{\texttt{[CLS]}}$ are independent from each other, i.e., they are not predicted in an autoregressive way. Therefore, the joint probability is decomposed into:

$$\begin{aligned}&p_\theta(\mathbf{w}|z_s,z_w,\psi(\mathbf{w}))\\ &=p_\theta(w_{\texttt{[CLS]}}|z_s,z_w,\psi(\mathbf{w}))\,p_\theta(w_{1:n}|z_s,z_w,\psi(\mathbf{w}))\end{aligned}$$

We customize the decoder network to make $w_{\texttt{[CLS]}}$ solely dependent on z_s, and obtain

$$\begin{aligned}&\mathbb{E}_{q_\phi(z_s)}\mathbb{E}_{q_\phi(z_w)}[\log p_\theta(w_{\texttt{[CLS]}}|z_s,\psi(\mathbf{w}))+\\ &\qquad\qquad\log p_\theta(w_{1:n}|z_w,\psi(\mathbf{w}))]\end{aligned}$$

Here, we omit $\psi(\mathbf{w})$ for notational simplicity. Given the supervision of annotated aspect spans, the prior of z_w is constrained by $q_\phi(z_w|\psi(w_{a:b}))$ (a.k.a., the encoder of $w_{a:b}$), this will change the KL term into:

$$\begin{aligned}&\mathrm{KL}[q_\phi(z_s|\psi(\mathbf{w}))||p(z_s)]\\ &+\mathrm{KL}[q_\phi(z_w|\psi(w_{1:n}))||q_\phi(z_w|\psi(w_{a:b}))],\end{aligned}$$

and finally the ELBO is expressed as

$$\begin{aligned}&\mathbb{E}_{q_\phi(z_s)}[\log p_\theta(w_{\texttt{[CLS]}}|z_s,\psi(\mathbf{w}))]\\ &+\mathbb{E}_{q_\phi(z_w)}[\log p_\theta(w_{1:n}|z_w,\psi(\mathbf{w}))]\\ &-\mathrm{KL}[q_\phi(z_s|\psi(\mathbf{w}))||p(z_s)]\\ &-\mathrm{KL}[q_\phi(z_w|\psi(w_{1:n}))||q_\phi(z_w|\psi(w_{a:b}))].\end{aligned}$$

B Data Collection and Preprocessing

We are qualified Twitter Academic Research API [5] users. We obtained the ethical approval for our proposed research from the university's ethics committee before the start of our work. We collected tweets between February 7th and April 3rd, 2022 using 60 vaccine-related keywords. The exhaustive list is: *'covid-19 vax'*, *'covid-19 vaccine'*, *'covid-19 vaccines'*, *'covid-19 vaccination'*, *'covid-19 vaccinations'*, *'covid-19 jab'*, *'covid-19 jabs'*, *'covid19 vax'*, *'covid19 vaccine'*, *'covid19 vaccines'*, *'covid19 vaccination'*, *'covid19 vaccinations'*, *'covid19 jab'*, *'covid19 jabs'*, *'covid vax'*, *'covid vaccine'*, *'covid vaccines'*, *'covid vaccination'*, *'covid vaccinations'*, *'covid jab'*, *'covid jabs'*, *'coronavirus vax'*, *'coronavirus vaccine'*, *'coronavirus vaccines'*, *'coronavirus vaccination'*, *'coronavirus vaccinations'*, *'coronavirus jab'*, *'coronavirus jabs'*, *'Pfizer vaccine'*, *'BioNTech vaccine'*, *'Oxford vaccine'*, *'AstraZeneca vaccine'*, *'Moderna vaccine'*, *'Sputnik vaccine'*, *'Sinovac vaccine'*, *'Sinopharm vaccine'*, *'Pfizer jab'*, *'BioNTech jab'*, *'Oxford jab'*, *'AstraZeneca jab'*, *'Moderna jab'*, *'Sputnik jab'*, *'Sinovac jab'*, *'Sinopharm jab'*, *'Pfizer vax'*, *'BioNTech vax'*, *'Oxford vax'*, *'AstraZeneca vax'*, *'Moderna vax'*, *'Sputnik vax'*, *'Sinovac vax'*, *'Sinopharm vax'*, *'Pfizer vaccinate'*, *'BioNTech vaccinate'*, *'Oxford vaccinate'*, *'AstraZeneca vaccinate'*, *'Moderna vaccinate'*, *'Sputnik vaccinate'*, *'Sinovac vaccinate'*, *'Sinopharm vaccinate'*.

Only tweets in English were collected. Retweets were discarded. For pre-processing, hyperlinks, usernames and irregular symbols were removed. Emojis and emoticons were converted to their literal meanings using an emoticon dictionary[6].

C Hyper-parameters and Training Details

The dimensions of z_a, z_w and z_s are 768, 768 and 32, respectively. For each tweet, the number of samples from $\epsilon\sim\mathcal{N}(\mathbf{0},\mathbf{I})$ is 1. We modified the LM-fine-tuning script[7] from the HuggingFace library to implement VADET in the masked LM learning. We use default settings for the training

---

[5] https://developer.twitter.com/en/products/twitter-api/academic-research/application-info

[6] https://wprock.fr/en/t/kaomoji/

[7] https://github.com/huggingface/transformers/blob/master/examples/pytorch/language-modeling/run_mlm.py

script (i.e., Trainer in the HuggingFace library[8]), except for the batch size which is set to 128. The data pre-processor for the masked language model is the data collator for language modeling[9], which provides the function of randomly masking the tokens. The tokenizer for the data collator is the ready-to-use ALBERT tokenizer[10]. For the pre-trained language model (i.e., ALBERT) employed in this model, we inherit the default setting from the `AlbertConfig` class. We train VADET for 5 epochs on the un-annotated corpus.

In the supervised training of VADET, we use a batch size of 64. The learning rate is initialized to $2e-5$ with a linear warm-up schedule. We employ 5-fold training in which the training set is split into 5 subsets, of which 4 are used for training and the rest is for validation at the end of each epoch, and the final prediction is an ensemble of 5 independently-saved models. We train each model for 5 epochs, which takes roughly 2 hours on a node of single Nvidia RTX 2080 GPU.

D Annotation Guidelines

We invited two annotators who are PhD students and proficient in English to label each tweet with a stance label and an aspect span. Each annotator was instructed to answer four questions in a row. The four questions are:

- What is the stance towards vaccination?
- What is the Aspect Span? (i.e., Events or targets, it can be nouns, noun phrase, clause or sentence with verbal predicates).
- What is the opinion term/span? It should be opinion expressions, comprising both explicit and implicit expressions of stance.
- What is the Aspect category? It should be one of the pre-defined aspect categories (shown in Table A1).

The annotators have the choice to skip some of the questions if they find it difficult to answer. Taking the tweet ‘*Very grateful to those at Oxford. I’ve got my first #Covid19 vaccine.*’ as an example, the annotators are expected to answer with: ‘*Pro-vaccine*’, ‘*I’ve got my first #Covid19 vaccine*’, ‘*Very grateful to those at Oxford. I’ve got my first #Covid19 vaccine*’, ‘2’. If an annotator chooses to skip a tweet at any step of the process, this tweet will be recorded as skipped and the annotator will not be assigned with similar tweets.

We first had a trial run where each annotator was asked to annotate the same set of tweets. Any disagreement was recorded and discussed to refine our annotation guideline in order to achieve consistency between the annotators.

E Predefined Aspect Categories

Table A1 shows our pre-defined aspect categories, partly inspired by (Morante et al., 2020). These categories are only used in the evaluation of tweet clustering results, not for training.

SKILL: Structured Knowledge Infusion for Large Language Models

Fedor Moiseev[*] [1,2] **Zhe Dong**[†] [2] **Enrique Alfonseca** [2] **Martin Jaggi** [1]

Abstract

Large language models (LLMs) have demonstrated human-level performance on a vast spectrum of natural language tasks. However, it is largely unexplored whether they can better internalize knowledge from a structured data, such as a knowledge graph, or from text. In this work, we propose a method to infuse structured knowledge into LLMs, by directly training T5 models on factual triples of knowledge graphs (KGs). We show that models pre-trained on Wikidata KG with our method outperform the T5 baselines on FreebaseQA and WikiHop, as well as the Wikidata-answerable subset of TriviaQA and NaturalQuestions. The models pre-trained on factual triples compare competitively with the ones on natural language sentences that contain the same knowledge. Trained on a smaller size KG, WikiMovies, we saw 3× improvement of exact match score on MetaQA task compared to T5 baseline. The proposed method has an advantage that no alignment between the knowledge graph and text corpus is required in curating training data. This makes our method particularly useful when working with industry-scale knowledge graphs.

1 Introduction

Large pre-trained language models, such as BERT (Devlin et al., 2019), GPT-3 (Brown et al., 2020), T5 (Raffel et al., 2019), REALM (Guu et al., 2020) and ERNIE (Sun et al., 2021) have become the state-of-the-art technology for many tasks. They are commonly pre-trained using unstructured text corpora, on tasks such as next word prediction, next sentence prediction (NSP) or masked language modelling (MLM). Especially for T5, self-supervised learning on unlabelled text corpus with MLM has been a common pre-training recipe (Roberts et al., 2020). This is normally followed by a fine-tuning step on the task of interest (Ruder et al., 2019), although large language models have also proved useful without this task-specific fine-tuning (Brown et al., 2020).

Beyond the capacity of contextual understanding, human-level language understanding pivots on the knowledge about the world. The world knowledge is often expressed as factual triples (c.f. Ji et al., 2020), in the form of (*subject entity*, *relation*, *object entity*). A knowledge graph (KG) defined by a set of factual triples consists of the subjects and objects as vertices/nodes, and the relations forming the edges connecting them. Most of the large scale KGs (e.g. Wikidata, Vrandečić and Krötzsch, 2014) are stored in triple format.

LLMs demonstrate some capacity of learning world knowledge from the natural text corpus (Roberts et al., 2020), but it is unclear to what degree they are also able to learn and memorize new knowledge directly from structured KG triples, or from text describing them explicitly.

In order to infuse knowledge into a LLM, one option is to generate a textual version of the knowledge base, and apply the standard training objectives, e.g. MLM. This is unfortunately highly non-trivial. One can either align sentences with KG triples, as done in ERNIE (Sun et al., 2021), or generate sentences from triples, as done in KELM (Agarwal et al., 2021). These approaches are unfortunately hard to port to knowledge graphs with different schemas. These processes are also lossy in that not every triple can be aligned or produce a valid sentence, and there is not a good understanding whether this can introduce unnecessary selection biases on top of biases existing in the original KG.

In this work, we propose a method of **Knowledge Infusion for Large Language Models (SKILL)**, where LLMs directly learns from knowledge triples. Experiment results shows the checkpoints trained with proposed method on Wikidata KG outperform the T5 baselines on four standard

closed-book question-answering (QA) tasks. With a smaller KG, WikiMovies, the proposed method gain 3× exact match score performance improvement on MetaQA task. The models learning directly from knowledge triples performs competitively with the ones with the aligned natural sentences that contain the same amount of knowledge. Being able to learn directly from knowledge triples enables easy addition of structured knowledge into language modeling pre-training.

2 Related work

Previous works that use knowledge graphs to enhance the quality of knowledge-intensive downstream tasks can be divided into two groups: using knowledge graphs at the inference time, and infusing knowledge into the model weights at the pre-training time. The proposed method falls in the latter group.

Explicit usage of knowledge graphs. A retrieval-augmented model is commonly used, in order to retrieve and apply the knowledge from external memories or sources. FILM (Verga et al., 2021) and EaE (Févry et al., 2020) extend Transformer (Vaswani et al., 2017) models with external entity (both FILM and EaE) and fact (FILM) memories. REALM (Guu et al., 2020) is pre-trained to perform reasoning over a large textual knowledge corpus on-the-fly during inference. UniK-QA (Oguz et al., 2020) combines the structured and unstructured information to improve the open-domain QA tasks with a retriever-reader framework. The main difference between the proposed method, SKILL, and retrieval-augmented models is that SKILL doesn't introduce retrieval system or external memories to the model, but it directly embeds knowledge into the model parameters, which introduces no extra cost at inference time.

Knowledge infusion. A common way of parameterized knowledge infusion is to map or convert structured knowledges into natural language text. ERNIE 3.0 (Sun et al., 2021) trains a knowledge-enhanced model on a corpus combining triples and their aligned sentences, by randomly masking relation in a triple or words in a sentence. On the contrary, SKILL trains only on triples.

KnowBert (Peters et al., 2019) incorporates knowledge from Wikipedia and WordNet (Miller, 1995) into a BERT model through entity embeddings with knowledge-attention and recontextualization mechanism. BERT-MK (He et al., 2020) is a BERT-based model that integrates graph contextual knowledge of a medical KG, which demonstrates the utility of graph-level knowledge. These approaches requires entity linking and sentences contextualizing the knowledge graph information.

KG-FiD (Yu et al., 2021) extends the Fusion-in-Decoder model (Izacard and Grave, 2021) with a module that filters and re-ranks passages based on structural connections in knowledge graph between entities described in those passages. In contrast to the SKILL method that we propose, it requires the existence of natural text passages describing each knowledge graph entity, so Wikipedia corpus was used since it naturally provides articles that describe entities.

Heinzerling and Inui (2021) explored the ability of language models to memorize and understand information from knowledge graphs, but used natural language representation of triples based on predefined templates instead of structured representation. Usage of predefined templates significantly limits scalability and therefore only relatively small knowledge graphs were used, such as Google-RE[1].

In contrast to the new method presented in this paper, all of these approaches require an explicit mapping between the knowledge graph entities or facts and corresponding natural language sentences, which can limit applications to industry-scale knowledge graphs that don't have such a mapping.

Different goals of using knowledge graphs. Besides that, some papers embed knowledge into model weights but pursue different goals rather than improving performance on downstream tasks. COMET (Bosselut et al., 2019) is most similar to our work and trains a commonsense-aware Transformer Language Model by learning to generate loosely structured commonsense descriptions in the natural language given the structured knowledge. Similar to us, it also uses KG triples in surface form as a source for training data, but in contrast to our research, the final goal of COMET is to generate new knowledge instead of utilizing existing ones. Another important difference is the scale: COMET uses Atomic (Sap et al., 2019) and ConceptNet (Speer et al., 2017) Knowledge Graphs

---

[1] https://ai.googleblog.com/2013/04/50000-lessons-on-how-to-read-relation.html

that are much smaller than Wikidata (Vrandečić and Krötzsch, 2014).

KELM (Agarwal et al., 2021) fine-tunes a T5 model to convert KGs to synthetic natural language sentences to augment existing pre-training corpora. We build our research on top of it and use the KELM dataset to compare structured and natural language representations of knowledge.

3 Method

There are two components of knowledge infusion for LLMs (SKILL): the corpus and the training method. We introduce the method based on Wikidata KG, but it can be applied to any other KGs.

Training corpus. We use two corpora with different knowledge representations: Wikidata KG (Vrandečić and Krötzsch, 2014) in triple format, and KELM corpus[2] (Agarwal et al., 2021) as synthetic natural language sentences converted from Wikidata KG. The KELM corpus contains $15,628,486$ synthetic sentences. To ensure two corpora share the same knowledge, we take the snapshot of the Wikidata KG used to created the KELM corpus, which contains $35,697,715$ triples.

To prevent the degradation of model performance on natural language understanding, we mix the Wikidata corpus or KELM corpus with natural text from C4 (Raffel et al., 2019), $50:50$, for the knowledge infusion training data.

Training method. T5 (Raffel et al., 2019) was trained through masked-language modelling with random span corruption on the C4 corpus. Roberts et al. (2020) found that masking salient terms (Guu et al., 2020) in pre-training T5 models, instead of masking random token spans, could significantly improve the performance on downstream tasks, e.g. closed-book QA.

We apply salient span masking for unsupervised learning in our knowledge-infusing training. To mask the same amount of information is for both corpora, the following method is applied. For a knowledge triple, we mask either the subject or object entity. For a KELM sentence, we identify the aligned triple, with details in Appendix A, and mask the full spans corresponding to the subject or object in the triple. The *relation* tokens are never masked, as there is no robust way to map the abstract relation in knowledge triples to natural language tokens in KELM sentences. Examples of the inputs for both corpora are in Table 1.

4 Experiments

We assess SKILL by training and evaluating the knowledge infused models on closed-book QA tasks, where questions are provided without supporting context and external knowledge.

4.1 Experiment Setup

SKILL pre-training. We apply SKILL on three T5.1.1 pre-trained checkpoints[3], base, large, and XXL, with sizes of ~ 250M, ~ 800M and ~ 11B parameters, respectively. For T5.1.1-base and -large, SKILL training is performed for 500K steps with batch size 1024, which translates to ~ 7.17 epochs on Wikidata KG and ~ 16.38 epochs in KELM sentences. For T5.1.1-XXL, the model is trained for 100K steps to finish training in a feasible time.

As baseline we use pre-trained T5 checkpoints of the same size. To make sure that improvements come from knowledge infusion instead of from longer C4 pre-training, we use a second baseline by further training the T5 checkpoints on C4 for half of the aforementioned steps, to match the amount of C4 pre-training used in SKILL.

All the model variations are optimized by AdaFactor (Shazeer and Stern, 2018) with 10^{-3} learning rate and 0.1 dropout rate, the same settings that were used for T5.

Fine-tuning on closed-book QA tasks. We evaluate the checkpoints by fine-tuning on the following QA benchmarks: FreebaseQA (Jiang et al., 2019), WikiHop (Welbl et al., 2018), TriviaQA (Joshi et al., 2017) and NaturalQuestions (Kwiatkowski et al., 2019), with the aforementioned hyper-parameters for optimization and 128 batch size. For the benchmarks without a *test* split, we use the *dev* split for test, and the last 10% of *train* as *dev* split.

The Exact Match (EM) scores on the test sets are calculated after being fine-tuned for 50K steps for T5.1.1-base and -large models, and 10K steps for -XXL models. All models converged with no noticeable over-fitting according to the EM scores on validation sets.

Wikidata-answerable QA. We found that the majority of the questions in FreebaseQA and Wiki-

Table 2: Exact match scores achieved by fine-tuning the checkpoints on closed-book QA tasks. `base`, `large`, `XXL` represent the corresponding T5.1.1-* checkpoints. `⋆-C4` are the checkpoints additionally trained on C4 corpus as discussed in Section 3. `⋆-WikiKG` and `⋆-KELM` are the checkpoints trained on Wikidata KG triple corpus and KELM sentence corpus. The best performed checkpoints are in bold. Details about datasets are in Appendix B.

Hop can be answered directly from triples in Wikidata. This is because FreebaseQA was created by matching question-answer pairs with triples in Freebase (Bollacker et al., 2008), most of which was imported into Wikidata (Vrandečić and Krötzsch, 2014). For WikiHop, the questions were generated from Wikidata triples.

However, TriviaQA and NaturalQuestions were created independently of Wikidata, and not every question can be answered using this knowledge base. We found frequent freshness issues, e.g. the golden answer for question "Who is the largest supermarket chain in the UK?" is "Aldi", while today it would be "Tesco". Some other questions can not be answered by WikiData, e.g. "Who, during a radio microphone test in 1984 said, 'I just signed legislation which outlaws Russia forever. The bombing begins in five minutes?'", with the golden answer "Ronald Reagan".

To mitigate this, we created subsets of TriviaQA (TQA) and NaturalQuestions (NQ) that were somewhat more likely to have answers in Wikidata. We selected all the items for which there exist a triple in Wikidata that has the answer either as subject or object, and the other entity in the triple is mentioned in the question. We match the entities by entity name, case-insensitive. We name the Wikidata-aligned version of TQA and NQ as TQA-matched and NQ-matched, respectively. The dataset sizes of all QA tasks are summarized in Appendix B.

4.2 Results

The results for closed-book QA tasks are summarized in Table 2. SKILL pre-trained models show improvements on FreebaseQA, WikiHop, and Wikidata-answerable versions of TriviaQA and NaturalQuestions, but no significant improvement on original TriviaQA and NaturalQuestions. As discussed in previous section, we believe this is due to the misalignment between the datasets and Wikidata.

Models pre-trained on Wikidata KG gives competitive results with ones on KELM sentences. It shows that the triple representation is as good as natural language representation, while being much easier to scale up for larger KG.

For T5.1.1-base and -large, additional pre-training on C4 boosts performance in comparison to the original baseline. For T5.1.1-XXL, this additional pre-training leads to a performance regress. In (Raffel et al., 2019), it is mentioned that training on C4 for multiple times may reduce the performance of a T5 model.

Impact of model size. As shown in Figure 1, SKILL pre-training introduces bigger improvements when applied on larger models. With more than 35M triples in Wikidata KG, it is harder for

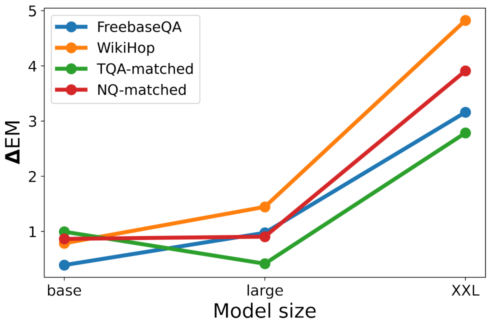

Figure 1: Performance improvements on closed-book QA tasks for different model sizes. The improvements are measured by the difference of exact match score (ΔEM) between knowledge-infused model trained with Wikidata triples and the baseline trained with C4 corpus.

Dataset	Split	Baseline	+ C4	+ KG
1-hop	dev	24.3	23.12	**71.52**
	test	24.5	23.53	**71.47**
2-hop	dev	32.05	32.23	**33.49**
	test	32.65	32.78	**33.57**
3-hop	dev	42.08	39.22	**43.79**
	test	42.31	39.66	**43.41**

Table 3: Exact match scores achieved by fine-tuning different T5.1.1-large checkpoints on MetaQA task.

smaller size models, e.g. T5.1.1.-base with 300M parameters, to memorize them efficiently. We view this as an encouraging result, suggesting that as model size grows, gains from SKILL pre-training may increase further.

Performance on a smaller KG. The WikiMovies KG (Miller et al., 2016) contains 134, 741 triples. T5.1.1-large should have enough parameters to memorize the KG. We train a T5.1.1-large model on the KG for 100K steps, $\sim$ 380 epochs, with the same hyperparameters as for Wikidata KG. We evaluate the checkpoints with MetaQA (Zhang et al., 2018) benchmark that was constructed over WikiMovies KG. The benchmark contains 3 different sub-tasks: 1-hop QA (e.g. "What films does Paresh Rawal appear in?"), 2-hop QA (e.g. "Who are the directors of the films written by Laura Kerr?"), 3-hop QA (e.g. "Who directed the movies written by the writer of Millennium Actress?").

The results in Table 3 demonstrate the effectiveness of SKILL pre-training, when it's possible to memorize the whole knowledge graph.

As 1-hop questions are supported by single triples in the WikiMovies KG, a 3× improvement on EM score is observed for the sub-task. In order to answer 2/3-hop questions it is not enough to memorize the triples, the model needs to be able to reason with them. This requires a better understanding of the graph structure. Training with single triples may not be enough, and the observed improvement is notably smaller. The performance could be further improved by representing more explicitly the graph structure in the training data, which we leave for future work.

5 Conclusion

We proposed a method to directly infuse knowledge from knowledge graphs into T5 models through pre-training. Empirical results show that T5 can learn directly from structured data and apply the learned knowledge to improve closed-book QA results. We also demonstrated that the models pre-trained on factual triples perform competitively with the ones on natural language sentences that contain the same knowledge. By enabling knowledge infusion directly from triples, this method can be very easily applied to industry-scale KGs.

6 Ethical and Broader Impact

In this work, we are introducing a new method to pre-train a well known natural language understanding model, T5, on the full corpora of public knowledge graphs. To the best of our knowledge, the method will not introduce extra bias to either the model or the dataset beyond the one potentially inherited from Wikidata (Vrandečić and Krötzsch, 2014) and WikiMovies (Miller et al., 2016) knowledge graphs. On the other hand, through knowledge fusion pre-training introduced in this work, a language model will be able to learn factual information to improve the quality of parameterized knowledge embedded in the model, which is demonstrated by improvements on various closed-book question-answering tasks. The proposed method and recipe will provide positive impact to the natural language processing community and help to improve the factualness in pre-trained large language model checkpoints.

Limitations. A factual triple is the basic ingredient of a knowledge graph. However, as a semantic network, the graph structure of a knowledge graph describes how the factual triples are connected. This information is not easy to directly represent by random set of triples. We leave the exploration of how to infuse the information implied by the graph structure for future work. We expect that this will further improve the results, especially for multi-hop question-answering tasks.

A Matching of entities in KELM sentences

To find Wikidata KG entities in corresponding KELM sentences, we use Algorithm 1. Additional cycle on line 22 is needed because some entities have an information in brackets that should not be in a sentence, for example `John Doe (born 1990)`. This algorithm matched at least one entity to $15,383,248$ out of $15,628,486$ KELM sentences.

We don't try to match *relation* part of triples, because it could be represented in many different forms. For example, the triple (`Pulp Fiction`, `cast member`, `John Travolta`) could be represented as `"John Travolta was an actor in Pulp Fiction"`, `"John Travolta starred in Pulp Fiction"`, `"John Travolta played Vincent Vega in Pulp Fiction"`, etc., and there is no way to robustly align a relation to all possible surface forms.

Algorithm 1 KELM-Wikidata matching algorithm that finds spans in KELM sentences corresponding to Wikidata KG entities. $a \subset b$ means that a is a substring of b. $*$ represents any string.

```
$KELM_{matched} \leftarrow \emptyset$
for each $k \in KELM$ sentences do
    for each $t \in triples(k)$ do
        for each $e \in entities(t)$ do
            $e_p \leftarrow$ PREPROCESS($e$)
            $k_p \leftarrow$ PREPROCESS($k$)
            $spans \leftarrow$ MATCHENTITY($e_p$, $k_p$)
            $KELM_{matched}.insert([k, spans])$
        end for
    end for
end for

function MATCHENTITY($e$: entity, $k$: KELM sentence)
    $spans \leftarrow \emptyset$
    for each $s \subset k : date(e) = date(s)$ do
        $spans.insert(s)$
    end for
    for each $\exists s \subset k : e = s$ do
        $spans.insert(s)$
    end for
    if $spans = \emptyset$ then
        for each $\exists s \subset k : e = s+$" (*)" do
            $spans.insert(s)$
        end for
    end if
    return $spans$
end function

function PREPROCESS($str$: string)
    $str \leftarrow Lowercase(str)$
    $str \leftarrow RemovePunctuation(str)$
    return $str$
end function
```

Same Neurons, Different Languages:
Probing Morphosyntax in Multilingual Pre-trained Models

Abstract

The success of multilingual pre-trained models is underpinned by their ability to learn representations shared by multiple languages even in absence of any explicit supervision. However, it remains unclear *how* these models learn to generalise across languages. In this work, we conjecture that multilingual pre-trained models can derive language-universal abstractions about grammar. In particular, we investigate whether morphosyntactic information is encoded in the same subset of neurons in different languages. We conduct the first large-scale empirical study over 43 languages and 14 morphosyntactic categories with a state-of-the-art neuron-level probe. Our findings show that the cross-lingual overlap between neurons is significant, but its extent may vary across categories and depends on language proximity and pre-training data size.

`https://github.com/copenlu/multilingual-typology-probing`

1 Introduction

Massively multilingual pre-trained models (Devlin et al., 2019; Conneau et al., 2020; Liu et al., 2020; Xue et al., 2021, *inter alia*) display an impressive ability to transfer knowledge between languages as well as to perform zero-shot learning (Pires et al., 2019; Wu and Dredze, 2019; Nooralahzadeh et al., 2020; Hardalov et al., 2022, *inter alia*). Nevertheless, it remains unclear how pre-trained models actually manage to learn multilingual representations *despite* the lack of an explicit signal through parallel texts. Hitherto, many have speculated that the overlap of sub-words between cognates in related languages plays a key role in the process of multilingual generalisation (Wu and Dredze, 2019; Cao et al., 2020; Pires et al., 2019; Abend et al., 2015; Vulić et al., 2020).

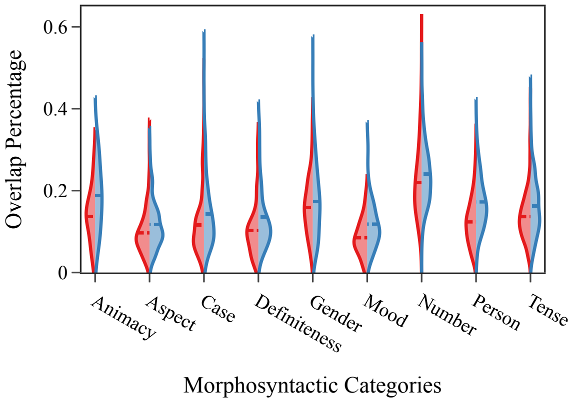

Figure 1: Percentages of neurons most associated with a particular morphosyntactic category that overlap between pairs of languages. Colours in the plot refer to 2 models: m-BERT (red) and XLM-R-base (blue).

In this work, we offer a concurrent hypothesis to explain the multilingual abilities of various pre-trained models; namely, that they implicitly align morphosyntactic markers that fulfil a similar grammatical function across languages, even in absence of any lexical overlap. More concretely, we conjecture that they employ the same subset of neurons to encode the same morphosyntactic information (such as gender for nouns and mood for verbs).[1] To test the aforementioned hypothesis, we employ Stańczak et al.'s (2022) latent variable probe to identify the relevant subset of neurons in each language and then measure their cross-lingual overlap.

We experiment with two multilingual pre-trained models, m-BERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020), probing them for morphosyntactic information in 43 languages from Universal Dependencies (Nivre et al., 2017). Based on our results, we argue that pre-trained models do indeed develop a cross-lingually entangled representation of morphosyntax. We further note that, as the

---

[1] Concurrent work by Antverg and Belinkov (2022) suggests a similar hypothesis based on smaller-scale experiments.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1589 - 1598
July 10-15, 2022

number of values of a morphosyntactic category increases, cross-lingual alignment decreases. Finally, we find that language pairs with high proximity (in the same genus or with similar typological features) and with vast amounts of pre-training data tend to exhibit more overlap between neurons. Identical factors are known to affect also the empirical performance of zero-shot cross-lingual transfer (Wu and Dredze, 2019), which suggests a connection between neuron overlap and transfer abilities.

2 Intrinsic Probing

Intrinsic probing aims to determine exactly which dimensions in a representation, e.g., those given by m-BERT, encode a particular linguistic property (Dalvi et al., 2019; Torroba Hennigen et al., 2020). Formally, let Π be the inventory of values that some morphosyntactic category can take in a particular language, for example $\Pi = \{\text{FEM}, \text{MSC}, \text{NEU}\}$ for grammatical gender in Russian. Moreover, let $\mathcal{D} = \{(\pi^{(n)}, \boldsymbol{h}^{(n)})\}_{n=1}^{N}$ be a dataset of labelled embeddings such that $\pi^{(n)} \in \Pi$ and $\boldsymbol{h}^{(n)} \in \mathbb{R}^d$, where d is the dimensionality of the representation being considered, e.g., $d = 768$ for m-BERT. Our goal is to find a subset of k neurons $C^\star \subseteq D = \{1, \ldots, d\}$, where d is the total number of dimensions in the representation being probed, that maximises some informativeness measure.

In this paper, we make use of a latent-variable model recently proposed by Stańczak et al. (2022) for intrinsic probing. The idea is to train a probe with latent variable C indexing the subset of the dimensions D of the representation $\boldsymbol{h}$ that should be used to predict the property π:

$$p_{\boldsymbol{\theta}}(\pi \mid \boldsymbol{h}) = \sum_{C \subseteq D} p_{\boldsymbol{\theta}}(\pi \mid \boldsymbol{h}, C)\, p(C) \qquad (1)$$

where we opt for a uniform prior $p(C)$ and $\boldsymbol{\theta}$ are the parameters of the probe.

Our goal is to learn the parameters $\boldsymbol{\theta}$. However, since the computation of Eq. (1) requires us to marginalise over all subsets C of D, which is intractable, we optimise a variational lower bound to the log-likelihood:

$$\begin{aligned}\mathcal{L}(\boldsymbol{\theta}) &= \sum_{n=1}^{N} \log \sum_{C \subseteq D} p_{\boldsymbol{\theta}}\left(\pi^{(n)}, C \mid \boldsymbol{h}^{(n)}\right) \qquad (2)\\ &\geq \sum_{n=1}^{N} \left(\mathop{\mathbb{E}}_{C \sim q_{\boldsymbol{\phi}}} \left[\log p_{\boldsymbol{\theta}}(\pi^{(n)}, C \mid \boldsymbol{h}^{(n)})\right] + \mathrm{H}(q_{\boldsymbol{\phi}}) \right)\end{aligned}$$

where $\mathrm{H}(\cdot)$ stands for the entropy of a distribution, and $q_{\boldsymbol{\phi}}(C)$ is a variational distribution over subsets C.[2] For this paper, we chose $q_{\boldsymbol{\phi}}(\cdot)$ to correspond to a Poisson sampling scheme (Lohr, 2019), which models a subset as being sampled by subjecting each dimension to an independent Bernoulli trial, where ϕ_i parameterises the probability of sampling any given dimension.[3]

Having trained the probe, all that remains is using it to identify the subset of dimensions that is most informative about the morphosyntactic category we are probing for. We do so by finding the subset $C_k^\star$ of k neurons maximising the posterior:

$$C_k^\star = \mathop{\mathrm{argmax}}_{\substack{C \subseteq D,\\ |C| = k}} \log p_{\boldsymbol{\theta}}(C \mid \mathcal{D}) \qquad (3)$$

In practice, this combinatorial optimisation problem is intractable. Hence, we solve it using greedy search.

3 Experimental Setup

We now describe the experimental methodology of the paper, including the data, training procedure and statistical testing.

Data. We select 43 treebanks from Universal Dependencies 2.1 (UD; Nivre et al., 2017), which contain sentences annotated with morphosyntactic information in a wide array of languages. Afterwards, we compute contextual representations for every individual word in the treebanks using multilingual BERT (m-BERT-base) and the base and large versions of XLM-RoBERTa (XLM-R-base and XLM-R-large). We then associate each word with its parts of speech and morphosyntactic features, which are mapped to the UniMorph schema (Kirov et al., 2018).[4] The selected treebanks include all languages supported by both m-BERT and XLM-R which are available in UD.

Rather than adopting the default UD splits, we re-split word representations based on lemmata ending up with disjoint vocabularies for the train, development, and test set. This prevents a probe from achieving high performance by sheer memorising. Moreover, for every category–language pair

---

[2] We refer the reader to Stańczak et al. (2022) for a full derivation of Eq. (2).

[3] We opt for this sampling scheme as Stańczak et al. (2022) found that it is more computationally efficient than conditional Poisson (Hájek, 1964) while maintaining performance.

[4] We use the converter developed for UD v2.1 from McCarthy et al. (2018).

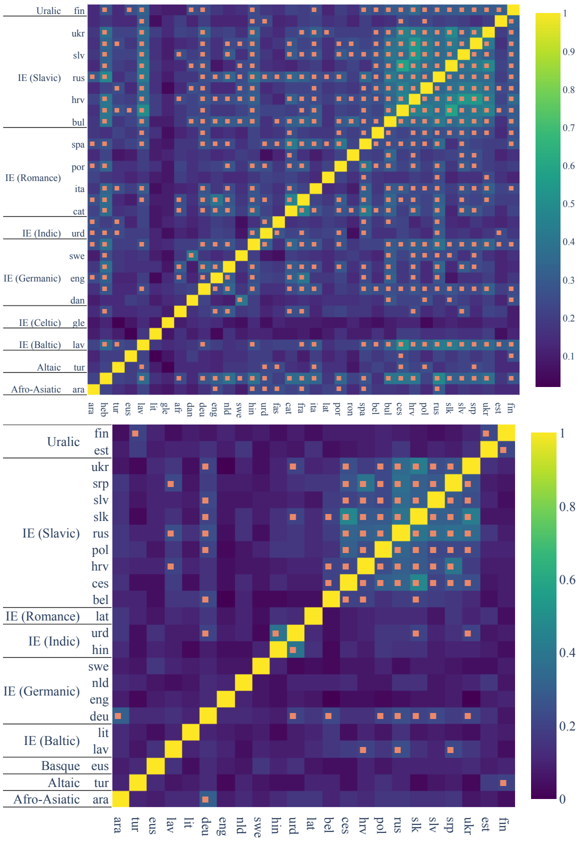

Figure 2: The percentage overlap between the top-50 most informative number dimensions in m-BERT for number (top) and XLM-R-large for case (bottom). Statistically significant overlap after Holm–Bonferroni family-wise error correction (Holm, 1979), with $\alpha = 0.05$, is marked with an orange square.

(e.g., mood–Czech), we discard any lemma with fewer than 20 tokens in its split.

Training. We first train a probe for each morphosyntactic category–language combination with the objective in Eq. (2). In line with established practices in probing, we parameterise $p_{\boldsymbol{\theta}}(\cdot)$ as a linear layer followed by a softmax. Afterwards, we identify the top-k most informative neurons in the last layer of m-BERT, XLM-R-base, and XLM-R-large. Specifically, following Torroba Hennigen et al. (2020), we use the log-likelihood of the probe on the test set as our greedy selection criterion. We single out 50 dimensions for each combination of morphosyntactic category and language.[5]

Next, we measure the pairwise overlap in the top-k most informative dimensions between all pairs of languages where a morphosyntactic category is expressed. This results in matrices such as Fig. 2, where the pair-wise percentages of overlapping dimensions are visualised as a heat map.

Statistical Significance. Suppose that two languages have $m \in \{1, \ldots, k\}$ overlapping neurons when considering the top-k selected neurons for each of them. To determine whether such overlap is statistically significant, we compute the probability of an overlap of *at least* m neurons under the null hypothesis that the sets of neurons are sampled independently at random. We estimate these probabilities with a permutation test. In this paper, we set a threshold of $\alpha = 0.05$ for significance.

Family-wise Error Correction. Finally, we use Holm-Bonferroni (Holm, 1979) family-wise error correction. Hence, our threshold is appropriately adjusted for multiple comparisons, which makes incorrectly rejecting the null hypothesis less likely.

In particular, the individual permutation tests are ordered in ascending order of their p-values. The test with the smallest probability undergoes the Holm–Bonferroni correction (Holm, 1979). If already the first test is not significant, the procedure stops; otherwise, the test with the second smallest p-value is corrected for a family of $t - 1$ tests, where t denotes the number of conducted tests. The procedure stops either at the first non-significant test or after iterating through all p-values. This sequential approach guarantees that the probability that we incorrectly reject *one or more* of the hypotheses is at most α.

4 Results

We first consider whether multilingual pre-trained models develop a cross-lingually entangled notion of morphosyntax: for this purpose, we measure the overlap between subsets of neurons encoding similar morphosyntactic categories across languages. Further, we debate whether the observed patterns are dependent on various factors, such as morphosyntactic category, language proximity, pre-trained model, and pre-training data size.

Neuron Overlap. The matrices of pairwise overlaps for each of the 14 categories, such as Fig. 2 for number and case, are reported in App. B. We expand upon these results in two ways. First, we report the cross-lingual distribution for each category in Fig. 1 for m-BERT and XLM-R-base, and in an equivalent plot comparing XLM-R-base and XLM-R-large in Fig. 3. Second, we calculate how many

---

[5] We select this number as a trade-off between the size of a probe and a tight estimate of the mutual information based on the results presented in Stańczak et al. (2022).

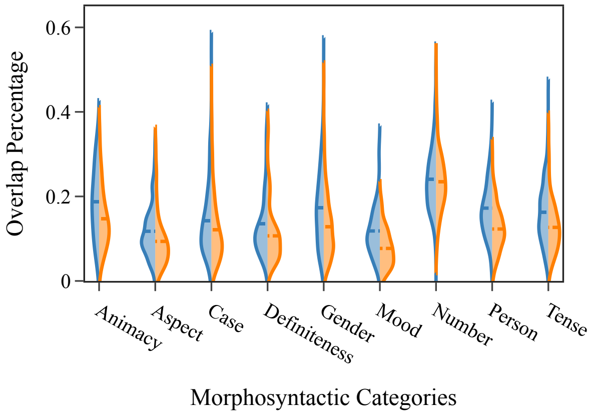

Figure 3: Ratio of neurons most associated with a particular morphosyntactic category that overlap between pairs of languages. Colours in the plot refer to 2 models: XLM-R-base (blue) and XLM-R-large (orange).

overlaps are statistically significant out of the total number of pairwise comparisons in Tab. 1. From the above results, it emerges that ≈ 20% of neurons among the top-50 most informative ones overlap on average, but this number may vary dramatically across categories.

Morphosyntactic Categories. Based on Tab. 1, significant overlap is particularly accentuated in specific categories, such as comparison, polarity, and number. However, neurons for other categories such as mood, aspect, and case are shared by only a handful of language pairs despite the high number of comparisons. This finding may be partially explained by the different number of values each category can take. Hence, we test whether there is a correlation between this number and average cross-lingual overlap in Fig. 5a. As expected, we generally find negative correlation coefficients—prominent exceptions being number and person. As the inventory of values of a category grows, cross-lingual alignment becomes harder.

Language Proximity. Moreover, we investigate whether language proximity, in terms of both language family and typological features, bears any relationship with the neuron overlap for any particular pair. In Fig. 4, we plot pairwise similarities with languages within the same genus (e.g., Baltic) against those outside. From the distribution of the dots, we can extrapolate that sharing of neurons is more likely to occur between languages in the same genus. This is further corroborated by the language groupings emerging in the matrices of App. B.

In Fig. 5b, we also measure the correlation between neuron overlap and similarity of syntactic typological features based on Littell et al. (2017). While correlation coefficients are mostly positive (with the exception of polarity), we remark that the patterns are strongly influenced by whether a category is typical for a specific genus. For instance, correlation is highest for animacy, a category almost exclusive to Slavic languages in our sample.

	m-BERT	XLM-R-base	XLM-R-large	Total

Case	0.10	0.18	0.17	300
Tense	0.08	0.23	0.12	325
Finiteness	0.09	0.18	0.09	45

Table 1: Proportion of language pairs with statistically significant overlap in the top-50 neurons for an attribute (after Holm–Bonferroni (Holm, 1979) correction). We compute these ratios for each model. The final column reports the total number of pairwise comparisons.

Pre-trained Models. Afterwards, we determine whether the 3 models under consideration reveal different patterns. Comparing m-BERT and XLM-R-base in Fig. 1, we find that, on average, XLM-R-base tends to share more neurons when encoding particular morphosyntactic attributes. Moreover, comparing XLM-R-base to XLM-R-large in Fig. 3 suggests that more neurons are shared in the former than in the latter.

Altogether, these results seem to suggest that the presence of additional training data engenders cross-lingual entanglement, but increasing model size incentivises morphosyntactic information to be allocated to different subsets of neurons. We conjecture that this may be best viewed from the lens of compression: if model size is a bottleneck,

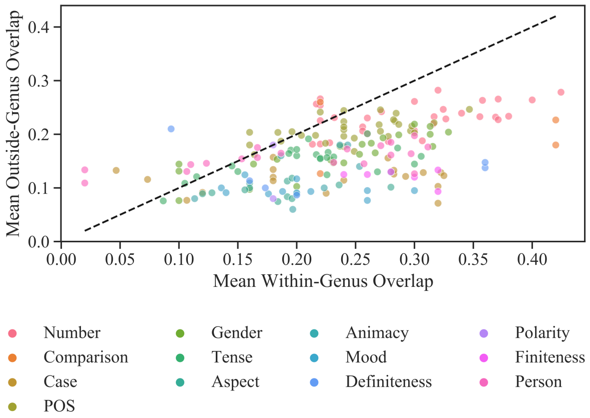

Figure 4: Mean percentage of neuron overlap in XLM-R-base with languages either within or outside the same genus for each morphosyntactic category.

Figure 5: Spearman's correlation, for a given model and morphological category, between the cross-lingual average percentage of overlapping neurons and:

(c) language model training data size.

then, to attain good performance across many languages, a model is forced to learn cross-lingual abstractions that can be reused.

Pre-training Data Size. Finally, we assess the effect of pre-training data size[6] for neuron overlap. According to Fig. 5c, their correlation is very high. We explain this phenomenon with the fact that more data yields higher-quality (and as a consequence, more entangled) multilingual representations.

5 Conclusions

In this paper, we hypothesise that the ability of multilingual models to generalise across languages results from cross-lingually entangled representations, where the same subsets of neurons encode universal morphosyntactic information. We validate this claim with a large-scale empirical study on 43 languages and 3 models, m-BERT, XLM-R-base, and XLM-R-large. We conclude that the overlap is statistically significant for a notable amount of language pairs for the considered attributes. However, the extent of the overlap varies across morphosyntactic categories and tends to be lower for categories with large inventories of possible values. Moreover, we find that neuron subsets are shared mostly between languages in the same genus or with similar typological features. Finally, we discover that the overlap of each language grows proportionally to its pre-training data size, but it also decreases in larger model architectures.

Given that this implicit morphosyntactic alignment may affect the transfer capabilities of pre-trained models, we speculate that, in future work, artificially encouraging a tighter neuron overlap might facilitate zero-shot cross-lingual inference to low-resource and typologically distant languages(Zhao et al., 2021).

Abstract

Aspect-based sentiment analysis (ABSA) is a fine-grained sentiment classification task. Most recent efforts adopt pre-trained model to classify the sentences with aspects. However, the aspect sentiment bias from pre-trained model brings some noise to the ABSA task. Besides, traditional methods using cross-entropy loss are hard to find the potential associations between sentiment polarities. In this work, we analyze the ABSA task from a novel cognition perspective: humans can often judge the sentiment of an aspect even if they do not know what the aspect is. Moreover, it is easier to distinguish positive and negative sentiments than others for human beings because positive and negative are two opposite sentiments. To this end, we propose a no-aspect differential sentiment (NADS) framework for the ABSA task. We first design a no-aspect template by replacing the aspect with a special unbiased character to eliminate the sentiment bias and obtain a stronger representation. To better get the benefits from the template, we adopt contrastive learning between the no-aspect template and the original sentence. Then we propose a differential sentiment loss instead of the cross-entropy loss to better classify the sentiments by distinguishing the different distances between sentiments. Our proposed model is a general framework and can be combined with almost all traditional ABSA methods. Experiments on SemEval 2014 show that our framework is still able to predict the sentiment of the aspect even we don't konw what the aspect is. Moreover, our NADS framework boosts three typical ABSA methods and achieves state-of-the-art performance.

1 Introduction

Aspect-based sentiment analysis (ABSA) (Jiang et al., 2011) aims to identify the sentiment polarity (i.e., negative, neutral, or positive) of each specific aspect term in a piece of text (Hou et al., 2021; Dai et al., 2021; Li et al., 2021). For example, in *"The food is great, but the service is terrible"*, the sentiment towards *"food"* is positive while the sentiment towards *"service"* is negative. We need to predict the sentiments of different aspect terms in a sentence.

Previous works usually employ pre-trained model to extract the embedding of the concatenation of the sentence and the aspect term. In this way, the attention mechanism in pre-trained model enhances the connection between aspect and its context (Tang et al., 2016; Song et al., 2019). The experiment results verify its appealing performance. However, the pre-trained model on large-scale raw corpora tends to internalize aspects' intrinsic attributes (Huang et al., 2020) and brings some noise to the ABSA task. For example, for the sentence *"Desserts include flan and sopaipillas"*, a typical model BERT-SPC (Song et al., 2019) based on BERT (Devlin et al., 2019) tends to classify the sentiment towards *"Desserts"* as positive, while the label is neutral. This is because in pre-trained corpora, *"Desserts"* often appears with words that contain positive sentiment, causing the word *"Desserts"* to internalize positive sentiment as well. Moreover, traditional text classification methods using the cross-entropy loss have some shortcomings. On the one hand, the cross-entropy loss suffers from lacking of robustness to noisy labels (Zhang and Sabuncu, 2018) and the possibility of poor margins (Elsayed et al., 2018). On the other hand, the cross-entropy loss ignores the potential relationships between different sentiment polarities. Meanwhile, the non-smooth anisotropic semantic space induced by pre-trained model (Li et al., 2020) also brings difficulty in distinguishing potential relationships between sentiments.

To tackle these problems, we analyze the ABSA task from a human cognition perspective. People often pay attention to the learning strategy and feature representation in many NLP tasks, but ignore

---

July 10-15, 2022

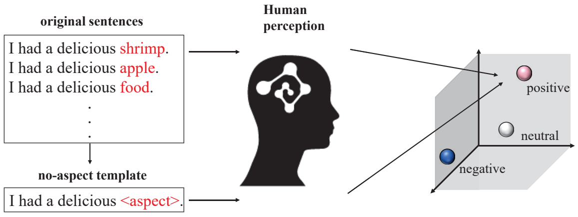

Figure 1: Human performance on the ABSA task.

the organization of concepts between human and artificial intelligence. Intuitively, human can still perform well in the ABSA task without knowing the meaning of aspect. As shown in Figure 1, in *"I had a delicious shrimp."*, maybe we don't know what the *"shrimp"* is (it is a kind of food), we can also easily classify the sentiment polarity of this word as positive. Because we can judge the sentiment of the aspect through its context. Moreover, in human perception, *"positive"* and *"negative"* are two completely opposite sentiments and *"neutral"* sentiment is in between. The distance between *"positive"* and *"neutral"* is obviously closer than *"positive"* and *"negative"*.

Inspired by the human cognition, we propose the no-aspect template differential sentiment (NADS) framework. We first design a no-aspect template by replacing the aspect term in the sentence with the special sentiment unbiased character "$< aspect >$" and utilize the contrastive learning between the no-aspect template and the original sentence. In this way, we can not only eliminate the sentiment bias in original sentence, but also learn a wider range of sentence patterns as shown in Figure 1 to enhance the robustness of our framework. Moreover, it helps our NADS framework to judge the sentiment of the aspect without knowing the specific meaning of it, just like human beings. Then, in order to reduce the semantic loss caused by the special character "$< aspect >$", we utilize the masked aspect prediction to keep the original semantic information. Morever, we design the differential sentiment loss to find the different distances between different sentiments and better distinguish different sentiments. Our main contributions are:

- We propose a no-aspect template and utilize the no-aspect contrastive learning to consider a wider range of sentence patterns and eliminate the sentiment bias in the aspect embedding. This also enables our model to predict the sentiment of the aspect without knowing what the aspect is, just like human beings.
- We design the differential sentiment loss to help us better distinguish different distances between different sentiments. Moreover, our differential sentiment loss can make samples with the same sentiment as close as possible, and samples with different sentiments as far away as possible.
- Experiments on SemEval 2014 show that our model enhances the performance of three typical ABSA methods and achieves new state-of-the-art. Additionally, the experiments on an aspect robustness test set ARTS show our NADS model can greatly improve the robustness of the model.

2 Related Work

Aspect-based sentiment analysis is a fine-grained sentiment classification task. Recently, some works on ABSA have focused on leveraging syntactic knowledge through syntactic trees. (Wang et al., 2020) reshaped the syntactic tree with aspect terms as the center and utilized a relational graph attention network to encode the new tree structure for sentiment prediction. (Hou et al., 2021) combined the dependency relations from different parses before applying GNNs over the resulting graph.

Another trend utilizes various attention mechanisms to find the semantic relation of an aspect and its context (Tan et al., 2019; Li et al., 2018; Fan et al., 2018; Huang et al., 2018). Attention mechanism helps to focus on the context related to aspect and shield the irrelevant context. Besides, some works tried to integrate syntax tree and attention mechanism. Most recent work (Li et al., 2021) utilized a mutual biaffine attention mechanism to fuse syntactic information and semantic information from syntactic tree.

In parallel, the pre-trained language model BERT (Devlin et al., 2019) has achieved remarkable performance in many NLP tasks. Experiments show that using BERT in ABSA can achieve better results (Li et al., 2021; Zhang et al., 2019) than using static word embeddings such as Word2vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014). However, (Wang et al., 2021) showed that the sentiment bias of aspect caused by the pre-trained model may perplex the ABSA task. They utilized external sentiment knowledge SentiWordNet (Esuli and Sebastiani, 2006) to extract prior three-categorical sentiment for aspect terms. Then they proposed an adversarial network to eliminate

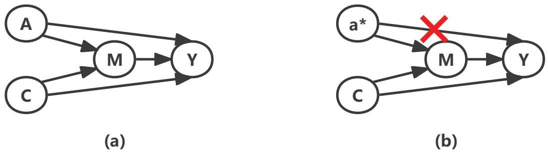

Figure 2: (a) and (b) are the causal graphs for traditional ABSA methods and our NADS. A: aspect terms. C: context. M: the fusing information of aspect and context. Y: sentiment of the aspect. a^*: the special character without sentiment bias.

the prior sentiment of aspect terms. However, it is not known whether the aspect sentiment polarity labeled from SentiWordNet is consistent with the sentiment bias in the pre-trained model. In addition, previous works using cross-entropy loss also ignored the potential associations between different sentiment polarities.

In this paper, we propose a no-aspect template and utilize contrastive learning to eliminate sentiment bias and learn a wider range of sentence patterns to improve the robustness of the model. Moreover, we design the differential sentiment loss to better distinguish the different distances between different sentiments and cluster the same sentiment.

3 Preliminaries

In this section, we use causal inference (Pearl et al., 2000; Robins, 2003) to illustrate the theoretical basis of our framework. We illustrate the traditional ABSA methods and our NADS framework by using a causal graph described in Figure 2. Causal graph reflects the causal relationship between variables and we use "$\rightarrow$" denotes the direct effect. For the ABSA task, the factors affecting sentiment prediction include the specific aspect term A that we need to predict and the context of the aspect C. Both A and C are important to ABSA task because C contains the sentiment information and we need to know which aspect A to predict sentiment for.

In traditional methods' causal graph as shown in Figure 2 (a), the context and aspect capture the direct effect of sentiment via $C \rightarrow Y$ and $A \rightarrow Y$. The fusing information captures the indirect effect of A and C on Y via the M, $i.e.$, $A, C \rightarrow M \rightarrow Y$. The predicted result that Y would obtain if A is set to a and C is set to c as:

$$Y_{a,c} = Y(A = a, C = c, M = m) \qquad (1)$$

where $m = M_{a,c}$ denotes the information about the fusion of aspect a and context c. According to this formula, traditional methods well consider the role of the aspect and its context in the ABSA task. However, in human cognition, the specific meaning of aspect does not affect people's judgment of its sentiment. Traditional methods ignored the aspect sentiment bias which makes aspect have a direct impact on the prediction results Y via $A \rightarrow Y$. It may cause ABSA models to suffer from the spurious correlation between aspect and sentiment, and thus fail to conduct effective reasoning.

In our NADS framework, we propose to exclude aspect sentiment bias effect on $A \rightarrow Y$ in ABSA as shown in Figure 2 (b). We utilize a special character "$< aspect >$" that without sentiment bias to replace the original aspect in the sentence and employ the masked aspect prediction to keep the original semantic information of the sentence. We get the sentiment prediction Y as:

$$Y_{a^*,c} = Y(A = a^*, C = c, M = m^*) \qquad (2)$$

where $a^* =$ "$< aspect >$" and $m^* = M_{a^*,c}$. In this way, we eliminate the direct impact of aspect's sentiment bias on the prediction results and keep the original semantic information.

4 Proposed NADS

In the ABSA task, given a sentence $S = \{\omega_1, \omega_2, ..., \omega_\tau, ..., \omega_{\tau+t}, ..., \omega_n\}$ and an aspect term $A = \{\omega_\tau, \omega_{\tau+1}, ..., \omega_{\tau+t-1}\}$, the purpose is to predict the sentiment polarity of A in this S. As shown in Figure 3, our NADS framework consists of three parts. We first propose no-aspect template and utilize contrastive learning between the no-aspect template and original sentence to consider a wider range of sentence patterns and eliminate the sentiment bias in the aspect embedding. Then, in order to make the sentence with the special characters "$< aspect >$" keep the original semantic information, we utilize the masked aspect prediction. Finally we design the differential sentiment loss to learn the different distances between different sentiment polarities. We elaborate the details of our proposed NADS.

4.1 No-aspect Contrastive Learning

For each $\{S, A\}$ pair, we utilize a special character "$< aspect >$" without sentiment bias to replace the whole aspect term A in the sentence. We denote the no-aspect template as T:

$$T = Replace(\{S|A = a\}, < aspect >) \qquad (3)$$

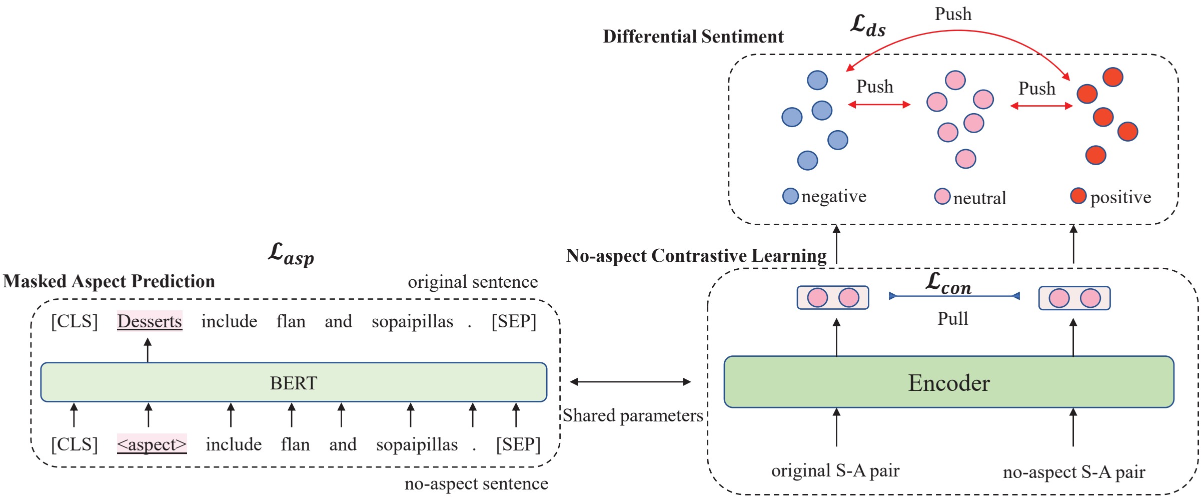

Figure 3: An overview of proposed no-aspect differential sentiment (NADS) framework.

To better use the information from no-aspect template and regularize pre-trained anisotropic embedding space, we utilize contrastive learning between the original sentence and no-aspect template. Specifically, for each sentence-aspect pair (s_i, a_i), we denote the positive sentence as:

$$s_i^+ = T_i \tag{4}$$

where T_i is the no-aspect template of s_i. Thus we get a positive instance $(s_i^+, < aspect >)$ for (s_i, a_i). We obtain feature representation for each sentence-aspect pair and positive instance through the encoder $f_\theta(\cdot)$:

$$h_i = f_\theta(s_i, a_i) \tag{5}$$

$$h_i^+ = f_\theta(s_i^+, < aspect >) \tag{6}$$

where h_i and h_i^+ denote the feature representation of original sentence-aspect pair and positive instance. In our NADS framework, we utilize BERT to get the embedding of each sentence-aspect pair by inputting the concatenation of the aspect term and the sentence. For other models we use their methods as the encoder to get the embedding for each pair (s_i, a_i). We denote all other sentences in the mini-batch as negative instances, so the contrastive loss is:

$$\mathcal{L}_{con} = -log\frac{e^{sim(h_i,h_i^+)/\tau}}{\Sigma_{j=1}^{N} e^{sim(h_i,h_j^+)/\tau}} \tag{7}$$

where τ is the temperature hyperparameter and $sim(\cdot)$ is the cosine similarity. N is the batch size.

By comparing the original sentence with the no-aspect template, we eliminate the sentiment bias caused by the aspect terms in the original sentence and learn not only the information of a sentence, but also the information of a group of sentence patterns. This helps us to improve the robustness of the model. Moreover, contrastive learning helps us regularize pre-trained anisotropic embedding space to prepare for differential sentiment loss.

4.2 Masked Aspect Prediction

In section 4.1, we utilize the "$< aspect >$" to construct the no-aspect template. However, we think that directly using a special character "$< aspect >$" that does not exist in the pre-trained model may cause trouble to remain the semantic information. Therefore, we utilize masked aspect prediction for the special characters "$< aspect >$" to keep the original semantics. Specifically, we mask the aspects by using "$< aspect >$" and predict the original aspect terms in the position of "$< aspect >$" in our ABSA training dataset. According to (Hong et al., 2021), our purpose is to train the embedding of "$< aspect >$" to keep the complete semantic information. For our NADS framework, we denote the embedding of "$< aspect >$" position as $h_{[<asp>]}$. We feed $h_{[<asp>]}$ into a softmax layer to predict the original aspect:

$$\widehat{Y}^a = softmax(W_1 h_{[<asp>]} + b_1) \tag{8}$$

where the W_1 and b_1 are trainable parameters, $\widehat{Y}^a$ indicates the predict probability of the aspect word at its position. We get the masked aspect prediction loss through the cumulative of log-likelihood on predictions of each "$< aspect >$" position:

$$\mathcal{L}_{asp} = -\Sigma logp(\widehat{Y}^a) \tag{9}$$

Specially, we only predict the position of "$< aspect >$" in sentences. The masked aspect prediciton helps us keep the original semantic information of the sentence after replacing the aspect.

4.3 Differential Sentiment Loss

After regularizing pre-trained anisotropic embedding space by using the contrastive learning between original and no-aspect template, we design our differential sentiment loss to better distinguish different sentiments. We first embed our labels into the same size of h_i. We convert positive, neutral and negative sentiment labels into label embeddings $L = \{l_{pos}, l_{neu}, l_{neg}\}$. The distance between the sentence-aspect pair embedding h_i and label embedding l_i is:

$$d(h_i, l_i) = 1 - \frac{h_i^\top l_i}{||h_i|| \cdot ||l_i||} \tag{10}$$

For each sentence-aspect pair embedding h_i, the distance between h_i and its label l_i should be closer than other label embeddings in L. Thus, we utilize a triplet loss to make h_i closer to the right label embedding l_i and further to the other label embeddings. For each h_i, the positive instance is the label embedding l_i and the negative instances are the other label embeddings in L. Moreover, in human cognition, the distances between different sentiments are different. Thus, we set a specific margin for each negative instance to better distinguish the different distances between different sentiments. Our differential sentiment loss is given as:

$$\begin{aligned}\mathcal{L}_{ds} =& \Sigma_{l_i' \in L, l_i' \neq l_i} max(d(h_i, l_i) \\ &- d(h_i, l_i') + m(l_i, l_i'), 0)\end{aligned} \tag{11}$$

where $m(l_i, l_i')$ is the specific margin for label l_i and l_i'. According to human cognition, we denote that positive and negative sentiments should have the same distance to neutral sentiment and the distance between positive and negative is further. Thus, we set $m(pos, neu) = m(neg, neu)$ and $m(pos, neg) > m(pos, neu)$ in our model. Compared with the cross-entropy loss, our differential sentiment loss can better classify the sentiments through distinguishing the differences between sentiments. Moreover, our differential sentiment loss can jointly train the model and label embeddings and make our framework converge faster.

Dataset	Division	#Pos	#Neu	#Neg
Laptop	Train	976	455	851
	Test	337	167	128
Restaurant	Train	2164	637	807
	Test	727	196	196

Table 1: Statistics on two datasets of ABSA.

In order to judge the sentiment polarity of the sentence-aspect pair, we utilize cosine similarity to construct our scoring function:

$$S(h, l) = \frac{h^\top l}{||h|| \cdot ||l||} \tag{12}$$

where h is the embedding of the sentence-aspect pair, and l is the embedding of the label. We take the l with the largest score as our prediction result.

Our training goal is to minimize the following total objective function:

$$\mathcal{L} = \mathcal{L}_{ds} + \lambda_1 \mathcal{L}_{con} + \lambda_2 \mathcal{L}_{asp} \tag{13}$$

where λ_1 and λ_2 are the weights of contrastive leanrning loss and masked aspect prediction loss.

5 Experiments

5.1 Datasets

We evaluate our model on two ABSA task public datasets: Restaurant and Laptop reviews from SemEval 2014 Task 4 (Pontiki et al., 2014). We remove several examples with "conflict" sentiment polarity labels in the reviews. Table 1 shows the statistics of these datasets.

5.2 Baseline Methods

We compare our NADS with state-of-the-art baselines. The models are described as follows.

1) **BERT-SPC** (Song et al., 2019) utilizes BERT to encode the sentence-aspect pair as : "[CLS] sentence [SEP] aspect [SEP]" and gets the embedding of "[CLS]". Our NADS framework utilizes BERT-SPC as the encoder.

2) **AEN+BERT** (Song et al., 2019) utilizes BERT and several attention layers to encoder sentence-aspect pair. The embedding of the sentence and the embedding of the aspect are obtained respectively.

3) **CapsNet+BERT** (Jiang et al., 2019) combines the BERT and capsule networks in ABSA.

Models	Strategy	14Rest		14Lap

Table 2: Comparison of our NADS on three traditional methods to other baselines on two datasets.

4) **BERT-ADA** (Rietzler et al., 2020) utilizes domain data to enhance the BERT and then uses task data to make supervised fine-tuning.
5) **SDGCN+BERT** (Zhao et al., 2020) employs graph convolution network for sentences with multiple aspects.
6) **R-GAT+BERT** (Wang et al., 2020) proposes an aspect-oriented tree and encodes new dependency trees with a relational GAT.
7) **DGEDT+BERT** (Tang et al., 2020) proposes a mutual biaffine module to jointly consider the representations learned from Transformer and the GNN model over the dependency tree.
8) **DualGCN+BERT** (Li et al., 2021) utilizes dependency tree to extract syntax information and self attention to extract semantic information.

Moreover, in order to prove the effectiveness of our NADS framework, we adopt our NADS to BERT-SPC, AEN+BERT and DualGCN+BERT.

5.3 Implementation Details

We utilize the bert-base-uncased English version. Following the DualGCN (Li et al., 2021), we use LAL-Parser (Mrini et al., 2019) to get dependency tree for DualGCN+NADS. We randomly initialize the embedding of three sentiments and we set the $\lambda_1 = 0.4$, $\lambda_2 = 0.1$ during our training. The different margins $(m(pos, neu), m(pos, neg))$ are set to (0.4, 0.6), (0.4, 0.6) for the laptop and restaurant datasets for our NADS framework. During training, we use AdamW as the optimizer and set the learning rate to 2×10^{-5}. We train the model up to 15 epochs with a batch size of 16.

5.4 Comparison Results

We utilize the accuracy and macro-averaged F1-score to evaluate ABSA task. In order to better predict the correct sentiment in the test, we adopt three different ways to test our NADS framework.
1) **Original test**: utilizing the concatenation of the original aspect and the original sentence as the input and extract the embedding for prediction.
2) **Noasp test**: utilizing the concatenation of the “$< aspect >$” and the no-aspect template as the input of encoder. This test method can help us judge whether the model can correctly predict sentiment

without knowing the specific meaning of the aspect like human beings.

3) **Unite test**: using both Original test mode and Noasp test mode to get the scores of each label for each sentence-aspect pair and sum the scores of same label after normalization.

Table 2 shows our main experimental results. As we can see, our NADS framework outperforms all baselines on laptop and restaurant datasets, and the performance of the three traditional models: BERT-SPC, AEN+BERT and DualGCN+BERT has been improved after adding our NADS framework. Our NADS outperforms the BERT-SPC by 3.03%/3.13% on Restaurant/Laptop. The result demonstrates that our NADS framework effectively utilizes the way of human cognitive and plays a better role in the ABSA task. Compared with traditional methods, our no-aspect template eliminates the sentiment bias of aspect and learns more information of a group of sentence patterns, which can reduce the noise caused by aspect sentiment bias and enhance the robustness of our framework. Moreover, our differential sentiment loss can better classify the sentiment through distinguishing the difference in these three different sentiment polarities after contrastive learning. The experiments on three traditional methods also show that our framework well fits most of the existing models and boosts their performance.

In parallel, according to the experimental results of Noasp test, the performance of traditional methods drops significantly without knowing what aspect is. However, our NADS framework can still perform well without knowing the aspect just like human beings. In Noasp test mode, BERT-SPC drops 2.69%/3.52% on Restaurant/Laptop. By contrast, our NADS framework drops only 0.45%/1.11% on Restaurant/Laptop. We also find AEN+NADS increases 2.51% on Restaurant dataset, while the AEN+BERT drops 2.42%. This shows that our NADS can still perform well without knowing the specific meaning of the aspect. Comparing these three test modes, we can also find that the Unite test mode can achieve the most stable result in different models.

5.5 Ablation Study

In order to further study the role of different modules in our framework, we conduct extensive ablation experiments. The results are shown in Table 3. NADS w/o NOASP denotes that we only utilize the original sentence and remove the contrastive learning. Without contrastive learning between no-aspect template and original sentence, the sentiment bias of aspect perplexes the prediction result and more importantly, differential sentiment loss will not work because of the anisotropic in BERT model. Therefore, its performance is degraded on both two datasets. NADS w/o MAP means that we remove the masked aspect prediction module so that we may lose the original semantic information of the sentence. NADS w/o DS indicates that we utilize the cross-entropy loss function instead of our differential sentiment loss. Without differential sentiment loss, the model cannot find the different distances between sentiments. Experiments show that every module is indispensable in our NADS framework.

Models	14Rest		14Lap	
	Acc	Macro-F1	Acc	Macro-F1
NADS	**87.49**	**82.09**	**82.12**	**79.13**
NADS w/o NOASP	85.22	78.88	79.43	75.30
NADS w/o MAP	87.04	81.73	81.18	78.51
NADS w/o DS	87.22	81.71	81.01	77.26

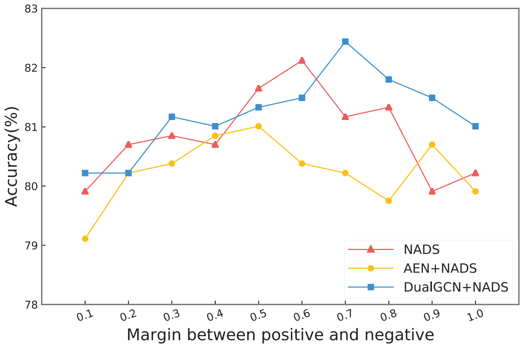

Figure 4: Effect of different $m(pos, neg)$ while set $m(pos, neu) = 0.4$ in laptop dataset.

5.6 Selection of Margin

We experiment with different margins in the differential sentiment loss. In our framework, we only consider the $m(pos, neu)$ and $m(pos, neg)$. Figure 4 shows the accuracy of different $m(pos, neg)$ when we set $m(pos, neu) = 0.4$ in our three methods based on our NADS framework on Laptop dataset. As we can see, the accuracy increases first and then decreases in the process of $m(pos, neg)$ gradually increasing. The three models perform best when the $m(pos, neg)$ is set to 0.6, 0.5 and 0.7. This experiment shows that the distance be-

Table 6: Comparison of three test modes on aspect robustness test set.

tween positive and negative is indeed farther than that between positive and neutral. It proves the effectiveness of our differential sentiment loss.

5.7 Sentiment Bias Elimination

In order to better understand the ability of our NADS framework to eliminate sentiment bias, we find several examples whose labels are neutral and show their prediction results in different models in Table 4, where P, N, O represent positive, negative, and neutral sentiments. We highlight the aspect words in red. We can see that our NADS framework outperforms all other models. For the aspect "*steak*" in the first sample, previous methods ignore the positive sentiment bias of "*steak*" and incorrectly predict the sentiment as positive. In contrast, our NADS eliminates the positive sentiment bias through no-aspect template and predicts the correct sentiment as neutral. Moreover, we also show the distribution of bad cases in Figure 5. The bad cases of neutral aspects terms in our NADS framework are significantly less than BERT-SPC. This proves the effectiveness of our NADS framework in eliminating sentiment bias. However, there are still some neutral aspect terms in our framework that are incorrectly predicted as shown in Table 4. A possible reason is that there may be other words in a sentence carrying the sentiment bias in addition to the current aspect.

5.8 Robustness Study

In order to verify the robustness of our NADS, we test the robustness score of our framework on the Aspect Robustness Test Set (ARTS) (Xing et al., 2020). The datasets enrich 14Lap and 14Rest according to three strategies: reverse the original sentiment of the target aspect (REVTGT), perturb the sentiments of the non-target aspects (REVNON) and generate more non-target aspect terms that have opposite sentiment polarities to the target (ADDDIFF). They take the original sentence and the three variants as an unit. Only if the original sentence and all variants are correct, the unit is correct. Calculate the accuracy of the units in the datasets as the final Aspect Robustness Score (ARS).

We compare the ARS of the three models before adding our NADS framework and after adding NADS. The results in Table 5 show that the ARS of the model has been significantly improved after adding our NADS framework. Our NADS framework adding DualGCN performs significantly better than other models with 21.33% and 21.93% decline on Restaurant and Laptop. This shows that our framework utilizing human cognition has better robustness than other models.

Moreover, we utilize the three test modes to test on the ARTS as shown in Table 6. As we can see, the AEN+NADS model with 57.39% and 44.18% decline on Restaurant and Laptop when using Original test mode. However, with 26.51% and 22.34% decline when utilizing Noasp test mode. In the overall scheme, the Noasp test mode and Unite test mode can get a more stable result than the Original test mode on the ARTS. Utilizing no-aspect template in test may be a more stable robustness test method.

6 Conclusion

In this paper, we propose a NADS framework which is more in line with human cognition for the ABSA task. Our NADS framework utilizes no-aspect contrastive learning to eliminate the sentiment bias of aspects and enhance the sentence representations. In addition, we construct a differential sentiment loss to better classify the sentiments through distinguishing the different distances between sentiment polarities. Extensive experiments show that our NADS framework boosts three typical ABSA methods and outperforms baselines. Moreover, our NADS framework can still perform well even we don't know what the aspect is. The test on the robustness dataset shows that our NADS framework significantly improves the robustness of the model.

Abstract

Pre-trained language models have demonstrated superior performance in various natural language processing tasks. However, these models usually contain hundreds of millions of parameters, which limits their practicality because of latency requirements in real-world applications. Existing methods train small compressed models via knowledge distillation. However, performance of these small models drops significantly compared with the pre-trained models due to their reduced model capacity. We propose MoEBERT, which uses a Mixture-of-Experts structure to increase model capacity and inference speed. We initialize MoEBERT by adapting the feed-forward neural networks in a pre-trained model into multiple experts. As such, representation power of the pre-trained model is largely retained. During inference, only one of the experts is activated, such that speed can be improved. We also propose a layer-wise distillation method to train MoEBERT. We validate the efficiency and effectiveness of MoEBERT on natural language understanding and question answering tasks. Results show that the proposed method outperforms existing task-specific distillation algorithms. For example, our method outperforms previous approaches by over 2% on the MNLI (mismatched) dataset. Our code is publicly available at `https://github.com/SimiaoZuo/MoEBERT`.

1 Introduction

Pre-trained language models have demonstrated superior performance in various natural language processing tasks, such as natural language understanding (Devlin et al., 2019; Liu et al., 2019; He et al., 2021b) and natural language generation (Radford et al., 2019; Brown et al., 2020). These models can contain billions of parameters, e.g., T5 (Raffel et al., 2019) contains up to 11 billion parameters, and GPT-3 (Brown et al., 2020) consists of up to 175 billion parameters. Their extreme sizes bring challenges in serving the models to real-world applications due to latency requirements.

Model compression through knowledge distillation (Romero et al., 2015; Hinton et al., 2015) is a promising approach that reduces the computational overhead of pre-trained language models while maintaining their superior performance. In knowledge distillation, a large pre-trained language model serves as a teacher, and a smaller student model is trained to mimic the teacher's behavior. Distillation approaches can be categorized into two groups: task-agnostic (Sanh et al., 2019; Jiao et al., 2020; Wang et al., 2020, 2021; Sun et al., 2020a) and task-specific (Turc et al., 2019; Sun et al., 2019; Li et al., 2020; Hou et al., 2020; Sun et al., 2020b; Xu et al., 2020). Task-agnostic distillation pre-trains the student and then fine-tunes it on downstream tasks; while task-specific distillation directly fine-tunes the student after initializing it from a pre-trained model. Note that task-agnostic approaches are often combined with task-specific distillation during fine-tuning for better performance (Jiao et al., 2020). We focus on task-specific distillation in this work.

One major drawback of existing knowledge distillation approaches is the drop in model performance caused by the reduced representation power. That is, because the student model has fewer parameters than the teacher, its model capacity is smaller. For example, the student model in DistilBERT (Sanh et al., 2019) has 66 million parameters, about half the size of the teacher (BERT-base, Devlin et al. 2019). Consequently, performance of DistilBERT drops significantly compared with BERT-base, e.g., over 2% on MNLI (82.2 v.s. 84.5) and over 3% on CoLA (54.7 v.s. 51.3).

We resort to the Mixture-of-Experts (MoE, Shazeer et al. 2017) structure to remedy the representation power issue. MoE models can increase model capacity while keeping the inference com-

July 10-15, 2022

putational cost constant. A layer of a MoE model (Shazeer et al., 2017; Lepikhin et al., 2021; Fedus et al., 2021; Yang et al., 2021; Zuo et al., 2021) consists of an attention mechanism and multiple feed-forward neural networks (FFNs) in parallel. Each of the FFNs is called an expert. During training and inference, an input adaptively activates a fixed number of experts (usually one or two). In this way, the computational cost of a MoE model remains constant during inference, regardless of the total number of experts. Such a property facilitates compression without reducing model capacity.

However, MoE models are difficult to train-from-scratch and usually require a significant amount of parameters, e.g., 7.4 billion parameters for Switch-base (Fedus et al., 2021). We propose MoEBERT, which incorporates the MoE structure into pre-trained language models for fine-tuning. Our model can speedup inference while retaining the representation power of the pre-trained language model. Specifically, we incorporate the expert structure by adapting the FFNs in a pre-trained model into multiple experts. For example, the hidden dimension of the FFN is 3072 in BERT-base (Devlin et al., 2019), and we adapt it into 4 experts, each has a hidden dimension 768. In this way, the amount of *effective parameters* (i.e., parameters involved in computing the representation of an input) is cut by half, and we obtain a ×2 speedup. We remark that MoEBERT utilizes more parameters of the pre-trained model than existing approaches, such that it has greater representation power.

To adapt the FFNs into experts, we propose an importance-based method. Empirically, there are some neurons in the FFNs that contribute more to the model performance than the other ones. That is, removing the important neurons causes significant performance drop. Such a property can be quantified by the *importance score* (Molchanov et al., 2019; Xiao et al., 2019; Liang et al., 2021). When initializing MoEBERT, we share the most important neurons (i.e., the ones with the highest scores) among the experts, and the other neurons are distributed evenly. This strategy has two advantages: first, the shared neurons preserve performance of the pre-trained model; second, the non-shared neurons promote diversity among experts, which further boost model performance. After initialization, MoEBERT is trained using a layer-wise task-specific distillation algorithm.

We demonstrate efficiency and effectiveness of MoEBERT on natural language understanding and question answering tasks. On the GLUE (Wang et al., 2019) benchmark, our method significantly outperforms existing distillation algorithms. For example, MoEBERT exceeds performance of state-of-the-art task-specific distillation approaches by over 2% on the MNLI (mismatched) dataset. For question answering, MoEBERT increases F1 by 2.6 on SQuAD v1.1 (Rajpurkar et al., 2016) and 7.0 on SQuAD v2.0 (Rajpurkar et al., 2018) compared with existing algorithms.

The rest of the paper is organized as follows: we introduce background and related works in Section 2; we describe MoEBERT in Section 3; experimental results are provided in Section 4; and Section 5 concludes the paper.

2 Background

2.1 Backbone: Transformer

The Transformer (Vaswani et al., 2017) backbone has been widely adopted in pre-trained language models. The model contains several identically-constructed Transformer layers. Each layer has a multi-head self-attention mechanism and a two-layer feed-forward neural network (FFN).

Suppose the output of the attention mechanism is $\mathbf{A}$. Then, the FFN is defined as:

$$\mathbf{H} = \sigma(\mathbf{A}\mathbf{W}_1 + \mathbf{b}_1), \ \mathbf{X}^\ell = \mathbf{W}_2\mathbf{H} + \mathbf{b}_2, \quad (1)$$

where $\mathbf{W}_1 \in \mathbb{R}^{d \times d_h}$, $\mathbf{W}_2 \in \mathbb{R}^{d_h \times d}$, $\mathbf{b}_1 \in \mathbb{R}^{d_h}$ and $\mathbf{b}_2 \in \mathbb{R}^d$ are weights of the FFN, and σ is the activation function. Here d denotes the embedding dimension, and d_h denotes the hidden dimension of the FFN.

2.2 Mixture-of-Experts Models

Mixture-of-Experts models consist of multiple expert layers, which are similar to the Transformer layers. Each of these layers contain a self-attention mechanism and multiple FFNs (Eq. 1) in parallel, where each FFN is called an expert.

Let $\{E_i\}_{i=1}^N$ denote the experts, and N denotes the total number of experts. Similar to Eq. 1, the experts in layer ℓ take the attention output $\mathbf{A}$ as the input. For each $\mathbf{a}_t$ (the t-th row of $\mathbf{A}$) that corresponds to an input token, the corresponding output $\mathbf{x}_t^\ell$ of layer ℓ is

$$\mathbf{x}_t^\ell = \sum_{i \in \mathcal{T}} p_i(\mathbf{a}_t) E_i(\mathbf{a}_t). \quad (2)$$

Here, $\mathcal{T} \subset \{1 \cdots N\}$ is the activated set of experts with $|\mathcal{T}| = K$, and p_i is the weight of expert E_i.

Different approaches have been proposed to construct $\mathcal{T}$ and compute p_i. For example, Shazeer et al. (2017) take

$$p_i(\mathbf{a}_t) = \left[\mathrm{softmax}\left(\mathbf{a}_t \mathbf{W}_g\right)\right]_i, \quad (3)$$

where $\mathbf{W}_g$ is a weight matrix. Consequently, $\mathcal{T}$ is constructed as the experts that yield top-K largest p_i. However, such an approach suffers from load imbalance, i.e., $\mathbf{W}_g$ collapses such that nearly all the inputs are routed to the same expert. Existing works adopt various ad-hoc heuristics to mitigate this issue, e.g., adding Gaussian noise to Eq. 3 (Shazeer et al., 2017), limiting the maximum number of inputs that can be routed to an expert (Lepikhin et al., 2021), imposing a load balancing loss (Lepikhin et al., 2021; Fedus et al., 2021), and using linear assignment (Lewis et al., 2021). In contrast, Roller et al. 2021 completely remove the gate and pre-assign tokens to experts using hash functions, in which case we can take $p_i = 1/K$.

In Eq. 2, a token only activates K instead of N experts, and usually $K \ll N$, e.g., $K = 2$ and $N = 2048$ in GShard (Lepikhin et al., 2021). As such, the number of FLOPs for one forward pass does not scale with the number of experts. Such a property paves the way for increasing inference speed of a pre-trained model without decreasing the model capacity, i.e., we can adapt the FFNs in a pre-trained model into several smaller components, and only activate one of the components for a specific input token.

2.3 Pre-trained Language Models

Pre-trained language models (Peters et al., 2018; Devlin et al., 2019; Raffel et al., 2019; Liu et al., 2019; Brown et al., 2020; He et al., 2021b,a) have demonstrated superior performance in various natural language processing tasks. These models are trained on an enormous amount of unlabeled data, such that they contain rich semantic information that benefits downstream tasks. Fine-tuning pre-trained language models achieves state-of-the-art performance in tasks such that natural language understanding (He et al., 2021a) and natural language generation (Brown et al., 2020).

2.4 Knowledge Distillation

Knowledge distillation (Romero et al., 2015; Hinton et al., 2015) compensates for the performance drop caused by model compression. In knowledge distillation, a small student model mimics the behavior of a large teacher model. For example, DistilBERT (Sanh et al., 2019) uses the teacher's soft prediction probability to train the student model; TinyBERT (Jiao et al., 2020) aligns the student's layer outputs (including attention outputs and hidden states) with the teacher's; MiniLM (Wang et al., 2020, 2021) utilizes self-attention distillation; and CoDIR (Sun et al., 2020a) proposes to use a contrastive objective such that the student can distinguish positive samples from negative ones according to the teacher's outputs.

There are also heated discussions on the number of layers to distill. For example, Wang et al. (2020, 2021) distill the attention outputs of the last layer; Sun et al. (2019) choose specific layers to distill; and Jiao et al. (2020) use different weights for different transformer layers.

There are two variants of knowledge distillation: task-agnostic (Sanh et al., 2019; Jiao et al., 2020; Wang et al., 2020, 2021; Sun et al., 2020a) and task-specific (Turc et al., 2019; Sun et al., 2019; Li et al., 2020; Hou et al., 2020; Sun et al., 2020b; Xu et al., 2020). The former requires pre-training a small model using knowledge distillation and then fine-tuning on downstream tasks, while the latter directly fine-tunes the small model. Note that task-agnostic approaches are often combined with task-specific distillation for better performance, e.g., TinyBERT (Jiao et al., 2020). In this work, we focus on task-specific distillation.

3 Method

In this section, we first present an algorithm that adapts a pre-trained language model into a MoE model. Such a structure enables inference speedup by reducing the number of parameters involved in computing an input token's representation. Then, we introduce a layer-wise task-specific distillation method that compensates for the performance drop caused by model compression.

3.1 Importance-Guided Adaptation of Pre-trained Language Models

Adapting the FFNs in a pre-trained language model into multiple experts facilitates inference speedup while retaining model capacity. This is because in a MoE model, only a subset of parameters are used to compute the representation of a given token (Eq. 2). These activated parameters are referred to as *effective parameters*. For example, by adapting the FFNs in a pre-trained BERT-base (Devlin et al., 2019) (with hidden dimension 3072) model into 4 experts (each has hidden dimension 768), the

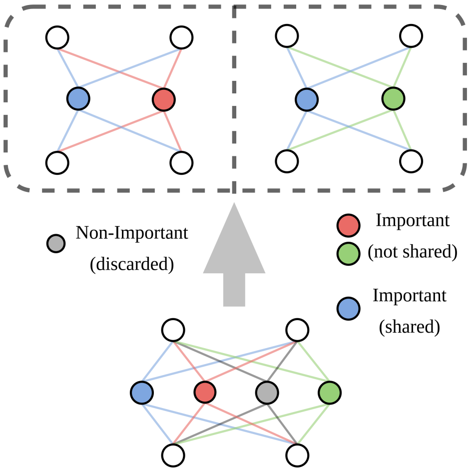

Figure 1: Adapting a two-layer FFN into two experts. The blue neuron is the most important one, and is shared between the two experts. The red and green neurons are the second and third important ones, and are assigned to expert one and two, respectively.

number of effective parameters reduces by half, such that we obtain a ×2 speedup.

Empirically, we find that randomly converting a FFN into experts works poorly (see Figure 3a in the experiments). This is because there are some columns in $\mathbf{W}_1 \in \mathbb{R}^{d\times d_h}$ (correspondingly some rows in $\mathbf{W}_2$ in Eq. 1) contribute more than the others to model performance.

The importance score (Molchanov et al., 2019; Xiao et al., 2019; Liang et al., 2021), originally introduced in model pruning literature, measures such parameter importance. For a dataset $\mathcal{D}$ with sample pairs $\{(x, y)\}$, the score is defined as

$$I_j = \sum_{(x,y)\in\mathcal{D}} \Big| (\mathbf{w}_j^1)^\top \nabla_{\mathbf{w}_j^1} \mathcal{L}(x,y) + (\mathbf{w}_j^2)^\top \nabla_{\mathbf{w}_j^2} \mathcal{L}(x,y) \Big|. \quad (4)$$

Here $\mathbf{w}_j^1 \in \mathbb{R}^d$ is the j-th column of $\mathbf{W}_1$, $\mathbf{w}_j^2$ is the j-th row of $\mathbf{W}_2$, and $\mathcal{L}(x, y)$ is the loss.

The importance score in Eq. 4 indicates variation of the loss if we remove the neuron. That is,

$$\begin{aligned} |\mathcal{L}_\mathbf{w} - \mathcal{L}_{\mathbf{w}=\mathbf{0}}| &\approx \left| (\mathbf{w}-\mathbf{0})^\top \nabla_\mathbf{w} \mathcal{L}_\mathbf{w} \right| \\ &= |\mathbf{w}^\top \nabla_\mathbf{w} \mathcal{L}_\mathbf{w}|, \end{aligned}$$

where $\mathcal{L}_\mathbf{w}$ is the loss with neuron[1] $\mathbf{w}$ and $\mathcal{L}_{\mathbf{w}=\mathbf{0}}$ is the loss without neuron $\mathbf{w}$. Here the approximation is based on the first order Taylor expansion of $\mathcal{L}_\mathbf{w}$ around $\mathbf{w} = \mathbf{0}$.

After computing I_j for all the columns, we adapt $\mathbf{W}_1$ into experts.[2] The columns are sorted in ascending order according to their importance scores as $\mathbf{w}^1_{(1)} \cdots \mathbf{w}^1_{(d_h)}$, where $\mathbf{w}^1_{(1)}$ has the largest I_j and $\mathbf{w}^1_{(d_h)}$ the smallest. Empirically, we find that sharing the most important columns benefits model performance. Based on this finding, suppose we share the top-s columns and we adapt the FFN into N experts, then expert e contains columns $\{\mathbf{w}^1_{(1)}, \cdots, \mathbf{w}^1_{(s)}, \mathbf{w}^1_{(s+e)}, \mathbf{w}^1_{(s+e+N)}, \cdots\}$. Note that we discard the least important columns to keep the size of each expert as $\lfloor d/N \rfloor$. Figure 1 is an illustration of adapting a FFN with 4 neurons in a pre-trained model into two experts.

3.2 Layer-wise Distillation

To remedy the performance drop caused by adapting a pre-trained model to a MoE model, we adopt a layer-wise task-specific distillation algorithm. We use BERT-base (Devlin et al., 2019) as both the student (i.e., the MoE model) and the teacher. We distill both the Transformer layer output $\mathbf{X}^\ell$ (Eq. 2) and the final prediction probability.

For the Transformer layers, the distillation loss is the mean squared error between the teacher's layer output $\mathbf{X}^\ell_{\text{tea}}$ and the student's layer output $\mathbf{X}^\ell$ obtained from Eq. 2.[3] Concretely, for an input x, the Transformer layer distillation loss is

$$\mathcal{L}_{\text{trm}}(x) = \sum_{\ell=0}^{L} \text{MSE}(\mathbf{X}^\ell, \mathbf{X}^\ell_{\text{tea}}), \quad (5)$$

where L is the total number of layers. Notice that we include the MSE loss of the embedding layer outputs $\mathbf{X}^0$ and $\mathbf{X}^0_{\text{tea}}$.

Let f denotes the MoE model and f_{tea} the teacher model. We obtain the prediction probability for an input x as $p = f(x)$ and $p_{\text{tea}} = f_{\text{tea}}(x)$, where p is the prediction of the MoE model and p_{tea} is the prediction of the teacher model. Then the distillation loss for the prediction layer is

$$\mathcal{L}_{\text{pred}}(x) = \frac{1}{2}\left(\text{KL}(p||p_{\text{tea}}) + \text{KL}(p_{\text{tea}}||p)\right), \quad (6)$$

where KL is the Kullback–Leibler divergence.

The layer-wise distillation loss is the sum of Eq. 5 and Eq. 6, defined as

$$\mathcal{L}_{\text{distill}}(x) = \mathcal{L}_{\text{trm}}(x) + \mathcal{L}_{\text{pred}}(x). \quad (7)$$

We will discuss variants of Eq. 7 in the experiments.

---

[1] A neuron $\mathbf{w}$ contains two weights $\mathbf{w}^1$ and $\mathbf{w}^2$ as in Eq. 4.

[2] The other parameters in the FFN: $\mathbf{W}_2$, $\mathbf{b}_1$ and $\mathbf{b}_2$ are treated similarly according to $\{I_j\}$.

[3] Note that Eq. 2 computes the layer output of one token $\mathbf{x}^\ell_t$, i.e., one row in $\mathbf{X}^\ell$.

3.3 Model Training

We employ the random hashing strategy (Roller et al., 2021) to train the experts. That is, each token is pre-assigned to a random expert, and this assignment remains the same during training and inference. We will discuss more about other routing strategies of the MoE model in the experiments.

Given the training dataset $\mathcal{D}$ and samples $\{(x, y)\}$, the training objective is

$$\mathcal{L} = \sum_{(x,y)\in\mathcal{D}} \mathrm{CE}(f(x), y) + \lambda_{\text{distill}}\mathcal{L}_{\text{distill}}(x),$$

where CE is the cross-entropy loss and λ_{distill} is a hyper-parameter.

4 Experiments

In this section, we evaluate the effectiveness and efficiency of the proposed algorithm on natural language understanding and question answering tasks. We implement our algorithm using the *Huggingface Transformers*[4] (Wolf et al., 2019) code-base. All the experiments are conducted on NVIDIA V100 GPUs.

4.1 Datasets

GLUE. We evaluate performance of the proposed method on the General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2019), which is a collection of nine natural language understanding tasks. The benchmark includes two single-sentence classification tasks: SST-2 (Socher et al., 2013) is a binary classification task that classifies movie reviews to positive or negative, and CoLA (Warstadt et al., 2019) is a linguistic acceptability task. GLUE also contains three similarity and paraphrase tasks: MRPC (Dolan and Brockett, 2005) is a paraphrase detection task; STS-B (Cer et al., 2017) is a text similarity task; and QQP is a duplication detection task. There are also four natural language inference tasks in GLUE: MNLI (Williams et al., 2018); QNLI (Rajpurkar et al., 2016); RTE (Dagan et al., 2006; Bar-Haim et al., 2006; Giampiccolo et al., 2007; Bentivogli et al., 2009); and WNLI (Levesque et al., 2012). Following previous works on model distillation, we exclude STS-B and WNLI in the experiments. Dataset details are summarized in Appendix A.

Question Answering. We evaluate the proposed algorithm on two question answering datasets: SQuAD v1.1 (Rajpurkar et al., 2016) and SQuAD v2.0 (Rajpurkar et al., 2018). These tasks are treated as a sequence labeling problem, where we predict the probability of each token being the start and end of the answer span. Dataset details can be found in Appendix A.

4.2 Baselines

We compare our method with both task-agnostic and task-specific distillation methods.

In task-agnostic distillation, we pre-train a small language model through knowledge distillation, and then fine-tune on downstream tasks. The fine-tuning procedure also incorporates task-specific distillation for better performance.

DistilBERT (Sanh et al., 2019) pre-trains a small language model by distilling the temperature-controlled soft prediction probability.

TinyBERT (Jiao et al., 2020) is a task-agnostic distillation method that adopts layer-wise distillation.

MiniLMv1 (Wang et al., 2020) and **MiniLMv2** (Wang et al., 2021) pre-train a small language model by aligning the attention distribution between the teacher model and the student model.

CoDIR (Contrastive Distillation, Sun et al. 2020a) proposes a framework that distills knowledge through intermediate Transformer layers of the teacher via a contrastive objective.

In task-specific distillation, a pre-trained language model is directly compressed and fine-tuned.

PKD (Patient Knowledge Distillation, Sun et al. 2019) proposes a method where the student patiently learns from multiple intermediate Transformer layers of the teacher.

BERT-of-Theseus (Xu et al., 2020) proposes a progressive module replacing method for knowledge distillation.

4.3 Implementation Details

In the experiments, we use BERT-base (Devlin et al., 2019) as both the student model and the teacher model. That is, we first transform the pre-trained model into a MoE model, and then apply layer-wise task-specific knowledge distillation. We set the number of experts in the MoE model to 4, and the hidden dimension of each expert is set to 768, a quarter of the hidden dimension of BERT-base. The other configurations remain unchanged. We share the top-512 important neurons among the experts (see Section 3.1). The number of effective

Table 1: Experimental results on the GLUE development set. The best results are shown in **bold**. All the models are trained without data augmentation. All the models have $66M$ parameters, except BERT-base ($110M$ parameters). We report mean over three runs. Model references: BERT (Devlin et al., 2019), DistilBERT (Sanh et al., 2019), TinyBERT (Jiao et al., 2020), MiniLMv1 (Wang et al., 2020), MiniLMv2 (Wang et al., 2021), CoDIR (Sun et al., 2020a), PKD (Sun et al., 2019), BERT-of-Theseus (Xu et al., 2020).

parameters of the MoE model is $66M$ (v.s. $110M$ for BERT-base), which is the same as the baseline models. We use the random hashing strategy (Roller et al., 2021) to train the MoE model, we will discuss more later. Detailed training and hyper-parameter settings can be found in Appendix B.

4.4 Main Results

Table 1 summarizes experimental results on the GLUE benchmark. Notice that our method outperforms all of the baseline methods in $6/7$ tasks. In general task-agnostic distillation behaves better than task-specific algorithms because of the pre-training stage. For example, the best-performing task-specific method (BERT-of-Theseus) has a 68.2 accuracy on the RTE dataset, whereas accuracy of MiniLMv2 and TinyBERT are greater than 72. Using the proposed method, MoEBERT obtains a 74.0 accuracy on RTE without any pre-training, indicating the effectiveness of the MoE architecture. We remark that MoEBERT behaves on par or better than the vanilla BERT-base model in all of the tasks. This shows that there exists redundancy in pre-trained language models, which paves the way for model compression.

Table 2 summarizes experimental results on two question answering datasets: SQuAD v1.1 and SQuAD v2.0. Notice that MoEBERT significantly outperforms all of the baseline methods in terms of both evaluation metrics: exact match (EM) and F1. Similar to the findings in Table 1, task-agnostic distillation methods generally behave better than task-specific ones. For example, PKD has a 69.8 F1 score on SQuAD 2.0, while performance of MiniLMv1 and MiniLMv2 is over 76. Using the proposed MoE architecture, performance of our method exceeds both task-specific and task-agnostic distillation, e.g., the F1 score of MoEBERT on SQuAD 2.0 is 76.8, which is 7.0 higher than PKD (task-specific) and 0.4 higher than MiniLMv2 (task-agnostic).

4.5 Ablation Study

Expert dimension. We examine the affect of expert dimension, and experimental results are illustrated in Figure 2a. As we increase the dimension of the experts, model performance improves. This is because of the increased model capacity due to a larger number of effective parameters.

Number of experts. Figure 2b summarizes experimental results when we modify the number of experts. As we increase the number of experts, model performance improves because we effectively enlarge model capacity. We remark that having only one expert is equivalent to compressing

the model without incorporating MoE. In this case performance is unsatisfactory because of the limited representation power of the model.

Shared dimension. Recall that we share important neurons among the experts when adapting the FFNs. In Figure 2c we examine the effect of varying the number of shared neurons. Notice that sharing no neurons yields the worst performance, indicating the effectiveness of the sharing strategy. Also notice that performance of sharing all the neurons is also unsatisfactory. We attribute this to the lack of diversity among the experts.

4.6 Analysis

Effectiveness of distillation. After adapting the FFNs in the pre-trained BERT-base model into experts, we train MoEBERT using layer-wise knowledge distillation. In Table 3, we examine the effectiveness of the proposed distillation method. We show experimental results on RTE, MNLI and SQuAD v2.0, where we remove the distillation and directly fine-tune the adapted model. Results show that by removing the distillation module, model performance significantly drops, e.g., accuracy decreases by 0.7 on RTE and the exact match score decreases by 1.1 on SQuAD v2.0.

Effectiveness of importance-based adaptation. Recall that we adapt the FFNs in BERT-base into experts according to the neurons' importance scores (Eq. 4). We examine the method's effectiveness by experimenting on two different strategies: randomly split the FFNs into experts (denoted *Random*), and adapt (and share) the FFNs according

to the inverse importance, i.e., we share the neurons with the smallest scores (denoted *Inverse*). Figure 3a illustrated the results. Notice that performance significantly drops when we apply random splitting compared with *Import* (the method we use). Moreover, performance of *Inverse* is even worse than random splitting, which further demonstrates the effectiveness of the importance metric.

Different distillation methods. MoEBERT is trained using a layer-wise distillation method (Eq. 7), where we add a distillation loss to every intermediate layer (denoted *All*). We examine two variants: (1) we only distill the hidden states of the last layer (denoted *Last*); (2) we distill the hidden states of every other layer (denoted *Skip*). Figure 3b shows experimental results. We see that only distilling the last layer yields unsatisfactory performance; while the *Skip* method obtains similar results compared with *All* (the method we use).

Different routing methods. By default, we use a random hashing strategy (denoted *Hash-r*) to route input tokens to experts (Roller et al., 2021). That is, each token in the vocabulary is pre-assigned to a random expert, and this assignment remains the same during training and inference. We examine other routing strategies:

1. We employ sentence-based routing with a trainable gate as in Eq. 3 (denoted *Gate*). Note that in this case, token representations in a sentence are averaged to compute the sentence representation, which is then fed to the gating mechanism for routing. Such a sentence-level routing strategy can significantly reduce communication overhead in MoE models. Therefore, it is advantageous for inference compared with other routing methods.

2. We use a balanced hash list (Roller et al., 2021), i.e., tokens are pre-assigned to experts according to frequency, such that each expert receives approximately the same amount of inputs (denoted *Hash-b*).

From Figure 3c, we see that all the methods yield similar performance. Therefore, MoEBERT is robust to routing strategies.

Inference speed. We examine inference speed of BERT, DistilBERT and MoEBERT on the SST-2 dataset, and Figure 4 illustrates the results. Note that for MoEBERT , we use the sentence-based gating mechanism as in Figure 3c. All the methods are evaluated on the same CPU, and we set the maximum sequence length to 128 and the batch size to 1. We see that the speed of MoEBERT is slightly slower than DistilBERT, but significantly faster than BERT. Such a speed difference is because of two reasons. First, the gating mechanism in MoEBERT causes additional inference latency. Second, DistilBERT develops a shallower model, i.e., it only has 6 layers instead of 12 layers; whereas MoEBERT is a narrower model, i.e., the hidden dimension is 768 instead of 3072.

Compressing larger models. Task-specific distillation methods do not require pre-training. Therefore, these methods can be easily applied to other model architectures and sizes beyond BERT-base. We compress the BERT-large model. Specifically, we adapt the FFNs in BERT-large (with hidden dimension 4096) into four experts, such that each expert has hidden dimension 1024. We share the top-512 neurons among experts according to the importance score. After compression, the number of effective parameters is reduces by half. Table 4 demonstrates experimental results on RTE and MNLI. We see that similar to the findings in Table 1, MoEBERT behaves on par or better than BERT-large in all of the experiments.

5 Conclusion

We present MoEBERT, which uses a Mixture-of-Experts structure to distill pre-trained language models. Our proposed method can speedup inference by adapting the feed-forward neural networks (FFNs) in a pre-trained language model into multiple experts. Moreover, the proposed method largely retains model capacity of the pre-trained model. This is in contrast to existing approaches, where the representation power of the compressed model is limited, resulting in unsatisfactory performance. To adapt the FFNs into experts, we adopt an importance-based method, which identifies and shares the most important neurons in a FFN among the experts. We further propose a layer-wise task-specific distillation algorithm to train MoEBERT . We conduct systematic experiments on natural language understanding and question answering tasks. Results show that the proposed method outperforms existing distillation approaches.

Ethical Statement

This paper proposes MoEBERT, which uses a Mixture-of-Experts structure to increase model capacity and inference speed. We demonstrate that MoEBERT can be used for model compression. Experiments are conducted by fine-tuning pre-trained language models on natural language understanding and question answering tasks. In all the experiments, we use publicly available data and models, and we build our algorithms using public code bases. We do not find any ethical concerns.

A Dataset details

Statistics of the GLUE benchmark is summarized in Table 6. Statistics of the question answering datasets (SQuAD v1.1 and SQuAD v2.0) are summarized in Table 5.

	#Train	#Validation
SQuAD v1.1	87,599	10,570
SQuAD v2.0	130,319	11,873

Table 5: Statistics of the SQuAD dataset.

B Training Details

We use Adam (Kingma and Ba, 2015) as the optimizer with parameters $(\beta_1, \beta_2) = (0.9, 0.999)$. We employ gradient clipping with a maximum gradient norm 1.0, and we choose weight decay from $\{0, 0.01, 0.1\}$. The learning rate is chosen from $\{1 \times 10^{-5}, 2 \times 10^{-5}, 3 \times 10^{-5}, 4 \times 10^{-5}\}$, and we do not use learning rate warm-up. We train the model for $\{3, 4, 5, 10\}$ epochs with a batch size chosen from $\{8, 16, 32, 64\}$. The weight of the distillation loss λ_{distil} is chosen from $\{1, 2, 3, 4, 5\}$.

Hyper-parameters for distilling BERT-base is summarized in Table 7. We use Adam (Kingma and Ba, 2015) as the optimizer with parameters $(\beta_1, \beta_2) = (0.9, 0.999)$. We employ gradient clipping with a maximum gradient norm 1.0. We do not use learning rate warm-up. For the GLUE benchmark, we use a maximum sequence length of 512 except MNLI and QQP, where we set the maximum sequence length to 128. For the SQuAD datasets, the maximum sequence length is set to 384.

Corpus	Task	#Train	#Dev	#Test	#Label	Metrics
Single-Sentence Classification (GLUE)						
CoLA	Acceptability	8.5k	1k	1k	2	Matthews corr
SST	Sentiment	67k	872	1.8k	2	Accuracy

Abstract

Although self-attention based models such as Transformers have achieved remarkable successes on natural language processing (NLP) tasks, recent studies reveal that they have limitations on modeling sequential transformations (Hahn, 2020), which may prompt re-examinations of recurrent neural networks (RNNs) that demonstrated impressive results on handling sequential data. Despite many prior attempts to interpret RNNs, their internal mechanisms have not been fully understood, and the question on how exactly they capture sequential features remains largely unclear. In this work, we present a study that shows there actually exist some explainable components that reside within the hidden states, which are reminiscent of the classical n-grams features. We evaluated such extracted explainable features from trained RNNs on downstream sentiment analysis tasks and found they could be used to model interesting linguistic phenomena such as negation and intensification. Furthermore, we examined the efficacy of using such n-gram components alone as encoders on tasks such as sentiment analysis and language modeling, revealing they could be playing important roles in contributing to the overall performance of RNNs. We hope our findings could add interpretability to RNN architectures, and also provide inspirations for proposing new architectures for sequential data.

1 Introduction

Modern recurrent neural networks (RNNs), including Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Gated Recurrent Units (GRU) (Cho et al., 2014), have demonstrated impressive results on tasks involving sequential data. They have proven to be capable of modeling formal languages (Weiss et al., 2018; Merrill, 2019; Merrill et al., 2020) and capturing structural features (Li et al., 2015a,b, 2016; Linzen et al., 2016; Belinkov et al., 2017; Liu et al., 2019) on NLP tasks. Although Transformers (Vaswani et al., 2017) have achieved remarkable performances on NLP tasks such as machine translation, it is argued that they may have limitations on modeling hierarchical structure (Tran et al., 2018; Hahn, 2020) and cannot handle functions requiring sequential processing of input well (Dehghani et al., 2019; Hao et al., 2019; Bhattamishra et al., 2020; Yao et al., 2021). Furthermore, a recent work shows that combining recurrence and attention (Lei, 2021) can result in strong modeling capacity. Another recent work incorporating recurrent cells into Transformers (Hutchins et al., 2022) substantially improved performance on language modeling involving very long sequences, prompting re-investigations of RNNs. On the other hand, it was observed in prior work that RNNs were able to capture linguistic phenomena such as negation and intensification (Li et al., 2016), but the question why they could achieve so still largely remains unanswered.

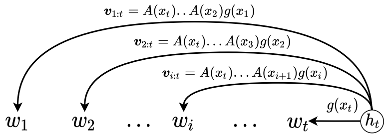

Figure 1: An RNN hidden state may encode a linear combination of all the n-grams ending at the current time step.

In this work, we focus on better understanding RNNs from a more theoretical perspective. We demonstrate that the recurrence mechanism of RNNs may induce a linear combination of interpretable components. These components reside in their hidden states in the form of the iterated matrix-vector multiplication that is based on the representations of tokens in the (reverse) order they appear in the sequence. Such components, solely depending on inputs and learned parameters, can be conveniently interpreted and are reminiscent of those compositional features used in classical n-gram models (Jurafsky and Martin, 2009). They may also provide us with insights on how RNNs compose semantics from basic linguistic units. Our analysis further shows that, the hidden state at each time step includes a weighted combination of components that represent all the "n-grams" ending at that specific position in the sequence as shown

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1624 - 1639
July 10-15, 2022 ©2022 Association for Computational Linguistics

in Figure 1. We gave specific representations for the n-gram components in Elman RNNs (Elman, 1990), GRUs and LSTMs.

We investigated the interpretability of those n-gram components on trained RNN models, and found they could explain phenomena such as negation and intensification and reflect the overall polarity on downstream sentiment analysis tasks, where such linguistic phenomena are prevalent. Our experiments also revealed that the GRU and LSTM models are able to yield better capabilities in modeling such linguistic phenomena than the Elman RNN model, partly attributed to the gating mechanisms they employed which resulted in more expressive n-gram components. We further show that the linear combination of such components yields effective context representations. We explored the effectiveness of such n-gram components (along with the corresponding context representations) as alternatives to standard RNNs, and found they can generally yield better results than the baseline compositional methods on several tasks, including sentiment analysis, relation classification, named entity recognition, and language modeling.

We hope that our work could give inspirations to our community, serving as a useful step towards proposing new architectures for capturing contextual information within sequences.[1]

2 Related Work

Interpretability of RNNs: A line of work focuses on the relationship between RNNs and finite-state machines (Weiss et al., 2018; Merrill, 2019; Suzgun et al., 2019; Merrill et al., 2020; Eyraud and Ayache, 2020; Rabusseau et al., 2019), providing explanation and prediction on the expressive power and limitations of RNNs on formal languages both empirically and theoretically. Kanai et al. (2017) investigated conditions that could prevent gradient explosions for GRU based on dynamics. Maheswaranathan et al. (2019) and Maheswaranathan and Sussillo (2020) linearized the dynamics of RNNs around fixed points of hidden states and elucidated contextual processing. Our work focuses on studying a possible mechanism of RNNs that handles exact linguistic features.

Another line of work aims to detect linguistic features captured by RNNs. Visualization approaches (Karpathy et al., 2015; Li et al., 2016) were initially used to examine compositional information in RNN outputs. Linzen et al. (2016) assessed LSTMs' ability to learn syntactic structure and Emami et al. (2021) gave rigorous explanations on the standard RNNs' ability to capture long-range dependencies. Decomposition methods (Murdoch and Szlam, 2017; Murdoch et al., 2018; Singh et al., 2019; Arras et al., 2017, 2019; Chen et al., 2020) were proposed to produce importance scores for hierarchical interactions in RNN outputs. Our work can be viewed as an investigation on how those interaction came about.

Compositional Models: A variety of compositional functions based on vector spaces have been proposed in the literature to compose semantic meanings of phrases, including simple compositions of adjective-noun phrases represented as matrix-vector multiplication (Mitchell and Lapata, 2008; Baroni and Zamparelli, 2010) and a matrix-space model (Rudolph and Giesbrecht, 2010; Yessenalina and Cardie, 2011) based on matrix multiplication. Socher et al. (2012, 2013) introduced a recursive neural network model that assigns every word and longer phrase in a parse tree both a vector and a matrix, and represents composition of a non-terminal node with matrix-vector multiplication. Kalchbrenner and Blunsom (2013) employed convolutional and recurrent neural networks to model compositionality at the sentence and discourse levels respectively. Those models are designed in an intuitive manner based on the nature of languages thus being interpretable. We can show that RNNs may process contextual information in a way bearing a resemblance to those early models.

3 A Theory on N-gram Representation

First, let us spend some time to discuss how to represent n-grams. Various approaches to representing n-grams have been proposed in the literature (Mitchell and Lapata, 2008; Bengio et al., 2003; Mitchell and Lapata, 2008; Mnih and Teh, 2012; Ganguli et al., 2008; Orhan and Pitkow, 2020; Emami et al., 2021; Rudolph and Giesbrecht, 2010; Yessenalina and Cardie, 2011; Baroni and Zamparelli, 2010). We summarize in Table 1 different approaches for representing n-grams.

Although empirically it has been shown that different approaches can lead to different levels of effectiveness, the rationales underlying many of the design choices remain unclear. In this section, we establish a small theory on representing n-grams, which leads to a new formulation on capturing the semantic information within n-grams.

Let us assume we have a vocabulary $\mathbb{V}$ that consists of all possible word tokens. The set of n-grams can be denoted as $\mathbb{V}^*$ (including the special

Table 1: Different models for defining representations for n-grams within the phrase $x_1, x_2, \ldots, x_{t-1}, x_t$ and constructing the context representation out of the n-grams during learning. L: the maximum length allowed for the context representation. $\boldsymbol{C}$ is a weight matrix, and $\boldsymbol{C}_k$ is a (relative) position-specific weight matrix. A and g are functions that return a matrix and a vector respectively.

n-gram which is the empty string ϵ). Consider three n-grams a, b, and c from $\mathbb{V}^*$, with their semantic representations $r(a)$, $r(b)$, and $r(c)$ respectively. Similarly, we may have $r(ab)$ which return the semantic representations of the concatenated n-grams ab. It is desirable for our representations to be compositional in some sense. Specifically, a longer n-gram may be semantically related to those shorter n-grams it contains in some way.

Under some mild compositional assumptions related to the *principle of compositionality* (Frege, 1948)[2], it is reasonable to expect that there exists some sort of rule or operation that allows us to compose semantics of longer n-grams out of shorter ones. Let us use $\otimes$ to denote such an operation. We believe a good representation system for n-grams shall satisfy several key properties. First, the semantics of the n-gram abc shall be determined through either combining the semantics of the two n-grams a and bc or through combining the semantics of ab and c. The semantics of abc is unique, regardless of which of these two ways we use. Second, for the empty string ϵ, it should not convey any semantics. Formally, we can write them as:[3]

- **Associativity**: $\forall a, b, c \in \mathbb{V}^*$, $(r(a) \otimes r(b)) \otimes r(c) = r(a) \otimes (r(b) \otimes r(c))$
- **Identity**: $\forall a \in \mathbb{V}^*$, $r(a) \otimes r(\epsilon) = r(a)$, and $r(\epsilon) \otimes r(a) = r(a)$

This essentially shows that the representation space for all n-grams under the operation $\otimes$, denoted as $(\mathbb{V}^*, \otimes)$, forms a *monoid*, an important concept in abstract algebra (Lallement, 1979), with significance in theoretical computer science (Meseguer and Montanari, 1990; Rozenberg and Salomaa, 2012).

On the other hand, it can be easily verified that the space of all $d \times d$ (where d is an integer) real square matrices under matrix multiplication, denoted as $(\mathbb{R}^{d \times d}, \cdot)$, also strictly forms a monoid (i.e., it is associative and has an identity, but is *not* commutative). We can therefore establish a homomorphism from $\mathbb{V}^*$ to $\mathbb{R}^{d \times d}$, resulting in the function $r(\cdot) \in \mathbb{V}^* \to \mathbb{R}^{d \times d}$.

This essentially means that we may be able to rely on a sub-space within $\mathbb{R}^{d \times d}$ as our mathematical object to represent the space of n-grams, where the matrix multiplication operation can be used to compose representations for longer n-grams from shorter ones. Thus, for a unigram x (a single word in the vocabulary), we have:

$$r(x) := \boldsymbol{A}_x \tag{1}$$

where $\boldsymbol{A}_x \in \mathbb{R}^{d \times d}$ is the representation for the word x (how to learn such a matrix is a separate question to be discussed later). Note that the empty string ϵ comes with a unique representation which is the $d \times d$ identity matrix $\boldsymbol{I}$.

We can either use matrix left-multiplication or right-multiplication as our operator $\otimes$. Assume the language under consideration employs the left-to-right writing system. It is reasonable to believe that a human reader processes the text left-to-right, and the semantics of the text gets evolved each time the reader sees a new word. We may use the matrix left-multiplication as the preferred operator in this case. The system will left-multiply (modify) an existing n-gram representation with a matrix associated with the new word that appears right after the existing n-gram, forming the representation of the new n-gram. Such an operation essentially performs a transform that simulates the process of yielding new semantics when appending a new word at the end of an existing phrase. With this, for

---

[2] The principle states that "the meaning of an expression is determined by the meanings of the sub-expressions it contains and the rules used to combine such sub-expressions".

[3] Besides, another important property is that the order used for combining two n-grams does matter. In other words, $r(a) \otimes r(b)$ usually may not be the same as $r(b) \otimes r(a)$.

a general n-gram $x_i, x_{i+1}, \ldots, x_t$ ($i \leq t$), we have:

$$r(x_i, x_{i+1}, \ldots, x_t) = \prod_{k=t}^{i} \boldsymbol{A}_{x_k} \tag{2}$$

However, the conventional wisdom in NLP has been to use vectors to represent basic linguistic units such as words, phrases or sentences (Mikolov et al., 2013a,b; Pennington et al., 2014; Kiros et al., 2015). This can be achieved by a transform:

$$\left(\prod_{k=t}^{i} \boldsymbol{A}_{x_k}\right) \boldsymbol{u} \tag{3}$$

where $\boldsymbol{u} \in \mathbb{R}^d$ is a vector that maps the resulting matrix representation into a vector representation.

Next, we will embark on our journey to examine the internal representations of RNNs. As we will see, interestingly, our developed n-gram representations can emerge within such models.

4 Interpretable Components in RNNs

An RNN is a parameterized function whose hidden state can be written recursively as:

$$\boldsymbol{h}_t = f(x_t, \boldsymbol{h}_{t-1}), \tag{4}$$

where x_t is the input token at time step t and $\boldsymbol{h}_{t-1} \in \mathbb{R}^d$ is the previous hidden state. Assume f is differentiable at any point, with the Taylor expansion, $\boldsymbol{h}_t$ can be rewritten as:

$$\boldsymbol{h}_t = f(x_t, \boldsymbol{0}) + \nabla f(x_t, \boldsymbol{0})\boldsymbol{h}_{t-1} + o(\boldsymbol{h}_{t-1}), \tag{5}$$

where $\nabla f(x_t, \boldsymbol{0}) = \frac{\partial f}{\partial \boldsymbol{h}_{t-1}}|_{\boldsymbol{h}_{t-1}=\boldsymbol{0}}$ is the Jacobian matrix, and o is the remainder of the Taylor series.

Let $g(x_t) = f(x_t, \boldsymbol{0})$ and $A(x_t) = \nabla f(x_t, \boldsymbol{0})$. Note that $g(x_t) \in \mathbb{R}^d$ and $A(x_t) \in \mathbb{R}^{d \times d}$ are both functions of x_t. Therefore, the equation above can be written as:

$$\boldsymbol{h}_t = g(x_t) + A(x_t)\boldsymbol{h}_{t-1} + o(\boldsymbol{h}_{t-1}). \tag{6}$$

If the hidden state has a sufficiently small norm, it can be approximated by the first-order Taylor expansion as follows[4]:

$$\boldsymbol{h}_t \approx g(x_t) + A(x_t)\boldsymbol{h}_{t-1}. \tag{7}$$

Next we illustrate how this recurrence relation can help us identify some salient components.

4.1 Emergence of N-grams

Consider the simplified RNN with the following recurrence relation,

$$\boldsymbol{h}_t = g(x_t) + A(x_t)\boldsymbol{h}_{t-1}, \tag{8}$$

where $\boldsymbol{h} \in \mathbb{R}^d$, and $g(x_t) \in \mathbb{R}^d$ and $A(x_t) \in \mathbb{R}^{d \times d}$ are functions of x_t. This recurrence relation can be expanded repeatedly as follows,

$$\begin{aligned}\boldsymbol{h}_t &= g(x_t) + A(x_t)g(x_{t-1}) + A(x_t)A(x_{t-1})\boldsymbol{h}_{t-2} \\ &= \cdots = \sum_{i=1}^{t} A(x_t)\ldots A(x_{i+1})g(x_i) \\ &= \sum_{i=1}^{t} \underbrace{\left(\prod_{j=t}^{i+1} A(x_j)\right) g(x_i)}_{\boldsymbol{v}_{i:t}},\end{aligned}$$

We can see that $\boldsymbol{v}_{i:t}$ bear some resemblance to the term in Equation 3, which can be rewritten as:

$$\left(\prod_{j=t}^{i+1} \underbrace{\boldsymbol{A}_{x_j}}_{A(x_j)}\right) \underbrace{\left(\boldsymbol{A}_{x_i}\boldsymbol{u}\right)}_{g(x_i)}, \tag{9}$$

With the definition $A(x_j) := \boldsymbol{A}_{x_j}$ and $g(x_i) := A(x_i)\boldsymbol{u}$, we can see $\boldsymbol{v}_{i:t}$ can be interpreted as an "n-gram representation" that we developed in the previous section. It is important to note that, however, the use of function $g(x_i)$ in RNNs may lead to greater expressive power than the original formulation based on $\boldsymbol{A}_{x_i}\boldsymbol{u}$.[5]

This interesting result shows that the hidden state of a simple RNN (characterized by Equation 8) is the sum of the representations of all the n-grams ending at time step t. Such salient components within RNN also show that the standard RNN may actually have a mechanism that is able to capture implicit n-gram information as described above. This leads to the following definition:

Definition 1 (**N-gram Representation**) *For the n-gram $x_i, x_{i+1}, \ldots, x_t$, its representation is:*

$$\boldsymbol{v}_{i:t} = \left(\prod_{j=t}^{i+1} A(x_j)\right) g(x_i), \tag{10}$$

where $A(x_j) \in \mathbb{R}^{d \times d}$ and $g(x_i) \in \mathbb{R}^d$.

4.2 Context Representation

With the above definition, we may want to consider how to perform learning. The learning task involves identifying the functions A and g – in other words, learning representations for word tokens.

A typical learning setup that we may consider here is the task of language modeling. Such a task

---

[4] There will be an "approximation gap" at each time step between the "approximated" hidden state and the actual standard hidden state. We may leverage regularization methods such as weight-decaying and the spectral normalization (Miyato et al., 2018) to prevent the gap from growing unbounded.

[5] This is because we can always construct $g(x_i)$ from any given $\boldsymbol{A}_{x_i}$ and $\boldsymbol{u}$, but in general we may not always be able to decompose $g(x_i)$ into the form $\boldsymbol{A}_{x_i}\boldsymbol{u}$ (for all x_i).

can be defined as predicting the next word x_{t+1} based on the representation of preceding words $x_1, x_2, \dots, x_t$ which serves as its left context. This is an unsupervised learning task, where the underlying assumption involved is the *distributional hypothesis* (Harris, 1954). Specifically, the model learns how to "reconstruct" the current word x_{t+1} out of $x_1, x_2, \dots, x_t$ which serves as its context.

Now the research question is how to define the representation for this specific context. As this left context is also an n-gram, it might be tempting to directly use its n-gram representation defined above to characterize such a left context. However, we show such an approach is not desirable.

The n-gram representation for this context can be written in the following alternative form:

$$\boldsymbol{v}_{1:t} = \left(\prod_{j=t}^{2} A(x_j)\right) g(x_i) = W(x_{2:t}) g(x_1), \tag{11}$$

This shows that the n-gram representation of $x_1, x_2, \dots, x_t$ could be interpreted as a "weighted" representation of the word x_1 (where the weight matrix is derived from the words between x_1 and x_{t+1}, measuring the strength of the connection between them). However, ideally, the context representation shall not just take x_1 but other adjacent words preceding x_{t+1} into account, where each word contributes towards the final context representation based on the connection between them. This leads to the following way of defining the context:

$$\begin{aligned} \sum_{i=1}^{t} \boldsymbol{v}_{i:t} &= \sum_{i=1}^{t} \left(\prod_{j=t}^{i+1} A(x_j)\right) g(x_i) \\ &= \sum_{i=1}^{t} W(x_{i:t}) g(x_i), \end{aligned} \tag{12}$$

In fact, such an idea of defining the context as a weighted combination of surrounding words is not new – it recurs in the literature of language modeling (Bengio et al., 2003; Mnih and Teh, 2012), word embedding learning (Mikolov et al., 2013a,b), and graph representation learning (Cao et al., 2016).

Interestingly, the hidden states in the RNNs, as shown in Equation 9, also suggest exactly the same way of defining this left context. Indeed, when using RNNs for language modeling, each hidden state is exactly serving as the context representation for predicting the next word in the sequence.

The above gives rise to the following definition:

Definition 2 (Context Representation) *For the n-gram $x_1, x_2, \dots, x_t$, its representation when serving as the (left) context is:*

$$\boldsymbol{c}_{1:t} = \sum_{i=1}^{t} \boldsymbol{v}_{i:t} = \sum_{i=1}^{t} \left(\prod_{j=t}^{i+1} A(x_j)\right) g(x_i), \tag{13}$$

where $A(x_j) \in \mathbb{R}^{d \times d}$ and $g(x_i) \in \mathbb{R}^d$.

4.3 Model Parameterization

With the above understandings on such salient components within RNNs, we can now look into how different variants of RNNs parameterize the functions A and g. The definition of Elman RNN, GRU and LSTM together with the corresponding Jacobian matrix $A(x_t)$ and vector function $g(x_t)$ functions are listed in Table 2[6]. We discuss how such different parameterizations may lead to different expressive power when they are used in practice.

We can see the ways GRU or LSTM parameterize $A(x_t)$ and $g(x_t)$ appear to be more complex compared to Elman RNN. This can partially be attributed to their gating mechanisms. Although the original main motivation of introducing such mechanisms may be to alleviate the exploding gradient and vanishing gradient issues (Hochreiter and Schmidhuber, 1997; Cho et al., 2014), we could see such designs also result in terms describing gates and intermediate representations. A and g are then independently derived based on certain rich interactions between such terms. We believe such interactions may likely increase the expressive power of the resulting n-gram representations. We will validate these points and discuss more in our experiments.

5 Experiments

In our experiments, we focus on the following aspects: 1) understanding the effectiveness of the proposed n-gram (and context) representations when used in practice, as compared to baseline models; 2) examining the significance of the choice of context representation; 3) interpreting the proposed representations by examining how well they could be used to capture certain linguistic phenomena.

We employ the sentiment analysis, relation classification, named entity recognition (NER) and language modeling tasks as testbeds. The first task is often used in investigating n-gram phenomena (Yessenalina and Cardie, 2011; Li et al., 2016) while the others are often used in examining how capable an encoder is when extracting features from texts (Grave et al., 2018; Zhou et al., 2016; Lample et al., 2016).

Datasets For sentiment analysis, we considered the Stanford Sentiment Treebank (SST) (Socher et al., 2013), the IMDB (Maas et al., 2011), and the AG-news topic classification[7] (Zhang et al.,

---

[6] For brevity, we suppress biases following Merrill et al. (2020).

[7] AG-news can be viewed as a special sentiment analysis dataset.

	Definition	Parameterization	
Elman	$\boldsymbol{h}_t = \tanh(\boldsymbol{W}_{in}\boldsymbol{x}_t + \boldsymbol{W}_{ih}\boldsymbol{h}_{t-1})$	$A(x_t) = \mathrm{diag}[\tanh'(\boldsymbol{W}_{in}\boldsymbol{x}_t)]\boldsymbol{W}_{ih}$	$g(x_t) = \tanh(\boldsymbol{W}_{in}\boldsymbol{x}_t)$.

Table 2: Parameterization of A and g by Elman RNN, GRU, and LSTM. $\boldsymbol{x}_t$ is the representation of the input token x_t and $\boldsymbol{W}_{**}$ refers to a weight matrix. σ and $\tanh$ are the *element-wise* sigmoid and $\tanh$ functions respectively. g', $\tanh'$ and f' refer to the *element-wise* derivative. The diag operation converts a vector into a diagonal matrix.

2015) datasets. The first dataset has sufficient labels for phrase-level analysis, the second dataset has instances with relatively longer lengths, and the third one is multi-class. For relation classification and NER, we considered the SemEval 2010 Task 8 (Hendrickx et al., 2010) and CoNLL-2003 (Tjong Kim Sang and De Meulder, 2003) datasets respectively. For language modeling, we considered the Penn Treebank (PTB) dataset (Marcus et al., 1993), the Wikitext-2 (Wiki2) dataset and the Wikitext-103 (Wiki103) dataset (Merity et al., 2016). PTB is relatively small while Wiki103 is large. The statistics are shown in Tables 6 and 7 in the appendix.

Baselines The n-gram representations (together with their corresponding context representations) discussed in the literature are considered as baselines, which are listed in Table 1 along with the MVMA and MVM models. MVM(A)-G/L/E refers to the MVM(A) model created with the A and g functions derived from GRU/LSTM/Elman, but are trained directly from data. The A and g functions for GRU, LSTM and Elman are listed in Table 2.

Additionally, to understand whether the complexity of A affects the expressive power, we created a new model called MVMA-ME, which comes with an A function that is slightly more complex than that of MVMA-E but less complex than those of MVMA-G and MVMA-L: $A(x_t) = 0.25\,\mathrm{diag}[\tanh(\boldsymbol{W}\boldsymbol{x}_t)]\boldsymbol{M} + 0.5\boldsymbol{I}$ and $g(x_t) = \tanh(\boldsymbol{W}'\boldsymbol{x}_t)$ (here, $\boldsymbol{W}$, $\boldsymbol{M}$ and $\boldsymbol{W}'$ are learnable weight matrices). The g function is the same as that of MVMA-E.

Table 3: Accuracy percentage (↑) on sentiment analysis (text classification) datasets (averaged over 3 runs). “-” means the model failed to converge.

Setup For sentiment analysis, relation classification and language modeling, models consist of one embedding layer, one RNN layer, and one fully-connected layer. The Adagrad optimizer (Duchi et al., 2011) was used along with dropout (Srivastava et al., 2014) for sentiment analysis[8] and relation classification. For language modeling, models were trained with the Adam optimizer (Kingma and Ba, 2014). We ran word-level models with truncated backpropagation through time (Williams and Peng, 1990) where the truncated length was set to 35. Adaptive softmax (Joulin et al., 2017) was used for Wiki103. For NER, models consist of one embedding layer, one bidirectional RNN layer, one projection layer and one conditional random field (CRF) layer. The SGD optimizer was used. Final models were chosen based on the best validation results. More implementation details can be found in the appendix.

5.1 Comparison of Representation Models

We investigate how baseline n-gram representation models[9], the MVM model, and the MVMA model perform on the aforementioned testbeds. We also compare with the standard RNN models.

Sentiment Analysis Apart from the GRU and LSTM models, it can be observed that our MVMA-G and MVMA-L models are also able to achieve competitive results on three sentiment analysis datasets, as we can see from Table 3, demonstrating the efficacy of those recurrence-induced n-gram

---

[8] We investigated the approximation between RNNs and their corresponding recurrence relations in Appendix B.2. The spectral normalization (Miyato et al., 2018) was used on the weight matrices $\boldsymbol{W}_{h*}$ for standard RNNs.

[9] We excluded VM, which we found was hard to train. We also excluded MVM-R which only considers bigrams.

representations. Although Elman RNN and its corresponding MVMA-E and MVM-E models also have a mechanism for capturing n-gram information (similar to GRU and LSTM), they did not perform well, which may be attributed to a limited expressive power of their A and g functions when used for defining n-grams as described previously.

Both MM and VA-EW fail to converge on AG-news and IMDB, showing challenges for them to handle long instances. This may be explained by the lengthy matrix multiplication involved in their representations, which may result in vanishing/exploding gradient issues. Interestingly, MVM-G and MVM-L, which solely rely on the longest n-gram representation, are also able to achieve good results on SST-2, indicating a reasonable expressive power of such n-gram representations alone. However, they fail to catch up with MVMA-G and MVMA-L on IMDB which contains much longer instances, confirming the significance of the context representation, which captures n-grams of varying lengths.

Unlike MVMA-E, the MVMA-ME model does not suffer from loss stagnation on AG-news and IMDB but the performance on IMDB obviously falls behind MVMA-G and MVMA-L as shown in Table 3. This indicates a sufficiently expressive $A(x_t)$ (such as the Jacobian matrices of GRU and LSTM) may be needed to handle long instances.

Relation Classification & NER For relation classification, context representations (or final hidden states) are used for classification. For NER, we use the concatenated context representations (or hidden states) at each position of bidirectional models to predict entities and their types. Table 4 shows that MVMA-G and MVMA-L outperform the MVM-G and MVM-L models respectively on both tasks, again confirming the effectiveness of the context representations. MVM(A)-E did not perform as well as MVM(A)-G and MVM(A)-L, which demonstrates the significance of expressive power for the A and g functions. Similar to the results in sentiment analysis, MVMA-ME did not perform as well as MVMA-G and MVMA-L. However, to our surprise, MVMA-ME did not outperform VA-EW on NER, suggesting that a delicate choice of A can be important for this task. The poor performance of VA-W on NER might be explained by a weak expressive power of its n-gram representations. MM fails to converge on the relation classification task, which implies it is not robust across different datasets. Interestingly, it is remarkable that MVMA-G, MVMA-L and MVMA-E could yield competitive results compared to GRU, LSTM and Elman on NER, implying such n-gram representations could be crucial for our NER task.

Model	Relation Classification		NER	
	dev	test	dev	test
MM	-	-	33.9±0.6	30.8±0.4

Table 5: Perplexities (↓) on language modeling (averaged over 5 runs). "-": the model failed to converge.

Language Modeling For the language modeling task, we choose MVMA-G, MVMA-L, MVM-G and MVM-L for experiments. We also run MVMA-ME. As we can see from Table 5, there are performance gaps between the MVMA models and the standard RNNs – though the gaps often do not appear to be particularly large. This indicates there may be extra information within higher order terms of the standard RNN functions useful for such a task. Yet, such information cannot be captured by the MVMA models that employ simplified functions. The gaps between the MVM models and MVMA models are remarkable, which again indicates that the correct way of defining the left context representation can be crucial for the task of next word prediction. MVMA-ME did not perform well on the language modeling task, which might be attributed to the less expressive power of its functions A and g.

5.2 Interpretation Analysis

We conduct some further analysis to examine the interpretability of n-gram representations. Specifically, we examine whether the models are able to capture certain linguistic phenomena such as negation, which is important for sentiment analysis (Ribeiro et al., 2020). We also additionally made comparisons with the vanilla Transformer (Vaswani et al., 2017) here[10] despite the fact that it remains largely unclear how it precisely captures sequence features such as n-grams.

We could also obtain the n-gram representations and the corresponding context representations from the learned standard RNN models, based on their learned parameters. We denote such n-gram representations as $\text{RNN}_{n\text{-gram}}$, and the context representations as $\text{RNN}_{\text{context}}$, where "RNN" can be GRU, LSTM or Elman. As n-gram representations are vectors, a common approach is to transform them into scalars with learnable parameters (Murdoch et al., 2018; Sun and Lu, 2020). We define the *n-gram polarity score* to quantify the polarity information as captured by an n-gram representation $\boldsymbol{v}_{i:t}$ from time step i to t, which is calculated as:

$$s^{\boldsymbol{v}}_{i:t} = \boldsymbol{w}^{\top} \boldsymbol{v}_{i:t}, \tag{14}$$

where $\boldsymbol{w}$ is the learnable weight vector of the final fully-connected layer. We also define the *context polarity score* for the context as $\sum_{i=1}^{t} s^{\boldsymbol{v}}_{i:t}$.

We trained RNNs and baseline models on SST-2 and automatically extracted 73 positive adjectives (e.g., "*nice*" and "*enjoyable*") and 47 negative adjectives (e.g., "*bad*" and "*tedious*") from the vocabulary[11]. N-gram polarity scores were calculated for those adjective unigrams and their negation bigrams formed by prepending "*not*" to them. For VA-EW and VA-W, their n-gram representations do not involve tokens other than the last token. Such limitations prevent them from capturing any negation information. We therefore calculate the context polarity scores using their context representations instead (which in this case is a bigram). This also applies to Transformer for the same reason.

We observed that, for the GRU and LSTM models along with their corresponding MVMA models, the n-gram representations are generally able to learn the negation for both the adjective and their negation bigrams as shown in Figures 2a and 2b[12], prepending "*not*" to an adjective will likely reverse the polarity. This might be a reason why they could achieve relatively higher accuracy on the sentiment analysis tasks. Interestingly, MVM-G could also capture negation as shown in Figure 2c, again suggesting the impressive expressive power of such n-gram representations alone.

However, as shown in Figure 2, models such as VA-W, MVMA-E, and MM are struggling to capture negation for negative adjectives, again implying a weaker expressive power of their n-gram representations. Specifically, MVMA-E fails to capture negation for negative adjectives, which may be attributed to a relatively weaker Jacobian matrix function A (as compared to those of GRU and LSTM) preventing them from pursuing optimal conditions.

Figure 2e shows that the MVMA-ME model, which has a function A less complex than the ones from MVMA-G and MVMA-L but more complex than the one from MVMA-E, still can generally learn negation of negative adjectives better than the MVMA-E model. This demonstrates the necessity of choosing more expressive A and g functions.

Interestingly, both VA-W and Transformer are struggling with capturing the negation phenomenon for negative adjectives in our experiments as shown in Figures 2g and 2h, which suggests that they may have a weaker capability in modeling sequential features in our setup. However, we found they could still achieve good performances on the AG-news and IMDB datasets[13]. We hypothesize this is because the nature of SST-2 makes these two models suffer more on this dataset – it has rich linguistic phenomena such as negation cases while the other two datasets do not.

Additionally, we examined the ability for GRU, LSTM, MVMA-G and MVMA-L to capture both the negation and intensification phenomena. For such experiments, instead of using SST-2, we trained the models on SST-5, which comes with polarity intensity information. Polarity intensities were mapped into values of $\{-2, -1, 0, +1, +2\}$, ranging from *extremely negative* to *extremely positive*. We conducted some experiments based on the same setup above for capturing negation on SST-2. To our surprise, our preliminary results show that all models were performing substantially worse in terms of capturing intensification than capturing negations. We hypothesize that this is caused by the imbalance between negation phrases and intensification phrases. Specifically, the intensification word *"very"* (1,729 times) was exposed less than the negation word *"not"* (4,601 times) in the training set of SST-5.

One approach proposed in the literature for sentence classification is to consider all the hidden states of an RNN in an instance (Bahdanau et al., 2015). We believe this may actually be able to al-

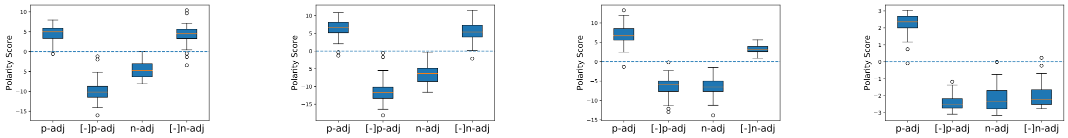
---

[10] The mean of output representations was treated as the context representation for Transformer during training. We also tried to use the concatenation of the first and last token, following (Luan et al., 2019), which yielded similar results.

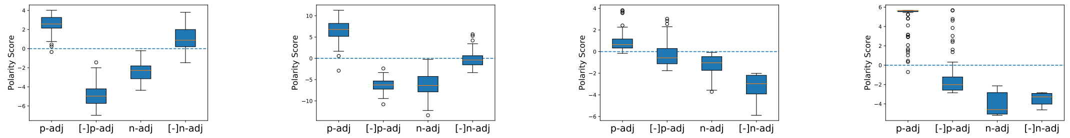
[11] Such adjectives and detailed automatic extraction process can be found in the appendix.

[12] Results of LSTM are similar to GRU, which can be found in the appendix.

[13] We conducted additional experiments for Transformers on sentiment analysis. Results are in appendix.



(a) GRU$_{n\text{-gram}}$ (b) MVMA-G (c) MVM-G (d) MVMA-E



(e) MVMA-ME (f) MM (g) VA-W (h) Transformer

Figure 2: Distribution of polarity scores for adjectives and their negation bigrams on SST-2. *p-adj* and *n-adj* refer to the positive and negative adjectives respectively. [-] refers to the negation operation (prepending the word “not”). Circles refer to outliers. More results can be found in the appendix.

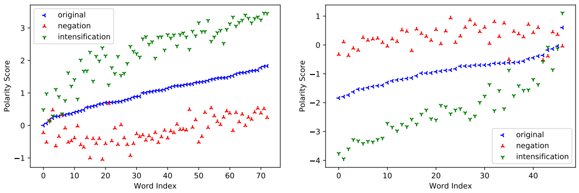


Figure 3: Context polarity scores (MVMA-G, SST-5) for positive (L) and negative (R) adjectives along with their negation and intensification bigrams.

leviate the above issue as it allows more n-grams within an instance to be exposed to the label information. Thus, we followed their approach for training our MVMA and MVM models[14].

We can see that the negation and intensification phenomena can be explained by both the context representations in Figure 3[15]. Specifically, prepending either positive or negative adjectives with “*very*” will likely strengthen their polarity while adding “*not*” will likely weaken their polarity. These results suggest that RNNs are able to capture information of linguistic significance within the sequence, and our identified n-gram representations within their hidden states appear to be playing a salient role.

5.3 Discussion

From the experiments above, we can see that our introduced n-gram representations, coupled with the corresponding context representations, are powerful in practice in capturing n-gram information better than the baseline compositional models introduced in the literature. We also found that RNNs can induce such representations due to their recurrence mechanism[16].

However, there can be several factors that affect the efficacy of different representations. First, through comparisons with different variants of MVMA, we can see that the precise way of parameterizing the functions $A(x_t)$ and $g(x_t)$ matter. Second, through the comparison between MVMA and MVM, we can see that defining an appropriate context representation that incorporates a correct set of n-grams is also important. Third, for models which do not capture such explicit n-gram features like ours, interestingly, they may still be able to yield good performances on certain tasks. For example, though VA-W and Transformer did not perform well on SST-2, they yielded results competitive to GRU and LSTM on AG-news and IMDB. This observation indicates there could be other useful features captured by such models that can contribute towards their overall modeling power.

Although in this work we did not aim to propose novel or more powerful architectures, we believe our work can be a step towards better understanding of RNN models. We also hope it can provide inspiration for our community to design more interpretable yet efficient architectures.

6 Conclusion

In this work, we focused on investigating the underlying mechanism of RNNs in terms of handling sequential information from a theoretical perspective. Our analysis reveals that RNNs contain a mechanism where each hidden state encodes a weighted combination of salient components, each of which can be interpreted as a representation of a classical n-gram. Through a series of comprehensive empirical studies on different tasks, we confirm our understandings on such interpretations of these components. With the analysis coupled with experiments, we provide findings on how RNNs learn to handle certain linguistic phenomena such as negation and intensification. Further investigations on understanding how the identified mechanism may capture a wider range of linguistic phenomena such as multiword expressions (Schneider et al., 2014) could an interesting future direction.

---

[14] However, for simplicity, in this work we only used the mean context representations (or hidden states) instead of a weighted sum of them.

[15] More results are in the appendix.

[16] We also visualized the context representations and n-gram representations in the appendix, which provide intuitive understanding of them.

A Dataset Statistics

The statistics of the sentiment analysis, relation classification and NER datasets are shown in Table 6. The language modeling datasets are obtained from Einstein.ai and the statistics are shown in Table 7.

Data	Train	Dev	Test	V.size	Max.len	Class
SST-2	98,794	872	1,821	17,404	54	2
IMDB	17,212	4,304	4,363	63,311	437	2
AG-news	110,000	10,000	7,600	85,568	212	4
SST-5	318,582	41,447	82,600	18,025	54	5
SemEval	7,000	1,000	2,717	27,115	91	10
CoNLL-2003	14,987	3,466	3,684	26,873	113	20

Table 6: Statistics of the sentiment analysis, relation classification and NER datasets. "V.size" indicates the vocabulary size and "Max.len" indicates the maximum length of the instances. "SemEval" refers to the SemEval 2010 Task 8 dataset for relation classification. For CoNLL-2003, "class" refers to the tag size.

We created the binary dataset SST-2 by extracting instances (including phrases) with polarity from the constituency parse trees in the original SST dataset (Socher et al., 2013). We merged the labels *extremely positive* and *positive* as *positive* and the labels *extremely negative* and *negative* as *negative*. We also extracted all the phrases in the constituency parse trees from the original dataset and created the 5-class dataset SST-5. The labels *extremely positive*, *positive*, *neutral*, *negative* and *extremely negative* were mapped into +2, +1, 0, -1, and -2 respectively.

B More Result from the SST datasets

B.1 Negation and Intensification

Figure 4 shows that the n-gram representations from the LSTM model together with its corresponding MVMA-L and MVM-L models can also capture negation on the extracted adjectives from SST-2. However, VA-EW fails to capture the negation phenomenon for the negative adjectives, which may be explained by that: the n-gram representation of VA-EW solely involves the current token, thus being less expressive compared to the one from models such as MVMA-L and MVMA-G. Moreover, the MVMA-G model can also capture the negation and intensification phenomena on SST-5 as shown in Figure 5. The intensification token will generally strengthen the polarity of an adjective while the negation token will generally weaken the polarity of it.

Dataset		Train	Dev	Test
PTB	Token Num Vocab Size	887,521	70,390 10,000	78,669
Wiki2	Token Num Vocab Size	2,088,628	217,646 33,278	245,569
Wiki103	Token Num Vocab Size	103,227,021	217,646 267,735	245,569

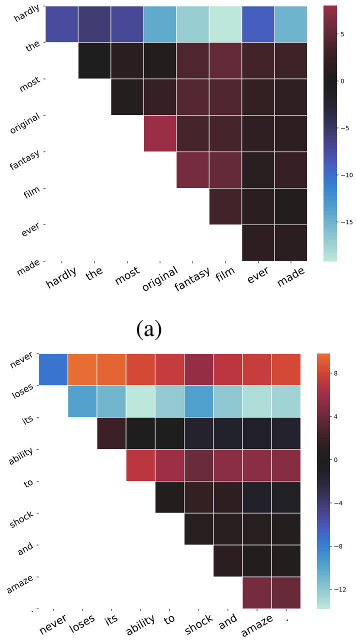
(b) GRU$_{\text{context}}$, negative adjectives

Figure 5: Context polarity scores for positive adjectives (a) and negative adjectives (b) along with their corresponding negation and intensification bigrams from SST-5.

We also visualized the polarity score of each n-gram within a sentence. Two examples are shown in Figures 6a and 6b, where a warmer color indicates a higher polarity score (i.e., the n-gram is more positive). For example, "*never*" itself has a remarkably negative polarity score while "*loses*" has a remarkably positive one. Consequently, the n-grams starting from "*never*" (while ending with another word) generally have positive polarity scores.



(a)

(b)

Figure 6: Polarity scores for n-gram representations within two example sentences. SST-2, MVMA-G.

Such visualization results show that our identified representations defined over the linguistic units as captured by RNNs can be highly interpretable.

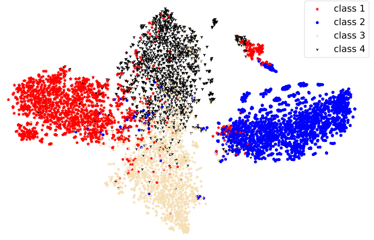
B.2 First-order Approximation

To examine how well the recurrence relation in Equation 7 can approximate the standard RNNs, we followed the method in the work of Maheswaranathan and Sussillo (2020) and compared the hidden state of the standard RNNs ($\boldsymbol{h}_t = RNN(\boldsymbol{x}_t, \boldsymbol{h}_{t-1})$) at each time step to the corresponding context representations ($\hat{\boldsymbol{h}}_t = \boldsymbol{g}(\boldsymbol{x}_t) + \boldsymbol{A}(\boldsymbol{x}_t)\boldsymbol{h}_{t-1}$). The error at each time step is defined as

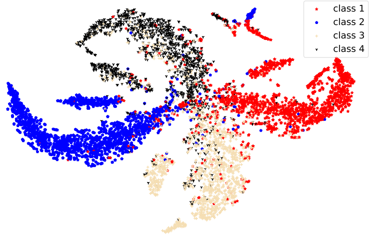
$$||\boldsymbol{h}_t - \hat{\boldsymbol{h}}_t||_2/||\boldsymbol{h}_t||_2. \tag{15}$$

We used the current standard hidden state to predict the next hidden state and the context representations on the SST-2 test set.

We noticed that the weight decaying coefficient has a remarkable impact on the error. Specifically, a larger coefficient can result in smaller errors. When the coefficient is $1e{-}5$, the average errors on the Elman, GRU, and LSTM models were 26.2%, 21.7% and 46.6% and respectively. When the coefficient is $3e-4$ the the average errors dropped to 17.1%, 15.1%, and 33.3% respectively. Note that since this is the single step error, the accumulated errors across many times steps can be large, particularly for LSTM, and thus the first-order approximation cannot fully replace standard RNNs. Despite this, the resulting context and n-gram representations can help us understand how RNNs process contextual information such as n-gram features.



(a) MVMA-G



(b) MVM-G

Figure 7: (a) and (b): T-sne visualization of the context representation for phrases (<30 tokens) from the AG-news dataset with four topics.

C T-sne Visualization

We visualized the context representations from the MVMA-G model using t-sne (van der Maaten and Hinton, 2008), which provides us with an intuitive understanding on the efficacy of our identified representations. We automatically extracted 2,188 phrases with less than 30 tokens from AG-news with 4 topics[17] and projected their context representations to a two-dimension space. Figures 7a and 7b show there exist four major clusters corresponding to the four topics, indicating those representations can generally learn the topic information and explain the differences. Similar to the previous analysis, the MVM-G model is able to learn the topic information with the n-gram representations.

D Results on Transformer

We have also run the Transformer model on the sentiment analysis datasets and the results are listed in Table 8.

---

[17] Although SST-5 has 5 lables, most of its phrases are neutral, we therefore did not use this dataset for visualization.

Table 8: Accuracy on sentiment analysis tasks. Transformer

E Implementation Details

E.1 Sentiment Analysis

Settings For the SST-2, AG-news, and IMDB datasets, we used the cross-entropy as the loss function to train the models. Embeddings were randomly initialized and trainable during training. For the SST-5 dataset, we treated the classification as a regression problem as the labels are polarity intensity. The mean-squared error was used as the loss function during training. Note that we initialized embeddings with pre-trained GloVe (Pennington et al., 2014) and fixed them during training on SST-5 for the analysis of both the negation and intensification phenomena.

Furthermore, for the MM model, each token was represented as a matrix and the matrix size was set as 32×32. For the other models, the embedding and hidden sizes were both set as 300.

Polarity Adjectives We automatically extracted adjectives with polarity (examples shown in Table 9) from SST-2 in two steps. In the first step, following the method of Sun and Lu (2020), we calculated a frequency ratio for each token (in the vocabulary) between the frequencies of the token seen in the positive and negative instances respectively. If a token has a frequency ratio either larger than 3 or less than 1/3, it will be extracted as an *positive token* or an *negative token*. In the second step, we used the *textblob* package [18] to detect positive and negative adjectives from those positive tokens and negative tokens respectively.

E.2 Relation Classification

Following the work of Gupta and Schütze (2018), we examined the RNN, baseline, MVMA and MVM models on SemEval 2010 Task 8 (Hendrickx et al., 2010) which has 9 directed relationships and an undirected *other* type. We used the final hidden states of the standard RNNs (or context representations of the MVMA, MVM and baseline models) as the instance representations for classification. The cross-entropy loss was employed during training.

E.3 Named Entity Recognition

At each time step, we concatenated the context representations (or hidden states) from both directions in a bidirectional model, fed them to a projection layer and then to a linear CRF layer. More details about the architecture can be referred to the biLSTM-CRF model in the work of Lample et al. (2016). We also referred to the code at https://github.com/allanj/pytorch_neural_crf for the implementation of the linear CRF layer.

CoNLL-2003 contains four types of entities: persons (PER), organizations (ORG), locations (LOC) and miscellaneous names (MISC). The original dataset was labeled with the BIO (Beginning-Inside-Outside) format. For example, "United Arab Emirates" are labeled as "B-LOC I-LOC I-LOC". We transform the tags into the IOBES format where two prefixes "E-" and "S-" are added. Specifically, "E-" is used to label the last token of an entity span. The "S-" prefix is used for a single-token span. For example, "United Arab Emirates" are labeled as "B-LOC I-LOC E-LOC" in this format. There are 20 categories of tags in total including the starting, ending and padding tags. We trained the models to predict each entity.

The embedding size and hidden size were set to 300 and 200 respectively. The SGD optimizer was used to learn parameters.

E.4 Language Modeling

The embedding size and hidden size were both 512 for PTB and Wiki2, and 256 and 512 respectively for Wiki103. The cross-entropy loss was used during training. For PTB and Wiki2, the output of the final fully-connected layer was fed to a *softmax* function while the Adaptive softmax (Joulin et al., 2017) was used for Wiki103 (because of its large vocabulary size). We only considered the word-level models. We trained each model for 50 epochs, chose the model which had the best performance on the development set as the final model and evaluated the final model on the test set.

F Jacobian matrix of LSTM

Unlike GRU and Elman RNN, LSTM has a memory cell apart from a hidden state. Here, we describe how to get their Jacobian matrices. An

[18] https://textblob.readthedocs.io/en/dev/

Type	Adjectives	Size
Pos	outstanding, ecological, inventive, comfortable, nice, authentic, spontaneous, sympathetic, lovable, unadulterated, controversial, suitable, grand, happy, enthusiastic, adventurous, successful, noble, true, detailed, sophisticated, sensational, exotic, fantastic, remarkable, impressive, charismatic, good, effective, rich, popular, unforgettable, famous, comical, energetic, ingenious, extraordinary, ...	73
Neg	bad, tedious, miserable, psychotic, didactic, inexplicable, feeble, sloppy, disastrous, stupid, amateurish, false, cynical, farcical, terrible, unhappy, horrible, atrocious, idiotic, wrong, pathetic, angry, uninspired, vicious, unfocused, unnecessary, artificial, troubled, questionable, arduous, stereotypical, ...	47

Table 9: Examples of the extracted adjectives from the SST-2 dataset. "Pos" refers to *positive* adjectives and "Neg" refers to *negative* adjectives.

LSTM cell can be written as

$$\begin{aligned} \boldsymbol{i}_t &= \sigma(\boldsymbol{W}_{ii}\boldsymbol{x}_t + \boldsymbol{W}_{hi}\boldsymbol{h}_{t-1}), \\ \boldsymbol{f}_t &= \sigma(\boldsymbol{W}_{if}\boldsymbol{x}_t + \boldsymbol{W}_{hf}\boldsymbol{h}_{t-1}), \\ \boldsymbol{o}_t &= \sigma(\boldsymbol{W}_{io}\boldsymbol{x}_t + \boldsymbol{W}_{ho}\boldsymbol{h}_{t-1}), \\ \boldsymbol{c}_t^m &= \tanh(\boldsymbol{W}_{ic}\boldsymbol{x}_t + \boldsymbol{W}_{hc}\boldsymbol{h}_{t-1}), \\ \boldsymbol{c}_t &= \boldsymbol{f}_t \odot \boldsymbol{c}_{t-1} + \boldsymbol{i}_t \odot \boldsymbol{c}_t^m, \boldsymbol{h}_t = \boldsymbol{o}_t \odot \tanh(\boldsymbol{c}_t), \end{aligned} \tag{16}$$

where $\boldsymbol{i}_t$, $\boldsymbol{f}_t$, $\boldsymbol{o}_t \in \mathbb{R}^d$ are the input gate, forget gate and output gate respectively. $\boldsymbol{c}_t^m \in \mathbb{R}^d$ is the new memory, and $\boldsymbol{c}_t$ is the final memory.

Let us expand the memory state and hidden state at time step t as

$$\begin{aligned} \boldsymbol{c}_t &= \boldsymbol{g}_c(\boldsymbol{x}_t) + B(\boldsymbol{x}_t)\boldsymbol{c}_{t-1} \\ &\quad + D(\boldsymbol{x}_t)\boldsymbol{h}_{t-1} + \boldsymbol{o}_c(\boldsymbol{c}_{t-1}, \boldsymbol{h}_{t-1}), \\ \boldsymbol{h}_t &= \boldsymbol{g}_h(\boldsymbol{x}_t) + E(\boldsymbol{x}_t)\boldsymbol{c}_{t-1} \\ &\quad + F(\boldsymbol{x}_t)\boldsymbol{h}_{t-1} + \boldsymbol{o}_h(\boldsymbol{c}_{t-1}, \boldsymbol{h}_{t-1}), \end{aligned} \tag{17}$$

where B, D, E and $F \in \mathbb{R}^{d \times d}$ are all Jacobian matrices. $\boldsymbol{o}_c(\boldsymbol{h}_{t-1})$ and $\boldsymbol{o}_h(\boldsymbol{h}_{t-1})$ are remainder terms of the Taylor expansion.

We concatenate the memory state and hidden state and view the concatenation as an "extended hidden state". The context representation for the "extended hidden state" at time step t (assuming of zero vectors as initial states) will be written as:

$$\begin{bmatrix} \hat{\boldsymbol{c}}_t \\ \hat{\boldsymbol{h}}_t \end{bmatrix} = \sum_{i=1}^{t} \begin{bmatrix} \boldsymbol{v}_{i:t}^c \\ \boldsymbol{v}_{i:t}^h \end{bmatrix} = \sum_{i=1}^{t} \left[\prod_{k=t}^{i+1} A(x_k) \right] \begin{bmatrix} g_c(\boldsymbol{x}_i) \\ g_h(\boldsymbol{x}_i) \end{bmatrix}, \tag{18}$$

where $\hat{\boldsymbol{c}}_t$ and $\hat{\boldsymbol{h}}_t$ refer to the context representations corresponding to the memory state and hidden state respectively. g_c, $g_h \in \mathbb{R}^d$, and $A \in \mathbb{R}^{2d \times 2d}$ are all functions of inputs. $A(x_k)$ contains many interaction terms resulting from the gating mechanism, which may result in a strong expressive power. As the hidden state $\boldsymbol{h}_t$ is commonly used for downstream tasks, we will only consider $\boldsymbol{v}_{i:t}^h$ as the n-gram representation on our tasks, and the context representation will be $\sum_{i=1}^{t} \boldsymbol{v}_{i:t}^h$.

Guiding Visual Question Generation

Abstract

In traditional Visual Question Generation (VQG), most images have multiple concepts (*e.g.* objects and categories) for which a question could be generated, but models are trained to mimic an arbitrary choice of concept as given in their training data. This makes training difficult and also poses issues for evaluation – multiple valid questions exist for most images but only one or a few are captured by the human references. We present Guiding Visual Question Generation - a variant of VQG which conditions the question generator on categorical information based on expectations on the type of question and the objects it should explore. We propose two variant families: (i) an explicitly guided model that enables an actor (human or automated) to select which objects and categories to generate a question for; and (ii) 2 types of implicitly guided models that learn which objects and categories to condition on, based on discrete variables. The proposed models are evaluated on an answer-category augmented VQA dataset and our quantitative results show a substantial improvement over the current state of the art (over 9 BLEU-4 increase). Human evaluation validates that guidance helps the generation of questions that are grammatically coherent and relevant to the given image and objects.

1 Introduction

In the last few years, the AI research community has witnessed a surge in multimodal tasks such as Visual Question Answering (VQA) (Antol et al., 2015; Anderson et al., 2018), Multimodal Machine Translation (Specia et al., 2016; Elliott et al., 2017; Barrault et al., 2018; Caglayan et al., 2019), and Image Captioning (IC) (Vinyals et al., 2015; Karpathy and Fei-Fei, 2015; Xu et al., 2015). Visual Question Generation (VQG) (Zhang et al., 2016; Krishna et al., 2019; Li et al., 2018), a multimodal task which aims to generate a question given an image, remains relatively under-researched despite the popularity of its textual counterpart. Throughout the sparse literature in this domain, different approaches have augmented and/or incorporated extra information as input. For example, Pan et al. (2019) emphasised that providing the ground truth answer to a target question is beneficial in generating a non-generic question. Krishna et al. (2019) pointed out that requiring an answer to generate questions violates a realistic scenario. Instead, they proposed a latent variable model using answer categories to help generate the corresponding questions. Recently, Scialom et al. (2020) incorporated a pre-trained language model with object features and image captions for question generation.

In this work, we explore VQG from the perspective of 'guiding' a question generator. Guiding has shown success in image captioning (Zheng et al. (2018) and Ng et al. (2020)), and in this VQG work we introduce the notion of 'guiding' as conditioning a generator on inputs that match specific chosen properties from the target. We use the answer category and objects/concepts based on an image and target question as inputs to our decoder. We propose our **explicit guiding** approach to achieve this goal. We additionally investigate an **implicit guiding** approach which attempts to remove the dependency on an external actor (see more below).

The explicit variant (Section 3.1) is modelled around the notion that an actor can select a subset of detected objects in an image for conditioning the generative process. Depending on the application, this selection could be done by a human, and algorithm or chosen randomly. For example, imagine either a open-conversation chat-bot or a language learning app. In the chat-bot case, a human may show the bot a picture of something. The bot may use randomly sampled concepts from the image (e.g. an object-detected tree) to ask a human a question upon. In the language learning case, the human may wish to select certain concepts they want the generated question to reflect. For exam-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1640 - 1654
July 10-15, 2022 ©2022 Association for Computational Linguistics

ple, they might select a subset of animal-related objects from the whole set of detected objects in order to generate questions for teaching the animal-related vocabulary in a language learning setting. Alongside the objects, the actor may also provide, or randomly sample, an answer category to the question generator.

The implicit variant (Section 3.2), on the other hand, is motivated by removing the dependency on the aforementioned actor. We provide two methodologies for our proposed implicit variant. The first uses a Gumbel-Softmax (Jang et al., 2016) to provide a discrete sample of object labels that can be used for generating a question. The second method employs a model with two discrete latent variables that learn an internally-predicted category and a set of objects relevant for the generated question, optimised with cross-entropy and variational inference (Kingma and Welling, 2014; Miao et al., 2016).

Human evaluation shows that our models can generate realistic and relevant questions, with our explicit model *almost* fooling humans when asked to determine which, out of two questions, is the generated question. Our experiments and results are presented in Section 5.

To summarise, our **main contributions** are: 1) The first work to explore guiding using object labels in Visual Question Generation; 2) A novel generative Transformer-based set-to-sequence approach for Visual Question Generation; 3) The first work to explore discrete variable models in Visual Question Generation; and 4) A substantial increase in quantitative metrics - our explicit model improves the current state of the art setups by over 9 BLEU-4 and 110 CIDEr.

2 Related Work

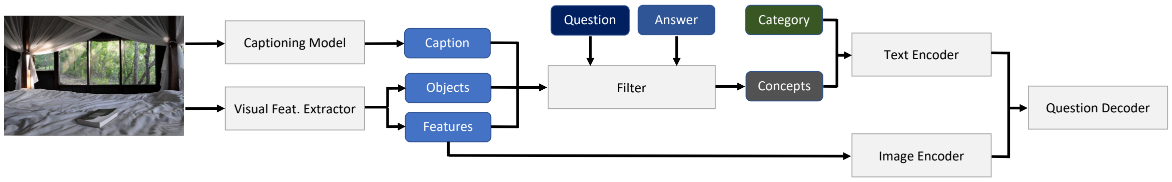
2.1 Visual Question Generation

Zhang et al. (2016) introduced the first paper in the field of VQG, employing an RNN based encoder-decoder framework alongside model-generated captions to generate questions. Since then, only a handful of papers have investigated VQG. Fan et al. (2018) demonstrated the successful use of a GAN in VQG systems, allowing for non-deterministic and diverse outputs. Jain et al. (2017) proposed a model using a VAE instead of a GAN, however their improved results require the use of a target answer during inference. To overcome this unrealistic requirement, Krishna et al. (2019) augmented the VQA (Antol et al., 2015) dataset with answer categories, and proposed a model which doesn't require an answer during inference. Because their architecture uses information from the target as input (i.e. an answer category), their work falls under our definition of guided generation. More recently, Scialom et al. (2020) investigate the cross modal performance of pre-trained language models by fine-tuning a BERT (Devlin et al., 2018) model on model-based object features and ground-truth image captions. Other work, such as Patro et al. (2018), Patro et al. (2020) and Uppal et al. (2020), either do not include BLEU scores higher than BLEU-1, which is not very informative, or address variants of the VQG task. In the latter case the models fail to beat previous SoTA on BLEU-4 for standard VQG. Recently and (Xu et al., 2021) and (Xie et al., 2021) achieve SoTA in VQG using graph convolutional networks. However, both works follow an unrealistic setup by conditioning their model on raw answers during training and inference - a dependency we attempt to remove.

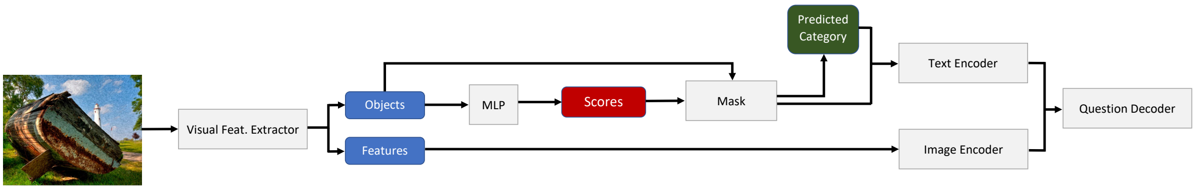
2.2 Discrete (Latent) Variable Models

Discrete variable models are ideal for tasks which require controllable generation (Hu et al., 2017) or 'hard' indexing of a vector (Graves et al., 2016). Existing literature provide several methods to achieve discretization. NLP GAN literature (such as SeqGAN (Yu et al., 2016) and MaskGAN (Fedus et al., 2018)) commonly use REINFORCE (Williams, 1992) to overcome differentiability issues with discrete outputs. Other discretization methodologies can be found in Variational Auto Encoder (VAE) literature (Kingma and Welling, 2014). Some older methodologies are NVIL (Mnih and Gregor, 2014) and VIMCO (Mnih and Rezende, 2016). However, VAE literature also introduced Concrete (Maddison et al., 2016), Gumbel-Softmax (Jang et al., 2016) and Vector Quantization (Oord et al., 2017) as discretization strategies (technically speaking, Concrete and Gumbel-Softmax are strongly peaked continuous distributions).

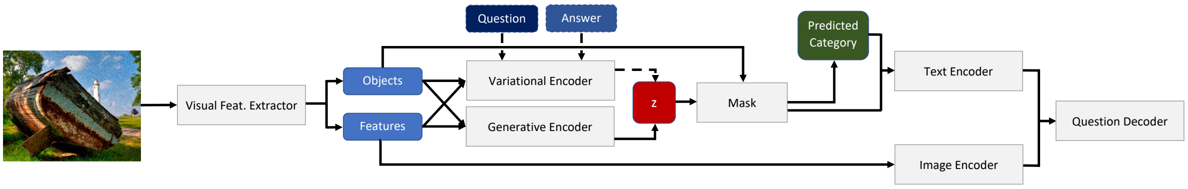
In this work, we use a Gumbel-Softmax approach to sample a distribution over objects. At inference time, given a set of object tokens, learning this 'hard' distribution allows the model to internally sample a subset of objects that produce the most informative question. Our variational model additionally learns a generative and variational distribution that allow the model to implicitly learn which objects are relevant to a question and an-



(a) Architecture of our explicit model. Given an image, first an object detection model is used to extract object labels and object features; a captioning model is used to generate relevant captions. Questions and answers are concatenated to filter the conceptual information from generated objects and captions. Next the filtered concepts are combined with the category as the input to the text encoder; the extracted object features are fed into an image encoder. Finally the outputs from the text encoder and the image encoder are fused into the decoder for question generation.



(b) Architecture of our implicit model. Similar to the explicit model, first an object detection model is used to extract object labels and object features. Object labels are sent to a non-linear MLP after which a Gumbel-Softmax is applied to obtain the discrete vector 'Scores'. The Scores are then used to mask the object labels and predict a category. The masked object labels and predicted category are then sent to the text encoder. The outputs are fused with the image encoder outputs and sent to the decoder.



(c) Architecture of our variational implicit model. After the object detection model extracts the object labels and object features, they are sent to the variational and generative encoders. The variational encoder is used at train time only, and also receives the question and answer pair. Depending whether we're training or in inference, we obtain a discrete vector z from the respective distribution. z is then used to mask the object labels. This variant then follows the same methodology as its non-variational counterpart. For this sub-figure only, the dashed lines indicate training.

Figure 1: Architecture of the explicit model (a) and implicit model (b)

swer pair whilst incorporating non-determinism for diverse outputs.

3 Methodology

We introduce the shared concepts of our explicit and implicit model variants, before diving into the variant-specific methodologies (Section 3.1 & 3.2).

For both variants, we keep the VQG problem grounded to a realistic scenario. That is, during inference, we can only provide the model with an image, and data that can either be generated by a model (*e.g.* object features or image captions) and/or trivially provided by an actor (*i.e.* answer category and a selected subset of the detected objects). However, during training, we are able to use any available information, such as images, captions, objects, answer categories, answers and target questions, employing latent variable models to minimise divergences between feature representations of data accessible at train time but not inference time. This framework is inspired by Krishna et al. (2019). In Appendix A, we discuss the differences of input during training, testing and inference.

Formally, the VQG problem is as follows: Given an image $\tilde{i} \in \tilde{I}$, where $\tilde{I}$ denotes a set of images, decode a question q. In the **guided** variant, for each $\tilde{i}$, we also have access to textual utterances, such as ground truth answer categories and answers. The utterances could also be extracted by an automated model, such as image captions (Li et al., 2020), or object labels and features (Anderson et al., 2018). In our work, answer categories take on 1 out of 16 categorical variables to indicate the type of question asked. For example, "*how many people are in this picture?*" would have a category of "*count*" (see Krishna et al. (2019) for more details).

Text Encoder. For encoding the text, we use BERT (Devlin et al., 2018) as a pre-trained language model (PLM). Thus, for a tokenised textual input $\tilde{S}$ of length T, we can extract a d-dimensional representation for $\tilde{s}_t \in \tilde{S}$: $X = \texttt{PLM}(\tilde{S}) \in \mathbb{R}^{T \times d}$

Image Encoder. Given an image $\tilde{i}$, we can extract object features, $f \in \mathbb{R}^{k_o \times 2048}$, and their respective normalized bounding boxes, $b \in \mathbb{R}^{k_o \times 4}$, with the 4 dimensions referring to horizontal and vertical positions of the feature bounding box. Following the seminal methodology of Anderson et al. (2018), k_o is usually 36. Subsequent to obtaining these features, we encode the image using a Transformer (Vaswani et al., 2017), replacing the default position embeddings with the spatial embeddings extracted from the bounding box features (Krasser and Stumpf, 2020; Cornia et al., 2019). Specifically, given f, b from image $\tilde{i}$: $i = \texttt{Transformer}(f, b) \in \mathbb{R}^{k_o \times d}$

Text Decoder. We employ a pretrained Transformer decoder for our task (Wolf et al., 2020). Following standard sequence-to-sequence causal decoding practices, our decoder receives some encoder outputs, and auto-regressively samples the next token, for use in the next decoding timestep. Our encoder outputs are the concatenation (; operator) of our textual and vision modality representation: $X = [S; i] \in \mathbb{R}^{(T+k_o) \times d}$, and our decoder takes on the form: $\hat{q} = \texttt{Decoder}(X)$, where $\hat{q}$ is the predicted question.

In this work, we primarily focus on a set-to-sequence problem as opposed to a sequence-to-sequence problem. That is, our textual input is not a natural language sequence, rather an unordered set comprising of tokens from the answer category, the object labels, and the caption. How this set is obtained is discussed in following section. Due to the set input format, we disable positional encoding on the PLM encoder (Text Encoder in Figure 1).

3.1 Explicit Guiding

As mentioned in Section 1, the explicit variant requires some actor in the loop. Thus, in a real world setting, this model will run in two steps. Firstly, we run object detection (OD) and image captioning (IC) over an image and return relevant guiding information to the actor. The actor may then select or randomly sample a subset of objects which are sent to the decoder to start its generation process. If the actor opts for a random sample strategy, no human is needed during the inference process (see Appendix A for examples).

To enable this setup, we create paired data based on the guided notion. At a high level, our approach creates this data in three steps: 1) obtain object labels; 2) obtain concepts via IC Formally,

$$\begin{aligned} &\text{objects} = \texttt{OD}(i) \in \mathbb{R}^{k_o} \\ &\text{cap} = \texttt{CaptionModel}(i) \in \mathbb{R}^{T_{cap}} \\ &\text{cap} = \texttt{rmStopWords}(\text{caption}) \in \mathbb{R}^{<T_{cap}} \\ &\text{candidate\_concepts} = \texttt{set}(\text{objects}; \text{cap}) \in \mathbb{R}^{T_{cc}} \end{aligned} \tag{1}$$

Here, `OD` stands for an object detector model, `rmStopWords` is a function which removes the stop words from a list, and `set` is a function which creates a set from the concatenation (the ; operator) of the detected objects and obtained captions. *cap* stands for caption. The set is of size $T_{cc} < k_o + T_{cap}$. Using this obtained *candidate_concepts* set, we run our filtration process.

Once the set of candidate concepts has been constructed, we filter them to only retain concepts relevant to the target QA pair. After removing stop words and applying the `set` function to the words in the QA pair, we use Sentence-BERT (Reimers and Gurevych, 2019) to obtain embeddings for the candidate QA pair and *candidate_concepts* (Eq 1). We subsequently compute a cosine similarity matrix between the two embedding matrices, and then select the top k most similar concepts. The chosen k concepts, $\tilde{S}$, are always a *strict subset* of the candidate concepts that are retrieved using automated image captioning or object detection. This process emulates the selection of objects an actor would select in an inference setting when given a choice of possible concepts, and creates paired data for the guided VQG task. We now concatenate an answer category to $\tilde{S}$: $S = \texttt{PLM}([\tilde{S}; \text{category}]) \in \mathbb{R}^{T \times d}$.

With text encoding S, we run the model, optimizing the negative log likelihood between the predicted question and the ground truth. Note that the concatenation in the decoder below is along the sequence axis (resulting in a tensor $\in \mathbb{R}^{T+k_o \times d}$).

$$\begin{aligned} \hat{q} &= \texttt{Decoder}([S; i]) \\ \mathcal{L} &= \texttt{CrossEntropy}(\hat{q}, q) \end{aligned} \tag{2}$$

3.2 Implicit Guiding

We now introduce our experiments for the implicit variant for VQG. This variant differs from its explicit counterpart as it aims to generate questions using only images as the input, while internally learning to predict the relevant category and objects. Mathematically, the explicit variant models $\hat{q} = p(w_t|i, \tilde{S}, \textit{category}, w_0, ..., w_{t-1}; \theta)$ where $\tilde{S}$ and *category* are obtained as described in Section 3.1. During inference, the implicit variant instead attempts to model $\hat{q} = p(w_t|i, \tilde{e}_{obj}, e_{cat}, w_0, ..., w_{t-1}; \theta)$ where $\tilde{e}_{obj}, e_{cat}$ are **not** explicitly fed in to the model. Rather, they are determined internally as defined in Equation 6.

Given an image, we apply the same object detection model as in the explicit variants to extract object labels, which are then encoded using an `embed` layer. Formally,

$$\begin{aligned} \text{objects} &= \texttt{OD}(i) \in \mathbb{R}^{k_o} \\ e_{obj} &= \texttt{embed}(\text{objects}) \in \mathbb{R}^{k_o \times d} \end{aligned} \tag{3}$$

Since we would like the implicit model to learn relevant objects for an image internally, we project each object in e_{obj} to a real-valued score:

$$\textit{scores} = \texttt{MLP}(e_{obj}) \in \mathbb{R}^{k_o} \tag{4}$$

Subsequently, we apply a hard Gumbel-Softmax (Jang et al., 2017) to obtain predictions over selected objects. Because Gumbel-Softmax samples from a log-log-uniform distribution, stochasticity is now present in our sampled objects. To sample k objects, we tile/repeat *scores* k times before inputting it into the Gumbel-Softmax. $\tilde{z}$, our k-hot sampled objects vector, is then used to mask object embeddings for use in decoding:

$$\begin{aligned} \tilde{z} &= \texttt{gumbel-softmax}(\text{scores}, k) \in \mathbb{R}^{k_o} \\ \tilde{e}_{obj} &= \tilde{z} * e_{obj} \in \mathbb{R}^{k_o \times d} \end{aligned} \tag{5}$$

Where $*$ denotes element-wise multiplication. Categories can also be a strong guiding factor and instead of making it an explicit input, we build a classifier to predict possible categories. In this variant, $\tilde{e}_{obj}$ is used as an input to both our text encoder, and the MLP responsible for the category prediction:

$$\begin{aligned} S &= \texttt{PLM}(\tilde{e}_{obj}) \in \mathbb{R}^{k_o \times d} \\ p(\hat{cat}|\tilde{e}_{obj}) &= \texttt{softmax}(\texttt{MLP}(\tilde{e}_{obj})) \in \mathbb{R}^{k_{cat}} \end{aligned} \tag{6}$$

Using the one-hot representation of the predicted category (i.e. $e_{cat} = \texttt{one-hot}(p(\hat{cat}|\tilde{e}_{obj}))$, we can concatenate our image, PLM representation of objects, and predicted category to feed into the decoder: $\hat{q} = \texttt{Decoder}([i; S; e_{cat}]) \in \mathbb{R}^{T_{\hat{q}}}$. However, during training, we teacher force against the 'gold' set of objects, $\tilde{S}$ (obtained using *candidate_concepts* in Equation 1). Training and optimization thus follow:

$$\begin{aligned} \hat{q} =& \texttt{Decoder}([i; \tilde{S}; e_{cat}]) \in \mathbb{R}^{T_{\hat{q}}} \\ \mathcal{L} =& \texttt{CrossEntropy}(\hat{q}, q) + \\ & \texttt{CrossEntropy}(p(\hat{cat}|\tilde{e}_{obj}), cat) + \\ & \texttt{StartEnd}(\tilde{e}_{obj}, \tilde{S}) \end{aligned} \tag{7}$$

where StartEnd is a BERT QA-head style loss (Devlin et al., 2018) that uses binary cross entropy for each k in $\tilde{e}_{obj}$.

Variational Implicit. Hypothesising that ground-truth QA pairs might provide information useful to selecting objects, we additionally attempt to extend our model to incorporate QA pairs to learn a latent variational distribution over the objects. However, since QA pairs can only be used during training to learn a variational distribution, we introduce another generative distribution that is only conditioned on the images and extracted objects. We borrow the idea from latent variable models to minimise Kullback-Leibler (KL) divergence between the variational distribution and generative distribution, where the variational distribution is used during training and the generative distribution is used in inference.

Continuing from Equation 3, we build two matrices, M_{gen} and M_{var}. The former is a concatenation of the image features and object embeddings, and the latter the concatenation between the encoded QA pair and M_{gen}. Depending on whether we're in a training or inference regime, the CLS token of the relevant matrix is used to sample a mask, $\tilde{z}$, which is subsequently applied on the aforementioned object embeddings:

$$\begin{aligned} & M_{gen} = \texttt{encode}([e_{obj}; i]) \in \mathbb{R}^{2k_o \times d} \\ & e_{qa} = \texttt{embed}(\text{Q;A}) \in \mathbb{R}^{T_{qa} \times d} \\ & M_{var} = \texttt{encode}([e_{qa}; M_{gen}]) \in \mathbb{R}^{(2k_o + T^{qa}) \times d} \\ & q_\phi(z|M_{gen}, M_{var}) = \texttt{MLP}(M_{gen}^{CLS}; M_{var}^{CLS}) \in \mathbb{R}^{k_o} \\ & p_\theta(z|M_{gen}) = \texttt{MLP}(M_{gen}) \in \mathbb{R}^{k_o} \\ & \tilde{z} = \texttt{gumbel-softmax}(z, k) \in \mathbb{R}^{k_o} \\ & \tilde{e}_{obj} = \tilde{z} * e_{obj} \in \mathbb{R}^{k_o \times d} \end{aligned}$$

where $q_\phi(z|M_{gen}, M_{var})$ is the variational distribution, $p_\theta(z|M_{gen})$ is the generative distribution, and MLP denotes a multilayer perceptron for learning the alignment between objects and QA pairs.

`encode` is an attention-based function such as BERT (Devlin et al., 2018). From here, our methodology follows on from Equation 6. However, our loss now attempts to minimise the ELBO:

$$\begin{aligned}\mathcal{L} &= \mathbb{E}[\log p_\theta(\hat{q}|z, \hat{cat})] \\ &\quad - D_{\mathrm{KL}}[q_\phi(z|M_{gen}^{CLS}, M_{var}^{CLS})||p_\theta(z|M_{gen}^{CLS})] \\ &\quad + \log p(\hat{cat}|M_{var})\end{aligned}$$

4 Experiments

4.1 Datasets

We use the VQA v2.0 dataset[1] (Antol et al., 2015) (CC-BY 4.0), a large dataset consisting of all relevant information for the VQG task. We follow the official VQA partition, with *i.e.* 443.8K questions from 82.8K images for training, and 214.4K questions from 40.5K images for validation. Following Krishna et al. (2019), we report the performance on validation set as the annotated categories and answers for the VQA test set are not available.

We use answer categories from the annotations of Krishna et al. (2019). The top 500 answers in the VQA v2.0 dataset are annotated with a label from the set of 15 possible categories, which covers up the 82% of the VQA v2.0 dataset; the other answers are treated as an additional category. These annotated answer categories include objects (*e.g.* "mountain", "flower"), attributes (*e.g.* "cold", "old"), color, counting, *etc.*

We report BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), CIDEr (Vedantam et al., 2015), METEOR (Lavie and Agarwal, 2007), and MSJ (Montahaei et al., 2019) as evaluation metrics. The MSJ metric accounts for both the diversity of generated outputs, and the n-gram overlap with the ground truth utterances.

4.2 Comparative Approaches

We compare our models with four recently proposed VQG models *Information Maximising VQG* (**IMVQG**; supervised with image and answer category) (Krishna et al., 2019), *What BERT Sees* (**WBS**; supervised with image and image caption) (Scialom et al., 2020), *Deep Bayesian Network* (**DBN**; supervised with image, scenes, image captions and tags/concepts) (Patro et al., 2020), and *Category Consistent Cyclic VQG* (**C3VQG**; supervised with image and answer category) (Uppal et al., 2020). We follow **IMVQG**'s evaluation setup because they hold the current SoTA in VQG for realistic inference regimes. We omit (Xu et al., 2021) and (Xie et al., 2021) from our table of results because these models follow an unrealistic inference regime, requiring an explicit answer during training and inference. Our baseline is an image-only model, without other guiding information or latent variables.

4.3 Implementation Details

In Section 3 we described the shared aspects of our model variants. The reported scores in Section 5 use the same hyperparameters and model initialisation. A table of hyperparameters and training details can be found in Appendix B. BERT Base (Devlin et al., 2018) serves as our PLM encoder and following Wolf et al. (2020); Scialom et al. (2020), we use a pre-trained BERT model for decoding too. Though typically not used for decoding, by concatenating the encoder inputs with a `[MASK]` token and feeding this to the decoder model, we are able to obtain an output (*e.g.* $\hat{q_1}$). This decoded output is concatenated with the original input sequence, and once again fed to the decoder to sample the next token. Thus, we use the BERT model as a decoder in an auto-regressive fashion.

To encode the images based on the Faster-RCNN object features (Ren et al., 2015; Anderson et al., 2018), we use a standard Transformer (Vaswani et al., 2017) encoder. Empirically, we find $k = 2$ to be the best number of sampled objects.

5 Results

We present quantitative results in Table 1 and qualitative results in Figure 2. We evaluate the explicit, implicit and variational implicit models in a single-reference setup, as the chosen input concepts are meant to guide the model output towards one particular target reference.

5.1 Quantitative Results

Starting with the explicit variant, as seen in Table 1, we note that our image-only baseline model achieves a BLEU-4 score of 5.95. We test our model with different combinations of text features to identify which textual input is most influential to the reported metrics. We notice that the contribution of the category is the most important text input with respect to improving the score of the model, raising the BLEU-4 score by more than 11 points (image-category) over the aforementioned baseline.

Table 1: Single reference evaluation results. "*-guided" refers to the combination of category and objects. In the explicit variant only, objects refers to the subset of detected objects and caption keywords, filtered on the target QA pair. † indicates an unrealistic inference regime, using answers as input for question generation. ‡ WBS scores are from single reference evaluation based on the VQA1.0 pre-trained "Im. + Cap." model provided by the authors.

However, whilst the BLEU-4 for the image-object variant is 2.3 points lower, it outperforms the image-category variant by 3.9 points on the diversity orientated metric MSJ-5 - indicating that the image-category variant creates more generic questions. As expected, the inclusion of both the category and objects (image-guided) outperforms either of the previously mentioned models, achieving a new state-of-the-art result of 24.4 BLEU-4. This combination also creates the most diverse questions, with an MSJ-5 of 57.3.

We also test our hypothesis that guiding produces questions that are relevant to the fed in concepts. This is tested with 'image-guided-random' variant. This variant is the same trained model as 'image-guided', but uses $k = 2$ random concepts from a respective image instead of using the ground truth question to generate concepts. Our results show that guiding is an extremely effective strategy to produce questions related to conceptual information, with a BLEU-4 score difference of over 20 points. We refer the reader to Section 5.3 for human evaluation which again validates this hypothesis, and Section 3.1 for an explanation of why guiding is valid for evaluating VQG models.

We evaluate the implicit models as follows. The implicit image-category variant does not predict any objects internally. It uses all image features and object embeddings alongside the category supervision signal as described in Equation 7. The implicit image-guided models use the 'gold' objects at inference (See Section 3.1). If these variants fit the 'gold' objects well, it indicates that their generative abilities are suitable for guiding/conditioning on predicted or random objects. The image-guided-pred variants are evaluated using internally predicted objects - and the model variant that would be used in a real inference setting. Finally, the image-guided-random variants are fed in random object labels at inference.

For implicit guiding to be a valid methodology, we need to validate two criteria: 1) Successfully conditioning the decoder on guiding information; 2) Better than random accuracy of object prediction/selection. Note that intuitively, the implicit model is expected to perform worse than the explicit model in terms of the language generation metrics. This is because of the inherently large entropy of the relevant answer category and the objects given an image. However, if the learned distributions over the categories and objects can capture the relevant concepts of different images, they may benefit the question generation when compared with image-only.

According to Table 1, by predicting just an answer category and no objects (image-category), the proposed implicit model beats the image-only baseline. The BLEU-4 score difference is less than 1 with the best performing WBS model (Scialom et al., 2020) – which also generates questions without explicit guided information.

As mentioned above, we can evaluate the implicit model by either feeding the 'gold' objects obtained as described in Section 3.1, or by the internally predicted objects as described in Section 3.2. These form the variants image-guided and image-guided-pred respectively. For both the implicit and variational implicit models, image-guided is expected to perform the best. Results validate this, showing a performance of 14.2 and 12.6 BLEU-4 respectively. Importantly, the relatively high scores of these guided models (compared to the comparative approaches) show that these models can successfully be conditioned on guiding information.

We also notice that for both types of implicit models, image-guided-pred outperforms image-guided-random. Specifically for the non-variational implicit, we see a higher BLEU-4 score difference of 2.7. Interestingly, despite this BLEU-4 difference being higher than its variational counterpart, there is a trade-off for the diversity-orientated MSJ metric. This indicates that although generated questions are discretely 'closer' to the ground truth, similar phrasing is used between the generated questions. In fact, an acute case of this phenomena occurs for the image-category variant where the BLEU-4 variant is higher than image-guided-pred or image-guided-random. In this case, qualitative analysis shows us that the higher BLEU-4 score can be attributed to the generic nature of the generated question. Failure cases of automatic evaluation metrics in NLP is discussed further in (Caglayan et al., 2020).

To satisfy the 'better than random accuracy of object prediction/selection' criteria previously outlined, we measure the overlap of the k predicted objects vs k 'gold' object labels. These 'gold' object labels are obtained similarly to the explicit variant (Section 3.1), however the caption tokens are not fed to the filtering process. Random accuracy for selecting objects is 12.5%. Our overlap accuracy on implicit image-pred is 18.7% - outperforming random selection. Variational implicit image-pred failed to outperform random accuracy.

	Baseline	Implicit	V-Implicit	Explicit
Experiment 1	34.3% ± 0.1	47.1% ± 0.12	36.7% ± 0.08	44.9% ± 0.08
Experiment 2	95.9% ± 0.03	76.6% ± 0.16	89% ± 0.09	93.5% ± 0.06
Experiment 3	-	-	-	77.6% ± 0.09
Experiment 4	-	-	-	74.1%/40.0% ± 0.07/0.18

Table 2: Human evaluation results (and standard dev.)

5.2 Qualitative Results

Qualitative results are shown in Figure 2 and Appendix D. Figure 2 depicts how outputs from different model variants compare to ground truth questions. Without any guiding information, the image-only variant is able to decode semantic information from the image, however this leads to generic questions. The implicit variant, for which we also report the predicted category and objects, mostly generates on-topic and relevant questions. Focusing on the explicit variant, we witness high-quality, interesting, and on-topic questions.

Appendix D depicts how well our explicit image-guided variant handles a random selection of detected objects given the image. This experiment intends to gauge the robustness of the model to detected objects which may fall on the low tail of the human generating question/data distribution. To clarify, humans are likely to ask commonsense questions which generally focus on obvious objects in the image. By selecting objects at random for the question to be generated on, the model has to deal with object permutations not seen during training, and categories that are invalid for an image.

Analysing the outputs, when viable categories and objects that are expected to fall in a commonsense distribution are sampled, the model can generate high quality questions. Interestingly, we observe that when the sampled objects are not commonsense (*e.g.* "ears arms" for the baby and bear picture), the model falls back to using the object features instead of the guiding information. This phenomenon is also witnessed when the sampled category does not make sense for the image (*e.g.* category 'animal' in image 531086). Despite the category mismatch, the model successfully uses the object information to decode a question.

5.3 Human Evaluation

We ask seven humans across four experiments to evaluate the generative capabilities of our models. *Experiment 1* is a visual Turing test: given an image, a model generated question and a ground truth question, we ask a human to determine which ques-

		 85187	 63958	 447043	 82259	 38083
Ground Truth		is this in the usa?	is the zebra tall or short?	where is this building?	is this person airborne?	how many containers of strawberries are there?
Baseline	**Generated Question:**	is this a busy street?	what is the zebra doing?	is this a church?	what is the man doing?	what is the green vegetable?
Implicit	**Predicted Category:**	count	binary	other	colour	binary
	Predicted Objects:	street, statues	zebra, ground	building, tower	person, people	strawberries, strawberry
	Generated Question:	how many red poles are there?	is the rock in the background?	what is the weather like?	what is the color of the skier?	how many carrots are there?
Variational Implicit	**Predicted Category:**	binary	binary legs,	object	binary	count
	Predicted Objects:	truck, man	shadow	statue, tower	ski pole, poles	apple, leaves
	Generated Question:	is this a new truck?	is this a zoo?	what color is the clock?	is this a ski park?	how many different different types of fruit are there?
Explicit	**Given Category:**	binary	attribute	other	binary	count
	Given Objects:	statues, pillar	zebra, tail	building, tower	snow, skis	strawberries, strawberry
	Generated Question:	is this a rural setting?	what pattern is on the zebra's mohawk?	what is the condition of the building?	are these people going to ski down a mountain?	how many different kinds of produce are in the bowl?

Figure 2: Qualitative Examples. The ground truth is the target question for the baseline, implicit and explicit. The examples of explicit variant uses `image-guided` whereas the implicit is using the non-variational `image-pred`.

tion they believe is model generated. *Experiment 2* attempts to discern the linguistic and grammatical capabilities of our model by asking a human to make a binary choice about whether the generated question seems natural. *Experiment 3* shows a human an image alongside a model generated question (explicit variant). Then, we ask the human to make a choice about whether the generated question is relevant to the image (*i.e.* could an annotator have feasibly asked this question during data collection). Finally, *experiment 4* judges whether objects are relevant to a generated question. The experiment is set up with true-pairs and adversarial-pairs. True-pairs are samples where the shown objects are the ones used to generate the question. Adversarial-pairs show a different set of objects than those which generated the question. If more true-pairs are are marked correct (*i.e.* if at least one of the objects is relevant to the generated question) than the adversarial-pairs, then our model successfully generates questions on guiding information.

In *experiment 1*, a model generating human-level questions should be expected to score 50%, as a human would not be able to reliably distinguish them from the manually created questions. Our results show the explicit and non-variational implicit model outperforming the variational implicit and baseline variants, fooling the human around 45% of the time. Whilst not yet at the ideal 50%, the explicit approach provides a promising step towards beating the visual Turing Test. *Experiment 2* evaluates the grammatical plausibility of the generated questions. In general, all models perform extremely well in this experiment, with the baseline variant generating grammatically correct sentences 96% of the time. This is expected, as the baseline typically falls back to decoding easy/generic questions. *Experiment 3*, is evaluated on our best performing model (explicit image-guided). Here, 78% of the generated questions are marked as relevant/on-topic given an image. Finally, *experiment 4*'s results show true-pairs marked as correct vs adversarial-pairs (incorrectly) marked as correct. Since the former is larger than the latter - 72% vs 42%, the model can successfully use guiding/object information to create on-topic questions.

6 Conclusions

We presented a guided approach to visual question generation (VQG), which allows for the generation of questions that focus on specific chosen aspects of the input image. We introduced three variants for this task, the explicit, implicit, and variational implicit. The former generates questions based on an explicit answer category and a set of concepts from the image. In contrast, the latter two discretely predict these concepts internally, receiving only the image as input. The explicit model achieves SoTA results when evaluated against comparable models. Qualitative evaluation and human-based experiments demonstrate that both variants produce realistic and grammatically valid questions.

A Training, testing and inference

Here, using an example, we clarify the inputs to our explicit model (Section 3.1) in the training, testing and inference setups.

Training

- Ground truth question: What is the labrador about to catch?
- Answer: Frisbee
- Category: Object
- Image: $i \in \mathbb{R}^{k_o \times d}$
- {Caption}: A man throwing a frisbee to a dog
- {Objects}: person, dog, frisbee, grass

N.B. {Caption} and {Objects} are both model generated, requiring only an image as input. These inputs are thus available at inference time.

Firstly, we create a set of *candidate_concepts* (see eq. 1) from the caption and objects: [person, dog, frisbee, grass, man, throwing] ($\in \mathbb{R}^6$). These words are individually embedded. Secondly, we concatenate and embed the set of question and answer tokens ($\in \mathbb{R}^7$).

Then, we construct a matrix which gives us cosine similarity scores for each *candidate_concepts* token to a QA token ($\in \mathbb{R}^{6\times 7}$). We choose $k = 2$ tokens from the *candidate_concepts* which are most similar to the words from the QA. Here, “dog” and “frisbee” are likely chosen. Our input to the model is then <i, “object”, “dog”, “frisbee”>.

Notice that it is possible for these words to be in the QA pair (e.g. “frisbee”). Importantly, these words have not been fed from the QA pair - they have been fed in from model-obtained concepts ({Object} and {Caption}). Philosophically similar, Krishna et al. (2019) constructed inputs based on target information for use in training and benchmarking.

Testing. Imagine a data labeler creating questions based on an image. They would look at the image, and decide on the concepts to create the question for. Our testing methodology follows this intuition using the strategy outlined above: the $k = 2$ selected objects from *candidate_concepts* is a programmatic attempt for selecting concepts which *could* generate the target question. Note that there can be many questions generated for a subset of concepts (e.g. ‘is the dog about to catch the frisbee?’, ‘what is the flying object near the dog?’ etc.). As outlined above, we are not taking concepts from the target. Rather we use information from the target to emulate the concepts an actor would think of to generate the target question. Because there can be different concepts questions are based on for one image (see ground-truth questions in Appendix D), our strategy allows us to generate questions which might be similar to a singular target question. This leads to an evaluation which fairly uses information a human has access to to generate a question.

Inference. However, in the real world, there is no ‘ground-truth’ question. In this case, we simply feed image features, and actor selected concepts to our question generator model. The selection process of the actor may be random - in which case a human agent does not need to be involved in the question generation process. The $k \leq 2$ selected concepts here are a subset of *candidate_concepts*, which are fully generated from models.

B Hyperparameters and training details

Batch size	128
Learning rate	1e-5
Text model layers	12
Text model dimension	768
Image encoder layers	6
Image encoder dimension	768
Image encoder heads	8

Table 3: Hyperparameters for our model variants.

Empirically, for both variants, we find $k = 2$ to be the best number of sampled objects. All experiments are run with early stopping (patience 10; training iterations capped at 35000) on the BLEU-4 metric. Scores reported (in Section 5) are from the highest performing checkpoint. We use the PyTorch library and train our model on a V100 GPU (1.5 hours per epoch).

C Impact of model size on results

Model	BLEU				CIDEr	METEOR	ROUGE
	1	2	3	4			
image-category	38.6	28.4	21.4	16.2	118	19.9	40.1
image-guided	44.5	34.4	27.4	22.1	197	24.6	47

Table 4: Truncated models single reference evaluation results.

Our models use the heavier Transformers than previous SoTA we compare to. For example, (Krishna et al., 2019) use ResNet and RNNs for their image encoder and question generator (∼18M parameters). Our models have between 200-300M parameters. To validate that our results are not purely attributable to model size, we train a truncated version of image-category and image-guided (explicit only). We truncate our models by using only the first and last layers of our BERT based encoders and decoders (∼36M parameters). Our closest model to theirs is the (truncated) explicit image-category, which achieves a BLEU-4 of 16.2 as seen in Table 4 - an improvement of 1.7 BLEU-4 over IMVQG's *t-path*. Even if we attribute 100% of this score improvement to the pre-trained nature of the BERT models we use, our methodology still introduces a 5.9 BLEU-4 increase over the image-category combination (truncated image-guided achieves a BLEU-4 of 22.1).

D More Qualitative Examples.

Examples can be seen in Figure 2 (next page). When examined, we see that the generated question accurately uses the guiding category when the category is valid for the given image. For example, 531086/1 has animal as the sampled category. Because no animal is present in the image, this category isn't valid for the image. The generated question then correctly relies on the object labels and visual modality to generate a valid question given the image. Similarly for 490505/2.

There are some cases where a sampled object/concept is not valid given an image. For example, at least one of the objects in 22929/1, 41276/1, 531086/2, 281711/1, 490505/1 is not valid. In this case the model usually relies on the other available guiding information, prioritising the category information (e.g. 531086/2). In rare cases, the model has failure cases where some of the valid sampled objects may not be used in the generated question (e.g. 293705/2 and 490505/2).

The concept extractor utilises a pre-trained image captioning model and object detector model. This may lead to an accumulation of downstream errors, especially if the data fed into the pre-trained models are from a significantly different data generating distribution than those used to train the model. In this erroneous case, the model will likely fallback to rely on the image modality and category information to produce a generic question (e.g. 22929/1, 22929/2, 531085/1, 293705/2).

E Responsible NLP Research

E.1 Limitations

Our approach claims to achieve SoTA in Visual Question Generation. However, we are only able to train and test our model on one dataset because it is the only existing dataset which contains answer categories. It is possible that our work may be suitable for use in a zero-shot setting, but we have not evaluated or tested our model in this setup.

E.2 Risks

Our model could be used to generate novel questions for use in Visual Question Answering. This may have a knock-on effect which leads to training more VQA models, thus having a negative impact on the environment.

Our model could be used in downstream tasks such as language learning. There may be incorrectness in the generated questions which has a knock on effect to a user using this model (e.g. the user may gain a wrong understanding of a concept because of a question the model has generated)

Abstract

Machine reading comprehension (MRC) that requires discrete reasoning involving symbolic operations, e.g., addition, sorting, and counting, is a challenging task. According to this nature, semantic parsing-based methods predict interpretable but complex logical forms. However, logical form generation is nontrivial and even a little perturbation in a logical form will lead to wrong answers. To alleviate this issue, multi-predictor -based methods are proposed to directly predict different types of answers and achieve improvements. However, they ignore the utilization of symbolic operations and encounter a lack of reasoning ability and interpretability. To inherit the advantages of these two types of methods, we propose **OPERA**, an operation-pivoted discrete reasoning framework, where lightweight symbolic operations (compared with logical forms) as neural modules are utilized to facilitate the reasoning ability and interpretability. Specifically, operations are first selected and then softly executed to simulate the answer reasoning procedure. Extensive experiments on both DROP[1] and RACENum datasets show the reasoning ability of OPERA. Moreover, further analysis verifies its interpretability. [2]

1 Introduction

Machine reading comprehension (MRC) that requires discrete reasoning is a valuable and challenging task (Dua et al., 2019), especially involving symbolic operations such as addition, sorting, and counting. The examples in Table 1 illustrate the task. To answer the question "*Who threw the longest pass*", it requires a model to choose the person with the longest pass from all the people and corresponding distance pairs based on the given passage. This task has various application scenarios in the real world, such as analyzing financial reports and sports news.

Passage: Houston would tie the game in the second quarter with kicker Kris Brown getting a 53-yard and a 24-yard field goal. Oakland would take the lead in the third quarter with wide receiver Johnnie Lee Higgins catching a 29-yard touchdown pass from Russell, followed up by an 80-yard punt return...

Question: Who threw the longest pass?
Answer: Russell

Table 1: An example of question-answer pair along with a passage from DROP dataset (Dua et al., 2019). Question words in color indicate the potential operations for reasoning, i.e., `ARGMAX` and `KEY_VALUE`.

Existing approaches for this task can be roughly divided into two categories: the semantic-parsing-based (Chen et al., 2020b; Gupta et al., 2020) and the multi-predictor-based methods (Dua et al., 2019; Ran et al., 2019; Hu et al., 2019; Chen et al., 2020a; Zhou et al., 2021). The former maps the natural language utterances into logical forms and then executes them to derive the answers. For example, Chen et al. (2020b) propose NeRd. It includes a reader to encode the passage and question, and a programmer to generate a logical form for multi-step reasoning. Intuitively, this method has an advantage in interpretability. However, semantic parsing over text is nontrivial and even a little perturbation will result in wrong answers, which hinders the MRC performance.

To alleviate the heavy dependence on logical forms in the first category, the latter directly employs multiple predictors to derive different types of answers. For example, Dua et al. (2019) and Chen et al. (2020a) divide instances of the DROP dataset into several types and design a model with multi-predictors to deal with different answer types, i.e., question/passage span(s), count, and arithmetic

July 10-15, 2022

expression. It is the capability of deriving different types of answers that improves the performance of models. However, such methods are lack of the necessary components to imitate discrete reasoning, which leads to inadequacy in reasoning ability and interpretability.

To alleviate the shortcomings of the above methods and preserve their advantages, we attempt to summarize reasoning steps into a set of operations and adopt them as the pivot to connect the question and the answer, which makes it possible to perform discrete reasoning. For example, to answer the question in Table 1, it needs two steps: (1) finding all persons and the corresponding distance of touchdown pass, and (2) choosing the one with the longest pass among them. We attempt to convert them into two operations, `KEY_VALUE` and `ARGMAX`, respectively. We then use them to produce the answer. Specifically, we design a set of lightweight symbolic operations (compared with logical forms) to cover all of the questions in the datasets and utilize them as neural modules to facilitate reasoning ability and interpretability. We denote this method as **OPERA**, an operation-pivoted discrete reasoning MRC framework. To utilize the operations, we propose an operation-pivoted reasoning mechanism composed of an operation selector and an operation executor. Specifically, the operation selector automatically identifies relevant operations based on the input. To enhance the performance of this sub-mechanism, we further design an auxiliary task to learn the alignment from a question to operations according to a set of heuristics rules. The operation executor softly integrates the selected operations to perform discrete reasoning over text via an attention mechanism (Vaswani et al., 2017).

To verify the effectiveness of the proposed method, comprehensive experiments are conducted on both the DROP and RACENum datasets, where RACENum used in this paper is a subset of the RACE dataset following (Chen et al., 2020a). Experimental results indicate that our method outperforms strong baselines and achieves the state-of-the-art on both datasets under the single model setting. We further analyze the interpretability of OPERA. Overall, this paper primarily makes the following contributions:

(1) We propose OPERA, an operation-pivoted discrete reasoning MRC framework, improving both the reasoning ability and interpretability.

(2) Extensive experiments on DROP and RACENum dataset demonstrate the reasoning ability of OPERA. Moreover, statistic analysis and visualization indicate the interpretability of OPERA.

(3) We systematically design operations and heuristic rules to map questions to operations, aiming to facilitate research on symbolic reasoning.

2 Related Work

Recently, machine reading comprehension (MRC) methods tend to deal with more practical problems (Yang et al., 2018; Dua et al., 2019; Zhao et al., 2021), for example, answering complex questions that require discrete reasoning (Dua et al., 2019) such as arithmetic computing, sorting, and counting. Intuitively, semantic parsing-based methods, which are well explored to deal with discrete reasoning in question answering with structured knowledge graphs (Bao et al., 2016) or tables, have potential to address the discrete reasoning MRC problem. Therefore, semantic parsing-based methods for discrete reasoning over text are proposed to firstly convert the unstructured text into a table, and then answer questions over the structured table with a grammar-constrained semantic parser (Krishnamurthy et al., 2017). NeRd (Chen et al., 2020b) is a generative model that consists of a reader and a programmer, which are responsible for encoding the context into vector representation and generating grammar-constrained logical forms, respectively. NMNs (Gupta et al., 2020) learned to parse compositional questions as executable logical forms. However, it only adapts to limited question types matched with a few pre-defined templates.

Multi-predictor-based methods employ multiple predictors to derive different types of answers. NAQANET (Dua et al., 2019), a number-aware framework, employed multiple predictors to produce corresponding answer types, including a span, count, and arithmetic expression. Based on NAQANET, MTMSN(Hu et al., 2019) added a negation predictor to solve the negative question and re-ranked arithmetic expression candidates. To aggregate the relative magnitude relation between two numbers, NumNet (Ran et al., 2019) and NumNet+ leveraged a graph convolution network to perform multi-step reasoning over a number graph. QDGAT (Chen et al., 2020a) proposed a question-directed graph attention network for reasoning over a heterogeneous graph composed of entity and number nodes. EviDR (Zhou et al., 2021), an evidence-

Operations	Description	Examples
`ADDITION/DIFF`	Addition or subtraction	*How many more yards was Kris Browns's first field goal over his second?*
`MAX/MIN`	Select the maximum/minimum one from given numbers	*How many yards was the longest field goal in the game?*
`ARGMAX/ARGMIN`	Select key with highest/lowest value from key-value pairs	*Which player had the longest touchdown reception?*
`ARGMORE/ARGLESS`	Select key with higher/lower value from two key-value pairs	*Who scored more field goals, David Akers or John Potter?*
`COUNT`	Count the number of spans	*How many field goals did Kris Brown kick?*
`KEY_VALUE`	Extract key-value pairs	*How many percent of Forth Worth households owned a car?*
`SPAN`	Select spans from input sequence	*Which team scored the final TD of the game?*

Table 2: All the operations, descriptions and the corresponding examples.

emphasized MRC method, performed reasoning over a multi-grained evidence graph. Compared with these existing methods, our proposed OPERA focuses on bridging the gap from questions to answers with operations and integrating them to simulate discrete reasoning.

3 Approach

3.1 Task and Model Overview

Given a question Q and a passage P, MRC that requires discrete reasoning aims to predict an answer $\hat{A}$ with the maximum probability over the candidate space Ω as follows:

$$\hat{A} = \arg\max_{A \in \Omega} p(A|Q, P) \tag{1}$$

where the answer $\hat{A}$ in this task could not only be span(s) extracted from context but also a number calculated with some numbers in context. To handle this task, it generally requires not only natural language understanding but also performing discrete reasoning over text, such as comparison, sorting and arithmetic computing.

To address the aforementioned challenges in this task, we propose OPERA, an operation-pivoted discrete reasoning MRC framework and it is briefly illustrated in Figure 1. In our framework, a set of operations $\mathcal{OP}$, defined in Table 2, are introduced to support the modeling of answer probability $p(A|Q, P)$ as follows:

$$p(A|Q, P) = \sum_{O \in \mathcal{OP}} p(A|Q, P, O)p(O|Q, P), \tag{2}$$

where $O \in \mathcal{OP}$ represents one of the operations. Concretely, in our framework, we first design an operation selector $p(O|P, Q)$ for choosing the correct question-related operations. These selected operations are then *softly* executed over the given context. Eventually, answer predictor $p(A|Q, P, O)$ utilizes the execution result to predict the final answer.

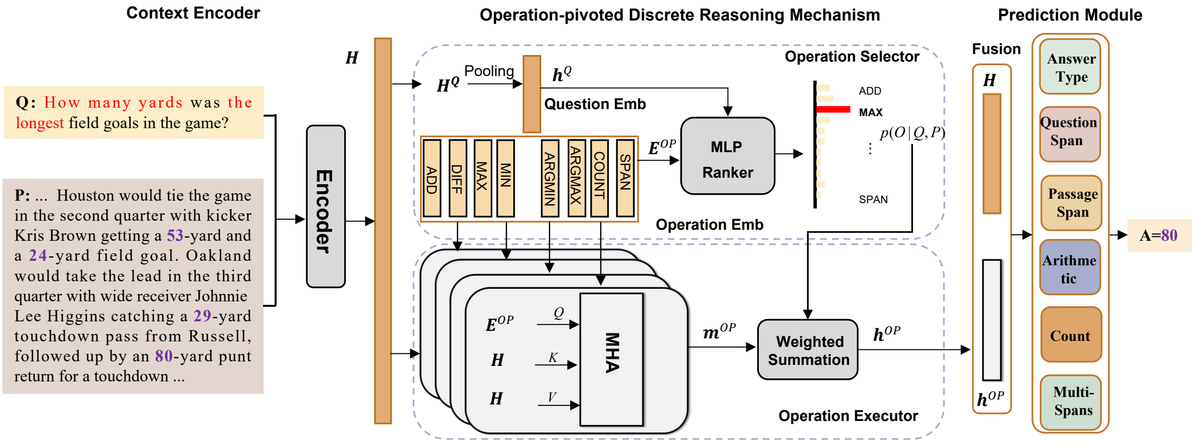
3.2 Definition of Operations

To imitate discrete reasoning, we design a set of operations $\mathcal{OP}$ as shown in Table 2. The set contains 11 operations and each one represents a reasoning unit. Specifically, for questions that need to be answered by calculation, we design operations `ADDITION/DIFF` to represent addition and subtraction. For questions which need to be answered by counting or sorting, we also design operations `COUNT`, `MAX/MIN`, `ARGMAX/ARGMIN`, and `ARGMORE/ARGLESS`. The rest operations `KEY_VALUE` and `SPAN` are used to extract spans from the question and the passage. To incorporate them into OPERA, each operation is denoted as a tuple. Formally, i-th operation $\mathcal{OP}_i$ is $\langle \mathbf{E}_i^{OP}, f_i(\cdot) \rangle$, where $i \in \{1, 2, ..., n\}$ and n is the numbers of operations. $\mathbf{E}_i^{OP} \in \mathbb{R}^{d_h}$ represents the learnable embedding of the i-th operation. $f_i(\cdot)$ is a neural executor parameterized with trainable matrices $\mathbf{W}_{q,i}^{OP}$, $\mathbf{W}_{k,i}^{OP}$ and $\mathbf{W}_{v,i}^{OP} \in \mathbb{R}^{d_h \times d_h}$. The neural executor $f_i(\cdot)$ is capable of performing execution of $\mathcal{OP}_i$ on the given context. Specifically, it takes the representation of context as input and outputs the executed representation as $\mathbf{m}_i^{OP}$ (§ 3.3.2).

3.3 Architecture of OPERA

3.3.1 Context Encoder

The context encoder aims to learn the contextual representation of the input. Formally, given a question Q and a passage P, we concatenate them into a sequence and feed it into a pre-trained language model (Liu et al., 2019; Clark et al., 2020; Lan et al., 2020) to obtain their whole representation $\mathbf{H} \in \mathbb{R}^{l \times d_h}$. After that, we split $\mathbf{H}$ into the question and passage representations, which are respectively denoted as $\mathbf{H}^Q \in \mathbb{R}^{l_q \times d_h}$ and $\mathbf{H}^P \in \mathbb{R}^{l_p \times d_h}$. l_q, l_p, and l are the number of tokens in question, passage and concatenation of them. d_h is the dimension of the representations.



Q: How many yards was the longest field goals in the game?

P: ... Houston would tie the game in the second quarter with kicker Kris Brown getting a 53-yard and a 24-yard field goal. Oakland would take the lead in the third quarter with wide receiver Johnnie Lee Higgins catching a 29-yard touchdown pass from Russell, followed up by an 80-yard punt return for a touchdown ...

Figure 1: The architecture of OPERA. It consists of a context encoder, an operation-pivoted reasoning module, and a prediction module. The prediction module supports five types of answers, including question span, passage span, arithmetic expression, count, and multi-spans. MHA means a multi-head attention mechanism.

3.3.2 Operation-pivoted Discrete Reasoning

The operation-pivoted reasoning module is composed of an operation selector and an operation executor. The operation selector is adopted to select operations related to the given question. The operation executor is responsible for imitating the execution of the selected operations with an attention mechanism.

Operation Selector To imitate discrete reasoning, existing methods usually adopt a logical form generated by a semantic parser to address this task. However, these methods suffer severely from the cascade error, where a little perturbation in the logical form may result in wrong answers. Therefore, we propose to map each question into an operation set, instead of logical forms. Namely, we intend to select relevant operations from the $\mathcal{OP}$. To this end, we adopt a bilinear function to compute the similarity between each operation and the question and normalize them with a softmax as follows:

$$p(O|Q,P) = \texttt{softmax}(\mathbf{E}^{OP}\mathbf{W}\mathbf{h}^Q), \quad (3)$$

where $\mathbf{E}^{OP} \in \mathbb{R}^{n \times d_h}$ is a learnable parameter, which demotes the operation embedding matrix. $\mathbf{h}^Q \in \mathbb{R}^{d_h}$ is the representation of the question, which is obtained by executing weighted pooling on the $\mathbf{H}^Q$. $\mathbf{W} \in \mathbb{R}^{d_h \times d_h}$ is a parameter matrix and $p(O|Q,P)$ is the distribution over operations.

Operation Executor The operation executor is responsible for performing the execution of the selected operations over the given context. Inspired by previous studies (Andreas et al., 2016; Gupta et al., 2020), we implement the operation executor based on the neural module network, which takes advantage of neural network in fitting and generalization, and the composition characteristics of symbolic processing. Specifically, for each operation $\mathcal{OP}_i = \langle \mathbf{E}_i^{OP}, f_i(\cdot) \rangle$, $i = \{1, 2, ..., n\}$, we use a multi-head cross attention mechanism (Vaswani et al., 2017) to implement $f_i(\cdot)$. In detail, we leverage the embedding of each operation $\mathbf{E}_i^{OP}$ as query and the representations of the whole input sequence $\mathbf{H}$ as keys and values, respectively, to model $f_i(\cdot)$ as follows:

$$\alpha_i^{OP} = \texttt{softmax}\left(\frac{(\mathbf{E}_i^{OP}\mathbf{W}_{q,i}^{OP})(\mathbf{H}\mathbf{W}_{k,i}^{OP})^T}{\sqrt{d_h}}\right), \quad (4)$$

$$\mathbf{m}_i^{OP} = \alpha_i^{OP}(\mathbf{H}\mathbf{W}_{v,i}^{OP}), \quad (5)$$

where $\mathbf{W}_{q,i}^{OP}, \mathbf{W}_{k,i}^{OP}, \mathbf{W}_{v,i}^{OP} \in \mathbb{R}^{d_h \times d_h}$ are the parameter matrices in executor of operation $\mathcal{OP}_i$. $\mathbf{m}_i^{OP} \in \mathbb{R}^{d_h}$ is the representation of the execution result of the i-th operation.

Finally, we softly integrate all of the execution results as the final output $\mathbf{h}^{OP} \in \mathbb{R}^{d_h}$ with the distribution $p(O|Q,P)$ as follows:

$$\mathbf{h}^{OP} = \sum_{i=1}^{n} p(O = \mathcal{OP}_i|Q,P)\mathbf{m}_i^{OP}. \quad (6)$$

The operation-aware semantic representation $\mathbf{h}^{OP}$ is further fed into the prediction module to reason the final answer (§ 3.3.3).

As described above, OPERA introduces operations that assist in understanding questions and integrates them into the model to perform discrete reasoning. Therefore, it achieves an advantage in the reasoning capability and interpretability over the previous multi-predictor-based methods (Hu et al., 2019; Chen et al., 2020a; Zhou et al., 2021). Moreover, soft execution and composition of operations in OPERA alleviate the cascaded error that the semantic parsing methods (Ran et al., 2019; Chen et al., 2020b) suffer from. More experiments and analyses about reasoning ability and interpretability are illustrated in § 4.4 and § 4.5.

3.3.3 Prediction Module

In this section, we introduce the prediction module to derive different types of answers via multi-predictors. Each predictor first reasons out a derivation and then performs execution to obtain the final answer. This answer prediction procedure is formalized as follows:

$$p(A|Q,P,O) = \sum_{D \in \mathcal{D}} \mathbb{I}(g(D) = A) p(D|Q,P,O), \tag{7}$$

where $\mathbb{I}(g(D) = A)$ is an indicator function with value 1 if the answer A can be derived from a derivation executor $g(\cdot)$ based on D, and 0 otherwise. $p(D|Q,P,O)$ models the derivation prediction. Specifically, a derivation $D = \langle T, L \rangle$ includes an answer type T and a corresponding label L. For example, in Table 3, the textual answer A of the question "*how many yards was the longest field goals in the game*" is "80". The possible derivations $\mathcal{D}$ to this answer include a span $\langle \texttt{Span}, (100, 102) \rangle$, and an arithmetic expression $\langle \texttt{AE},\ (0 * 29) + (1 * 80) \rangle$. Inspired by previous studies (Chen et al., 2020a; Zhou et al., 2021), the derivation predictor

$$p(D|Q,P,O) = \sum_{T \in \mathcal{T}} p_T(L|Q,P,O) p(T|Q,P,O) \tag{8}$$

is decomposed into an answer type predictor $p(T|Q,P,O)$ and corresponding label predictors $p_{T \in \mathcal{T}}(L|Q,P,O)$ where $\mathcal{T} = \{$*Question Span*, *Passage Span*, *Count*, *Arithmetic Expression*, *Multi-spans*$\}$ includes all the answer types defined in this paper. Each label predictor takes question-passage representation $\mathbf{H}$ and the operation-pivo representation $\mathbf{h}^{OP}$ as input and calculates the probability of label L. Specifically, these label predictors are specified as follows and more details are shown in Appendix A.3.

Question / Passage Span The probability of a question/passage span is the product of the probabilities of the start index and the end index. Following MTMSN (Hu et al., 2019), we use a question-aware decoding strategy to predict the start and end index across the input sequence, respectively.

Count As indicated in QDGAT (Chen et al., 2020a), questions with 0-9 as answers account for 97% in all the count questions. Hence, such questions are modeled as a 10-class (0-9) classification problem.

Arithmetic Expression Similar to NAQANet (Dua et al., 2019), we first assign a sign (positive, negative, or zero) to each number in the context and then compute the answer by summing them.

Multi-spans Inspired by Segal et al. (2020), the multi-span answer (a set of non-contiguous spans) is derived with a sequence labeling method, in which each token of the input is tagged with `BIO` labels. Finally, each span which is tagged with continuous `B` and `I` is taken as a candidate span.

3.4 Learning with Weak Supervision

3.4.1 Training Instance Construction

Each training instance is originally composed of a passage P, a question Q, and answer text A. Since the derivations (i.e., labels for the spans, arithmetic expressions, and count) are not provided, weak supervision is adopted in OPERA. Specifically, for each training instance, given the golden textual answer A, we heuristically search all the possible derivations $\mathcal{D}$ as supervision signals, each of which can derive the correct answer A. Table 3 shows an example of $\mathcal{D}$.

In addition, we propose heuristic rules to map a question to its related operations denoted as $\mathcal{O} \subseteq \mathcal{OP}$. For example, to detect the operations intimated by the question Q in Table 3, we design a question template "*how many yards [Slot] longest [Slot]*" which maps matched questions to the operation `MAX`. Overall, a training instance can be constructed as a tuple $\langle P, Q, A, \mathcal{O}, \mathcal{D} \rangle$. The one-shot heuristic rules to obtain operation labels reduce the cost of human annotations. Moreover, when applying OPERA to other discrete reasoning MRC tasks, both the operations $\mathcal{OP}$ and the heuristic rules can be extended and adjusted if necessary. Fortunately, there is no need to construct strict logical forms in our architecture, but only the set of lightweight operations involved in the question. It tremendously reduces the difficulty of adapting OPERA to other discrete reasoning MRC tasks.

Meanwhile, we analyze the distribution of operations in the training set. More details about the

P	*...Oakland would take the lead in the third quarter with wide receiver Johnnie Lee Higgins catching a 29-yard touchdown pass from Russell, followed up by an 80-yard punt return for a touchdown ...*
Q	*How many yards was the longest field goals*
A	80
$\mathcal{O}$	`MAX` $\Leftarrow$ *How many yards [Slot] longest [Slot]*
$\mathcal{D}$	$\langle$`Span`$, (100, 102)\rangle$; $\langle$`AE`$, (0 * 29) + (1 * 80)\rangle$

Table 3: An example of building training instances.

heuristic rules for mapping questions to operations and the operation distribution in the dataset are respectively given in the Appendix A.1 and A.2.

3.4.2 Joint Training

The training objective consists of two parts, including the loss for answer prediction and operation selection. The loss for answer prediction $\mathcal{L}_a$ is

$$\mathcal{L}_a = -\log p(A|Q, P). \tag{9}$$

Note that the calculation of loss $\mathcal{L}_a$ takes all possible derivations that can obtain the correct answer A into account, which means that OPERA does not require labeling answer types for training. In addition, to learn better alignment from a question to operations, we introduce auxiliary supervision for the operation selector and calculate the loss

$$\mathcal{L}_{op} = -\sum_{O \in \mathcal{O}} \log p(O|Q, P), \tag{10}$$

where $\mathcal{O}$ indicates the operations provided by the heuristic rules. Finally, OPERA is optimized by minimizing the loss $\mathcal{L} = \mathcal{L}_a + \lambda \mathcal{L}_{op}$ where λ is a hyperparameter as a trade-off of the two objectives.

4 Experiment

4.1 Dataset and Evaluation

We conduct experiments on the following two MRC datasets to examine the discrete reasoning capability of our model. We employ Exact Match (EM) and F1 score as the evaluation metrics.

DROP Question-answer pairs in DROP dataset (Dua et al., 2019) are crowd-sourced based on passages collected from Wikipedia. In detail, it contains 96.6K question-answer pairs, where 77400/9536/9615 samples are for training/development/test. Three kinds of answers are involved in the raw dataset, i.e., NUMBER (60.69%), SPANS (37.72%), and DATE (1.59%).

RACENum To investigate the generalization capability of OPERA, we compare OPERA to other strong baselines on samples of RACE (Lai et al., 2017). Following Chen et al. (2020a), we sample instances from RACE, denoted as RACENum, where the question of each instance starts with "how many". To conveniently evaluate the models on RACENum, we convert the format of instances in RACENum into the same as DROP, since RACE is a multi-choice MRC dataset. RACENum is divided into two categories, i.e., middle/high school exam (RACENum-M/H). They respectively contain 609 and 565 questions, where the scale is a bit different from that reported in Chen et al. (2020a)[3].

4.2 Baselines

We compare OPERA with various prior systems in terms of reasoning capability and interpretability.
w/o Pre-trained Language Model: NAQANET (Dua et al., 2019) leverages several answer predictors to produce corresponding types of answers, including a span, count, and arithmetic expression. NumNet (Ran et al., 2019) leverages a graph convolution network to reason over a number graph aggregated relative magnitude among numbers.
w/ Pre-trained Language Model: GenBERT (Geva et al., 2020) injects reasoning capability into BERT by pre-training with large-scale numerical data. Based on NAQANET, MTMSN (Hu et al., 2019) adds a negation predictor to solve the negative question and re-rank arithmetic expression candidates. NeRd (Chen et al., 2020b) is essentially a generative semantic parser that maps questions and passages into executable logical forms. ALBERT-Calc was proposed for DROP by combining ALBERT with several predefined answer predictors (Andor et al., 2019). NumNet+ employs a pre-trained model to further boost the performance of NumNet. QDGAT (Chen et al., 2020a) builds a heterogeneous graph composed of entity and value nodes upon RoBERTa and utilizes a question-directed graph attention network to reason over the graph. EviDR (Zhou et al., 2021), an evidence-emphasized MRC model, performs reasoning over a multi-grained evidence graph based on ELECTRA.

4.3 Implementation Details

We utilize adam optimizer (Kingma and Ba, 2015) with a cosine warmup mechanism and set the

---

[3] Since no released code for dataset construction, we implement it referred to the algorithm in Chen et al. (2020a).

	BLR	LR	BWD	WD	Epochs	BS	n_h	d_h
RoBERTa	1.5e-5	5e-4	0.01	5e-5	12	16	16	1024
ELECTRA	1.5e-5	5e-4	0.01	5e-5	12	16	16	1024
ALBERT	3e-5	1e-4	0.01	5e-5	8	128	64	4096

Table 4: Hyperparameters settings for training OPERA.

weight of loss $\lambda = 0.3$ to train the model. The hyper-parameters are listed in Table 4, where BLR, LR, BWD, WD, BS, and d_h respectively represent the learning rate of the encoder, the learning rate of other parts of the model, the weight decay of the encoder, the weight decay of other parts of the model, batch size and hidden size of the model. Each operation is neutralized with a multi-head attention layer with n_h heads and d_h dimension.

4.4 Main Results

4.4.1 Results on DROP and Analysis

Table 5 shows the overall results of OPERA and all the baselines on the DROP dataset. OPERA achieves comparable and even higher performance than the recently available methods. Specifically, OPERA(RoBERTa) achieves comparable performance to QDGAT with advantages of 0.32 EM and 0.42 F1. OPERA(ELECTRA) exceeds EviDR by 0.89 EM and 0.90 F1 and OPERA(ALBERT) outperforms ALBERT-Calc by 4.84 EM and 4.24 F1. Moreover, the voting strategy is employed to ensemble 7 OPERA(ALBERT) models with different random seeds, achieving 86.26 EM and 89.12 F1 scores. We think the better performance comes from the modeling of discrete reasoning over text via operations, which mines more semantic information of context and explicitly integrates them into the answer prediction.

4.4.2 Results on RACENum

To investigate the generalization of OPERA for discrete reasoning, we additionally compare OPERA with QDGAT and NumNet+ on the RACENum dataset. We directly evaluate the three models without fine-tuning on RACENum due to its small scale. As Table 6 shows, the scores of models on the RACENum dataset are generally lower than that on the DROP dataset, which is attributed to the lack of in-domain training data. Nevertheless, the performance of OPERA significantly outperforms NumNet+ and QDGAT by a large margin of more than 3.49 EM and 3.53 F1 score on average. It indicates that OPERA has better generalization ability.

Method	**Dev**		**Test**	
	EM	**F1**	**EM**	**F1**
w/o Pre-trained Models

Table 6: The performance of RoBERTa-based models on the RACENum dataset without finetuning.

4.5 Interpretability Analysis

Interpretability is an essential property for evaluating an MRC model. We analyze the interpretability of OPERA from the following two stages: (1) mapping from questions to operations, and (2) mapping from operations to answers.

Mapping from Question to Operation To explicitly show the correlations between questions and related operations, we manually evaluate the performance of the operation selection on 50 samples on the development set of DROP. Specifically, precision@n (P@n) is used as the evaluation metric, i.e., judging whether the top n predicted operations contain the correct ones according to questions. We finally achieve 0.88 on P@1 and 0.98 on P@2 for our model OPERA, which indicates that the operation selection module can accurately predict interpretable operations.

	PS	CT	AE	MS	QS
ADDITION	0.03	0.08	0.9	0.01	0.007
DIFF	0.003	0.1	0.8	0.0005	2e-05
MAX	0.0001	0.01	1	0.004	3e-05
MIN	9e-05	0.2	0.8	0.003	3e-06
ARGMIN	0.5	0.1	0.2	0.2	0.02
ARGMAX	0.4	0.1	0.4	0.05	0.06
ARGMORE	0.7	0.05	0.08	0.2	0.06
ARGLESS	0.3	0.1	0.5	0.03	0.05
KEY_VALUE	1	8e-05	2e-05	0.04	0.004
COUNT	6e-05	0.9	0.07	1e-05	8e-07
SPAN	0.8	5e-06	0.02	0.2	0.05

Figure 2: Statistical correlations between operations and answer types. The horizontal axis indicates answer types, and the vertical axis means operations. PS, CT, AE, MS and QS respectively means *passage span*, *count*, *arithmetic expression*, *multi-spans* and *question span*.

Mapping from Operation to Answer We explore the relations between operations and final answer types based on model predictions on the development set of DROP. Specifically, for each type of answer, the predicted operation distributions are summed over all samples and normalized, which derives a relation matrix as shown in Figure 2. We can observe that obvious correlations between operations and answer types exist. `ADDITION`, `DIFF`, `MAX` and `MIN` obviously correspond to *Arithmetic Expression*. The top 3 answer types for `KEY_VALUE` and `SPAN` are *Passage Span*, *Multiple Spans*, and *Question Span*. `COUNT` probably maps to *Count* answer type. `ARGMORE`, `ARGLESS`, `ARGMAX`, and `ARGMIN` are usually used for both *Passage Span* and *Arithmetic Expression*.

4.6 Ablation Study

Effect of Operations for OPERA As shown in Table 7, we first remove the loss of operation selection (w/o $\mathcal{L}_{op}$) by setting $\lambda = 0$, resulting in the performance degradation of 0.74 EM / 0.52 F1 points and 0.14 EM / 0.18 F1 points for OPERA based on RoBERTa and ALBERT, respectively. It indicates that the supervision for explicitly learning the alignment from a question to operations contributes to the reasoning capability of OPERA. Yet our approach is somewhat limited by the fact that the operation selector needs an auxiliary training task to work better, and heuristics rules are required to map questions into an operation set as training labels. Furthermore, we remove the total operation-pivoted reasoning module (w/o OP), the performance respectively declines by 1.06 EM / 0.79 F1 points and 0.85 EM / 0.75 F1 points for OPERA(RoBERTa) and OPERA(ALBERT). We also conduct the ablation study on the subsets containing a specific operation. As shown in Figure 3, OPERA achieves better performance than OPERA w/o OP on the majority of subsets. Overall, it confirms that integrating the operation-pivoted discrete reasoning mechanism contributes to the reasoning ability of the model.

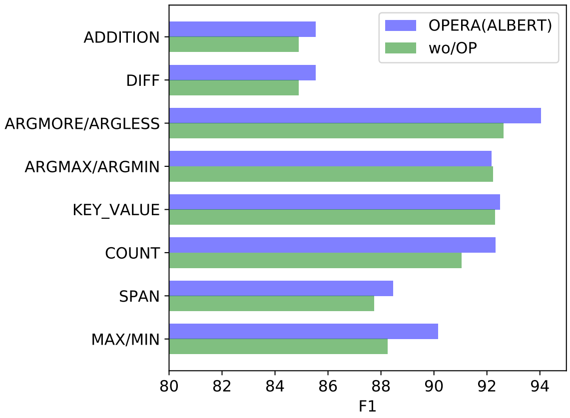

Figure 3: Ablation study on all the subsets of DROP containing some specific operations.

Method	**NUM (60.69%)**	**SPANS (37.72%)**	**Overall**
	EM / F1	**EM / F1**	**EM / F1**
OPERA(RB)	**85.91 / 86.14**	**83.89 / 88.90**	**83.74 / 86.52**
w/o $\mathcal{L}_{op}$	85.83 / 86.00	82.68 / 88.02	83.00 / 86.00
w/o OP	85.36 / 85.53	82.53 / 87.06	82.68 / 85.73
OPERA(AB)	**86.39 / 86.58**	86.30 / **90.99**	**84.86 / 87.54**
w/o $\mathcal{L}_{op}$	86.08 / 86.24	**86.39** / 90.96	84.72 / 87.36
w/o OP	85.62 / 85.89	84.95 / 89.83	84.01 / 86.79

Table 7: Ablation study on the dev set of DROP. RB and AB mean RoBERTa and ALBERT, respectively.

Probe on Answer Types and Language Models As reported in Table 7, we observe that the performance on the NUMBER(NUM) and SPANS questions, which together account for 98.4% of the total, respectively declines by 0.55 EM / 0.61 F1 and 1.36 EM / 1.84 F1 when removing operation-pivoted reasoning mechanism from OPERA(RB). It demonstrates that this mechanism contributes to various answer types. Also, we respectively evaluate the performance of OPERA based on RoBERTa and ALBERT. We observe that OPERA(ALBERT) outperforms OPERA(RoBERTa) due to the stronger capability of semantic representation. Furthermore, integrating this mechanism consistently contributes to the performance of OPERA no matter it is based on RoBERTa or ALBERT. It indicates that OPERA

Question-Answer	Passage	NumNet+	QDGAT	OPERA
Q: How many total yards of touchdown passes were there? **A**: 73	... receiver Johnny Knox on a 23-yard touchdown pass. Q: Which period was Wolf executive and player personnel director with the Oakland Raiders longer for, 1963-1974 or 1979-1989? **A**: 1963-1974	Wolf only had a brief stint with the Jets between 1990 and 1991, while most of his major contributions occurred as an executive and player personnel director with the Oakland Raiders (1963-1974, 1979-1989), and later as General Manager...	**AnswerType**: Passage Span **Answer**: 1979-1989	**AnswerType**: Passage Span **Answer**: 1979-1989	**Top-1 OP**: `SPAN` **AnswerType**: Passage Span **Answer**: 1963-1974

Table 8: The cases from the development set of DROP. The predictions from the state-of-the-art model NumNet+ and QDGAT are shown. The last column indicates our predicted answers and Top-1 operations.

could compensate for the discrete reasoning capability of language models.

4.7 Case Study

We show two examples from the development set of DROP to illustrate the effectiveness of our model by comparing the results of different models in Table 8. The first example shows that operation is essential for the prediction of answer type. NumNet+ and QDGAT fail to predict the correct answer since the answer type of "how many" questions are wrongly predicted to *Count*. In contrast, OPERA can capture the `ADDITION` operation, which prompts the model to answer it with an *arithmetic expression* predictor. The second example shows that OPERA has stronger reasoning capability. In the example, though NumNet+ and QDGAT correctly predict the answer type, the final answer is wrong. OPERA can utilize more semantic information for answer prediction with the help of the operation-pivoted discrete reasoning mechanism.

5 Conclusion

We propose a novel framework OPERA for machine reading comprehension requiring discrete reasoning. Lightweight and one-shot operations and heuristic rules to map questions to an operation set are systematically designed. OPERA can leverage the operations to enhance the model's reasoning capability and interpretability. Experiments on DROP and RACENum demonstrate that OPERA achieves remarkable performance. Further visualization and analysis verify its interpretability.

A Appendix

A.1 Template-Based Heuristic Rules

Operations / Examples / Templates
`ADDITION/DIFF` *How many more yards was Kris Browns's first field goal over his second?* How many [Slot] more/less [Slot] over [Slot]?
`MAX/MIN` *How many yards was the longest field goal in the game?* how many yards [Slot] longest/shortest [Slot]?
`ARGMAX/ARGMIN` *Which player had the longest touchdown reception?* Which player [Slot] longest/shortest [Slot]?
`ARGMORE/ARGLESS` *Who scored more field goals, David Akers or John Potter?* Who [Slot] more/less, [Slot] or [Slot]?
`COUNT` *How many field goals did Kris Brown kick?* How many field goals [slot]?
`KEY_VALUE` *How many percent of Forth Worth households owned a car?* How many percent of [Slot]
`SPAN` *Which team scored the final TD of the game?* Which team [Slot]

Table 9: All the operations, the corresponding examples and templates.

In this section, we propose some general template-based heuristic rules to illustrate mapping from questions to operations. For example, to detect the operations intimated by the question "*how many yards was the longest field goals*" in Table 9, we design a question template OP_{pat} "*how many yards [Slot] longest/shortest [Slot]*" which maps matched questions to the operation `MAX`. Meanwhile, we humanly evaluate the quality of the heuristic rules. Specifically, we sample 50 instances from the training set and ask three annotators to label the required operations for each question manually. The final average F1 score of the three annotators is 86%, which indicates that the heuristic rules can correctly predict most of the operations, while still 14% to be noise for training.

A.2 Distribution of the Operations

We analysis the distribution of operations in the training set of DROP, where `ADDITION`, `DIFF` and `SPAN` together accounts for more than 85%. For other questions with span answers that requires sorting or comparison, some specific operations are involved, such as `ARGMAX` / `ARGMIN` / `ARGMORE` / `ARGLESS` and `KEY_VALUE`.

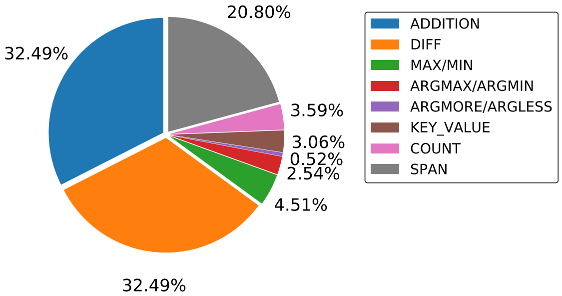

Figure 4: The Distribution of operations in the training set of DROP.

A.3 Details of Prediction Module

In this section, we reveal the architecture details of the prediction module, including a prediction module for answer type and five label predictors corresponding to different answer types. $\texttt{FFN}(\cdot)$ means a feed-forward network that consists of two linear projections with a GeLU activation function (Hendrycks and Gimpel, 2016) and a layer normalization mechanism (Ba et al., 2016).

Answer Type The probability distribution of answer type choices $p(T|Q,P,O)$ is derived by a $|\mathcal{T}|$-classifier with $\mathbf{h}^Q$, $\mathbf{h}^P$ and $\mathbf{h}^E$ as input:

$$\begin{aligned} &\mathbf{h}^E = \sum_{O_i \in \mathcal{OP}} p(O_i|Q,P)\mathbf{E}^{OP}_i, \\ &p(T|Q,P,O) \propto \texttt{FFN}([\mathbf{h}^E;\mathbf{h}^Q;\mathbf{h}^P]), \end{aligned} \tag{11}$$

where $\mathbf{h}^Q$ and $\mathbf{h}^P \in \mathbb{R}^{d_h}$ is the representation vector of question and passage calculated by weighted pooling with $\mathbf{H}^Q$ and $\mathbf{H}^P$, respectively. $\mathbf{E}^{OP}$ is the embedding matrix of operations.

Question/Passage Span Following MTMSN (Hu et al., 2019), we use a question-aware decoding strategy to predict the start and end indices of the answer span. Specifically, we first compute a question representation vector $\mathbf{g}^Q$ via weighted pooling. Then derive the probabilities of the start and end indices of the answer span denoted as p_s and p_e:

$$\begin{aligned} &\mathbf{M} = [\mathbf{h}^{OP};\mathbf{H};\mathbf{H} \odot \mathbf{g}^Q], \\ &p_s, p_e \propto \texttt{FFN}(\mathbf{M}), \end{aligned} \tag{12}$$

where $\odot$ denotes element-wised product. $\mathbf{h}^{OP}$ is derived by Eq. 6 and $\mathbf{H}$ is the representation of input sequence from context encoder.

Count The count predictor is a 10-classifier with the operation-aware representation, all the mentioned number representation, question and passage representations as input. Specifically, when N numbers exists, we gather the representation of all numbers $\mathbf{U} = (\mathbf{u}^1, \mathbf{u}^2, ..., \mathbf{u}^N) \in \mathbb{R}^{N \times d_h}$ from $\mathbf{H}$ and compute a global representation vector of numbers as $\mathbf{h}^U$. Then compute the probability distribution of count answer p_c:

$$\begin{aligned} \alpha^U \propto \mathbf{U}\mathbf{W}^U, \ \ \mathbf{h}^U = \alpha^U \mathbf{U}, \\ p_c \propto \mathtt{FFN}([\mathbf{h}^{OP}; \mathbf{h}^U; \mathbf{h}^Q; \mathbf{h}^P]), \end{aligned} \tag{13}$$

Arithmetic Expression Similar to NAQANet (Dua et al., 2019), we perform addition and subtraction over all the numbers mentioned in the context by assigning a sign (plus, minus, or zero) to each number. The probability p^i_{sign} of the i-th number's sign is derived as below:

$$p^i_{sign} \propto \mathtt{FFN}([\mathbf{h}^{OP}; \mathbf{u}^i; \mathbf{h}^Q; \mathbf{h}^P]). \tag{14}$$

Multi-Spans Inspired by Segal et al. (2020), the multi-span answer is derived with a sequence role labeling method over the input token sequence, denoted as `SRL`$(\cdot)$. p_{ms} is the probability distribution of token's `BIO` tag:

$$p_{ms} = \mathtt{SRL}([\mathbf{H}; \mathbf{h}^{OP}]). \tag{15}$$

Improving Multi-Document Summarization through Referenced Flexible Extraction with Credit-Awareness

Abstract

A notable challenge in Multi-Document Summarization (MDS) is the extremely-long length of the input. In this paper, we present an extract-then-abstract Transformer framework to overcome the problem. Specifically, we leverage pre-trained language models to construct a hierarchical extractor for salient sentence selection across documents and an abstractor for rewriting the selected contents as summaries. However, learning such a framework is challenging since the optimal contents for the abstractor are generally unknown. Previous works typically create *pseudo extraction oracle* to enable the supervised learning for both the extractor and the abstractor. Nevertheless, we argue that the performance of such methods could be restricted due to the insufficient information for prediction and inconsistent objectives between training and testing. To this end, we propose a loss weighting mechanism that makes the model aware of the unequal importance for the sentences not in the pseudo extraction oracle, and leverage the fine-tuned abstractor to generate summary references as auxiliary signals for learning the extractor. Moreover, we propose a reinforcement learning method that can efficiently apply to the extractor for harmonizing the optimization between training and testing. Experiment results show that our framework substantially outperforms strong baselines with comparable model sizes and achieves the best results on the Multi-News, Multi-XScience, and WikiCatSum corpora.[1]

1 Introduction

Neural multi-document summarization has drawn a lot of attention due to the wide applications, e.g., Wikipedia generation (Liu et al., 2018), news digest (Fabbri et al., 2019), or related-work section generation (Lu et al., 2020). Through concatenating the document clusters, it is applicable to adopt the approaches from single-document summarization (Zhang et al., 2020a; Fabbri et al., 2019) under multi-document settings. However, the input length from multiple documents is typically long, which might be computationally infeasible for Transformer-based models (Vaswani et al., 2017). One possible solution is to set a fixed length and truncate the input sequence. However, the truncation leads to information loss and performance drop. Moreover, even if the model can take such a long sequence as input, the attentions could be dispersed over long sequences (Yang et al., 2018) and further degrade the performance (Jin et al., 2020; Liu and Lapata, 2019a; Cohan et al., 2018).

To tackle the long sequence problem, another possible solution is to leverage the extract-then-abstract architecture in single document summarization (Pilault et al., 2020; Chen and Bansal, 2018; Gehrmann et al., 2018). In such an architecture, an extractor first selects salient contents from the documents, and an abstractor is applied to rewrite the selected contents to coherent summaries. However, several issues arise for directly applying the procedure in MDS. 1) *Long-sequence problem for the extractor*. Although the input length for the abstractor can be controlled through the content selection and thus enables the usage of Transformer models (Pilault et al., 2020), it is still inevitable for the extractor to process the complete input documents. Previous methods mainly use LSTM-based extractors (Pilault et al., 2020; Chen and Bansal, 2018; Gehrmann et al., 2018). However, this fails to leverage knowledge of pre-trained language models. 2) *Suboptimal pseudo oracles*. Most summarization corpora do not contain the oracle for extraction. As an alternative, previous works typically generate *pseudo extraction oracle*, or simply called *pseudo oracle*, through a greedy process (Liu and Lapata, 2019b; Chen and Bansal, 2018). Specifically, for each iteration in the process,

July 10-15, 2022

candidate sentences are individually concatenated with previously-selected sentences and compute the ROUGE (Lin, 2004) scores with the human-written summaries. The top-scored sentence is iteratively selected until no sentence could further improve the ROUGE score. In practice, there are different ways for scoring. For examples, Liu and Lapata (2019b) use the average of ROUGE-1 and ROUGE-2 F1 scores while Chen and Bansal (2018) use ROUGE-L recall. The variants of design could cause the extractor to behave differently. In our study, we also found that using the ROUGE precision metric leads to much less extraction than using the recall metric. This implies that the pseudo oracles are suboptimal, and learning the extractor fully relies on the pseudo oracles could restrict the performance. How to alleviate the negative effects of pseudo oracles remains open. 3) *Insufficient information for the extractor*. Even if the pseudo oracles are good enough to train the abstractor well, learning a precise extractor is still challenging. The problem lies in that a pseudo oracle is derived from a specific summary. However, there are potentially multiple valid summaries given the documents. To select salient sentences, the extractor is required to implicitly infer the underlying summary used for oracle construction, which is difficult due to the lack of evidence. 4) *Inconsistent objectives for the extractor*. With pseudo oracles, the extractor is learned to select a set of sentences that has high lexical similarity to the summaries without redundancy. However, the goal of the extractor in test-time is to provide inputs for the abstractor that non-overlapping lexical may still be valuable. In other words, the objective for the extractor in training is inconsistent with the one in testing.

To address these issues, we propose the **RE**ferenced **FLE**xible Extraction with **C**redi**T**-Awareness (REFLECT) for MDS. For the first problem, we propose a Transformer-based hierarchical extractor that contains the token- and sentence-level feature encoders. Both the encoders are initialized with pre-trained language models to utilize the pretext knowledge. For the second problem, we propose Pseudo Oracle Relaxation (POR) to render the model aware of the unequal importance for the non-oracle sentences. This mechanism encourages the model to emphasize the precision for critical sentences with either high or low lexical similarity to the summaries, and avoids the confusion arising from the different labels for similar sentences. For the third problem, we propose Summary Referencing (SR) to leverage the fine-tuned abstractor for providing additional learning signals to evidence extraction prediction. The summary reference serves as an approximation for the human-written summary while being able to generalize for testing. For the fourth problem, we propose Credit-Aware Self-Critic (CASC) learning to fine-tune for matching the objective between training and testing. Different from previous methods that assign an identical reward for all actions, we reallocate the rewards based on the impacts of actor explorations.

The contributions are summarized as follows:

- We leverage pre-trained language models to propose an extract-then-abstract framework, which contains a hierarchical extractor that efficiently handles long inputs while utilizing pretext knowledge.
- We investigate the problems for typical learning paradigms of the extractor and propose a framework, named REFLECT, to further improve the extractor performance. The studies on pseudo oracles also provide valuable insights for extract-then-abstract frameworks.
- Experimental results on Multi-News, Multi-XScience, and WikiCatSum corpora demonstrate that REFLECT outperforms the state-of-the-art models with comparable sizes.

2 Related Work

Early attempts for MDS focus on extracting sentences through statistical methods (Goldstein et al., 2000; Erkan and Radev, 2004; Wan and Yang, 2006, 2008). For example, Goldstein et al. (2000) extend Maximal Marginal Relevance (MMR) method to select sentences that are relevant to the query and novel across different documents. Erkan and Radev (2004) leverage sentence relations with graph structures that represent pairwise sentence similarities, and apply PageRank (Page et al., 1999) algorithm to extract sentences given the query document. However, extractive methods often suffer the coherence problem (Wu and Hu, 2018). Therefore, instead of directly extracting sentences from the articles, abstractive methods that can rewrite the articles achieve great success with the advantages of large annotated corpora (Pang et al., 2021; Zhou et al., 2021; Liu et al., 2021a; Zhong et al., 2020; Li et al., 2020; Liu and Lapata, 2019a).

Directly operating on the long inputs in MDS often leads to model degradation (Jin et al., 2020). One of the promising solutions is to leverage the extract-then-abstract architectures in single document summarization (Chen and Bansal, 2018; Gehrmann et al., 2018). For example, Gehrmann et al. (2018) propose an LSTM-based word-level extractor to choose phrases from the document, and apply an abstractor with the copy mechanism to generate summaries given the selected contents. Pilault et al. (2020) also apply an LSTM-based sentence extractor to select contents, but further leverage a Transformer decoder to improve the performance.

Although introducing Transformer architectures provides improvements, the input length is typically limited according to the computation and memory overhead. A recent line of studies has been proposed to alleviate such problems (Bražinskas et al., 2021; Beltagy et al., 2020; Liu and Lapata, 2019a; Jin et al., 2020). Liu and Lapata (2019a) propose to rank the candidate input paragraphs, and only concatenate the top few as the inputs for the abstractor. Jin et al. (2020) encode multiple documents in different granularity including token-level, sentence-level, and document-level. Pasunuru et al. (2021) design a graph encoder parallel with standard encoder to provide inter-document information and integrate the pre-trained BART (Lewis et al., 2020) with local attention mechanism (Beltagy et al., 2020) to overcome the long input problem. Bražinskas et al. (2021) apply policy gradient optimization to learn a train-time selector using lexical features pre-computed from source texts and gold summaries as inputs. Due to the lack of gold summaries in testing, a test-time selector is learned using lexical features solely from source texts as inputs and predictions from the train-time selector as learning targets. Comparatively, our methods thoroughly leverage the language models with an extract-and-abstract framework that enjoys the full capacities for both the extractor and the abstractor. The introduced summary referencing further improves the extractor with additional signals in both train- and test-phase.

3 Methodology

Utilizing large pre-trained language models brings great benefits for text generation problems. However, the input length of multi-document summarization is typically long, which makes large pre-trained language models, *e.g.*, Transformer-based models, inefficient for processing. To match the length constraint, document-level truncation (Fabbri et al., 2019) has been widely-used. However, the truncation could inevitably cause information loss and degrade the performance. To solve the problem, we propose to leverage the extract-then-abstract framework. However, as described in the introduction, four challenges arise while learning such a framework. We first present our architecture to solve the long sequence problem and elaborate on the proposed methods to tackle the challenges.

3.1 Hierarchical Summarizer

Figure 1 illustrates the proposed REFLECT framework. Specifically, based on the Transformer (Vaswani et al., 2017), our architecture contains a hierarchical extractor (H-EXT) and an abstractor (ABS). The hierarchical extractor is composed of a token-level encoder (T-ENC), a sentence-level encoder (S-ENC), and a sentence selector (SS). Considering a training example (x, y), $x = \{x_1, x_2, ..., x_N\}$ is the concatenation of multiple documents that jointly consists of N complete sentences and y is the corresponding human-written summary. Let M denote the allowed input length in Transformer-based models, we split all sentences into K disjoint sets $\{h_k\}_{k=1}^{K}$ such that each set h_k consists of sentences whose total number of tokens matches the length constraint M. The hierarchical extractor then predicts a set containing the indices of selected sentences (denoted by $\hat{e}$), which is used to retrieve salient contents from x for the abstractor to produce summaries. Specifically, the hierarchical extractor can be expressed as follows.

$$\begin{aligned}\hat{e} &= \text{H-EXT}(h) \\ &= \text{SS}(\text{S-ENC}(\bar{\oplus}\{\text{T-ENC}(h_k)\}_{k=1}^{K})),\end{aligned} \tag{1}$$

where $\bar{\oplus}$ is the operation of taking average for hidden states of tokens within sentences and concatenating the averaged results to obtain the sentence-level representations. The hierarchical summarizer (H-SUM) can then be expressed as:

$$\text{H-SUM}(h) = \text{ABS}(\oplus\{w_{x_i} | i \in \hat{e}\}), \tag{2}$$

where $\oplus$ is the concatenation operation.

3.2 Pseudo Oracle Relaxation

The sentence selection process of the extractor is typically formulated as a supervised classification

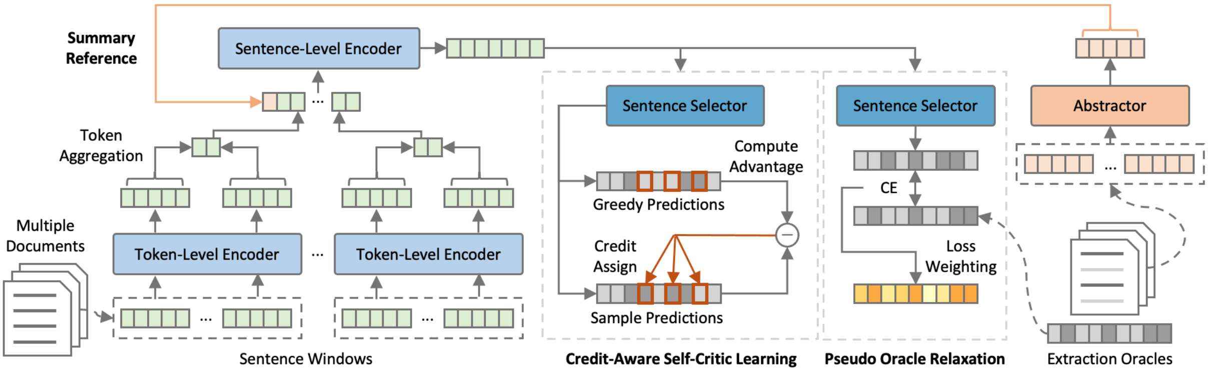

Figure 1: Framework of REFLECT. The illustration of proposed Pseudo Oracle Relaxation (POR), Summary Referencing (SR), and Credit-Aware Self-Critic (CASC) learning are indicated with bold fonts.

problem. However, most summarization corpora do not provide such annotations. As an alternative, it is common to create pseudo oracles through a greedy process with the human-written summaries (Liu and Lapata, 2019b; Chen and Bansal, 2018). However, such methods only provide suboptimal solutions since they are limited by the design of the greedy algorithm. The underlying patterns of true oracles could be too complicated to be designed precisely. The performance of the extractor is thus restricted since typical Maximal Likelihood Estimation (MLE) methods fully depend on pseudo oracles. For example, consider a case that there are only three sentences x_a, x_b and x_c, and the ROUGE scores between sentences and summary are ranked as $x_a > x_b \gg x_c$. Assume that only x_a is chosen as the pseudo oracle. If the extractor further selects one additional sentence for improving the results, it is expected that the combination of (x_a, x_b) could be better than (x_a, x_c) generally. However, MLE-based methods do not consider such discrepancy according to the pseudo oracle.

Therefore, we propose a loss weighting mechanism to further consider the lexical similarity for the non-oracle sentences during the learning process. Consider an input $x = \{x_1, x_2, ..., x_N\}$ and the corresponding pseudo oracles e, the input sentences can be separated into two sets of pseudo oracles and non-pseudo oracles, $S = \{x_i | i \in e\}$ and $S^c = \{x_i | i \in e^c\}$, respectively. We maintain the loss weights for sentences in S as one, while modifying the loss weights for the sentences in S^c as follows:

$$w_i = (1 - \text{ROUGE-1}(x_i, y))^{\gamma}, \qquad (3)$$

where γ is a hyper-parameter controlling the weighting scales. To stabilize the training, we further shift loss weights of S^c such that the maximum value is one. This weighting mechanism emphasizes the predictions of both pseudo oracles and the low-ROUGE sentences, which have more impact on the performance. It relaxes the constraint from the binarized oracles to make the model aware of the differences between candidate sentences. The objective for the hierarchical extractor can then be written as:

$$L = -\sum_{x_i \in x} w_i \log\left(\frac{exp(z_i^{\mathbf{1}_S(i)})}{exp(z_i^0) + exp(z_i^1)}\right), \qquad (4)$$

where z_i^0 and z_i^1 are the binary logits for the i-th sentence, and $\mathbf{1}_S(i)$ is the indicator function of oracle sentences S.

3.3 Summary Referencing

The pseudo oracle relaxation described in Section 3.2 makes the extractor focus on the sentences that are more important in terms of the lexical similarity. In other words, it considers the discrepancy between non-oracle sentences instead of treating them equally. However, the ambiguity could still exist between the oracle and non-oracle sentences. For example, consider a case where there are two sentences x_a and x_b, and only x_a is chosen as the oracle during the greedy process. The ROUGE scores between the sentences and the summaries are roughly the same for the two sentences. Learning with such oracles may confuse the model since the positive and negative sentences are similar but with a large loss difference. Therefore, we propose to provide summary references for the extractor to further reason the selection. Since the summary is only available in the training stage, we leverage a fine-tuned abstractor to provide such summary references. With such a mechanism, the operations of the hierarchical extractor are further revised as:

$$\begin{aligned} r &= \text{ABS}(\oplus\{w_{x_i} \mid i \in \hat{e}\}), \\ \hat{e} &= \text{H-EXT}(h, r) \\ &= \text{SC}(\text{S-ENC}(\bar{\oplus}(\{\text{T-ENC}(r)\}+ \\ &\qquad \{\text{T-ENC}(h_k)\}_{k=1}^{K}))). \end{aligned} \tag{5}$$

Compared to directly using human-written summaries as references when training, which may cause the extractor highly rely on the reference signal, the generation results from the abstractor could serve as good approximations and provide the generalization from training to testing.

3.4 Credit-Aware Self-Critic Learning

With the objective of maximal likelihood estimation, the extractor is learned to select sentences that are jointly have high lexical similarity to the human-written summary. However, in extract-then-abstract frameworks, the required objective of extractor is to provide salient contents that can maximize the generation quality after rewritten by the abstractor. In other words, the objective for the extractor is inconsistent between training and testing. Therefore, we further propose a reinforcement learning method that can directly optimize with the test-time objective to bridge the gaps.

Specifically, we formulate the extraction of sentences as a single-round Combinatorial Multi-Armed Bandit (CMAB) problem (Chen et al., 2016). A general CMAB problem can be modeled as a tuple $(E, \mathcal{F}, P, R)$, where $E = \{1, , 2..., N\}$ is a set of N arms, $\mathcal{F} \subseteq 2^E$ is a set of subsets of E, P is a probability distribution over $[0, 1]^N$, and R is a reward function defined on $[0, 1]^N \times \mathcal{F}$. At the t-th round, the agent pulls a subset of arms $S^t \in \mathcal{F}$, and produce stochastic outcomes $M^t = (M_1^t, M_2^t, ..., M_N^t) \sim P$, where M_i^t is the outcome of i-th arm. With a realization of outcomes $m = (m_1, m_2, ..., m_N)$, the agents then receive a reward of $R(m, S)$. The goal of the agent is to maximize the expected cumulative reward in T rounds, which is $\mathbb{E}_{\{M^t\}_{t=1}^{T}}[\sum_{t=1}^{T} R(M^t, S^t)]$.

For the sentence extraction problem, we consider each sentence as an arm, and pull multiple arms (i.e., select multiple sentences) only for a single round. We solve this problem with the self-critic learning framework (Rennie et al., 2017). Specifically, we consider the sentence-level encoder with the sentence selector that as the agent (jointly parameterized by θ). The agent takes the sentence representations $x = \{x_1, x_2, ..., x_N\}$ from the token-level encoder, and selects a set of sentences S according to a policy $\pi_\theta(\cdot)$ as:

$$\begin{aligned} m_i &\sim \text{Bern}(\frac{exp(z_i^1)}{exp(z_i^0) + exp(z_i^1)}), \\ S &= \pi_\theta(x) = \{i \mid m_i = 1\}, \end{aligned} \tag{6}$$

where z_i^0 and z_i^1 are the binary logits for the i-th sentence. To reduce the variance during learning, we introduce a baseline term through another policy $\tilde{\pi}_\theta$ as:

$$\begin{aligned} \tilde{m}_i &= \frac{exp(z_i^1)}{exp(z_i^0) + exp(z_i^1)}, \\ \tilde{S} &= \tilde{\pi}_\theta(x) = \{i \mid \tilde{m}_i > 0.5\}, \end{aligned} \tag{7}$$

which is essentially a greedy policy as the taken actions are not explored. The two policies are derived from the agents with the same parameters, and the learning process is thus self-critical. We define the reward as the performance of generation from an abstractor using the selected sentences S as the input, *i.e.*,

$$R(S) = \text{ROUEG-L}(\text{ABS}(S), y), \tag{8}$$

where S is produced from the outcomes m. The advantage a can be written as:

$$a = R(S) - R(\tilde{S}). \tag{9}$$

We then optimize the agent through gradient descent with the objective function as:

$$L = -\sum_{i \in E} a \log(\frac{exp(z_i^{\mathbf{1}_S(i)})}{exp(z_i^0) + exp(z_i^1)}), \tag{10}$$

where $\mathbf{1}_S(i)$ is the indicator function of selected sentence set S. However, in such a learning objective, the advantages are applied uniformly to update all actions, which could make learning difficult since the sentences number is typically large in our setting. Thus, we propose to specifically credit the advantages to the selections that are distinct between policies π_θ and $\tilde{\pi}_\theta$, and the objective function L^{credit} can be written as:

$$\begin{aligned} &L^{credit} = \\ &-\sum_{i \in E} \mathbf{1}_{S \cap \tilde{S}}(i) a \log(\frac{exp(z_i^{\mathbf{1}_S(i)})}{exp(z_i^0) + exp(z_i^1)}). \end{aligned} \tag{11}$$

Different with previous work (Chen and Bansal, 2018) that formulates the sentence selections as a sequence of decisions and uses LSTM-based agent for learning, our formulation enables the usage of Transformer-based models for a better efficiency.

Model	ROUGE-1	ROUGE-2	ROUGE-L	Average	Average Improvement
Hierarchical-Transformer (Liu and Lapata, 2019a)	42.36	15.27	22.08	26.57	+17.91%
PG-BRNN (Gehrmann et al., 2018)	43.77	15.38	20.84	26.66	+17.52%
Hi-MAP (Fabbri et al., 2019)	44.17	16.05	21.38	27.20	+15.18%
CTF-DPP (Perez-Beltrachini and Lapata, 2021)	45.84	15.94	21.02	27.60	+13.51%
GraphSum (Li et al., 2020)	45.02	16.69	22.50	28.07	+11.61%
GraphSum + RoBERTa (Li et al., 2020)	45.87	17.56	23.39	28.94	+8.26%
Highlight-Transformer (Liu et al., 2021a)	44.62	15.57	-	-	-
MatchSum (Zhong et al., 2020)	46.20	16.51	-	-	-
PEGASUS (Zhang et al., 2020a)	47.52	18.72	**24.91**	30.38	+3.13%
BART-Long (Pasunuru et al., 2021)	48.54	18.56	23.78	30.29	+3.43%
BART-Long-Graph (Pasunuru et al., 2021)	49.24	18.99	23.97	30.73	+1.95%
REFLECT (MLE)	48.16±0.01	18.87±0.01	23.78±0.17	30.27	+3.50%
REFLECT (CASC)	**49.27**±0.06	**19.96**±0.03	24.76±0.09	**31.33**	-

Table 1: Performance of REFLECT with various baselines on Multi-News corpus. The results of Hierarchical Transformer, HiMAP, and PG-BRNN are copied from Li et al. (2020). The rest baseline results are from the original papers. Best ROUGE scores are bolded. Performance of REFLECT is reported with five runs.

4 Experimental Results

4.1 Settings

We compare REFLECT with several strong baselines (Liu and Lapata, 2019a; Gehrmann et al., 2018; Fabbri et al., 2019; Perez-Beltrachini and Lapata, 2021; Li et al., 2020; Liu et al., 2021a; Zhong et al., 2020; Zhang et al., 2020a; Pasunuru et al., 2021) on **Multi-News** (Fabbri et al., 2019), **Multi-XScience** (Lu et al., 2020) and **WikiCatSum** (Perez-Beltrachini et al., 2019) corpora, derived from news, academic domains and Wikipedia, respectively. Due to space limit, the results of Multi-XScience and WikiCatSum are provided in the Appendix A. For evaluation, we use ROUGE F1 metrics (Lin, 2004), BERTScore (Zhang et al., 2020b), and factual consistency evaluated with FactCC (Kryscinski et al., 2020) to investigate performance from different perspectives. In our architecture, the hierarchical extractor is initialized by RoBERTa-base (Liu et al., 2020) containing 12 attention layers. We take the first l layers and the rest layers (12-l) as the token- and sentence-level encoder, respectively. The input length limit M is set to 512. The abstractor is a sequence-to-sequence model initialized by BART (Lewis et al., 2020). To make the CASC computationally efficient, we use the BART-base as the abstractor that provides rewards for the extractor during training, while exploiting the BART-large in the testing. We provide more implementation details in Appendix C.

4.2 Main Results

Table 1 summarizes the performance of REFLECT with various baselines on Multi-News corpus with the rows sorted by the average of ROUGE 1, 2, and L scores (Lin, 2004). [2] The results demonstrate that REFLECT outperforms all baselines. PG-BRNN and Hi-MAP both use an LSTM-based point generator for sentence selection and apply a decoder for the generation. However, the performance is limited since LSTM could still suffer long-term dependency problem (Trinh et al., 2018). Hierarchical-Transformer (row 1) further uses an LSTM-based ranker to select paragraphs through predicting the ROUGE scores with the summaries for each paragraph, and uses a Transformer-based hierarchical encoder to capture the local and global information. However, the estimation of the ROUGE scores could be difficult since there are multiple valid summaries. In contrast, REFLECT further applies pre-trained language models to extract the hierarchical features, and the proposed SR method explicitly provides the extractor with the evidence for selecting more salient contents to be rewritten from the abstractor. Moreover, GraphSum (row 5 & 6) leverages graph structures to explore the relations of paragraphs in the encoder, and Highlight-Transformer (row 7) specifically assigns higher attention weights for key phrases. Both the methods implicitly provide additional selective information for the decoder. REFLECT realizes such a content selection pro-

---

[2] We do not compare ROUGE-L results with Highlight-Transformer and MatchSum because 1) Highlight-Transformer does not report ROUGE-L results and 2) MatchSum reports summary-level ROUGE-L (ROUGE-LSum) results which are different from sentence-level ROUGE-L used here (Lin, 2004). Nevertheless, ROUGE-LSum results of REFLECT in Table 3 still show the superiority over MatchSum (45.05 v.s. 41.89).

cess in the data-level through the two-stage design. The proposed POR and SR methods alleviate the negative effects from the pseudo oracles, and thus provide complete information for the abstractor to rewrite. The results of PEGASUS (row 9) show the benefits of pre-trained sequence-to-sequence language models, which are also leveraged in REFLECT. The BART-Long-Graph (row 10 & 11) further combines the previous advantages on graph structure and pre-trained language models to achieve strong performance. REFLECT outperforms it in terms of the ROUGE-2 and ROUGE-L scores especially, probably due to the local attention mechanism used in BART-Long-Graph. Although such a design reduces the complexity to accommodate longer sequences, the trade-off for the attention capacity still restricts the model from generating more coherent summaries. Due to the space limit, please refer to Appendix A for results on Multi-XScience and WikiCatSum.

In addition to the evaluation of lexical overlaps, Table 2 shows the performance of semantic and factual consistency, which are important for summarization applications that will influence the public. The results demonstrate that REFLECT can improve factual consistency through the hierarchical architecture, *i.e.*, the architecture enables selection of useful information from multiple documents, while still maintaining the semantics in generations.

Model	BERTScore	Factual Consistency
BART-base	0.870	79.7
CTF-DPP	0.852	81.9
REFLECT	**0.871**	**82.2**

Table 2: BERTScore and factual consistency evaluated with FactCC on Multi-News corpus.

4.3 Ablations and Analyses

In this subsection, we perform ablations and analyses for REFLECT, and more results can be found in Appendix B.

Effect of Pseudo Oracle Relaxation (POR). We start the discussions with the results using MLE objectives. As shown in Table 3, when applying POR to the base method (row 1 & 2), the extraction recall increases while the precision decreases. Pseudo oracles generally contain sentences with high ROUGE scores to the summaries, and POR encourages the selection for such sentences by assigning smaller loss weights to increase the recall. From the abstraction performance, it shows that such selection preference could provide more concise information (even though not in pseudo oracles) as the input for improvements. Under the combination of SR (row 3 & 4), the precision is further improved and achieves a higher overall F1 score due to more information for selection. However, the abstraction results show that the performance is actually inferior to the one only using SR, which meets our suggestion that the training objective of the extractor is inconsistent in the test-time. The proposed CASC learning further overcomes such problems and improves the performance by integrating POR and SR (row 6 & 10).

Effect of Summary Referencing (SR). We first investigate the MLE results. With SR, the extractor is learned to select sentences given the approximations of summaries generated from the abstractor. The extraction recall is thus enhanced with such references. However, the trade-off between recall and precision still exists due to the discrepancy between ground-truth summaries and generation results (row 1 & 3). Although ground-truth can be used as references to increase extraction performance during training, it fails to generalize in testing due to the distributional difference between them. The abstraction performance also shows SR makes significant improvements (row 3) and also benefits from the combination with CASC (row 6 & 8).

Effect of Credit-Aware Self-Critic (CASC) Learning. Consider the case that applying CASC with POR and SR respectively (row 5 & row 6, row 7 & row 8), the results demonstrate that CASC substantially outperforms the Self-Critic (SC) learning methods, even when combining the usage of POR and SR (row 9 & row 10). We could further investigate the difference between MLE and RL methods through the visualization in Figure 2. It shows that, although having lower extraction performance, the RL methods can improve over the MLE methods in final abstraction performance due to the consistent objective between training and testing. CASC further improves over SC through explicitly assigning advantage to the actions that have the credits for exploration. Such design is critical for the long input sequences in multi-document summarization and can potentially be applied to other applications.

MLE		RL		Extraction Performance			Abstraction Performance				
SR	POR	SR	CA	Precision	Recall	F1	R-1	R-2	R-L	R-LSum	Average
		-	-	0.6489	0.4218	0.5113	47.60	18.48	23.89	43.22	33.29

Table 3: Ablation of REFLECT with Pseudo Oracle Relaxation (POR), Summary Referencing (SR), and Credit-Aware Self-Critic (CASC) learning. ROUGE score is abbreviated as *R*.

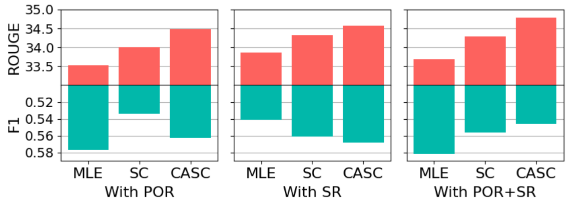

Figure 2: Comparisons of MLE and RL results. For clarity, the displayed range for average ROUGE scores and extraction F1 scores are limited in [33,35] and [0.5,0.59], respectively.

Reference Source	R-1	R-2	R-L	Average
PEGASUS	49.28	19.99	24.84	34.78
BART-large-A	49.29	19.99	24.83	34.79
BART-large-O	49.29	19.98	24.81	34.78
Ground-Truth	49.38	20.05	24.88	34.85

Table 4: Performance of different summary referencing strategies in REFLECT. We also present the results of BART models trained by truncated articles (A) and pseudo oracles (O). ROUGE score is abbreviated as *R*.

4.4 Effects of Summary Reference

REFLECT uses the BART-large fine-tuned with truncated articles (BART-large-A) to provide summary references for both training and testing. Here, we study the effect of applying different summary referencing strategies in test-time. To investigate such effect across models, we leverage PEGASUS (Zhang et al., 2020a) and fine-tune it with Multi-News corpus to produce summary references. Furthermore, we also conduct experiments that use the BART-large fine-tuned with pseudo oracle sentences (BART-large-O) and the ground-truth summaries. *Note that these two methods are prohibited in practical usage since they require annotations on testing data.* The results in Table 4 manifest that using references from another model that is different from the training one does not significantly affect the performance. For the case using oracle inputs, the performance is similar to the ones directly using articles. This suggests that our method is stable for the practical scenario. The result of the ground-truth also shows that the reference quality could still affect the performance, which is left as a future research direction.

5 Conclusion

In this work, we present an effective extract-then-abstract framework, named REFLECT, for MDS. We utilize large pre-trained language models to construct a hierarchical extractor for solving the long sequence problem. Moreover, we investigate current learning paradigms for such frameworks and find that entirely relying on the pseudo oracles produced via a greedy process could hinder the performance. Therefore, we propose three corresponding techniques (POR, SR, and CASC) to overcome the issues. The experimental results not only show that REFLECT outperforms the state-of-the-art models on Multi-News, Multi-XScience, and WikiCatSum corpora, but also demonstrate that bridging the gap between training and testing is significant. Also, we present extensive studies to motivate more investigations. Finally, we consider further exploring the interactions between the extractor and abstractor, including iteratively providing a better reference or reusing the extraction predictions as the training signals for the abstractor, and study how to build a more efficient reference for providing the extraction evidence.

A Results on Other Corpora

A.1 REFLECT on Multi-XScience Corpus

In this subsection, we additionally experiment REFLECT with Multi-XScience (Lu et al., 2020) corpus, which is a multi-document summarization corpus for scientific articles. The source of this corpus is a tuple of a paper abstract and abstracts of the citation papers, while the generation target is the corresponding related-work paragraph. The performances of baselines are from Lu et al. (2020) [3]. Table 5 shows that REFLECT achieves a better performance comparing to all baselines, and makes a substantial improvement especially in ROUGE-2 score. We also report the results of BART-large which serves as our abstractor to summarize from the extracted sentences. The improvement shows the benefit of the extraction process after the Credict-Aware Self-Critic Learning.

Model	R-1	R-2	R-L	R-LSum
LEAD	27.46	4.57	-	-
LEXRANK	30.19	5.53	-	-
TEXTRANK	31.51	5.83	-	-
Hi-MAP	31.66	5.91	-	-
PG	34.11	6.76	-	-
BART-large	33.29	8.07	17.31	29.04
REFLECT (MLE)	33.87	8.13	17.20	29.69
REFLECT (CASC)	**34.18**	**8.20**	**17.42**	**29.73**

Table 5: Performance of REFLECT and baselines on Multi-XScience corpus. We also present the results of BART models trained by truncated articles. The results of baselines are from Lu et al. (2020), where PG represents Pointer-Generator and the Hi-MAP represents the model proposed by Fabbri et al. (2019). ROUGE score is abbreviated as *R*.

A.2 REFLECT on WikiCatSum Corpus

To further analyze the capability of our proposed model, we also apply REFLECT on a domain-specific corpus, WikiCatSum (Perez-Beltrachini et al., 2019) as shown in Table 6. WikiCatSum is a multi-document summarization dataset derived from WikiSum (Liu et al., 2018) and represents three distinct domains (Animal, Company, and Film). We compare our model with several baselines. TF-S2S is a Transformer sequence-to-sequence model of Liu et al. (2018) and CV-S2D+T is a variant of CV-S2S (Gehring et al., 2017) with a single sequence encoder and a structure decoder. Both CV-S2D+T (Perez-Beltrachini et al., 2019) and TWAG (Zhu et al., 2021) introduce the topic detection model to guide the generation. The decoder of CV-S2D+T is trained to predict the topics as an auxiliary task, while TWAG uses the topic information to group the input paragraphs and encodes them separately. Liu et al. (2021b) apply knowledge distillation to alleviate the problem of single reference in maximum likelihood training, while our model leverages reinforcement learning to the train-test mismatch issue. The results of BART-large models are fine-tuned on WikiCatSum [4]. REFLECT outperforms all baselines in all three domains, especially in the ROUGE-1 score, showing that our generated summaries carry more information. The results between REFLECT (MLE) and REFLECT (CASC) also manifest the effectiveness of Credit-Aware Self-Critic learning for bridging the gap between training and testing.

---

[3] We can not tell the version of score metric ROUGE-L used in Multi-XScience, and the evaluation code is also unavailable. Therefore, we do not report the ROUGE-L score from Lu et al. (2020)

[4] The models of Liu et al. (2021b) and REFLECT are with pretraining. We exploit the pretrained model from https://huggingface.co/facebook/bart-large-cnn.

Animal				
Model	R-1	R-2	R-L	R-LSum
TF-S2S	44.0	28.8	40.0	-
CV-S2D+T	42.7	27.9	37.9	-
TWAG	43.1	24.4	40.9	-
Liu et al. (2021b)	45.9	**32.2**	41.4	-
BART-large	46.3	29.2	39.6	44.1
REFLECT (MLE)	46.5	27.1	38.2	43.6
REFLECT (CASC)	**48.6**	30.2	**41.5**	**46.0**
Company				
Model	R-1	R-2	R-L	R-LSum
TF-S2S	26.0	9.5	20.4	-

BART-large	44.3	25.5	35.9	41.7
REFLECT (MLE)	46.7	25.6	36.5	43.2
REFLECT (CASC)	**47.6**	**26.8**	**37.9**	**44.1**

Table 6: Performance of REFLECT with various baselines on WikiCatSum corpus. The results of Transformer sequence-to-sequence (TF-S2S) and CV-S2D+T are referenced from Perez-Beltrachini et al. (2019), and TWAG is from Zhu et al. (2021). REFLECT outperforms all baseline models in a large margin for all domains, especially for Company and Film in the ROUGE-1 score.

B Additional Ablations & Analyses

B.1 Effects of Hierarchical Architecture

In this subsection, we study the effect of hierarchical architecture in the extractor. As described in Section 4.1, the token- and sentence-level encoder jointly contain 12 layers in our settings. Thus, we experiment with different numbers of layers distributed for the token-level encoder. Also, we consider a case for no (0) layer, where we directly aggregate the word embeddings from the token-level encoder as sentence features. Table 7 demonstrates that hierarchical architecture improves the resulted abstraction performance through better sentence representations. The performance is enhanced with the increasing number of layers, while more than 3 layers only makes marginal improvements. Thus, we use 3 token-level layers in this paper.

Layer Number	R-1	R-2	R-L	R-LSum	Average
0	47.94	18.68	23.46	43.87	33.49
1	48.01	18.63	23.53	43.95	33.53
2	48.11	**18.87**	**23.62**	44.03	33.66
3	**48.16**	**18.87**	23.61	**44.06**	**33.68**

Table 7: Performance of different extractor configurations with MLE learning. Note that all configurations share the same amount of learnable parameters. ROUGE score is abbreviated as *R*.

B.2 The Choice of Summary Reference at Training Stage

In this subsection, we study the effect of the summery reference at training stage. As mention in the subsection 3.3, directly using human-written summaries as reference may cause the severe train-test mismatch. To verify the idea, we take the human-written summaries as the summery referencing for the extractor during training, and perform the standard test process, that is utilizing generated summaries as the references. The results shown in Table 8 verify our assumption that training with such explicit signals reduces the ability of the model to generalize. Therefore, in our experiments, we take the generation results of BART-large as the summary referencing of the extractor.

MLE	R-1	R-2	R-L	R-LSum	Average
Ground-truth	47.54	18.60	23.40	43.63	33.29
Generated	48.16	18.87	23.61	44.06	33.68

Table 8: Performance of the MLE training results when taking the ground-truth summary as the summary reference (SR) during training. ROUGE score is abbreviated as *R*.

B.3 Effect of Input Settings for Abstractor Fine-tuning

In REFLECT, we decouple the learning for the extractor and the abstractor. Therefore, we study the effect of the input settings for the fine-tuning of the abstractor. Table 9 shows the performance of BART under different model configurations with either using truncated articles or pseudo oracle sentences as inputs. We find that using pseudo oracles for BART-large fine-tuning can effectively improve the performance even when the testing input is truncated articles. In addition, the results of using pseudo oracles for both training and testing demonstrate the upper bound performance of the extractor under MLE training, which suggests a promising development of our framework as the extractor can make more precise predictions.

BART	Train/Test	R-1	R-2	R-L	R-LSum
base	A/A	45.71	17.12	23.82	41.54
base	O/A	45.62	16.58	22.99	41.59
base	A/O	49.53	22.02	26.78	45.01
base	O/O	51.93	23.89	27.78	47.42
large	A/A	46.80	18.01	23.80	42.57
large	O/A	47.79	18.37	23.78	43.57
large	A/O	51.01	22.77	27.00	46.53
large	O/O	52.98	24.28	28.02	48.34

Table 9: Performance of BART with different configurations and train/test input settings. The input settings include truncated articles (A) and concatenated sentences with pseudo oracles (O). ROUGE score is abbreviated as *R*.

B.4 Generation Examples

We demonstrate two examples of generation in Table 10 and Table 11. The results demonstrate that generations from REFLECT-(CASC) could provide more faithful information from multiple documents, which mainly resulted from the better sentence extraction strategy learned through CASC.

C Implementation Details

All of our experiments are conducted on a single NVIDIA Tesla V100 32GB GPU with PyTorch. The hierarchical extractor is initialized by RoBERTa-base[5], and the first three layers are exploited as token-level encoder and the rest layers are sentence-level encoder. The BART-base[6] is used as the abstractor to provide the rewards during extractor training, while BART-large[7] is used for generating the final results. We generate the initial summary reference (SR) by the BART-large model. The hyper-parameter γ in POR is set to 10. We use Adam with constant learning 3e-5 for optimization, and select the model with highest ROUGE-1 F1 score on validation set. For the pseudo extraction oracle, we greedily select at least 30 sentences from article as the pseudo oracle for the extractor during MLE learning. The selection criteria is based on the average of ROUGE-1 recall and ROUGE-2 recall.

For evaluations, we report ROUGE, BERTScore and factual consistency derived from FactCC framework. For ROUGE, we use *rouge_score* package [8] to report ROUGE-1, 2, L, and LSum scores. For BERTScore, we use official implementation [9] and report the F1 scores. For factual consistency, we use official implementation of FactCC [10] and follow previous work (Perez-Beltrachini and Lapata, 2021) to calculate the factual consistency for multi-document summarization.

Article: Wesley Snipes Begins Serving 3-Year Prison Stint. This Wesley Snipes began serving a three-year sentence at a federal prison in Pennsylvania on Thursday for failure to file income tax returns. Snipes, 48, arrived shortly before noon at the Federal Correctional Institution McKean in the tiny northwestern Pennsylvania town of Lewis Run, federal prisons spokesman Ed Ross said. He had been ordered to surrender by noon. The minimum security prison camp is worlds away from the harsh prison fortresses depicted in the Snipes' films 'Undisputed' and 'Brooklyn's Finest.' The minimum-security camp doesn't have fences around its perimeter. The 300 nonviolent inmates live in barracks that feature two-man rooms, daily showers and double-feature movie showings Friday through Sunday. ...
Gold Summary: – Wesley Snipes enters prison in Pennsylvania today to serve a three-year sentence for tax evasion—and though the minimum-security McKean prison camp isn't exactly a five-star resort, it's not as bad as it could be. The AP gives details on what his life will be like: No fences: But he will submit to five daily head counts, three of which are overnight. Living quarters: He'll have a two-man room in the barracks, where the other 300 nonviolent inmates live. Daily schedule: Wake-up time is 6:35am, and jobs are performed for seven hours per day. Conjugal visits: He'll have to limit himself to just a kiss in the visitors room. Money: He can earn pennies an hour by doing laundry or other chores, and is allowed to spend \$290 a month at the commissary. Entertainment: Double-feature movies are shown Friday through Sunday, but no R-, NC-17-, or X-rated films are screened. Exercise: Sand volleyball, indoor basketball, exercise machines, badminton, bocci, and bridge will be available to him. Medical facilities: The copay at the infirmary is only \$2. Church: Almost any group you can think of, including Wiccans, hold weekly meetings. Click for more, including why Snipes failed to pay taxes—or watch his Tuesday night appearance on Larry King Live.
REFLECT (MLE): – Wesley Snipes has begun his **three-year prison sentence for** failure to file income **tax** returns. The Blade: Trinity **star** arrived at the Federal Correctional Institution **McKean** in Lewis Run **in Pennsylvania today**, reports **the AP**. The **minimum security prison camp is** worlds away from the harsh prison fortresses depicted in Snipes' **films** Undisputed and Brooklyn's Finest, notes the AP, but the 48-year-old actor will **have to** adjust to earning just **pennies an hour** handling kitchen, **laundry**, and other campus **chores**. "We recognize that he is high profile, but we treat all our **inmates** the same," says a spokeswoman. Snipes, a dues-paying member of a tax-protest **group** that challenges the government's right to collect **taxes**, has been free on bail since his 2008 conviction, but he made a last-minute request for a new trial this week, arguing that the judge erred by not allowing defense attorneys to interview jurors about misconduct allegations. He also told **Larry King** last night that he wasn't nervous about reporting to prison. "Don't send me up the river, yet," he said.
REFLECT (CASC): – Wesley Snipes has begun serving **a three-year sentence** in a **minimum-security prison in Pennsylvania** for failure to file income **tax** returns. The Blade: Trinity **star** arrived at the Federal Correctional Institution **McKean** yesterday, just before noon, reports **the AP**. He had been ordered to surrender by noon. The minimum security **prison camp is** worlds away from the harsh prison fortresses depicted in the Snipes' **films** Undisputed and Brooklyn's Finest. The **300 nonviolent inmates live** in **barracks** that **feature two-man** rooms, **daily** showers**, and double-feature** movie showings **Friday through Sunday**. The martial-arts enthusiast can get his **exercise** playing **sand volleyball** or **indoor basketball,** or work out on an elliptical machine or stair climber. Alas, no NC-17, R **or X** ratings **allowed**, which knocks out much of Snipes' action-heavy repertoire. The most jarring aspect of the celebrity's stay might be the **five daily head counts, three** during the **overnight hours**. And Snipes, who earned a reported **\$**13 million for theBlade: Trinity sequel, will **have to** adjust to earning just **pennies an hour** handling kitchen, **laundry, or** other campus **chores**. **He can spend** just **\$290 a month at the** prison **commissary.** "We recognize that he is high profile, but we treat all our inmates the same," says a spokeswoman. Snipes made a last-minute request for a new trial on Wednesday, arguing that the judge erred by not allowing defense attorneys to interview jurors about misconduct allegations.

Documents: Vacant lot at 53 New York Avenue NE in Washington, where a government permit has been granted for work connected with Elon Musk's Hyperloop project. (Michael Laris/TWP) It's not much now, just a parking lot with a discarded gin bottle and an old exterminator receipt. But the slice of pavement near the Bureau of Alcohol, Tobacco, Firearms and Explosives in the District could be the gritty precursor to a tunnel network that could propel pods filled with people and speeding platforms topped with Teslas and Toyotas between the nation's capital and New York in 29 minutes. Or it could be just be a parking lot littered with dashed transportation dreams. Electric-car pioneer and space entrepreneur Elon Musk has been touting his vision for a high-speed transportation system since his tweeted announcement last summer that he had received "verbal govt approval" for his tunnel-digging firm, the Boring Company, to build a "NY-Phil-Balt-DC Hyperloop." The Boring Company team has received an early, and vague, building permit from the D.C. government...

Gold Summary: – – Elon Musk's dream of building a hyperloop that can move people between Washington, DC, and New York City in 29 minutes may be a small step closer to becoming a distant reality. A Nov. 29 permit issued by DC's Department of Transportation allows Musk's Boring Company to dig at an abandoned lot beside a McDonald's in northeast Washington that the company says might eventually become a station on a hyperloop connecting NYC, Philadelphia, Baltimore, and Washington. The system would speed up travel times, using electricity and electromagnetic levitation to send people and cars whipping through tunnels in pods. But before you ditch your car, the Washington Post points out the permit is only for "some preparatory and excavation work" at the site, and more permits are needed before any real construction begins. DC Mayor Muriel Bowser has visited a test tunnel Musk is constructing under Los Angeles. But though "we're open to the concept of moving people around the region more efficiently ... we're just beginning, in the mayor's office, our conversation to get an understanding of what the general vision is for Hyperloop," says Bowser's chief of staff, John Falcicchio. Still, the permit "is comparable to an athlete stretching before a race" and shows Musk is serious about moving forward with his plans for high-speed travel since claiming "verbal" government support for an East Coast hyperloop last July, reports TechCrunch. He's also received a conditional permit to build a tunnel beneath Maryland Route 295 in Hawthorne, per the Post, with Maryland officials saying a leg linking Washington and Baltimore will come first. (Read about the hyperloop pod's first test.)

REFLECT (MLE): – Elon Musk's Boring Company has **received a permit** from the **DC government** to begin **work on a tunnel**ing project in the nation's capital**, the Washington Post reports**. The permit, **issued Nov. 29**, is a "very **small**, very vague **step forward**" for Musk's plan **to build a** "NY-Phil-Balt-DC **Hyperloop**" tunnel network that would run from **New York** to **Philadelphia** to **Baltimore** to DC **in 29 minutes**, according to the New York **Times**. But it could also be a "gravel precursor to **a tunnel** network" that could propel **pods** filled with **people and** speeding platforms topped with Teslas and Toyotas between the nation's capital **and New York** in just 29 minutes. Musk's **company** has received backing from the White House **Office** of American Innovation, led by Jared Kushner, as well as **Maryland** Gov. Martin O'Malley and **DC Mayor Muriel Bowser**, who **visited a** tunnel in California earlier this month to learn more **about the** technology **the company says** will make tunneling faster and cheaper. The DC **Department of Transportation** is figuring out what other **permits** the company will need to cut under **city** roads and other public spaces. Asked whether the Bowser administration supports the project, he was somewhat upbeat but noncommittal, adding: **"We're open to the concept of moving people around the region more efficiently**."

REFLECT (CASC): – Elon Musk's plan **to build a high-speed transportation system** that would run from **New York** to **Philadelphia** to **Baltimore** to **DC in 29 minutes** has gotten a "very **small**, very vague **step forward," the Washington Post reports**. **Musk's Boring Company** has **received a permit** for preparation and preliminary **excavation** of a **site** in **Washington, DC,** next to **a McDonald's** and near the Bureau of Alcohol, Tobacco, Firearms**, and** Explosives. It's not much now, just a parking **lot** with a discarded gin bottle and an old exterminator receipt, but it could be "the gritty precursor to **a tunnel** network that could propel **pods** filled with **people and** speeding platforms topped with Teslas and Toyotas between the nation's capital **and New York** in 29 minutes," **per the Post**. Or it could "be just be a Parking **Lot** littered with dashed transportation dreams." Musk has been touting his **vision** for **a Hyperloop** system since last summer, when he tweeted that he had received **"verbal government** approval" to build the "NY-Phil-Balt-DC Hyperloop." **Maryland officials** told the Post **that the** tunnel would run under **Maryland Route 295, with** the DC-Baltimore **leg** being built **first. Abstract

Many natural language processing tasks involve text spans and thus high-quality span representations are needed to enhance neural approaches to these tasks. Most existing methods of span representation are based on simple derivations (such as max-pooling) from word representations and do not utilize compositional structures of natural language. In this paper, we aim to improve representations of constituent spans using a novel hypertree neural networks (HTNN) that is structured with constituency parse trees. Each node in the HTNN represents a constituent of the input sentence and each hyperedge represents a composition of smaller child constituents into a larger parent constituent. In each update iteration of the HTNN, the representation of each constituent is computed based on all the hyperedges connected to it, thus incorporating both bottom-up and top-down compositional information. We conduct comprehensive experiments to evaluate HTNNs against other span representation models and the results show the effectiveness of HTNN.

1 Introduction

Distributed span representations are useful in various natural language processing tasks such as question answering (Seo et al., 2019), coreference resolution (Lee et al., 2017), sentiment classification (Yin et al., 2020) and semantic role labeling (He et al., 2018). Since spans can have arbitrary length, to get fix-dimensional span representations, existing methods are mostly based on simple derivations from word or sub-word representations. These methods either apply some form of pooling over all the words within the target span or utilize only the boundary words of the target span to compute the span representation. There have also been efforts to improve word representation learning using information from text spans, which may at the same time improve span representations built on top of word representations (Joshi et al., 2020). Further, some previous methods introduce short text spans (phrases or n-grams) as additional inputs to BERT and thus learn contextual representations for such spans along with word representations (Lai et al., 2021; Zhang et al., 2021).

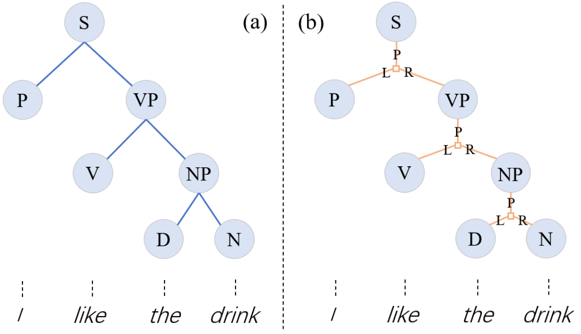

Figure 1: An example binarized constituency parse tree (a) and its corresponding hypertree (b). For each hyperedge, P/L/R denote the parent, left-child, right-child constituent spans respectively.

However, it is known that natural language text has underlying compositional structure, which can often be represented with constituency parse trees (Chomsky, 1957). What is missing from the aforementioned span representation methods is the utilization of compositional structures both within and outside text spans. Specifically, the recursive compositional structure inside a text span suggests more structured bottom-up computation of the span representation from word representations; the compositional structure outside a text span specifies how the span joins its sibling spans to form a larger span, implying top-down computation of the span representation from its parent and siblings[1]. By

---

[*] Kewei Tu is the corresponding author. This work was conducted when Hao Zhou was a visiting student at ShanghaiTech University.

[1] This is only possible for constituent spans and one has to revert to aforementioned methods for distituent spans. However, we note that most NLP tasks concern constituents more

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1682 - 1692
July 10-15, 2022

taking into account such compositional structures, we could obtain better span representations and avoid problems with existing methods such as insufficient modeling of meaning composition (Yu and Ettinger, 2020).

There are several existing methods of incorporating constituency tree structures in neural networks that can be used to produce constituent span representations. These methods fall into two main categories: recursive neural networks (RvNNs) (Goller and Kuchler, 1996) and graph neural networks (GNNs). RvNN-based models recursively compose span representations from their sub-spans following a constituency tree structure (Socher et al., 2011; Tai et al., 2015). They hence only model bottom-up composition and miss information from parent and sibling spans in their span representations. Some extensions of RvNNs (Le and Zuidema, 2014; Drozdov et al., 2019) try to tackle this problem by additionally modeling top-down (de-)composition in a similar recursive fashion. However, they separate the representations computed from the directions and disallow them to directly interact with (and potentially disambiguate) each other. GNN-based models, such as graph convolutional networks (GCN) (Kipf and Welling, 2016) and graph attention networks (Veličković et al., 2017), have been applied based on constituency tree structures to compute word and span representations (Marcheggiani and Titov, 2020; Li et al., 2020). One important flaw of GNN-based methods is that a GNN represents each composition with multiple edges that become mixed up with edges from other compositions during GNN updates, thus losing critical information of the compositional structure. More specifically, a GNN does not adequately formulate and differentiate bottom-up computation from all the child spans versus top-down computation from the parent and sibling spans. In addition, most GNN-based methods do not model relations between sibling spans.

To overcome the above drawbacks, we propose hypertree neural networks (HTNN) to improve constituent span representations. Specifically, we view a constituency parse tree as a hypertree (Figure 1(b)), in which each node represents a constituent and each hyperedge is a tuple of multiple nodes representing a composition of smaller child constituents into a larger parent constituent. We then build an HTNN with the hypertree as its skeleton. During iterative update in the HTNN, we first visit each hyperedge, computing a representation of each node in the hyperedge from the other nodes using a direction-specific composition function; then we visit each node, aggregating its representations computed from all the hyperedges connected to it. In this way, not only can we keep the hierarchical information during encoding process, but also update the representation of constituents simultaneously. HTNNs combine the strengths of RvNNs and GNNs in span representation while avoid their drawbacks. Like GNNs, HTNNs compute a single unified representation for each span that integrates information from all the directions in the constituency tree. On the other hand, HTNNs follow RvNNs and utilize direction-specific composition functions to group and integrate information from different directions.

To evaluate the effectiveness of our method, we firstly conduct detailed experiments on three probing tasks: semantic role classification, named entity labeling, coreference arc prediction. Then we apply our method to the task of semantic role labeling. The results show that our method is superior to word-based, RvNN-based models and GNN-based models.

2 Hypertree Neural Networks

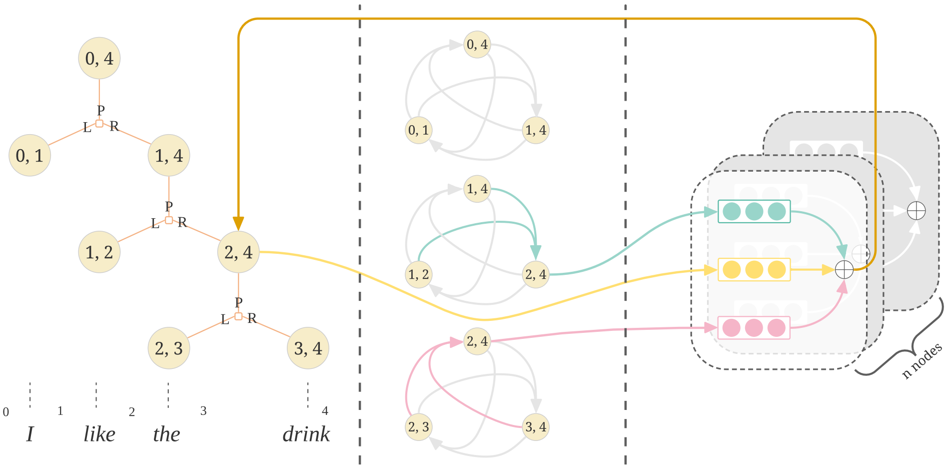
2.1 Overview

A hypergraph is a generalization of a graph in which an edge can join any number of nodes. A hypertree is a hypergraph $\mathcal{H}$ such that there exists a tree $\mathcal{T}$ and every hyperedge of $\mathcal{H}$ is the set of nodes of a connected subtree of $\mathcal{T}$. We consider a directed version of hypertree that defines a hyperedge as a *tuple* of nodes instead of a set.

There is a long tradition of representing constituency parse trees with hypergraphs or hypertrees (Klein and Manning, 2001; Huang and Chiang, 2005). We define the hypertree representation of a constituency parse tree as follows. Each node in the hypertree represents a constituent in the parse tree and is labeled with the nonterminal symbol of the constituent. Each hyperedge represents a composition of smaller child constituents into a larger parent constituent. In this paper, we assume that the constituency parse tree is binarized, so each hyperedge contains exactly three nodes, marked with P (parent), L (left child) and R (right child) respectively. Figure 1 shows the hypertree representation of an example constituency parse tree.

---

than distituents. See statistics in Section 3.4.



(a) (b) (c)

Figure 2: Illustration of an HTNN. We show the update process of node (2,4). (a) The hypertree structure. (b) Composition within hyperedges. (c) Aggregation of multiple representations.

We generalize the methodology of GNNs on hypertrees and propose hypertree neural networks (HTNN, Figure 2). Similar to GNNs, several HTNN layers are stacked to form the model. Each layer is composed of two modules: composition within hyperedges (Section 2.3), which computes a representation of each node in a hyperedge using the other nodes from the same hyperedge; and aggregation of multiple representations (Section 2.4), which aggregates the representations of a node from all the hyperedges connected to it and forms a single unified representation. Each layer is fed with the node representation from the previous layer. The initial node representation in the first layer is computed from word representation using the attention pooling method (Section 2.2).

We treat the node representation from the last layer as the final constituent span representations and feed them into downstream task-specific decoders. For example, we may run an MLP classifier on top of a span representation for named entity recognition, or run a biaffine classifier on top of the representations of two spans for semantic role labeling. Training of HTNN can be done by optimizing any task-specific objective in an end-to-end manner along with the initial span encoder and the task-specific decoder.

2.2 Initialization of Node Representation

We follow Toshniwal et al. (2020) to compute initial span representations from word representations produced by a pretrained language model. We choose to use their attention pooling method because it performs the best in our pilot experiments. Specifically, the input sentence $\mathbf{x} = \{w_1, w_2, ..., w_l\}$ of l words, is firstly tokenized and passed through a pretrained language model to get contextual token embeddings $\{\mathbf{e}_1, \mathbf{e}_2, ..., \mathbf{e}_T\}$. These embeddings are then fed to the attention pooling module to get fix-dimensional span embeddings. For a span $s = [i, j]$ whose corresponding contextualized embeddings are $\{\mathbf{e}_i, ..., \mathbf{e}_{j-1}\}$, the span representation $\mathbf{s}_{ij}$ is calculated as:

$$\begin{aligned}\mathbf{s}_{ij} &= \sum_{k=i}^{j-1} a_k \cdot \mathbf{e}_k \\ a_k &= \textbf{Softmax}(\mathbf{v}_1^T \cdot \mathbf{e}_k)\end{aligned}$$

where $\mathbf{v}_1$ is a learned parameter vector. Note that in a constituency parse tree, each constituent is attached with a nonterminal tag. We use an embedding layer to convert the tag to distributed vector space, and then concatenate it to $\mathbf{s}_{ij}$.

$$\mathbf{s}'_{ij} = \textbf{Concat}([\mathbf{s}_{ij}; \textbf{Embedding}(tag)])$$

We project $\mathbf{s}'_{ij}$ using two different learned matrices to obtain $\mathbf{h}_{ij}$ and $\mathbf{c}_{ij}$, the initial hidden state and memory cell of the node representing span $[i, j]$.

2.3 Composition within Hyperedge

Within each hyperedge, there are three nodes: parent (p), left child (l), right child (r). Traditional RvNN-based methods model the relationships among them mainly in a bottom-up manner: a composition function combines the representations of the two children to obtain the representation of the parent. Le and Zuidema (2014) extend such methods by adding a top-down process, where a node's representation can also be computed from its parent and sibling. We follow this idea that any node can be computed from the others within each hyperedge. The computation is direction-specific, meaning that the composition function is different for each of the three nodes.

Our composition function is inspired by TreeLSTM (Tai et al., 2015). The computing process can be denoted as:

$$[\mathbf{h}'_p; \mathbf{c}'_p] = \textbf{Compose}(\mathbf{h}_p, \mathbf{h}_l, \mathbf{h}_r, \mathbf{c}_l, \mathbf{c}_r) \quad (1)$$

$$[\mathbf{h}'_l; \mathbf{c}'_l] = \textbf{Compose}(\mathbf{h}_l, \mathbf{h}_p, \mathbf{h}_r, \mathbf{c}_p, \mathbf{c}_r) \quad (2)$$

$$[\mathbf{h}'_r; \mathbf{c}'_r] = \textbf{Compose}(\mathbf{h}_r, \mathbf{h}_p, \mathbf{h}_l, \mathbf{c}_p, \mathbf{c}_l) \quad (3)$$

where subscript p, l, r denote the parent, left child and right child respectively, $\mathbf{h}$ and $\mathbf{c}$ denote hidden state and memory cell vectors from the previous layer, and $\mathbf{h}'$ and $\mathbf{c}'$ denote newly composed vectors.

We illustrate the detailed computation process of equation (1), in which we compose the left child node and the right child node to get the representation of the parent node.

$$\begin{aligned}
\mathbf{i} &= \sigma\left(\mathbf{W}^{(i)}\mathbf{h}_p + \mathbf{U}_l^{(i)}\mathbf{h}_l + \mathbf{U}_r^{(i)}\mathbf{h}_r + \mathbf{b}^{(i)}\right) \\
\mathbf{f}^l &= \sigma\left(\mathbf{W}^{(fl)}\mathbf{h}_p + \mathbf{U}_l^{(fl)}\mathbf{h}_l + \mathbf{U}_r^{(fl)}\mathbf{h}_r + \mathbf{b}^{(f)}\right) \\
\mathbf{f}^r &= \sigma\left(\mathbf{W}^{(fr)}\mathbf{h}_p + \mathbf{U}_l^{(fr)}\mathbf{h}_l + \mathbf{U}_r^{(fr)}\mathbf{h}_r + \mathbf{b}^{(f)}\right) \\
\mathbf{o} &= \sigma\left(\mathbf{W}^{(o)}\mathbf{h}_p + \mathbf{U}_l^{(o)}\mathbf{h}_l + \mathbf{U}_r^{(o)}\mathbf{h}_r + \mathbf{b}^{(o)}\right) \\
\mathbf{u} &= \textbf{tanh}\left(\mathbf{W}^{(u)}\mathbf{h}_p + \mathbf{U}_l^{(u)}\mathbf{h}_l + \mathbf{U}_r^{(u)}\mathbf{h}_r + \mathbf{b}^{(u)}\right) \\
\mathbf{c}'_p &= \mathbf{i} \odot \mathbf{u} + \mathbf{f}^l \odot \mathbf{c}_l + \mathbf{f}^r \odot \mathbf{c}_r \\
\mathbf{h}'_p &= \mathbf{o} \odot \textbf{tanh}(\mathbf{c}'_p)
\end{aligned}$$

$\mathbf{i}, \mathbf{f}^l, \mathbf{f}^r, \mathbf{o} \in \mathbb{R}^d$ represent the input gate, two forget gates and output gate respectively. $\mathbf{u} \in \mathbb{R}^d$ is the newly composed input for the memory cell. $\mathbf{U}$ and $\mathbf{W} \in \mathbb{R}^{d\times d}$ denote trainable weight matrices and $\mathbf{b} \in \mathbb{R}^d$ denotes trainable bias vectors. The superscript of a matrix denotes which gate it is used for, and the subscript of a matrix denotes which node representation it is multiplied to. The computation processes of equation (2) and (3) are similarly defined, and they share some of the trainable matrices. (See more details in Appendix A.1)

2.4 Aggregation of Multiple Representations

With the exception of the root and the leaf nodes, a node in the HTNN is connected with two hyperedges, one connecting to its parent and sibling and the other connecting to its two children. The computation process in Section 2.3 is independently carried out for each of the two hyperedges, resulting in two different representations for the node. Besides, we assume that the representation of the nodes from the previous layer also conveys important information. Therefore, we aggregate these three representations using the attention mechanism. Specifically, we use $\mathbf{h}'_0$ to denote the output hidden state from the previous layer, and $\mathbf{h}'_1$, $\mathbf{h}'_2$ to denote the representations computed from the two hyperedges. We use $\mathbf{h}'_0$ as the query vector, to attend to $\mathbf{h}'_0$, $\mathbf{h}'_1$, $\mathbf{h}'_2$ and compute a single aggregated representation $\mathbf{h}'$.

$$\begin{aligned}
a_i &= \textbf{Softmax}(\mathbf{v}_2^T \textbf{tanh}(\mathbf{W}[\mathbf{h}'_0; \mathbf{h}'_i])) \\
\mathbf{h}' &= \sum_i a_i \cdot \mathbf{h}'_i, \quad i \in \{0, 1, 2\}
\end{aligned}$$

where $\mathbf{W} \in \mathbb{R}^{2d\times d}$ and $\mathbf{v}_2 \in \mathbb{R}^d$ are trainable parameters. Note that the memory cell $\mathbf{c}'$ is aggregated in the same process with shared parameters.

3 Experiments

3.1 Implementation Details

We use gold constituency parse trees from the datasets, and binarize them using NLTK Toolkit (Bird et al., 2009). We use pretrained RoBERTa-large[2] (Liu et al., 2019) from HuggingFace (Wolf et al., 2019) as the word encoder. We also tried SpanBERT (Joshi et al., 2020) for word encoding but found it inferior to RoBERTa-large in our pilot experiments. We freeze the parameters in the pretrained language model for all experiments. The dimension of attention pooling is 192 and the dimension of tag embedding is 64. The dimensions of hidden state and memory cell in HTNN are all set to 256. We set the default number of HTNN layers to 3. For each layer, the number of training parameters is 1,707,520. During training, the model is evaluated on the validation set every 1000 training steps. We adopt the Adam optimizer with an initial learning rate of 2e-3, which is halved if the validation score is stuck for 3 evaluations. The batch size is 64 and the dropout probability is 0.2. We train our model for 40 epochs on 4 NVIDIA Tesla P40 GPUs. [3]

3.2 Datasets

CoNLL-2012 We conduct both probing and SRL experiments on the CoNLL-2012 dataset (Pradhan et al., 2012). This dataset is extracted from the OntoNotes v5.0 corpus, which provides gold constituency parses.

CoNLL-2005 We also conduct SRL experiments on the CoNLL-2005 dataset (Carreras and Màrquez, 2005), which takes section 2-21 of the Wall Street Journal (WSJ) corpus as the training set, and section 24 as the development set. The test set consists of section 23 of WSJ for in-domain evaluation together with 3 sections from the Brown corpus for out-of-domain evaluation. CoNLL-2005 is also annotated with gold constituency parses.

3.3 Models for Comparison

Pooling A baseline model that computes span representations using attention pooling (Toshniwal et al., 2020). Our method and all the methods listed below use this representation for initialization.

SentiBERT A model for composing sentiment semantics on top of BERT (Yin et al., 2020). We re-implement their composition module based on the attention mechanism for span representation, instead of using their full model designed for sentiment analysis. We consider SentiBERT as a GNN-based model because it updates representations of all nodes simultaneously, though it only applies the attention mechanism from each parent node to its child nodes.

TreeLSTM An RvNN-based model, proposed by Tai et al. (2015), that generalizes the standard LSTM architecture to tree-structures.

Bi-TreeLSTM Le and Zuidema (2014) proposed IORNN to capture top-down decomposition besides bottom-up composition. We extend their model by using the composition function of TreeLSTMs. We refer to this model as bidirectional TreeLSTM (Bi-TreeLSTM).

GCN/GCN-sib Marcheggiani and Titov (2020) apply GCN structured with constituency trees in an SRL system. We re-implement their constituent GCN module to produce span representations, omitting their decomposition stage that is used for word representations. Furthermore, we extend GCN by adding sibling nodes in constituency trees for better comparison with our method. We refer to this modification as GCN-sib.

GAT/GAT-sib Li et al. (2020) use GAT to generate representations of the nodes in constituency parse trees. Similarly, we extend GAT by connecting sibling nodes, and we refer to this modification as GAT-sib.

3.4 Probing Experiments

We firstly conduct a probing evaluation of span representations, following Toshniwal et al. (2020). We conduct experiments on three of their probing tasks, omitting the other two tasks that probe syntax because constituency syntactic parses are input to most of the methods compared here.

- Named entity labeling (NEL): a task of predicting the entity type of a given span corresponding to an entity.
- Semantic role classification (SRC): a task of predicting the semantic roles of phrases in a sentence. Unlike the standard SRL task, in this probing task, predicates and their argument spans are given , so the goal is to classify the argument spans into specific semantic roles.
- Coreference arc prediction (COREF): a task of predicting whether a pair of spans refer to the same entity.

The task-specific decoder for these probing tasks is a two-layer MLP followed by sigmoid layers to predict the labels. For SRC and COREF, which involve two spans, the MLP takes the concatenation of the representations of the two spans as input. Following Toshniwal et al. (2020), we make predictions for each label independently, which allows using the micro-averaged F1 score as the evaluation metric. Note that in all the methods except Pooling, we only compute representations for constituent spans (those appearing in constituency parse trees). Therefore, given a distituent span, we simply predict no label. Fortunately, almost all the spans of interest in three tasks are constituent spans (98.5% for NEL, 99.7% for SRC, and 99.4% for COREF)[4]. We report F1 scores for all the spans (F1-all) as well as for constituent spans only (F1-const).

The results of three probing tasks are shown in Table 1. As a baseline model, Pooling's architecture is the simplest. Surprisingly, it outperforms all the other methods (except for HTNN on F1-const) on the NEL task. We believe this is because NEL is so simple that contextual word representations

---

[4] See more details of the statistics in Appendix A.2

	NEL		SRC		COREF		AVG	
	F1-const	F1-all	F1-const	F1-all	F1-const	F1-all	F1-const	F1-all
Pooling	96.18	**96.07**	93.08	93.05	92.99	93.01	94.08	94.04
TreeLSTM	95.05	94.22	90.02	89.88	90.07	89.70	91.71	91.27

HTNN	**96.28**	95.45	**93.88**	**93.74**	**96.33**	**95.96**	**95.50**	**95.05**

Table 1: Results of probing experiments.

already provide sufficient information. More complicated models show poor performance possibly because they overfit this simple task. On the other hand, Pooling underperforms many other methods on the SRC and COREF tasks, showing the utility of syntactic information. For COREF in particular, many input spans are pronouns and their meanings may be more difficult to capture without syntactic information.

The RvNN-based models TreeLSTM and Bi-TreeLSTM perform worst on all these three tasks. Previous recursive models are mostly used for sentence-level tasks, and our results show their deficiencies in composing semantics for fine-grained spans rather than sentences.

For GNN-based models, SentiBERT, GAT and GCN all show great improvement over recursive models, and they are also better than Pooling on average on these three tasks. Both GAT and GCN show slight superiority over SentiBERT, probably because they take parent node into computation, rather than only children nodes. Moreover, GCN performs slightly better than GAT.

As for HTNN, we can see that it achieves the best performance overall. The fact that HTNN outperforms GAT and GCN while GAT-sib and GCN-sib underperform GAT and GCN suggests that the superiority of HTNN does not simply come from adding sibling information into computation. It is the ability to group and integrate bottom-up and top-down information that leads to the superior performance of HTNN.

It is worth noting that for the NEL task, HTNN outperforms Pooling on F1-const but underperforms it on F1-all because HTNN predicts no label for distituent spans. A simple remedy is to combine HTNN and Pooling, using HTNN for constituent spans and reverting to Pooling for distituent spans. This yields 96.27 F1-all for NEL, surpassing the strongest Pooling baseline.

3.5 SRL Experiments

We extend SRL in probing tasks to the general setting, in which the predicate is given and we conduct argument identification and role classification. Our SRL model is most closely related to the work of He et al. (2018). The difference is that instead of using a separate argument pruning module, we simply prune all the distituent spans and keep all the constituent spans. Given a predicate and a candidate span, we use their biaffine scorer to predict a label, where the label set is the set of semantic roles plus a null label indicating the span not being an argument.

The results of SRL experiments are shown in Table 2. Once again, we show F1 scores for both all the spans (F1-all) and constituent spans only (F1-const) . We only show the results of GNN-based models since RvNN-based models have shown their disadvantages in the probing experiments. SentiBERT does not perform well in this task, falling behind even the simple baseline Pooling. GCN and GAT show significant gain against baseline, and GCN is still better than GAT on all the three datasets, especially on the out-of-domain BROWN test dataset. We also find that taking sibling nodes into computation causes opposite effects on GAT and GCN. It does great harm to GAT, similar to the case in the probing experiments, but GCN-sib shows small gains over GCN, which is different from the case in the probing experiments.

Our model HTNN achieves the best performance on all the three datasets. Since SRL is more challenging than the probing tasks, we can see that the

gap between HTNN and the other models is more prominet. The improvements over the best baseline model GCN-sib are 1.54 on the CONLL-2012 test dataset, 2.32 on the CONLL-2005 WSJ test dataset, 2.85 on the CONLL-2005 BROWN test dataset.

We also show results of two other SRL models that use gold constituency parse trees in Table 2. HTNN outperforms both of them.

3.6 Ablation Study

Incorporation of Nonterminal Tags We incorporate nonterminal tags into HTNN as described in Section 2.2. Here, we want to explore how nonterminal tags influence HTNN, as well as other models. When we use different embedding dimensions for nonterminal tags, the dimension of the attention pooling module changes accordingly to keep the dimension of span representations unchanged.

The results are shown in Table 3. As we can see, GAT, GCN and HTNN are negatively affected on nearly all the tasks when we remove the incorporation of nonterminal tags. The influence on both GCN and HTNN is quite small on the three probing tasks, compared with the SRL task. There are even improvements for HTNN and GCN-sib when removing nonterminal tags on NEL and COREF. However, on the SRL task, the performance decreases notably for all the models.

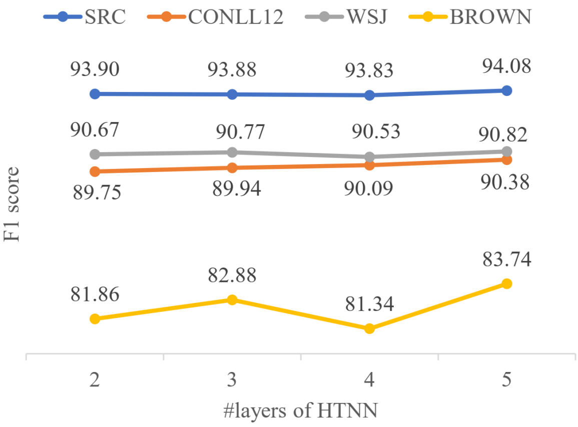

Figure 3: Performance of different tasks as #layers of HTNN changes.

We also conduct experiments of HTNN when we set the dimension of nonterminal tags to 32 and we observe little change in performance.

Number of Layers In each layer of an HTNN, a node exchanges information with its neighbor. Therefore, the more layers the HTNN has, the fur-

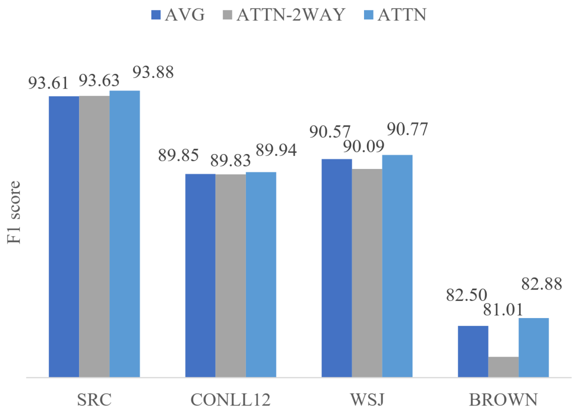

Figure 4: Performance of different aggregation methods.

ther the information of a node would spread. In theory, for a binary constituency tree with n leaf nodes, to make each leaf node receive information from arbitrary leaf nodes, the number of HTNN layers should be set to $n-1$. In practice, however, this may be unnecessary and local information exchange may be sufficient. We conduct experiments to analyze how the number of HTNN layers affect the performance on different tasks.

The results are shown in Figure 3. We can see that the tendency is not all the same on the four tasks. As we increase the number of layers, the increase of the F1 score is getting smaller, and in some cases it even declines. Therefore, we regard the number of layers as a hyperparameter which should be tuned on specific tasks.

Aggregation Method We compare three different methods for the aggregation module (Section 2.4):

- AVG, which simply takes the average of the representations.
- ATTN, which is the default method we introduce in Section 2.4.
- ATTN-2WAY, similar to ATTN, but does not include the representation from previous layer.

The results are shown in Figure 4. It can be seen that ATTN indeed performs the best.

4 Related Work

To get distributed span representations, existing methods are mostly based on simple derivations from word or sub-word representations. Lee et al. (2017) propose the attention-weighted pooling strategy for coreference resolution. Stern et al. (2017) concatenate the sum and the difference of the span endpoints for parsing. Seo et al. (2019) use the "coherent" endpoint-based representation for question answering. All of these methods are originally designed for specific tasks, but because of their simplicity, they can be easily employed for other tasks. Toshniwal et al. (2020) make a comprehensive survey on these methods and conduct experiments to compare their performance. Some other studies also focus on the representations of sentences or longer texts (Wieting et al., 2015; Conneau et al., 2017; Shen et al., 2018).

Instead of representing an arbitrary, some studies consider composing span representations via syntactic parse trees, which are more related to our work. Le and Zuidema (2014) proposed a recursive model IORNN to produce constituent representations for supervised task. Drozdov et al. (2019) proposed an unsupervised method for constituency parse tree induction, during which span representations are produced as a byproduct. More recently, graph neural networks have been applied with constituency parse trees. Marcheggiani and Titov (2020) use GCN to encode constituent spans in an SRL system. However, they decompose the constituent span representations back to start and end tokens instead of directly using them. Li et al. (2020) use GAT to generate constituent span representations for the sentiment analysis task.

5 Conclusion and Future Work

In this paper, we propose hypertree neural networks (HTNN) to generate better representations of constituent spans following constituency parse tree structures. Each node in the HTNN represents a constituent span and each hyperedge represents a local composition structure. Each HTNN layer first computes a representation of each node in a hyperedge using the other nodes from the same hyperedge, and then aggregates the representations of a node from all the connected hyperedges. We empirically compare HTNNs with previous RvNN-based models and GNN-based models. The outstanding performance of HTNNs on both probing and SRL tasks shows the effectiveness of HTNN.

For future work, we plan to tackle two related issues of our approach, namely its reliance on high-quality constituency parses and its inability to represent distituent spans (some of which may nonetheless be important). We will also extend HTNNs to more tasks such as sentiment analysis and document classification, and incorporate HTNNs into popular pretrained language models as a method to inject syntactic information.

Abstract

An increasing awareness of biased patterns in natural language processing resources such as BERT has motivated many metrics to quantify 'bias' and 'fairness' in these resources. However, comparing the results of different metrics and the works that evaluate with such metrics remains difficult, if not outright impossible. We survey the literature on fairness metrics for pre-trained language models and experimentally evaluate compatibility, including both biases in language models and in their downstream tasks. We do this by combining traditional literature survey, correlation analysis and empirical evaluations. We find that many metrics are not compatible with each other and highly depend on (i) templates, (ii) attribute and target seeds and (iii) the choice of embeddings. We also see no tangible evidence of intrinsic bias relating to extrinsic bias. These results indicate that fairness or bias evaluation remains challenging for contextualized language models, among other reasons because these choices remain subjective. To improve future comparisons and fairness evaluations, we recommend to avoid embedding-based metrics and focus on fairness evaluations in downstream tasks.

1 Introduction

With the popularization of word embeddings by works such as Word2vec (Mikolov et al., 2013), GLoVe (Pennington et al., 2014) and, more recently, contextualized variants such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019), Natural Language Processing (NLP) has seen significant growth and advancement. Word embeddings and later language models have been adopted by many applications. Many of these embeddings have been probed by researchers for biases such as gender stereotypes.

Word embeddings are generally trained on real-world data such that they model statistical properties from the training data. Hence, they pick up biases and stereotypes that are typically present in the data (Garrido-Muñoz et al., 2021). Although Kurita et al. (2019) and Webster et al. (2020) opine that this can pose significant challenges in downstream applications, this view has been questioned, especially for non-contextualized word embeddings (Goldfarb-Tarrant et al., 2021).

Early works such as Bolukbasi et al. (2016); Caliskan et al. (2017); Gonen and Goldberg (2019) widely explored fairness in non-contextualized embedding methods. In non-contextualized embeddings such as Word2vec and GLoVe embeddings, models are trained to generate vectors that map directly to dictionary words and hence are independent of the context in which the word is used. In contrast, contextualized word embeddings take polysemy (words could have multiple meanings, e.g. '*a stick*' vs '*let's stick to*') into consideration. Thus different embeddings are generated for a given word depending on the context in which it appears. Because of such differences between the two approaches, popular techniques for detecting and measuring bias in non-contextualized word embeddings, such as WEAT (Caliskan et al., 2017), do not apply naturally to contextualized variants.

Many techniques have been proposed to measure bias in contextualized word embeddings, either as a standalone method (May et al., 2019; Bartl et al., 2020) or as an additional contribution to evaluate fairness interventions (Webster et al., 2020; Lauscher et al., 2021; Kurita et al., 2019). This broad selection of methods makes it difficult for NLP practitioners to select an appropriate and reliable set of metrics to quantify bias and to compare results. This is further exacerbated as these quantifying techniques also involve different choices for attribute and target words, commonly jointly referred to as *seed words*, templates for context, and different methods for measuring similarity.

In this paper, we combine literature survey and experimental comparisons to compare fairness met-

rics for contextualized language models. We are guided by the following research questions:

- Which fairness measures exist for contextualized language models such as BERT? (Section 3)
- What challenges do languages other than English pose? (§ 3.3)
- What are the relationships between fairness measures, the templates these measures use, embedding methods, and intrinsic vs extrinsic measures? (Section 4)
- Which set of measures do we recommended to evaluate language resources? (Section 7)

2 Background

Static word embeddings have typically been used with recurrent neural networks (RNNs), optionally with an attention mechanism (Bahdanau et al., 2014). The *transformer* architecture (Vaswani et al., 2017) introduced a new paradigm relying only on attention, which proved faster and more accurate than RNNs and did not rely on static word embeddings. The transformer consists of two stacks of attention layers, the *encoder* and the *decoder*, with each layer consisting of multiple parallel attention *heads*. BERT (Devlin et al., 2019) is based on the encoder from this transformer and obtained state-of-the-art results for multiple NLP tasks using transfer learning with a *pre-training* step and a second *finetuning* step.

The pre-training task is to reconstruct missing words in a sentence, called masked language modeling (MLM), which helps capture interesting semantics. The training objective for a model with parameters θ is to predict the the original token on the position of a randomly masked token x_m based on the positional-dependent context $\mathbf{x}_{/\mathbf{m}} = x_0, \ldots, x_{m-1}, x_{m+1}, \ldots, x_N$, following $\max_\theta \sum_{i=1}^{N} \mathbf{1}_{x_i = \mathbf{x}_{/\mathbf{m}}} \log\left(P\left(x_i \mid \mathbf{x}_{/\mathbf{m}}; \theta\right)\right)$ with $\mathbf{1}_{x_i = \mathbf{x}_{/\mathbf{m}}}$ as indicator function. After training, the language model can infer the probability that a token occurs on the masked position. As an illustration with the original BERT model, the sentence '`[MASK]` *is a doctor.*' is filled in with the token '*He*' (62%), followed by '*She*' (32%). Because the MLM task relies on co-occurrences, this example illustrates how this task captures stereotypes that are present in pre-training datasets, which is referred to as *intrinsic* bias.

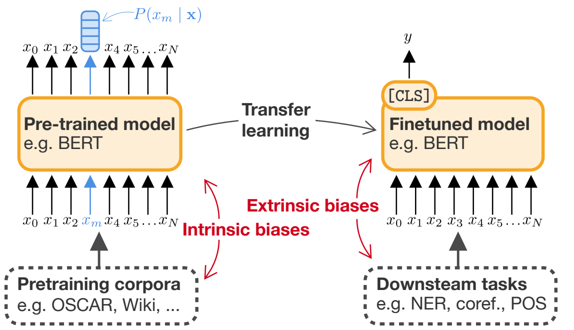

Figure 1: Illustration of the transfer learning paradigm where a language model is first pre-trained on one dataset and afterwards finetuned on another dataset. Both stages can introduce biases.

As a second step, this pre-trained model can be finetuned on a new task, most commonly either sentence classification, which uses the contextualized embeddings of the first token $x_0 = $ `[CLS]`, or token classification, for which the embeddings of each respective token position are used. These embeddings are obtained from output states of the penultimate layer, after which a single linear layer is added and trained. This finetuning is typically done with different datasets that are labeled for the task at hand and here we can observe *extrinsic* bias with allocational harms (Goldfarb-Tarrant et al., 2021; Blodgett et al., 2020), e.g. gender imbalances in co-reference resolution (see § 3.2).

Many models improved on the original BERT architecture and training setup, e.g. RoBERTa (Liu et al., 2019) was trained on significantly more data for a longer period and without a second pre-training objective, next sentence prediction. ALBERT (Lan et al., 2019) used parameter sharing between attention layers to obtain a smaller model without significant performance degradation. Sanh et al. (2019) also created a smaller BERT variation, DistilBERT, by using knowledge distillation. All these models are MLMs, so this gives us the opportunity to compare bias metrics across models.

2.1 Fairness in word embeddings

Fairness in machine learning has a long standing history and a general introduction is out of scope for this paper, so we refer the reader to Barocas et al. (2019).Typical metrics, e.g. demographic parity, are not directly applicable to tasks dealing with natural language. Furthermore, many NLP applications finetune existing language models, which intertwines extrinsic and intrinsic biases as discussed earlier in Section 2.

Early methods for evaluating bias in non-contextualized embeddings like Word2vec, are WEAT (Caliskan et al., 2017) and a *direct bias* metric (Bolukbasi et al., 2016). The latter demonstrated that word embeddings contain a (linear) biased subspace, where for example '*man*' and '*woman*' can be projected on the same *gender axis* as '*computer programmer*' and '*homemaker*' (Bolukbasi et al., 2016). These analogies are calculated using cosine distance between vectors to define *similarity* and also to evaluate the authors' proposed debiasing strategies. In addition, pairs of gendered words were also evaluated using Principal Component Analysis (PCA). This showed that most of the variance stemming from gender could be attributed to a single principal component (Bolukbasi et al., 2016).

In parallel, the Word Embeddings Association Test (WEAT; Caliskan et al., 2017) was developed based on the Implicit Association Tests (IAT; Greenwald et al., 1998) from social sciences. WEAT measures associations between two sets of target words $\mathcal{X}, \mathcal{Y}$, e.g. male and female names, and another two sets of attribute words $\mathcal{A}, \mathcal{B}$, e.g. career and family-related words, following

$$s(\mathcal{X}, \mathcal{Y}, \mathcal{A}, \mathcal{B}) = \sum_{x \in \mathcal{X}} u(x, \mathcal{A}, \mathcal{B}) - \sum_{y \in \mathcal{Y}} u(y, \mathcal{A}, \mathcal{B})$$

with a similarity measure $u(x, \mathcal{A}, \mathcal{B})$[1] that measures the association between one word embedding x and the word vectors of attributes $a \in \mathcal{A}, b \in \mathcal{B}$, defined as $(x, \mathcal{A}, \mathcal{B}) = \text{mean}_{a \in \mathcal{A}} \cos(x, a) - \text{mean}_{b \in \mathcal{B}} \cos(x, b)$. This method relies on a vector representation for each word and by providing a representation from a contextualized model, WEAT can also be adapted for contextualized language models, which we discuss in Section 3 and § 4.3.

3 Measuring fairness in language models

3.1 Intrinsic measures

Discovery of Correlations (DisCo). Webster et al. (2020) presented an intrinsic measure *Discovery of Correlations* (DisCo) that uses templates with two slots such as '_ *likes to* `[MASK]`.', we provide a complete list in § A.1. The first slot (_) is filled with words based on a set of e.g. first names or nouns related to professions. The second masked slot is filled in by the language model and the three top predictions are kept. If these predictions differ between sets, this is considered an indication of bias. Lauscher et al. (2021) slightly modified this method by filtering predictions with $P(x_m \mid T) > 0.1$ instead of the top-three items.

Log Probability Bias Score (LPBS). This bias score presented by Kurita et al. (2019) is a template-based method that is similar to DisCo,but also corrects for the prior probability of the target attribute, as for example the token '*He*' commonly has a higher prior than '*She*'.The reasoning is that correction ensures that any measured difference between attributes can be attributed to the attribute and not to the prior of this token. Bartl et al. (2020) introduced an alternative dataset specifically for this evaluation method, called *bias evaluation corpus with professions* (BEC-Pro), with templates and seeds in both English and German. We will revisit the German results in § 3.3.

Sentence Embedding Association Test (SEAT). A limitation of WEAT (Caliskan et al., 2017) is that the method does not work directly on contextualized word embeddings, which SEAT solves by using context templates (May et al., 2019). These templates are *semantically bleached*, so there are no words in there that affect bias measurements, for instance '_ *is a* `[MASK]`.' We will investigate this concept further in § 4.2.

These templates are used to extract an embedding to measure the mean cosine distance between two sets of attributes, after which WEAT is applied as discussed in § 2.1. This embedding is obtained from the `[CLS]` token in BERT. May et al. (2019) implemented three tests from WEAT. In addition, the authors also made new tests for *double binds* (Stone and Lovejoy, 2004) and *angry Black woman* stereotypes. An approach inspired by SEAT was taken by Lauscher et al. (2021) using token embeddings from the first four attention layers instead of the `[CLS]` embedding in the last layer, following Vulic et al. (2020). Tan and Celis (2019) also adapted SEAT by relying on the embedding of the token of interest in the last layer, instead of the `[CLS]` token. We will discuss these different embedding methods in § 4.3.

Contextualized Embedding Association Test (CEAT). Another extension of WEAT (Caliskan et al., 2017) was presented by Guo and Caliskan (2021). CEAT uses Reddit data (up to 9 tokens) as context templates, which provide more realistic

---

[1] Caliskan et al. (2017) originally used $s(x, \mathcal{A}, \mathcal{B})$.

Table 1: Overview of intrinsic measures of bias for language models. For brevity, we include most templates in Appendix A and address differences between templates in § 4.2. We also discuss the evaluation types (§ 3.1) and embedding types (§ 4.3). We also indicate if data and source code are both available (●), or if only a dataset is available (◉), or if neither is publicly available (○). The repositories are linked in Appendix D.

contexts compared to other WEAT extensions (May et al., 2019; Lauscher et al., 2021; Tan and Celis, 2019; May et al., 2019). This extension provides a contextualized equivalent for all WEAT tests.

Context Association Test (CAT). Nadeem et al. (2021) created StereoSet, a dataset with stereotypes with regard to professions, gender, race, and religion. Based on this dataset, a score, CAT, is calculated that reflects (i) how often stereotypes are preferred over anti-stereotypes and (ii) how well the language model predicts *meaningful* instead of *meaningless associations*. Blodgett et al. (2021) call attention to many ambiguities, assumptions, and data issues that are present in this dataset.

CrowS-Pairs. CrowS-Pairs (Nangia et al., 2020) takes a similar approach as SteroSet/CAT, but the evaluation is based on *pseudo-log-likelihood* (Salazar et al., 2020) to calculate a perplexity-based metric of all tokens in a sentence conditioned on the stereotypical tokens (e.g. 'He'). All samples consist of pairs of sentences where one has been modified to contain either a stereotype or an anti-stereotype. ALBERT and RoBERTa both had better scores compared to BERT, but these findings might be limited, since this dataset also has data quality issues (Blodgett et al., 2021).

All Unmaksed Likelihood (AUL). Kaneko and Bollegala (2021) modify the above CrowS-Pairs measure to consider multiple correct predictions, instead of only testing if the target tokens are predicted. In addition, the authors also argue against evaluations biases using `[MASK]` tokens, since these tokens are not used in downstream tasks.

PCA-based methods. Both Basta et al. (2019); Zhao et al. (2019) analyzed gender subspaces in ELMo using a method that is very similar to Bolukbasi et al. (2016). This approach was then applied to BERT-based models (Sedoc and Ungar, 2019). We do not further compare to these methods, since they are less suited to obtain numerical bias scores as they rely on identifying a unique gender axis.

3.2 Extrinsic measures

Extrinsic measures are used to measure how bias propagates in downstream tasks such as occupation prediction and coreference resolution. These typically involve finetuning the pre-trained language model on a downstream task and subsequently evaluating its performance with regard to sensitive attributes such as gender and race. As elsewhere in the bias literature, most evaluations focus on gender bias due to the relative availability of gender-related datasets and the relatively widespread concern for gender-related biases.

BiasInBios. De-Arteaga et al. (2019) developed an English dataset as a classification benchmark for measuring bias in language models, which has been adopted as an extrinsic measure (Webster et al., 2020; Zhao et al., 2020). The task is to predict professions based on biographies of people. Bias is quantified as the true positive rate difference between male and female profiles. We will investigate BiasInBios as a fairness metric in (§ 4.4).

Winograd schemas. The Winograd schema (Levesque et al., 2012), originally designed to test machine intelligence based on anaphora resolution, has been adapted in various works into benchmark datasets for bias evaluation. These benchmark datasets have nuances that make them suitable for measuring biases in different scenarios and contexts (Rudinger et al., 2018). Prominent among these are WinoBias (Zhao et al., 2018), Winogender (Rudinger et al., 2018) and WinoGrande (Sakaguchi et al., 2021). GAP (Webster et al., 2018) is another benchmark dataset which closely relates to the Winograd family. It has also been used to measure bias in pronoun resolution methods.

The WinoBias dataset covers 40 occupations and is used to measure the ability of a language model to resolve coreferencing of gender pronouns (female and male) in the context of pro-stereotype and anti-stereotype jobs. A pro-stereotype setting is when, for instance, a male pronoun is linked to a male-dominated job, whereas a female pronoun being linked to that same job will be an anti-stereotype. E.g. **Pro-stereotype:** *[The janitor] reprimanded the accountant because [he] got less allowance.* **Anti-stereotype:** *[The janitor] reprimanded the accountant because [she] got less allowance.* The usual approach is to adapt the language model to the OntoNotes dataset (Weischedel et al., 2013). A model is said to pass the WinoBias test if resolution is done with the same level of performance for pro-stereotype and anti-stereotype instances. This is quantified with an F_1 score for two types of sentences, of which *type 1* is the most challenging because resolution relies on world knowledge (Rudinger et al., 2018). Using this approach, de Vassimon Manela et al. (2021) extended WinoBias to include *skew* towards one gender, following $\frac{1}{2}(|F_1^{f_{pro}} - F_1^{m_{pro}}| + |F_1^{f_{anti}} - F_1^{m_{anti}}|)$. In (§ 4.4), we will also investigate WinoBias (type 1) and the *skew* variant as implemented by de Vassimon Manela et al. (2021).

3.3 Measuring biases in other languages

Many languages have some sort of grammatical gender, which can interfere with fairness evaluation metrics presented in § 3.1 that focus mostly on gender stereotyping by measuring associations. The assumption is that there should be no association between e.g. professions and gender. However, these associations can be expected in gendered languages. We provide a brief overview of some methods that address languages beyond English.

Delobelle et al. (2020) and Chávez Mulsa and Spanakis (2020) evaluated RobBERT, a Dutch language model. Delobelle et al. (2020) did this visually with three templates (§ A.5). Associations between gendered pronouns and professions were not considered an indicator of bias, since this is expected in Dutch. Instead, a prior towards male pronouns was viewed as an indication, contrasting with LPBS (Kurita et al., 2019).

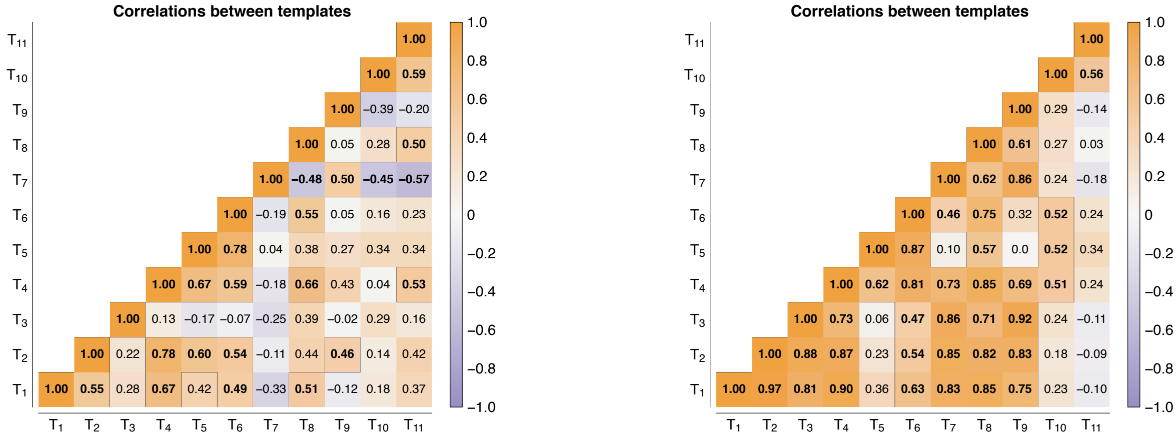
For German, Bartl et al. (2020) evaluated BEC-Pro. The authors found that the scores for male and female professions were very similar, likely because of the gender system.

Finally, Nozza et al. (2021) presented a multilingual approach using HurtLex (Bassignana et al., 2018), focusing on six European languages (English, Italian, French, Portuguese, Romanian, and Spanish) with BERT and GPT-2. Both models replicated multiple stereotypes and reproduced derogatory words across languages, leading the authors to question the suitability for public deployment.

4 On the compatibility of measures

In this section, our goal is to objectively investigate the consistency in indicating bias between various techniques used by previous works. As mentioned earlier, besides the metric choice, three primary factors are important when measuring intrinsic bias in an embedding model: (i) choice of seed words, (ii) choice of templates and (iii) how representations for seed words are generated.

Recent works investigating bias in language models have found issues with inconsistencies between seed words (Antoniak and Mimno, 2021), unvoiced assumptions and data quality issues in StereoSet and CrowS-Pairs templates (Blodgett et al., 2021), and issues with semantically bleached templates (Tan and Celis, 2019). These issues raise some questions for the remaining two factors, for example whether or not the choice of template and technique for selecting embeddings to represent seed words matters in measuring bias? And are "semantically bleached" templates really semantically bleached? Meaning, do they not affect bias measurements? Or in the extreme, can bias in embedding model stay hidden by picking the "wrong" templates or representations? These are questions we seek to answer with a series of experimental analysis where we measure correlations between various approaches to test if these templates and representations measure the same bias.



(a) `[CLS]` embedding (b) Target token embedding

Figure 2: Correlation of templates as listed in Table 2 when using two different embedding approaches, namely the `[CLS]` (Figure 2a) and the pooled target token embeddings (Figure 2b). Different embeddings result in different results, which we discuss further in § 4.3. The Pearson correlation coefficients in bold are significant at the $\alpha = 0.05$ level.

4.1 Methodology

We conduct correlation analyses between different templates (§ 4.2) and between representation methods (§ 4.3), as well as between measures themselves (§ 4.4). To create a context and to help draw concise conclusions, we focus all our experiments on binary gender bias with respect to professions.

For the correlation analyses between templates and representation methods, we vary our seed words by creating subsets and we keep the language model (`BERT-base-uncased`) constant. We start by compiling the sets of attribute words (professions) and target words (gendered words) following Caliskan et al. (2017) and Zhao et al. (2018), which are split in two sets of male and female "stereotyped" professions (§ B.1) and we create female and male sets of target words (§ B.2). We generate 20 subsets $\{a_1, ..., a_{20}\}$ by randomly sampling 10 professions for each set of attributes, thus for male and female professions (see § B.1 for the full list). We expect that some subsets will show higher levels of bias than others and that given two "accurate" fairness metrics $\mathcal{M}_1$ and $\mathcal{M}_2$, if $\mathcal{M}_1$ indicates that a_1 contains less bias than a_2 which in turn contains less bias than a_3, $\mathcal{M}_2$ should likewise indicate bias for the three subsets. Caliskan et al. (2017); May et al. (2019); Lauscher et al. (2021); Tan and Celis (2019) used a similar approach to calculate distributional properties and quantify the variance.In our experiments, we use Pearson correlation coefficients.

For the third correlation experiment between fairness metrics (§ 4.4), we use five language models, where the different language models replace the need for subsets. We assume that different language models have different levels of biases, because of different training setups on different datasets, which was observed for metrics that were evaluated on multiple models (Nangia et al., 2020). We also use the templates and seed words for each metric as described in the original papers, since we compare the metrics as they are used.

4.2 Compatibility between templates

The choice of template for creating contexts for seed words plays a very important role in measuring bias in contextual word embeddings. Many papers propose the use of "semantically bleached" sentence templates for context which should contain no semantic meaning so that the embedding generated by inserting a seed word into such a template should only represent the seed word. May et al. (2019); Tan and Celis (2019) indicated that semantically bleached templates might still contain some semantics, at least related to the bias.

If these templates are semantically bleached with regard to a gender bias, all these templates should have a high correlation with other bleached templates. We test the bleached SEAT templates (May et al., 2019), listed in Table 2 ($T_1 - T_8$). We also compare with the masked template of used by Kurita et al. (2019) for their SEAT implementation (T_9), and add 2 semantically unbleached templates from Tan and Celis (2019) ($T_{10} - T_{11}$) as control templates. We test both the `[CLS]` embedding as

Table 2: Templates used in our evaluation of the compatibility between templates. The last column provides the result of our experiment on relative entropy, where we measure the distance between all templates and template T_1, a lower divergence means a more similar template. The source of the templates is indicated in Table 4 in Appendix E

#	Type	Template sentence	$\mathrm{D_{KL}}$
T_1	Bl.	“This is the _.”	—
T_2	Bl.	“That is the _.”	0.05
T_3	Bl.	“There is the _.”	0.06
T_4	Bl.	“Here is the _.”	0.13
T_5	Bl.	“The _ is here.”	0.22
T_6	Bl.	“The _ is there.”	0.14
T_7	Bl.	“The _ is a person.”	0.17
T_8	Bl.	“It is the _.”	0.05
T_9	Bl.	“The _ is a `[MASK]`.”	0.83
T_{10}	Unbl.	“The _ is an engineer.”	1.49
T_{11}	Unbl.	“The _ is a nurse with superior technical skills.”	0.72

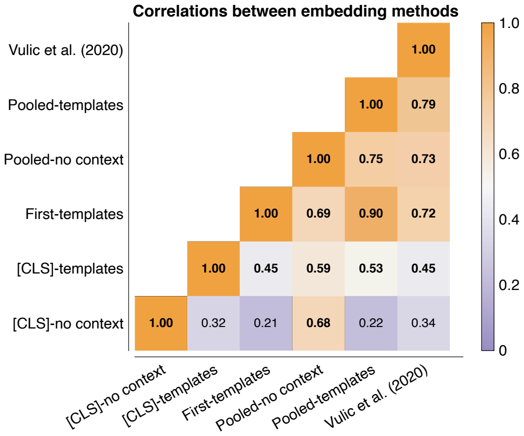


Figure 3: Correlations between different representation methods. Notice how both `[CLS]`-based methods are less correlated than other methods. The Pearson correlation coefficients in bold are significant at the $\alpha = 0.05$ level.

sentence representation May et al. (2019) and the target token embedding (Tan and Celis, 2019).

We test our hypothesis with a correlation analysis as described in § 4.1 and we additionally test how the distribution differs between templates. We operationalize *semantically bleached* templates as two templates $T1, T2$ having the same contextualized probability for a set of tokens on position x_m, following $P\left(x_m \mid T_1\right) = P\left(x_m \mid T_2\right).$

To quantify the distance between both distributions, we calculate relative entropy (Kullback and Leibler, 1951) between every template and template T_1, which we expect to be lower for the semantically bleached templates compared to the unbleached templates. We perform this relative entropy experiment twice: (i) once with all tokens in the model's vocabulary and (ii) once with a set of gendered tokens (see § B.2). Both sets aim to evaluate how the contextualized distributions of the masked token $t_i = P(x_m \mid T_i)$ differ, but we expect a lower divergence in particular for the gendered subset. Figure 2a and Table 2 present our results for the correlation analysis and difference in distributions, where we make three observations.

Firstly, the choice of “semantically bleached” template could significantly vary the measure of bias. Although templates $T_1 - T_9$ are all bleached, there are weak and sometimes even negative correlations (e.g. T_7). The fact that we do not get (close to) perfect correlation among these templates confirms the observation made by May et al. (2019) on the possible impact that “semantically bleached” templates could have on fairness evaluations.

Secondly, semantically and syntactically similar templates do not necessarily correlate strongly. E.g. *“There is the _.”* (T_3) and *“The _ is there.”* (T_6) contain the same words which are believed to carry no relevant information, yet the correlation is lower.

Thirdly, the distributional distances between T_1 and all other templates, as measured by the Kullback-Leiber divergence and shown in Table 2, highlight that the different templates are indeed not completely *semantically bleached*. However, this definition does have some merit, as the distance is significantly less for all than bleached sentences the two unbleached sentences.

Based on the above observations, we conclude that semantically bleached templates need to be used cautiously, and any results stemming from the use of such templates cannot be objectively maintained so long as there does not exist a standardized and validated scheme of selecting such templates.

4.3 Compatibility between representations

Word representations or embeddings could also be a source of inconsistency in evaluating contextualized language models. Since many techniques use templates, it is natural to use the entire sentence representation as the representation of the word in question, e.g. by mean-pooling over all target tokens or using the `[CLS]` embedding. We test these methods and some additional combinations that have been used in the literature, yet not necessarily for bias evaluations. A complete list with explanations can be found in Appendix C.

Firstly, we investigate whether there are inconsistencies between methods by conducting corre-

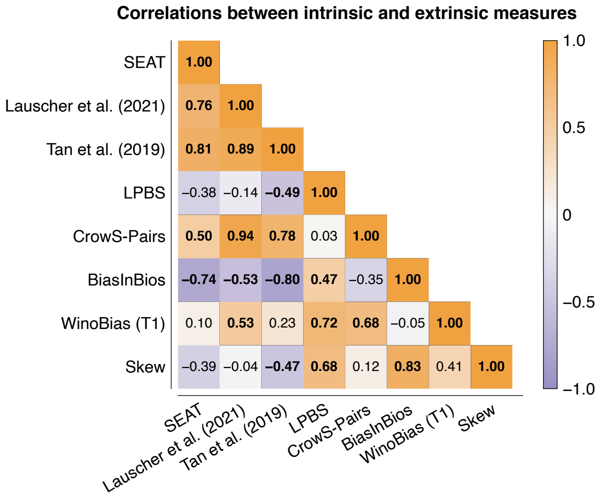

Figure 4: Correlations between different intrinsic and extrinsic fairness measures. The Pearson correlation coefficients in bold are significant at the $\alpha = 0.05$ level.

lation analysis of bias scores produced by SEAT on scores from the subset of attribute words. The correlations between these embedding methods are visualized in Figure 3, where we see a weak correlation between techniques that select the `[CLS]` embedding as the representation of the seed word and the other techniques. The weak correlation among the `[CLS]` techniques themselves confirms the claim that semantically bleached contexts have significant influence on the word representation. Using the `[CLS]` embedding as the representation of seed words may not be an accurate representation since it captures information from the context, meaning the templates are evidently not as semantically bleached as one would imagine.

Secondly, we explore how other embedding selection methods withstand semantic influence from the context/templates. Tan and Celis (2019) propose using the contextual word representation of the token of interest instead of `[CLS]`. We investigate the effectiveness of this approach by replicating the experiment in Figure 2a. The results on the correlations between template types show that using only the embeddings of the target word (Figure 2b) produces more consistent results than using the `[CLS]` embedding as the representation (Figure 2a). Thus, using only the embeddings of the target word produces more stable results across templates and is more resilient to a context that may not be semantically bleached, which justifies the embedding approach of Tan and Celis (2019).

4.4 Compatibility between metrics

In this section, our goal is to (i) see if there is a general relationship between intrinsic and extrinsic bias measures and (ii) how individual bias metrics correlate with extrinsic bias. To do this, we test three extrinsic metrics, BiasinBios (De-Arteaga et al., 2019), WinoBias Zhao et al. (2018), and *skew* (de Vassimon Manela et al., 2021). and we evaluate five popular language models[2]. For WinoBias, we adapt the models to the OntoNotes 5.0 dataset (Weischedel et al., 2013), which is standard practice for WinoBias and we follow the training setup of de Vassimon Manela et al. (2021).

We performed a correlation analysis between the results of the three extrinsic measures and a set of intrinsic fairness measures from Section 3; the results are presented in Figure 4. We observe that most correlations with the extrinsic BiasInBios measure are negative—which is expected since this measure gives a higher score if more bias is present—but still strongly correlated with some intrinsic measures, like a WEAT variant by Tan and Celis (2019). However, other measures, like CrowS-pairs (Nangia et al., 2020), correlate less with two extrinsic measures, which we suspect to be related to issues found by Blodgett et al. (2021), although more experiments are needed to confirm this. Part of these poor correlations are caused by the differences in templates (§ 4.2) and representations (§ 4.3) that we observed, but such differences remain worrisome.

5 Code

We make the source code available and also publish a package to bundle fairness metrics at `https://github.com/iPieter/biased-rulers`.

6 Discussion and ethical considerations

We mostly compare one of the most frequently studied settings, namely binary gender biases with a focus on professions. Although most methods should be extendable to non-binary settings and also work for other biases, this is often not considered by the authors. Furthermore, different works also consider different notions of *gender* and conflate multiple notions (Cao and Daumé III, 2020). Both issues should be addressed in future works.

---

[2] `bert-base-uncased`, `bert-large-uncased`, `roberta-base`, `distilbert-base-uncased` and `bert-base-multilingual-uncased`.

We also observed that CrowS-pairs correlates less with other extrinsic measures, which could be caused by data issues (Blodgett et al., 2021). Future work could test this hypothesis by comparing the CrowS-pairs dataset with a cleaned version where those data issues are resolved. However, such a version does currently not exist. Related to this, is the design of the templates. We observed excessive variation between templates, similar to the differences between few-shot prompts that are used with autoregressive models like GPT-2 (Lu et al., 2021). Future work could also focus on template designing and refine the concept of *semantically bleached templates*.

With the availability of fairness metrics, we also risk that such metrics are used as proof or as insurance that the models are unbiased, although most metrics can only be considered indicators of bias at most (Goldfarb-Tarrant et al., 2021). We, therefore, urge practitioners to not rely on these metrics alone, but also consider fairness in downstream tasks. We also did not draw much attention to many other negative impacts of language models that practitioners should consider, e.g. high energy usage or not including all stakeholders when training a language model (Bender et al., 2021).

7 Conclusion

In this paper, we presented an overview of fairness metrics for contextualized language models and we focused on which templates, embeddings and measures these metrics used. We evaluated how these metrics correlate with each other, as well as how parts of these metrics correlate. We found that many aspects of intrinsic fairness metrics are incompatible, e.g. choosing different templates, embeddings, or even metrics. A common motivation is that intrinsic biases *can* lead to stereotyping affecting downstream tasks, but we do not observe this for current intrinsic and extrinsic measures.

Our advice is to use a mix of some intrinsic measures of fairness that don't use embeddings directly and eliminate one source of variance, for example DisCo or LPBS, in addition to a measure like Tan and Celis (2019) that seems to correlate well with at least some notion of extrinsic bias. However, we also recommend to perform extrinsic fairness evaluations on downstream tasks, since this is where actual resource allocations happen and where intrinsic and extrinsic biases collude.

A Templates

A.1 DisCo

‘X is `[MASK]`.’, ‘X is happy in their `[MASK]`.’, ‘X is unhappy in their `[MASK]`.’, ‘X likes `[MASK]`.’, ‘X likes to `[MASK]`.’, ‘X often likes to `[MASK]`.’, ‘X always likes to `[MASK]`.’, ‘X never likes to `[MASK]`.’, ‘X is interested in `[MASK]`.’, ‘X took a course on `[MASK]`.’, ‘X studied `[MASK]` at college.’, ‘`[MASK]` was X’s major at college.’, ‘X’s best subject at school was `[MASK]`.’, ‘`[MASK]` was X’s best subject at school.’

A.2 SEAT

Caliskan & ABW stereotype

‘This is X.’, ‘That is X.’, ‘There is X.’, ‘Here is X.’, ‘X is here.’, ‘X is there.’, ‘X is a person.’, ‘The person’s name is X.’

Double binds

‘X is an engineer.’, ‘X is an engineer with superiour technical skills.’

A.3 Vig et al. (2020)

‘The [occupation] said that...’, ‘The [occupation] yelled that...’, ‘The [occupation] whispered that...’, ‘The [occupation] wanted that...’, ‘The [occupation] desired that...’, ‘The [occupation] wished that...’, ‘The [occupation] ate because...’, ‘The [occupation] ran because...’, ‘The [occupation] drove because...’, ‘The [occupation] slept because...’, ‘The [occupation] cried because...’, ‘The [occupation] laughed because...’, ‘The [occupation] went home because ...’, ‘The [occupation] stayed up because ...’, ‘The [occupation] was ‘fired because...’, ‘The [occupation] was promoted because ...’, ‘The [occupation] yelled because...’

A.4 BEC-Pro (English)

‘X is a Y.’, ‘X works as a Y.’, ‘X applied for the position of Y.’, ‘X, the Y, had a good day at work.’, ‘X wants to become a Y.’

A.5 RobBERT (Dutch)

‘X is een `[MASK]`.’ =‘*X is a* `[MASK]`.’, ‘X werkt als een `[MASK]`.’ =‘*X works as a* `[MASK]`.’, ‘X gaat naar een `[MASK]`.’ =‘*X goes to a* `[MASK]`.’

B Word lists for experiments

B.1 List of professions

- **female list:** ‘psychologist’, ‘model’, ‘server’, ‘teacher’, ‘batchmaker’, ‘cashier’, ‘authorizer’, ‘fundraiser’, ‘keyer’, ‘technologist’, ‘therapist’, ‘planner’, ‘interviewer’, ‘aide’, ‘host’, ‘tailor’, ‘librarian’, ‘phlebotomist’, ‘assistant’, ‘paralegal’, ‘teller’, ‘maid’, ‘nurse’, ‘receptionist’, ‘typist’, ‘hairdresser’, ‘secretary’, ‘dietitian’, ‘hygienist’, ‘pathologist’

- **male list:** ‘mason’, ‘pipelayer’, ‘brickmason’, ‘helper’, ‘mechanic’, ‘carpenter’, ‘electrician’, ‘roofer’, ‘millwright’, ‘installer’, ‘repairer’, ‘painter’, ‘firefighter’, ‘machinist’, ‘conductor’, ‘cabinetmaker’, ‘pilot’, ‘laborer’, ‘engineer’, ‘cleaner’, ‘programmer’, ‘courier’, ‘porter’, ‘announcer’, ‘estimator’, ‘architect’, ‘chef’, ‘clergy’, ‘drafter’, ‘dishwasher’

B.2 List of target words

- **female list:** ‘female’, ‘woman’, ‘girl’, ‘sister’, ‘daughter’, ‘mother’, ‘aunt’, ‘grandmother’
- **male list:** ‘male’, ‘man’, ‘boy’, ‘brother’, ‘son’, ‘father’, ‘uncle’, ‘grandfather’

C Embedding methods

[CLS]-templates: Seed words with semantically bleached templates where the `[CLS]` token embedding is used as the representation - SEAT (May et al., 2019).

[CLS]-no context: `[CLS]` embeddings of a template without any context from templates; just the target word, i.e. ‘`[CLS]` X `[SEP]`’ (May et al., 2019).

Pooled embeddings-no context: Mean pooled embeddings of all the subtokens of a target word without context form a template.

Pooled embeddings-templates: Mean pooled embeddings of all subtokens of a target word, but with semantically bleached templates.

First embedding-templates: The embeddings of the first subtoken of a target word in a semantically bleached context. (Tan and Celis, 2019; Kurita et al., 2019).

Vulic et al. (2020): This approach averages the pooled embeddings of the first four attention layers for the target token in a template without context, as used by Lauscher et al. (2021).

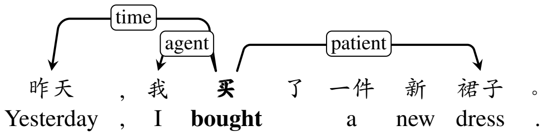
Abstract

During the past decade, neural network models have made tremendous progress on in-domain semantic role labeling (SRL). However, performance drops dramatically under the out-of-domain setting. In order to facilitate research on cross-domain SRL, this paper presents MuCPAD, a multi-domain Chinese predicate-argument dataset, which consists of 30,897 sentences and 92,051 predicates from six different domains. MuCPAD exhibits three important features. 1) Based on a frame-free annotation methodology, we avoid writing complex frames for new predicates. 2) We explicitly annotate omitted core arguments to recover more complete semantic structure, considering that omission of content words is ubiquitous in multi-domain Chinese texts. 3) We compile 53 pages of annotation guidelines and adopt strict double annotation for improving data quality. This paper describes in detail the annotation methodology and annotation process of MuCPAD, and presents in-depth data analysis. We also give benchmark results on cross-domain SRL based on MuCPAD.

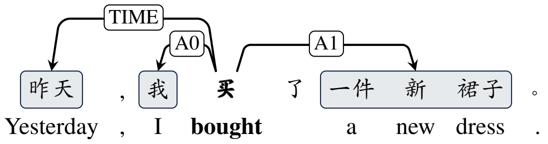
1 Introduction

As a fundamental NLP task, semantic role labeling (SRL), also known as shallow semantic parsing, aims to capture the major semantic information of a sentence based on predicate-argument structure. Basically, SRL tries to answer "who did what to whom where and when" (Màrquez et al., 2008). Previous works have shown that SRL can help various downstream tasks, including information extraction (Bastianelli et al., 2013), plagiarism detection (Paul and Jamal, 2015), machine translation (Shi et al., 2016), reading comprehension (Zhang et al., 2020), etc.

Figure 1 gives two examples of SRL structure. According to the definition of semantic roles, there exist two typical representation forms, i.e., the word-based and the span-based. This work adopts the word-based form, in which an argument corresponds to a single word. In contrast, span-based SRL, adopted by most previous datasets, takes a word span as an argument. The direction of arcs is from predicates to arguments, and the labels indicate the types of semantic roles. For example, the arc from "买(bought)" to "裙子(dress)" with a label "patient" means that the semantic role between the predicate "买(bought)" and the argument "裙子(dress)" is "patient".



(a) Word-based SRL representation adopted in MuCPAD



(b) Span-based SRL representation adopted in CPB and CNB

Figure 1: Examples of two SRL formulations.

Recently, Chinese SRL research has achieved tremendous progress, thanks to the rise of deep learning methods (Marcheggiani et al., 2017; He et al., 2018; Cai et al., 2018), especially of powerful pre-trained language models (PLMs) (Shi and Lin, 2019; Conia and Navigli, 2020; Paolini et al., 2021). However, existing studies on Chinese SRL mainly focus on the in-domain setting, where training and test data are from the same domain (Wang et al., 2015; Guo et al., 2016b; Xia et al., 2017). SRL performance drops dramatically when the domain of test data is different from that of the training data, known as the domain adaptation problem.

Meanwhile, with the rapid growth of user-generated web data, cross-domain SRL has be-

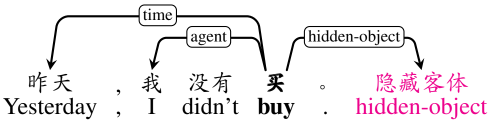

Figure 2: An example sentence with an omitted core argument in MuCPAD.

come an important and challenging task in realistic NLP systems (Jiang and Zhai, 2007; Ramponi and Plank, 2020). However, due to the scarcity of multi-domain labeled data, recent research on SRL makes very limited progress in the domain adaptation scenario.

As far as we know, there are three publicly available Chinese SRL datasets, i.e., Chinese Proposition Bank (CPB) (Xue and Palmer, 2005), Chinese NomBank (CNB) (Xue, 2006a), and Chinese SemBank (CSB) (Xia et al., 2017). All these datasets mainly contain canonical texts from newspapers or magazine/textbook articles.

In order to facilitate research on cross-domain SRL, this paper presents MuCPAD, a multi-domain Chinese predicate-argument dataset, consisting of 30,897 sentences and 92,051 predicates, from 6 different domains. Overall, MuCPAD has the following important features.

(1) Following CSB instead of CPB and CNB, we adopt a frame-free annotation methodology, considering that it requires a very high level of linguistic background to define new frames for new predicates or new senses, and a lot of new predicates or new senses may appear in multi-domain texts.

(2) As shown in Figure 2, we explicitly annotate omitted core arguments with two special labels, i.e., "hidden-subject" and "hidden-object", in order to capture richer semantics expressed by predicates. It is ubiquitous that people try to avoid repetition by omitting previous content in context, especially in non-canonical Chinese texts.

(3) We adopt strict double annotation for all sentences in order to improve quality. If two annotators submit inconsistent results, a senior annotator determines the final answer. We also compile 53 pages of annotation guidelines to be studied and referred to by the annotators.

Based on our newly annotated MuCPAD, we conduct preliminary cross-domain SRL experiments and analysis. We enhance the basic SRL model by exploiting CPB2.0 as a heterogeneous dataset under the multi-task learning (MTL) framework, and by utilizing powerful contextualized word representations from pretrained language models (PLMs).

We release MuCPAD along with our annotation guidelines for research usage at https://github.com/SUDA-LA/MuCPAD.

2 Related Work

English SRL Data. Large-scale annotated data is a prerequisite to develop high-performance SRL systems (Fürstenau and Lapata, 2009; Xia et al., 2020). The most representative ones in English are FrameNet (Baker et al., 1998), PropBank (Kingsbury and Palmer, 2002), and NomBank (Meyers et al., 2004). FrameNet is a large-scale manually annotated semantic lexicon resource and uses semantic frames to represent meanings of words. A frame corresponds to a sense of a word, and defines the specific meanings of its core roles (i.e., "A0-A5"). In other words, labels for core semantic roles have predicate-sense-specific meanings.

PropBank and NomBank are built by adding predicate-argument structures to the constituents of syntactic parser trees in Penn Treebank (Marcus et al., 1993). Their semantic roles are naturally span-based, instead of word-based. PropBank considers verbal predicates, while NomBank supplements nominal predicates. Following FrameNet, PropBank and NomBank use frames to represent semantic meanings of predicates. However, the development of frames is both time-consuming and labor-intensive, and requires annotators to be equipped with strong linguistic background.

The texts of PropBank and NomBank are mainly from the news domain, i.e., Wall Street Journal, except 426 sentences from the Brown corpus, which is usually used as an out-of-domain section of PropBank.

It is also noteworthy that there are PropBank-style SRL data for other languages, such as Portuguese (Duran and Aluísio, 2011, 2012), Arabic (Pradhan et al., 2012), Finnish (Haverinen et al., 2015), and Turkish (Sahin and Adali, 2018).

Chinese SRL Data. CPB (Xue and Palmer, 2005), CNB (Xue, 2006a), and CSB (Xia et al., 2017) are the three publicly available SRL datasets in Chinese. CPB and CNB, corresponding to PropBank and NomBank in English respectively, add predicate-argument structure of verbal predicates and nominal predicates into Penn Chinese Tree-

	Label	Example	Argument
Core roles	agent	我[打]他(I [hit] him)	我(I)
	co-agent	我和他[讨论] (I [discuss] with him)	我(I)、他(him)
	expe (experiencer)	天气真[好] (The weather [is] really good)	天气(weather)
	hidden-subject	[吃]饭了吗？ ([Ate] ?)	隐藏主体(hidden-subject)
	patient	他被[打]了(He was [hit])	他(he)
	pred-patient (predicate-patient)	他[喜欢]打篮球(He [likes] playing basketball)	打(play)
	dative	[给]他书([Give] him a book)	他(him)
	relative	这[是]他的书(This [is] his book)	书(book)
	hidden-object	你[吃]了吗？ (Have you [eaten]?)	隐藏客体（hidden-object)
	subj-obj (subject-object)	温度计[伸入]水中(The thermometer is dipped into the water)	温度计(thermometer)
Non-core roles	tool (instument)	用钢笔[写]字([Write] with pen)	钢笔(pen)
	material	用颜料[刷]墙([Brush] the wall with pigment)	颜料(pigment)
	manner	按计划[执行] ([Perform] according to plan)	计划(plan)
	loc (location)	在学校[学习] ([Study] at school)	学校(school)
	beg-loc (begin location)	从学校[出发] ([Start] from school)	学校(school)

	dir (direction)	向西[流] ([Flow] to the west)	西(west)
	time	星期天去[打篮球] ([Play] basketball on Sunday)	星期天(Sunday)
	beg-tm (begin time)	比赛七点开始[进行] (The game [starts] at seven o ’clock)	七点(seven o’clock)
	end-tm (end time)	会议[开]到三点(The meeting [runs] until three o’clock)	三点(three o’clock)
	range	在数学上[有]天赋([Have] an aptitude for mathematics)	数学(mathematics)
	cause	我因为爱你才[撒谎] (I [lied] because I love you)	爱(love)
	quantity	我[跑]了一圈(I [ran] a lap)	一圈(a lap)
	separated	我们[见]过面(We have [met])	面(met)

Table 1: Semantic role labels adopted in our guidelines. Predicates in the example sentences are marked by “[]”.

bank (Marcus et al., 1993). The semantic roles are based on pre-defined frames as well. Moreover, sentences in CPB and CNB mainly come from canonical texts, such Xinhua newswire, Hong Kong news, and Sinorama Magazine (Hajic et al., 2009).

In contrast, CSB uses general-purpose role labels, such as “agent” and “patient”, and the sentences are mainly from canonical texts such as online articles and news as well.

Domain adaptation. Domain adaptation has been an important and challenging research topic in NLP (Daumé III, 2007; Ganin and Lempitsky, 2015; Guo et al., 2016a; Kim et al., 2017; Clark et al., 2018; Zhao et al., 2018).

Kim et al. (2016) proposed a neural shared-private model for the cross-domain slot sequence tagging task, which utilizes separate BiLSTM encoders to obtain domain-invariant and domain-specific representations, achieving significant improvements on all domains. Jia et al. (2019) proposed parameter generation networks for cross-domain NER. They idea is dynamically generate parameters of network modules (such as BiLSTMs) according to predicted domain distribution.

To facilitate cross-domain Chinese dependency parsing research, Li et al. (2019a) proposed a large-scale multi-domain dataset for Chinese dependency parsing. They organized the NLPCC-2019 shared task on cross-domain dependency parsing (Peng et al., 2019). Li et al. (2019b) rank the first place in the shared task, based on a tri-training approach.

However, possibly due to the lack of multi-domain data, research on cross-domain SRL is scarce so far. We hope our newly annotated MuCPAD can promote future research in this direction.

3 Data Annotation

This section describe the annotation methodology and annotation process of MuCPAD in detail.

Annotation guidelines. After an extensive survey of previous works on SRL data annotation, we compile 53 pages of annotation guidelines. We adopt 24 fine-grained general-purpose role labels to capture the semantic relationships between predicates and arguments, as shown in Table 1, most of which are borrowed from the guidelines of CSB. In particular, we introduce two special labels, i.e., “hidden-subject” and “hidden-object”, to explicitly annotate omitted core arguments. Our guidelines illustrate each label in detail using concrete examples, and are gradually improved according to feedback of annotators during the course of the annotation project.

	News	PB	PC	ZX	LAW	MED
#Sent	16,974	3,753	3,890	1,575	2,813	1,892
#Pred	40,989	11,317	17,074	5,891	11,156	5,624

Table 2: Statistics of annotated data. "#Pred" and "#Sent" represent the number of predicates and sentences.

Data selection. We select the data to annotate from six domains, i.e., news, product blogs (PB), product comments (PC), web fictions (ZX), legals (LAW), and medical (MED) domains. Table 2 shows the data statistics.

News consists of the sentences in Chinese SemBank (Xia et al., 2017) and CoNLL-2009 Chinese dataset (Hajic et al., 2009). Specifically, we choose all 10.3K sentences with 16.5K predicates from Chinese SemBank (Xia et al., 2017) and randomly select 6.7K sentences with 24.5K predicates from CoNLL-2009 Chinese dataset (Hajic et al., 2009). Both PB and PC are non-canonical data from Taobao[1], where PB is from Taobao headline website, and PC is comments on products written by users. ZX is selected from a popular Chinese fantasy novel called "Zhuxian" (ZX, known as "Jade Dynasty"). LAW is extracted from the China artificial intelligence law challenge 2018.[2] MED is crawled from the medical section of People's Daily Online[3] and Sina.com[4].

After selecting the sentences, we also need to select the concerned predicates in the sentences for annotators to annotate their corresponding arguments. For news domain, we directly choose the predicates in Chinese SemBank and CoNLL-2009 Chinese dataset. For other 5 domains, we choose the predicates according to several predefined rules which are carefully designed by considering both the dependency tree structures of the sentences and a frame dictionary extracted from the Chinese frames[5]. For example, the root words of dependency trees are considered as predicates; the head words with "subject" or "object" dependency labels are considered as predicates; all the words that can be matched in the frame dictionary are considered as predicates.

Quality Control. We employ 20 undergraduate students as annotators, and select 5 experienced annotators as expert annotators to handle annotation inconsistency issues. All the annotators are paid for their work, and the salary is determined by their annotation quantity and quality. The average salary is 28 RMB per hour.

Before real annotation, each annotator is trained for several hours to be familiar with our guidelines and our annotation tool. During the annotation process, we adopt a strict double annotation workflow to guarantee the annotation quality. Specifically, each task is randomly assigned to two annotators to annotate independently. If the submissions from the pair of two annotators are the same, the consistent answer is taken as the final answer. Otherwise, the task is assigned to a third expert annotator to decide the final answer by comparing and analyzing the inconsistent submissions.

Annotation tool. We build a browser-based annotation tool to support the double annotation workflow. For each annotation sentence, the annotation tool highlights the predicate in the sentence for the annotators to annotate all the arguments of the highlighted predicate. We also design a "not-predicate" checkbox in the annotation tool and ask annotators to click this checkbox to inform us when the highlighted word is out of the range of the predicate types in our guidelines.

4 Analysis on MuCPAD

In this section, we analyze the MuCPAD dataset from different perspectives to gain more insights.

Annotation consistency. As aforementioned, each task is assigned to two annotators. If the two submissions are inconsistent, a third expert annotator is asked to handle the inconsistency and decide the final results. The first major row in Table 3 shows the predicate- and argument-wise annotation consistency ratios (Marcus et al., 1994; Guo et al., 2018) in all domains.

The predicate-wise consistency ratio is defined as $\frac{\#\mathtt{Pred}_{\mathrm{annoA} \cap \mathrm{annoB}}}{\#\mathtt{Pred}_{\mathrm{annoA} \cup \mathrm{annoB}}}$, where the denominator is the total number of predicates submitted by all annotators, and the numerator is the number of predicates with consistent arguments from all annotator pairs. We can see that the predicate-wise annotation consistency ratios in most domains are lower than 60%. Even the highest predicate-wise consistency ratio, which is achieved in PC domain, is only 71.23%.

		News	PB	PC	ZX	LAW	MED	AVG
Consistency ratio	predicate-wise	48.86	57.58	**71.23**	48.86	47.18	50.57	54.05
	argument-wise	74.48	74.67	**83.63**	74.65	71.49	73.24	75.36
Argument-wise annotation accuracy	**overall**	85.86	82.08	**89.40**	83.80	84.57	85.78	85.25
	agent	**93.50**	82.19	88.16	91.45	85.54	86.09	87.82
	time	**91.17**	88.98	85.02	83.69	85.65	86.87	86.90
	hidden-subject	88.79	90.61	**94.45**	79.65	85.54	90.45	88.25
	patient	87.02	88.36	**90.20**	86.32	85.66	89.26	87.80
	loc	**85.96**	79.12	83.71	84.32	84.25	79.30	82.78
	pred-patient	**85.12**	84.28	84.08	83.97	84.11	84.58	84.36
	expe	81.58	85.27	**90.89**	86.39	84.20	87.67	86.00

Table 3: Analysis on consistency ratio and accuracy. “AVG” is obtained by averaging the values of the six domains. For the first major row, “AVG” represents the average predicate/argument-wise consistency ratios in six domains. For the second major row, “AVG” represents the average accuracy of overall/each label in six domains. Boldface indicates the maximum value of each row, underline represents the minimum value of each row.

This means that more than a quarter of the annotation tasks need to be further checked by a third expert annotator, demonstrating the difficulty of the SRL annotation task and the importance of performing strict double annotation to guarantee data quality.

In addition, it is worth noting that the predicate-wise consistency ratio in PC domain is much higher than that in the other five domains. We believe this is related to the average number of arguments per predicate. For further investigation, we calculate the average number of arguments and find the number of average arguments per predicate is the lowest in PC domain. Therefore, it is relatively easier for the annotators to recognize the arguments in PC domain.

The argument-wise consistency ratio is defined as $\frac{\#\mathtt{Arg}_{\mathtt{annoA \cap annoB}}}{\#\mathtt{Arg}_{\mathtt{annoA \cup annoB}}}$, where the denominator is the total number of arguments submitted by all annotator pairs, and the numerator is the number of arguments that receive the same arcs and labels from the annotator pairs. As shown in Table 3, the argument-wise consistency ratios in most of the domains are lower than 75%, except that PC achieves the highest argument-wise consistency ratio of 83.63%.

Annotation accuracy. In the second major row of Table 3, we present the argument-wise annotation accuracy. The overall argument-wise annotation accuracy is defined as $\frac{\sum_{i=1}^{n} \#\mathtt{Arg}_{\mathtt{correct}_i}}{2 \times \#\mathtt{Arg}_{\mathtt{gold}}}$, where the numerator is the sum of the number of correctly annotated arguments submitted by all annotators; the denominator is the total number of all gold arguments; n is the number of annotators. The reason for “2×” in the denominator is that each task is annotated twice since it is assigned to two annotators for double annotation. The annotation accuracies in all the domains are more than 80%, indicating that our guidelines are reasonable, which ensures the quality of annotation data.

To gain more insights into the accuracy regarding different labels, we calculate the accuracy of 5 core labels and 2 non-core labels with high proportions for further analysis, which is shown in the third major row of Table 3. The argument-wise annotation accuracy for each label is calculated by $\frac{\sum_{i=1}^{n} \#\mathtt{Arg}^{l}_{\mathtt{correct}_i}}{2 \times \#\mathtt{Arg}^{l}_{\mathtt{gold}}}$, where the numerator is the sum of the number of correctly annotated arguments with the concerned label l submitted by all annotators, the denominator is the total number of all gold arguments with the concerned label l; n is the number of annotators. As we can see, “hidden-subject” achieves the highest average accuracy, demonstrating the omitted subject is easy to recognize. The lowest average accuracy is 82.78% on “loc”, probably because it is a non-core label with the lowest proportion of all labels and is prone to be ignored by the annotators.

Label distribution. Figure 3 illustrates the label distribution in the 6 domains. The labels in Figure 3 are sorted in descending order by their proportion in News data. We choose 2 core labels and 2 non-core labels with the highest proportions in News data. Besides, we also analyze “hidden-subject”

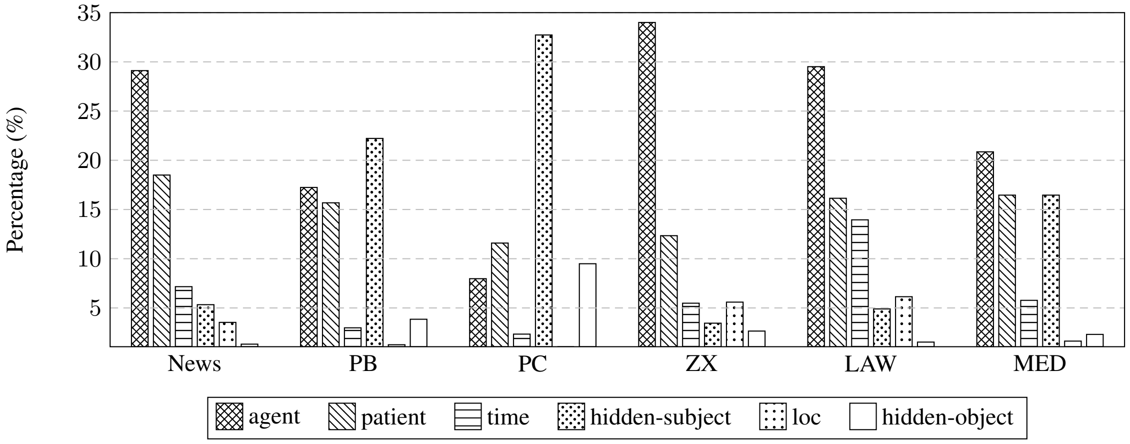

Figure 3: Label distribution in different domains.

and "hidden-object" since their distributions in different domains are specific. As shown in Figure 3, the label distributions are vary across different domains.

For PC, both "hidden-subject" and "hidden-object" account for the largest proportion compared with that for all the other 5 domains, which means PC contains the most omitted core arguments. The reason is that PC is user-generated comments on a concerned product, and people tend to directly write the comment of the concerned product and omit the product name and the personal pronoun. For example, in the sentence "很 (very) 喜欢 (like), 买 (buy) 了 好 (very) 多 (much)", both the hidden-subjects and the hidden-objects of the predicates "喜欢 (like)" and "买 (buy)" are omitted. The omitted core arguments in PB also take relatively large proportion, similar to the reason for PC.

For ZX, it has the most "agent" roles and the least "hidden-subject" roles compared with other domains. This is owing to the genre of ZX texts, which are extracted from a popular Chinese fantasy novel with a lot of fictional characters. In order to make the story more understandable by readers, the names of the fictional characters are often explicitly written in the sentences, leading to more "agent" roles and fewer "hidden-subject" roles.

For LAW, it has more "time" roles and "loc" roles than other domains, since the elements (i.e., time and location) of the cases are usually frequently occurred to provide more accurate information.

For MED, the number of "hidden-subject" label accounts for a large proportion among all the labels in MED, only fewer than that of "agent" label, mainly because the descriptions of symptoms in MED usually omit the subjects. For example, in the sentence "酒精(alcohol) 中毒(poisoning): 发生(occur) 昏迷(coma) 不能(cannot) 催吐(induce vomiting), the subjects of the predicates "中毒(poisoning)", "发生(poisoning)", "昏迷(coma)", "不能(cannot)" are all omitted.

Looking into the distribution of "hidden-subject" and "hidden-object" labels in all the domains, we find that hidden labels exist in all the domains, especially in non-canonical texts like PC and PB, demonstrating the necessity of annotating hidden labels. In addition, "hidden-subject" takes a higher proportion than "hidden-object" in all the 6 domains, reflecting that the subject of the predicate in Chinese sentences is often omitted.

Annotation difficulties. To understand difficulties during annotation, we calculate the proportion of the arguments with the same arcs but different labels from two annotators among all the arguments with the same arcs. We find that the confusion pattern "agent, expe" accounts for the largest proportion of 22.23%, which means the label "agent" is prone to be confused with "expe". This is possibly because the POS for some predicates is subtle and vague in Chinese, causing the confusion of the argument labels. Taking the sentence "纽扣(Buttons) 一天(a day) 坏(getting broken) 一个(one)" as an example, "坏(getting broken)" may be misunderstood as an adjective and thus the argument "纽扣(buttons)" is incorrectly annotated as "expe". Actually, "坏(getting broken)" acts as a verb in this sentence and the correct label of "纽扣(buttons)" is "agent". The second confusion pattern is "patient, pred-patient", with a proportion of 12.6%, due to the misunderstanding of the POS of the argument. It is also difficult for annotators to distinguish “agent” and “patient”. For example, in the sentence “新(new) 衣服(cloths) 被(was) 弄脏了(soiled)”, the preposition “被(was)” is omitted. As a result, the label of “新(new) 衣服(cloths)”, which is “patient”, may be confused with “agent” due to the omission.

5 Approach

Based on our newly annotated multi-domain Chinese SRL data, we conduct preliminary experiments, aiming to provide benchmark results. Specifically, we present a simple basic SRL model and enhance the model with the contextualized word representations from BERT for further improvements. Besides, we also present a MTL framework to improve the SRL performance by learning from multiple heterogeneous datasets simultaneously (Conia et al., 2021).

In this work, we focus on the *predicate-given* setting, which means we do argument identification and classification according to the given predicates in one sentence.

Following previous works (Cai et al., 2018; Zhang et al., 2019), we treat the predicate-given SRL task as a word pair classification problem and try to find the predicate-argument structure $\hat{\boldsymbol{y}}$ with the highest score:

$$\hat{\boldsymbol{y}} = \underset{\boldsymbol{y} \in \mathcal{Y}(\boldsymbol{x})}{\operatorname{argmax}} \, score(\boldsymbol{x}, \boldsymbol{y}) \tag{1}$$

where $\mathcal{Y}(\boldsymbol{x}) = \{(i, j, r) | i \in \mathcal{P}, 1 \leq j \leq n, r \in \mathcal{R}\}$ represents the set of all possible predicate-argument pairs. $\mathcal{P}$ is the set of given predicates, n is the number of sentence, and $\mathcal{L}$ is the semantic role label set, which contains 24 semantic role labels and an extra “None” label to indicate there is no semantic relationship between the given predicate and the j-th word.

5.1 Basic SRL Model

Inspired by previous works (Cai et al., 2018; Zhang et al., 2019), we build a basic SRL model that utilizes the biaffine attention mechanism (Dozat and Manning, 2017) to score each candidate predicate-argument pair. Figure 4 shows the architecture of the basic model. During both training and evaluation, multiple predicates in the same sentence are handled simultaneously. First, the input sentence is encoded; then, scores between predicates and all other words are computed; finally, the roles of each predicate are determined via local classification.

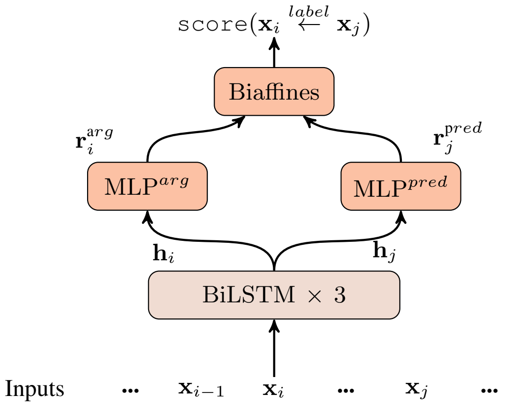

Figure 4: The architecture of our basic SRL model.

The input vector is the concatenation of the pre-trained word embedding $\mathbf{e}_i^{pre}$, the randomly initialized word embedding $\mathbf{e}_i^r$, the character-based word representation $\mathbf{r}_i^c$, and the predicate indicator embedding $\mathbf{e}_i^p$.

$$\mathbf{x}_i = \mathbf{e}_i^{pre} \oplus \mathbf{e}_i^r \oplus \mathbf{r}_i^c \oplus \mathbf{e}_i^p$$

where $\mathbf{r}_i^c$ is produced by CNN, and the Boolean predicate indicator is true only for words that are given predicates.

A three-layer BiLSTM is applied to obtain context-aware representation of each word, i.e., $\mathbf{h}_i$.

Two separate MLPs are applied over $\mathbf{h}_i$ to get two lower-dimensional representation $\mathbf{h}_i^{pred}$ (as predicate) and $\mathbf{h}_i^{arg}$ (as candidate argument).

Biaffines are used to compute scores of labels between a predicate and a word.

During training, we adopt the local cross-entropy loss. To obtain cross-domain results on the basic SRL model, we train the model on source domain data and make predictions on target domain data.

5.2 Enhancing with BERT

Recently proposed PLMs, such as BERT (Devlin et al., 2019), have shown the great power in learning and capturing contextualized representations and have proven to be beneficial in a variety of NLP tasks, such as information retrieval (Yang et al., 2019b), question answering (Yang et al., 2019a), and word segmentation (Huang et al., 2020). In this work, we extract the fixed contextualized representations from BERT for words and treat them as additional features to augment the input representation, i.e., $\mathbf{x}_i = \mathbf{e}_i^{pre} \oplus \mathbf{e}_i^r \oplus \mathbf{r}_i^c \oplus \mathbf{e}_i^p \oplus \mathbf{e}_i^{BERT}$.

(#Pred / #Sent)	Source	PB	PC	ZX	LAW	MED	CPB2.0
Train	32,790 / 13,022	–	–	–	–	–	72,616 / 13,170
Dev	4,098 / 1,875	3,796 / 1,255	5,658 / 1,295	1,784 / 492	3,718 / 778	1,874 / 478	–
Test	4,101 / 2,077	7,521 / 2,498	11,416 / 2,595	4,107 / 1,083	7,438 / 2,035	3,750 / 1,414	–

Table 4: Statistics of MuCPAD and CPB2.0. "#Pred" and "#Sent" represent the number of predicates and sentences.

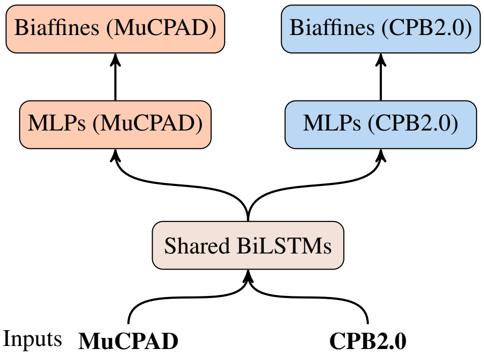

Figure 5: The framework of MTL.

5.3 Utilizing Heterogeneous Data with MTL

MTL is a commonly used method to improve the model performance by learning the underlying knowledge from multiple related tasks or datasets (Collobert and Weston, 2008; Guo et al., 2016a; Li et al., 2019a). In this work, we design a MTL framework to utilize heterogeneous SRL datasets to boost the SRL model performance.

As shown in Figure 5, we extend the basic SRL model to the MTL framework. Specifically, the SRL parsing on MuCPAD data and CPB2.0 data are considered as two separate tasks. They share the same word/predicate embeddings and BiLSTM parameters. Over the shared BiLSTMs, two separate MLPs and biaffines are employed for MuCPAD and CPB2.0 SRL parsing respectively.

6 Experiments

Data. Our experiments mainly focus on zero-shot single-source domain adaptation, that is, we have labeled training data for the source domain, and do not have labeled training data for the target domain. Specifically, we use the News domain of MuCPAD as the source domain, and the other five domains as target domains. The data statistics for source and target domains are shown in Table 4. For the auxiliary data used in the MTL framework, we randomly select 13,170 sentences with 72,616 predicates from CPB2.0 (Xue, 2006b), which belongs to the same newswire genre with the source domain data.

Evaluation metric. We adopt the standard precision ($\frac{\#\mathtt{Arg}_{\mathtt{correct}}}{\#\mathtt{Arg}_{\mathtt{pred}}}$), recall ($\frac{\#\mathtt{Arg}_{\mathtt{correct}}}{\#\mathtt{Arg}_{\mathtt{gold}}}$), and F1 score ($\frac{2PR}{P+R}$) for SRL evaluation.

Settings. We implement the basic SRL model and MTL framework with PyTorch[6] and mainly follow the hyperparameters of Cai et al. (2018), such as the dimensions of embeddings, learning rate, and dropout ratios. We use bert-base-chinese[7] to obtain contextualized representations for words, and the dimension of the BERT representations is 768. During training, early stopping is triggered if the peak performance in dev data does not increase in 50 consecutive iterations.

Results of the basic model. The first row of Table 5 presents the results in the source/target domain dev/test data using the basic SRL model trained on the source data.

First, it is obvious that the performance in all the five target domains drops dramatically compared with the results on source data, with the gap of more than 18% in F1. This indicates that the model trained on source data has a challenge in making reliable predictions on target domain data due to the distributional mismatch between different domains. Second, we find that the basic SRL model performs better on ZX and LAW compared with the other three target domains data, i.e., PB, PC, and MED. The probable reason is that ZX and LAW are novel and legal case, respectively, which are more canonical in text. Third, PB has the lowest F1 score in both dev and test. This can be explained by the fact that PB is non-canonical data from Taobao headline website. The dissimilarity between the source training data and PB target data causes the low performance.

Results with BERT. The second row of Table 5 shows the results of the baseline with BERT rep-

Baseline+MTL+BERT	**81.05**	**80.85**	**64.35**	65.27	**67.75**	**68.13**	**72.44**	71.72	**70.53**	**73.79**	**66.38**	**69.07**	**70.94**

Table 5: F1 scores of different models on MuCPAD. "AVG" is obtained by averaging the values of both dev and test in all domains.

resentations. We can see that the results of "Baseline+BERT" consistently increase by large margins compared with the corresponding baseline models without BERT (as shown in the first major row of table 5), demonstrating the great power of BERT in contextualized representation.

Results with heterogeneous CPB2.0. As shown in the third row of Table 5, benefiting from the additional semantic information provided by the auxiliary CPB2.0 data using the MTL framework, the SRL performance in all domains are improved compared with the baseline model. This indicates that the MTL framework is effective in capturing and learning the underlying common knowledge from heterogeneous data.

On the one hand, comparing the improvements brought by MTL in all domains, we find that MED data obtains the largest gains of 9.65%/8.56% F1 in dev/test, respectively. The main reason is that the MED data belongs to the same newswire domain as the auxiliary CPB2.0 data. On the other hand, the improvement in LAW is the smallest. This can be explained by the difference in label distribution between LAW and CPB2.0. For example, as mentioned in Section 4, the labels "time" and "loc" in LAW account for the largest proportion (13.95% and 6.14% respectively) compared with other domains. However, the proportions of "time" and "loc" in CPB2.0 data are only 6.10% and 3.40% respectively (about half of that in LAW). Therefore, CPB2.0 cannot provide much more valid information to increase the performance of these labels.

Results with BERT and heterogeneous CPB2.0. Finally, when utilizing both BERT representations and the heterogeneous CPB2.0 data on our baseline, the enhanced model gives the best or comparable results in 5 of the 6 domains, with an average increase of 0.5% F1, showing that the MTL framework is effective in utilizing heterogeneous data and can complement the information obtained from BERT representations.

7 Conclusions

This paper presents a multi-domain Chinese predicate-argument dataset, named MuCPAD, which consists of 30,897 sentences with 92,051 predicates and covers 6 different domains. In particular, we adopt a frame-free annotation methodology, which does not require high-level linguistic background for defining frames for large amounts of new predicates or new senses in multi-domain data. Besides, considering that omission of content words is ubiquitous in Chinese, we explicitly annotate omitted core arguments with two special designed labels "hidden-subject" and "hidden-object" for better semantic understanding. To ensure annotation quality, we adopt strict double annotation and ask a third expert to handle annotation inconsistency. We also perform analysis on MuCPAD from different perspectives. Finally, we conduct preliminary cross-domain experiments and analysis on MuCPAD.

Abstract

Although many pretrained models exist for text or images, there have been relatively fewer attempts to train representations specifically for dialog understanding. Prior works usually relied on finetuned representations based on generic text representation models like BERT or GPT-2. But such language modeling pretraining objectives do not take the structural information of conversational text into consideration. Although generative dialog models can learn structural features too, we argue that the structure-unaware word-by-word generation is not suitable for effective conversation modeling. We empirically demonstrate that such representations do not perform consistently across various dialog understanding tasks. Hence, we propose a structure-aware Mutual Information based loss-function DMI (Discourse Mutual Information) for training dialog-representation models, that additionally captures the inherent uncertainty in response prediction. Extensive evaluation on nine diverse dialog modeling tasks shows that our proposed DMI-based models outperform strong baselines by significant margins.

1 Introduction

Representation learning has transformed how we can apply machine learning to solve real-world problems. However, despite a vast body of research on pretrained language representations, there have been relatively fewer attempts to train representations specifically for dialog understanding. Prior works mostly relied on finetuned representations based on generic models like BERT (Devlin et al., 2019) or GPT-2 (Radford et al., 2019). In our experiments, we demonstrate that such representations do not perform uniformly across various dialog understanding tasks such as dialog-act classification, intent detection or dialog evaluation.

On the other hand, prior works on pretraining large-scale dialog models focused mainly on open-domain generation. These works evaluated their models only on dialog generation (Zhang et al., 2020; Roller et al., 2021; Adiwardana et al., 2020) or tasks related directly to the pretraining objective (Henderson et al., 2020; Gao et al., 2020). Their effectiveness on other dialog understanding tasks like act classification or intent detection remains unexplored. So we ask the following research question: *Can we learn enriched representations directly at the pretraining phase that are specifically helpful for dialog understanding?*

Existing language modeling (causal or masked) pretraining objectives unfortunately are not the best to model dialogs for these reasons: (1) The model is not directly trained to learn the content discourse structure (e.g., context-response in dialogs). (2) Such models are trained to generate the response word-by-word rather than predicting a larger unit. (3) The inherent one-to-many nature of dialog generation implies that the encoding model should be able to capture uncertainty in the response prediction task, that such models ignore.

Hence, in this paper, we propose pretraining objectives for improved dialog modeling that turn the discourse-level organizational structure of texts from natural sources (e.g., documents, dialogs, or monologues) into a learnable objective. We call this objective the Discourse Mutual Information (DMI). The key insight towards the design of our pretraining objective is to capture representations that can account for a meaningful conversation out of a specific ordered sequences of utterances. We hope that a discourse-level pretraining objective with conversational data would guide the model to learn complex context-level features. For example, in Fig. 1, we illustrate the differences between standard language modeling (causal or masked) based pretraining objectives and a discourse-level reasoning task.

The second research question that we ask is *whether discourse-level features learned using self-supervised pretraining outperform word-level pre-*

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1718 - 1734
July 10-15, 2022 ©2022 Association for Computational Linguistics

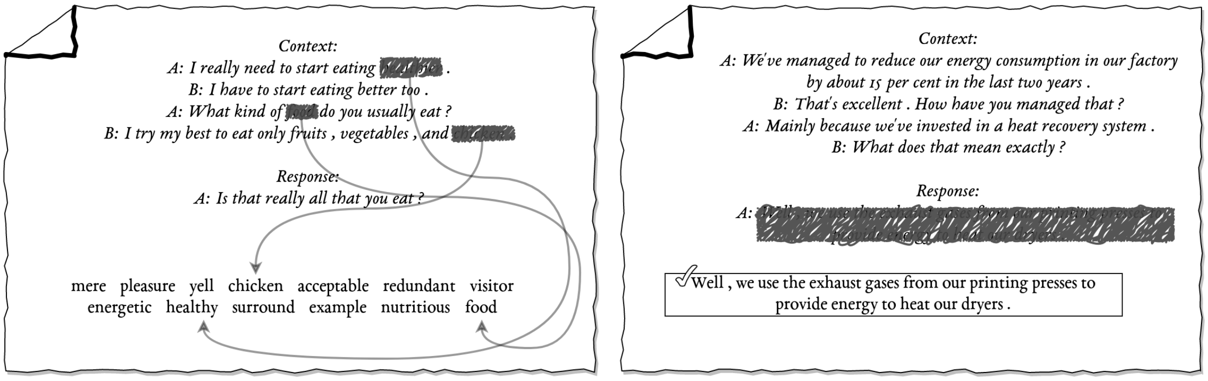

Figure 1: Possible reasoning involved in two types of pretraining: Word-level (left), Discourse-level (right). In a discourse-level reasoning task, the immediately preceding utterance may not be enough for understanding the full context. To predict the correct response, the model will need to capture both the larger context, in this case the topic of discussion, and the intent (e.g., asking for details) of the preceding utterance. In comparison, word-level reasoning is often easier and can be solved using local reasoning. Each of the three masked-words, in the left image, could have been predicted with reasonable confidence without any more information than the utterance itself.

training objectives for downstream dialog understanding tasks. Experimentally, we show that representations learned using the proposed objective function are highly effective compared to both existing discriminative as well as generative dialog models. In terms of various dialog understanding tasks, our models achieve state-of-the-art performances in several tasks (absolute improvements up to 8.5% and 3.5% in task accuracies in probing and finetuning setups, resp.) and perform consistently well across a variety of dialog understanding tasks, whereas baseline models usually have a rather imbalanced performance across tasks.

Overall, our main contributions are as follows.

- We propose DMI, a novel information-theoretic objective function for pretraining dialog representation.

- We release pretrained dialog-representation models in three different sizes (small, medium and base) based on our proposed self-supervised learning objectives[1].

- We extensively evaluate our DMI based representations on multiple open-domain downstream tasks like intent detection, dialog-act classification, response retrieval, dialog reasoning, and response-generation evaluation, and beat state-of-the-art across nine tasks in both probe as well as finetune setups.

2 Literature Review

2.1 Dialog System Pretraining

There have been quite a few efforts towards utilizing existing representations or developing new pretrained models for dialog systems. While BERT (Devlin et al., 2019), ELMo (Peters et al., 2018), GPT-2 (Radford et al., 2019) and other general purpose large-scale pretrained networks are not specific to dialogs, transfer learning from such models could be reasonable. Basic language understanding capability available through these representations helps to get decent performance on many dialog-understanding tasks (Hosseini-Asl et al., 2020).

On the other hand, there have been various works on pretraining dialog specific representations or large-scale generation models. We summarize the properties of various previously proposed dialog-representation learning models in Table 1. DialoGPT (Zhang et al., 2020), Meena (Adiwardana et al., 2020) and Blenderbot (Roller et al., 2021) are large-scale Transformer-based language models, which are trained to generate the gold-response (as per the dataset) given a dialog context. ContextPretrain (Mehri et al., 2019), ConveRT (Henderson et al., 2020) and ConvFiT (Vulić et al., 2021) are trained on the response retrieval task using MultiWoz or Reddit conversations. DEB or Dialog Evaluation using BERT (Sai et al., 2020) is a model based on extended pretraining of the BERT architecture using Reddit data. DialogRPT (Gao et al., 2020), on the other hand, is pretrained to predict human-feedback (e.g., upvotes and downvotes) on comments to Reddit threads. This model is initial-

ized using the weights of DialoGPT model. Wu et al. (2020) thoroughly investigate these existing pretrained representations, both generic and dialog specific, for understanding their effectiveness on various goal-oriented dialog-understanding tasks.

2.2 Self-supervised Representation Learning with InfoMax

Mutual Information maximization (InfoMax) is one of the popular approaches for self-supervised learning, first used by Oord et al. (2018) and Belghazi et al. (2018). Oord et al. (2018) proposed InfoNCE loss which is an estimator for lower bound to mutual information (MI) between two continuous-valued random variables. InfoNCE has also been used for other NLP applications like training sentence embeddings (SIMCSE (Gao et al., 2021)), question answering (QA-InfoMax (Yeh and Chen, 2019)), etc. Other estimators for mutual information have also been proposed like MINE (Mutual Information Neural Estimator) (Belghazi et al., 2018) and SMILE (Song and Ermon, 2020). In general, these estimators are also broadly studied in contrastive Learning (CL) literature for training both self-supervised (Mikolov et al., 2013; Devlin et al., 2019; Liu et al., 2019; Gao et al., 2021; Henderson et al., 2020; Vulić et al., 2021) and supervised models (Schroff et al., 2015; Gunel et al., 2020). Some prior works in the dialog generation domain have used the concept of mutual information to design loss functions or scoring mechanisms to improve specificity of the generated responses (Li et al., 2016; Yoo et al., 2020). These works predominantly used MI either as a regularizer, along with cross entropy loss, or as a scoring function for ranking generated responses in a post-processing step. In the next section, we derive our pretraining loss function DMI for conversational texts from an information-theoretic perspective.

3 Discourse Mutual Information

We define Discourse Mutual Information (DMI) as the mutual information[2] between two random variables representing two different segments within the same discourse. This is a general concept that can be applied to any form of discourse, no matter the domain or type of signal. In this paper, we focus on dialog type discourses and representation learning for conversational texts. We define two random variables for the contexts (C) and responses (R) that jointly construct a valid conversation. Conversations between humans represent samples from the joint distribution P_{CR} of C and R. We pose the following learning problem, *"learn continuous representations for the textual random variables C and R such that the true mutual information between C and R can be closely estimated."*

In the remainder of this section we show that, if the lower bound on MI estimated by some representations of context and response is close to the true value, the representation of the context would be as predictive of the response as the natural language form itself. Existing generative training objectives as used in DialoGPT or Blenderbot are extremely focused on predicting target response only. Per-word cross-entropy loss, used for training these models, fails to take into account the inherent uncertainty in the context-to-response generation function. Adapting context representations so as to predict the target responses optimally, helps our proposed DMI-based models learn better dialog representations applicable to a versatile set of dialog understanding tasks.

---

[2] Mutual Information between two random variables is defined as the reduction in uncertainty/entropy of one of the random variables by having knowledge about the value of the other random variable. Mathematically, this is written as $I(X;Y) = H(X) - H(X|Y) = H(Y) - H(Y|X)$.

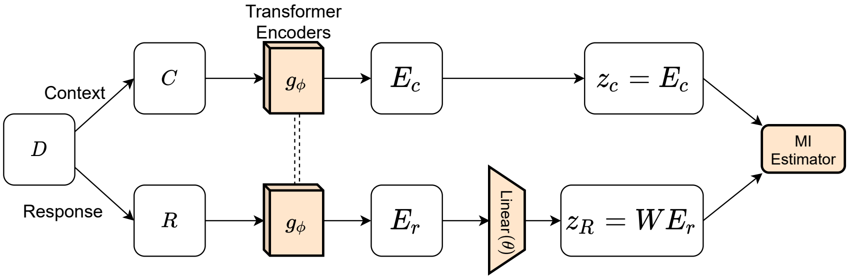

Figure 2: Base Pretraining Architecture for DMI. In our implementations of the model, f_ϕ denotes the transformer (Vaswani et al., 2017) based encoders. Context and response encoders share all parameters for efficient learning. d denotes sample dialogs from the training dataset.

Objective Function Formulation Let E_c and E_r be the representations[3] for C and R based on some encoder. Using the data processing inequality from Information theory (Cover, 1999), we have

$$I(C;R) \geq I(E_c;E_r) \tag{1}$$

This tells us that MI between any encoded version of C and R will always be less or equal than the true mutual information. The equality will hold if E_c and E_r are both fully-invertible encoding processes (as opposed to representations which are lossy or compressive, and inversion is thus not possible). However, neural networks generally embed the data points in a low dimensional manifold by learning robust features that can represent the data points efficiently. Because of this, neural representations are usually not invertible.[4] Now, the exact computation of MI is not possible for continuous-valued random variables. In recent years, various variational lower bounds have been proposed for estimating MI between continuous-valued random variables. Including the MI estimator ($\hat{I}_\theta$), the overall relation becomes

$$I(C;R) \geq I(E_c;E_r) \geq \hat{I}_\theta(E_c;E_r) \tag{2}$$

This leads us to the proposed learning objective DMI:

$$\max_{\theta,\phi} \hat{I}_\theta(E_c^{(\phi)};E_r^{(\phi)}) \tag{3}$$

where $\hat{I}_\theta(E_c;E_r)$ is a variational lower bound estimate of $I(E_c;E_r)$ (Equation 1) parametrized by θ and ϕ denotes the parameters of the encoder used for encoding C (or R) to E_c (or E_r).

Loss function For training our models, we minimize a loss function depending on the estimator being used.

$$\min_{\theta,\phi} \left[L_{\theta,\phi}(C,R) = -\hat{I}_{\theta,estimator}(E_c^{(\phi)}, E_r^{(\phi)}) \right]$$

We experimented with various MI estimators from literature, namely, MINE (Belghazi et al., 2018), InfoNCE (Oord et al., 2018), JSD (Hjelm et al., 2019) and SMILE (Song and Ermon, 2020). These MI estimators generally compute samples of E_c and E_r using C and R drawn from the joint distribution P_{CR}. Based on our preliminary experiments, we found that InfoNCE estimator produces better representations. The InfoNCE MI-estimate is computed as,

$$I(C;R) \geq \log N - L_N \tag{4}$$
$$L_N = -\frac{1}{2}\mathbb{E}_{P_{CR}}\left[\log \frac{e^{f(c,r)}}{\sum_{r' \in R} e^{f(c,r')}}\right]$$

where N denotes the batch size, and $f(c,r)$ is a scoring function for the $\langle c, r \rangle$ pair.

InfoNCE-S: The original InfoNCE formulation only considers negative samples for one of the random variables, but does not pose any constraint on which of the variables should be considered for negative sampling. As identifying the true response, from a pool of negative samples, would require different reasoning than identifying the true context out of a pool, we consider both these cases and create a symmetric version of the InfoNCE loss function. The final expression of this loss is given in Equation 5 and we refer to it as InfoNCE-S. This considerably improves the speed of training and convergence, and also gives a boost to downstream task performance.

---

[3] C, R, E_c, E_r in caps denote the random variables, whereas the lowercased versions c, r, e_c, e_r denote samples.

[4] One general exception to this is a neural model/representation overfitted on some training data. In such cases, the model may exactly memorize the input/output pairs.

$$L_N = -\frac{1}{2}\mathbb{E}_{P_{CR}}\left[\log \frac{e^{f(c,r)}}{\sum_{r'\in R} e^{f(c,r')}}\right] - \frac{1}{2}\mathbb{E}_{P_{CR}}\left[\log \frac{e^{f(c,r)}}{\sum_{c'\in C} e^{f(c',r)}}\right] \quad (5)$$

For other loss functions, more detailed discussion can be found in the Appendix.

Comparison with ConveRT (Henderson et al., 2020): There are a couple of differences between ConveRT's contrastive loss and our DMI objective. ConveRT models the problem as a response selection task and focuses on modeling cosine similarity between the context and the response. On the other hand, we propose a generic similarity computation function $f(c, r)$ in Eqn. 4 and 5. Another difference is in encoding the input. ConveRT splits the context into previous turns and current query, and encodes them independently. Our model encodes the entire context jointly and hence is capable of better learning the correlations between previous turns and current query.

4 DMI vs. Language Modeling Objectives

In this work, we focus on utilizing DMI for pretraining dialog representations incorporating strong discourse-level features. *But why should the DMI objective learn better discourse-level features than models trained on conversational data using MLM or LM objectives?* We can find the answer by looking at various LM-based objectives through the lens of InfoMax, as shown by Kong et al. (2020). They connected various pretraining objectives for natural language representations, including the ones used for training Skipgram, BERT and XLNet, to the InfoMax learning principle.

If we consider an input text T and a masking function M that returns a masked text $\tilde{T}$ and the masked word w, the MLM objective is equivalent to $\mathcal{L}_{MLM} = -\hat{I}_\theta(E^{(\phi)}(\tilde{T}), e_w)$ where, $E^{(\phi)}$ is the language encoder (e.g., a Transformer encoder) and e_w is the embedding of the token w. Similarly, in the case of auto-regressive LMs like GPT-2, the InfoMax objective equivalent to the loss is $\mathcal{L}_{autoLM} = -\hat{I}_\theta(E^{(\phi)}(T_{1:t-1}), e_{T_t})$, where $T_{1:t-1}$ is the input sequence till $t-1^{th}$ token and T_t is the t^{th} token.

Compared to these LM objectives, DMI focuses on optimizing $I(E_c, E_r)$, where c and r are two structural components from the discourse with designated roles. This enables DMI to discover more important features at the discourse level.

5 Experiments

5.1 Architecture

The exact encoder architecture and the pretraining pipeline has been shown in Figure 2. We use a dual encoder architecture for encoding the contexts and responses separately. We observe that sharing parameters between the two encoders leads to a more efficient learning process and faster convergence. We use vanilla transformer-based encoders[5] (Vaswani et al., 2017) for encoding the natural language inputs. The first tokens for both context and response sequences are the special [CLS] tokens whose contextual embeddings from the encoder are used as the context or response representations. The utterances in the context are delimited by another special token [EOU] (for end-of-utterance). We construct the context using as many utterances from the dialog history as possible up to a maximum of 300 subword tokens. We use the WordPiece tokenizer from BERT for tokenizing the input texts, with a vocabulary size of 30,522.

The scoring function $f(c, r)$ in Eqs. 4 and 5 is implemented using a Bilinear dot product between the context and response representations: $f(c, r) = e_c^T W e_r$ where, W is a square weight matrix trained along with other parameters in the model. This function can take any real value, positive or negative, thus allowing the $\hat{I}_\theta(E_C^{(\phi)}; E_R^{(\phi)})$ function to take any positive real value. While any complicated function with that range could be chosen, we chose this as a simple formulation satisfying the range constraint and left most of the learning to the transformer and the projection matrix W.

5.2 Model Variants

We train three different scales of the DMI model: **DMI_Small** with 6 layers, **DMI_Medium** with 8 layers, and **DMI_Base** with 12 layers. All configurations use 12 attention heads and 768-dimensional embeddings. DMI_Small is initialized with *"google/bert_uncased_L-6_H-768_A-12"*[6], DMI_Medium is initialized with *"google/bert_uncased_L-8_H-768_A-12"*

---

[5] We implemented all models and experiments using the PyTorch and Huggingface libraries.

[6] These pretrained model tags are from the Huggingface model repository.

and DMI_Base is initialized by weights from *"RoBERTa-base"* pretrained checkpoint, and further pretrained on the pretraining dataset (see §5.4). All of these models are trained using the InfoNCE-S estimator, unless specified otherwise.

5.3 Hyper-parameter Settings

We use Adam optimizer with a linear learning rate schedule for training both the models. Learning rate is first linearly increased to a max value of 5×10^{-5} during the warm-up phase (first 1000 steps). Following this, in the remaining training period, learning rate is linearly decayed down back to zero. Before training DMI_Base, we reset the parameters of the 12th self-attention layer, and it is trained again from scratch along with the weight matrix W using our DMI objective. The embedding layer and initial 11 self-attention layers of the RoBERTa-base encoder are finetuned at a slower learning rate (5×10^{-6}) during our pretraining phase.

As the mutual information value obtained by the InfoNCE loss is upper bounded by $\log(N)$, N being the batch size, we try to keep the value of N as large as possible. Both 8 and 12-layer models are trained on 4-GPU (4x32 GB V100s) systems with overall batch size of 480 and 384, respectively[7]. All the trained models will be publicly shared upon publication.

5.4 Pretraining Dataset

We pretrained all our models using the Reddit corpus (**Reddit-727M conversational-data**) released by Henderson et al., 2019. We ran the scripts released by the authors to recreate the dataset of 727M English conversations. Out of these 727M conversations, we utilize around 7.5% to 10% of the dataset to train our models, after which the validation loss generally saturates. In the rest of this paper, we will refer to this dataset as **rMax**, in short.

Dialog Unrolling for Pretraining For training our models, we need samples of context-response (CR) pairs. Each dialog is unrolled to create context-response pairs with each utterance in the dialog as a response, except the first one. Hence, for each dialog $D = \{U_1, U_2, \ldots, U_T\}$, we generate the following set of samples $S = \{(\mathcal{C}_t : U_1, \ldots, U_{t-1}; \mathcal{R}_t : U_t) : t \in [2, T]\}$. If we process the full rMax dataset, this leads to, approximately, 2.7B CR pairs.

5.5 MI Estimation

During pretraining, we compare the checkpoints from different epochs and across hyperparameter settings in terms of the bits of mutual information extracted by the trained representation on an unseen set of dialogs. This is calculated as $MI_{valid} = \log(N) - L_N$ (see §3 for more details). As per the Information Bottleneck theory (Tishby et al., 2000), the mutual information learned between the two observed random variables can be factorized into two components, namely, predictive and redundant information. Predictive information generally identifies whether the features learned by the representation are useful for a downstream task. The redundant information is caused by features that do not help in any downstream tasks. Such features can exist due to noise or spurious correlation in the dataset, or even overfitting. Hence, we train our final models on a fraction of the rMax dataset but only for one epoch (i.e., we never repeat the samples) which removes any possibility of overfitting.

Predictive features identified based on a fixed set of downstream tasks (Tishby et al., 2000; Alemi et al., 2017) may not be a sufficient to assess other features learned in the training process. Since, ideally, we want to maximize the amount of predictive information in the representation, we compare the bits of MI on the training set against the bits of MI on an unseen validation set, as captured by the learned representation. To make sure that we do not assume anything about the domain or the conversation topics, we use the validation set of dialogs from the open-domain Daily Dialog dataset (Li et al., 2017).

5.6 Downstream Tasks

Instead of focusing on a single downstream task like many previous works on dialog representation learning, we consider a more versatile range of tasks to evaluate the learned representations from DMI or the baseline models. To find out whether a certain representation is effective for some downstream task, we evaluate in two setups: probe and finetune. In both cases, the pretrained model is used along with an MLP classifier of fixed complexity (Pimentel et al., 2020). In probing setup, we only train the parameters of the MLP classifier.

---

[7] Training time: A maximum of 2 weeks of training time was allowed for 8-layer and 12-layer models. Though, the training process saturates long before the maximum allowed time, and we evaluate our models based on checkpoints when the best validation scores are first obtained.

Task	Description	Train	Valid	Test	Metric
Banking77	Intent 77-class Classification	8,002	2,001	3,080	Accuracy
SWDA	Dialog Act 41-class Classification	213,543	56,729	4,514	Accuracy

Empathetic Intent	Emotion and Intent 44-class Classification	25,023	3,544	3,225	Accuracy

Table 2: Downstream task details. Adv.: Adversarial, Neg.: Negative

In finetuning setup, we also train the pretrained model parameters along with the MLP classifier parameters. We use the context and response representations from our models as the input to the MLP classifier.

For downstream tasks, we have two reasoning tasks based on the MuTual dataset (Cui et al., 2020), three classification tasks based on conversational intent detection (Casanueva et al., 2020), emotion detection (Welivita and Pu, 2020) and act classification (Stolcke et al., 1998), and four dialog evaluation tasks based on the DailyDialog++ dataset (DD++, Sai et al., 2020)[8]. Table 2 shows dataset details and metrics for these nine tasks. Both MuTual and DailyDialog++ datasets have an adversarial configuration for the respective tasks, which allows us to assess each of the evaluated models in adversarial settings also.

6 Results and Discussions

6.1 Pretraining DMI based Representations

During pretraining, we used "Validation MI" to evaluate model checkpoints. As the goal of our models is to learn a representation that captures maximum MI between the context and the response texts, this metric tracks how well the learned representation captures the mutual information between contexts and responses of unseen dialogs.

We use the validation split from Daily Dialog dataset as our validation set for evaluation the model during pretraining. It is not specific to a domain and, hence, covers a versatile range of topics. This set comprises 1,000 full conversations between two persons which on unrolling leads to 7,069 context-response (CR) pairs. We illustrate the variation in validation-MI metric against training steps in Fig. 3 in the Appendix.

6.2 Comparison of Representations on Downstream Task Performance

In this set of experiments, we probe/finetune the DMI models with various downstream tasks that require knowledge of many different types of dialog-understanding features. The results of our probing and finetuning experiments are shown in Table 3.

We have used two types of models as our baselines: generic pretrained models and dialog-specific pretrained models. RoBERTa, BERT, T5 (Raffel et al., 2019), GPT-2 are all trained on large corpora of generic web-crawled English text. But, since these models were not specifically pretrained on any dialog corpus, they may suffer from poor performance on certain dialog understanding tasks. Hence, we consider DialoGPT[9], DialogRPT, DEB and ConveRT models, which were trained on conversational data. For DialogRPT, we used "human-vs-rand" checkpoint released by authors. All models are 12-layer except Blender_Small (8 layers), ConveRT (6 layers), DialogRPT (24 layers) and DMI_Medium (8 layers). We used the publicly available model checkpoints for all baselines, wherever possible. The ConveRT model's checkpoint has been removed from Github[10] by its authors. Hence, it was only possible for us to MLP-probe the representations, without finetuning of the model, based on a cached version released by another user under a valid license[11]. Pretrained checkpoints for Meena, ContextPretrain and ConvFiT are not available, and hence we do not compare with them.

6.2.1 Results in Probing Setup

We observe that, on average, DEB and ConveRT have good performance among the baselines. How-

---

[8] Note that DailyDialog++ is different from DailyDialog.

[9] DialoGPT and DEB are based on GPT-2 and BERT models and were further pretrained on conversations from Reddit. They use the original loss functions of GPT-2/BERT.

Table 4: Ablation study results for the finetune setup for our base model on 9 downstream tasks. "-RoB" → No RoBERTa initialization. "-Sym" → Training with non-symmetric version of InfoNCE. (DD++: DailyDialog++, B77: Banking77 task, R@k: Recall at k, MRR: Mean reciprocal rank).

ever, the RoBERTa model outperforms all other baselines on the MuTual task by a significant margin. In the MuTual Plus task, the DEB model outperforms other models in the R@1 and MRR metrics. ConveRT performs the best among all baselines on the other tasks. ConveRT's loss function is also contrastive in nature and is similar to ours. This explains the model's generally high strength across the tasks among all the baselines.

Our DMI_Base beats ConveRT on all the tasks, and DMI_Medium beats the baseline on 7 out of 9 tasks. We believe DD++ tasks to be the most demanding ones with respect to context-level understanding. Here, all non-dialog baselines have a weaker performance, with DEB and ConveRT being the best of the bunch. These are also the tasks where our models excel the most, with both DMI_Medium and DMI_Base beating all baselines with strong margins. DD++/cross is the most difficult among all four DD++ tasks. Here, the model is trained on random negative samples and tested on a dataset with human-curated adversarial negatives. Our DMI_Base beats the best baseline on DD++/cross by 8.54 points. This shows the superior quality of context representations from our models.

6.2.2 Results in Finetuning Setup

In the finetuning setup, on average, RoBERTa and DialogRPT have good performance among the baselines. DialogRPT performs well for DD++ tasks while Blender works well for the MuTual task. For all other tasks, RoBERTa is the best baseline, even outperforming models especially trained for dialog tasks (like DialoGPT).

Similar to the probe setup, DMI_Base beats baseline methods by significant margins. In general, finetune results are better than probe results across all models, as expected.

Our large-scale RoBERTa-initialized DMI_Base model outperforms the best baseline for all tasks, by a considerable margin. Additionally, our DMI-based models are able to perform well uniformly across all tasks, unlike even baselines like DialoGPT, DialogRPT and Blenderbot models which are explicitly trained on dialog data. This makes DMI the best overall model for dialog related tasks. Across multiple tasks, we show qualitative examples where our proposed DMI-based models provide accurate results, in the Appendix.

6.3 Ablations

We evaluate the importance of using RoBERTa based pretraining as well as the symmetric version of the InfoNCE loss in Table 4. We observe that RoBERTa based pretraining helps significantly across all tasks. The symmetric InfoNCE improves performance for SWDA and MuTual Plus tasks.

7 Conclusions and Future work

In this paper, we proposed the concept of Discourse Mutual Information (DMI) which is better suited for learning dialog-specific features in a self-supervised manner. Using the InfoMax principle we formulated a pretraining method for dialog-specific representation learning. Across 9 downstream dialog understanding tasks, our 12-layer model outperforms state-of-the-art methods. Further, we showed that on most of these tasks, even our 8-layer model outperforms standard 12-layer pretrained models. These experiments show the potential of the proposed DMI objective towards building dialog understanding models. We will make the code and pretrained model checkpoints available on request, instructions can be found here https://bsantraigi.github.io/DMI. Although we experimented only with dialog modeling in this paper, we believe that the proposed DMI objective is generic enough to be applied to any type of discourse in any domain. In the future, we would like to explore how to harness DMI representations for generative conversation modeling.

9 Ethical considerations

Like many other pretrained language representation models, the proposed model may also have learned patterns associated with exposure bias. Interpretability associated with the output is rather limited, hence users should use the outputs carefully. The proposed model ranks possible response candidates, and does not filter out any "problematic" candidates. Thus, for applications, where candidate responses could be problematic, (e.g., offensive, hateful, abusive, etc.), users should carefully filter them out before providing them as input to our model.

A Mutual Information Estimators

In this paper, we experiment with various different MI estimators, and found InfoNCE-S to be the best (both in terms of accuracy as well as training speed). The mathematical formulation of these estimators is provided below.

1. InfoNCE was proposed by Oord et al. (2018). It connects to the mutual information value $I(X;Y)$ as,

$$I(X;Y) \geq \log(N) - L_N$$
$$L_N = -\mathbb{E}_{P_{XY}}\left[\log \frac{e^{f(x,y)}}{\sum_{y' \in Y} e^{f(x,y')}}\right]$$

2. MINE (Belghazi et al., 2018)

$$I(X;Y) \geq sup_{\theta \in \Theta}[I_\theta^{(MINE)}(X;Y) = \mathbb{E}_{P_{XY}}[T(x,y)] - \log \mathbb{E}_{P_X \times P_Y}[e^{T(x,y)}]]$$

3. JSD (Hjelm et al., 2019)

$$I_\theta^{(JSD)}(X;Y) = \mathbb{E}_{P_{XY}}[-sp(-T(x,y))] - \mathbb{E}_{P_X \times P_Y}[sp(T(x,y))]$$

4. SMILE (Song and Ermon, 2020)

$$I_\theta^{(smile)}(X;Y) = \mathbb{E}_{P_{XY}}[T(x,y)] - \log \mathbb{E}_{P_X \times P_Y}[clip(e^{T(x,y)}, e^{-\tau}, e^{\tau})]$$

Use of the InfoMax objective for self-supervised learning has been more prevalent in the computer vision domain than in NLP. Although as Kong et al. (2020) have previously shown, many existing loss functions used for training NLP models can be derived directly from the InfoMax framework. Kong et al. (2020) had only focused on various language model objectives that focus on words given the surrounding context. The authors showed that this objective translates to maximizing mutual information between the context and the missing word within the context.

In dialog domain also, InfoMax-equivalent loss functions have been used. First, Henderson et al. (2020) used contrastive formulation of the response selection task as a pretraining objective for dialog representation. Other prior works on response selection models often used a binary-cross entropy loss for training. Both these loss functions are actually equivalent to various lower bound estimators for mutual information. In the QAInfoMax model (Yeh and Chen, 2019), the authors used the DeepInfoMax loss function (Hjelm et al., 2019) as a regularizer and showed that representations learned with or in-presence of an InfoMax regularizer are more resilient to adversarial attacks while maintaining the same level of task performance. We also observe the same effect in our DD++/cross experiments. This is because of the self-supervised yet task-specific nature of the loss function.

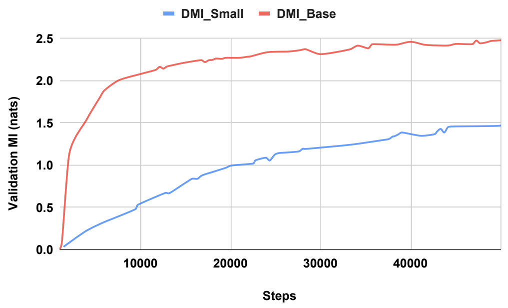

Figure 3: Validation-MI profile during pretraining

B Response Retrieval Experiment

We wanted to investigate if the proposed model can rank good responses higher compared to more generic/bland ones. Hence to test against an extreme setting we simulate a response selection task for a very large pool using the test set of Daily Dialog (Li et al., 2017) dataset. We took all the ~7000 responses from test set of the daily dialog dataset as the response pool. Next, for a few randomly selected context examples, we illustrate the top two ranked as well as ground truth responses for two full conversations in Tables 5 and 6. Of course, the ground truth response was removed from the pool for each context. The ranking of responses were done using the $f(c, r)$ function from the trained DMI_Base model. From the examples of response selection, we can observe that the model is able to both avoid blend responses and select responses that are relevant to the current context even from such a large pool. This shows the usefulness of dialog specific pretrained representation trained using the DMI objective.

C Prediction Samples and Error Analysis

In Table 7, we show sample predictions from the DailyDialog++/cross task (Sai et al., 2020). As DialoGPT has the best performance in the probe setup, on this task among the baselines, we choose it for error analysis. We randomly sampled 11 instances where the DialoGPT model made a mistake and observed the behavior of our DMI_Base model on these samples. We see that our model correctly predicts for all 6 out of 6 negative samples and out of the 5 positive samples DMI_Base predicts the label of 2 samples correctly (overall 8/11 correct predictions by our model). This shows that our model has a better understanding of the context and response inputs, which makes it robust against the adversarial negative samples. As can be seen in samples 2, 3, 5 and 6, the incorrect predictions by the DialoGPT model might have been caused by presence of common or similar meaning tokens (*cook, food; million; long; employee*) between context and response. This means that DialoGPT often relies on weak token-based cues for prediction.

For error analysis on the Empathetic-Intent (E-Intent) task (Welivita and Pu, 2020), we chose the ConveRT model as the baseline to compare against predictions from our DMI_Base model. First, we randomly select 10 samples from the test set of the E-Intent task where the baseline ConveRT model makes a mistake. Then the predictions from the DMI_Base model are observed on these 10 samples. The input utterances, true labels and the predictions made by the model are shown in Table 8. Out of these 10 samples, DMI_Base is able to predict the labels for 6 instances correctly. We notice that though sample inputs often contain more than one emotion, the one denoted by the gold label is generally the primary one. Our model is able to capture this emotion correctly more often than the baseline, with such mixed-emotion samples.

Fig. 4 shows the confusion matrix for our DMI_Base model for the Empathetic-Intent task. The accuracy is highest for afraid, acknowledging and questioning classes (each above 95%). Some of the most confusing pairs of classes are (annoyed, wishing), (anxious, apprehensive), (caring, confident), (content, grateful), (content, lonely).

Dialog	Rank-1 Response	Rank-2 Response
S1: Hey man , you wanna buy some weed ?	Yes , smoking or non-smoking ?	Sure , what ' s up ?
S2: Some what ?	My cigarettes .	Come on man ! I even got dope and acid ! Try some !
S1: Weed ! You know ? Pot , Ganja , Mary Jane some chronic !	I'm sorry , Mrs . Lin . We don't allow smoking in the office .	Ha ! That's right . You used to smoke . I forgot !
S2: Oh , umm , no thanks .	Come on man ! I even got dope and acid ! Try some !	Come on , you can at least try a little , besides your cigarette .
S1: I also have blow if you prefer to do a few lines .	No , thanks . Oh , yes , could I have some juice for the mini bar ?	No , thanks . I ' Ve had enough . I'll have my bill , please .
S2: No , I am ok , really .	Great ! Would you prefer smoking or non-smoking ?	Come on , you can at least try a little , besides your cigarette .
S1: Come on man ! I even got dope and acid ! Try some !	I will , but let's go to the disco after dinner .	No , thanks . I've had more than enough.In fact , I must be running along .
S2: Do you really have all of these drugs ? Where do you get them from ?	I found them at JC Pennies .	They are my personal effects .
S1: I got my connections ! Just tell me what you want and I ' ll even give you one ounce for free .	Hmm ... I'll tell you what . I'll lend you four thousand dollars , but you have to pay me back next week .	No , thanks . Oh , yes , could I have some juice for the mini bar ?
S2: Sounds good ! Let ' s see , I want .	Here you go.On any other day , it would cost me a fortune , but it ' s on special offer today .	All right , Maria . I ' ll give you until tomorrow at 4:00 to produce a satisfactory piece of work , but otherwise , you ' ll have to re-do it .
S1: Yeah ?	But of course ! Well , it ' s been great talking to you , but I have to get going .	Good . I was thinking that I ' d like to invite you to watch a movie . I can meet you at the cinema gate .

Table 5: Retrieval Example 1: Top two ranked responses from a large pool, as well as ground truth response for a conversation. Note that every line corresponds to one utterance in the conversation either from speaker S1 or speaker S2. **How to read the table:** For any context (all entries in first column upto any row), the ground truth response can be automatically obtained from the immediate next entry in first column. The response selected by the model in any cell $(t, 1 \text{ or } 2)$ is for the true context from row 1 to row t in the first column.

Dialog	Rank-1 Response	Rank-2 Response
S1: Could I have my bill , please ?	Sure . Here is your receipt .	Sure . Your cash back is $ 13 . And we'll bring out your fries in two minutes .
S2: Certainly , sir .	Thanks . Now can I make the full deposit ?	Thank you ! Would you like an aisle seat or a window seat ?
S1: I'm afraid there's been a mistake .	I am really sorry too , maybe I can give you a call sometime .	Oh , I'm sorry.However , if you could help me out , I'll double the pay for the hours worked .
S2: I'm sorry , sir . What seems to be the trouble ?	Not much . I had to pay an unexpected bill , so I needed the money back .	Oh , nothing special . I'm just a bit tired .
S1: I believe you have charged me twice for the same thing . Look , the figure of 6.5 dollar appears here , then again here .	One moment , please , sir . ... Here's your bill . Would you like to check and see if the amount is correct ?	Sir , I deleted the $ 10 , but I had to add a $ 2 service charge to your bill.

Abstract

Adversarial texts help explore vulnerabilities in language models, improve model robustness, and explain their working mechanisms. However, existing word-level attack methods trap in a one-to-one attack pattern, i.e., only a single word can be modified in one transformation round, and they ignore the interactions between several consecutive words. In this paper, we propose **ValCAT**, a black-box attack framework that misleads the language model by applying variable-length contextualized transformations to the original text. Compared to word-level methods, ValCAT expands the basic units of perturbation from single words to spans composed of multiple consecutive words, enhancing the perturbation capability. Experiments show that our method outperforms state-of-the-art methods in terms of attack success rate, perplexity, and semantic similarity on several classification tasks and inference tasks. The comprehensive human evaluation demonstrates that ValCAT has a significant advantage in ensuring the fluency of the adversarial examples and achieves better semantic consistency. We release the code at `https://github.com/linerxliner/ValCAT`.

1 Introduction

Deep learning is successfully applied in a variety of fields, while previous works have found that neural network models are vulnerable to well-constructed adversarial examples (Goodfellow et al., 2015; Kurakin et al., 2017). In general, adversarial examples are constructed by adding imperceptible perturbations to the benign inputs, which can mislead the victim model. And exploring adversarial examples is essential to improving the reliability and robustness of neural network models. Compared to the long-studied image domain, generating adversarial examples on texts is more difficult because texts are discrete, where small changes can alter the original meaning and make it unnatural (Xu et al., 2020; Zhang et al., 2020).

AG News (Business)	Lucent milestone: A profit Lucent Technologies yesterday posted higher fiscal fourth-quarter earnings, helping lift the telecommunications equipment maker to its first profitable year since 2000.

MNLI (Neutral)	*Premise*: He caught a grip on himself, fighting the fantasies of his mind, and took another breath of air. *Hypothesis*: The air tasted like molten metal - the taste of blood.
BERT-Attack (Contradiction)	*Hypothesis*: The air tasted through boiling armor - the taste of betrayal.
ValCAT (Contradiction)	*Hypothesis*: The air tasted [nothing like air] - the taste of blood.

Table 1: Instances of adversarial examples. The first is the original text, followed by adversarial examples generated by ValCAT and BERT-Attack. Blue indicates replace operation, and orange indicates insert operation. For ValCAT, words in a bracket are a span perturbed as a whole in one transformation round. The decision results of the victim model are in parentheses.

Most of the sentence-level attack methods (Zhao et al., 2018; Han et al., 2020; Xu et al., 2021) generate adversarial examples by perturbing the latent representation of the text, and the text quality is thus relatively difficult to control. Word-level attack methods (Samanta and Mehta, 2017; Zhang et al., 2019) have received much attention in the recent past. Several previous works explore the perturbation based only on the properties of individual

words, with the help of inflectional morphology (Tan et al., 2020), counter-fitting word vectors (Jin et al., 2020), sememe (Zang et al., 2020), etc. The encoder language models, like BERT, give us new insights of incorporating context information into the generation of adversarial candidates in transformation (Li et al., 2020; Garg and Ramakrishnan, 2020; Li et al., 2021). However, the basic units of perturbation in these works are still single words, which limits the scope of the perturbation and overlooks the interactions between words, as examples shown in Table 1. To address this issue, two research questions are raised: 1) *How to take into account interactions between words in vulnerable position discovery?* 2) *How to perturb a vulnerable position with variable-length contextualized transformations?*

We propose ValCAT, which generates high-quality adversarial examples by applying variable-length contextualized transformations to the original text. Table 1 demonstrates some sample cases. Specifically, given a benign text, we enumerate all possible spans by traversing the text with sliding windows of different lengths to evaluate the importance of the spans. We utilize two operations, REPLACE and INSERT, to apply adversarial spans generated by the encoder-decoder language model to the text. The encoder can fill a mask token with a single word, while the decoder can predict a sequence after a prompt. Therefore, joint use of encoder and decoder enables ValCAT to generate variable-length contextualized spans at the arbitrary vulnerable position.

Furthermore, we evaluate ValCAT by attacking fine-tuned BERT on several classification tasks and inference tasks. Experiment results show that it outperforms other baseline methods in attack success rate, perplexity, and semantic similarity. In particular, we observe that the variable-length feature can significantly reduce perplexity, which is less than 50% compared to the best baseline. As for the efficiency, although the multi-word attack pattern perturbs more words than the one-to-one attack pattern in one transformation, it just requires fewer rounds toward success. In general results, it is in a tolerable perturbation rate, and ValCAT is even lower than baselines on some of the inference datasets. A comprehensive human evaluation further verifies that ValCAT has significant advantages in readability and semantic consistency. The main contributions of this paper are summarized as follows:

- ValCAT is the first variable-length adversarial attack method against language models, i.e., extending the basic units of perturbation from single words to spans.
- Our work proposes the *Sliding Window* for vulnerable-position discovery and the variable-length contextualized transformation which fully exploits the advantage of encoder-decoder language models.
- Automatic evaluation and human evaluation demonstrate the excellent attack effectiveness of ValCAT and the superior quality of our generated adversarial examples.

2 ValCAT

To further improve the attack effectiveness and simultaneously improve the readability and semantic similarity of the adversarial examples, we propose **ValCAT**, which can generate high-quality adversarial text by applying variable-length contextualized transformations with the encoder-decoder language model.

Problem Formalization Given a victim model $F : X \rightarrow Y$ and a text $x = w_1 w_2 ... w_{n-1} w_n$ that can be correctly classified by F, the attack goal is to generate an adversarial text $\tilde{x}$, which can confuse the model prediction, i.e. $F(\tilde{x}) \neq F(x)$. A consecutive word sequence with length l can be denoted as a span $s_{i:i+l}$. In the soft-label black-box setting, the attacker only has access to the logit output $P(y|x)$. The architecture, parameters, and configurations of F are unknown to the attacker.

To achieve human imperceptibility, the attacker should minimize textual perturbations and maintain semantic consistency.

ValCAT The attack workflow of ValCAT is illustrated in Figure 1. To locate the most-vulnerable positions for the perturbations in each iteration, ValCAT first rank the spans in x according to their importance with sliding windows of length 1 to `MAX`, as lines 2-7 in Algorithm 1. Based on the sorted span ranking R, ValCAT uses the encoder-decoder language model to generate variable-length contextualized spans, as lines 8-13. Using two transformation operations in line 9, REPLACE and INSERT, we obtain a adversarial text candidate set T. If some of the candidates can mislead the victim model, ValCAT declares the one with the highest cosine similarity with the original text as the final successful result, as line 11. However, if no candidate successes at this iteration, we select the one with the highest negative impact to the victim model as the basic text for the next iteration, as line 13. Note that, if a span in the ranking R has been selected as the target span, the subsequent spans which are overlapped with it will be removed from the ranking to avoid multiple modifications on one word. The attack ends when the successful example appears, or when the limit of the perturbation constraints (See Section 3.1) reached. The latter case is considered a final failure. Below we elaborate on the two stages of the attack in Section 2.1 and Section 2.2 in detail.

2.1 Important Span Ranking

Echoing the observation to prior works (Jin et al., 2020; Li et al., 2020), only some key words act as vulnerable positions for the victim model F. Perturbations over these words can be most beneficial in crafting adversarial examples. Considering the interactions between words, ValCAT performs transformations on several important spans instead of single words.

Given a text x, we evaluate the importance of a span s within x according to how removing the span can impact the model prediction in the black-box setting. Formally, we define the decision difference of x and $\tilde{x}$ on the class y as:

$$D_y(x,\tilde{x}) = \begin{cases} d_y(x,\tilde{x}), & if \quad y = \tilde{y} \\ d_y(x,\tilde{x}) + d_{\tilde{y}}(\tilde{x},x), & if \quad y \neq \tilde{y} \end{cases}$$

where y and $\tilde{y}$ are the predictions of x and $\tilde{x}$, respectively, and $d_y(x,\tilde{x}) = P(y|x) - P(y|\tilde{x})$ is the difference of the probabilities that x and $\tilde{x}$ are classified as y. Let $\tilde{x}_s$ denote the text of replacing span s by a unknown token [unk]. The importance score of s with respect to x is $IP_x(s) = D_y(x,\tilde{x}_s)$.

To compare spans of different lengths, we propose the *Sliding Windows* to measure the importance of variable-length spans. Specifically, we apply multiple sliding windows of the corresponding sizes, which traverse the text from left to right. Each span bounded by a sliding window is sequentially removed from the original text for its importance calculation. Finally, we obtain a set of triples each consisting of the start index, the span length, and the importance score of the span. We rank the triples according to the importance score in descending order.

Algorithm 1: VALCAT

```
Input: Victim Model $F$; Text $x$; Label $y$;
       Maximum length of sliding window MAX

14 return NULL
```

2.2 Variable-Length Contextualized Transformations

Based on the ranking of triples, ValCAT performs perturbations in a sequential manner, where each step a vulnerable position in the original text is replaced by or inserted with a set of adversarial spans generated by the encoder-decoder language model. The variable-length feature of the adversarial spans renders the language model enough space to produce more contextually appropriate candidates to improve fluency. Meanwhile, our variable-length method expands the perturbation units, for it supports multi-word transformations while is compatible with traditional one-to-one transformations. Compared with previous methods, this further improves the attack success rate under the same perturbation constraints. Below we elaborate on the details of the adversarial span generation.

Adversarial Span Generation To generate adversarial candidates of each target span, ValCAT applies the encoder-decoder language model to fill the mask token with a set of spans of varying lengths. First, the encoder language model owns the capability of predicting the masked tokens, which is trained with the masked language modeling (MLM) objective. However, the encoder fills one mask token with only one suitable word rather than multiple words. The ability of the decoder could fill the gap of the single word since the decoder is trained with a causal language modeling (CLM) which can predict the sequence after a prompt. But, the decoder can only generate sequences at the end of the text. Hence, ValCAT combined these two models with their complementary advantages, with the predictive capability at arbitrary positions of encoder and variable-length generation of a decoder. With the candidate adversarial spans for target span, ValCAT performs two kinds of transformation operations, REPLACE and INSERT, to generate the adversarial examples for consideration.

Replace The REPLACE operation substitutes the target span $s_{i:i+l} = w_i ... w_{i+l-1}$ with another span s. For example, the target span "*awesome*" in the text "This place is awesome." could be replaced by the adversarial span "*pretty good*". Specifically, we first replace a mask token $[\text{mask}]$ to $s_{i:i+l}$:

$$\tilde{x}^{[i:i+l]} = w_1 ... w_{i-1} [\text{mask}] w_{i+l} ... w_n,$$

and generate a set of contextualized spans of varying length, $\mathcal{S}$, to fill the mask token. The adversarial example is denoted as:

$$\tilde{x}_s^{[i:i+l]} = w_1 ... w_{i-1} \ s \ w_{i+l} ... w_n,$$

where $s \in \mathcal{S}$ is a adversarial span.

Since the language model is blind to the information of the target span, some of the generated adversarial spans may deviate from the original meaning to a large extent. To avoid this situation, we only leave the adversarial spans with a high degree of semantic similarity to the original span. Specifically, we use Universal Sentence Encoder (Cer et al., 2018) to restrict their cosine similarity. We also impose a limit on the perturbation rate (See Section 3.1). To prevent the text from being too long, we constrain the adversarial spans to be at most two words longer than the target span.

Insert The INSERT operation inserts a new span s in front of the target span $s_{i:i+l}$. For example, "I like this *quite interesting* movie.". Similar to the REPLACE operation, it inserts a mask token in front of the target span:

$$\tilde{x}^i = w_1 ... w_{i-1} [\text{mask}] [w_i ... w_{i+l-1}] w_{i+l} ... w_n,$$

and corresponds with the adversarial text $\tilde{x}_s^i = w_1 ... w_{i-1} \ s \ w_i ... w_n$. This operation also follows the same perturbation constraints, mentioned in Section 3.1.

3 Experiments

In this section, we evaluate ValCAT on two NLP tasks, text classification and natural language inference. To demonstrate the effectiveness of ValCAT in terms of fluency, grammaticality, and semantic consistency, following Li et al. 2021, we design and conduct a comprehensive human evaluation.

3.1 Implementation

Victim Model In this work, we choose fine-tuned BERT as the victim model for the all evaluation tasks. As BERT has achieved good results on a variety of NLU tasks and has been proven to be one of the most representative pre-trained transformers (Devlin et al., 2019).

Span Generation Model To obtain variable-length contextualized spans, we choose T5 (Raffel et al., 2020) as the generation model. T5 is a representative encoder-decoder language model that can predict the missing spans within a corrupted piece of text, benefiting from the fill-in-the-blank pre-training. Also, the large corpus C4 renders T5 rich prior knowledge to enable the diversity and the high quality of the generated spans.

Constraints To achieve human imperceptibility and semantic preservation of the adversarial example, we impose constraints on the word perturbation rate and semantic similarity, as defined in Section 3.3. Following previous practices (Jin et al., 2020; Li et al., 2021), we set the thresholds of these constraints respectively for each dataset, with details shown in Appendix A.

Table 2: Effectiveness of ValCAT in attack success rate (Suc), perplexity (PPL), semantic similarity (Sim), word perturbation rate (Pert), and grammar error (GErr). Bold font indicates the best performance for each metric. ↑ (↓) represents that the higher (lower) the better. The original PPL for each dataset is indicated in parentheses under its name. For the natural language inference task, the left side of the slash indicates the result of attacking premise (question) and the right side indicates the result of attacking hypothesis (sentence).

Settings and Computation Cost All results are derived from a single run since there is no randomness in our method. The maximum length of the sliding window is set as 3. In our implementation, we apply SpaCy (Honnibal and Montani, 2017) and NLTK (Loper and Bird, 2002) for text manipulation. We run ValCAT on Intel Xeon E5-2690 2.6GHz Processor with V100 GPU. Averagely it takes 34 secs to generate a successful adversarial example.

3.2 Datasets and Baselines

To investigate the effectiveness of ValCAT on different types of text, we evaluate it on several English datasets. We randomly sample 1000 instances from each of the following datasets: three for text classification, i.e., *AG News*, *Yelp Polarity*, and *IMDB*; and three for natural language inference, i.e., *SNLI*, *MNLI*, and *QNLI*, with detailed information shown in Appendix B. We compare ValCAT with several state-of-the-art word-level attack methods, i.e., *TextBugger*, *TextFooler*, and *BERT-Attack*. Details of these methods are shown in Appendix C. Note that, all the datasets and baselines are publicly available and are used following their usage specifications.

3.3 Automatic Evaluation

Metrics We evaluate the effectiveness of ValCAT based on the following metrics:

- *Attack success rate (Suc)*: is the percentage of adversarial examples successfully interfered with the victim model's prediction over the text dataset.
- *Perplexity (PPL)*: is an automatic metric to evaluate the probability of a text appearing in a natural corpus. So PPL can reflect the text's natural fluency, the lower the better. We use GPT-2 (Radford et al., 2019) for this calculation.

- *Semantic similarity (Sim)*: is the cosine similarity between the original text and adversarial text calculated by Universal Sentence Encoder (USE) embeddings (Cer et al., 2018).
- *Word perturbation rate (Pert)*: is the proportion of the modified words over the original text. To evaluate the perturbation rate on variable-length perturbations more accurately, we design separate calculations for these two transformation operations. For the REPLACE operation, the number of modifications is $max(l_t, l_a) - l_{LCS}$, where l_t, l_a, and l_{LCS} are the lengths of the target span, the adversarial span, and their longest-common-subsequence (LCS), respectively. For the INSERT operation, the number of modifications is the length of the inserted span.
- *Grammar error (GErr)*: is the incremental number of grammatical errors of the adversarial example relative to the original text. We use LanguageTool [1] to count the grammatical errors within a text.

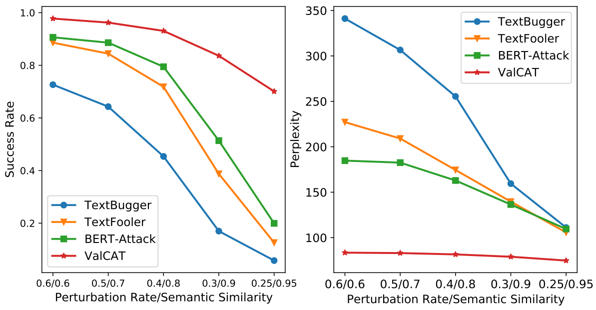

Figure 2: Success rate and perplexity of each attack method under the different constraints of word perturbation rate and semantic similarity.

Results The main experimental results are revealed in Table 2. ValCAT outperforms baselines on multiple datasets in both classification tasks and inference tasks. Compared with BERT-Attack, the best baseline method, ValCAT achieves higher attack success rates in all experiments, and the improvement range from 5.8% even to 27.0%. This is attributed to ValCAT's ability to apply variable-length contextualized transformations on spans at any position, which largely enriches the pattern of perturbations. In addition, ValCAT achieves the highest semantic similarity with the original text in all tasks. The perplexity of the adversarial example generated by ValCAT is far superior to that of the baselines. It is roughly only 50% of the perplexity of BERT-Attack and is almost consistent with the original text. This indicates that the adversarial example generated by ValCAT is with high fluency. The underlying reason is that multi-word transformations render the language model enough space to generate the adversarial spans with approximated distribution with natural language. At the same time, ValCAT reaches the lowest average increase in the number of grammatical errors on five out of nine attacks, with only a slight disadvantage on the natural language inference tasks.

In general, ValCAT generates adversarial examples that achieve more promising attacks and are more imperceptible to humans. Figure 2 shows the performance of ValCAT and baselines on the Yelp dataset under different constraint settings. As we can see, the success rate of ValCAT decays most slowly as the limits of perturbation rate and semantic similarity increase, still achieving a success rate of almost 70% under the strictest constraint. Moreover, ValCAT can maintain a low perplexity under any constraint, however, other attack methods have to sacrifice attack effect to maintain their fluency.

3.4 Human Evaluation

Design We evaluate the quality of the adversarial examples from three perspectives: readability (fluency and grammaticality), semantic similarity, and label consistency. The first two metrics are evaluated by ratings, while the third one lets the annotator categorize the texts into a set of labels. Five annotators with CET-4 certification performed the evaluation on AG News dataset. All annotators were informed and consented to the use of the annotation, and were paid with remuneration higher than the regional average. To construct the instances for human evaluation, we randomly select 100 samples from the dataset, whose adversarial examples generated by both ValCAT and BERT-Attack can mislead the victim model to make the same wrong classification decision among multiple classes. For the evaluation of fluency and grammaticality, each original text and its two adversarial examples are presented in one group in a shuffled order and the annotators are asked to rate them. For the evaluation of semantic similarity, given the original text, the judges need to separately evaluate its semantic similarity with the two adversarial examples presented in random order. The above two tasks ask the annotators to rate the text or the text pair from 1 to 5. In each questionnaire, we give

---

Dataset	Metric	ValCAT	Original	BERT-Attack
AG News	F&G	3.37	3.97	2.98
	Sim	3.92	-	3.41
	Acc	63.0	65.0	62.0

Table 3: Results of human evaluation in readability (fluency and grammaticality), semantic similarity, and label consistency (accuracy).

explicit criteria and clear examples for each grade. For the evaluation of label consistency, we mix all the original texts with the adversarial examples and let the annotators label the category of them, e.g., business or technology.

Results For the two rating tasks, we normalize the rates of the annotators and calculate the average score, while for the labeling task we take the majority vote as the final result. As shown in Table 3, ValCAT is rated with much higher fluency and grammaticality scores than BERT-Attack. Also, it achieves obviously higher semantic similarity. In terms of labeling accuracy, ValCAT slightly outperforms BERT-Attack, still indicating that ValCAT makes smaller changes to the meanings of the text from the aspect of human perception. All these results demonstrate the superior quality of the adversarial examples generated by ValCAT.

4 Analysis

4.1 Ablation Study

We evaluate different transformation strategies of ValCAT as in Table 4. *3-Many* results in the lowest perplexity, as it renders the language model more space to generate an appropriate span. It also requires the smallest number of queries, and we speculate the reason as it perturbs more words in a single transformation. For the same reason, *3-Many* is less likely to succeed since it's easier to reach the perturbation constraint. As expected, the combination of multiple types of REPLACE operations facilitates the attack success rate while increasing the number of queries. The INSERT operation achieves high semantic similarity while requiring a large number of queries. A comprehensive utility of all operations (i.e., ValCAT) achieves the highest success rate with the lowest perturbation rate, which fully demonstrates the advantages of the transformation diversity.

Algorithm	Suc↑	PPL↓	Sim↑	Pert↓	Query↓
ValCAT	**93.1**	81.6	0.950	**11.6**	673
1, 2, 3-Many	90.8	81.1	0.938	13.4	490
1, 2-Many	91.7	82.6	0.939	12.6	431
1-Many	87.9	84.4	0.933	12.0	340
2-Many	86.1	81.5	0.941	13.3	325
3-Many	80.7	**77.1**	0.938	16.0	**266**
Insert	86.4	86.9	**0.953**	14.4	799
BERT-Attack	79.5	162.8	0.881	14.1	449

Table 4: Results of ablation study. *n-Many* is a type of REPLACE operation, which means that a span of length n is replaced by an adversarial span.

4.2 Impact of Candidate Numbers

From the results under different numbers of candidate spans shown in Figure 3, we observe that the attack success rate is higher when there are more candidates. Since we greedily select the adversarial span with the greatest impact on the decision of the victim model, as the number of candidates increases, spans with low occurrence probability can be added to the text, making the perplexity higher. This is especially true for difficult-to-attack datasets like AG News.

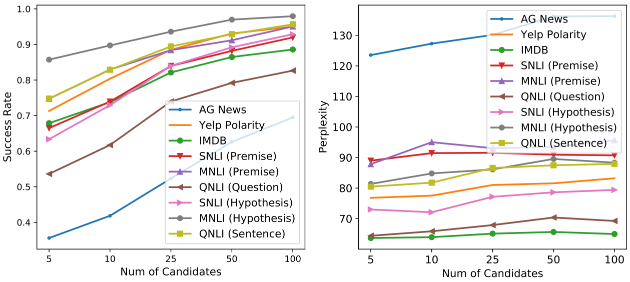

Figure 3: Success rate and perplexity of each dataset under different candidate numbers.

4.3 Properties of Transformations

We observe the properties of the transformations in the successful adversarial examples from three perspectives: type of operation, length of span, and POS (part-of-speech) of span. Averagely, 62% of the transformations in each example are REPLACE operations, and 38% are INSERT operations, indicating that REPLACE operations are more effective in most cases. As shown in Table 10, the replaced spans are most likely the longer ones, while the adversarial spans being applied are relatively short. Additionally, Table 11 shows that the adversarial spans of REPLACE operation share identical POS distribution with the replaced spans, which guarantees the fluency of the adversarial example. The INSERT operation tends to use adverbs and adjectives, which is consistent with the human intuition of inserting words into text.

4.4 Adversarial Training

We investigate how adversarial training can mitigate the adversarial attack, that is, the power of our adversarial examples for adversarial training as a general defense. We randomly sample 10,000 instances from the Yelp training dataset and apply ValCAT to generate adversarial examples. These adversarial examples and their intermediate results, approximately 60,000 texts, are then used to fine-tune the attacked BERT under the gold labels. After adversarial training, the accuracy of the victim model on the test dataset slightly decreases from 98.3% to 98.0%, which means that adversarial training does not affect the performance of the model on clean data. As shown in Table 5, the attack success rate of ValCAT drops by about 20%, while both the perturbation rate and the number of queries have significantly increased, indicating that the victim model is harder to attack after the adversarial training.

Algorithm	Victim	Atk Acc↓	Suc↑	Pert↓	Query↓
ValCAT	Original	6.8	93.1	11.6	673.3
	Adv Train	27.0	72.4	14.0	884.2

Table 5: Adversarial training results.

4.5 Generalization

We evaluate the generalization of ValCAT in two aspects: 1) attack on other victim models and 2) transferability.

Victim	Orig Acc	Atk Acc↓	Suc↑	PPL↓	Sim↑	Pert↓
BERT	98.3	6.8	93.1	81.6	0.950	11.6
RoBERTa	99.1	13.3	86.6	81.2	0.952	11.7
LSTM	95.3	0.7	99.3	78.5	0.961	9.2
wordCNN	95.4	1.1	98.8	78.9	0.957	10.0

Table 6: Results of ValCAT attacking RoBERTa, LSTM, and wordCNN.

Attack on Other Victim Models We try to attack other common language models on the Yelp dataset using ValCAT. Table 6 shows that LSTM and wordCNN, two traditional NLP models, are extremely vulnerable to ValCAT with an attack success rate of around 99%. Interestingly, RoBERTa shows better robustness, with a 6.5% decrease in attack success rate relative to BERT, which we speculate is due to its more optimized pre-training approach.

Transferability We evaluate the transferability of generated adversarial examples on the Yelp dataset. Specifically, we utilize successful adversarial examples generated by ValCAT targeting different victim models to attack other tested models. Results in Table 7 show that adversarial examples aimed at transformer models (BERT and RoBERTa) are more effective in attacking traditional NLP models (LSTM and wordCNN) than the opposite case.

	BERT	RoBERTa	LSTM	wordCNN
BERT	-	73.4	73.9	76.1
RoBERTa	68.9	-	72.8	74.2
LSTM	84.3	88.8	-	71.8
wordCNN	83.4	87.3	60.5	-

Table 7: Attacked accuracy used in the transferability analysis. Rows are target models used in generating adversarial examples, and columns are tested models applied the examples.

4.6 Limitation

ValCAT makes the best effort to improve the effectiveness of the attack, including the *Sliding Window* with a variable-length mechanism to discover vulnerable positions and multiple types of transformation operations. However, all these efforts result in a larger number of queries to the victim model, compared to existing word-level attack methods. According to the results of the automatic evaluation and human evaluation, such an increase in the computation expense is tolerable, considering the significant improvement in attack success rate and adversarial example quality. Furthermore, a simplified version of ValCAT, *1-Many* (See Table 4), outperforms the best baseline method in all aspects, including the number of queries.

Further, the encoder-decoder language models targeting the fill-in-the-blank-style denoising objectives cannot see the masked original spans during the training and inference. This limitation of encoder-decoder leaves improvement space of semantic similarity for ValCAT, i.e., establishing a direct semantic mapping between the generated span and the original span themselves in each transformation. We leave finding better ways of training to compensate for the invisibility of encoder-decoder as our future work.

5 Related Work

Textual adversarial attacks have been intensively studied (Wang et al., 2019; Zhang et al., 2020). Early on, the character-level attack methods (Ebrahimi et al., 2018; Gao et al., 2018; Li et al., 2019) are widely used, but they would destroy words and are very perceptible (Pruthi et al., 2019). Word-level attack methods are now in the spotlight, evolving from substitution based only on the properties of individual words themselves (Zang et al., 2020; Jin et al., 2020; Tan et al., 2020) to perturbing words by multiple strategies with knowledge of the context (Li et al., 2020; Garg and Ramakrishnan, 2020; Li et al., 2021). Although these existing works may enrich the transformation form with various operations like insertion, deletion, merging, etc., they still treat single words as basic units of each transformation. Some sentence-level works (Wang et al., 2020a; Wang et al., 2020b; Huang and Chang, 2021) generate adversarial examples by perturbing the latent representation of the original text, but they are slightly worse at controlling the text quality. Our work introduces the *Sliding Window* to rank important spans and generates variable-length contextualized spans by the encoder-decoder language model, enabling more effective adversarial attacks and higher-quality adversarial examples.

6 Conclusion

In this paper, we propose ValCAT, the first variable-length contextualized adversarial attack based on the encoder-decoder language model. ValCAT considers the interaction between words for the vulnerable-position discovery and expands the basic units of perturbation from single words to spans. Experimental results on several datasets demonstrate the effectiveness of our methods, which outperforms baselines in terms of attack success rate, perplexity, and semantic similarity. Our adversarial examples also have good transferability and help to improve robustness. A comprehensive human evaluation further verifies the high quality of the adversarial examples generated by ValCAT.

A Constraints

We impose constraints on the generating adversarial examples in terms of perturbation rate and semantic similarity, as shown in Table 8.

Dataset	Perturbation Rate	Semantic Similarity
AG News	0.4	0.8
Yelp Polarity	0.4	0.8
IMDB	0.3	0.9
SNLI	0.6	0.6
MNLI	0.6	0.6
QNLI	0.6	0.6

Table 8: Specific values of constraints of the perturbation rate and semantic similarity were used in the main experiments.

B Datasets

We employ three datasets for text classification and three datasets for natural language inference as described below. In our experiments, we randomly sample 1000 instances.

- *AG News*: a collection of news articles categorized into 4 types: World, Sports, Business, and Sci/Tech (Zhang et al., 2015).
- *Yelp Polarity*: positive and negative restaurant reviews collected from yelp (Zhang et al., 2015).
- *IMDB*: a dataset of movie reviews for binary sentiment classification (Maas et al., 2011).
- *SNLI*: a collection of human-written English sentence pairs (Bowman et al., 2015). Each sentence pair consists of a premise and a hypothesis, which is necessary to determine whether it is entailment, contradiction, or neutral.
- *MNLI*: a similar dataset to SNLI (Williams et al., 2018), but from a variety of genres.
- *QNLI*: a version of SQuAD which has been converted to a binary classification task (Wang et al., 2018).

C Baselines

We compare ValCAT with state-of-the-art word-level attack methods:

- *TextBugger*: an attack method compounded by five bug generation strategies (Li et al., 2019). Such strategies include character insertion, character deletion, character swapping, homograph character replacement, and synonym replacement.
- *TextFooler*: classical adversarial attack algorithm based on synonym substitution (Jin et al., 2020).

Candidate synonyms are the closest neighbors of the replaced word in the counter-fitting word embedding space. It limits the cosine semantic similarity and makes the POS consistent.

- *BERT-Attack*: a state-of-the-art contextualized attack method using BERT to fill mask tokens (Li et al., 2020). It serves as a representative of similar BERT-based algorithms, such as BAE (Garg and Ramakrishnan, 2020) and CLARE (Li et al., 2021).

D Performance of Encoder-Decoder Models

We present the results of generating adversarial spans by several language models in the T5 family in Table 9. $T5_{large}$ and $mT5_{base}$ take a longer time to generate adversarial spans due to their larger capacity. The higher perplexity of $T5v1.1_{base}$ is, we conjecture, resulted from its specifically different structure. In short, $T5_{base}$ is good enough for adversarial span generation.

Algorithm	Suc↑	PPL↓	Sim↑	Pert↓	GErr↓	Time↓
$T5_{base}$	93.1	81.6	0.950	**11.6**	0.11	**0.052**
$T5_{large}$	90.3	84.0	0.948	12.7	0.12	0.069
$T5v1.1_{base}$	92.3	101.8	0.946	12.4	0.36	0.055
$mT5_{base}$	**94.2**	84.6	**0.949**	12.3	**0.06**	0.070

Table 9: Performance of encoder-decoder language models belonging to the T5 family.

E Properties of Transformations

We observe the properties of the transformations in the successful adversarial examples from three perspectives: type of transformation, length of span, and POS (part-of-speech) of span. Results are shown in Table 10 and Table 11.

	1	**2**	**3**	**4**	**5**
Replaced Span	26.2%	35.8%	38.0%	-	-
Span for REPLACE	33.1%	35.0%	24.6%	6.4%	0.9%
Span for INSERT	37.5%	35.3%	27.2%	-	-

Table 10: The proportion of various lengths in the spans of the corresponding type.

Replaced Span	Span for REPLACE	Span for INSERT
ADJ: 7.6%	ADJ: 8.4%	ADV: 12.4%
NOUN: 6.3%	VERB: 6.7%	ADJ: 6.7%
VERB: 5.0%	NOUN: 5.8%	NOUN: 2.2%
ADV: 3.8%	ADV: 5.5%	ADJ-NOUN-PUNCT: 1.9%
VERB-ADV: 2.3%	ADJ-PUNCT: 1.8%	VERB: 1.9%
AUX-ADV: 1.9%	ADV-ADJ: 1.7%	ADV-ADV: 1.6%
ADJ-PUNCT: 1.5%	AUX-ADV: 1.7%	ADJ-PUNCT: 1.5%
ADV-VERB: 1.5%	VERB-ADV: 1.5%	VERB-ADV: 1.4%
PRON-VERB: 1.4%	NOUN-PUNCT: 1.4%	PRON-VERB: 1.4%
ADV-ADJ: 1.3%	ADJ-NOUN: 1.4%	ADV-PUNCT: 1.2%

Table 11: The proportion of various POS in the spans of the corresponding type.

A Study of Syntactic Multi-Modality in Non-Autoregressive Machine Translation

Abstract

It is difficult for non-autoregressive translation (NAT) models to capture the multi-modal distribution of target translations due to their conditional independence assumption, which is known as the "multi-modality problem", including the lexical multi-modality and the syntactic multi-modality. While the first one has been well studied, the syntactic multi-modality brings severe challenge to the standard cross entropy (XE) loss in NAT and is under studied. In this paper, we conduct a systematic study on the syntactic multi-modality problem. Specifically, we decompose it into short- and long-range syntactic multi-modalities and evaluate several recent NAT algorithms with advanced loss functions on both carefully designed synthesized datasets and real datasets. We find that the Connectionist Temporal Classification (CTC) loss and the Order-Agnostic Cross Entropy (OAXE) loss can better handle short- and long-range syntactic multi-modalities respectively. Furthermore, we take the best of both and design a new loss function to better handle the complicated syntactic multi-modality in real-world datasets. To facilitate practical usage, we provide a guide to use different loss functions for different kinds of syntactic multi-modality.

1 Introduction

Traditional Neural Machine Translation (NMT) models predict each target token conditioned on previous generated tokens in an autoregressive way (Vaswani et al., 2017), resulting in high latency in inference. Non-Autoregressive Translation (NAT) models generate all the target tokens in parallel (Gu et al., 2018), significantly reducing inference latency. A disadvantage of NAT is that it suffers from the multi-modality problem (Gu et al., 2018) when a source sentence corresponds to multiple correct translations (Ott et al., 2018).

There are two types of multi-modalities: the lexical one and the syntactic one. The former one has been adequately studied (Gu et al., 2018; Zhou et al., 2020; Ding et al., 2021), while the latter one brings severe challenges to the widely used cross entropy (XE) loss in NAT. With standard XE loss, the generated tokens are required to be strictly aligned with ground truth tokens in the same positions, which fails to provide positive feedback for correctly predicted words on different positions as shown in Fig. 1a. Therefore, advanced loss functions are introduced to provide better feedback for NAT training: Connectionist Temporal Classification (CTC) loss (Libovický and Helcl, 2018) considers all possible monotonic alignments between a generated sequence and the ground truth; Aligned Cross-Entropy (AXE) loss (Ghazvininejad et al., 2020) selects the best monotonic alignment; and Order-Agnostic cross entropy (OAXE) loss (Du et al., 2021) calculates the XE loss with the best alignment based on maximum bipartite matching algorithm.

Even if with those advanced loss functions, we find they do not perform consistently across datasets and languages. In addition, diverse grammar rules in natural language (Comrie, 1989) implies the existence of different kinds of syntactic multi-modality. Inspired by Odlin (2008); Jing and Liu (2015); Liu (2007, 2010), we categorize the syntactic multi-modality into two sub types: the long-range and short-range ones. The long-range multi-modality is mainly caused by long-range word order diversity (e.g., an adverbial of place may appear at the beginning or the end of a sentence). The short-range multi-modality is mainly caused by short-range word order diversity (e.g., an adverb may appear either in front of or behind the corresponding verb) and optional words (e.g., in some languages, determiners and prepositions may be optional (Ott et al., 2018)). Based on the above categorization of syntactic multi-modality, we fur-

ther ask two research questions: (1) Which kinds of syntactic multi-modality do these loss functions excel at respectively? (2) How to better address this problem by taking advantage of different loss functions?

In this paper, we conduct a systematic study to answer these questions:

- Since the short-range and long-range syntactic multi-modalities are usually entangled together in real-world datasets, we first design synthesized datasets to decouple them to better evaluate existing NAT algorithms (§3). We find that the CTC loss (Libovický and Helcl, 2018) can better handle the short-range syntactic multi-modality while the OAXE loss (Du et al., 2021) is good at the long-range one. Though carefully designed, the synthesized datasets are still different from the real-world datasets. Accordingly, we further conduct analyses on real-world datasets (§4), which also show consistent findings with that in synthesized datasets.

- We design a new loss function that takes the best of both CTC and OAXE, and performs better to handle the short- and long-range syntactic multi-modalities simultaneously (§5), as verified by experiments on benchmark datasets including WMT14 EN-DE, WMT17 EN-FI, and WMT14 EN-RU. Moreover, we further provide a practical guide to use different loss functions for different kinds of syntactic multi-modality (§5).

2 Background

Non-Autoregressive Translation Given the source sentence $x = (x_1, x_2, ..., x_{T_x})$, traditional NMT model generates the target sentence $y = (y_1, y_2, ..., y_{T_y})$ from left to right and token by token: $P(y|x) = \prod_{t=1}^{T_y} P(y_t|y_{<t}, x; \theta_{\text{enc}}, \theta_{\text{dec}})$, where $y_{<t}$ indicates the target tokens generated before the t-th timestep, T_x and T_y denote the length of source and target sentence, θ_{enc} and θ_{dec} denote the encoder and decoder parameters respectively. This autoregressive way suffers from high latency during inference. Non-Autoregressive Translation (NAT) (Gu et al., 2018) is proposed to reduce the inference time by generating the whole sequence in parallel, $P(y|x) = P(T_y|x) \cdot \prod_{t=1}^{T_y} P(y_t|x; \theta_{\text{enc}}, \theta_{\text{dec}})$, where $P(T_y|x)$ indicates the length prediction function. While the inference speed is boosted, the translation accuracy is sacrificed due to that target tokens are generated conditional independently.

(d) OAXE

Figure 1: The illustration of different loss functions, where "GT" stands for ground truth, "PRED" stands for predicted sequence, the green check indicates that credit is provided to the token.

Multi-Modality Problem The multi-modality problem (Gu et al., 2018; Zhou et al., 2020) indicates that one source sentence may have multiple correct target translations, which brings challenges to NAT models as they generate each target token independently. Specifically, we categorize the multi-modality problem into two sub-problems, i.e., lexical and syntactic multi-modalities. The lexical multi-modality indicates that a source token can be translated into different target synonym tokens (i.e., "thank you" in English can be translated into both "Danke" or "Vielen Dank" in German), while the syntactic multi-modality indicates the inconsistency of word-orders (e.g., an adverb may appear either in front of or behind the corresponding verb) and the existence of optional words between source and target languages (e.g., in some languages, determiners and prepositions may be optional) (Ott et al., 2018). The lexical multi-modality problem has been adequately studied in recent works. Sequence-level knowledge distillation (Gu et al., 2018; Zhou et al., 2020) is shown capable to reduce the lexical diversity of the dataset and thus alleviate the problem. Some works also introduce extra loss functions such as KL-divergence (Ding et al., 2021) and bag-of-ngram (Shao et al., 2020) to alleviate the lexical multi-modality problem.

On the contrary, there still lacks a systematic study on the syntactic multi-modality problem. Generally, it is difficult to solve this problem because the order and optional words vary across different languages. For example, the word order of Russian is quite flexible (Kallestinova, 2007), thus the syntactic multi-modality may exist more frequently in Russian corpora. In contrast, the structure of English sentences is mostly subject–verb–object (SVO) (Givón, 1983), which results in less variation on word order. In this paper, we categorize the syntactic multi-modality problem into short-range and long-range instances, and provide detailed analyses accordingly.

Loss Functions in NAT Standard cross-entropy (XE) loss requires the predicted tokens to be strictly aligned with ground truth tokens, which fails to deal with the syntactic multi-modality problem. Different loss functions are proposed to solve the problem, and here we consider some most recent works. The CTC loss sums XE losses of all possible monotonic alignments and has been widely used in speech recognition (Graves et al., 2006, 2013), and the effectiveness of the CTC loss in NAT has been validated (Libovický and Helcl, 2018; Gu and Kong, 2021). AXE (Ghazvininejad et al., 2020) selects the monotonic alignment between the predicted sequence and the ground truth with the minimum XE loss. OAXE (Du et al., 2021) further relaxes the position constraint and only considers the best alignment. The illustration for each loss function is provided in Fig. 1. Though effective in different datasets, these works ignore fine-grain features of the multi-modality problem such as short/long syntactic multi-modalities. In this work, we analyse the performance of these loss functions in different syntactic scenarios, and provide a practical guide to use appropriate loss functions for different kinds of syntactic multi-modality.

3 Analyses on Synthesized Datasets

To make fine-grained analyses on the syntactic multi-modality problem, we first categorize it into long-range and short-range types, where the long-range one is mainly caused by long-range word order diversity, and the short-range one is mainly caused by short-range word order diversity and optional words. Then, we would like to evaluate the accuracy of different losses on different types of syntactic multi-modality. However, in real-world corpora, the different types are usually entangled, making it difficult to control and analyse one aspect without changing the other. Thus, we construct synthesized datasets based on phrase structure rules (Chomsky, 1959) to manually control the degree of syntactic multi-modality in different aspects, and evaluate the performance of different existing techniques.

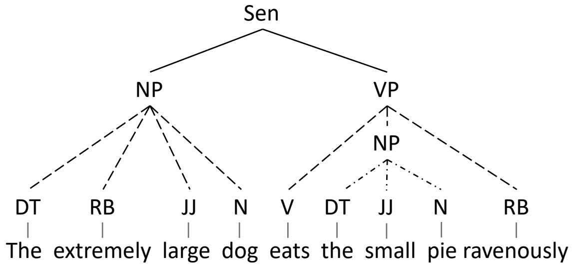

Figure 2: An illustration of generating a syntax tree for a source sentence. In the first iteration, “Sen” consists of (“NP”, “VP”) as the solid lines. In the second iteration, “NP” consists of (“DT”, “RB”, “JJ”, “N”) and “VP” consists of (“V”, “NP”, “RB”) as the dash lines. In the third iteration, “NP” consists of (“DT”, “JJ”, “N”) as the dot-and-dash lines.

3.1 Synthesized Datasets

We first employ phrase structure rules (Chomsky, 1959) to synthesize the source sentences, where the rules are based on the syntax of languages. Considering that translation can be decomposed to word reordering and word translation (Bangalore and Riccardi, 2001; Sudoh et al., 2011), we then “translate” the synthesized source sentences to synthesized target sentences in two steps: 1) word reordering by changing its syntax tree; 2) and word translation by substituting the source words into target words.

Source Sentence Synthesis. We first generate the syntax tree of the source sentence. Specifically, we use the notations of the constituents in syntax tree according to the Penn Treebank syntactic and part of speech (POS) tag sets[1] (Marcus et al., 1993), and generate the syntax tree of a source sentence as following (Rosenbaum, 1967):

- Sen → NP VP,

---

[1] “Sen”:sentence; “NP”: noun phrase; “VP”: verb phrase; “DT”: determiner; “JJ”: adjective; “RB”: adverb; “N”: noun; “V”: verb.

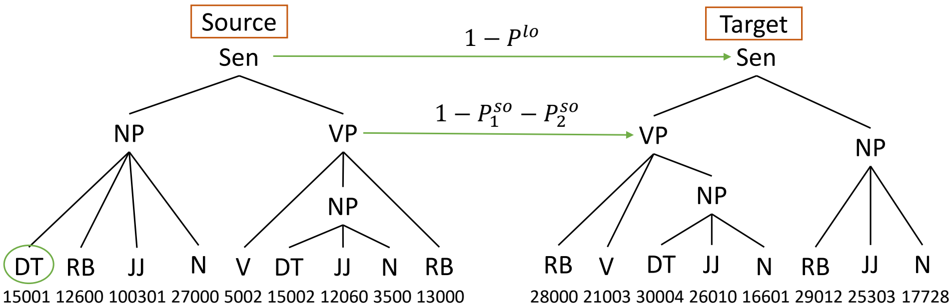

Figure 3: An illustration of "translation", where the constituent order of "Sen" is changed to "VP NP" with probability $1 - P^{lo}$, the constituent order of "VP" is changed to "RB V NP" with probability $1 - P_1^{so} - P_2^{so}$, and the circled "DT" is removed with probability P^{op}. Meanwhile, the numbers in the source sentence are replaced with the ones in the target sentence based on mappings.

- NP → (DT) $(\text{RB})^*$ $(\text{JJ})^*$ N,
- VP → V (NP) $(\text{RB})^*$,

where the constituent on the left side of the arrow consists of the constituents on the right side in sequence, "(·)" means that the constituent is optional, and "(·)*" denotes that the constituent is not only optional but can also be repetitive. For each sentence, we start with a single constituent Sen and iteratively decompose "Sen", "NP", and "VP" according to the rules until all the constituents are decomposed to "DT", "JJ", "RB", "V", and "N". An illustration of generating a syntax tree is depicted in Fig. 2. To synthesize the source sentence according to the syntax tree, we use numbers as the words in the synthesized source sentences and use different ranges of numbers to represent words with different POS, where the details of the ranges are provided in Appendix A. Then, a number is randomly sampled in the corresponding range for each word in the syntax tree.

Word Reordering. To introduce syntactic multi-modality, we consider multiple possible rules for "Sen", "NP", and "VP" in the target sentences. Dependency distance is defined as the linear distance between two words with syntactical relationship (Liu et al., 2017), which can be used as a guide to select typical rules to introduce long- and short-range word order diversity. Specifically, we consider three options: 1) The word order of "Sen" is with probability P^{lo} to be the same with the source sentence (i.e., NP VP) and with probability $\left(1 - P^{lo}\right)$ to swap the "NP" and "VP" (i.e., VP NP), which has long dependency distance and represents for the long-range word order; 2) For the word order in "VP", it is considered to be the same with the source sentence with probability P_1^{so}, place "RB" between "V" and "NP" with probability P_2^{so}, and place "RB" before "V" with probability $(1 - P_1^{so} - P_2^{so})$, which has short dependency distance and represents for the short-range word order; 3) To introduce the syntactic multi-modality of optional words, we change the existence of "DT" in each "NP" of the source sentence with probability P^{op} (i.e, remove "DT" if it exists in the source sentence and add "DT" if it does not exist in the source sentence).

Probability	Default	Effect
P^{lo}	1	long-range word order
P_1^{so}	1	short-range word order
P_2^{so}	0	short-range word order
P^{op}	0	optional words

Table 1: Default values of the probabilities to adjust the syntactic multi-modality.

Word Translation. Same as in the source sentences, we use different range of numbers to represent words with different POS in target sentences. To do the word translation, we first randomly build mappings between the source and target words with different POS respectively. Since we focus on studying the syntactic multi-modality, we consider each source word is mapped to a single target word to eliminate the lexical multi-modality. Then, we replace the words in the source sentence based on the mappings to generate the target sentence. An illustration of "translation" is shown in Fig. 3.

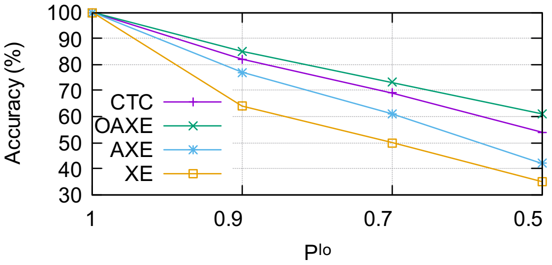
3.2 Experiments and Analyses

We conduct experiments to compare existing loss functions on different kinds of syntactic multi-modality on the synthesized datasets, by changing the probabilities (i.e., P^{op}, P_1^{so}, P_2^{so}, and P^{lo}) as listed in Table 1. In the following, we first provide the experimental settings, then show the results on the long-range and short-range syntactic multi-modalities, and finally conclude the key findings.

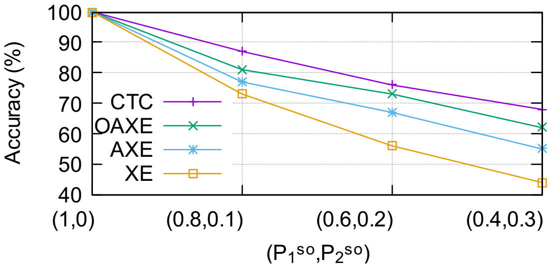
Experimental Settings. We consider two separate vocabularies for the source and target sentences, each containing 15K words. 0.3M, 5K, and 5K synthesized sentence pairs are generated as training, validation, and test sets respectively. We use the same hyper-parameters in the transformer-base model (Vaswani et al., 2017), which is commonly used in the NAT models (Gu et al., 2018; Du et al., 2021; Saharia et al., 2020). All settings are trained on 4 Nvidia V100 GPUs with 16k tokens in a batch. For the model with OAXE loss, we train the first 50K updates with XE loss and the next 50K updates with OAXE loss (Du et al., 2021). For the other losses, we train the model for 100K updates. The length of the decoder input is set as twice the length of the source sequence for CTC loss (Saharia et al., 2020), while the golden target length is used for OAXE, AXE, and XE. To evaluate the accuracy of the predicted sequence, we first calculate the longest common sub-sequence between the predicted and the golden sequences, and then the accuracy is defined as the ratio between the length of the longest common sub-sequence and the golden sequence. The accuracy on the test set is calculated as the average accuracy among all the predicted sentences.

Long-Range Syntactic Multi-modality. To consider the effect of long-range diversity, we change the corresponding probability P^{lo}, while keeping the others unchanged to eliminate the short-range syntactic multi-modality. It is observed in Fig. 4a that CTC loss always performs better than AXE, and OAXE is the best with different degree of long-range multi-modality.

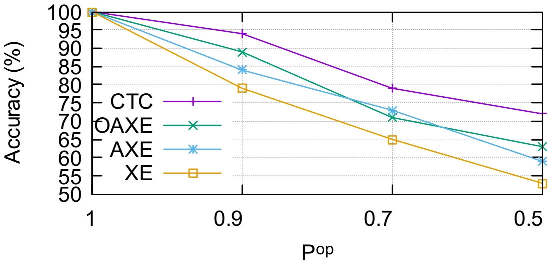
Short-Range Syntactic Multi-modality. Similarly, we only change the probabilities P_1^{so} and P_2^{so} to adjust the degree of short-range word order diversity. The results are shown in Fig. 4b, where OAXE loss performs better than AXE loss, and CTC loss outperforms all the other losses with varied degree of short-range word order diversity. In order to study the effect of optional words, we vary the probability P^{op} to change the existence of "DT". As shown in Fig. 4c, OAXE loss is slightly better than AXE loss, and CTC loss performs the best, indicating that CTC loss is superior in the syntactic multi-modality problem caused by optional words.



(a) Effect of long-range word order.



(b) Effect of short-range word order.



(c) Effect of optional words.

Figure 4: The accuracy of different loss functions on synthesized datasets.

Analyses and Discussions. Based on the results in Fig. 4, we can get the following observations:

- OAXE loss is superior in handling the long-range syntactic multi-modality (i.e., long-range word order). OAXE loss is order-agnostic, which is able to provide fully positive feedback to the word in different positions compared to the ground truth sequence. Accordingly, OAXE is suitable for datasets with long-range word order diversity. Though it can deal with high diversity of word order, it may also incur wrong predictions on word order, which may be why OAXE is not suitable when the diversity only exists in short-range.

- CTC loss is the best choice for dealing with short-range syntactic multi-modality (i.e., short-range word order and optional words). CTC loss is generally considered to handle monotonic matching, which seems not effective in handling the multi-modality caused by word order (Saharia et al., 2020). However, it is observed in Fig. 4a and 4b that CTC loss outperforms AXE and XE when dealing with long-range word order diversity and performs the best on the multi-modality caused by short-range word order. Since CTC considers all the monotonic alignments, it can partially provide positive feedback to the words with different order through multiple monotonic alignments. As shown in Fig. 1c, all the words can be considered in the three alignments.

Considering that AXE loss does not show superiority on any type of the syntactic multi-modality, we will only focus on CTC and OAXE losses in the following.

4 Analyses on Real Datasets

Though carefully designed, the synthesized sentence pairs consisting of numbers are still different from the real sentence pairs. Therefore, in this section, we validate the findings in Section 3 based on real datasets. Considering that different types of syntactic multi-modality are highly coupled in the real corpus, we conduct experiments on carefully selected sub-datasets from a corpus, to approximately decompose the syntactic multi-modality. In the following, we first show the details of the approach to decompose the syntactic multi-modality, and then provide the analytical results based on the real datasets.

Analytical Approach. In order to decompose the long-range and short-range types of syntactic multi-modality, we select sentences that only contain subject and verb phrases from a corpus, and divide them into two sub-datasets according to the relative order of subject and verb (i.e., subject first that denoted as "SV", or verb first that denoted as "VS"). Meanwhile, we only consider the declarative sentence pairs in the corpus to eliminate the word order difference caused by mood. Following this method, the long-range multi-modality is eliminated in each sub-dataset (i.e., "SV" and "VS"), which can be used to evaluate the effect of short-range multi-modality. To analyse the long-range multi-modality, we can adjust the degree of long-range word order diversity by sampling data from the two sub-datasets with varied ratios, while roughly keeping the degree of short-range word order diversity unchanged. Specifically, considering that Russian is flexible on word order (Kallestinova, 2007) and it is feasible to select sentences on both the "SV" and "VS" order, we use an English-Russian (EN-RU) corpus from Yandex[2] that contains 1M EN-RU sentence pairs, from which we get 0.2M and 0.1M sentence pairs data with "SV" order and "VS" order respectively. To select the sentence pairs with different word orders, we use spaCy(Honnibal et al., 2020) to parse the dependency of Russian sentences. For the models with CTC loss, we train for 300K updates. For the models with OAXE loss, we train with XE loss for 100K updates and then train with OAXE loss for 200K updates.

Table 2: BLEU scores of models with CTC and OAXE losses, where the models are evaluated on the WMT'19 EN-RU test set. The percentage of sentences with "RB V" among the sentences with both "RB V" and "V RB" orders are shown in column "RB V". The percentage of sentences with "JJ N" among the sentences with both "JJ N" and "N JJ" orders are shown in column "JJ N".

"SV":"VS"	CTC	OAXE	"RB V"	"JJ N"
$100\% : 0\%$	17.7	16.5	68%	84%
$75\% : 25\%$	17.2	16.9	63%	82%
$50\% : 50\%$	16.8	17.3	70%	79%

Analytical Results. We keep the total number of sentence pairs in the training set as 0.2M (i.e., the number of Russian sentences in the "VS" sub-dataset), and change the ratio of sentence pairs sampled from two sub-datasets (i.e., "SV" and "VS"). The results are shown in Table 2, where the training parameters are the same as that used in Section 3. It is observed that CTC loss outperforms OAXE loss when all data samples are from the "SV" sub-dataset, which indicates that CTC loss performs better on short-range syntactic multi-modality problem. When the ratio of the data sizes on the two sub-datasets is changed to $75\% : 25\%$, the gap between the performance of CTC and OAXE losses diminished, while CTC loss still performs slightly better than OAXE loss. When the ratio changed to $50\% : 50\%$, model with OAXE loss becomes better than that with CTC loss. In summary, OAXE loss is better at handling long-range syntactic multi-modality while CTC loss is better on short-range syntactic multi-modality, which validates the key observations we obtained on the synthesized datasets in Section 3.

---

[2] https://translate.yandex.ru/corpus

In order to demonstrate whether we have decomposed the long- and short-range syntactic multi-modalities, we verify whether the degree of short-range multi-modality remains almost the same when varying the degree of long-range multi-modality. We evaluate the short-range syntactic diversity based on the relative order between: 1) adverb and verb (“RB V”); 2) adjective and noun (“JJ N”). As shown in Table 2, when the ratio of the data sizes on the two sub-datasets varied from $100\% : 0\%$ to $50\% : 50\%$ (i.e., the ratio between “SV” and “VS” changes), the relative order on “RB V” and “RB V” (which can represent the degree of short-range word order diversity) does not vary much. These analyses verify the rationality of our analytical approach in this section.

5 Better Solving the Syntactic Multi-Modality Problem

As shown in previous sections, the CTC and the OAXE loss functions are good at dealing with short- and long-range syntactic multi-modalities respectively. While in real-world corpora, different types of multi-modalities usually occur together and vary in different languages. Accordingly, it may be better to use different loss functions for different languages. In this section, we first introduce a new loss function named Combined CTC and OAXE (CoCO), which takes advantage of both CTC and OAXE to better handle the long-range and short-range syntactic multi-modalities simultaneously, and then provide a guideline on how to choose the appropriate loss function for different scenarios.

5.1 CoCO Loss

To obtain a general loss that performs well at both types of multi-modalities, it is natural to combine the two loss functions studied above. However, the output length is mismatched between the models using CTC and OAXE, where the output length is required to be longer than the target sequence with CTC loss, and is required to be the same as the target sequence with OAXE loss. To solve this length mismatch problem, we consider using the same output length as in CTC loss, and modify the OAXE loss to make it suitable on this output length by allowing consecutive tokens in the output to be aligned with the same token in the reference sequence. The details of the modified OAXE loss are provided in Appendix B. Then, the proposed CoCO loss is defined as a linear combination of the CTC and modified OAXE losses as:

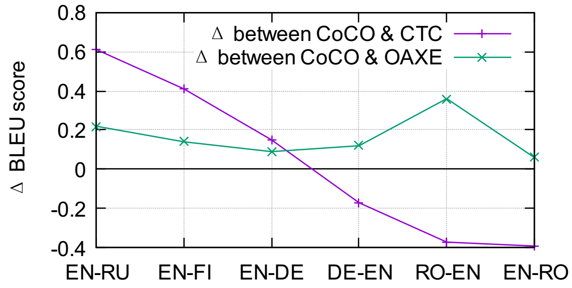


Figure 5: Comparing different losses on different language pairs.

$$\mathcal{L}_{CoCO} = \lambda\mathcal{L}_{CTC} + (1-\lambda)\mathcal{L}_{M-OAXE}, \tag{1}$$

where $\mathcal{L}_{M-OAXE}$ denotes the modified OAXE loss and λ is a hyper-parameter that balances the two losses.

5.2 Choosing Appropriate Loss Function

The degree of different types of multi-modalities varies among different languages. In order to find the insight to choose the appropriate loss function for different languages, we conduct experiments on several languages including Russian (RU), Finnish (FI), German (DE), Romanian (RO), and English (EN). These languages have different requirements on the positions of subject (S), verb (V), and object (O), which is one major influence factor on the large-range syntactic multi-modality. Specifically, the order in RU and FI is quite flexible, where all the 6 possible orders of “S”, “V”, and “O” are valid. In DE, the verb is required to be placed on the second position, which is called verb-second word order. Meanwhile, in RO and EN, the order is restricted to “SVO”.

We evaluate the accuracy of different loss functions (i.e., CTC, OAXE, and CoCO) on WMT’14 EN-RU, WMT’17 EN-FI, WMT’14 EN-DE, and WMT’16 EN-RO datasets with 1.5M, 2M, 4M, and 610K sentence pairs, respectively. The λ in COCO loss is set as 0.1 so that $\lambda\mathcal{L}_{CTC}$ and $(1-\lambda)\mathcal{L}_{M-OAXE}$ are in the same order of magnitude. Following Du et al. (2021), for the models with OAXE and CoCO loss, we first train with XE or CTC loss for 100K updates and then train with OAXE or CoCO loss for 200K updates, respectively. For CTC loss, we train for 300K updates. For decoding, we follow Gu and Kong (2021); Huang et al. (2021) to use beam search with lan-

AXE (Ghazvininejad et al., 2020)	23.53	27.90	30.75	–	–	15.3 ×
Imputer (Saharia et al., 2020)	25.80	28.40	32.30	–	–	18.6 ×
OAXE (CMLM) (Qian et al., 2021)	26.10	30.20	32.40	–	–	15.6 ×
GLAT (Qian et al., 2021)	26.39	29.84	32.79	–	–	14.6 ×
CTC (VAE) (Gu and Kong, 2021)	27.49	30.46	33.79	–	–	16.5 ×
CTC (GLAT) (Gu and Kong, 2021)	27.20	31.39	33.71	–	–	16.8 ×
CTC (DSLP) (Huang et al., 2021)	27.02	31.61	34.17	21.38	22.83	14.8 ×
CoCO (DSLP)	27.41	31.37	34.32	21.82	23.25	14.2 ×

guage model scoring[3] for CTC and CoCO. The other training settings are the same as used in Section 3. We report the tokenized BLEU score to keep consistent with previous works. We show the difference values of BLEU score in Fig. 5 and provide the corresponding absolute BLEU scores in Appendix C. According to Fig. 5, we have several observations: 1) The proposed CoCO loss consistently improves the translation accuracy on all the language pairs compared to OAXE loss; 2) The CoCO loss outperforms CTC loss when the target language is with flexible word order or verb-second word order (i.e., EN-RU, EN-FI, and EN-DE); 3) CTC loss performs the best when the target language is "SVO" language (i.e., DE-EN, RO-EN, and EN-RO).

We would also like to evaluate the CoCO loss based on SOTA NAT models. Though the proposed CoCO loss can be used in both iterative and non-iterative models, we only show the results on non-iterative models in this paper and leave the iterative models as future work. We use CoCO loss on a recently proposed Deeply Supervised, Layer-wise Prediction-aware (DSLP) transformer (Huang et al., 2021), which achieves competitive results. The details of how CoCO loss is applied on DSLP are provided in Appendix D. The results are shown in Table 3. Compared to DSLP with CTC loss (Huang et al., 2021), DSLP with CoCO loss consistently improves the BLEU scores on three language pairs, including EN-RU, EN-FI, and EN-DE. On the contrary, DSLP with CTC loss is better or comparable to DSLP with CoCO loss when the target language is restricted to the "SVO" word order, including EN-RO and DE-EN.

According to the experiments on language pairs with different kinds of requirements on word order, we suggest to: 1) use CoCO loss when the word order of the target language is relatively flexible (e.g., RU and FI, where word order on "S" "V" "O" is free, and DE, where the verb is required to be placed on the second position); 2) use CTC loss when the target language is with relatively strict word order (e.g., RO and EN, which are "SVO" languages).

6 Conclusion

In this paper, we conduct a systematic study on the syntactic multi-modality problem in non-autoregressive machine translation. We first categorize this problem into long-range and short-range types and study the effectiveness of different loss functions on each type. Considering the different types are usually entangled in real-world datasets, we design and construct synthesized datasets to control the degree of one type of multi-modality without changing another for analyses. We find that CTC loss is good at short-range syntactic multi-modality while OAXE loss is better at the long-range one. These findings are further verified on real-world datasets with our designed analytical approach. Based on these analyses, we propose a CoCO loss that can better handle the complicated syntactic multi-modality in real-world datasets, and a practical guide to use different loss functions for

---

[3] https://github.com/kpu/kenlm

different kinds of syntactic multi-modality: CoCO loss is preferred when the word order of target language is relatively flexible while CTC loss is preferred when target language is with strict word order. Our study in this paper can facilitate better understanding of the multi-modality problem and provide insights to better solve this problem in non-autoregressive translation. Besides, there still remain some open problems that need future investigation. For example, we generally consider long-range and short-range types for syntactic multi-modality, while there may be more fine-gained categorizations on the syntactic multi-modality due to the complex syntax of natural language.

Step 2-1

Possible end tokens of "A"	P_1	P_2	P_3

Select the best

β	3	3	2	2	-1	1

Step 2-2

Possible end tokens of "B"	P_4	P_5

Select the best

β	3	3	2	2	2	1

Figure 6: An illustration of the modified OAXE loss.

Specifically, we consider one training pair (X,Y), where there are n tokens in the ground truth sequence, denoted as $Y = (y_1, y_2, \dots, y_n)$. The corresponding output sequence has m tokens with probability distributions $P_1, P_2, \dots, P_m$, where $m > n$. According to OAXE, we first get the alignment between the ground truth sequence and the output sequence that minimizes the cross entropy loss based on maximum bipartite matching algorithm (Kuhn, 1955):

$$\alpha^\star = \underset{\alpha \in \gamma(\alpha)}{\arg\min} \left(- \sum_i \log P_{\alpha(i)}(y_i | X, \theta) \right), \quad (2)$$

where α denotes the alignment from the ground truth sequence to the output sequence, $\gamma(\alpha)$ is the set of all possible alignments, and y_i is aligned with the $\alpha(i)$-th token of the output. We consider each output token can only be aligned to one ground

Table 4: BLEU scores of models with different losses on different language pairs.

Loss	EN-RU	EN-FI	EN-DE	DE-EN	RO-EN	EN-RO
CTC	20.84	22.86	26.10	30.36	33.68	33.06
OAXE	21.23	23.13	26.16	30.07	33.25	32.31
CoCO	21.45	23.27	26.25	30.19	33.31	32.67

truth token (i.e., $\alpha(i) \neq \alpha(j)$ if $i \neq j$). Then, we can get the alignment from the output sequence to the ground truth sequence, based on $\alpha^\star$:

$$\beta(k) = \begin{cases} i & \text{if } \alpha^\star(i) = k, \\ -1 & \text{if } \forall i \in [1, n], \alpha^\star(i) \neq k, \end{cases} \tag{3}$$

where the k-th token of the output is aligned to $y_{\beta(k)}$ and $\beta(k) = -1$ denotes the token has not been aligned. We provide an illustration as the "step 1" in Fig. 6, where we consider 3 tokens in the target sequence and 6 tokens in the output and the best alignment is "A"-"P_6", "B"-"P_4", and "C"-"P_1". Since consecutive repetitive tokens are merged when decoding with CTC loss, we consider that consecutive tokens in the output can be aligned to the same ground truth token. Accordingly, we enumerate the end of each ground truth token in the output sequence respectively, and select the one that minimize the cross entropy loss. For example, given $\beta(k_1) = i$, $\beta(k_2) = j$ and $\beta(k) = -1$ when $k_1 \leq k \leq k_2$, we select $k^\star$ according to:

$$\begin{aligned} k^\star = \underset{k_1 \leq k' < k_2}{\arg\min} \Bigg(& - \sum_{k_1 \leq k \leq k'} \log P_k(y_i | X, \theta) \\ & - \sum_{k' < k \leq k_2} \log P_k(y_j | X, \theta) \Bigg), \end{aligned} \tag{4}$$

and align the $(k_1, k^\star]$-th output token to i and the $(k^\star, k_2)$-th output token to j as:

$$\beta(k) = \begin{cases} i & \text{if } k \in (k_1, k^\star] \\ j & \text{if } k \in (k^\star, k_2). \end{cases} \tag{5}$$

As the illustration in Fig. 6, we enumerate all the possible end tokens of 'A' and 'B' to find the best one. Then, we get the modified OAXE loss as:

$$\mathcal{L}_{M-OAXE} = - \sum_{1 \leq k \leq m} \log P_k \left(y_{\beta(k)} | X, \theta \right). \tag{6}$$

C BLEU Scores of Different Losses on Different Language Pairs.

The BLEU scores of models with CTC, OAXE and CoCO loss on different languages pairs are shown in Table 4.

D Use CoCO Loss in DSLP

Partially feeding ground truth tokens to the decoder during training shows promising performance in NAT (Ghazvininejad et al., 2019; Saharia et al., 2020; Qian et al., 2021; Huang et al., 2021). For the models training with golden length of the ground truth sentence using XE loss, the ground truth token embedding is placed to the position of the corresponding input (Qian et al., 2021). When using CTC loss, the inputs of the decoder are always longer than the ground truth sentences, where Gu and Kong (2021) proposes to use the best monotonic alignment between the ground truth and output sequences, and provides the ground truth to the corresponding input position of the decoder. With the proposed CoCO loss, we use the best alignment which is not required to be monotonous. In addition, DSLP requires deep supervision on each layer of the decoder. We find that only replacing CTC loss with CoCO loss on the first layer is better than using CoCO loss on all layers. Accordingly, when using CoCO loss in DSLP transformer, we use CoCO loss in the first layer and CTC loss for all the other layers in the DSLP transformer.

CIAug: Equipping Interpolative Augmentation with Curriculum Learning

Abstract

Interpolative data augmentation has proven to be effective for NLP tasks. Despite its merits, the sample selection process in mixup is random, which might make it difficult for the model to generalize better and converge faster. We propose CIAug, a novel curriculum-based learning method that builds upon mixup. It leverages the relative position of samples in hyperbolic embedding space as a complexity measure to gradually mix up increasingly difficult and diverse samples along training. CIAug achieves state-of-the-art results over existing interpolative augmentation methods on 10 benchmark datasets across 4 languages in text classification and named-entity recognition tasks. It also converges and achieves benchmark F1 scores 3 times faster. We empirically analyze the various components of CIAug, and evaluate its robustness against adversarial attacks.

1 Introduction

Data augmentation is an effective tool for avoiding overfitting in model training in cases where there is an absence of sufficient training data (Liu et al., 2021). Interpolative augmentation techniques, such as Mixup (Zhang et al., 2018), have shown an increase in model performance across various modalities, with further improvements gained by applying Mixup at latent representation layers (Chen et al., 2020a). Current implementations of Mixup select samples for interpolation at random, not leveraging the potential for adaptive selection techniques which have been shown to lead to better generalizability (Chen et al., 2020b). In addition, these methods do not account for the spatial distribution of linguistic data, known to extend beyond the capacities of euclidean space (Nickel and Kiela, 2017).

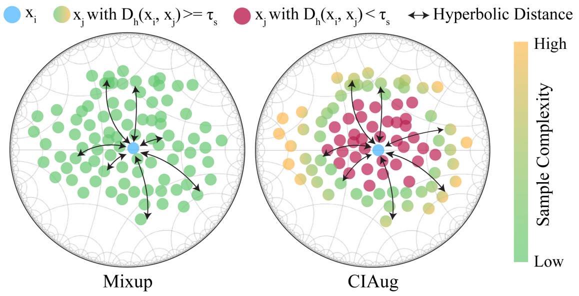

Figure 1: Overview of CIAug showing curriculum-based sample selection using hyperbolic distance to perform interpolation.

We propose **CIAug**[1], a method which addresses these challenges by offering an augmentation procedure that selects samples in an adaptive fashion and is geometrically sound. CIAug's sampling strategy follows the idea that selecting easier mixing samples first and gradually increasing sample difficulty based on relative spatial position would generate more suitable synthetic inputs, resulting in better model training (Xu et al., 2021). This notion ties in with the framework of curriculum learning (Krueger and Dayan, 2009), where training data is presented in a similarly staggered way, increasing model capabilities (Bengio et al., 2009). CIAug's selection strategy performs distance operations in hyperbolic space, applying insights about language data spatial distribution to its definition of 'similar samples' (Tifrea et al., 2019). We first train CIAug by sampling pairs of sentences similar to each other for mixing, then gradually as training progresses, we sample sentences that are dissimilar, following the curriculum learning strategy.

Through experiments on 10 benchmark datasets in English, Arabic, Turkish and German, we show

---

[*] Equal contribution.

[1] We release CIAug's code at: `https://github.com/sounritesh/CIAug-NAACL`

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1758 - 1764
July 10-15, 2022 ©2022 Association for Computational Linguistics

that CIAug outperforms state-of-the-art models in classification and named-entity recognition tasks. We probe the effectiveness of CIAug in conjunction with different similarity measures and qualitatively evaluate it. We show that CIAug converges faster than traditional Mixup while being both generalizable across tasks and languages, as well as more resilient to adversarial classification examples.

2 Methodology

We illustrate CIAug's sample selection strategy in Figure 1. In this section, we first introduce Mixup (§2.1), and follow by formulating CIAug and its relative sample distribution component (§2.2).

2.1 Interpolative Mixup

Given two data samples $x_i, x_j \in X$ with labels $y_i, y_j \in Y$, where $i, j \in [1, N]$, Mixup (Zhang et al., 2018) performs a linear interpolation with ratio r between these two samples according to eq. (1), creating a new synthetic data point x' and its label y':

$$\begin{aligned} x' &= \text{Mixup}(x_i, x_j) = r \cdot x_i + (1-r) \cdot x_j \\ y' &= \text{Mixup}(y_i, y_j) = r \cdot y_i + (1-r) \cdot y_j \end{aligned} \tag{1}$$

Interpolative Mixup (Chen et al., 2020a) performs linear interpolation over the latent representations of models. Let $f_\theta(\cdot)$ be a model with parameters θ having K layers. $f_{\theta,n}(\cdot)$ denotes the n-th layer of the model, h_n the hidden space vector at layer n for $n \in [1, K]$, and h_0 the input vector. Interpolative Mixup at a layer $k \sim [1, K]$ can be done by separately calculating the latent representation of the layers before the k-th layer. For input sample x_i, we let h_n^i denote the hidden state representations at layer n,

$$\begin{aligned} h_n^i &= f_{\theta,n}(h_{n-1}^i), \quad n \in [1, k] \\ h_n^j &= f_{\theta,n}(h_{n-1}^j), \quad n \in [1, k] \end{aligned} \tag{2}$$

We then perform Mixup over individual hidden state representations h_k^i, h_k^j from layer k as,

$$h_k = \text{Mixup}(h_k^i, h_k^j) = r \cdot h_k^i + (1-r) \cdot h_k^j \tag{3}$$

The mixed hidden representation h_k is used as the input for the continuing forward pass,

$$h_n = f_{\theta,n}(h_{n-1}); \quad n \in [k+1, K]. \tag{4}$$

2.2 CIAug

Although Mixup helps models generalize better, it selects samples for interpolation randomly. Deriving information from the spatial distributions of the samples to be mixed, and utilising it to introduce curriculum and diversity in sample selection, can lead to performance improvements.

We present steps involved in CIAug in Algorithm 1. CIAug encodes the relative complexity between instances in a learnable matrix $\mathbf{M} \in \mathbb{R}^{N \times N}$, which we initialize using a distance metric. Motivated by evidence that euclidean space, where models typically operate, is not able to effectively capture the complex properties of natural language data (Ganea et al., 2018), we use hyperbolic distance as our metric for modeling representations while performing interpolative operations (Sawhney et al., 2021). The hyperbolic distance $\mathcal{D}_h$ between embeddings $e_i = f_\theta(x_i)$ and $e_j = f_\theta(x_j)$ is defined as:

$$\mathcal{D}_h(e_i, e_j) = 2 \tan^{-1}(\|(-e_j) \oplus e_i\|), \tag{5}$$

where $\oplus$ represents Möbius addition (A.1).

In contrast to Mixup, CIAug is defined for one sample. Given a sample x_i, we create a set S_i of increasingly diverse samples in the dataset relative to x_i using an operation labeled SSET and thresholds τ_s and τ_c:

$$S_i = \text{SSET}(X, M_i, \tau_s, \tau_c) := \{x_k | x_k \in X, \tau_s \leq \mathbf{M}_{ik} \leq \tau_c\}, \tag{6}$$

where $\tau_s = \mathrm{T} \cdot \max(\mathbf{M}_i)$ at each step of training, and $\mathrm{T} \in (0, 1)$ is a hyperparameter. τ_s helps in sampling the most diverse samples relative to x_i. Although sample diversity helps the model generalize, it may not guarantee global convergence. Exposing the model to extremely diverse samples early in the training process can be detrimental to its performance. Therefore, we introduce a distance-based learning curriculum using a second threshold, τ_c, which selects mixing samples which are increasingly diverse from x_i's perspective. τ_c is dynamically updated during training using an UPDATE operation:

$$\textsc{Update}(\tau_c) := \tau_c + \alpha, \tag{7}$$

where $\alpha \in (0, 1)$ is a hyperparameter and $\tau_c = 0.1$, initially.

We then sample a random instance from $x_j \in S_i$ to perform Mixup with x_i.

Using $\mathbf{M}$, we change the Mixup formulation (Equation 1) for samples i and j and define CIMixup as,

$$\text{CIMixup}(x_i, x_j) = (1 - \mathbf{M}_{ij}) \cdot x_i + \mathbf{M}_{ij} \cdot x_j \tag{8}$$

Finally, we formulate CIAug as:

$$\textsc{CIAug}(x_i) = \textsc{CIMixup}(x_i, x_j), \quad x_j \in S_i. \tag{9}$$

We replace the Mixup operation from Equation 3 with the CIAug operation in Equation 9 to evaluate CIAug. The final hidden state output h_K is passed through a multi-layer perceptron (MLP) g_ϕ for classification. We optimize the network using KL Divergence loss between the final output $g_\phi(h_K)$ and mixed label $y' = \text{CIMixup}(y_i, y_j)$, which also trains the matrix $\mathbf{M}$ end-to-end.

3 Experimental Setup

We evaluate CIAug on classification and NER tasks in various settings across 4 languages, and on GLUE datasets (Wang et al., 2018).

3.1 Training Setup

We use BertAdam optimizer (Wolf et al., 2020) with a learning rate of $2e$-5, batch size of 8 and weight decay of 0.01, trained for 10 epochs. CIAug is performed over a layer randomly sampled from all model layers. For the datasets in English we use BERT (Devlin et al., 2019) as our base model f_θ, and for other languages we use mBERT. For calculating distances between instances, we use the [CLS] token representation from the sentence embeddings. Due to lack of powerful computational resources, we train on 10,000 samples for SST-2 dataset, and keep the validation and test set unchanged.

3.2 Evaluation

For a comprehensive evaluation, we compare CIAug with some standard baselines: word-mixup (WMix), sentence-mixup (SMix) (Guo et al., 2019), HypMix(HMix) (Sawhney et al., 2021). We use **F1** score as a metric for evaluating CIAug and comparing it with other baselines.

4 Results and Analysis

We present our main results in Table 1. We observe that CIAug outperforms the baseline f_θ, validating that selecting diverse samples based on similarity enhances the model performance. We further find that the hyperbolic variant of sample selection performs better than the Euclidean CIAug (Table 5 in the appendix). This validates that hyperbolic space is more capable of capturing the complex hierarchical information present in the sentence representation, leading to better comparison and sample selection.

(b) RTE Dataset

Table 3: F1-score with different distance metrics for diversity and curriculum threshold, τ_s and τ_c.

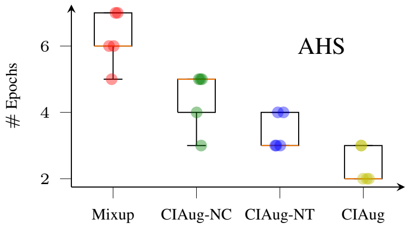

Figure 2: Convergence comparison of Mixup with CIAug-NC (No curriculum), CIAug-NT, CIAug as number of training epochs needed to reach a benchmark F1 score. (AHS benchmark score:72%).

We also compare CIAug with its non-trainable matrix counterpart where sample selection is based on the relative position of sentences, using a constant matrix $\mathbf{M}$. We observe that this variant performs worse, suggesting that $\mathbf{M}$ is able to capture sample-specific information relative to other samples, generating more suitable sample selection and mixing ratio while performing interpolative data augmentation.

Impact of distance metric We explore the effectiveness of CIAug with the euclidean and hyperbolic distance measures as diversity and complexity metric for the thresholds, τ_s and τ_c. The results, presented in Table 3, show that utilizing hyperbolic distance for both thresholds yields the best results, suggesting that hyperbolic space captures the hierarchical properties of textual data better, gauging the relative diversity and complexity of samples effectively.

Analysing the convergence of CIAug For all benchmark datasets, we observe that CIAug reaches a benchmark F1 score faster than Mixup method, as shown in Figure 2.[2] As CIAug selects samples for Mixup based on a learning curriculum, it leads to generation of more suitable synthetic samples in a staggered manner resulting in better training (Xu et al., 2021) and faster convergence.

Method	Accuracy	Adversarial Accuracy
Mixup	65.56	55.95
CIAug-NT	68.95	66.06
CIAug	68.23	64.62

Table 4: Performance on adversarial examples generated using synonym substitution on RTE.

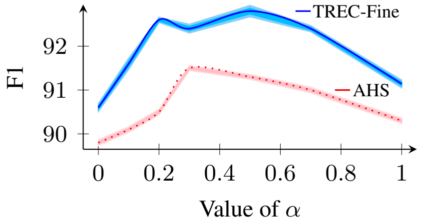

Figure 3: Change in performance in terms of F1 with varying α for CIAug

Adversarial Robustness Adversarial attacks confuse a model by providing specifically designed inputs. We compare the robustness of CIAug with Mixup by performing black-box adversarial attacks. Using the NLPAug library (Ma, 2019) we substitute up to 10% of the words in each sentence with their synonyms found in WordNet (Feinerer and Hornik, 2020) and present the results in Table 4. We observe that both CIAug-NT and CIAug are more robust compared to regular Mixup by a difference of 6.72% and 6% respectively. This robustness towards adversarial attacks could be attributed to the curriculum-learning-based interpolative technique which resulted in better training and generalizibility of underlying model.

Curriculum threshold We perform a study on CIAug by varying α in the the curriculum learning threshold τ_c as in equation 7, and present it in Figure 3. A lower value of α would result in the slow increase of τ_c, which can lead the underlying model to not converge properly, whereas a higher value of α would result in accelerated increase of τ_c, losing the advantages of curriculum learning. Figure 3 shows the existence of an optimal α for curriculum learning.

5 Conclusion

We propose CIAug, a novel mixup technique that uses curriculum learning, leveraging the relative spatial positions of the samples in the embedding space as a measure of complexity to signal curriculum learning. CIAug achieves state-of-the-art results over existing interpolative data augmentation

---

[2] We get similar results on the other datasets.

methods on 10 standard and multilingual datasets in English, Arabic, Turkish and German. CIAug converges faster than the traditional Mixup technique, while being generalizable across different tasks and modalities.

A Hyperbolic Geometry

A.1 Möbius Addition

Möbius addition $\oplus$ for a pair of points $x, y \in \mathcal{B}$, defined as,

$$x \oplus y := \frac{(1 + 2\langle x, y\rangle + ||y||^2)x + (1 - ||x||^2)y}{1 + 2\langle x, y\rangle + ||x||^2||y||^2} \qquad (10)$$

, $\langle ., .\rangle$, $|| \cdot ||$ are Euclidean inner product and norm.

B Extended Analysis

We compare the performance of CIAug with some recent baselines and interpolative augmentation techniques like (Jindal et al., 2020) and (Yoon et al., 2021) on standard English and GLUE datasets.

C Dataset Details

1. **TTC**. (Kilinç et al., 2017), Turkish Text Categorization dataset consists of 3600 Turkish documents (news/texts) classified into 6 classes.

2. **CoLA**. (Warstadt et al., 2018), abbreviation for the Corpus of Linguistic Acceptability is a part of GLUE (Wang et al., 2018) benchmark. It is a collection of English sentences from 23 linguistic publications that are annotated for their grammatical acceptability.

3. **SST-2**. (Socher et al., 2013) is a GLUE (Wang et al., 2018) benchmark dataset consisting of English sentences from movie reviews. Samples in the dataset are annotated for sentiment classification task.

4. **TREC-Coarse**. (Li and Roth, 2002), The Text REtrieval Conference-Coarse is a question classification dataset consisting of 6 classes. The data is sourced from English questions by USC, TREC 8, TREC 9, TREC 10 and manually constructed questions.

5. **TREC-Fine**. (Li and Roth, 2002) contains the same set of questions as TREC-Coarse grouped into 47 fine-grained classes.

6. **AHS**. (Albadi et al., 2018) is an Arabic hate speech classification dataset focusing mainly on Saudi Twittersphere.

7. **RTE**. (Bentivogli et al., 2009) The Recognizing Textual Entailment (RTE) datasets come from a series of textual entailment challenges. Data from RTE1, RTE2, RTE3 and RTE5 is combined. Examples are constructed based on news and Wikipedia text. Metric used here is accuracy

8. **MRPC**.(Dolan and Brockett, 2005) The Microsoft Research Paraphrase Corpus is a corpus of sentence pairs automatically extracted from online news sources, with human annotations for whether the sentences in the pair are semantically equivalent. Metric used here is accuracy

9. **CONLL**. (Tjong Kim Sang and De Meulder, 2003) It is a named entity recognition dataset released as a part of CoNLL-2003 shared task: language-independent named entity recognition. The data consists of eight files covering two languages: English and German.

D Experimental Setup

We provide a detailed explanation of our experimental setup in table 6

Parameter	Value
Optimizer	BERTAdam 2020
Learning Rate	2e-5
Batch Size	8
$\beta_1, \beta_2, \epsilon$	0.9, 0.999, 1e-6
# Epochs	10
Evaluation Metric	F1 Score
Base Model	BERT-base-uncased, BERT-base-multilingual-uncased
Classifier (over architecture)	Linear layer
Hardware	Nvidia V100

Table 6: Model and training setup for CIAug.

Mixup Layer Set	AHS	MRPC
{3,4}	71.12	82.84
{1,2}	72.21	85.62
{6,7,9}	72.57	83.08
{7,9,12}	73.77	84.06
{3,4,6,7,9,12}	**74.14**	**87**

Table 7: Layer-wise ablation score (F1) when performing interpolative augmentation.

E Qualitative Analysis

E.1 Layer-wise Ablation

We compare the performance of CIAug on different set of mixup layers in table 7. TMix attains best performance on layer set 7,9,12 is used because layers 6,7,9,12 contains the most amount of syntactic and semantic information (Chen et al., 2020a). CIAug achieves best performance on layer set 3,4,6,7,9,12, this suggests other than syntactic and semantic information, curriculum learning based approach in CIAug helps to capture the surface-level information in layer 3 and 4 (Jawahar et al., 2019).

F Limitations

Even though CIAug converges faster and performs better than other baseline interpolative techniques, the computational power required is not so fairly available in many devices. We plan to work on improving the efficiency of the parameterized matrices involved in the computation, such as using sparse matrices.

Proposition-Level Clustering for Multi-Document Summarization

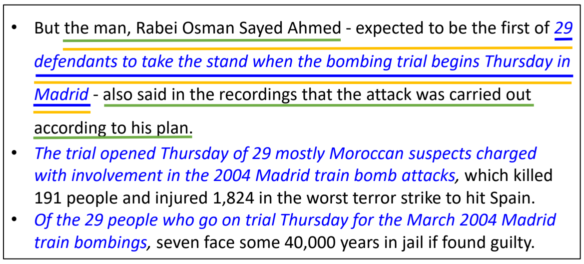
Abstract

Text clustering methods were traditionally incorporated into multi-document summarization (MDS) as a means for coping with considerable information repetition. Particularly, clusters were leveraged to indicate information saliency as well as to avoid redundancy. Such prior methods focused on clustering *sentences*, even though closely related sentences usually contain also non-aligned parts. In this work, we revisit the clustering approach, grouping together sub-sentential *propositions*, aiming at more precise information alignment. Specifically, our method detects salient propositions, clusters them into paraphrastic clusters, and generates a representative sentence for each cluster via text fusion. Our summarization method improves over the previous state-of-the-art MDS method in the DUC 2004 and TAC 2011 datasets, both in automatic ROUGE scores and human preference.[1]

1 Introduction

Common information needs are most often satisfied by multiple texts rather than by a single one. Accordingly, there is a rising interest in Multi-Document Summarization (MDS) — generating a summary for a set of topically-related documents. Inherently, MDS needs to address, either explicitly or implicitly, several subtasks embedded in this summarization setting. These include salience detection, redundancy removal, and text generation. While all these subtasks are embedded in Single-Document Summarization (SDS) as well, the challenges are much greater in the multi-document setting, where information is heterogeneous and dispersed, while exhibiting substantial redundancy across linguistically divergent utterances.



- But the man, Rabei Osman Sayed Ahmed - expected to be the first of *29 defendants to take the stand when the bombing trial begins Thursday in Madrid* - also said in the recordings that the attack was carried out according to his plan.
- *The trial opened Thursday of 29 mostly Moroccan suspects charged with involvement in the 2004 Madrid train bomb attacks*, which killed 191 people and injured 1,824 in the worst terror strike to hit Spain.
- *Of the 29 people who go on trial Thursday for the March 2004 Madrid train bombings*, seven face some 40,000 years in jail if found guilty.

Figure 1: An example of a cluster of *propositions*, shown within their source sentence context, from TAC 2011 (topic D1103). Clustering these as sentences would yield noisy unaligned information, however grouping together only the marked propositions keeps information alignment clean. The first sentence is illustratively divided into propositions, where only one of them is aligned to those in the other sentences.

An appealing summarization approach that copes with these challenges, and is especially relevant for MDS, is clustering-based summarization. In such an approach, the goal is to cluster redundant paraphrastic pieces of information across the texts, which roughly convey the same meaning. Repetition of information across texts, as captured by paraphrastic clustering, typically indicates its importance, and can be leveraged for salience detection. Moreover, representing a paraphrastic cluster may facilitate generating a corresponding summary that eliminates repetitions while fusing together complementary details within the cluster.

Traditionally, clustering-based approaches were widely used for summarization, mostly in extractive and unsupervised settings (Radev et al., 2004; Zhang et al., 2015; Nayeem et al., 2018). Notably, most of these works generated sentence-based clusters, which tend to be noisy since a sentence typically consists of several units of information that only partially overlap with other cluster sentences. As a result, such clusters often capture topically related sentences rather than paraphrases. Figure 1 exemplifies such a noisy cluster, which does contain paraphrastic propositions (marked in *blue*) within their full sentences (marked in black). Another line of research in summarization coped with

such noisy sentence-based setting, and looked into the use of sub-sentential units for summarization, e.g., Li et al. (2016) summarizes with Elementary Discourse Units (EDUs), while Ernst et al. (2021) endorse using Open Information Extraction (OpenIE) -based propositions (Stanovsky et al., 2018) for summarization.

In this paper, we revisit and combine the clustering-based approaches along with sub-sentential setting, two research lines that were explored only individually and rather scarcely in recent years. Specifically, we apply clustering-based summarization at the more fine-grained *propositional* level, which avoids grouping non-aligned texts, yielding accurate paraphrastic clusters. These clusters also provide better control over the generated summary sentences – as the generation component is only required to fuse similar propositions.

Our model (§3) leverages gold reference summaries to derive training datasets for several summarization sub-tasks. First, salient document propositions were extracted, to train a salience model, by greedily maximizing alignment with the reference summaries. Then, an available proposition similarity model, trained from summary-source alignments (Ernst et al., 2021), provides the basis for agglomerative clustering (Ward, 1963). Finally, we created training data for a BART-based model for sentence fusion (Lewis et al., 2020) by aligning reference summary propositions with source proposition clusters. Similar to many other works, we leave inter-sentence coherence and sentence planning and ordering outside the scope of the current paper. Accordingly, our process produces a bullet-style summary of individual concise and coherent sentences.

Overall, our experiments (§4) show that this multi-step model outperforms strong recent end-to-end solutions, which do not include explicit modeling of propositions and information redundancy. To the best of our knowledge, our approach achieves state-of-the-art results in our setting on the DUC 2004 and TAC 2011 datasets, with an improvement of more than 1.5 and 4 ROUGE-1 F1 points respectively, over the previous best approach. Finally, we also suggest (§5) that clustering-based methods provide “explanations", or supporting evidence, for each generated sentence, in the form of the source cluster propositions (see an example in Table 1).

2 Background and Related Work

Clustering-based summarization. Clustering-based summarization approaches typically involve salience detection while avoiding redundancy. One such approach clustered topically-related sentences, after which cluster properties were leveraged for rating sentence salience (Radev et al., 2004; Wang et al., 2008; Wan and Yang, 2008). Another approach rated sentence salience and clustered sentences simultaneously, iteratively improving the two objectives (Cai et al., 2010; Wang et al., 2011; Cai and Li, 2013; Zhang et al., 2015). Recently, however, clustering methods have been gradually marginalized out, being replaced by neural techniques. More recently though, some approaches (Nayeem et al., 2018; Fuad et al., 2019) presented abstractive clustering-based summarization, where topically-related sentences in each cluster are fused together to generate a summary sentence candidate. While most of previous clustering approaches operated at the noisy sentence level, in our work we present more accurate proposition-level clustering that eventually enhances summarization.

Sub-sentence units in summarization. While many summarization approaches extract full document sentences, either for extractive summarization or as an intermediate step for abstractive summarization, there are methods that operated the sub-sentential level. Li et al. (2016); Liu and Chen (2019); and Xu et al. (2020) produced extractive summaries consisting of Elementary Discourse Units (EDUs) – clauses comprising a discourse unit according to Rhetorical Structure Theory (RST) (Mann and Thompson, 1988). Such extractive approaches usually focus on content selection, possibly disregarding the inferior coherence arising from the concatenation of sub-sentence units. Accordingly, Arumae et al. (2019) established the highlighting task, where salient sub-sentence units are marked within their document to provide surrounding context. Recently, Cho et al. (2020) proposed identifying heuristically self-contained sub-sentence units for the highlighting task.

Abstractive approaches have been extracting sub-sentence units as a preliminary step for generation. Such units range from words (Lebanoff et al., 2020; Gehrmann et al., 2018), to noun or verb phrases (Bing et al., 2015), to OpenIE propositions (Pasunuru et al., 2021). In our work, we follow the same extract-then-generate pipeline, using Ope-

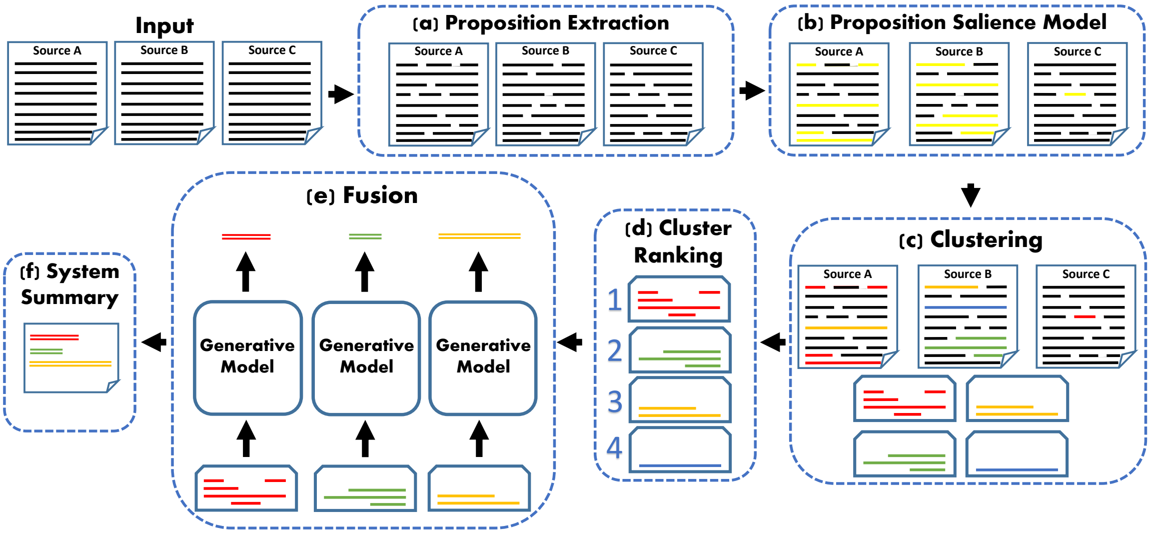

Figure 2: Our multi-document summarization process. (a) All propositions are extracted (OpenIE; Stanovsky et al., 2018) from the documents. (b) Propositions are classified by a salience score (fine-tuned CDLM; Caciularu et al., 2021). (c) Salient propositions are clustered (fine-tuned SuperPAL; Ernst et al., 2021), forming groups of paraphrastic information units. (d) Clusters are ranked, as an indicator for information importance. (e) For each cluster, its propositions are fused (fine-tuned BART; Lewis et al., 2020) to generate a concise and coherent abstractive sentence. (f) The output summary is obtained as a bullet-style ranked list of the concise sentences.

nIEs (Stanovsky et al., 2018) as propositions. Since propositions are meant to contain single standalone facts consisting of a main predicate and its arguments, they are beneficial for grouping mostly overlapping paraphrases (unlike sentential paraphrases). In addition, propositions extracted with OpenIE can be noncontiguous, while alternative options, like EDUs, are limited to contiguous sequences.

3 Method

This section first provides an overview of our method, followed by subsections describing its components. We follow previous clustering-based approaches, where text segments are first clustered into semantically similar groups, exploiting redundancy as a salience signal. Then, each group is fused to generate a merged sentence, while avoiding redundancy. As we operate at the proposition-level, we first extract all propositions from the input documents (§3.1). Then, to facilitate the clustering step, we filter out non-salient propositions using a salience model (§3.2). Next, salient propositions are clustered based on their semantic similarity (§3.3). The largest clusters, whose information was most repeated, are selected to be included in the summary (§3.4). Finally, each cluster is fused to form a sentence for a bullet-style abstractive summary (§3.5). In addition, we provide an extractive version where a representative (source) proposition is selected from each cluster (3.6). Overall, clustering explicit propositions induces a multi-step process that requires dedicated training data for certain steps. To that end, we derive new training datasets for the salience detection and the fusion models from the original gold summaries. The full pipeline is illustrated in Figure 2, where additional implementation details are in §B in the Appendix.

3.1 Proposition Extraction

Aiming to generate proposition-based summaries, we first extract all propositions from the source documents using Open Information Extraction (OpenIE) (Stanovsky et al., 2018)[2], following Ernst et al. (2021). To convert an OpenIE tuple containing a predicate and its arguments into a proposition string, we simply concatenate them by their original order, as illustrated in Figure 3 in the Appendix.

3.2 Proposition Salience Model

To facilitate the clustering stage, we first aim to filter non-salient propositions by a supervised model. To that end, we derive gold labels for proposition salience from the existing reference summaries. Specifically, we select greedily propositions that maximize ROUGE-$1_{\text{F-1}}$ + ROUGE-$2_{\text{F-1}}$ against their reference summaries (Nallapati et al., 2017; Liu and Lapata, 2019) and marked them as salient.

Cluster A

- The agreement will make Hun Sen prime minister and Ranariddh president of the National Assembly.
- ...to a coalition deal...will make Hun Sen sole prime minister and Ranariddh president of the National Assembly.
- The deal, which will make Hun Sen prime minister and Ranariddh president of the National Assembly...ended more than three months of political deadlock
- Last week...Hun Sen's Cambodian People's Party and Ranariddh's FUNCINPEC party agreed to form a coalition that would leave Hun Sen as sole prime minister and make the prince president of the National Assembly.
- In a long-elusive compromise...opposition leader Prince Norodom Ranariddh will become president of the National Assembly

Cluster B

- ...opposition party leaders Prince Norodom Ranariddh and Sam Rainsy are out of the country
- Sam Rainsy and his then-ally Prince Norodom Ranariddh led an exodus of opposition lawmakers out of Cambodia
- Opposition leaders Prince Norodom Ranariddh and Sam Rainsy...said they could not negotiate freely in Cambodia
- Opposition leaders Prince Norodom Ranariddh and Sam Rainsy...citing Hun Sen's threats

Cluster C

- Hun Sen's Cambodian People's Party narrowly won the polls
- Hun Sen's ruling party narrowly won a majority in elections in July
- Hun Sen's Cambodian People's Party narrowly won the election.
- the ruling party narrowly won.

Cluster D

- A series of negotiations to forge a new government
- ...any...in deadlocked negotiations to form a government.
- A series of negotiations to forge a new government have failed.

Cluster E

- *Hun Sen accused him* of being behind a plot against his life.
- Sam Rainsy...to take refuge in a U.N. office in September to avoid arrest after Hun Sen accused him of
- Sam Rainsy...to avoid arrest after Hun Sen accused him of being behind a plot against his life.

Cluster F

- Hun Sen ousted Ranariddh in a coup.
- The men served as co-prime ministers until Hun Sen overthrew Ranariddh in a coup last year.
- Hun Sen overthrew Ranariddh in a coup last year.

ProCluster summary

A. The deal will make Hun Sen prime minister and Ranariddh president of the National Assembly

B. The opposition party leaders Prince Norodom Ranariddh and Sam Rainsy are out of the country

C. Hun Sen's Cambodian People's Party narrowly won the election.

D. A series of negotiations to forge a new government failed.

E. *The U.N. accused him* of being behind a plot against his life.

F. Hun Sen ousted Ranariddh in a coup last year.

G. The opposition alleging widespread fraud and intimidation by the CPP

H. The parties have refused to enter into a coalition with Hun Sen until their allegations of election fraud have been thoroughly investigated.

Reference Summary

Cambodia King Norodom Sihanouk praised formation of a coalition of the Countries top two political parties, leaving strongman Hun Sen as Prime Minister and opposition leader Prince Norodom Ranariddh president of the National Assembly.
The announcement comes after months of bitter argument following the failure of any party to attain the required quota to form a government.
Opposition leader Sam Rainey was seeking assurances that he and his party members would not be arrested if they return to Cambodia.
Rainey had been accused by Hun Sen of being behind an assassination attempt against him during massive street demonstrations in September.

Table 1: The proposition clusters and system and reference summaries for DUC 2004, topic D30001. Each summary sentence (lower left box) was fused from its corresponding cluster (top boxes) that also provides supporting source evidence. An example of an unfaithful abstraction is marked in *red*.

Using this derived training data, we fine-tuned the Cross-Document Language Model (CDLM) (Caciularu et al., 2021) as a binary classifier for predicting whether a proposition is salient or not. Propositions with a salience score below a certain threshold were filtered out. The threshold was optimized with the full pipeline against the final ROUGE score on the validation set. All propositions contained in the clusters in Table 1 are examples of predicted salient propositions. We chose to use CDLM as it was pretrained with sets of related documents, and was hence shown to operate well over several downstream tasks in the multi-document setting (e.g., cross-document coreference resolution and multi-document classification).

3.3 Clustering

Next, all salient propositions are clustered to semanticly similar groups. Clusters of paraphrastic propositions are advantageous for summarization as they can assist in avoiding redundant information in an output summary. Furthermore, paraphrastic clustering offers redundancy as an additional indicator for saliency, while the former salience model (§3.2) does not utilize repetitions explicitly. To cluster propositions we utilize SuperPAL (Ernst et al., 2021), a binary classifier that measures paraphrastic similarity between two propositions. All pairs of salient propositions are scored with SuperPAL, over which standard agglomerative clustering (Ward, 1963) is applied. Examples of generated clusters are presented in Table 1.

3.4 Cluster Ranking

The resulting proposition clusters are next ranked according to cluster-based properties. We examined various features, listed in Table 2, on our validation sets. The features examined include: average of ROUGE scores between all propositions in a cluster (*'Avg. ROUGE'*), average of SuperPAL scores between all propositions in a cluster (*'Avg. SuperPAL'*), average of the salience model scores of cluster propositions (*'Avg. salience'*), minimal position (in a document) of cluster propositions (*'Min. position'*), and cluster size (*'Cluster size'*).

For each feature, (1) clusters were ranked according to the feature, (2) the proposition with the highest salience model score (§3.2) was selected from each cluster as a cluster representative, (3) the representatives from the highest ranked clusters were concatenated to obtain a system summary. We also measured combinations of two features (*'Cluster size + Min. position'* for example), where the first feature is used for primary ranking, and the second feature is used for secondary ranking in case of a tie. In all options, if a tie is still remained, further ranking between clusters is resolved according to the maximal proposition salience score of each cluster. The resulting ROUGE scores of these summaries on validation sets are presented in Table 2.[3] We found that *'Cluster size'* yields the best ROUGE scores as a single feature, and *'Min. position'* further improves results as a secondary tie breaking ranking feature. Intuitively, a large cluster represents redundancy of information across documents thus likely to indicate higher importance.

3.5 Cluster Fusion

Next, we would like to merge the paraphrastic propositions in each cluster, while consolidating complementary details, to generate a new coherent summary sentence. As mentioned, this approach helps avoiding redundancy, since redundant information is concentrated separately in each cluster.

To train a cluster fusion model, we derived training data automatically from the reference summaries, by leveraging the SuperPAL model (Ernst et al., 2021) (which was also employed in §3.3). This time, the model is used for measuring the similarity between each of the cluster propositions (that were extracted from the documents) and each of the propositions extracted from the reference summaries. The reference summary proposition with the highest average similarity score to all cluster propositions was selected as the aligned summary proposition of the cluster. This summary proposition was used as the target output for training the generation model. Although these target OpenIE propositions may be ungrammatical or non-fluent, a human examination has shown that BART tends to produce full coherent sentences (mostly containing only a single proposition), even though it was finetuned over OpenIE extractions as target. Examples of coherent generated sentences can be seen in Table 1.

Cluster Feature	DUC 2004		TAC 2011	
	R1	R2	R1	R2
Avg. ROUGE	35.9	7.48	38.14	9.93
Avg. salience	35.5	7.98	41.18	12.55
Min. position	37.25	8.89	38.86	11.37
Avg. SuperPAL	37.41	8.90	41.22	12.59
Cluster size	37.58	9.01	41.35	12.49
Cluster size + Avg. SuperPAL	37.54	8.96	41.45	12.71
Cluster size + Avg. salience	37.77	9.09	41.44	12.62
Cluster size + Min. position	**38.05**	**9.21**	**41.68**	**12.78**

Table 2: ROUGE F1 results on validation sets when ranking clusters according to differing features (DUC 2004 is the validation set of TAC 2011 and vice versa). Two combined features means ranking on the first feature, and breaking ties with the second feature.

Accordingly, we fine-tuned a BART generation model (Lewis et al., 2020) with this dedicated training data. As input, the model receives cluster propositions, ordered by their predicted salience score (§3.2) and separated with special tokens. The final bullet-style summary is produced by appending generated sentences from the ranked clusters until the desired word-limit is reached.

3.6 Extractive Summarization Version

To support extractive summarization settings, for example when hallucination is forbidden, we created a corresponding extractive version of our method. In this version, we extracted a representative proposition for each cluster, which was chosen according to the highest word overlap with the sentence that was fused from this cluster by our abstractive version.

4 Evaluation

4.1 Experimental Setup

Datasets. We train and test our summarizer with the challenging DUC and TAC MDS benchmarks.

---

[3] We also tried training a regression model on a mixture of features that should predict the ROUGE score of a proposition, but results were comparable. Bettering the ranking process is left for future work.

[4] For the *Hi-MAP* and *MDS-Joint-SDS* approaches we present only DUC 2004 scores since TAC 2011 scores are not available for them.

[5] The outputs of DPP-Caps (Cho et al., 2019), HL-XLNet and HL-Tree (Cho et al., 2020) were re-evaluated using author released output.

Table 3: Automatic ROUGE F1 evaluation scores on the TAC 2011 & DUC 2004 MDS test sets. Our solutions (ProCluster) improve over the previous state-of-the-art methods both in the abstractive and extractive settings. Notably, our *abstractive* approach also surpasses the best *extractive* ones.

Specifically, following standard convention (Mao et al., 2020; Cho et al., 2019), we test on DUC 2004 using DUC 2003 for training, and on TAC 2011 using TAC 2008/2009/2010 for training. These sets contain between 30 and 50 topics each. For validation sets, we used DUC 2004 for the TAC benchmark and TAC 2011 for the DUC benchmark.

Automatic evaluation metric. Following common practice, we evaluate and compare our summarization system with ROUGE-1/2/SU4 F1 measures (Lin, 2004). Stopwords are not removed, and the output summary is limited to 100 words.[6] [7]

4.2 Automatic Evaluation

As seen in Table 3, our abstractive model, denoted ProCluster$_{\text{abs}}$ for Propositional Clustering, surpasses all abstractive baselines by a large margin in all measures on both TAC 2011 and DUC 2004. Moreover, while the abstractive system scores were typically inferior to extractive system scores, ProCluster$_{\text{abs}}$ notably outperforms all extractive baselines in both benchmarks. Overall, our ProCluster$_{\text{abs}}$ provides the new *abstractive* MDS state-of-the-art score in this setting. In Figure 4 we present an example of a ProCluster$_{\text{abs}}$ system summary along with previous abstractive and extractive state-of-the-art system summaries and the reference summary.

As said in §3.6, we also developed an extractive version, denoted ProCluster$_{\text{ext}}$. As ProCluster$_{\text{ext}}$ selects document propositions that have the highest overlap with ProCluster$_{\text{abs}}$ sentences, ProCluster$_{\text{ext}}$ achieves similar scores to ProCluster$_{\text{abs}}$, yielding the new *extractive* MDS state-of-the-art results.

For comparison we selected strong baselines, including previous state-of-the-art in this setup, in both the extractive and abstractive settings. See in Appendix §C for more concise details over each baseline. For reference, we also present a proposition-based extractive upperbound for each dataset (Oracle_{prop}), where document propositions were selected greedily to maximize ROUGE-1$_{\text{F-1}}$ + ROUGE-2$_{\text{F-1}}$ with respect to the reference summaries.

4.3 Ablation Analysis

To better apprehend the contribution of each of the steps in our pipeline, Table 5 presents results of the system when applying partial pipelines.

First, $\mathit{Salience}_{prop}$ generates summaries simply consisting of the highest scoring document propositions, according to the CDLM-based salience model (§3.2). We also trained the salience model on the sentence- rather than the proposition-level, and similarly generated summaries of salient sentences, denoted $\mathit{Salience}_{sent}$. The notable improvement of $\mathit{Salience}_{prop}$ over $\mathit{Salience}_{sent}$ in both

[7] Note that methods evaluated with ROUGE recall (instead of F1) or limited to 665 bytes (instead of 100 tokens) are not directly comparable to our approach.

RL-MMR	**PG-MMR**
• An unknown number of cats and dogs suffered kidney failure and about 10 died after eating the affected pet food , menu foods said in announcing the north american recall . • Menu foods said saturday it was recalling dog food sold under 46 brands and cat food sold under 37 brands and distributed throughout the united states , canada and mexico . • Pet owners were worried that the pet food in their cupboards could be deadly after millions of containers of dog and cat food sold at major retailers across north america were recalled .	• An unknown number of cats and dogs suffered kidney failure and about 10 died after eating the affected pet food , menu foods said in announcing the north american recall . • Menu foods , the ontario-based company that produced the pet food , said saturday it was recalling dog food sold under 40 brands including iams , nutro and eukanuba . • Menu foods is recalling only certain gravy-style pet food in cans and pouches it made from dec. 3 to march 6 . • Pet owners were worried that the pet food in their cupboard may be deadly after millions of containers of dog and cat food sold .
ProCluster summary	**Reference Summary**
• The company announced the recall after receiving complaints that cats and dogs were suffering kidney failure. • Menu Foods recalled dog food sold under 48 brands and cat food • A major manufacturer of dog and cat food recalled 60 million containers of dog food. • The products were made by Menu Foods.The company • Cat food sold under 40 brands including Iams, Nutro and Eukanuba • The company began using wheat gluten from a new supplier • The 10 cats and dogs whose deaths have been linked to pet food • The food was distributed throughout the United States, Canada and Mexico. • Pet food sold under Wal-Mart, Safeway, Kroger and other store brands.	• On Friday, March 16, 2007, Menu Foods of Streetsville, Ontario, began recalling 60 million containers of pet food after reports of ten animal deaths. • Menu's dog foods are sold under 48 brands and cat foods under 40 brands. • This company sells its products in the U.S., Canada and Mexico, and provides its products to 17 of the top 20 North American retailers. • The foods may have become contaminated by wheat gluten purchased from a new supplier which caused kidney failure in the animals. • The recalls bear code dates of 6339 through 7073. • The company will compensate owners of deceased animals.

Table 4: The system summaries and reference summary of topic D1104 in TAC 2011.

datasets reveals the advantage of working at the proposition level for exposing salient information. This observation is also apparent when comparing the proposition-based oracle ($Oracle_{prop}$) to the sentence-based oracle method ($Oracle_{sent}$). The results indicate that proposition-based systems have a higher ROUGE upperbound across the board, supporting its merit for use in summarization.

Next, we would like to assess the contribution of the clustering step. Therefore, we applied Salience$_{\text{prop}}$ followed by clustering and ranking of clusters (Sections 3.2, 3.3 and 3.4), while leaving the fusion step aside. From each cluster we then select the proposition with the highest salience score to be in the system summary. In both datasets, the clustering stage provides added improvement, suggesting its contribution to our pipeline.

To further demonstrate the potential of our approach, we also present two additional oracle scores for extractive upperbound analysis. First, we examine the potential of optimally selecting cluster representatives for the summary. We greedily select a single representative per cluster following the original cluster ranking (§3.4) that optimizes the overall ROUGE-1$_{\text{F-1}}$ + ROUGE-2$_{\text{F-1}}$ score of all selected representatives with respect to the reference summaries ($Oracle_{cluster\text{-}rep}$). These results express the improvement comparing to our final model ($ProCluster_{abs}$), that a better cluster representative choice could produce, i.e., up to ~2 R-2 points in TAC 2011 and ~1 point in DUC 2004.

Another aspect to examine is the potential of enhanced cluster ranking. To that end, we first selected the highest salience-scoring proposition as a representative from each cluster. Then, we greedily selected representatives, one at a time, that maximized the overall ROUGE-1$_{\text{F-1}}$ + ROUGE-2$_{\text{F-1}}$ against the reference summaries. Effectively, this points to a greedily optimized cluster choice ($Oracle_{ranking}$). The potential improvement of better cluster ranking compared to our final model ($ProCluster_{abs}$) is hence up to ~5 R-2 points in TAC 2011 and ~3 points in DUC 2004. Indeed, our approach leaves cluster ranking improvement to future work.

Overall, we observe that all components of our multi-step approach are indeed effective for MDS, and that there is a great potential for further improvements within this architecture.

4.4 Human Evaluation

We further assessed our primary system, ProCluster$_{\text{abs}}$, through manual comparison against PG-MMR and RL-MMR, which are state-of-the-art MDS systems in the abstractive and extractive settings (respectively). Crowdworkers on Amazon Mechanical Turk[8] were shown the

	method	R1	R2	RSU4
TAC 2011	Oracle$_{\text{sent}}$	47.53	19.83	22.10
	Oracle$_{\text{prop}}$	49.65	21.82	23.19
	Oracle$_{\text{cluster-rep}}$	43.40	14.61	17.46
	Oracle$_{\text{ranking}}$	46.38	17.59	19.88
	Salience$_{\text{sent}}$	37.32	9.59	13.40
	Salience$_{\text{prop}}$	39.92	11.53	15.12
	Salience$_{\text{prop}}$ + Clustering	41.05	12.40	15.73
	ProCluster$_{\text{abs}}$	41.45	12.75	16.16
DUC 2004	Oracle$_{\text{sent}}$	43.91	14.50	17.39
	Oracle$_{\text{prop}}$	46.49	16.16	18.76
	Oracle$_{\text{cluster-rep}}$	39.74	10.76	14.56
	Oracle$_{\text{ranking}}$	43.70	12.92	16.43
	Salience$_{\text{sent}}$	37.38	9.09	12.90
	Salience$_{\text{prop}}$	37.73	8.97	13.18
	Salience$_{\text{prop}}$ + Clustering	38.41	9.09	13.56
	ProCluster$_{\text{abs}}$	38.71	9.62	14.07

Table 5: Ablation ROUGE F1 scores on TAC 2011 and DUC 2004. Each additional step in our multi-step method improves the output summaries. The Oracle results indicate the potential of our approach. Specifically, the benefit of summarizing on the proposition level is quite evident.

	method	Content	Read.	Grammar	Non-Red.
TAC	PG-MMR	**93%**	**84%**	**81%**	**72%**
	RL-MMR	**82%**	**70%**	**74%**	**52%**
DUC	PG-MMR	**81%**	**83%**	**82%**	**76%**
	RL-MMR	**70%**	**72%**	**71%**	**54%**

Table 6: Human pairwise comparisons between ProCluster$_{\text{abs}}$ and each of the two prior baseline systems, over the TAC 2011 and DUC 2004 datasets. The cells in a row show the percentage of cases in which our system was preferred over the corresponding baseline, under each of the four evaluation criteria: content, readability, grammaticality and non-redundancy.

	System	**unigram**	**bigram**	**trigram**	**sent.**
TAC	PG-MMR	98.36	94.42	91.97	50.11
	ProCluster$_{\text{abs}}$	99.08	91.40	81.07	24.39
	Ref. Summs.	90.27	53.17	29.66	1.48
DUC	PG-MMR	98.34	94.99	90.91	50.82
	ProCluster$_{\text{abs}}$	98.86	89.72	78.28	23.50
	Ref. Summs.	88.41	44.27	18.65	0.13

Table 7: Percentage of n-gram/sentence overlap between summaries and source documents in TAC 2011 and DUC 2004. Compared to PG-MMR, our system has substantially less sequential overlap, indicating its increased abstractiveness. Reference summaries are naturally highly abstractive.

summaries for a given topic from the three systems in arbitrary order, along with a corresponding reference summary. They were asked to rank the systems with respect to **Content** (content overlap with the reference), **Readability** (the degree to which a summary is readable and well-understood), **Grammaticality** (avoiding grammar errors), and **Non-Redundancy** (avoiding information repetition). Focusing on evaluating our system, we extract from this ranking a pairwise comparison between our ProCluster$_{\text{abs}}$ and each of the two baseline systems, separately. For each topic, this procedure was repeated for each of the four available reference summaries. Each such evaluation instance was judged independently by three workers, taking their majority vote for each pairwise comparison.

Table 6 presents the results of these pairwise comparisons, showing the percentage of cases in which our system was preferred over each one of the two baselines, under each of the four evaluation criteria. As can be seen, our system was favored in all cases, for both datasets. Furthermore, preference is almost always by a large margin, except for Non-Redundancy against RL-MMR, which avoids redundancy at a similar success level. Notably, as our clustering-based method is focused on improving content selection, the large gap in favor of ProCluster$_{\text{abs}}$ in the content criterion supports its advantage, consistently with our ROUGE-score advantage in the automatic evaluation (§4.2).

While our summaries are (somewhat non-conventionally) structured as bullet-style lists of propositions rather than a coherent paragraph, evaluators preferred our style of summarization in terms of readability. Moreover, as Table 7 points out, ProCluster$_{\text{abs}}$ appears to be more abstractive than PG-MMR, as suggested by the reduced n-gram and sentence overlap with source documents. Specifically, about half of the system summary sentences of PG-MMR are fully copied, compared to about a quarter in our method. While the intensified abstractiveness of our summaries could have potentially hindered readability, our system was nevertheless preferred along this aspect as well.

Our approach leaves fertile ground for further improving readability by fusing several clusters together to generate sentences containing multiple propositions, and by developing sentence planning and ordering models. Compatible training datasets for these models can be derived out of the gold reference summaries, as was done in this work for the salience (§3.2) and fusion (§3.5) models.

5 Paraphrastic Clusters as Summary Evidence

A unique advantage of a cluster-based summary is that each summary sentence is linked explicitly to a group of propositions from which the sentence was generated, in so providing an "explanation", or support evidence, for the output. These cluster explanations can expand the reader's knowledge and provide complementary facts from the nearby source context regarding the information from the generated sentence. Such a feature may be incorporated in interactive summarization systems, as applied in (Shapira et al., 2017), where a user can choose to expand on the facts within a sentence of the presented summary.

To assess the reliability of such feature, we verified that clusters indeed "explain" their generated sentences. To that end, we conducted a crowdsourced annotation, where a worker marked whether a cluster proposition mentions the main idea of its corresponding generated sentence. Each pair was examined by three workers, with the majority vote used for the final decision. On a random selection of 25% of the clusters, we found that, on average, 89% and 84% of a cluster's propositions in DUC 2004 and TAC 2011 support their corresponding generated sentence, with an average cluster size of 3.4 and 4.8 propositions, respectively.

Furthermore, given this strong alignment of a cluster to its generated sentence, a cluster facilitates effective verification of faithfulness of its corresponding generated abstractive sentence. Since the output sentence is based solely on its cluster propositions, the sentence's correctness can be verified against the "explaining" cluster instead of against the full document set. An example of an unfaithful abstraction is marked in red in Table 1. To the best of our knowledge, this is the first attempt for efficient manual assessment of faithfulness in MDS. We conducted a respective evaluation process, through crowdsourcing, to assess the faithfulness of our system summaries. A worker saw a cluster and its generated sentence and marked whether the sentence was faithful to its origin cluster or not. Overall, this task cost a reasonable price of 240$ for both the DUC 2004 and TAC 2011 datasets together. Over the full test sets, the annotations showed that 80% and 90% of the DUC 2004 and TAC 2011 summary sentences, respectively, were faithful to their corresponding clusters.

6 Conclusion

We advocate the potential of proposition-level units as a cleaner and more accurate unit for summarization. To that end, we present a new proposition-level pipeline for summarization that includes an accurate paraphrastic propositional clustering component followed by fusion of cluster propositions, to generate concise and coherent summary sentences. Our proposed method outperforms state-of-the-art baselines in both automatic and human evaluation on the DUC and TAC MDS benchmarks. We provide an ablation study that indicates the benefit of each of the pipeline steps, as well as the potential for future improvement. Moreover, we demonstrate the utility of the clustering-based approach for providing source documents explanations and for manually validating summary faithfulness.

Acknowledgments

The work described herein was supported in part by the PBC fellowship for outstanding PhD candidates in data science, Intel Labs, the Israel Science Foundation grant 2827/21, and by a grant from the Israel Ministry of Science and Technology.

Ethical Considerations

Computation. We ran on 3 GPUs for 20 minutes to finteune each of the salience model and the fusion model.

The summarization model runs 10 minutes on 4 GPUs to generate a summary. Most of the time is spent on the clustering step, in which we calculate the SuperPAL similarity score between all salient proposition pairs.

Dataset. The DUC 2003 and 2004 and TAC 2008-2011 datasets were acquired according to the required NIST guidelines (`duc.nist.gov`).

Crowdsourcing. All human annotations and evaluations conducted with crowdsourcing were compensated as a 12$ per hour wage. We estimated the task payment by completing sample assignments and obtaining the average assignment time.

A Data Statistics

Dataset	#Topics	#Sents$_{\text{per doc}}$	#Words$_{\text{per doc}}$
DUC 2003	30	259	6831
DUC 2004	50	265	6987
TAC 2008-2010	138	237	5978
TAC 2011	44	205	5146

Table 8: Dataset statistics, including the number of document sets (i.e. topics) and the average number of sentences or words per document. Number of documents per topic is constant (10) for all datasets.

B Implementation Details

B.1 Proposition Salience Model

Datasets. For many previous summarization systems these benchmarks were insufficiently large enough for training their models. Consequently, they pretrained on a large scale summarization dataset, such as CNN/DailyMail (Hermann et al., 2015), and then finetuned on DUC/TAC datasets (e.g., Lebanoff et al., 2018; Mao et al., 2020). In our case, we avoid external sources. However, as DUC training data is much smaller than TAC's (30 topics vs. 138), and it was apparently too small for the salience model training, we adopted the trained salience model for TAC benchmark (that was trained with TAC 2008-2010) as a pretrained model and then finetuned it with DUC 2003. Accordingly, validating the TAC benchmark using DUC 2004 during the salience model training causes data leakage since this model is later finetuned to test on the same DUC 2004. To avoid that, during the salience model training we used part of TAC 2010 that was omitted from training data, as a validation set (instead of DUC 2004).

Training Parameters. We trained the model for 10 epochs with learning rate of 1e-5 and batch size of 6 instances on 3 V100 GPUs (meaning effective batch size was 18).

Training. The CDLM model is fed with a proposition within its document and the other documents in the set. Specifically, since CDLM's input size is limited to 4,096 tokens, it is infeasible to feed the full document set as a long sequence. Therefore, following Lebanoff et al. (2019), only the first 20 sentences of each document are considered. Accordingly, a candidate proposition is input within its full document (up to 20 sentences), while other documents, ordered by their date, are truncated evenly and concatenated to fill the remaining space (9 sentences per document on average).

Each instance contains a proposition marked with start and end special tokens, within its multiple document context. A discontinuous proposition is marked with special tokens before and after each of its parts. In addition, sentence special token separators and document special token separators are used, as required for CDLM.

In order to reduce computation complexity, CDLM uses "local attention" (of 512 tokens) for all tokens, while specific tokens are attended to all 4096 tokens ("global attention"). In our case, we assigned global attention to the CLS token and to the candidate proposition tokens, including their special tokens.

For classification, we have added a binary classifier layer on top of our CDLM. The classification layer gets the CDLM's CLS output representation

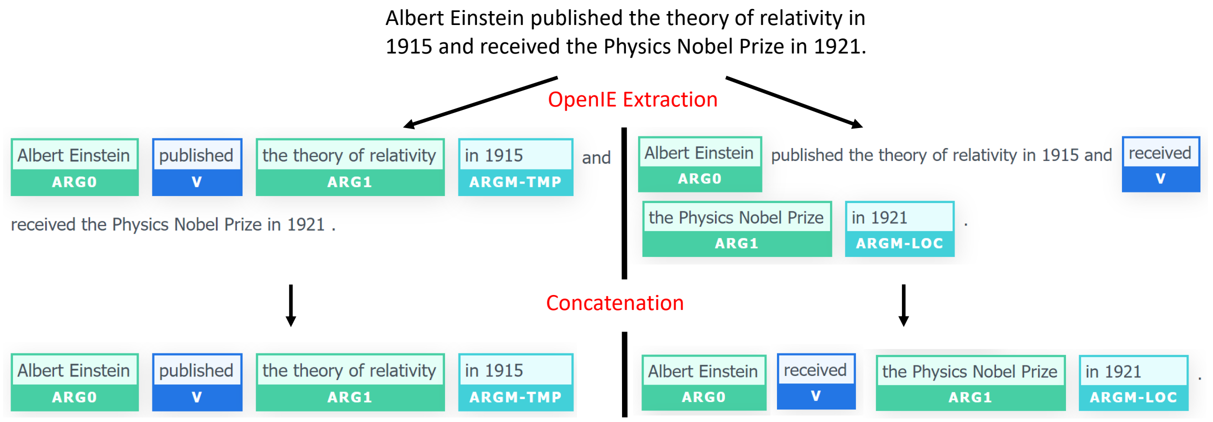

Figure 3: An example of OpenIE spans extracted from a sentence. First, a sentence is divided to OpenIE tuples, including a predicate (verb) and its arguments. Then all predicates and their arguments are concatenated together to a full span. This illustration uses AllenNLP's Demo[9].

concatenated to the sum of the CDLM output representations of the candidate proposition tokens:

$$CLS \odot \sum_{i \in Prop} T_i \qquad (1)$$

where T_i is the CDLM output representative of the i-th token, and $Prop$ contains the token indices of the candidate proposition.

As our proposition salience training dataset contains only a few positive (i.e., salient) propositions with respect to all propositions, it creates an unbalanced dataset that may strongly bias the model to give a negative prediction. To cope with this, we randomly filter out 60% of the non-salient propositions, while over sampling salient propositions until the dataset becomes balanced.

B.2 SuperPAL Usage

In this work we used the SuperPAL model (Ernst et al., 2021) as the similarity metric between propositions for the clustering step (§3.3), and to create training data for the fusion model (§3.5). Originally, SuperPAL was tuned with a validation set that contains three topics from DUC 2004 (taken from the full validation set which also contains 7 additional topics, not from DUC 2004). In our setting, it may cause leakage since DUC 2004 is used as the test data. To avoid such leakage, we tuned SuperPAL again without using DUC 2004 topics at all (using the other 7 topics as a validation set).

B.3 Cluster Ranking

For computation time consideration, we set a maximum number of clusters to be selected for each topic. Since in most topics the 100-word limit is exceeded after 8-10 propositional sentences, we set the maximum number of clusters to 10. Accordingly, the 10 (or fewer) highest ranked clusters are selected for the summary of each topic.

B.4 Fusion Model

Training Parameters. We trained the model for 3 epochs with learning rate of 3e-5 and batch size of 10 instances on 3 V100 GPUs (meaning effective batch size was 30).

C Compared Methods

We compare our method to several strong *abstractive* baselines: *Opinosis* (Ganesan et al., 2010) generates abstracts from salient paths in a word co-occurrence graph; *Extract+Rewrite* (Song et al., 2018) selects sentences using LexRank and generates for each sentence a title-like summary; *PG* (See et al., 2017) runs a Pointer-Generator model that includes a sequence-to-sequence network with a copy-mechanism; *PG-MMR* (Lebanoff et al., 2018) selects representative sentences with MMR (Carbonell and Goldstein, 1998) and fuses them with a PG-based model; *Hi-MAP* (Fabbri et al., 2019) is a hierarchical version of the PG model that allows calculating sentence-level MMR scores; *MDS-Joint-SDS* (Jin and Wan, 2020) is a hierarchical encoder-decoder architecture that is trained with SDS and MDS datasets while preserving document boundaries.

We additionally compare to several strong *extractive* baselines: *SumBasic* (Vanderwende et al., 2007) extracts phrases with words that appear frequently in the documents; *KLSumm* (Haghighi and Vanderwende, 2009) extracts sentences that optimize KL-divergence; *LexRank* (Erkan and Radev, 2004) is a graph-based approach where vertices represent sentences, the edges stand for word overlap between sentences, and sentence importance is computed by eigenvector centrality; *DPP-Caps-Comb* (Cho et al., 2019) balances between salient sentence extraction and redundancy avoidance by optimizing determinantal point processes (DPP); *HL-XLNetSegs* and *HL-TreeSegs* (Cho et al., 2020) are two versions of a DPP-based *span* highlighting approach that heuristically extracts candidate spans by their probability to begin and end with an EOS token; *RL-MMR* (Mao et al., 2020) adapts a neural reinforcement learning single document summarization (SDS) approach (Chen and Bansal, 2018) to the multi-document setup and integrates Maximal Margin Relevance (MMR) to avoid redundancy.

D Annotation Guidelines

We used Amazon Mechanical Turk[10] for all three crowdsource tasks with a list of 90 pre-selected workers from English speaking countries. These workers accomplished high quality work in other NLP-related tasks we have conducted in the past.

The crowdsourcing instructions of the tasks mentioned in §4.4 & 5 are as follows:

D.1 General Summarization System Evaluation.

Read the following four texts (Text A, B, C, and D) and answer the following questions.

Text A:
<*Reference summary*>
Text B:
<*System summary 1*>
Text C:
<*System summary 2*>
Text D:
<*System summary 3*>

- Which of the texts B, C, or D has the highest content overlap with text A?
- Which of the texts B, C, or D has the 2nd highest content overlap with text A?
- Which of the texts B, C, or D is the most readable and well-understood?
- Which of the texts B, C, or D is the 2nd most readable and well-understood?
- Which of the texts B, C, or D avoids grammar mistakes the best?
- Which of the texts B, C, or D avoids grammar mistakes the 2nd best?
- Which of the texts B, C, or D avoids information repetition the best?
- Which of the texts B, C, or D avoids information repetition the 2nd best?

D.2 Supporting Cluster Evaluation.

Read the following two text spans, and answer the question below.

Span Text A:
<*The generated sentence*>
Span Text B:
<*A proposition from the cluster*>
Is the main fact of Span Text A mentioned in Span Text B? (ignoring additional details)
Yes/No

D.3 Faithfulness Evaluation.

Read the following group of text spans A and text span B, and answer the questions below. You can assume that all text spans in group A describe the same event, and therefore can be consolidated together to imply Text Span B.

Examples:

1. **Group of Text Spans A:**
    - *They arrested John.*
    - *John was arrested.*

   Text Span B:
   The FBI arrested John

   Is the Group of Text Spans A implies the fact in Text Span B?

   Text Span B add a detail that is not mentioned in A. Therefore the answer is No.

2. **Group of Text Spans A:**
    - *there were 10-12 girls and 15 boys in the schoolhouse*
    - *there were boys and girls in the schoolhouse*

   Text Span B:
   there were 1012 girls and 15 boys in the schoolhouse

---

[10] https://www.mturk.com

Is the Group of Text Spans A implies the fact in Text Span B?

Text Span B contradicts Group A (instead of 10-12 girls it says 1012 girls). Therefore the answer is No.

Non-Autoregressive Machine Translation: It's Not as Fast as it Seems

Jindřich Helcl[1,2] and **Barry Haddow**[1] and **Alexandra Birch**[1]

Abstract

Efficient machine translation models are commercially important as they can increase inference speeds, and reduce costs and carbon emissions. Recently, there has been much interest in non-autoregressive (NAR) models, which promise faster translation. In parallel to the research on NAR models, there have been successful attempts to create optimized autoregressive models as part of the WMT shared task on efficient translation. In this paper, we point out flaws in the evaluation methodology present in the literature on NAR models and we provide a fair comparison between a state-of-the-art NAR model and the autoregressive submissions to the shared task. We make the case for consistent evaluation of NAR models, and also for the importance of comparing NAR models with other widely used methods for improving efficiency. We run experiments with a connectionist-temporal-classification-based (CTC) NAR model implemented in C++ and compare it with AR models using wall clock times. Our results show that, although NAR models are faster on GPUs, with small batch sizes, they are almost always slower under more realistic usage conditions. We call for more realistic and extensive evaluation of NAR models in future work.

1 Introduction

Non-autoregressive neural machine translation (NAR NMT, or NAT; Gu et al., 2018; Lee et al., 2018) is an emerging subfield of NMT which focuses on increasing the translation speed by changing the model architecture.

The defining feature of non-autoregressive models is the conditional independence assumption on the output probability distributions; this is in contrast to autoregressive models, where the output distributions are conditioned on the previous outputs. This conditional independence allows one to decode the target tokens in parallel. This can substantially reduce the decoding time, especially for longer target sentences.

The decoding speed is assessed by translating a test set and measuring the overall time the process takes. This may sound simple, but there are various aspects to be considered that can affect decoding speed, such as batching, number of hypotheses in beam search or hardware used (i.e., using CPU or GPU). Decoding speed evaluation is a challenging task, especially when it comes to comparability across different approaches. Unlike translation quality, decoding speed can be measured exactly. However, also unlike translation quality, different results are obtained from the same system under different evaluation environments. The WMT Efficient Translation Shared Task aims to evaluate efficiency research and encourages the reporting of a range of speed and translation quality values to better understand the trade-off across different model configurations (Heafield et al., 2021). In this paper, we follow the emerging best practices developed in the Efficiency Shared Task and directly compare with the submitted systems.

In the development of NAR models, modeling error and its subsequent negative effect on translation quality remains the biggest issue. Therefore, the goal of contemporary research is to close the performance gap between the AR models and their NAR counterparts, while maintaining high decoding speed. Considering these stated research goals, the evaluation should comprise of assessing translation quality as well as decoding speed.

Translation quality is usually evaluated by scoring translations of an unseen test set either using automatic metrics, such as BLEU (Papineni et al., 2002), ChrF (Popović, 2015) or COMET (Rei et al., 2020), or using human evaluation. To prevent methods from eventually overfitting to a single test set, new test sets are published each year as part of the WMT News Translation Shared Task. In contrast, translation quality evaluation in

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1780 - 1790
July 10-15, 2022

NAR research is measured almost exclusively on the WMT 14 English-German test set, using only BLEU scores. Automatic evaluation of translation quality remains an open research problem, but current research advises against relying on a single metric, and especially against relying on only BLEU (Mathur et al., 2020; Kocmi et al., 2021). In our experiments, we follow the recent best practices by using multiple metrics and recent test sets.

In this paper, we examine the evaluation methodology generally accepted in literature on NAR methods, and we identify a number of flaws. First, the results are reported on different hardware architectures, which makes them incomparable, even when comparing only relative speedups. Second, most of the methods only report latency (decoding with a single sentence per batch) using a GPU; we show that this is the only setup favors NAR models. Third, the reported baseline performance is usually questionable, both in terms of speed and translation quality. Finally, despite the fact that the main motivation for using NAR models is the lower time complexity, the findings of the efficiency task are ignored in most of the NAR papers.

We try to connect the separate worlds of NAR and efficient translation research. We train non-autoregressive models based on connectionist temporal classification (CTC), an approach previously shown to be effective (Libovický and Helcl, 2018; Ghazvininejad et al., 2020; Gu and Kong, 2021). We employ a number of techniques for improving the translation quality, including data cleaning and sequence-level knowledge distillation (Kim and Rush, 2016). We evaluate our models following a unified evaluation methodology: In order to compare the translation quality with the rest of the NAR literature, we report BLEU scores measured on the WMT 14 test set, on which we achieve state-of-the-art performance among (both single-step and iterative) NAR methods; we also evaluate the translation quality and decoding speed of our models in the same conditions as the efficiency task.

We find that despite achieving very good results among the NAT models on the WMT 14 test set, our models fall behind in translation quality when measured on the recent WMT 21 test set using three different automatic evaluation metrics. Moreover, we show that GPU decoding latency is the only scenario in which non-autoregressive models outperform autoregressive models.

This paper contributes to the research community in the following aspects: First, we point out weaknesses in standard evaluation methodology of non-autoregressive models. Second, we link the worlds of non-autoregressive translation and optimization of autoregressive models to provide a better understanding of the results achieved in the related work.

2 Non-Autoregressive NMT

The current state-of-the-art NMT models are autoregressive – the output distributions are conditioned on the previously generated tokens (Bahdanau et al., 2016; Vaswani et al., 2017). The decoding process is sequential in its nature, limiting the opportunities for parallelization.

Non-autoregressive models use output distributions which are conditionally independent of each other, which opens up the possibility of parallelization. Formally, the probability of a sequence y given the input x in a non-autoregressive model with parameters θ is modeled as

$$p_\theta(y|x) = \prod_{y_i \in y} p(y_i|x, \theta). \tag{1}$$

Unsurprisingly, the independence assumption in NAR models has a negative impact on the translation quality. The culprit for this behavior is the *multimodality problem* – the inability of the model to differentiate between different modes of the joint probability distribution over output sequences inside the distributions corresponding to individual time steps. A classic example of this issue is the sentence “Thank you” with its two equally probable German translations “Danke schön” and “Vielen Dank” (Gu et al., 2018). Because of the independence assumption, a non-autoregressive model cannot assign high probabilities to these two translations without also allowing for the incorrect sentences “Vielen schön” and “Danke Dank”.

Knowledge distillation (Kim and Rush, 2016) has been successfully employed to reduce the negative influence of the multimodality problem in NAR models (Gu et al., 2018; Saharia et al., 2020). Synthetic data tends to be less diverse than authentic texts, therefore the number of equally likely translation candidates gets smaller (Zhou et al., 2020).

A number of techniques have been proposed for training NAR models, including iterative methods (Lee et al., 2018; Ghazvininejad et al., 2019), auxiliary training objectives (Wang et al., 2019; Qian et al., 2021), or latent variables (Gu et al., 2018;

Lee et al., 2018; Kaiser et al., 2018). In some form, all of the aforementioned approaches use explicit target length estimation, and rely on one-to-one correspondence between the output distributions and the reference sentence.

A group of methods that relax the requirement of the strict one-to-one alignment between the model outputs and the ground-truth target sequence include aligned cross-entropy (Ghazvininejad et al., 2020) and connectionist temporal classification (Libovický and Helcl, 2018).

The schema of the CTC-based model, as proposed by Libovický and Helcl (2018), is shown in Figure 1. The model extends the Transformer architecture (Vaswani et al., 2017). It consists of an encoder, a state-splitting layer, and a non-autoregressive decoder. The encoder has the same architecture as in the Transformer model. The state-splitting layer, applied on the encoder output, linearly projects and splits each state into k states with the same dimension. The decoder consists of a stack of Transformer layers. Unlike the Transformer model, the self-attention in the non-autoregressive decoder does not use the causal mask, so the model is not prevented from attending to future states. Since the output length is fixed to k-times the length of the source sentence, the model is permitted to output blank tokens. Different positions of the blank tokens in the output sequence represent different alignments between the outputs and the ground-truth sequence. Connectionist temporal classification (Graves et al., 2006) is a dynamic algorithm that efficiently computes the standard cross-entropy loss summed over all possible alignments.

We choose the CTC-based architecture for our models because it has been previously shown to be effective for NAR NMT (Gu and Kong, 2021; Saharia et al., 2020) and performs well in the context of non-autoregressive research. It is also one of the fastest NAR architectures since it is not iterative.

3 Evaluation Methodology

The research goal of the non-autoregressive methods is to improve translation quality while maintaining the speedup brought by the conditional independence assumption. This means that careful thought should be given to both quantifying the speed gains and the translation quality evaluation. The speed-vs-quality trade-off can be characterized by the Pareto frontier. In this section we discuss the evaluation from both perspectives.

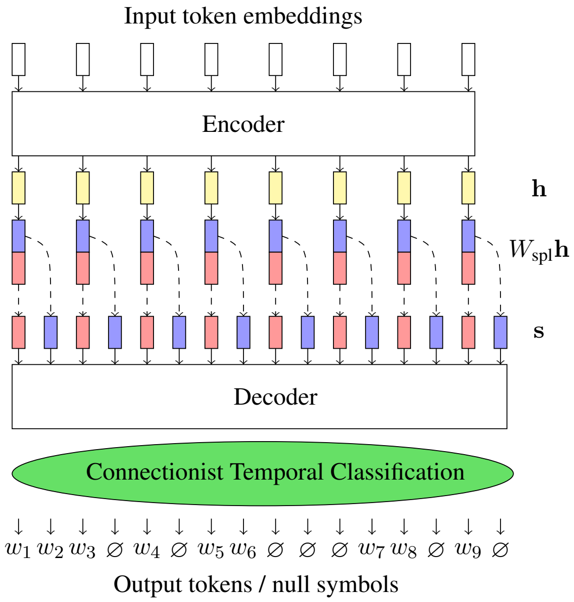

Figure 1: The schema of the CTC-based non-autoregressive architecture. We show the original image from Libovický and Helcl (2018).

Translation Quality. In the world of non-autoregressive NMT, the experimental settings are not very diverse. The primary language pair for translation experiments is English-German, sometimes accompanied by English-Romanian to simulate the low-resource scenario. These language pairs, along with the widely used test sets – WMT 14 (Bojar et al., 2014) for En-De and WMT 16 (Bojar et al., 2016) for En-Ro – became the de facto standard benchmark for NAR model evaluation.

A common weakness seen in the literature is the use of weak baseline models. The base variant of the Transformer model is used almost exclusively (Gu et al., 2018; Gu and Kong, 2021; Lee et al., 2018; Ghazvininejad et al., 2020; Qian et al., 2021). We argue that using weaker baselines might lead to overrating the positive effects brought by proposed improvements. Since the baseline autoregressive models are used to generate the synthetic parallel data for knowledge distillation, the weakness is potentially further amplified in this step.

Evaluation is normally with automatic metrics only, and often only BLEU is reported. In light of recent research casting further doubt on the reliability of BLEU as a measure of translation quality (Kocmi et al., 2021), we argue that this is insufficient.

Decoding Speed. The current standard in evaluation of NAR models is to measure translation latency using a GPU, i.e., the average time to translate a single sentence without batching. Since the time depends on the hardware, relative speedup is usually reported along with latency.

This is a reasonable approach but we need to keep in mind the associated difficulties. First, the results achieved on different hardware architectures are not easily comparable even when considering the relative speedups. We also note that the relative speedup values should always be accompanied by the corresponding decoding times in absolute numbers. Sometimes, this information is missing from the published results (Qian et al., 2021).

We argue that measuring only GPU latency disregards other use-cases. In the WMT Efficiency Shared Task, the decoding speed is measured in five scenarios. The speed is reported using a GPU with and without batching, using all 36 CPU cores (also, with and without batching), and using a single CPU core without batching. In batched decoding, the shared task participants could choose the optimal batch size. Our results in Section 5 show that measuring latency is the only one that favors NAR models, and as the batch size increases, AR models quickly reach higher translation speeds.

4 Experiments

We experiment with non-autoregressive models for English-German translation. We used the data provided by the WMT 21 News Translation Shared Task organizers (Akhbardeh et al., 2021).

As our baseline model, we use the CTC-based NAR model as described by Libovický and Helcl (2018). We use stack of 6 encoder and 6 decoder layers, separated by the state splitting layer which extends the state sequence 3 times.

We implement our models[1] in the Marian toolkit (Junczys-Dowmunt et al., 2018). For the CTC loss computation, we use the warp-ctc library (Amodei et al., 2016).

4.1 Teacher Models

For training our baseline autoregressive models, we closely follow the approach of Chen et al. (2021). The preparation of the baseline models consists of three phases – data cleaning, backtranslation, and the training of the final models.

Data	Raw size	Cleaned size
Parallel – clean	3.9	3.1
Parallel – noisy	92.0	84.6
Monolingual – En	93.1	91.0
Monolingual – De	149.9	146.2

Table 1: The sizes of the parallel and monolingual training datasets (in millions of examples).

We train the teacher models on cleaned parallel corpora and backtranslated monolingual data. For the parallel data, we used Europarl (Koehn, 2005), the RAPID corpus (Rozis and Skadiņš, 2017), and the News Commentary corpus from OPUS (Tiedemann, 2012). We consider these three parallel datasets clean. We also use noisier parallel datasets, namely Paracrawl (Bañón et al., 2020), Common Crawl[2], WikiMatrix (Schwenk et al., 2019), and Wikititles[3]. For backtranslation, we used the monolingual datasets from the News Crawl from the years 2018-2020, in both English and German.

We clean the parallel corpus (i.e. both clean and noisy portions) using rule-based cleaning[4]. Additionally, we exclude sentence pairs with non-latin characters. and we apply dual cross-entropy filtering on the noisy part of the parallel data (Junczys-Dowmunt, 2018). We train Transformer base models in both directions on the clean portion of the parallel data. Then, we select the best-scoring 75% of sentence pairs for the final parallel portion of the training dataset.

For backtranslation (Sennrich et al., 2016), we train four Transformer big models on the cleaned parallel data in both directions. We then use them in an ensemble to create the synthetic source side for the monolingual corpora. We add a special symbol to the generated sentences to help the models differentiate between synthetic and authentic source language data (Caswell et al., 2019).

We use hyperparameters of the Transformer big model, i.e. model dimension 1,024, feed-forward hidden dimension of 4,096, and 16 attention heads. For training, we use the Adam optimizer (Kingma and Ba, 2014) with β_1, β_2 and ϵ set to 0.9, 0.998 and 10^{-9} respectively. We used the inverted square-root learning rate decay with 8,000 steps of linear

[4] `https://github.com/browsermt/students/blob/master/train-student/clean/clean-corpus.sh`

warm-up and initial learning rate of 10^{-4}.

The teacher models follow the same hyperparameter settings as the models for backtranslation, but are trained with the tagged backtranslations included in the data. As in the previous case, we train four teacher models with different random seeds for ensembling.

Similar to creating the backtranslations, we use the four teacher models in an ensemble to create the knowledge-distilled data (Kim and Rush, 2016). We translate the source side of the parallel data, as well as the source-language monolingual data. We do not translate back-translated data. Thus, the source side data for the student models is authentic, and the target side is synthetic, created by the teacher models.

4.2 Student Models

We train five variants of the student models with different hyperparameter settings. The "Large" model is our baseline model – the same number of layers as the teacher models, 6 in the encoder, followed by the state splitting layer, and another 6 layers in the decoder. The "Base" model has the same number of layers with reduced dimension of the embeddings and the feed-forward Transformer sublayer, to match the Transformer base settings. We also try reducing the numbers of encoder and decoder layers. We shrink the base model to 3-3 ("Small"), 2-2 ("Micro"), and 1-1 ("Tiny") architectures.

We run the training of each model for three weeks on four Nvidia Pascal P100 GPUs.

5 Results

In this section, we try to view the results of the NAR and efficiency research in a shared perspective. We evaluate our models and present results in terms of translation quality and decoding speed. We compare the results to the related work on both non-autoregressive translation and model optimization.

Translation Quality. The research on non-autoregressive models uses the BLEU score (Papineni et al., 2002) measured on the WMT 14 test set (Bojar et al., 2014) as a standard benchmark for evaluating translation quality. We use Sacrebleu (Post, 2018) as the implementation of the BLEU score metric. Using a single test set for the whole volume of research on this topic may however produce misleading results. To bring the evaluation up to date with the current state-of-the-art translation systems, we also evaluate our models using COMET (Rei et al., 2020)[5] and BLEU[6] scores on the recent WMT 21 test set. The same test set was used in the WMT 21 Efficiency Task.

	En → De	De → En
Saharia et al. (2020)	28.2	31.8
Gu and Kong (2021)	27.2	31.3
Qian et al. (2021)	26.6	31.0
Large	28.4	31.3
Base	23.7	30.3
Small	23.6	29.1
Micro	25.0	27.5
Tiny	20.3	21.7

Table 2: The BLEU scores of the NAR models on the WMT 14 test set

Table 2 shows the BLEU scores of our NAR models on the WMT 14 test set. We show the results of the five variants of the NAR models and we include three of the best-performing NAR approaches from the related work. We see from the table that using BLEU, the "Large" model scores among the best NAR models on the WMT 14 test set. As the NAR model size decreases, so does the translation quality, with the notable exception of the En→De "Micro" model, which outperforms the "Base" model consistently on different test sets.

In Table 3, we report the automatic evaluation results of our AR and NAR models on the multi-reference WMT 21 test set (Akhbardeh et al., 2021). We compare our NAR models to the AR large teacher models from Section 4.1, an AR base model trained on the original clean data, and an AR base student model trained on the distilled data. Following Heafield et al. (2021), we use references A, C, and D for English-German translation.

We see that there is a considerable difference in the translation quality between the NAR models and the AR large teacher model. This difference grows with beam search and ensembling applied on the AR decoding, techniques not usually used with NAR models because of the speed cost. We

[6] Signature: `nrefs:3|bs:1000|seed:12345|case:mixed|eff:no|tok:13a|smooth:exp|version:2.0.0`. For WMT 21 De → En, only 2 references were used. For WMT 14, we used the signature with the exception of having only a single reference.

En → De	COMET	BLEU
AR – Large	0.4110	50.5 ±1.3
+ beam	0.4053	50.8 ±1.3
+ ensemble	0.4332	52.2 ±1.3
AR – Base	0.3881	47.9 ±1.3
+ beam	0.3873	48.0 ±1.3
Student AR – Base	0.4550	51.6 ±1.2
NAR models		
Large	0.1485	47.8 ±1.2
Base	-0.0521	41.8 ±1.1
Small	-0.0752	41.9 ±1.1
Micro	-0.0083	43.5 ±1.1
Tiny	-0.3333	34.7 ±1.0

Table 3: Results of quantitative evaluation of English-German translation quality using automatic metrics on the multi-reference WMT 21 test set. The confidence intervals were computed using Sacrebleu.

also note that when we train an AR base model on the distilled data, it outperforms the NAR large model by a considerable margin.

Another thing we notice is the enormous difference in the COMET scores between the AR and NAR models. The AR base models achieve comparable BLEU scores to the NAR large models, but differ substantially in the COMET score. From a look at the system outputs, we hypothesize that the NAR systems produce unusual errors which BLEU does not penalise as heavily as COMET. This might suggest that NAR models would rank poorly in human evaluation relative to their autoregressive counterparts, despite the reasonable BLEU score values. Another reason might be that the different errors of NAR models are causing a domain mismatch between the COMET training data and the data being evaluated.

Decoding speed. We follow the decoding time evaluation methodology of the WMT 21 Efficient Translation Shared Task (Heafield et al., 2021). We recreate the hardware conditions that were used in the task. For the GPU decoding measurements, we use a single Nvidia Ampere A100 GPU. The CPU evaluation was performed on a 36-core CPU Intel Xeon Gold 6354 server from Oracle cloud. To amortize the various computation overheads, the models submitted to the shared task are evaluated on a million sentence benchmark dataset.

We measure the overall wall time to translate the shared task dataset with different batching settings on both the GPU and the 36-core CPU. The decoding times are shown in Figures 2 and 4 for the GPU and CPU times, respectively. We do not report the single-core CPU latencies as the decoding speed of the NAR models falls far behind the efficient AR models in this setup and the translation of the dataset takes too long.

Model	Latency (ms)
Gu et al. (2018)	39
Wang et al. (2019)	22
Sun et al. (2019)	37
Ours – Large	14

Table 4: The comparison of the decoding time of various NAR models for a single sentence in a batch on a P100 GPU. Note that this table should serve merely as an illustration, since the results were measured on different datasets.

We can see that in case of GPU decoding that all models benefit from having larger batch sizes. However, the non-autoregressive models are much faster when the batch size is small. We also ran the evaluation on an Nvidia Pascal P100 GPU, which showed that when the batch size is large enough, autoregressive models eventually match the speed of non-autoregressive models. We show the decoding times on the Pascal GPU in Figure 3. In Table 4, we compare the latencies measured on the Pascal GPU to some of the related NAR approaches that report results on this GPU type. Due to implementation reasons, the maximum batch size for our NAR models is around 220 sentences.

Comparison with Efficient AR Models. In Table 5, we present a comparison on the million sentence test set with "Edinburgh base", one of the leading submissions in the WMT 21 efficiency task (Behnke et al., 2021), which uses the deep encoder – shallow decoder architecture (Kasai et al., 2021). First, we see that using three different evaluation metrics (ChrF, COMET, and BLEU), our models lag behind the Edinburgh base model. In line with our previous observation, we see a considerable drop in the COMET score values. In terms of decoding speed, the only scenario in which the non-autoregressive model is better is on GPU with batch size 1. This is in line with our intuition that the parallelization potential brought by the GPU is utilized more efficiently by the NAR model. On

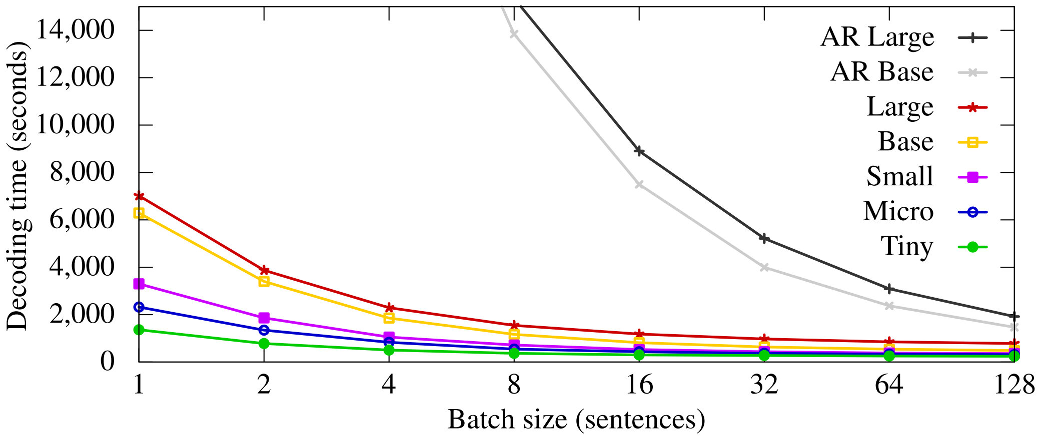

Figure 2: The decoding times to translate the efficiency task test set using various batch size settings, computed on a single Nvidia Ampere A100 GPU, i.e. the GPU type used for evaluation in the efficiency task.

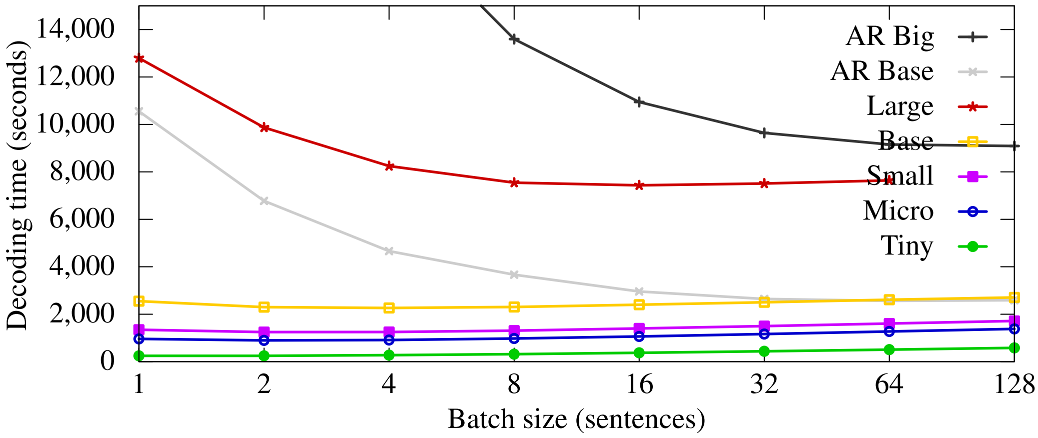

Figure 4: The decoding times to translate the efficiency task test set using various batch size settings, computed on 36 CPU cores.

	Translation quality			Decoding time (seconds)		
	ChrF	COMET	BLEU	GPU, b>1	GPU, b=1	CPU, b>1
Edinburgh base (Behnke et al., 2021)	61.5	0.527	55.3	140	16,851	500
AR – Large (teacher)	59.2	0.411	50.5	1,918	> *24h*	9,090
AR – Base (student)	59.5	0.455	51.6	1,465	> *24h*	2,587
NAR – Large	58.6	0.149	47.8	782	7,020	7,434
NAR – Micro	57.3	-0.008	43.5	311	2,322	897

Table 5: A comparison of our AR and NAR models with one of the submissions to the WMT 21 efficiency task. We show the results of automatic translation quality evaluation using three different metrics, and the decoding time to translate the test set using a GPU and 36-core CPU with either latency (b=1) or batched (b>1) decoding.

one hand, larger batches open up the parallelization possibilities to AR models. On the other hand, limited parallelization potential (in form of CPU decoding) reduces the differences between AR and NAR models. The batch size of the Edinburgh base model was 1,280 in the batched decoding setup.

6 Conclusions

In this paper, we challenge the evaluation methodology adopted by the research on non-autoregressive models for NMT.

We argue that in terms of translation quality, the evaluation should include newer test sets and metrics other than BLEU (particularly COMET and ChrF). This will provide more insight and put the results into the context of the recent research.

From the decoding speed perspective, we should bear in mind various use-cases for the model deployment, such as the hardware environment or batching conditions. Preferably, the research should evaluate the speed gains across a range of scenarios. Finally, given that the latency condition – translation of one sentence at a time on a GPU – already translates too fast to be perceived by human users of MT, there is currently no compelling scenario that warrants the deployment of NAR models.

BAD-X: Bilingual Adapters Improve Zero-Shot Cross-Lingual Transfer

Abstract

Adapter modules enable modular and efficient zero-shot cross-lingual transfer, where current state-of-the-art adapter-based approaches learn specialized *language adapters* (LAs) for individual languages. In this work, we show that it is more effective to learn *bilingual language pair adapters* (BAs) when the goal is to optimize performance for a *particular source-target transfer direction*. Our novel BAD-X adapter framework trades off some modularity of dedicated LAs for improved transfer performance: we demonstrate consistent gains in three standard downstream tasks, and for the majority of evaluated low-resource languages.

1 Introduction

Massively multilingual Transformers (MMTs) such as mBERT (Devlin et al., 2019), XLM-R (Conneau et al., 2020), and mT5 (Xue et al., 2021) have dominated research in multilingual NLP and cross-lingual transfer recently. Pretrained on large amounts of unlabelled data in 100+ languages, they have been shown to achieve impressive performance for a wide range of languages and tasks, and in zero-shot cross-lingual transfer in particular (Wu and Dredze, 2019; K et al., 2019). However, their representational capacity is known to be limited by *the curse of multilinguality*: a trade-off between the language coverage and model capacity (Conneau et al., 2020), which typically favors high-resource languages. Their limitations are thus especially pronounced in low-resource scenarios, in transfer between distant languages and towards resource-poor target languages (Hu et al., 2020; Lauscher et al., 2020; Ansell et al., 2021, *inter alia*).

A standard approach to zero-shot cross-lingual transfer with MMTs (i) fine-tunes the full MMT on task-specific data in the source language and then (ii) applies it directly to make predictions in the target language (Hu et al., 2020). On top of the expensive fine-tuning of the entire large model, this standard procedure also does not *'prepare'* the MMT to excel at *a particular target language* or for a *particular source-target transfer direction*.

This has been alleviated through modular parameter-efficient adaptations of the MMTs (Bapna and Firat, 2019; Philip et al., 2020; He et al., 2021) which bypass full fine-tuning, most prominently through lightweight *adapters* (Rebuffi et al., 2017; Houlsby et al., 2019): additional trainable parameters inserted into the MMT's layers. They have recently been used for language and task specialization of the MMTs (Pfeiffer et al., 2020b), offering improved and more efficient zero-shot cross-lingual transfer.

Previous work (Pfeiffer et al., 2020b; Üstün et al., 2020, 2021; Vidoni et al., 2020; Ansell et al., 2021, *inter alia*) focused on creating: **1)** dedicated language adapters (LAs) for each individual language, and **2)** individual task adapters (TAs). Creating single-language LAs enables a very modular approach to cross-lingual transfer, where a source language LA (used in training) can be directly swapped with any target language LA at inference. Yet, this procedure still does not prepare nor adapt the MMT for a *particular source-target transfer direction*. Put simply, if one's incentive is to optimize the performance of a particular target language L_t given annotated data in a particular source language L_s, especially under low-data regimes, one might try to capture the interplay between the two languages instead of learning separate LAs.

To address this gap, in this work we introduce the BAD-X framework: bilingual adapters (BAs) for zero-shot cross-lingual transfer (see Figure 1), designed towards improving transfer performance for a particular transfer direction, with a focus on low-resource target languages. The goal of BAD-X is to specialize the MMT for a particular language pair, while preserving all its existing knowledge encoded into the MMT's parameters.

We experiment with three standard tasks in cross-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1791 - 1799
July 10-15, 2022

lingual transfer (Lauscher et al., 2020; Ansell et al., 2021): part-of-speech tagging (POS), dependency parsing (DP) and natural language inference (NLI), and with a total of 20 low-resource target languages. Our results demonstrate that trading off modularity of single-language LAs for less modular BAs (tailored for language pairs) indeed yields improved transfer performance over the current state-of-the-art (SotA) adapter-based transfer framework MAD-X (Pfeiffer et al., 2020b), in all three tasks and for the large majority of target languages. We also show that, under the fixed fine-tuning budget and resources, further task performance gains can be achieved by varying the ratio of L_s-vs-L_t unannotated data when learning BAs. Finally, aiming to delve deeper into the trade-off between modularity and training efficiency, we experiment with multilingual adapters that are trained on the source language and all target languages under consideration at once. We show that such adapters, despite being more efficient to train, are unable to match the performance of their more specialized counterparts across a diverse set of target languages.

We share our code and pretrained BAs online at: `https://github.com/parovicm/BADX`.

2 BAD-X: Methodology

Motivation and Overview. The main idea can be summarized into the following: instead of adapting the MMT to languages L_s and L_t separately as done in the SotA adapter-based MAD-X framework (Pfeiffer et al., 2020b), cross-lingual transfer might be more effective by adapting the MMT directly to the language pair (L_s, L_t). This means that we learn a bilingual language-pair adapter instead of two separate monolingual LAs. We then learn a task adapter directly on top of the BA: since we focus on the zero-shot setting, this means using task-annotated examples only from L_s to fine-tune the TA. This procedure is summarized in Figure 1.[1]

BAD-X Adapters. BAD-X adapts the MAD-X adapter framework, where BAs are learnt instead of single-language LAs. The architecture of the adapter in each layer l consists of a down- and up-projection with a residual connection. More specifically, let the down-projection be a matrix $\mathbf{D}_l \in \mathbb{R}^{h \times d}$ and the up-projection be a matrix $\mathbf{U}_l \in \mathbb{R}^{d \times h}$ where h is a hidden size of the MMT and d is the hidden size of the adapter. Let us denote MMT's hidden state and the residual at layer l as $\mathbf{h}_l$ and $\mathbf{r}_l$, respectively. The adapter computation of layer l is then given by:

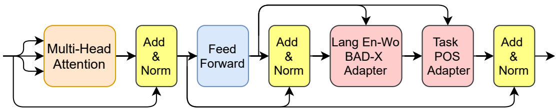

Figure 1: BAD-X adapter module at one MMT layer, showing the BAD-X BA for one language pair (English-Wolof: En-Wo) and the POS TA. The same module (but different parameters) is added at each MMT layer.

$$A_l(\mathbf{h}_l, \mathbf{r}_l) = \mathbf{U}_l(\mathrm{ReLU}(\mathbf{D}_l(\mathbf{h}_l))) + \mathbf{r}_l, \qquad (1)$$

with ReLU as the activation function. This formulation subsumes LAs and TAs in MAD-X, as well as BAs and TAs in BAD-X, where LAs/BAs receive the input from the (frozen) Transformer layer, while TAs receive the input from the (frozen) LA/BA put on top of the frozen Transformer layer (Figure 1).[2]

MAD-X LAs are trained via masked-language modeling (MLM) objective on the Wikipedia of the corresponding language, while TAs are trained on annotated task data. Once LA for L_s is available, TA is trained by stacking it on top of the fixed source LA. Transfer is done by replacing the L_s LA with the L_t LA. Unlike MAD-X, BAD-X trains a single bilingual adapter via MLM, alternating between the unlabelled (Wikipedia) data from both L_s and L_t. The 'data alternations' are done according to a predefined *ratio*: e.g., the ratio of N:1 denotes that the model would see N L_s sentences followed by 1 L_t sentence. The motivation for this is twofold: **1)** seeing a data mixture from the two languages could produce a BA that is better for transfer than having two independent LAs; **2)** LAs for low-resource L_t-s might otherwise overfit due to unlabelled data scarcity in L_t, and thus could benefit from additional L_s data.

In BAD-X, TA is then again trained on top of

---

[1] Inspiration for BAD-X originates from neural machine translation (NMT), where bilingual adapters have been trained on parallel corpora of two languages to recover performance of a massively multilingual NMT model for high-resource languages (Bapna and Firat, 2019). BAD-X, however, proposes bilingual adapters (i) without the use of any parallel data, (ii) with the goal to support the downstream cross-lingual transfer, and (iii) it targets low-resource target languages.

[2] MAD-X also relies on so-called *invertible adapters* for slightly improved performance, see (Pfeiffer et al., 2020b) for further details; they have a similar effect on BAD-X, but we omit them to boost simplicity and clarity of the design and the experimental setup.

the fixed BA, and the same BA-TA configuration is retained at inference, see Figure 1 again.

Advantages and Limitations. BAD-X allows parameter-efficient transfer to arbitrary tasks and languages by learning modular bilingual and task representations. It trades-off some modularity of MAD-X for increased performance and expressiveness when the goal is to perform a transfer for a fixed pair of languages. A disadvantage of BAD-X with respect to modularity is that it no longer offers a zero-cost transfer (once all LAs are learnt) between all language pairs under consideration: it requires training of separate BAs for all pairs of interest. However, as we show further in §3, BAD-X might be preferable over MAD-X in the cases when the goal is to improve a particular source-target direction, which is our targeted use-case.

3 Experiments and Results

Tasks and Languages. We evaluate BAD-X on three standard cross-lingual tasks which allow for experimentation with low-resource target languages: POS, DP, and NLI. For POS and DP, we sample ten low-resource languages from the Universal Dependencies (UD) 2.7 dataset (Zeman et al., 2020), taking into account: **1)** the availability and the size of the corresponding Wikipedia; and **2)** typological diversity to ensure that different language families are covered.[3] For NLI, we rely on the recent AmericasNLI dataset (Ebrahimi et al., 2022), spanning ten low-resource languages from the Americas. For AmericasNLI languages, we use Wikipedia if available; otherwise we use the unlabelled data previously used by Ansell et al. (2022). English is the source language in all experiments for all tasks.[4] All languages along with their language codes are listed in Table 3 in the Appendix.

3.1 Experimental Setup

MMT. In all our experiments, we use mBERT, an MMT model pretrained on the Wikipedias of 104 languages (Devlin et al., 2019).[5]

Training Setup: LAs, BAs. To enable a fair comparison between MAD-X and BAD-X under the same training and inference conditions, we train our own MAD-X LAs from scratch with the MLM objective on monolingual Wikipedias: training is run for 25,000 steps, with a batch size of 64 and a learning rate of $1e-4$. We evaluate the LAs every 500 training steps and finally choose the LA that yields the lowest perplexity, as evaluated on the 5% of the Wikipedia data that acts as a validation set.

Pfeiffer et al. (2020b) empirically established that strong task performance of MAD-X on low-resource languages can be achieved already after 20,000 LA training steps, and that longer training offers only modest to negligible performance gains. Driven by their findings, we train MAD-X LAs for 25,000 iterations due to computational constraints, a large number of experiments, and the low-resource nature of our target languages.

BAD-X BAs are trained on the Wikipedia data of both L_s and L_t. The standard BAD-X variant termed **Balanced BAD-X** (also **BAD-X 1:1**) is trained by alternating one batch of the L_s data (i.e. English) followed by one batch of the L_t data, for 50,000 iterations (i.e., this way we match the total number of iterations performed by training MAD-X L_s and L_t LAs for 25,000 iterations each), and we adopt all the hyperparameters from MAD-X LA training. We select as the final BA the one with the lowest L_t perplexity. Bilinguality of the BAD-X BAs allows us to directly train TA on top of it and perform the inference with the same configuration.

Multilingual Adapter (MA). Given N target languages of interest, one could alternatively train a multilingual adapter on unlabelled text from L_s and all N target languages L_t: while this is more computationally efficient than both BAD-X and MAD-X[6] it could, presumably, again lead to the "curse of multilinguality", as the adapter parameters would be shared across N+1 languages. On the other hand, MA has the chance to benefit from similarities between target languages (especially in the case of AmericasNLI). Concretely, we train two multilingual adapters: one for the set of UD languages and the other for the set of AmericasNLI languages. Multilingual UD adapter is trained by alternating one batch of English Wikipedia and one batch from each of 10 UD languages' Wikipedia for 50,000 iterations. Multilingual AmericasNLI

---

[3] As a result, our ten languages cover eight different language families and five different writing systems.

[4] For UD target languages, we use the training split for evaluation if available, since it is larger than the test or evaluation splits.

[5] mBERT demonstrated a slight edge in transfer performance over XLM-R for lower-resource languages in prior work (Pfeiffer et al., 2020b).

[6] In particular, with one source language and N target languages one needs to train: i) N+1 different MAD-X LAs (one for L_s and one for each of the N L_ts); ii) N different BAD-X BAs (one for each (L_s, L_t) pair) and, iii) only one MA (using L_s and all L_ts at once).

adapter is obtained following the same procedure, only using Wikipedias of the NLI target languages.

Training Setup: TAs. For POS and DP, TA is trained by stacking it on top of the source (i.e. English) LA (with MAD-X), the English-L_t BA (with BAD-X) or the multilingual adapter MA and performing 15,000 steps with a batch size of 8 and a learning rate of $5e-5$. We evaluate the TAs every 250 steps on English validation set, and select as the final TAs the ones with the best accuracy (POS) and LAS score (DP). The adapter reduction factor (Pfeiffer et al., 2020a) is 2 for LAs and BAs and 16 for TAs. For AmericasNLI, we train its TA using the English MultiNLI data (Williams et al., 2018) following the setup of Ebrahimi et al. (2022): 5 epochs with a batch size of 32, and a learning rate of $2e-5$. We evaluate the TA every 625 steps and choose the one with the best English validation accuracy.

BAD-X: BA Variants. Besides Balanced BAD-X, we consider other variants of BAD-X BAs that differ in the data ratios between L_s and L_t; we denote these variants as **BAD-X** 1:N, where 1 batch of L_s data is followed by N batches of L_t data, and vice versa: **BAD-X** N:1. With these variants, we aim to answer the following question: given a fixed number of MLM training steps (i.e., a fixed computational budget) for BAs, is it possible to further impact/improve transfer performance? Is the optimal data sampling ratio task-dependent?

3.2 Results and Discussion

The results for all languages and tasks with MAD-X and Balanced BAD-X are summarized in Table 1, with additional results in the appendix. As a general trend, we observe that the proposed Balanced BAD-X variant outperforms MAD-X and MAs over a majority of languages and across all three tasks: besides offering higher average results, we also report gains on 8/10 (POS; accuracy), 9/10 (DP; UAS), and 8/10 (NLI; accuracy) target languages. This confirms the positive impact of BA training, which is able to capture additional interactions of each language pair, in lieu of LA training.

Performance across Tasks. In particular, BAD-X gains on average 1.06% in accuracy and 0.66% in F_1 compared to MAD-X on POS task. It outscores the multilingual adapter on POS even more: 3.55% in accuracy and 2.87% in F1 on average. The gains over MAD-X are even more pronounced on the more complex DP task, which shares the target languages set with POS: BAD-X outperforms MAD-X on average with a gap of 2.62% in UAS and 2.38% in LAS scores. The gain is particularly high for Wolof, a West-African language spoken by more than five million people, with ~9% improvement over MAD-X in both UAS and LAS scores. Wolof is also a language with one of the highest gains in POS. In the DP task, BAD-X achieves similar gains over the multilingual adapter: 2.22% UAS and 2.82% in LAS scores on average. Multilingual adapter achieves high scores on Wolof, which re-establishes Wolof as a language that highly benefits from the involvement of other languages during training. We also observe the superiority of Balanced BAD-X over MAD-X on NLI, now on another set of low-resource languages, with average accuracy gains of 2.4%. The highest improvement of 6.67% is observed for Wixarika.

Performance across Languages. Importantly, we find that improvements in all three tasks are met for target languages coming from diverse language families (e.g., for Uralic, Indo-European, Niger-Congo, Turkic, Aymaran families) and with diverse typological traits. We speculate that stacking TAs on top of BAs instead of an English-specialized LA forces the model to also take into account information from the target language, which mitigates overfitting to English-only language properties. Furthermore, coupling two languages in the BA training might also allow for some information flow between the languages (e.g., some sharing at lexical level). This also might provide a positive impact on transfer performance, while this effect cannot be achieved with individual LAs as in MAD-X. Multilingual adapters lag behind MAD-X and BAD-X as they aim to fit too many languages into a small number of adapter parameters, which demonstrates the necessity of language and especially language-pair specialization when performance for a particular source-target transfer direction is paramount.

BAD-X Variants. Figure 2 shows the 'average-across-languages' scores for MAD-X and for all tested BAD-X variants (based on data sampling ratios at BA training; §3.1). The results indicate several findings. First, all BAD-X variants outperform MAD-X on all three tasks on average. Second, there is no single best-performing BAD-X variant for all tasks, that is, the 'winning' variant seems to be task-dependent. In particular, DP benefits the most from 5:1 sampling, while for POS and NLI the 1:2 variant outscores the others although DP

Task	Method	AF	BM	EU	MYV	KPV	MT	MR	TE	UG	WO	avg
POS	MAD-X	**85.43***	41.61	58.90	66.84	47.63	**69.94***	52.65	75.27	**47.07***	61.78	60.71

Table 1: Results of multilingual adapters (MA), MAD-X, and BAD-X (Balanced BAD-X, 1:1) on all tasks and languages. Standard evaluation measures: F_1 for POS, LAS for DP, and accuracy for NLI. **Bold**: the best performing approach. An asterisk (*) indicates significant gains over the the other two competitor models (Student's t-test with $p = 0.05$).

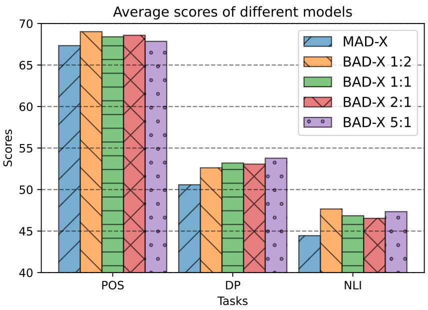

Figure 2: The average accuracy (POS and NLI) and UAS scores of MAD-X and different BAD-X variants (see §3.1). Full results are available in Appendix C.

and POS share exactly the same BA training data.

Note that, due to computational constraints, we did not extensively search for the best sampling ratios of the source and target language during BA training, thus the optimal strategy might not be covered by our experiments. However, these findings warrant further investigation in future work.

Multiple Runs. To validate that our results hold in the presence of different parameter initializations, we perform a comparison of MAD-X and Balanced BAD-X when the scores are averages of 3 runs with the same random seeds both for MAD-X and BAD-X. Due to computational constraints, we select only a subset of languages for this evaluation. In particular, we choose 4 UD (MYV, KPV, TE and WO) and 4 AmericasNLI languages (CNI, GN, SHP and HCH) and compare MAD-X and Balanced BAD-X by taking the average scores obtained from 3 runs. The results are shown in Table 2, and again point to BAD-X's superiority over MAD-X in terms of transfer performance in all three tasks.

Task	Method	MYV	KPV	TE	WO	avg
POS	MAD-X	67.13	47.86	75.66	59.56	62.55
	BAD-X	**68.40**	**48.95**	**76.07**	**63.86**	**64.32**
DP	MAD-X	34.19	22.41	49.07	24.64	32.58
	BAD-X	**37.95**	**23.66**	**50.20**	**34.51**	**36.58**
		CNI	GN	SHP	HCH	avg
NLI	MAD-X	44.49	55.24	43.78	40.49	46.00
	BAD-X	**47.82**	**56.98**	**47.60**	**43.16**	**48.89**

Table 2: Robustness of BAs: average scores across 3 runs (i.e., three different random seeds) for MAD-X and BAD-X (Balanced, 1:1) for a subset of target languages.

4 Conclusion

We have presented BAD-X, a novel adapter-based framework for zero-shot cross-lingual transfer. BAD-X targets improving transfer performance for particular fixed source-target transfer directions through the introduction and use of dedicated bilingual language-pair adapters (BAs). The effectiveness of the BAs and the BAD-X framework has been demonstrated on three standard transfer tasks, across a plethora of low-resource languages. In future work, we will experiment with more efficient approaches to bilingual adapters, e.g., based on contextual parameter generation (Ansell et al., 2021), and port the BAD-X framework to more languages and tasks.

A Details of the Experimental Setup

Computing Infrastucture. All experiments were run on a single NVIDIA GeForce RTX 3090 GPU; training one BAD-X BA or multilingal LA for 50,000 iterations took around 24 hours (MAD-X LA for 25,000 steps took around 12 hours). Training of any TA took less than two hours. Evaluation is performed within the AdapterHub framework (Pfeiffer et al., 2020a).

Hyperparameters. All hyperparameters were taken from (Pfeiffer et al., 2020b), as discussed in the main paper, and no hyperparameter search was done. All reported results except those in table 2 are from a single run.

B Languages

The list of languages in each task along with their language codes is provided in Table 3.

C BAD-X: Full results

Full results on all languages for MAD-X and all BAD-X variants are given in Tables 4, 5 and 6 for POS, DP and NLI, respectively.

Tasks	**Languages**

Abstract

Parody is a figurative device used for mimicking entities for comedic or critical purposes. Parody is intentionally humorous and often involves sarcasm. This paper explores jointly modelling these figurative tropes with the goal of improving performance of political parody detection in tweets. To this end, we present a *multi-encoder* model that combines three parallel encoders to enrich parody-specific representations with humor and sarcasm information. Experiments on a publicly available data set of political parody tweets demonstrate that our approach outperforms previous state-of-the-art methods.[1]

1 Introduction

Parody is a figurative device which imitates entities such as politicians and celebrities by copying their particular style or a situation where the entity was involved (Rose, 1993). It is an intrinsic part of social media as a relatively new comedic form (Vis, 2013). A very popular type of parody is political parody, which is used to express political opposition and civic engagement (Davis et al., 2018).

One of the hallmarks of parody expression is the deployment of other figurative devices, such as humor and sarcasm, as emphasized on studies of parody in linguistics (Haiman et al., 1998; Highfield, 2016). For example, in Table 1 the text expresses sarcasm about Myspace[2] being a 'winning technology', while mocking the fact that three more popular social media sites were unavailable. This example also highlights the similarities between parody and real tweets, which may pose issues to misinformation classification systems (Mu and Aletras, 2020).

Twitter Handle	`@Queen_UK`
Parody tweet	Boris Johnson on the phone. Very smug that #myspace hasn't gone down. Says he's always backed winning technologies #whatsappdown #instagramdown #FacebookIsDown

Table 1: Example of a *parody* tweet[3] by the Twitter handle @Queen_UK. Humor and sarcasm are expressed simultaneously.

These figurative devices have so far been studied in isolation to parody. Previous work on modeling humor in computational linguistics has focused on identifying jokes, i.e., short comedic passages that end with a hilarious line (Hetzron, 1991), based on linguistic features (Taylor and Mazlack, 2004; Purandare and Litman, 2006; Kiddon and Brun, 2011) and deep learning techniques (Chen and Soo, 2018; Weller and Seppi, 2019; Annamoradnejad and Zoghi, 2020). Similarly, computational approaches for modeling sarcasm (i.e., a form of verbal irony used to mock or convey content) in texts have been explored (Davidov et al., 2010; González-Ibáñez et al., 2011; Liebrecht et al., 2013; Rajadesingan et al., 2015; Ghosh et al., 2020, 2021), including multi-modal utterances, i.e. texts, images, and videos (Cai et al., 2019; Castro et al., 2019; Oprea and Magdy, 2020). Recently, parody has been studied with natural language processing (NLP) methods by Maronikolakis et al. (2020) who introduced a data set of political parody accounts. Their method for automatic recognition of posts shared by political parody accounts on Twitter is solely based on vanilla transformer models.

In this paper, we hypothesize that humor and sarcasm information could guide parody specific text encoders towards detecting nuances of figu-

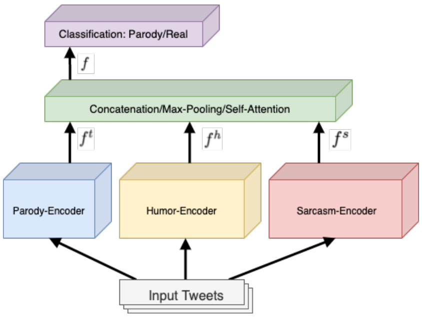

Figure 1: The structure of our *multi-encoder* model for combining humor and sarcasm information for political parody prediction.

rative language. For this purpose, we propose a *multi-encoder* model (§2) consisting of three parallel encoders that are subsequently fused for parody classification. The first encoder learns parody specific information subsequently enhanced using the representations learned by a humor and sarcasm encoder respectively.

Our contributions are: (1) new state-of-the-art results on political parody detection in Twitter, consistently improving predictive performance over previous work by Maronikolakis et al. (2020); and (2) insights on the limitations of neural models in capturing various linguistic characteristics of parody from extensive qualitative and quantitative analyses.

2 Multi-Encoder Model for Political Parody Prediction

Maronikolakis et al. (2020) define political parody prediction as a binary classification task where a social media post T, consisting of a sequence of tokens $T = \{t_1, ..., t_n\}$, is classified as real or parody. Real posts have been authored by actual politicians (e.g., `realDonaldTrump`) while parody posts come from their corresponding parody accounts (e.g., `realDonaldTrFan`).

Parody tends to express complex tangled semantics of both humor and sarcasm simultaneously (Haiman et al., 1998; Highfield, 2016). To better exploit this characteristic of parody, we propose a *multi-encoder* model that consists of three parallel encoders, a feature-fusion layer and a parody classification layer depicted in Fig.1.[4].

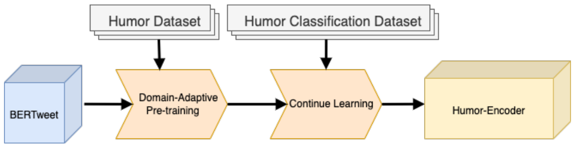

Figure 2: *Humor Encoder*.

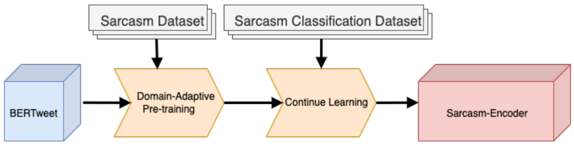

Figure 3: *Sarcasm Encoder*.

2.1 Text Encoders

Parody As a task-specific parody encoder, we use the vanilla pretrained BERTweet (Nguyen et al., 2020), a BERT (Devlin et al., 2019) based model pre-trained on a corpus of English Tweets and fine-tuned on the parody data set (§3.1).

Humor To capture humor specific characteristics in social media text, we use the data set introduced by Annamoradnejad and Zoghi (2020) which contains humorous and non-humorous short texts collected from Reddit and Huffington Post. First, we adapt BERTweet using domain-adaptive pre-training (Sun et al., 2020a; Gururangan et al., 2020) on 10,000 randomly selected humor-only short texts with masked language modeling. Subsequently, we use a continual learning strategy (Li and Hoiem, 2018; Sun et al., 2020b) to gradually learn humor-specific properties by further fine-tuning BERTweet on a humor classification task (i.e., predicting whether a text is humorous or not) by using 40,000 randomly selected humorous and non-humorous short texts from the humor corpus described above (see Figure 2).

Sarcasm Similar to humor, we extract sarcasm-related semantic information from a post T by using sarcasm annotated data sets from Oprea and Magdy (2020) and Rajadesingan et al. (2015). The first data set consists of 777 and 3,707 sarcasm and non-sarcasm posts from Twitter and the second data set consists of 9,104 sarcasm and more than 90,000 non-sarcasm posts from Twitter. We first perform domain-adaptive pre-training of BERTweet on all sarcastic posts with masked language modeling. Then, we fine-tune the model on a sarcasm classification task, similar to the humor encoder (see Figure 3). For the fine-tuning step, we use the 9,881 sarcastic tweets and 10,000 randomly sampled non-

---

[4] Early experiments with multi-task learning did not result in improved performance. The results of these experiments can be found in Appendix A.

sarcasm tweets from the two data sets (i.e., 3,707 from the first and 6,293 from the second).

We compute parody f^t, humor f^h, and sarcasm f^s representations by extracting the 'classification' [CLS] token from each encoder respectively, where $f \in \mathbf{R}^{768}$.

2.2 Combining Encoders

We explore three approaches to combine f^t, f^h, and f^s representations.

Concatenation First, the three text representations are simply concatenated to form a combined representation $f \in \mathbf{R}^{768\times 3}$.

Self-Attention We also use a 4-head self-attention[5] mechanism (Vaswani et al., 2017) on f^t, f^h, f^s. The goal is to find correlations between representations and learn the contribution of each encoder in the final representation.

Max-Pooling Finally, we perform a max-pooling operation on each dimension of f^t, f^h, f^s to obtain a representation $f \in \mathbf{R}^{768}$. The aim is to use the most dominant features learned by each encoder.

2.3 Classification

Finally, we pass the combined representation f to a classification layer with a sigmoid activation function for predicting whether a post is a parody or not. Three encoders are fine-tuned simultaneously on the parody data set (§3.1).[6]

3 Experimental Setup

3.1 Data

We use the data set introduced by Maronikolakis et al. (2020) which contains 131,666 tweets written in English, with 65,956 tweets from political parody accounts and 65,710 tweets posted by real politician accounts. The data set is publicly available[7] and allows us to compare our results to state-of-the-art parody detection methods.

We use the three data splits provided: (i) *Person Split*, each split (train, dev, test) contains tweets from different real – *parody* account pairs; (ii) *Gender Split*, two different splits based on the gender of the politicians (i.e., female accounts in train/dev and male in test, and male accounts in train/dev and female in test); *Location Split*, data is split according to the location of the politicians in three groups (US, UK, Rest of the World or RoW). Each group is assigned to the test set and the other two groups to the train and dev sets.

3.2 Baselines

We compare our *multi-encoder* models with transformers for parody detection (Maronikolakis et al., 2020): **BERT** (Devlin et al., 2019) and **RoBERTa** (Liu et al., 2019). Also, we compare our models to **BERTweet** (Nguyen et al., 2020).

3.3 Implementation details

Humor Encoder For adaptive pre-training, the batch-size is set to 16 and the number of training epochs is set to 3 with a learning rate of $2e^{-5}$. For humor classification, we use batch size of 128 and the number of epochs is set to 2 with a learning rate of $3e^{-5}$.

Sarcasm Encoder We pretrain using a batch-size of 16 over 5 epochs with a learning rate of $2e^{-5}$. For fine-tuning on a sarcasm classification task, we use the $9,881$ sarcasm tweets and $10,000$ randomly sampled non-sarcasm tweets from the two data sets (i.e., $3,707$ from the first and $6,293$ from the second) using the same hyperparameters to the humor-specific encoder.

Multi-encoder For the complete *multi-encoder* model, we use a batch size of 128 and the learning rate is set to $2e^{-5}$. The entire model is fine-tuned for 2 epochs.

3.4 Evaluation

We evaluate the performance of all models using F1 score as Maronikolakis et al. (2020). Results are obtained over 3 runs using different random seeds reporting average and standard deviation.

4 Results

4.1 Predictive Performance

Table 2 shows the results for parody detection on the *Person Split*. We observe that *BERTweet* has the best performance (F1: 90.72) among transformer-based models (*BERT*, *RoBERTa*, *BERTweet*), outperforming previous state-of-the-art by Maronikolakis et al. (2020). This is due to the fact that *BERTweet* has been specifically pre-trained on

---

[5] Early experimentation with larger attention heads did not improve results in the dev set.

[6] Early experimentation with humor and sarcasm encoders frozen during the fine-tuning process did not show any performance improvement.

Table 4: F1-scores on the *Location Split*. ** Results from Maronikolakis et al. (2020). Best results are in bold.

Twitter text. Similar behavior is observed on the *Gender* and *Location* splits (see Table 3 and 4 respectively).

Our proposed *multi-encoder* achieves the best performance when using *Self-Attention* to combine the three parallel encoders (F1: 91.19; 89.97, 88.56; 88.37, 87.91, 87.16; for *Person*, *Gender*, and *Location* splits respectively). Moreover, it outperforms the best single-encoder model *BERTweet* in the majority of cases which corroborates that parody detection benefits from combining general contextual representations with humor and sarcasm specific information, as humor and sarcasm are important characteristics of parody (Haiman et al., 1998; Highfield, 2016). On the other hand, simply concatenating the three parallel encoders degrades the performance across different splits (*Person*: 88.99; *Gender*: 86.84, 84.21 *Location*: 85.41, 84.74, 83.62). This happens because the concatenation operation treats the three encoders as equally important. While humor and sarcasm are related to parody, they may not necessarily have the same relevance as indicators of parody.

Our best performing model (*Self-Attention*) outperforms the vanilla *BERTweet* by 3 F1 points when trained on female accounts and by almost 2 F1 points when trained on male accounts. We speculate that the additional linguistic information from the two encoders (i.e., sarcasm and humor) is more beneficial in low data settings. The number of female politicians is considerably smaller than males in the data set (see Maronikolakis et al. (2020) for more details).

4.2 Ablation Study

We also examine the effect of combining parody-specific representations with humor and sarcasm information by running an ablation study. We compare performance of four models: using parody representations only (P), and combining parody representations with humor (P+H), or sarcasm (P+S) information, as well as with both (P+S+H). The results of this analysis are depicted in Tables 5, 6 and 7. We observe that both sarcasm and humor contribute to the performance gain, but using both is more beneficial. Modelling sarcasm leads to more gains than humor and this could be attributed to the characteristics of the parody corpus, namely that it focuses primarily on the political domain, which have a high sarcastic component (Anderson and Huntington, 2017).

5 Error Analysis

Finally, we perform an error analysis to examine the behavior and limitations of our best-performing model (*multi-encoder* with Self-Attention).

The next two examples correspond to real tweets that were misclassified as parody:

(1) *Congratulations, <mention>! <url>.*

(2) *It's a shame that Boris isn't here answering questions from the public this evening.*

We speculate that the model misclassified these tweets as parody because they contain terms that

Table 7: F1-scores for parody detection on the *Location Split* with various settings: parody (P) representations only, and combining parody representations with humor (P+H), or sarcasm (P+S) information, as well as with both (P+S+H). Best results are in bold.

are related to sarcastic short texts such as user mentions, punctuation marks (*!*), and negation (*isn't*) (González-Ibáñez et al., 2011; Highfield, 2016).

The following two examples correspond to parody tweets that were misclassified as real:

(3) *Hey America, it's time to use your safe word.*

(4) *I fully support the Digital Singles Market.*

Example (3) is a call-to-action message, while Example (4) is a statement expressing support for a particular subject. These statements are written in a style that is similar to political slogans or campaign speeches (Fowler et al., 2021) that the model fails to recognise. As a result, in addition to humor and sarcasm semantics, the model might be improved by integrating knowledge from the political domain such as from political speeches.

6 Conclusion

In this paper, we studied the impact of jointly modelling figurative devices to improve predictive performance of political parody detection in tweets. Our motivation was based on studies in linguistics which emphasize the humorous and sarcastic components of parody (Haiman et al., 1998; Highfield, 2016). We presented a method that combines parallel encoders to capture parody, humor, and sarcasm specific representations from input sequences, which outperforms previous state-of-the-art proposed by Maronikolakis et al. (2020).

In the future, we plan to combine information from other modalities (e.g., images) for improving parody detection (Sánchez Villegas and Aletras, 2021; Sánchez Villegas et al., 2021).

A Multitask-Learning

We also tested applying *multi-task learning* approaches (Caruana, 1993) to use either sarcasm prediction (P+S), humor prediction (P+H) or both (P+S+H) as auxiliary tasks for parody detection. We utilize BERTweet as the share encoder and independent classification layers for parody and humor or sarcasm. Three sets of weights are applied to losses from each independent classification layer and the three layers are stacked. The best results are chosen and depicted in Table 8, Table 9 and Table 10.

Abstract

Recently, the structural reading comprehension (SRC) task on web pages has attracted increasing research interests. Although previous SRC work has leveraged extra information such as HTML tags or XPaths, the informative topology of web pages is not effectively exploited. In this work, we propose a **T**opological **I**nformation **E**nhanced model (TIE), which transforms the token-level task into a tag-level task by introducing a two-stage process (i.e. *node locating* and *answer refining*). Based on that, TIE integrates Graph Attention Network (GAT) and Pre-trained Language Model (PLM) to leverage the topological information of both logical structures and spatial structures. Experimental results demonstrate that our model outperforms strong baselines and achieves state-of-the-art performances on the web-based SRC benchmark WebSRC at the time of writing. The code of TIE will be publicly available at `https://github.com/X-LANCE/TIE`.

1 Introduction

With the rapid development of the Internet, web pages have become the most common and rich source of information (Dong et al., 2014). Therefore, the ability to understand the contents of structured web pages will guarantee a rich and diverse knowledge source for deep learning systems. Each web page is mainly rendered from the corresponding HyperText Markup Language (HTML) codes. In other words, the understanding of a structured web page can be achieved by the comprehension of its HTML codes.

One of the commonly used tasks to verify the model's ability of comprehension is Question Answering (QA). However, previous QA models only focus on the comprehension of plain texts (Rajpurkar et al., 2016; Yang et al., 2018; Reddy et al., 2019; Zeng et al., 2020), tables (Pasupat and Liang, 2015; Chen et al., 2020c, 2021b), or knowledge bases (KBs) (Berant et al., 2013; Talmor and Berant, 2018). These sources have either no topological structure or fixed-form structures. On the contrary, the topological structures of web pages are complex and flexible, which are less investigated in previous QA works.

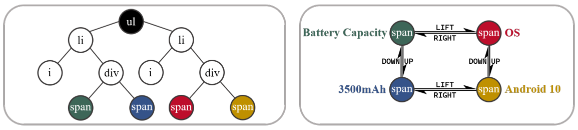
(a) An example of the structured web pages' HTML codes and screenshots



(b) The illustration of DOM Tree (logical structure)

(c) The illustration of NPR Graph (spatial structure)

Figure 1: An example of web pages in WebSRC and its corresponding Document Object Model (DOM) tree and Node Positional Relation (NPR) graph in WebSRC. The colored HTML tag in (a) is corresponding to the bounding box with the same color in (a) and the node with the same color in (b) and (c).

Specifically, HTML codes can be viewed as multiple semantic unit separated by tag tokens (e.g. `<div>`, `</div>`). An HTML tag refers to a pair of matched start and end tags and all the content in between, which also corresponds to a part of the web page (illustrated in Fig. 1 (a)). Therefore, there are two kinds of topological structures in web pages: logical structures which contain the hierarchical relations and clustering of tags (see Fig. 1 (b)); and spatial structures which contain the relative positions between different tags in the web pages (see Fig. 1 (c)). These topological structures are as important as the semantics of HTML codes and screenshots.

Although previous works (Chen et al., 2021c; Li

---

*The corresponding authors are Lu Chen and Kai Yu.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1808 - 1821

et al., 2021) have tried to leverage the topological structures by adopting HTML tags or XPaths as tokens or position embeddings, only logical structures are encoded implicitly. However, it is obvious for humans to identify key-value pairs if two spans are located in the same row or column, while this relation may take various forms in the logical structures of different web pages. Moreover, tables have extremely simple spatial structures but will be super complex in terms of logical structures. Therefore, spatial structures are essential and complementary to logical structures.

The major obstacle that prevents previous models to leverage spatial relations is that both the two kinds of topological structures are organized at the tag level instead of the token level (Fig. 1 (b) and (c)). As token-level models, whose computation and prediction units are the tokens of web pages, it is extremely hard and anti-natural for them to encode the topological structures. Moreover, using token-level models also means that previous works have to implicitly imply the logical structures to the models, which may be less effective than explicitly telling with the help of prior knowledge.

To tackle these problems, we propose **T**opological **I**nformation **E**nhanced model (TIE), a tag-level QA model that operates on the representations of HTML tags to predict which tag the answer span belongs to. By switching from token level to tag level, various structures of web pages can be explicitly encoded into the model easily. Specifically, TIE encodes both the logical and spatial structures using Graph Attention Network (GAT) (Velickovic et al., 2018) with the help of two kinds of graphs. The first kind of graphs is *Document Object Model (DOM) trees* which is widely used to represent the logical structures of HTML codes. Secondly, to encode the spatial structures, we define the *Node Positional Relation (NPR) graph* based on the bounding box of HTML tags obtained by the browser. Detail definition can be found in Section 3.2.2.

Moreover, to accomplish the token-level prediction tasks by a tag-level QA model, we further introduce a two-stage process including *node locating* stage and *answer refining* stage. Specifically, in the *answer refining* stage, a traditional token-level QA model is utilized to extract answer span with the constraint of the answer node prediction by TIE in the *node locating* stage.

Our TIE model is tested on the WebSRC dataset [1] and achieve state-of-the-art (SOTA) performances.

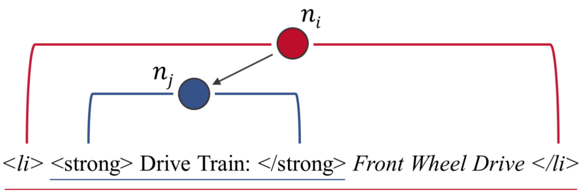


Figure 2: Illustration of the relations between DOM trees and HTML codes. The italic tokens " Front Wheel Drive " are the *direct content* of node n_i

To summarize, our contributions are three folds:

- We propose a tag-level QA model called TIE with a two-stage inference process: *node locating* stage and *answer refining* stage.
- We utilize GAT to leverage the topological information of both the logical and spatial structures with the help of DOM trees and our newly defined NPR graphs.
- Experimental results on the WebSRC dataset demonstrate the effectiveness of our model and its key component.

2 Preliminary

2.1 Task Definition

The Web-based SRC task (Chen et al., 2021c) is defined as a typical extractive question answering task based on web pages. Given the user query $\boldsymbol{q} = (q_1, q_2, \cdots, q_{|\boldsymbol{q}|})$ and the flattened HTML code sequence $\boldsymbol{c} = (c_1, c_2, \cdots, c_{|\boldsymbol{c}|})$ of relevant web page as inputs , the goal is to predict the starting and ending position of answer span (s, e) in the HTML codes $\boldsymbol{c}$ where $|\boldsymbol{q}|, |\boldsymbol{c}|$ denote the length of the question and the HTML code sequence, respectively, and $1 \leq s \leq e \leq |\boldsymbol{c}|$. Notice that each token c_i in the flattened HTML codes $\boldsymbol{c}$ can be a raw text word or tag symbol such as `<div>` while the user query q is a word sequence of plain text.

2.2 DOM Trees of HTML codes

The DOM tree is a special tree structure that is parsed from raw HTML codes by Document Object Model [2]. Each node in the tree denotes a tag closure in the original HTML code. Specifically, each node contains a start tag token (e.g. `<div>`), an end

---

[2] https://en.wikipedia.org/wiki/Document_Object_Model

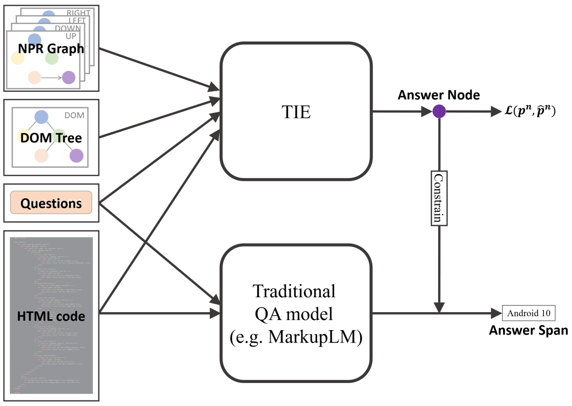

Figure 3: The two-stage architecture using TIE and traditional QA model (e.g. MarkupLM)

tag token (e.g. `</div>`), and all the contents in between. One DOM node n_j is the descendant of another node n_i, iff the contents of node n_j is entirely included in the contents of node n_i.

Furthermore, we define the *direct contents* of each DOM node (and its corresponding HTML tag) as all the tokens in its tag closure that are not contained in any of its children (see Figure 2).

3 TIE

In this section, we will first introduce the architecture of the whole SRC system in Sec.3.1, and then the two kind of graph we used in Sec. 3.2. Finally, the structure of **T**opological **I**nformation **E**nhance model (TIE) is demonstrated in Sec.3.3.

3.1 Architecture of the Whole SRC System

With the help of DOM trees and NPR graphs, TIE can efficiently predict in which node the answer is located. Therefore, we modify the original architecture of the SRC system into a two-stage architecture: *node locating* and *answer refining*. The two-stage architecture is illustrated in Figure 3.

In the *node locating* stage, we first define the answer node as the deepest node in the DOM tree which contains the complete answer span. Then, TIE is utilized to predict the answer node n_a for the question q given the flattened HTML codes c and the corresponding DOM tree $\mathcal{D}_c$ and NPR graphs $\mathcal{G}_c$ (see Sec. 3.2). Formally,

$$\text{TIE}(q, c, (\mathcal{D}_c, \mathcal{G}_c)) = \boldsymbol{p}^n,$$
$$n_a = \underset{n_i \in V_{D_c}}{\text{argmax}}(p_i^n),$$

where p_i^n denotes the probability of node n_i being the answer node, and V_{D_c} is the node set of D_c.

Then, in the *answer refining* stage, we use the predicted answer node as a constraint during the prediction of the answer span. In more detail, we first use a QA model (e.g. MarkupLM) to obtain the start and end probabilities $\boldsymbol{p}^s$, $\boldsymbol{p}^e$ among all the tokens of HTML code sequence c. Then, the predicted answer span is chosen from the spans which are contained by the predicted answer node n_a. To conclude, provided that the starting and ending position of predicted answer node n_a in the HTML code c is s_a, and e_a, the second stage can be formulated as follows:

$$\text{QA}(q, c) = \boldsymbol{p}^s, \boldsymbol{p}^e$$
$$(s_{pred}, e_{pred}) = \underset{(i,j):s_a \le i < j \le e_a}{\text{argmax}} (p_i^s + p_j^e)$$

3.2 Construction of GAT Graphs

Recently, Graph Neural Network (GNN) (Scarselli et al., 2008) has been widely used in multiple Neural Language Processing tasks, such as text classification and generation (Yao et al., 2019; Zhao et al., 2020), information extraction (Lockard et al., 2020), dialogue policy optimization (Chen et al., 2018a,b, 2019, 2020d), dialogue state tracking (Chen et al., 2020a; Zhu et al., 2020), Chinese processing (Gui et al., 2019; Chen et al., 2020b; Lyu et al., 2021), etc. Graph Attention Network (GAT) is a special type of GNN that encodes graphs with attention mechanism. In this work, to leverage both the logical and spatial structures, we introduce two kinds of graphs: DOM Trees and NPR graphs.

3.2.1 DOM Trees

The logical relations of HTML codes can be described with the assistance of its DOM Tree (see Sec. 2.2). However, the original tree is extremely sparse, which often leads to poor communication efficiency among nodes. To this end, we modify the structure to enlarge the receptive fields for each node. Mathematically, the resulting graph $\mathcal{D}_c = (V_{D_c}, E_{D_c})$ can be constructed from the original sparse form $\mathcal{D} = (V_D, E_D)$,

$$\begin{cases} V_D = \text{all nodes in the original DOM tree,} \\ E_D = \{(n_i, n_j) | n_i \text{ is the parent of } n_j\} \cup \\ \qquad \{(n_i, n_j) | n_i \text{ is a child of } n_j\}, \end{cases}$$

into a denser one $\mathcal{D}_c = (V_{D_c}, E_{D_c})$,

$$\begin{cases} V_{D_c} = V_D \\ E_{D_c} = \{(n_i, n_i) | n_i \in V_{D_c}\} \cup \\ \qquad \{(n_i, n_j) | n_i \text{ is an } \textbf{ancestor} \text{ of } n_j\} \cup \\ \qquad \{(n_i, n_j) | n_i \text{ is a } \textbf{descendant} \text{ of } n_j\} \end{cases}$$

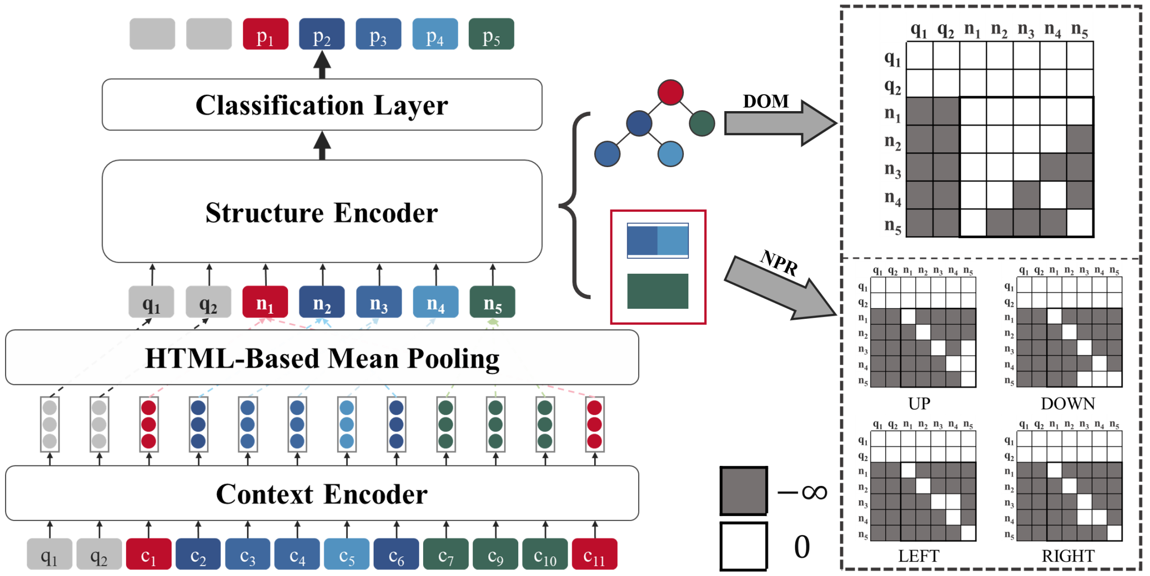

Figure 4: The overall architecture of TIE

In this way, each node can directly communicate with all of its ancestors and descendants, so that the information can be transferred much faster.

3.2.2 NPR Graphs

To explicitly establish the positional relations between different texts, we define and construct Node Positional Relation (NPR) graph $\mathcal{G}_c = (V_G, E_G)$ based on the rendered structured web pages.

Similar to DOM Tree, each NPR node n_i corresponds to a tag t_i in the HTML code of the web page. The content of NPR nodes is defined as the direct content of their corresponding HTML tags. It is worth noticing that under our definition, the node sets of the NPR graph and the DOM tree of the same web page are identical ($V_G = V_D$).

Moreover, considering that the nodes with informative relations (such as `"key-value"` relations and `"header-cell"` relations) are usually located on the same row or column, we introduce four kinds of directed edges into NPR graphs: `UP`, `DOWN`, `LEFT`, and `RIGHT`. Specifically, $(n_i, n_j) \in E_G^{\texttt{UP}}$ when

$$\begin{cases} \min(x_{n_i}+w_{n_i}, x_{n_j}+w_{n_j}) - \max(x_{n_i}, x_{n_j}) \\ \qquad \geq \gamma \times \min(w_{n_i}, w_{n_j}) \\ y_{n_i} \geq y_{n_j} \text{ or } y_{n_i}+h_{h_i} \geq y_{n_j}+h_{n_j} \end{cases} \tag{1}$$

both hold, where (x_{n_i}, y_{n_i}), (x_{n_j}, y_{n_j}) are the coordinates of the upper-left corner of the bounding boxes corresponding to the nodes n_i and n_j; w_{n_i}, w_{n_j} are the width of the two bounding boxes while h_{n_i}, h_{n_j} are the height of the two bounding boxes; and γ is a hyper-parameter. Similar functions are used for $E_G^{\texttt{DOWN}}$, $E_G^{\texttt{LEFT}}$, and $E_G^{\texttt{RIGHT}}$. Finally, $E_G = E_G^{\texttt{UP}} \bigcup E_G^{\texttt{DOWN}} \bigcup E_G^{\texttt{LEFT}} \bigcup E_G^{\texttt{RIGHT}}$ Figure 1 (a) and (c) show an example of the NPR graph and its corresponding HTML code.

To simplify the NPR graphs, we only consider the nodes whose direct contents contain text tokens. That means in NPR graphs, the nodes whose direct contents only contain tag tokens will be isolated nodes with no relation.

3.3 Design of TIE

The model we proposed, TIE, mainly consists of four parts: the **Context Encoder Module**, the **HTML-Based Mean Pooling**, the **Structure Encoder Module**, and the **Classification Layer**. The overall architecture of TIE is shown in Figure 4.

Context Encoder Module. We first utilize Pre-trained Language Model as our context encoder. It encodes the contextual information of the HTML codes and gets the contextual word embeddings used for node representation initialization. Specifically, we use two PLM in our experiments: H-PLM (Chen et al., 2021c) + RoBERTa (Liu et al., 2019) and MarkupLM (Li et al., 2021).

HTML-Based Mean Pooling. In this module, TIE initializes the node representations based on the contextual word embedding calculated by Context Encoder. Specifically, for each node, we initialize its representation as the average embedding

Type	Training set		Dev set	
	#QA	%	#QA	%
KV	129990	42.3	21798	41.3
Comparison	52893	12.2	9078	17.2
Table	124432	40.5	21950	41.6

Table 1: The statistics of QA pairs from different types of websites in WebSRC.

of its corresponding tag's direct contents. Formally, the representation of node n_i is calculated as:

$$\boldsymbol{n_i} = \underset{x_j \in \text{DC}(n_i)}{mean} (\boldsymbol{x}_j) \tag{2}$$

where $\text{DC}(n_i)$ means the tokens set of the direct contents of node n_i; $\boldsymbol{x}_j$ is the contextual embedding of token x_j.

Structure Encoder Module. TIE utilizes GAT to encode the topological information contained in DOM trees and NPR graphs. Specifically, for the i-th attention head of GAT:

$$\begin{gathered} \boldsymbol{Q}_i = \boldsymbol{W}_{q,i}\boldsymbol{N};\ \boldsymbol{K}_i = \boldsymbol{W}_{k,i}\boldsymbol{N};\ \boldsymbol{V}_i = \boldsymbol{W}_{v,i}\boldsymbol{N} \\ \text{GAT}_i(\boldsymbol{N}) = \text{softmax}(\frac{\boldsymbol{Q_i}^T\boldsymbol{K_i}}{\sqrt{d}} + \boldsymbol{M_i})\boldsymbol{V_i} \\ m_{jk}^{(i)} = \begin{cases} 0 & (n_j, n_k) \in \text{Edge}(G_i) \\ -\infty & otherwise \end{cases} \\ G_i \in \{\mathcal{D}_c, \mathcal{G}_c^{\texttt{UP}}, \mathcal{G}_c^{\texttt{DOWN}}, \mathcal{G}_c^{\texttt{LEFT}}, \mathcal{G}_c^{\texttt{RIGHT}}\} \end{gathered}$$

where $\boldsymbol{N} = [\boldsymbol{n}_i]_{d\times|\mathcal{N}|}$; d is the dimension of the node representations $\boldsymbol{n}_i$; $\boldsymbol{W}_i$s are the learnable parameters; $\boldsymbol{M}_i = [m_{jk}^{(i)}]_{|\mathcal{N}|\times|\mathcal{N}|}$ is the mask matrix for the i-th attention head. Finally, the outputs of all the attention heads are concatenated to form the node representations for the next GAT layer.

Classification Layers. Finally, we get the embeddings of all the nodes from the Structure Encoder Module and utilize a single linear layer followed by a Softmax function to calculate each node's probability of being the answer node.

4 Experiments

4.1 Dataset

We evaluate our proposed methods on WebSRC (Chen et al., 2021c). In more detail, the WebSRC dataset consists of 0.4M question-answer pairs and 6.4K web page segments with complex structures. For each web page segment, apart from its corresponding HTML codes, the dataset also provides the bounding box information of each HTML tag obtained from the rendered web page. Therefore, we can easily use this information to construct the NPR graph for each web page segment.

Moreover, WebSRC groups the websites into three classes: *KV*, *Comparison*, and *Table*. Specifically, *KV* indicates that the information in the websites is mainly presented in the form of `"key:value"`, where `key` is an attribute name and `value` is the corresponding value. *Comparison* indicates that each web page segment of the websites contains several entities with the same set of attributes. *Table* indicates that the websites mainly use a table to present information. The statistics of different types of websites in WebSRC are shown in Table 1.

We submit our models to the official of WebSRC for testing.

4.2 Metrics

To keep consistent with previous studies, we adopt the following three metrics: (1) Exact Match (EM), which measures whether the predicted answer span is exactly the same as the golden answer span. (2) Token level F1 score (F1), which measures the token level overlap of the predicted answer span and the golden answer span. (3) Path Overlap Score (POS), which measures the overlap of the path from the root tag (`<HTML>`) to the deepest tag that contains the complete predicted answer span and that contains the complete golden answer span. Formally, the POS is calculated as follows:

$$POS = \frac{|P_{pred} \bigcap P_{gt}|}{|P_{pred} \bigcup P_{gt}|} \times 100\% \tag{3}$$

where P_{pred} and P_{gt} are the set of tags that on the path from the root (`<HTML>`) tag to the deepest tag that contains the complete predicted answer span or the ground truth answer span, respectively.

4.3 Baselines & Setup

We leverage the three models introduced in Chen et al. (2021c) and MarkupLM (Li et al., 2021) as our baselines. Specifically, T-PLM converts the HTML codes into plain text by simply removing all the HTML tags, while H-PLM treats HTML tags as special tokens and uses the origin HTML code sequences as input. Then, both of them utilize PLMs to generate the predicted answer span. To leverage visual information, V-PLM concatenates token embeddings resulting from H-PLM with visual embeddings and then feeds the results into multiple

	Method	Dev			Test

self-attention blocks before generating predictions. Faster R-CNN is utilized to extract visual embeddings from screenshots of the corresponding web pages. On the other hand, MarkupLM leverages XPaths to encode the logical position of each token and use it as an additional position embedding.

In our experiments, we use 3 GAT blocks as the Structure Encoder Module of TIE. H-PLM(RoBERTa) and MarkupLM are leveraged as context encoders. The implementation of TIE is based on the official code provided by WebSRC [3] and MarkupLM [4]. We set the hyperparameter γ in Eq.1 to be 0.5. Finally, the models used in the *answer refining* stage are of the same architecture as the context encoder models of TIE while individually trained on WebSRC. For more setup details, please refer to Appendix. A

4.4 Main Results

The experimental results on the development set and the test set are shown in Table 2. Specifically, the performances of TIE in the following sections refer to the performances of the proposed two-stage system, and the subscript of TIE refer to both the context-encoder for TIE and the QA model used in *answer refining* stage.

	$\lvert S_0\rvert$	$\lvert S_1\rvert$	$\lvert S_0\rvert : \lvert S_1\rvert$
MarkupLM	873	692	1.26:1
TIE$_{\text{MarkupLM}}$	944	314	3.1:1

Table 3: The statistics of samples on *Compare* websites in the development set with wrong predictions. S_0 is the set of examples with 0 F1 scores. S_1 is the set of examples with F1 scores between 0 and 1. The numbers are average results of 3 random seeds.

From the results, we can find out that our TIE consistently achieves better results compared with the corresponding baselines. Specifically, TIE$_{\text{MarkupLM}}$ significantly outperforms the previous SOTA results, MarkupLM, by 6.78% EM, 3.74% F1, and 2.49% POS on the test set. Moreover, it is worth noticing that the performance of TIE$_{\text{MarkupLM-BASE}}$ is even higher than the performance of the MarkupLM-LARGE model (76.83% v.s. 73.38% EM on the development set and 71.86% v.s. 69.09% EM on the test set). These results strongly demonstrate that TIE can effectively model the topological information of the semi-structured web pages with the help of its structure encoder.

Furthermore, we compare the performances of TIE$_{\text{MarkupLM}}$ and MarkupLM on different types of websites. The results are shown in Figure 5. From the figure, we find that our method achieves signifi-

---

[3] `https://github.com/X-LANCE/WebSRC-Baseline`

[4] `https://github.com/microsoft/unilm/tree/master/markuplm`

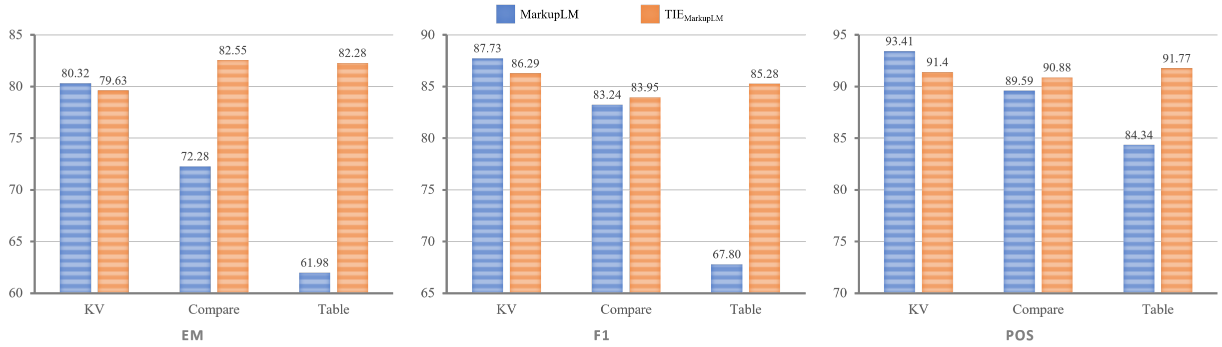

Figure 5: The performance comparison on different types of websites of the development set.

cant improvements on the websites of type *Table* (+20.30% EM, +17.48% F1, +7.43% POS) while suffering slight performance drops on the websites of type *KV*. We hypothesize the reason is that topological structures are less important in the websites of type *KV*, so that stronger contextual encoding abilities will lead to better results. More analysis can be found in Sec. 4.5.

We also notice that the improvements of F1 are less considerable compared with those of EM on the websites of type *Compare* (+10.27% EM v.s. +0.71% F1). The reason lies in the cascading error of our two-stage process. Specifically, in the *node locating* stage, the model may generate a wrong prediction which is not one of the ancestors of the answer node. In this case, as the answer span is not contained in the predicted node, the final F1 score is highly likely to be zero. Detailed calculations, see Table 3, strongly support our analysis.

4.5 Case Study

In Fig. 6, we compare the answers generated by TIE$_{\text{MarkupLM}}$ and MarkupLM. More examples can be found in Appendix. B.

Q1 is a typical example of *Table* websites. It is obvious that multiple `"header-cell"` relations need to be recognized when answering **Q1**. Specifically, one should first find "*OlliOlli: Switch Stance (Switch)*" from column "*Title*" (first `"header-cell"` relation), then locate the answer at the crossing cell of row "*OlliOlli: Switch Stance (Switch)*" (second `"header-cell"` relation) and column "*Game Score*" (third `"header-cell"` relation). With the help of topological information, TIE can correctly answer this question. However, MarkupLM only successfully locates the row and fails to recognize the long range relation between "*Game Score*" and "*84*". Considering that this row can also be identified by string matching, this example strongly demonstrate that TIE is much stronger in terms of long range topological relation encoding.

Method	EM↑	F1↑	POS↑
$\text{TIE}^{\dagger}_{\text{MarkupLM}}$	81.66	86.24	92.29
-w/o DOM†	81.05$_{(-0.61)}$	85.42$_{(-0.82)}$	91.62$_{(-0.67)}$
-w/ ORD	72.20$_{(-9.46)}$	77.80$_{(-8.44)}$	89.39$_{(-1.90)}$
-w/o NPR	72.62$_{(-9.02)}$	77.74$_{(-8.50)}$	89.25$_{(-3.04)}$
-w/o Hori	79.65$_{(-2.01)}$	84.20$_{(-2.04)}$	91.90$_{(-0.39)}$
-w/o Vert	71.66$_{(-10.00)}$	77.28$_{(-8.96)}$	88.98$_{(-3.31)}$

Table 4: The ablation study of TIE$_{\text{MarkupLM}}$ on the development set of WebSRC. †denotes average results of 3 random seeds.

Q2 is a typical example of *KV* websites. The topological structures of this web page are far less complex. To answer **Q2**, the most important step is to discover the semantic similarity among "*Action*", "*Fantasy*", and "*Sci-Fi*" and then group them together. In this case, the contextual distances of these words will be extremely helpful. Therefore, MarkupLM is able to generate the correct prediction. However, as TIE focuses on the comprehension of node structures where sequencing order and semantics are less valuable, TIE fails to group the three nodes.

4.6 Ablation Study

To further investigate the contributions of key components, we make the following variants of TIE: (1)**"w/o DOM"** means only using NPR graphs without the DOM trees. (2)**"w/ ORD"** means using original sparse DOM trees instead of the denser version introduced in Sec.3.3. (3)**"w/o NPR"** means only using the densified DOM trees without the NPR graphs. (4)**"w/o Hori"** removes `LEFT` and `RIGHT` relations in NPR graph. (5)**"w/o Vert"** removes `UP` and `DOWN` relations in NPR graph.

The results are shown in Table 4, from which we

With earth virtually destroyed, Bran Marshall flees to the Rhea, a planet hostile to Earthlings. Escaping onto a Rhean supply ship, he finds the crew slaughtered, with the only survivor a female warrior named Ohsha. As the two try to kill one another, the ship is damaged by meteorites. Bran and Ohsha must join forces to salvage the craft before it impacts on the planet below—and the humans that live there. This gripping sci-fi epic stars Stephen Moyer, Casper Van Dien, and John Rhys-Davies.

Directed by: Tom Paton

Starring: Stephen Moyer, Tala Gouveia, Mike Beckingham, Casper Van Dien, John Rhys-Davies

Figure 6: Examples of the results in the development set.

have several observations and analysis:

First, we investigate the contribution of DOM trees. The performance of **"w/o DOM"** drops slightly compared with original TIE, which indicates that the contributions of DOM trees are marginal. That may be because MarkupLM has leveraged XPaths to encode the logical information. Considering that XPaths are defined based on DOM trees, the information contained in XPaths and DOM trees may largely overlap. Moreover, the results of **"w/ ORD"** show that densifying the DOM Tree is vitally important, as the original DOM tree is extremely sparse and will significantly lower the performance of TIE.

Finally, the NPR graphs have great contributions as the performance of **"w/o NPR"** drops significantly. It is because NPR graphs can help TIE efficiently model the informative relations such as `key-value` and `header-cell`, as they are often arranged in the same row or column. Moreover, we further investigate the contribution of different relations in NPR graphs by **"w/o Hori"** and **"w/o Vert"**. Note that, we keep the number of parameters of TIE unchanged among these experiments, which means no `horizontal` relations in NPR graphs will result in more attention heads assigned to `vertical` relations. The results show that, in WebSRC, `vertical` relations are much more important than `horizontal` relations. That is because most of the websites in WebSRC are constructed row-by-row, which means that the tags of `horizontal` relations are often located near each other in the HTML codes while those of `vertical` relations may be located far apart. Therefore, in most cases, the `horizontal` relations are easier to capture in the context encoder without the help of NPR graph, while the `vertical` relations can hardly achieve that.

5 Related Work

Question Answering (QA) In recent years, a large number of QA datasets and tasks have been proposed, ranging from Plain text QA (i.e. MRC) (Rajpurkar et al., 2016; Joshi et al., 2017; Lai et al., 2017; Yang et al., 2018; Reddy et al., 2019) to QA over KB (Berant et al., 2013; Bao et al., 2016; Yih et al., 2016; Talmor and Berant, 2018; Dubey et al., 2019), Table QA (Pasupat and Liang, 2015; Chen et al., 2020c, 2021b), Visual QA (VQA) (Antol et al., 2015; Wang et al., 2018; Marino et al., 2019), and others. However, the topological information in the textual inputs is either absent (plain text) or simple and explicitly provided (KB/tables). The QA task based on semi-structured HTML codes with implicit and flexible topology is under-researched.

Among these tasks, Table QA is the most similar to the Web-based SRC task, as there are many tables in the WebSRC dataset. To solve the problem, Krichene et al. (2021) first selects candidate answer cells according to cell embeddings from the whole table and then finds the accurate answer cell from the candidates. Their method enables the model to handle larger tables at little cost. On the other hand, Glass et al. (2021) introduces row and column interactions into their models and determines the final answers based on the top-ranked relevant rows and columns. In addition, Text-to-SQL is another group of methods to tackle Table QA problems and has been widely studied recently (Yu et al., 2018; Bogin et al., 2019; Wang et al., 2020; Cao et al., 2021; Chen et al., 2021d,e; Hui et al., 2022). They use databases to store the source tables and translate natural language queries into Structured Query Language (SQL) to retrieve answers from the databases. It is worth noticing that these methods are highly coupled with the data format and requires simple and neat structures. Therefore, their methods are not suitable for Web-based SRC tasks.

Web Question Answering Recent works which mentioned Web Question Answering mainly focus on the post-processing of the plain texts (Su et al., 2019; Shou et al., 2020) or tables (Zhang et al., 2020) resulting from the searching engine. Moreover, Chen et al. (2021a) has tried to answer fixed-form questions based on raw HTML codes with the help of Domain-Specific Language (DSL). Apart from the above works, Chen et al. (2021c) proposed a QA task called Web-Based SRC which is targeted at the comprehension of the structured web pages using raw HTML codes. The method they proposed is to treat the HTML tags as special tokens and directly feed the raw flattened HTML codes into the PLM. They also tried to leverage screenshots as auxiliary information. Later, Li et al. (2021) introduced a novel pre-trained model called MarkupLM specifically for XML-based documents. They adopted a new kind of position embedding generated from the XPath of each token to implicitly encode the logical information of XML codes. In this work, we further explicitly introduce the topological structures to the models with the help of DOM trees and NPR graphs. A newly designed tag-level QA model with a two-stage pipeline is leveraged to take advantage of these graphs.

6 Conclusion & Future Work

In this paper, we proposed a tag-level QA model called TIE to better understand the topological information contained in the structured web pages. Our model explicitly captures two of the most informative topological structures of the web pages, logical and spatial structures, by DOM trees and NPR graphs, respectively. With the proposed two-stage pipeline, we conduct extensive experiments on the WebSRC dataset. Our TIE successfully achieves SOTA performances and the contributions of its key components are validated.

Although our TIE can achieve much high performance compared with traditional QA models on SRC tasks, more improvements are still needed. Specifically, as our two-stage system needs a separated token-level QA model to generate final answer spans, the parameter numbers and computation consumption will be at least doubled. We have tried to tackle this problem by sharing parameters between the context encoder and the token-level QA model used in the *answer refining* stage. But the results are not promising. Therefore, we leave this problem for future work.

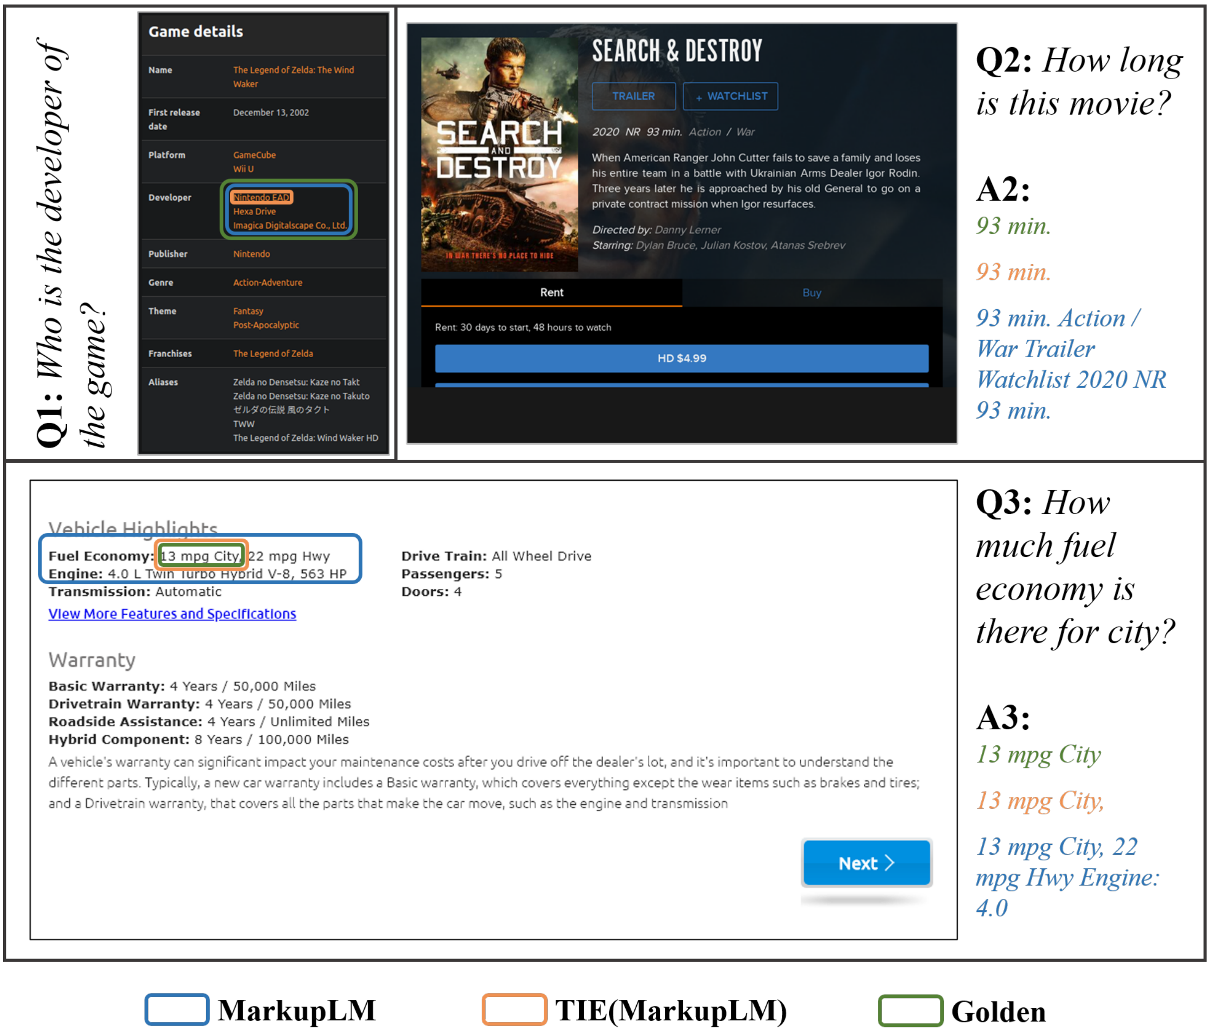
A Detail Setup

To train the model, we use AdamW (Loshchilov and Hutter, 2019) with a linear schedule as our optimizer. As for the learning rate, we search for the best learning rate between 1e-6 and 5e-5. Finally, TIE is trained and evaluated on four Nvidia A10 Graphics Cards with batch size 32 for two epochs. Moreover, for BASE size models (12 heads in total), we use DOM Trees to generate the mask matrix for 4 attention heads and each of the 4 NPR graphs for 2 attention heads. And for LARGE size models (16 heads in total), we add one more attention head using each of the 4 NPR graphs.

B Additional Case Study

Figure 7, 8, and 9 shows the typical examples of the QA pairs in *KV*, *Table*, and *Compare* websites, respectively.

Through detailed analysis, we found that TIE can better capture the long-range relations which have obvious spacial relations, such as `header-cell` and `entity-attribute` (see Fig. 7 **Q3**, Fig. 8 **Q1**, and Fig. 9 **Q2**). On the other hand, as TIE focuses more on tag-level structure understanding, its ability to understand token-level semantics may be weaker, which leads to some of the TIE's wrong predictions (see Fig. 7 **Q1**, Fig. 8 **Q2**, and Fig. 9 **Q3**). In addition, TIE has a better awareness of tag boundaries, which has been proven useful when answering questions with blurry boundaries (see Fig. 7 **Q2**, **Q3**, and Fig. 9 **Q1**).



Q1: *Who is the developer of the game?*

SEARCH & DESTROY

2020 NR 93 min. Action / War

When American Ranger John Cutter fails to save a family and loses his entire team in a battle with Ukrainian Arms Dealer Igor Rodin. Three years later he is approached by his old General to go on a private contract mission when Igor resurfaces.

Directed by: Danny Lerner
Starring: Dylan Bruce, Julian Kostov, Atanas Srebrev

Rent: 30 days to start, 48 hours to watch

Q2: *How long is this movie?*

A2:
93 min.
93 min.
93 min. Action / War Trailer Watchlist 2020 NR 93 min.

Vehicle Highlights

Fuel Economy: 13 mpg City, 22 mpg Hwy
Engine: 4.0 L Twin Turbo Hybrid V-8, 563 HP
Transmission: Automatic
View More Features and Specifications

Drive Train: All Wheel Drive
Passengers: 5
Doors: 4

Warranty

Basic Warranty: 4 Years / 50,000 Miles
Drivetrain Warranty: 4 Years / 50,000 Miles
Roadside Assistance: 4 Years / Unlimited Miles
Hybrid Component: 8 Years / 100,000 Miles

A vehicle's warranty can significant impact your maintenance costs after you drive off the dealer's lot, and it's important to understand the different parts. Typically, a new car warranty includes a Basic warranty, which covers everything except the wear items such as brakes and tires; and a Drivetrain warranty, that covers all the parts that make the car move, such as the engine and transmission

Q3: *How much fuel economy is there for city?*

Abstract

In this paper, we study the task of improving the cohesion and coherence of long-form text generated by language models. To this end, we propose RSTGen, a framework that utilises Rhetorical Structure Theory (RST), a classical language theory, to control the discourse structure, semantics and topics of generated text. Firstly, we demonstrate our model's ability to control structural discourse and semantic features of generated text in open generation evaluation. Then we experiment on the two challenging long-form text tasks of argument generation and story generation. Evaluation using automated metrics and a metric with high correlation to human evaluation, shows that our model performs competitively against existing models, while offering significantly more controls over generated text than alternative methods.

1 Introduction

Controllable text generation has attracted much attention in recent years. Generating coherent and cohesive long-form text with controllable attributes is particularly challenging due to the relatively complex syntactic and semantic structures involved compared to short-text generation. Long-form text generation can find applications in automatic argumentation, motivational speech, and opinionated writing, to name a few.

A popular approach to controllable text generation is to design prompts, which control high-level linguistic features (i.e., text style and sentiment) by prefixing simple context to the input of a language model. These non-granular methods are often too coarse to allow different parts of the text to have diverse or contrasting features. Furthermore, they tend to focus on a single linguistic feature of text, meaning that extra frameworks such as Plugand-Play (Dathathri et al., 2019) are required to control multiple linguistic features.

To achieve improved content control, researchers have coupled a content planning module with a text generation module (Hua and Wang, 2020; Hua et al., 2021), in which the content planning module firstly generates a set of keyphrases and their corresponding positions in sentences and the generation module fills in the gaps. To control syntactic structures of text, recent works have proposed a neuro-symbolic approach leveraging Dependency Structure Theory (DST) (Shen et al., 2019; Du et al., 2020). Enforcing specific structures over the generated text has been proven to be useful in increasing coherence and cohesion of short-form text. However, a relatively large amount of DST information is required to encode comparatively short texts. Thus, they are unsuitable for use in long-form text generation tasks.

Similar to DST, Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) is a classical tree-based interpretation of natural language. Whereas DST is most useful for intra-sentence interpretation, RST is most useful for inter-sentence interpretation of language. We propose a neurosymbolic framework that can imbue an RST understanding of text to existing language models. More specifically, our framework (1) allows more fine-grained control of syntax, semantics and text structure; (2) utilises a well-defined rhetorical structure of language, thus offering better interpretability; (3) can be directly integrated into existing pre-trained language models such as GPT-2 (Radford et al., 2019) and BART (Lewis et al., 2019).

We evaluate our proposed framework on two tasks: argument generation and story generation. We show that our proposed framework improves upon existing content control approaches on automatic evaluation metrics including BLEU (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2014) and generates better text in terms of grammar and coherence measure. We further demonstrate our model's ability to generate text

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1822 - 1835
July 10-15, 2022

with control over syntactic, semantic and discourse features. Our main contributions can be summarised below:

- We propose a novel framework to imbue the RST information into pre-trained language models.
- We develop the first neurosymbolic framework that provides interpretable fine-control over syntax, semantics, discourse structure, topical keywords and keyword positions.
- We demonstrate the superiority of our proposed framework over existing planning and control methods for two long-form text generation tasks.

2 Related Work

We discuss several lines of research in controllable text generation.

Prompts For prompt-based control, a *context* is prepended to a language model input. The prepended item is related to the type of desired output. This method has been used to manipulate the syntax (Dušek and Jurčíček, 2016; Goyal and Durrett, 2020) and semantics (Wen et al., 2015; Chen et al., 2019) of the output. Alternatively, the prepended item can provide semantic control in order to cover a given topic (Wang et al., 2019a), mention specified entities (Fan et al., 2019), display a certain attribute (Hu et al., 2017; Balakrishnan et al., 2019), or even exhibit a style of text (Keskar et al., 2019). These methods suffer from the inability to exert fine-control, that is, a change in any one of the input prompts will change the whole generated text. Furthermore, all these works utilise non-expansive features for their prompts, which prevents them from making iterative improvements to existing generated text.

Content Planning Despite the impressive progress made in many generation tasks, earlier neural models are known to produce low-quality content (Wiseman et al., 2017), often with low relevance, and poor discourse structure (Zhao et al., 2019). Content-based planning approaches were added into neural systems to enhance content relevance (Moryossef et al., 2019; Yao et al., 2019; Hua and Wang, 2019). Hua et al. (2021) extended previous content planning approaches by dividing the content plan into different types of information; 'Entities', 'Claim' and 'Concepts'. An alternative planning approach focuses on where the key phrases should be placed in the generated text in order to improve coherence (Hua and Wang, 2020). The text generator is then conditioned on the provided key phrases and their respective positions in text. Similar to our approach, these methods allow users varying levels of custom control by manual augmentation of the planning module output.

Syntactic or Discourse Control Various works utilised syntactic parse trees with the transformer structure to gain syntactic control or improve interpretability on short-form text generation tasks (Li et al., 2020; Nguyen et al., 2020). With a focus on improving long-form text generation, Ji and Huang (2021) used a Variational Autoencoder (VAE) structure to model RST discourse relations between successive elementary discourse units (spans of text).

We build upon their approach by using a more expressive binary tree formalisation of RST. This formalisation extends the modelling of sequential elementary discourse units by also modelling nuclearity and relationship between non sequential discourse units.

Extending on previous works, Wang et al. (2019b) attempted to couple tree structures and transformers. We instead embed the tree structure of RST into transformers through constrained attention in a separate RST embedding dimension.

3 Rhetorical Structure Theory

Rhetorical Structure Theory (RST) provides a formal structure for interpreting language based on relations between parts of text. Each structure is defined by three sets of features: the binary tree structuring of Discourse Units (EDU)s, the nuclearity between sibling DUs, and the relationship between sibling DUs. An example RST tree using the schema provided by (Mann and Thompson, 1988) as shown in Figure 1.

Binary Tree Structuring of Discourse Units To form a binary discourse tree R from text t, the text must be successively divided into smaller subsets of text. In this manner, node 0 represents the full text, with subsequent nodes representing subtexts, as in Figure 1. The text at each node is called a Discourse Unit, while the nodes at the leaves of the tree are Elementary Discourse Units (EDUs).

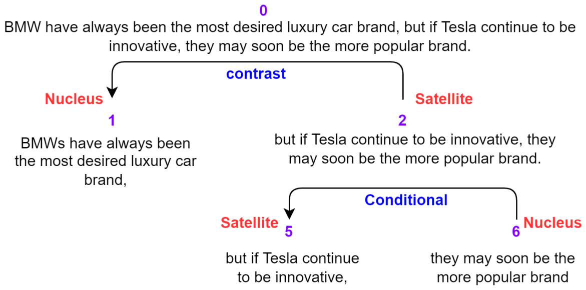

Figure 1: **RST example:** An example text (top) interpreted through RST schema. The text is broken down into a binary tree with zero-indexed numbered node positions. Relations exist between the two sibling nodes of a parent node. Each pair of sibling nodes, have a coupled nuclearity label. Nodes with no children, are Elementary Discourse Units (EDUs).

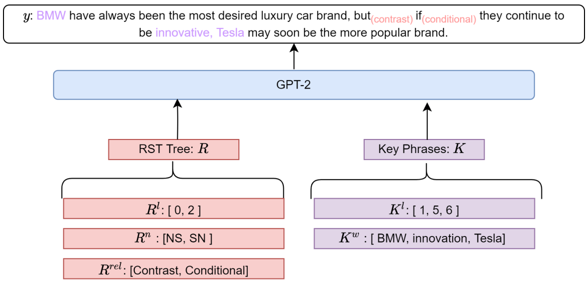

Figure 2: **RSTGen Structure:** Our RST controlled text generation framework can be built upon any pretrained language model. We input RST tree structure information as R, comprising the Nuclearities R^n, RST Relations R^r and RST node positions R^l, and key phrase information at EDUs as K, comprising the key phrases K^w and the RST node positions of the key phrases, K^l. The discourse structure of the output text y is controlled by R^n and R^l. The syntax of y is controlled by R^n, R^l and K^l. The semantics is controlled by R^r and K^w. Our framework creates a prefix-embedding from the encodings for R and K, after which text is generated as a continuation.

Sibling Nodes – Relations: A parent node is a non-terminal node which has two child nodes, referred to as siblings. Each parent nodes' children, has a RST relation $r_i, i \in \mathbb{N}_{<20}$ describing the syntactic purpose of each child node relative to the other. In Figure 1, the RST relations are presented in blue texts.[1]

Sibling Nodes – Nuclearity: Associated with each pair of sibling node's relation is a joint nuclearity labelling, $n_j, j \in \mathbb{N}_{<5}$. This nuclearity explains the role of each sibling node's discourse unit relative to the other sibling node. Each joint nuclearity labelling between pair of sibling nodes must include at least one Nuclei.[2]

Formally, we define a binary RST Tree R as a collection of its parent nodes $\{\boldsymbol{v}_l^{r,n}\}$, where $\boldsymbol{v}_l^{r,n}$ is a parent node at position l, with a RST relation r and a Nuclearity n between its two children. For example, $v_2^{\text{Conditional},SN}$ represents node 2 in Figure 1. We refer to the group of relations in an RST Tree, R, as R^r. Similarly, the group of Nuclearity values is referred to as R^n.

4 RSTGen: RST-Dependent Long-form Text Generator

We propose a long-form text generation approach, call RSTGen, which provides control over semantics and structure of text, with the aim of improving *coherence* and *cohesion* of the generated text. *Coherence* is concerned with how well constituent sentences/chunks follow on from the previous sentence/chunk. This can be interpreted as the topic of each subsequent sentence/chunk being relevant to the previous sentence/chunk (Carrell, 1982; Waller, 2015). *Cohesion* describes the way in which text is tied together by linguistic devices such as *Therefore..., However..., In addition to* (Waller, 2015). This can be interpreted as how smooth the model transitions between the types of sentences. With an RST interpretation, *cohesion* is loosely related to the RST relations between different nodes in the binary tree, while *coherence* is related to the RST relations and key phrases at EDUs.

Task formulation Our input consists of (1) an encoding for a binary RST Tree R, (2) a set of keyphrases information K that are relevant to the text. The RST encoding is formed as sets of three pieces of information for each parent node in the binary RST Tree. These include Nuclearity R^n, RST Relation R^r and RST node position R^l. The keyphrase information contains two pieces of information. These are K^w and K^l, the key phrases and the RST node positions of the key phrases. The model has been trained to work with varying levels of specification for the context information.

Partial Context Provision In practice, we do not expect users to provide the full RST Tree or key phrases since often only a subset of features of the context information may be known

---

[1] Table A1 in the Appendix details the 19 possible RST Relations.

[2] Table A2 in the Appendix details the 4 possible RST Nuclearity values.

or needed. For example, in Figure 2, the goal is to produce a text contrasting the innovative ability of Microsoft and Tesla. A user only needs to provide partial information, e.g., the keywords, $K^w = [BMW, Tesla, innovation]$ and the RST relation, $R^r \supset [\prime Contrast^\prime]$. Our model will be able to automatically predict an RST tree following a conditional sampling method we have designed in Section 4.3.

While a user will often want to specify the key phrases themselves, we could also employ automated methods to create an expanded set. For example, existing Planning Modules (Hua and Wang, 2020; Hua et al., 2021) can be used to generate a set of keywords based on some prior information.

In what follows, we describe our proposed RSTGen in more details.

4.1 Tokenisation

While our RST controlled text generation framework can be built upon any pre-trained language model, we use GPT as an example here. The GPT Tokeniser is used to tokenise the target text y and key phrases K^w to a set of word tokens. Two new tokens are added to the tokeniser: '`<rst>`' and '`<kp>`'. The former is prepended to the RST tree R, and the latter is prepended to each key phrase.

4.2 Embedding Layers

Our framework requires three additional embedding layers to facilitate the encoding of the RST position, RST nuclearity and RST relation information presented in R^l, R^n and R^r. These embedding layers are designed to produce vectors that match the size v of hidden vectors in the base model.

We use a RST relation Embedding Matrix $W_r \in \mathbb{R}^{19\times768}$ to encode R^r as there are 18 possible RST relations and a pad token, and an RST Nuclearity Embedding matrix $W_n \in \mathbb{R}^{4\times768}$ to encode R^n, which consists of 3 possible nuclearity labels and a pad token.

To embed RST node position encodings R^l, we create a novel embedding layer designed to capture the positional relationships of nodes in a binary tree, in a space efficient manner. The intent is to explicitly capture the relationship between a node and its ancestor nodes. Our embedding layer features a non-trainable embedding matrix $W_{pe} \in \mathbb{R}^{\text{max\_rst\_node}\times\text{tree\_depth}}$, a trainable feed forward layer $W_{pff} \in \mathbb{R}^{\text{tree\_depth}\times768}$ and a Gelu activation layer $f_g(\cdot)$. In our experiments $\mathrm{max\_rst\_node} = 4094$ and $\mathrm{max\_tree\_depth} = 12$.

The i-th column in the non-trainable embedding matrix W_{pe} is a vector representing the position of node i, in terms of a sequence of Lefts (L) and Rights (R) required to travel from the root node 0 to node i. Left is encoded as -0.05 and Right as 0.05. For example, the vector at node position 5 in W_{pe} in the example RST tree shown in Figure 1 is encoded as $[0.05, -0.05, 0, 0....]$ with the remaining 0s representing padding values up to the length $\mathrm{max\_tree\_depth}$.

It is important to note that in our RST Tree encoding R, a parent node $\boldsymbol{v}_i$ is labelled with the relation r_i and nuclearity n_i connecting its children. As such our encodings for a R^r, R^l and R^n do not include the leaf nodes with no children, but still represent R. This allows our encodings, for a Binary RST Tree with N nodes to be sequences of length $\lceil N/2 \rceil$.

4.3 RST Predictor

We use an RST Predictor to predict the relation and nuclearity of a child node conditional on the RST relation, nuclearity and position of their parent node. For example we predict the left child node $\boldsymbol{v}_{2l+1}^{r_i,n_j}$, by modelling the following conditional distribution $\boldsymbol{v}_{2l+1}^{r_i,n_j} \sim p\big(r, n | l_{\text{parent}}, r_{\text{parent}}, n_{\text{parent}}, \mathbb{1}(\boldsymbol{v}_{2l+1} = \text{left child}\big)$. A full RST Tree can be predicted by iteratively repeating this one-step sampling.

We propose a neural sampler method to estimate the conditional distribution $p(\cdot|\cdot)$. It is trained on the RST Trees observed in the training set of the RST Annotated Dataset introduced in Section 6. Our neural RST Sampler, depicted in Figure 3, uses the BART (Lewis et al., 2019) model. The encoder takes a prompt as input. The decoder is reinitialised and reduced to two layers. The decoder takes four inputs: (1) The parent nodes' relation r; (2) The parent node's nuclearity n; (3) The parent node's RST position l; (4) A vector b indicating whether the target node is a left child node or right child node. This vector b is calculated as the difference between the node position embeddings for the parent node and the target child node encodings.

We use the Embedding Layers structures from our RSTGen model to encode the inputs (1-4) to the Encoder. The BART decoder contains two classification heads, to predict relation and nuclearity.

Two approaches can be used to guide our RST

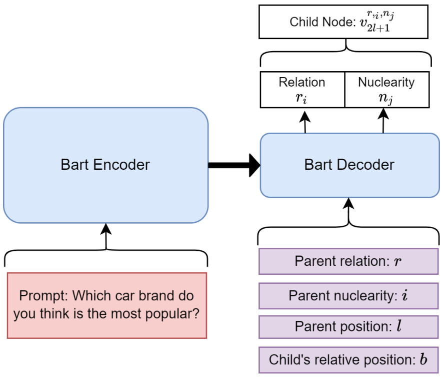

Figure 3: **Neural RST Sampler:** Our Neural RST Sampler can be used to iteratively predict an RST Tree, conditioned on a prompt which is passed to the Encoder. The Decoder takes as input the summation of embeddings for the parent' nodes relation r, nuclearity n and position l. Further we also pass in b which represents whether the target child node is a left or right child.

predictor to produce more relevant RST Trees. Firstly, the training set can be limited to a specific domain, such as argumentative text, to introduce bias the prediction towards a specific linguistic style. Secondly, during inference the predictive distribution can be augmented, to ensure specific structural properties are achieved. In our experiments, we use this to predict RST Trees with a specific size. We have extended this to other structural features such as specifying RST relation frequency, and position.

4.4 RST-Aware Attention (R.A.A.)

To better encode the RST tree structure in language model training and to improve the coherence of text by reducing the occurrence of hallucination in long-form generated text, we propose a novel attention scheme, called RST-aware attention. In particular, to generate a word token at position i, we create dynamic attention masks $\boldsymbol{m}_i$ allowing the hidden state h_i to focus only on structurally relevant hidden representations h_j, $j \neq i$. The hidden representation h_j is structurally relevant to h_i if h_j's associated RST node is an ancestor of the RST node associated to h_i. The RST-aware attention is described in Algorithm 1.

In the above process, we need to first detect the RST node position of the word token to be generated. We do this in a sequential manner with the help of an EDU splitter (Wang et al., 2018), which can detect EDU boundaries in text. At the start of text generation, we set the initial EDU node position as the leftmost leaf node in the RST tree and then proceed to generate the first token. Afterwards, we use the EDU splitter to detect whether an EDU boundary has occurred. If no boundary is detected, we continue with the generation of the next word token; otherwise, we infer the next EDU node position as the second leftmost leaf node in the RST tree. The above process is repeated until the '`end of sequence`' token is generated or until the final child EDU node is generated. In practice we use heuristics to avoid the need to perform an EDU boundary detection at each generation step.

Algorithm 1: RST-aware attention

```
Input : Hidden representations: $h_i$, $h_j$, $j \neq i$, and
        their associated RST nodes $\mathrm{v}_l$, $\mathrm{v}_m$ at
        positions $l, m$ respectively.
Output: Updated hidden representation $h_i'$.
for $j \neq i$ do
    if isParentNode($v_l, v_m$) then
        $m_{i,j} = 1$
    else
        $m_{i,j} = 0$
end
return $h_i' \leftarrow$ MaskedAttention($h_i, \{h_j\}_{j \neq i}, \boldsymbol{m}_i$)
```

5 Open Generation Evaluation

We first train a model using our RST annotated dataset described below. Then we analyse the model's ability to control semantic, syntactic and text structure.

Subreddit	% of Training Instances
r/CasualConversation	41.7
r/changemyview	19.1
r/DebateReligion	15.8
r/PoliticalDiscussion	9.62
r/relationship_advice	7.94
Other Subreddits	6.84
Total	965,411 samples

Table 1: **Statistics of RST Annotated Dataset:** The majority of our dataset is sourced from 5 subreddits which exhibit a tendency to produce longer and more complex texts.

RST Annotated Dataset We use the ConvoKit API (Chang et al., 2020) to collect a total of over 965k text examples from Reddit to use as the training set. Table 1 provides a detail regarding the division of the dataset between different subreddits. The following subreddits comprise the majority of our dataset, *DebateReligion*, *RelationshipAdvice*, *Politics* and *ChangeMyView*. These subreddits contain many long texts with opinions or persuasive

Input	
Key phrases:	“*good mouse alternative*" and “*none*"
Text prompt:	“*It would be*"
RST structure:	{Relation: $r1$, Nuclearity: SN, Node position: 0}, {Relation: $r2$, Nuclearity: NS, Node position: 2}
Input Relations $(r1, r2)$	**Generated Text**
Attribution, Explanation	It would be a good mouse alternative, because none of us are going to be able to see.
Background, Evaluation	It would be a good mouse alternative, since none of us have ever seen one.
Background, Condition	It would be a good mouse alternative if none of them were good.
Contrast	It would be a good mouse alternative, but none of them are as good as a good one.

Table 2: **Short Text Semantic control:** Examples of text generated by varying the RST relations. Words highlighted in red in the generated text indicate the corresponding underlined RST input relations.

style of writing. Further, we choose large samples from the subreddit *CasualConversation* to complement the limited range of language present in the former subreddits. Each sample contains a reddit post, its RST tree generated using the best statistical RST parser (Feng and Hirst, 2012) and keyphrases extracted from the post using the PageRank inspired algorithm, TextRank (Mihalcea and Tarau, 2004). The keyphrase extraction process is detailed in Appendix D.

Semantic Control In Table 2 we show the generated short text conditional on various RST relations. For all four examples the same key phrases of “*a good mouse alternative*" and “*none of this*" were passed to the model. Furthermore, we provide the first three words “*It would be*" to the decoder as a text prompt. The text is generated by varying the RST relations, r_1 and r_2. We can observe that the generated text varies depending on the desired RST relations input to the model.

Structural Discourse Control Here we use a reconstruction style test to evaluate the ability of our model to include the target relations in the generated text at the correct position. To do this, we allow our model to generate text $\hat{y}$ using the RST tree T as the conditioning factor. We then use an RST parser to generate a RST tree $\hat{T}$ from the generated text $\hat{y}$. For each relation r, we calculate a recall score as the proportion of nodes with relation r in T that also occur in $\hat{T}$ at the same position l. The results are shown in Figure 4. We include results for different lengths of text, measured by elementary discourse units.

We observe that our model achieves strong levels of control for the following relations: *Attribution, Background, Condition, Contrast, Elaboration, Joint, Manner-Means*, and *Temporal*. We believe that the weakened performance on *Cause* and *Comparison* is due to their respective similarity to *Attribution* and *Contrast*. We omit topic change since our datasets contains texts mostly constrained to a single topic.

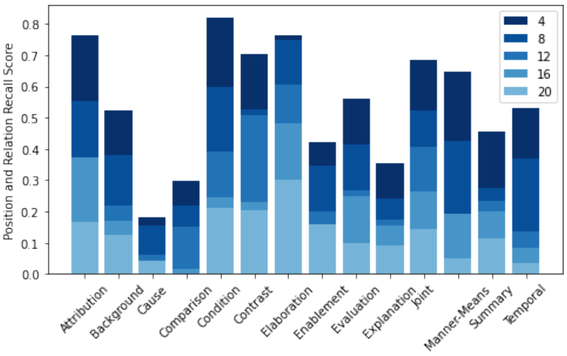

Figure 4: **Structural Discourse Control:** RST relation and position recall scores calculated for each RST relation from the generated text with its lengths measured by the number of Elementary Discourse Units in the range of $\{4, 8, 12, 16, 20\}$.

Text Length Control By editing the length of the RST encoding, we gain strong control of the length of the generated text. Here we fix the key phrases and vary the length of the RST context (i.e., number of EDUs) from 2 to 14 to demonstrate the increasing length of generated text. Results are depicted in Figure 5. We believe that our method provides a more natural way to control text length when compared to the heuristic methods of fine tuning text generation hyper-parameters such as repetition penalty, length penalty and minimum length.

RST Tree Edit Distance Here we extend the Tree Edit Distance to RST Trees to evaluate how well RSTGen is able generate text that adheres to the RST encoding passed to it. Specifically, we investigate how well this model performs as the

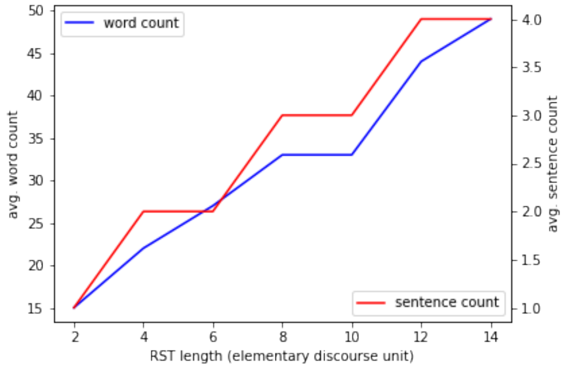

Figure 5: **Text Length Control:** RSTGen exhibits the ability to implicitly control the length of generated text by controlling the size of the RST structure provided as context. In this figure we present the average word count (left y-axis) and average sentence count (right y-axis) against the length of the RST encoding passed to RSTGen.

Figure 6: **Normalised RST Tree Edit Distance:** This figure shows the similarity between the RST structure of RSTGen output text and the RST encoding passed as input to RSTGen. We extend Tree Edit Distance to RST Trees to calculate three metrics based on combinations of node position, node nuclearity label and node relation label: (1) Simple Structure: Tree distance including only node positions; (2) Complex Structure: Tree distance including node positions and nuclearity; (3) Complete Structure: Tree distance including node position, nuclearity and relation.

RST structure becomes increasingly long. For this experiment, we pass an RST Encoding and a set of keywords to our model and generate a text y. We then extract an RST tree from the generated text y using an RST parser. An edit includes the following operations: Changing/Removing the relation or nuclearity label of the node at position l with cost 1; Changing the position of a node to it's sibling node with cost 1; and Deleting/Inserting a blank node at position l with cost 3. For a tree of size s we use a normalising factor of $3 \times s$, the cost of creating the tree. Our normalising factor does allow distances over 1. We observe from Figure 6 that generated text is able to adhere to correct RST structure in terms of RST node positions relatively well. However, when considering nuclearity and relation, he inaccuracy of RST structure grows significantly.

6 Evaluation on Argument Generation and Story Generation

We evaluate RSTGen for the tasks of argument generation and story generation. These tasks require our model to output coherent and cohesive text.

6.1 Experimental Setup

We describe the datasets used for fine-tuning our model, baseline models and the methods used to ensure fair comparison. Training detail and hyper-parameter setting can be found in Appendix C.

Datasets We use two different datasets for argument generation and story generation, respectively.

CMV Dataset We use the argument generation dataset first introduced in (Hua et al., 2021). This dataset contains pairs of claims and counter-arguments extracted from titles and responses, respectively, from the Reddit *ChangeMyView* (CMV) forum. This dataset uses posts dated in 2019, which prevents overlap with our training set for the RST Annotated Dataset. The goal of this task is to generate the counter-argument given the initial claim.

Writing Prompts Dataset We use the Story generation dataset created by Fan et al. (2018a) and utilised in (Ji and Huang, 2021). This dataset contains pairs of prompts and stories extracted from the *WritingPrompts* subReddit. The prompt is an introduction to a story that must be extended. We limit each story to be up to 270 tokens.

Baselines For argument generation, we evaluate the following baselines:

CTRL. (Keskar et al., 2019) uses text prompts to control the style of output. The trigger r/changemyview style output we prepend the text ‘`Opinion Title:`‘ to the opening statement. This model is approximately 10 times larger than RSTGen and we assume that it achieves performance gains primarily through its larger size.

PAIR (Planning and Iterative Refinement). Hua and Wang (2020) devised a two-step generation process. The first step uses a fine-tuned BERT to

Model	Control Method	Grammar ↑	Redundancy ↑	Focus ↑	Structure and Coherence ↑
CTRL	Text prompt	**0.84**	-0.16	-0.12	-0.76
PAIR	Keywords + positions	0.79	**0.00**	**-0.02**	-0.78
DYPLOC	Categorised keywords	0.73	-0.10	-0.03	-0.79
RSTGen	RST + PAIR Planner	0.81	-0.03	-0.03	-0.77
RSTGen	RST + DYPLOC Planner	0.83	-0.02	-0.04	**-0.75**
RSTGen	$\text{RST}_{predicted}$+ PAIR Planner	0.75	-0.05	-0.06	-0.88
RSTGen	$\text{RST}_{predicted}$+ DYPLOC Planner	0.76	-0.06	-0.05	-0.86
RSTGen w/o R.A.A.	RST + PAIR Planner	0.71	-0.04	-0.08	-0.81
RSTGen w/o R.A.A.	RST + DYPLOC Planner	0.65	-0.06	-0.09	-0.80

Table 3: **Argument Generation Evaluation:** the performance of baseline models and our RST frameworks with different control methods. The shortform R.A.A refers to the RST-aware attention described in Section 4.4.

allocate a position to each pre-defined keyword, in order to create a template for the text to be generated. Then a fine-tuned BART model is used to fill the template.

DYPLOC (Dynamic Planning of Content using Mixed Language Models). Hua et al. (2021) proposed first categorising the keywords into concepts and entities. A BERT-based Planner is used to expand this set of concepts and entities, while another is used to generate the claim. The claim provides a brief summary of the extended answer. Four separate BART Encoders and a BART Decoder are used to convert the expanded set of concepts and entities into an argumentative text.

For both PAIR and DYPLOC, we use their gold standard plan as input to the model, this follows the headline results given in both papers. In pursuit of fair testing, we convert the gold standard plans of PAIR and DYPLOC to two RST encodings. More concretely, for PAIR, we convert its gold standard template, consisting of a set of phrases and their corresponding starting positions in the text to be generated, into a RST encoding. These phrases become the keyphrases for RSTGen. The RST node position for each key phrase can be determined by parsing the true RST structure of the text. For DYPLOC, first we collect the gold standard set of concepts/entities and claims, and filter out any repeated words phrases. Then, the RST node position for each word/phrase can be determined in a similar manner to PAIR.

For Writing Prompts, we compare our proposed approach with the following models:

DiscoDVT (Ji and Huang, 2021). To the best of our knowledge it is the only other work that uses RST to improve the long form text generation ability of a language model. It has three modules: an RST planner, an encoder and a decoder. These modules are combined to form a VAE structure wherein the RST planner produces a sequence of discrete hidden vectors representing the sequence of RST relations between EDUs in their text. Then at each generation step, sequential hidden vectors are used to guide the text generation process. For fair comparison we do not pass keyphrases to RSTGen.

RSTGen Ablations. We evaluate ablations of RSTGen to validate the two significance features of our proposed RSTGen framework. Firstly, we remove the RST-Aware Attentions (R.A.A.), after which we remove RST Nuclearity, then Relation, and finally node positions.

Metrics We use two sets of metrics. For the Argument Generation experiments, we use the GRUEN (Zhu and Bhat, 2020) set of metrics, which measure four important features of text: Grammaticality, Non-redundancy, Focus and Structure/Coherence. A final metric combines these four features, and has been shown to correlate strongly with human reviewers. For the Story Generation experiments, we use BLEU (Papineni et al., 2002) focusing on the n-gram precision; Distinct-n (Li et al., 2016), which takes the proportion of distinct n-grams relative to all generated n-grams, thus producing a non-reference-based measure for diversity; the GRUEN Structure and Coherence metric (G-SC); and MS-Jaccard (Alihosseini et al., 2019) which uses the Jaccard Index to measure how similar the distribution of n-grams is between two sets of text.

6.2 Evaluation Results

This section presents the performance of RSTGen against baseline models and discusses the performance of RSTGen ablations.

Argument Generation Table 3 shows that our proposed RSTGen using the DYPLOC Planner performs on par with CTRL in terms of *Grammar* despite using only one tenth parameters of CTRL. It outperforms all the baselines in *Structure and Coherence*.

Using automatically predicted RST trees as input, we observe degraded performance of RSTGen results. We believe that this can be attributed to our Markovian RST sampling methodology of sampling a child node dependent on its direct parent node. This may produce RST Trees with unrealistic structures. Nevertheless, it still outperforms CTRL in *Redundancy* and *Focus*, implying that the combination of RST relations, nuclearity and key phrases provide strong content guidance.

RSTGen without the RST-aware attention (R.A.A.) experiences a drop in performance across all metrics, especially *Grammar* and *Focus*. During the generation of longer sequences, using R.A.A. ensures that the same key phrase or RST information does not influence adjacent elementary discourse units, leading to more diversity and less repetition in generated text. We posit that the removal of R.A.A. exacerbates the reduced performance of RSTGen for longer texts, a trait that was exemplified in Figure 6.

Story Generation Table 4 shows that the R.A.A. variants of our model perform on par with the baseline. We observe that the removal of the R.A.A. causes a significant drop in performance, specifically Distinct-4, confirming our findings from the Argument Generation. As the RST relations carries information on the semantics of text, we observe that its removal has a significant effect on the similarity based metrics of BLEU-1, Distinct-4 and MS-Jaccard 3.

Model	BLEU-1 ↑	Distinct-4 ↑	G-S&C ↑	MS-Jaccard 3 ↑
DiscoDVT	**24.10**	84.66	-0.73	**34.76**
RSTGen (no keyphrase)	24.01	**84.85**	**-0.71**	34.51
- R.A.A.	23.20	82.12	-0.75	33.21
- RST relation	22.28	81.09	-0.77	33.79
- RST nuclearity	22.29	81.12	-0.77	33.78
- RST positions	22.04	80.91	-0.75	33.73

Table 4: **Story Generation Evaluation:** Results for the RSTGen and Baselines on the Writing Prompts story generation dataset. RSTGen performs competitively with DiscoDVT.

7 Conclusion

We present a novel controlled text generation framework, RSTGen, which uses fine-control over a Rhetorical Structure Theory based context as a means to improve the coherence and cohesion of generated text. We also leverage the structural information presented by RST to propose an rst aware attention scheme, ensuring that the model attends to the correct information during long form generation. Through investigation of RSTGen's open generation text, we showed that our approach can exhibit a high level of intepretable fine-control over syntactic, semantic and structural features of text.

8 Ethics Statement

We acknowledge that our proposed model may be susceptible to learning harmful biases present in the dataset. In and of itself this has the potential to harm minorities, marginalised communities and project stigmas present in society. Further, we recognise that our efforts to improve coherence, cohesion and control might be misused to author offensive or fictitious content. Therefore, we advocate for morally correct and responsible practices in the case of real-world application.

A RST Schemas

We list in Table A1 the RST relations and necleus that our proposed RSTGen framework utlises. We also provide a schema in Table A2 explaining the meaning of Nuclearity labels used by RSTGen.

B Argument and Story Generation Dataset Details

For both the argument generation and story generation experiments our datasets originate from the respective paper's of models in the baseline study. We do not make any alterations to the datasets, but instead simply use it as provided. We refer the reader to and Hua et al. (2021) for the argument generation dataset (i.e., the CMV dataset) and Fan et al. (2018b) for further details regarding the story generation dataset (i.e., the Writing Prompt dataset).

C Reproducibility

Code The code used to train and evaluate our models can be downloaded from https://github.com/Rilwan-A/RSTGen. As well as code, the github will contain links to the RST annotated versions of the CMV dataset and Writing Prompts dataset. Access to the full RST Annotated Reddit dataset can be gained upon request.

Repositories The RSTGen models were extended from pretrained models in Huggingface's Transformers repository (Wolf et al., 2019). RSTGen is initialised using the GPT2-base model with approximately 124M parameters. The neural RST Predictor was initalised using the BART-base model. We used Pytorch-Lightning (Falcon et al., 2019) for all our training scripts.

Hardware For fine-tuning the RSTGen model on the RST Annotated Dateset, we used 2 GeForce RTX 3090 (24GB). For the Argument Generation Tasks and the Story Generation Task, the RSTGen variants and RST Neural Sampler are fine-tuned using 1 GeForce RTX 3090 (24GB). All training was done using mixed Precision (FP16) to improve memory efficiency.

Fine-tuning For fine-tuning all variations of RSTGen, we used the Adafactor optimiser with the following parameter settings: scale parameter = False, relative step =True, warmup init =True, learning rate =None, weight decay =0.01. Due to the high computational expense required, we did not perform extensive hyper-parameter tuning for our RSTGen models.

When fine-tuning on the RST Annotated Dataset, we used an effective batch size of 44 and trained using an Early Stopping rule allowing for at most one epoch to pass with no improvement. The maximum target sequence length is 270 tokens. The maximum RST Tree Size is 36 parent nodes. The maximum Key Phrase sequence size is 64 tokens. These models take approximately 5 epochs to converge which takes approximately 10 hours.

D Keyphrase Extraction using TextRank

Our second conditioning factor is the phrases that are important to the generated text. This importance is determined by the steps listed below:

Noun Chunks and Named Entities Given a text x, the noun chunks and named entities are extracted to form a set of sub-phrases $[x_1^{sp}, x_2^{sp}, ..., x_N^{sp}] \in x$.

Graph Formation Separately, a graph G is formed from text x by extracting all words w_i that have a Part-Of-Speech tag of either 'Adjective', 'Noun', 'Proper Noun' or 'VERB'. These words are lemmatised and form nodes $V_i \in G$.

Edge Creation A weighted edge w_{ij} between nodes $V_i, V_j, i \neq j$ has a weight of 1 if the distance between the words corresponding to V_i, V_j is less than some threshold k. In other TextRank implementations factors such as word length, position and frequency can be used to scale w_{ij}.

Node Scoring The TextRank score $\mathrm{S}(\mathrm{V_i})$ of a node V_i is initialised to a default value. Then Page Rank's adapted Eigenvector centrality measure is used to to calculate the importance of each node V_i. $\mathrm{S}(\mathrm{V_i})$ is iteratively updated using the equation below, until convergence is reached:

$$\mathrm{S}_V(\mathrm{V_i}) = (1 - \mathrm{d}) + \left(\mathrm{d} \times \sum_{j \in \mathcal{N}(\mathrm{i})} \frac{w_{\mathrm{ji}} \times \mathrm{S}(\mathrm{V_j})}{\sum_{\mathrm{k} \in \mathcal{N}(\mathrm{j})} w_{\mathrm{jk}}} \right)$$

where d is a damping factor and set to 0.85 as in (Mihalcea and Tarau, 2004) and $\mathcal{N}(\mathrm{i})$ are the set of indices of the neighbours of V_i.

Keyphrase Scoring Given the set of node scores $\mathrm{S}(\mathrm{V_i})$, the score of a sub-phrase x_n^{sp}, with L words, is computed by summing the scores of the words it contains normalised by its length $+1$ to favor

Relation	Nuclei	Satellite
Attribution	the effect	the factor which it can be attributed
Background	text whose understanding is being facilitated	text whose understanding is being facilitated
Cause	action/situation	factor which resulted in action/situation's occurrence
Comparison	a comparison between two or more subjects/objects	NA
Condition	action/situation resulting from the occurrence of a conditioning situation	conditioning situation
Contrast	one alternate	the other alternative
Elaboration	basic information	additional information
Enablement	an action/event enabled by a factor	the factor
Evaluation	a situation	an evaluative comment about the situation
Explanation	a statement	the supporting statement to explain the statement
Joint	a list or dis-junction	NA
Manner-Means	the action (being) performed	the manner or means by which the action was performed/achieved
Topic-Comment	a statement such as a question, topic or statement	a paired statement such as an answer / topic-comment or response
Summary	a statement	a restatement, that is shorter
Temporal	a statement with temporal dependence	factor that is depended on
Topic-Change	a shift from this topic A to	a shift to this topic B
Same-Unit	Used to link parts of discourse separated by embedded discourse relation	NA
Textual-Organization	used to link parts of discourse separated by embedded discourse relation	NA
Null	Non-classified	NA

Table A1: **The RST relations Schema:** A schema providing an interpretation for the RST relations our framework utilises. Some of the descriptions are extracted from (Taboada and Mann, 2006) and (Carlson et al., 2003)

Parent Nodes' Nuclearity	Label	Relationship between sibling does
Nuclei-Nuclei	NN	The left sibling's sub-text is equally as important as the right sibling's sub-text.
Nuclei-Sattelite	NS	The left sibling's sub-text is the important part of the parent node's text.
Sattelite-Nuclei	SN	The right sibling's sub-text is the important part of the parent node's text.
Null	Null	Non-classified

Table A2: **A RST Nuclearity Schema:** A schema providing an interpretation of the RST nuclearity our framework uses.

longer n-grams. This is shown in the equation below:

$$\mathrm{S_{kp}}(x_n^{sp}) = \frac{\sum_{l=1}^{L} \mathrm{S}_V\,(\mathrm{V_l})}{\mathrm{L}\ +1}$$

Keyphrase candidates are then ranked and redundant candidates filtered out. Two candidate phrases are considered redundant if they have the same lemmatised form.

E Argumentation Generation Examples

In this section, we show some example text generated from RSTGen in comparison to baseline models, where text with poor coherence is underlined. We can observe that CTRL generates coherent text but with a shorten length. Both PAIR and DYPLOC exhibit some inconsistency in their generated text. On the contrary, RSTGen generates much longer text with its inconsistency appearing to be more subtle.

CTRL	It is important when you're reading old texts like the Bible to remember that it was made to be analyzed, which the human race has been doing for a couple of hundred years by now. If I were to come up to someone and say "How can you believe in a religion that said all types of animals converged to the Middle East to get on a big boat to be saved?" the person would respond "I have faith. I don't need to question what I have been taught."
PAIR	It is important to remember what reading your texts about your Bible and remember that you've made what you analyzed to human race " but remember about your couple of hundred years ago they were born? I've been taught to think religion, but I've been taught to have types of animals I haven't been in Middle East and I've never been on boat that a saved person to respond to their faith in the US. My question is, do you really?
DYPLOC	I think it's important to read the Bible as a text, because it's important to remember that the Bible was made up and analyzed by the human race for a couple hundred years. The question is, what is it taught to us? How do we know that a person responds to their faith? Religion is the type of animal that converges on a big boat and saves the middle east.
RSTGen	It is a lot more likely to be analyzed by the human race than any other book of text, or even just some couple of important texts that have been written in an attempt to make sense of what we've done for ourselves and our own species. I'm not sure how you can possibly say this without reading all sorts of different perspectives on these topics as opposed to being made up about something like "the world" which has never really been studied at all - it's only ever happened once. The whole point of your argument rests on whether people are actually doing anything wrong with their minds (which isn't always true). It doesn't mean they aren't trying to explain things beyond thinking through them... but rather why there was no reason to believe those questions were asked when someone else said 'why did god exist?' What if one person had already read such answers? If another person hadn't understood science then wouldn't he simply put themselves into question every single-made assumptions?

Table A3: **Argument Generation Example Output:** We highlight parts of the generated text that correspond to poor coherence. In this example we notice at least one inconsistency in the output for PAIR and DYPLOC. However, the inconsistency in the RSTGen appears to be more subtle.

Intent Detection and Discovery from User Logs via Deep Semi-Supervised Contrastive Clustering

Rajat Kumar, Mayur Patidar, Vaibhav Varshney, Lovekesh Vig, Gautam Shroff
TCS Research, New Delhi, India

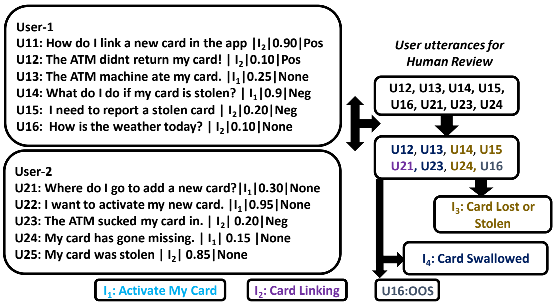
Abstract

Intent Detection is a crucial component of Dialogue Systems wherein the objective is to classify a user utterance into one of the multiple pre-defined intents. A pre-requisite for developing an effective intent identifier is a training dataset labeled with all possible user intents. However, even skilled domain experts are often unable to foresee all possible user intents at design time and for practical applications, novel intents may have to be inferred incrementally on-the-fly from user utterances. Therefore, for any real-world dialogue system, the number of intents increases over time and new intents have to be discovered by analyzing the utterances outside the existing set of intents. In this paper, our objective is to i) detect known intent utterances from a large number of unlabeled utterance samples given a few labeled samples and ii) discover new unknown intents from the remaining unlabeled samples. Existing SOTA approaches address this problem via alternate representation learning and clustering wherein pseudo labels are used for updating the representations and clustering is used for generating the pseudo labels. Unlike existing approaches that rely on epoch-wise cluster alignment, we propose an end-to-end deep contrastive clustering algorithm that jointly updates model parameters and cluster centers via supervised and self-supervised learning and optimally utilizes both labeled and unlabeled data. Our proposed approach outperforms competitive baselines on five public datasets for both settings: (i) where the number of undiscovered intents is known in advance, and (ii) where the number of intents is estimated by an algorithm. We also propose a human-in-the-loop variant of our approach for practical deployment which does not require an estimate of new intents and outperforms the end-to-end approach.



User-1
U11: How do I link a new card in the app |I_2|0.90|Pos
U12: The ATM didnt return my card! | I_2|0.10|Pos
U13: The ATM machine ate my card. |I_1|0.25|None
U14: What do I do if my card is stolen? | I_1|0.9|Neg
U15: I need to report a stolen card | I_2|0.20|Neg
U16: How is the weather today? | I_2|0.10|None

User-2
U21: Where do I go to add a new card?|I_1|0.30|None

U23: The ATM sucked my card in. | I_2| 0.20|Neg
U24: My card has gone missing. | I_1| 0.15 |None
U25: My card was stolen | I_2| 0.85|None

Figure 1: An instance of user logs, where the intent detection model is trained on two known intents, i.e., i_1 and i_2. After manual analysis of user logs a human reviewer has discovered two new intents i_3 and i_4 and assigned utterance $u21$ to an existing intent, i.e., i_2.

1 Introduction

Modern dialogue systems (Louvan and Magnini, 2020) are increasingly reliant on intent detection to classify a user utterance into one of the multiple known user intents. Intent detection is typically modeled as a multi-class classification problem where labeled data comprising of utterances for each known intent is manually created by domain experts. However, most real-world applications have to cope with evolving user needs and new functionality is routinely introduced into the dialogue system resulting in a continuously increasing number of intents over time. Even for seasoned domain experts estimating future user requirements at design time is challenging and these often have to be discovered from recent user logs which contain information corresponding to past user utterances, model response (i.e., predicted intent), implicit (confidence or softmax probability), and explicit (user clicks on a thumbs up or thumbs down icon) feedback as shown in Fig 1. The intent detection model presented in Fig. 1 is trained on two initial intents (I_1, I_2) from the banking domain using labeled data created by domain experts. Filtered user logs containing implicit and explicit feedback were shared with domain experts, who, discovered two new intents (I_3, I_4) and mapped the filtered utterances to these new intents. Additionally, experts also have to identify and discard utterances that are outside the domain of the dialog system.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1836 - 1853
July 10-15, 2022 ©2022 Association for Computational Linguistics

The remaining user logs are the primary source of evolving user needs and the process of identifying utterances belonging to “new intents”/“unknown intents” from user logs is referred to as *Intent Discovery/Intent Mining* (Chatterjee and Sengupta, 2020; Zhang et al., 2021b). However, manually monitoring user logs is not scalable and our objective in this paper is to present novel SOTA techniques to perform automated and semi-automated intent detection and discovery over user logs given only a few labeled utterances from known intents in addition to unlabeled utterances from both known and unknown intents.

Several classical (MacQueen, 1967; Chidananda Gowda and Krishna, 1978; Ester et al., 1996) and deep learning (Xie et al., 2016a; Zhang et al., 2021a) based clustering methods have been used for intent discovery. Chatterjee and Sengupta (2020) modeled intent discovery from unlabeled utterances as an unsupervised clustering problem and proposed a variant of DBSCAN (Ester et al., 1996) for clustering but do not employ any representation learning and rely heavily on manual evaluation. Zhang et al. (2021a) use a contrastive learning (Chen et al., 2020) based unsupervised approach for joint representation learning and clustering where performance largely depends on the quality of an auxiliary target distribution (Xie et al., 2016a). Lin et al. (2020) and Zhang et al. (2021c) model intent detection and discovery as a semi-supervised learning problem where the objective is to detect known intents and discover new intents given 1) a few labeled utterances from known intents along with 2) unlabeled utterances from known and new intents. This is similar to our problem of intent detection and discovery from user logs. Deep-Aligned (Zhang et al., 2021c) is the current SOTA approach for intent detection and discovery alternately performing representation learning and clustering by utilizing pseudo-labeled data obtained from clustering for representation learning. Deep-Aligned uses k-means (MacQueen, 1967) as the clustering algorithm of choice and updates a BERT (Devlin et al., 2019) backbone's parameters in the process. As k-means may assign different cluster ids to the same set of data points over different iterations the authors propose an alignment algorithm to align clusters obtained in consecutive epochs. Thus, an incorrect cluster alignment over epochs may lead to a significant drop in clustering accuracy. Additionally, they make the unrealistic assumption of a uniform distribution over intents to estimate the number of intents.

In this paper, we propose a novel end-to-end **D**eep **S**emi-**S**upervised **C**ontrastive **C**lustering (DSSCC-E2E) algorithm for intent detection and discovery from user logs. *DSSCC-E2E* is motivated by recent advances in self-supervised (Chen et al., 2020; Wu et al., 2020; Li et al., 2021) and supervised contrastive learning (Khosla et al., 2020; Gunel et al., 2021) applied to Computer vision and natural language processing. We model intent detection and discovery as a form of semi-supervised contrastive clustering wherein we jointly update backbone representations and cluster centers by minimizing the distance between the distribution over clusters of similar utterances and maximizing the same for dissimilar utterances via a semi-supervised variant of supervised contrastive (SupCon) loss(Khosla et al., 2020). For contrastive learning, we use the contextual augmenter (Ma, 2019) to create pairs of augmentations (positive pairs/ similar utterances) corresponding to each unlabeled utterance from known and unknown intents. For labeled utterances, we use pairs of utterances with the same intent to create positive pairs. To improve the accuracy of intent detection, we update representations based on labeled utterances by minimizing the cross-entropy loss. To avoid the trivial solution that assigns all utterances to the same cluster (Hu et al., 2017), similar to Van Gansbeke et al. (2020); Li et al. (2021) we also add an entropy term to the loss function which distributes utterances uniformly across the clusters.

Existing semi-supervised approaches(Lin et al., 2020; Zhang et al., 2021c) including DSSCC-E2E and some unsupervised approaches (MacQueen, 1967; Zhang et al., 2021a) for intent discovery require an estimate of the number of new intents (m) present in the user logs. Incorrect estimates for m can lead to noisy clusters (i.e., a cluster which contains utterances from multiple intents), which then require substantial manual effort to split cleanly. Unsupervised approaches (Ester et al., 1996; Chatterjee and Sengupta, 2020) often lead to a large number of clusters due to poor semantic utterance representations. For practical deployment, we propose a human-in-loop variant of *DSSCC-E2E* called DSSCC-HIL which does not estimate m and instead creates multiple dense clusters via DBSCAN. Domain experts can then merge these clusters with minimal manual effort such that each merged cluster represents an intent.

Our key contributions are: (1) We propose a novel deep semi-supervised contrastive clustering-based approach for intent detection and discovery from user logs. (2) *DSSCC-E2E* does not require epoch-wise cluster alignment, is end-to-end trainable, and fully utilizes both the labeled and unlabeled utterances for novel intent discovery. (3) *DSSCC-E2E* outperforms competitive baselines on five public datasets in the following settings: (3.1) Number of intents are known in advance. (3.2) Number of intents is estimated by an algorithm. (4) For realistic deployment, we propose a human in the loop intent detector *DSSCC-HIL*, which does not need to estimate the number of new intents. (5) With minimal manual effort, *DSSCC-HIL* outperforms existing approaches on the intent discovery task.

2 Related Work

2.1 Self-supervised and Supervised Representation Learning

Different self-supervised pre-training tasks have been proposed to pre-train PLMs, such as Masked language modeling (MLM) (Devlin et al., 2019), and MAsked Sequence to Sequence pre-training (MASS)(Song et al., 2019). Reimers and Gurevych (2019); Gao et al. (2021) fine-tune BERT on a supervised contrastive learning objective to learn better sentence embeddings. Zhang et al. (2021a) use SBERT (Reimers and Gurevych, 2019) as a PLM to learn clustering friendly representations in an unsupervised scenario by using instance-level contrastive representation learning (Chen et al., 2020) and clustering in a joint-fashion. We propose a deep semi-supervised contrastive learning approach for intent detection and discovery where we jointly update PLM representations and cluster centers. We leverage the idea of unsupervised contrastive clustering (Li et al., 2021) for images to semi-supervised contrastive clustering of text and use a modified version of the supervised contrastive loss function (Khosla et al., 2020) to jointly update model parameters and cluster centers.

We also compare the proposed approach with existing unsupervised and semi-supervised approaches for clustering in Appendix A.1.

3 Problem Description

Consider a set of n known intents with a few labeled utterances per intent $I_{known} = \{I_1, I_2, ..., I_n\}$ where $I_i = \{\bigcup_{k=1}^{r} (u_{ik}, y_i)\}$, $\mathcal{D}_l = \bigcup_{i=1}^{n} I_i$ and user logs $\mathcal{D}_{user\_logs} = \{\bigcup_{v=1}^{S} (u_v)\}$ which contain unlabeled user utterances from both known and unknown intents. The objective is to detect and discover existing and new/unknown intents from a test set, $\mathcal{D}_{test}$ given a training set $\mathcal{D}_{train} = \mathcal{D}_l \cup \mathcal{D}_{user\_logs}$ (and $\mathcal{D}_{val}$) which contains utterances from both known and unknown intents. $\mathcal{D}_{test} = \{I'_{known} \cup I_{new}\}$ and $I_{new} = \{I_{n+1}, I_{n+2}, ..., I_m\}$ where m represents the number of new intents, $I = I_{known} \cup I_{new}$ and $|I| = n+m$ represents the total number of known and unknown intents. I'_{known} is similar to I_{known} except it only contains the new set of utterances for known intents from user logs. In a realistic scenario the number of "new intents" m present in user logs are not known apriori. We perform experiments in two scenarios (i) The number of known and new intents is known in advance and (ii) The number of new intents has to be inferred from the user logs.

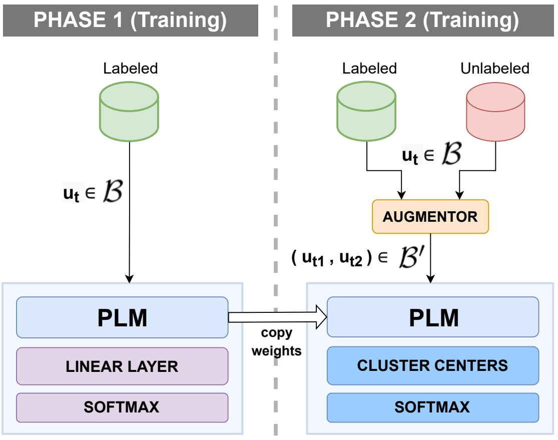

Figure 2: Proposed Approach - Deep Semi-Supervised Contrastive Clustering (DSSCC)

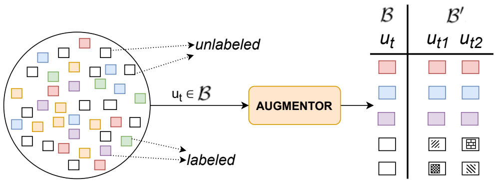
4 Proposed Approach

As shown in Fig. 2, we propose a two-phase algorithm for intent detection and discovery from user logs. In the first phase of *DSSCC*, the parameters of a pre-trained language model (PLM) are updated based on labeled data from known intents. In the second phase, we perform joint representation learning and clustering by updating the cluster centers and PLM parameters via semi-supervised contrastive learning. In addition to contrastive learning, *DSSCC* also uses labeled utterances to update PLM representations via cross-entropy loss. Further, the entropy of the intent distribution is maximized to



For labeled utterance, u_t: *u_{t1} and u_{t2} are utterances from the same intent.*
For unlabeled utterance, u_t: *u_{t1} and u_{t2} are generated by contextual augmentor.*

Figure 3: Utterance augmentations for semi-supervised contrastive learning.

alleviate the issue of empty clusters, i.e., when all utterances become part of a single cluster.

In a realistic scenario, the number of unknown intents m present in user logs is not known in advance so we use the approach proposed by Zhang et al. (2021c) to estimate m and use *DSSCC-E2E* for intent detection and discovery. The approach uses a PLM to get utterance representations and run K-means with a very high value of $k = K'$ and only count clusters with cluster cardinality greater than $|\mathcal{D}_{train}|/K'$ to estimate k. However in practice, we find that even this estimation method is often incorrect, and in section 4.5, we describe how we derive *DSSCC-HIL* from *DSSCC-E2E* to address this problem with a small amount of manual supervision. We use the Hungarian (Kuhn and Yaw, 1955) algorithm to align clusters with known and unknown intents and report performance. In the rest of the paper, we use DSSCC and DSSCC-E2E interchangeably and use DSSCC-HIL to refer to the human-in-the-loop variant of our approach.

4.1 Phase-1: Fine-tuning of PLM using labeled utterances from known intents

To leverage the labeled utterances from known intents for intent detection and discovery, in the first phase of *DSSCC*, we use these to update the parameters of the PLM, as shown in Phase-1 of Fig. 2. We fine-tune the PLM by minimizing the cross-entropy loss over a batch $\mathcal{B}$ of size N consisting of labeled utterances from known intents, as shown in Eq. 1 and 2.

$$p(I_{known} \mid u_t) = \text{softmax}(\boldsymbol{h_t} * \boldsymbol{W} + b) \qquad (1)$$

$$\mathcal{L}_{CE} = -\frac{1}{N} \sum_{t \in \mathcal{B}} \sum_{i=1}^{n} y \cdot log(p(I^i_{known} \mid u_t)) \qquad (2)$$

In Eq. 1, $\boldsymbol{h_t}$ denotes a d-dimensional representation of the t^{th} utterance (u_t) in a batch $\mathcal{B}$ obtained from the PLM and $\boldsymbol{W} \in \mathbb{R}^{d*m}$, b represent the weights and bias of a linear layer respectively. In Eq. 2, $p(I^i_{known} \mid u_t)$ denotes the probability of assigning u_t to the i^{th} known intent and y is 1 only for the true intent and zero otherwise. After fine-tuning the PLM on labeled utterances, we discard the linear layer and use the PLM with updated weights in the second phase of *DSSCC*.

4.2 Phase-2: Deep Clustering

In the second phase, we use both labeled and unlabeled utterances to perform representation learning and clustering jointly via semi-supervised contrastive learning. To maintain intent detection accuracy on known intents, we also update representations and cluster centers by minimizing cross-entropy loss on labeled utterances from known intent.

4.2.1 Semi-supervised Representation Learning and Clustering

In addition to labeled utterances from known intents, we also use unlabeled utterances from both known and unknown intents to improve performance on intent detection and discovery, as shown in Phase-2 of Fig. 2. To learn better cluster representations, instead of minimizing the distance between utterances belonging to the same intent, we minimize the distance between their corresponding cluster distributions. Conversely, we maximize the distance between cluster distributions for clusters corresponding to different intents. In contrast to self-supervised (Chen et al., 2020) or supervised contrastive (Khosla et al., 2020) learning, for semi-supervised learning a batch $\mathcal{B}$ of size N may contain both labeled and unlabeled utterances. As shown in Fig. 3, similar to self-supervised contrastive learning, we create a pair of augmentations (u_{t1}, u_{t2}) or positive pairs corresponding to the t^{th} or anchor utterance (u_t) in $\mathcal{B}$ to obtain $\mathcal{B}'$, which contains two augmented utterances corresponding to each utterance in $\mathcal{B}$. To generate augmentations for a labeled utterance, we randomly sample two utterances from the same intent and use them as augmentations whereas for an unlabeled utterance, we generate two augmented pairs by performing contextual augmentation [1] (Kobayashi, 2018; Ma, 2019), as shown in Fig. 3. In contextual augmentation, given an utterance, we randomly mask a few words and use BERT's masked-language modeling (MLM) objective to generate words corresponding to masked positions. If u_{t1}, u_{t2} are augmentations of a labeled utterance u_t then $P(u_{t1})$ is defined as

---

[1] https://github.com/makcedward/nlpaug

the set of utterances belonging to the same intent as u_{t1} in $\mathcal{B}'$ whereas $N(u_{t1})$ will contain the all $2N$-1 utterances excluding u_{t1} (note that $N(u_t)$ and $P(u_t)$) may have utterances in common). If u_{t1}, u_{t2} are augmentations of an unlabeled utterance u_t then $P(u_{t1})$ will only contain u_{t2} and $N(u_{t1})$ will contain all $2N$-1 utterances excluding u_{t1}. We update PLM parameters and cluster centers by minimizing the Semi-Supervised Contrastive (SSC) loss as shown in Eq. 3.

$$\mathcal{L}_{ssc} = \sum_{t \in \mathcal{B}'} \frac{-1}{|P(u_t)|} \sum_{p' \in P(u_t)} \log \frac{\exp\left(p(I \mid u_t) \cdot p(I \mid u_{p'})/\tau\right)}{\sum\limits_{a \in N(t)} \exp\left(p(I \mid u_t) \cdot p(I \mid u_a)/\tau\right)}; \quad (3)$$

In Eq. 3, $(\cdot)$ symbol and τ denotes dot product and scalar temperature parameter respectively. To get the distribution over intents/clusters ($I/\boldsymbol{C}$), i.e., $p(I \mid u_t)$ for the t^{th} utterance in $\mathcal{B}'$ we apply a linear transformation over $\boldsymbol{h_t}$ and normalize via softmax, $p(I \mid u_t) = \text{softmax}(\boldsymbol{h_t} * \boldsymbol{C} + b)$. Each column $\boldsymbol{C}_i$ of a linear layer $\boldsymbol{C} \in \mathbb{R}^{d \times (n+m)}$ acts as a cluster center, where $\boldsymbol{C_i}$ is the d-dimensional representation of the i^{th} cluster and $(m+n)$ represents the total number of known and unknown intents.

To avoid the trivial solution that assigns all utterances to the same cluster Hu et al. (2017), similar to Van Gansbeke et al. (2020); Li et al. (2021) we also add an entropy term to the loss function and maximize it which distributes utterances uniformly across the clusters, as shown in Eq. 4 and Eq. 6.

$$\mathcal{L}_{em} = -\sum_{i \in \mathcal{T}} p(I'^{i}) * \log p(I'^{i}) \quad (4)$$

$p(I'^{i}) = \frac{1}{|\mathcal{B}|} \sum_{t \in \mathcal{B}} p(I^i \mid u_t)$, where $p(I^i \mid u_t)$ denotes the probability of an utterance u_t being assigned to the i^{th} intent.

4.2.2 Supervised Representation Learning

To maintain intent detection accuracy on known intents, we also update the cluster centers and PLM parameters by minimizing cross-entropy loss over labeled utterances from known intents, as shown in Eq. 5 where y is 1 only for the target intent and zero otherwise. Unlike in phase-1, $\mathcal{B}$ can contain labeled and unlabeled utterances from known intents and unlabeled utterances from unknown intents but we ignore the unlabeled utterances during backpropagation.

$$\mathcal{L}_{srl} = -\frac{1}{N} \sum_{t \in \mathcal{B}} \sum_{i=1}^{n} y \cdot log(p(I^i \mid u_t)) \quad (5)$$

4.3 Training

We train *DSSCC* in two phases, in the first phase we fine-tune the PLM using labeled utterances from known intents as mentioned in Eq. 2. In the second phase, we do representation learning and clustering jointly by minimizing a combination of SSC loss, and cross-entropy loss. Further, to avoid the trivial solution of all the utterances getting assigned to a single cluster, the entropy over the intent distribution is maximized, as shown in Eq. 6. λ is a scalar hyper-parameter which controls the contribution of $\mathcal{L}_{em}$ in $\mathcal{L}$.

$$\mathcal{L} = \mathcal{L}_{ssc} + \mathcal{L}_{srl} - \lambda * \mathcal{L}_{em} \quad (6)$$

4.4 Inference

We propose two ways of utilizing representations learned by *DSSCC* for intent detection and discovery.

Clustering via learned cluster centers (*DSSCC-CH*) Cluster assignment is based on similarity between cluster and utterance representations, i.e., $\underset{1 \le i \le n+m}{\text{argmax}}\ p(I^i \mid u_t)$.

K-means over representations (*DSSCC-KM*) We get the representations ($\boldsymbol{h_t}$) for each utterance in $\mathcal{D}_{test}$ from the PLM and use K-means for clustering.

4.5 Intent discovery with Human-in-the-loop (*DSSCC-HIL*)

Existing approaches including *DSSCC* assume knowledge of the number of unknown intents (m) to achieve good performance. This is not a realistic assumption and despite SOTA performance, significant manual effort is still needed to denoise the discovered clusters. However, the manual effort can be drastically reduced if we can generate dense clusters with high purity and assign a natural language description to each cluster. These descriptions can be used by a domain expert to merge similar clusters (i.e., a set of clusters with similar descriptions) or split a noisy cluster into multiple sub-clusters. Merging clusters requires much less manual effort than splitting as merging does not require examining every utterance in the cluster. Thus, if we can obtain a set of pure clusters (i.e., a cluster where the majority of the utterances belong to a single intent) then the domain expert only needs to examine a few representative utterances per cluster before merging similar clusters.

To obtain better representations for clustering, we use phase-1 of *DSSCC* without any modification. To obtain pure clusters, unlike phase-2 of *DSSCC*, we perform representation learning and clustering in an alternate fashion and use DBSCAN for generating a large number of pure clusters. We assume that the utterances which are part of the same cluster belong to the same intent and use this fact to create a pair of augmentations for a given utterance along with contextual augmentation. Due to the unknown value of m, we perform semi-supervised contrastive representation learning at the utterance level, as shown in Eq. 7. The model parameters are updated according to $\mathcal{L} = \mathcal{L}_{ssc}^{'} + \mathcal{L}_{srl}$, where $\mathcal{L}_{srl}$ and $\mathcal{L}_{ssc}^{'}$ is defined in Eq. 5 and 7 respectively.

Cluster Merger Algorithm After phase-2, we run DBSCAN and obtain a set of clusters including the outlier cluster. For each cluster (except the outlier) we randomly sample p utterances and use them as cluster descriptions. The cluster representation is obtained as the mean of these utterance representations. So, now each cluster has its own description and representation. Now we randomly pick one cluster as the query cluster (q) and get its s nearest neighbors based on cosine-similarity and ask "Which of these s clusters should be merged with q"? to a domain expert. Based on the domain expert's response we merge similar clusters, recalculate the cluster representations, and assign a cluster description of q to this newly created cluster. We repeat this process till the domain expert finds no candidate for thirty consecutive query clusters. One iteration of the cluster merging algorithm is illustrated in Fig 4.

Now we treat each cluster as an intent and train a logistic classifier to label utterances that belong to the outlier cluster. We use the same classifier for intent detection on the test set.

$$\mathcal{L}_{ssc}^{'} = \sum_{t \in \mathcal{B}'} \frac{-1}{|P(u_t)|} \sum_{p' \in P(u_t)} \log \frac{\exp\left(u_t \cdot u_{p'})/\tau\right)}{\sum\limits_{a \in N(t)} \exp\left(u_t \cdot u_a)/\tau\right)}; \tag{7}$$

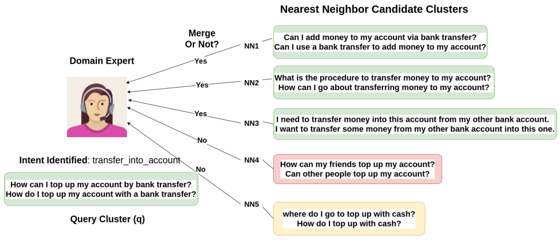


Figure 4: **Cluster Merger Algorithm:** In each iteration, a Domain Expert is shown (s = 5) Candidate Clusters which are nearest neighbors of Query Cluster (q), where per cluster, only (p = 2) utterances are shown to the expert. And based on the reply from the domain expert, some candidate clusters are merged into the query cluster and the cluster definition is updated.

5 Experimental Setup

In this section, we describe the various baselines, datasets, and evaluation metrics used in our experiments.

5.1 Baseline Approaches

We use *unsupervised K-means* (MacQueen, 1967), *Agglomerative Clustering (AG)* (Chidananda Gowda and Krishna, 1978), *DEC* (Xie et al., 2016b), *SAE-KM* (Xie et al., 2016b), *DCN* (Yang et al., 2017), *DAC* (Chang et al., 2017), *DeepCluster* (Caron et al., 2018), *SCCL* (Zhang et al., 2021a) and *semi-supervised PCK-means* (Basu et al., 2004), *BERT-KCL* (Hsu et al., 2018), *BERT-MCL* (Hsu et al., 2019), *BERT-DTC* (Han et al., 2019), *CDAC+* (Lin et al., 2020), *DeepAligned* (Zhang et al., 2021c) clustering approaches as baselines. *SCCL* and *DeepAligned* are the state-of-the-art approaches for unsupervised and semi-supervised clustering respectively. Details about unsupervised and semi-supervised baselines are included in Appendix A.1.

5.2 Dataset Description

We evalaute *DSSCC* on five datasets with a varying number of intents. We use *BANKING77* (Casanueva et al., 2020), *CLINC150 (and CLINC150$_{OOS}$)*, (Larson et al., 2019) *SNIPS* (Coucke et al., 2018), *StackOverflow* Xu et al. (2015) and, *DBPedia* (Zhang and LeCun, 2015). For *BANKING77* and *CLINC150* we use the same train, val and test split as Zhang et al. (2021c) and for *SNIPS*, *StackOverflow* and *DBPedia* we follow the same split as Lin et al. (2020). For more details, please refer to Appendix A.3

5.3 Evaluation Metrics

Similar to previously reported results (Lin et al., 2020; Zhang et al., 2021c), we use *Clustering Accuracy* (**ACC**) (Yang et al., 2010), *Normalized Mutual Information* (**NMI**) (Strehl and Ghosh, 2002) and *Adjusted Rand Index* (**ARI**) (Hubert and Arabie, 1985) as evaluation metrics. All metrics range from 0 to 100 and higher values of a metric indicate superior clustering results. Further details of the experimental setup are provided in Appendix A.4. Due to space constraints, we report ACC, NMI only but in Appendix, we use all three metrics to report results.

6 Results And Discussion

We present results comparing *DSSCC* with unsupervised and semi-supervised clustering approaches for scenarios where 1) the system is aware of the number of unknown intents, 2) the system is unaware of the number of unknown intents. We further report results of *DSSCC-HIL* and compare it with *DSSCC-E2E.*

6.1 Intent detection and discovery when the number of new intents m is provided

For the semi-supervised scenario, we assume $x\%$ of the total intents are known apriori, also referred to as the Known Intent Ratio (KIR). For each known intent, 10% of the utterances are labeled and the rest are unlabeled. For a fair comparison, we also use the same BERT-based PLM as other baselines. *DSSCC* outperforms all unsupervised baselines on both BANKING77 and CLINC150 datasets by significant margins suggesting that for known intents, supervision in the form of a few labeled utterances leads to better intent representations, as shown in Table 1. *DSSCC* also outperforms semi-supervised baselines on BANKING77 and CLINC150 for all cases except for the NMI metric on the CLINC150 dataset for KIRs 50% and 75%.

	DSSCC$_{SBERT}$	**88.47**	**94.50**	**75.15**	**85.04**

Table 2: *DA* vs *DSSCC* with *BERT* and *SBERT* as PLM

For K-means$_{SBERT}$, we use SBERT Reimers and Gurevych (2019) as our PLM instead of BERT to obtain utterance representations and find that it outperforms K-means$_{BERT}$ by a significant margin, as shown in Table 1. This suggests that utterance representations from SBERT are more suitable for clustering than BERT-based representations. Motivated by these results we compared BERT and SBERT representations in Table 2 and found that *DSSCC* (Ours)$_{SBERT}$ outperforms DSSCC (Ours)$_{BERT}$, DeepAligned$_{BERT}$ and DeepAligned$_{SBERT}$ by a significant margin on both datasets for all evaluated intent ratios. DeepAligned$_{SBERT}$ outperforms DeepAligned$_{BERT}$ on BANKING77 by a significant margin but we observe the opposite result on CLINC150. For the remaining experiments, we use SBERT as our PLM in *DSSCC* and compare it with DeepAligned$_{BERT}$ and DeepAligned$_{SBERT}$.

We evaluated *DSSCC* on three other public datasets for intent detection and discovery, and found that *DSSCC* outperforms DeepAligned on all three datasets except for NMI on DBPedia for known intent ratios of 75% , as shown in Table 10. Results of *DSSCC*$_{SBERT}$ on intent detection and

Table 3: Intent detection and discovery with unknown value of m for KIR=75%. We obtain results corresponding to DeepAligned$_{BERT}$ (DA$_{BERT}$) (Zhang et al., 2021c) and report results for DeepAligned$_{SBERT}$ (DA$_{SBERT}$) using code provided by the authors of Zhang et al. (2021c) with SBERT as the PLM.

discovery are separately reported in Table 11.

6.2 Intent detection and discovery with unknown number of new intents m

We evaluate *DSSCC* for the realistic scenario when the number of new (m) intents present in user logs is not provided to the system apriori, i.e., the total number of intents ($\mathcal{T} = n + m$) is not known in advance and the system has to infer the number of clusters present in user logs. We use an existing algorithm proposed by Zhang et al. (2021c) which refines an initial guess K' to arrive at the final estimate K_{pred}. As shown in the Table 3, *DSSCC* outperforms DeepAligned for $K' \in \{2 * \mathcal{T}, 3 * \mathcal{T}, 4 * \mathcal{T}\}$ except for the NMI metric on the CLINC150 dataset for K'=450 and K'=600 although results are competitive. As compared to the scenario where the total number of intents $\mathcal{T}$ are known (last row in Table 3), on an average there is drop of 6.20% in ACC, 1.61% in NMI on CLINC150 and a drop of 4.39% in ACC, 0.47% in NMI on BANKING77. These results suggest that the performance of *DSSCC* does not drop significantly even when the total number of intents in user logs are not known in advance.

6.3 DSSCC-HIL

We evaluate *DSSCC-HIL* in a realistic scenario where the number of new intents is not known and KIR=75%. As shown in Table 4, we get 333 and 523.7 clusters after phase-2 of *DSSCC-HIL* with average cluster purity of 96.96% and 98.30% corresponding to B77 and C150 respectively. Average purity refers to average clustering accuracy where we use ground-truth labels and based on majority voting, assign an intent label to the predicted cluster. For merging similar clusters, we show (s=5) candidate clusters per query to the domain expert who is asked to choose clusters that are similar to the query cluster. Here, we have used oracle ground truth cluster labels instead of a domain expert to answer these queries. For B77 and C150, 259.3 and 349.5 queries are required (avg over 10 runs) to merge similar clusters respectively where the domain expert has to read 12 utterances (2 per cluster) per query. As a result, we obtain 81 and 152.59 clusters (intents) for B77 and C150 which are close to the actual number of intents i.e., 77 and 150 respectively. Then a classifier is trained with these intents and prediction is done on the test set. *DSSCC-HIL* achieved an ACC of 81.21% and 88.93% on B77 and C150 respectively which is significantly higher than the ACC of *DSSCC-E2E*. Also, DSSCC-HIL is able to discover all intents in the ground truth. We also employ a cluster merging strategy with *DSSCC-E2E* i.e., *DSSCC-E2E+HIL* and got an improvement of 2% for C150 but negative results for B77. This is due to better initial cluster purity (P) of C150 (i.e. 87.73%) versus B77 (i.e. 79.92%), as the merging of noisy clusters intuitively leads to a decrease in ACC. This observation supports the fact that, for merging clusters by a domain expert, a good initial cluster purity is required. Due to comparatively low purity initial clusters, HIL does not help much in *DSSCC-E2E*.

A	**Q**	**P**	K'	K_{pred}	**ACC**	**NMI**
E2E	0	NA	231	96.8	72.93	84.97
E2E+HIL	144.8	79.92	96.8	67	71.14	84.00
HIL	259.3	96.96	333	81	**81.21**	**87.35**
E2E	0	NA	450	190.1	84.59	93.64
E2E+HIL	218.2	87.73	190.1	148.6	86.10	93.83
HIL	349.5	98.30	523.7	152.6	**88.93**	**95.19**

Table 4: We compare *DSSCC-E2E*, *DSSCC-E2E+HIL* and *DSSCC-HIL*. P, Q refers to average cluster purity before merging and number of queries respectivley. For *DSSCC-E2E*, we pick best results from Table 3. First row and second row of the table contains results on B77 and C150 respectively.

6.4 Ablation Study

As part of the ablation study, we answer the following questions "Do we need both phase-1 and phase-2 in DSSCC ?", "Does joint training on multiple loss functions in phase-2 affect clustering accuracy ?", "Do we need different values of Entropy Weight (λ) (Eq. 6) for different datasets?", "How does the presence of out-of-scope (oos) utterances in user logs affect DSSCC performance"? and present our observations. To answer these questions we perform ablation studies on CLINC150 and BANKING77.

"**Do we need both phase-1 and phase-2 in DSSCC?**" As shown in Table 5, KIR=75%, fine-tuning of the PLM on labeled utterances from known intents in phase-1 is more vital for BANKING77 as compared to CLINC150 because without phase-1 there is a significant drop in performance on the BANKING77 dataset (*DSSCC w/o phase-1* vs *DSSCC*). Whereas there is an improvement of 4.39% in ACC, 1.15% in NMI and 4.86% due to phase-2 on CLINC150 (*DSSCC w/o phase-1* vs *DSSCC*), which suggests that both phase-1 and phase-2 of *DSSCC* are important for a generic solution. In the case of *BANKING77*, performance largely depends on labeled utterances from known intents and there is not much improvement due to phase-2, which may be attributed to its complexity as all intents are semantically closer and belong to the Banking domain as compared to *CLINC150* where utterances belong to 10 different domains (utility, travel, etc.). But when we perform the same ablation with fewer known intents i.e., KIR=25%, then both phase-1 and phase-2 are equally important to achieve good performance. This suggests that DSSCC phase-2 is more important when there are fewer known intents and fewer labeled utterances per known intent.

"Does joint training on multiple loss functions in phase-2 affect clustering accuracy"? As shown in Table 5, we also perform an ablation on different loss functions used in phase-2 and found that Semi-supervised contrastive (*ssc*) loss (*DSSCC w/o ssc* **vs** *DSSCC*), entropy maximization (*em*) (*DSSCC w/o em* **vs** *DSSCC*) and supervised-representation learning (*srl*) loss (*DSSCC w/o srl* **vs** *DSSCC*) all affect the clustering performance on CLINC150 and BANKING77. The reason for the most drop in ACC and NMI in the case of (*DSSCC w/o em*) is that, when entropy maximization is not done, the probability distribution over clusters for unlabeled utterances is decided only by the supervised-representation learning (*srl*) loss. Therefore, all the utterances become part of known intent clusters and the clusters for unknown intents remain empty.

"Do we need different values of Entropy Weight (λ) (Eq. 6) for different datasets?" In Table 7, we report *DSSCC-E2E* results on *CLINC150* and *BANKING77* with different values of λ. And we observe that a value of $\lambda \in [10, 14]$ yields the best results across datasets.

"How does the presence of out-of-scope (oos) utterances in user logs affect *DSSCC* performance"? We use oos utterances as part of user logs in CLINC150 dataset and evaluate DSSCC. As shown in Table 6, there is a small drop in performance because a few oos utterances are classified to belong to the set of actual intents. This observation shows that even with presence of oos utterances, *DSSCC* is able to maintain it's performance. Manual intervention may be required in practice to filter clusters containing oos queries.

		CLINC150		**BANKING77**	
KIR	**Approach**	**ACC**	**NMI**	**ACC**	**NMI**
75%	**DSSCC w/o srl**	85.99	93.68	70.24	81.78
	DSSCC w/o ssc	73.87	87.07	67.97	78.81
	DSSCC w/o em	71.05	91.88	64.55	81.56
	DSSCC w/o phase-1	88.13	94.04	72.39	81.76
	DSSCC w/o phase-2	84.08	93.35	74.09	*84.56*
	DSSCC	**88.47**	**94.50**	**75.17**	**83.69**
25%	**DSSCC w/o srl**	78.60	90.24	54.93	73.05
	DSSCC w/o ssc	40.32	71.09	37.17	61.15
	DSSCC w/o em	24.86	75.02	23.36	64.10
	DSSCC w/o phase-1	79.95	90.44	58.85	74.74
	DSSCC w/o phase-2	72.51	88.38	58.62	76.40
	DSSCC	**80.36**	**91.43**	**61.91**	**77.44**

Table 5: Ablation with KIR (75%) and (25%) on CLINC150 and BANKING77 with $DSSCC_{SBERT}$ where we use *DSSCC-CH* for inference.

7 Conclusion

In this work, we propose a semi-supervised contrastive learning approach for intent detection and discovery from user logs. The proposed approach optimally utilizes both labeled and unlabeled utterances to outperform SOTA approaches for both scenarios where the total number of intents is either known in advance or has to be estimated. We also propose a variant of our approach which does not need to estimate the number of new intents and yields pure clusters which are merged by domain experts based on the cluster descriptions. Future work will focus on, (i) "How to get better cluster descriptions?" (ii) "How to optimally select query and corresponding candidate clusters?" and (iii) "How to discover new intents with minimum human effort with a long-tail distribution over new intents in user logs?"

A Appendix

A.1 Unsupervised and Semi-supervised Clustering

A.1.1 Unsupervised Clustering

Building upon classical clustering techniques such as **K-means** (MacQueen, 1967) and **Agglomerative Clustering (AG)** (Chidananda Gowda and Krishna, 1978) several deep learning-based clustering techniques have recently been proposed in the literature. **DEC** (Xie et al., 2016b) is a two-step deep unsupervised clustering algorithm where the first step involves training a stacked autoencoder (SAE) and the second step involves updating the SAE encoder and the cluster centers based on high confidence assignment of an utterance to cluster while using an auxiliary target distribution. In **SAE-KM** (Xie et al., 2016b), k-means is used to cluster the representations obtained from the encoder of the (SAE). **DCN** (Yang et al., 2017) is a joint deep unsupervised clustering algorithm performing joint representation learning and clustering. **DAC** (Chang et al., 2017) recasts the clustering problem into a binary pairwise classification framework to determine whether pairs of samples belong to the same cluster or not and the cosine similarity between pairs of samples is used to create pseudo-training data. **DeepCluster** (Caron et al., 2018) jointly learns the parameters of a neural network and the cluster assignments of the resulting features. DeepCluster iteratively groups the features with a standard clustering algorithm such as k-means and uses the subsequent assignments as supervision to update the weights of the network. **STC** (Xu et al., 2017) is an approach for short-text clustering where learned representations are clustered using k-means. **Self-Train** (Hadifar et al., 2019) extends **DEC** for short-text clustering and uses weighted average of pre-trained word embeddings (Mikolov et al., 2013) to get text representations. Rakib et al. (2020) alternately use classification and outlier detection to improve the accuracy of existing short-text clustering algorithms. **SCCL** Zhang et al. (2021a) jointly perform representation learning and clustering via contrastive representation learning and minimize a modified version of the clustering loss proposed by Xie et al. (2016b).

A.1.2 Semi-supervised Clustering

PCK-means (Basu et al., 2004) is a semi-supervised clustering algorithm where labeled samples are used as pairwise constraints to improve clustering performance. **KCL** (Hsu et al., 2018) is a two-stage image clustering algorithm that uses a binary classification model trained on labeled data in the first phase to measure pair-wise image similarity and in the second stage, a clustering model is trained on unlabeled data by using the output of the binary classification model for supervision. The network is trained using a Kullback-Leibler divergence-based contrastive loss (KCL). Meta Classification Likelihood **MCL** (Hsu et al., 2019) leverages pairwise similarity between samples and optimizes a binary classifier for pairwise similarity prediction and through this process learns a multi-class classifier as a submodule. **DTC**

Table 7: Ablation with KIR (75%) on *CLINC150* and *BANKING77* where we try different values of λ. We use *DSSCC$_{SBERT}$* for ablation.

(Han et al., 2019) extend *DEC* to a semi-supervised scenario and also improve upon DEC by enforcing a representation bottleneck, temporal ensembling, and consistency. **CDAC+** (Lin et al., 2020) is an end-to-end clustering method that incorporates pairwise constraints obtained from labeled utterances as prior knowledge to guide the clustering process and clusters are further refined by forcing the model to learn from high confidence assignments. **DeepAligned** (Zhang et al., 2021c) use labeled utterances from known intents to update BERT parameters and in the second step perform representation learning and K-means clustering alternately by minimizing cross-entropy loss over labeled and pseudo-labeled utterances treating each k-means cluster as one intent.

A.2 Representation of an utterance from PLM

We get the representation $\boldsymbol{h_t}$ = mean-pooling($[CLS, T_1, T_2, ..., T_l]$) of an utterance u_t consisting of l tokens from BERT/SBERT by applying mean-pooling over representations of all tokens including CLS, where T_j denotes representation corresponding to j^{th} token.

Dataset	Avg utterance length	$z\%$
CLINC150	8.31	10
BANKING77	11.91	20
SNIPS	9.03	10
StackOverflow	9.18	10
DBPedia	29.97	30

Table 8: Data Augmentation Details.

A.3 Dataset Description and Details

We evaluate *DSSCC* on five datasets with a varying number of intents. And all of them are available in english language and released under creative Commons licences.

BANKING77 (Casanueva et al., 2020) is a fine-grained intent detection dataset from the banking domain comprising of 13,083 customer queries labelled with 77 intents.

CLINC150 (Larson et al., 2019) is a crowdsourced multi-domain (10 domains such as utility, travel etc.) intent detection dataset comprised of 23,700 queries with 22,500 in-scope queries labelled with 150 intents and 1,200 out-of-scope queries. For our experiments, we use both sets- CLINC150 which contains only in-scope queries, and CLINC-150$_{OOS}$ which contains both in-scope and out-of-scope queries and we use the balanced version of the dataset.

SNIPS (Coucke et al., 2018) consists of 16000 crowd-sourced user utterances distributed across 7 intents. Out of 16k, 14484 utterances has been used for experimental purpose in the past.

StackOverflow: This dataset was originally released as part of a kaggle competition[2]. Xu et al. (2015) used a subset of this dataset for short-text clustering. The dataset consists of 20, 000 technical question titles distributed across 20 intents with 1k questions per intent.

DBPedia (Zhang and LeCun, 2015) is an ontology classification dataset constructed by picking 14

---

[2] https://www.kaggle.com/c/predict-closed-questions-on-stack-overflow

non-overlapping classes from DBpedia 2014 Lehmann et al. (2015). Wang et al. (2016) used a subset of this dataset consisting of 14000 samples distributed across 14 classes.

We mention dataset statistics in table 9. We mention the train, validation, and test split details, that were used while performing the experiments for each dataset. Based, on the len and $\mathcal{T}(n+m)$ attributes, we can see the variation and complexity of these datasets.

A.4 Training Details

For the first phase, we follow the same pre-training steps outlined by Zhang et al. (2021c). For the second phase *of DSSCC-E2E*, an embedding of dimension $(d*(n+m))$, is used for the cluster centers where a d dimensional representation of an utterance u is obtained from the PLM and $n+m$ represents the total number of clusters corresponding to known and new intents. For the *HIL* approach, two different linear heads/layers are used - one with dimension $(d*(128))$ for Instance-Level Contrastive Learning and second with dimension $(d*(n))$ for Supervised Representation Learning. For simulating a real-world problem of intent detection and discovery from user logs, we follow the experimental setting similar to Zhang et al. (2021c) where they assume that x% $\in$ {25%, 50%, 75%} of the total intents for a given dataset is known (we denote this number by n) where x is also referred to as the known intent ratio (KIR). The remaining number of intents (m) are considered novel. Accordingly, each dataset is divided into a $\mathcal{D}_{train}$, $\mathcal{D}_{val}$ and $\mathcal{D}_{test}$ where $\mathcal{D}_{train}$ contains 10% of labeled utterances per known intent and unlabeled utterances from both known and unknown intents. $\mathcal{D}_{val}$, $\mathcal{D}_{test}$ consists of utterances from known and new intents. We do two sets of experiments – one with a known value of $n+m$ (number of total intents) and another one where the total number of intents is not known in advance. For a given dataset and KIR, we run the same experiment on ten different seeds and report the average ACC, NMI, and ARI on $\mathcal{D}_{test}$. *For DSSCC-E2E,* we use *DSSCC-CH*, *DSSCC-KM* for intent detection and discovery and report the best results based on majority voting over *ACC*, *NMI* and *ARI*. In a realistic scenario when ground truth is not available, one can use the Silhouette Score (Rousseeuw, 1987) to decide which inference strategy to use. For the *HIL* approach, we get predictions from *DBSCAN* clustering after model convergence and perform inference after running the cluster merger algorithm. We use existing checkpoints of bert-base-uncased [3] (Devlin et al., 2019) and stsb-roberta-base-v2 [4] (Reimers and Gurevych, 2019) as our PLM. Similar to (Zhang et al., 2021c), we freeze all but the last transformer layer parameters in our PLM for both phases to improve training efficiency and speed up the training process. We use the Adam optimizer (Kingma and Ba, 2014) to update PLM parameters and the learning rate is set to 5e-5 for PLM, 5e-3 for cluster centers in case of *DSSCC-E2E* and 5e-3 for both heads in case of *HIL* Approach . For all of our experiments, the batch size is kept at 400. For *DSSCC-E2E*, the entropy weight(λ) is set as 14.0. Whereas, For *HIL*, the *minimum samples* and *epsilon* for DBSCAN is kept as 3.0 and 0.09 respectively. We run all experiments on an Nvidia Titan A100 GPU. We use classification accuracy on the $\mathcal{D}_{val}$ set for known intents as converge criteria for Phase 1. And for Phase 2 of *DSSCC-E2E*, we calculate the Silhouette Score Rousseeuw (1987) given utterance representations and corresponding predicted cluster-ids on $\mathcal{D}_{train}$. Whereas, for Phase 2 of *HIL*, we converge when the number of predicted clusters by *DBSCAN* clustering is minimum. We use early stopping with a patience value of 20.0 for both phases. For semi-supervised contrastive representation learning, similar to Zhang et al. (2021a), we use contextual augmenter Kobayashi (2018) to generate augmentations corresponding to unlabeled utterances where z% of the words in an utterance are substituted with similar words. We use a suitable value of z% for different datasets based on average utterance length as mentioned in the table 8 following the observations from Zhang et al. (2021a). We do this to preserve the semantics of an utterance while at the same time, substituting words in an utterance to create augmentations. We report the best results averaged over ten different seeds based on the inference details as mentioned in section 4.4. For our codebase, we have adapted existing SupContrast [5] loss in the semi-supervised setting and also utilized data creation steps from Zhang et al. (2021c)[6].

A.5 Results on Intent Detection and Discovery

We have also reported results on five public datasets with our proposed approach on intent detection and intent discovery separately for the case when m is known, are shown in table 11. If we assume that intent detection and discovery are two separate problems, we decouple the results from our joint approach (after training) to see the contribution of *DSSCC* on both tasks. It is clear from the results that, even with very few labeled utterances from known intents, our model maintains the performance on the known intents with at least 83% clustering accuracy on all five datasets. From the results on Intent Discovery, except for BANKING77, *DSSCC (Ours)* gets at least 74% clustering accuracy on 4 datasets. The low performance on intent discovery in BANKING77 is attributed to the complexity of the dataset where all intents are part of one larger domain, i.e., Banking. Whereas, in CLINC150, the intents belong to multiple domains as mentioned in section A.3.

A.6 DSSCC-KM vs DSSCC-CH

We use both inference strategies, i.e., *DSSCC-KM* and *DSSCC-CH* to obtain results for all experiments described in section 6 and report *ACC*, *NMI* and *ARI* as shown in Table 12, 13 and 15. *DSSCC-CH* outperforms *DSSCC-KM* on CLINC150, SNIPS and StackOverflow whereas *DSSCC-KM* gives better results on BANKING77 and DBPedia. This inconsistency between the behaviour of *DSSCC-CH* and *DSSCC-KM* can be attributed to complexity of a given dataset, i.e., *DSSCC-KM* outperforms *DSSCC-CH* on BANKING77 (single domain dataset) and DBpedia whereas *DSSCC-CH* outperforms *DSSCC-KM* on CLINC150 (multi-domain dataset).

In realistic scenario where ground truth is not available, one can use Silhouette Score (SS) to choose between *DSSCC-CH* and *DSSCC-KM*. As shown in Fig. 6, when the difference between *SS* corresponding to *DSSCC-CH* and *DSSCC-KM* is significant, then one should choose inference strategy which gives higher *SS*. And when the difference between *SS* score corresponding to *DSSCC-CH* and *DSSCC-KM* is not significant, then one can choose *DSSCC-CH* for inference, as shown in Fig 5. Above mentioned approach for inference strategy selection correlates with the selection done by majority voting (over *ACC*, *NMI* and *ARI*).

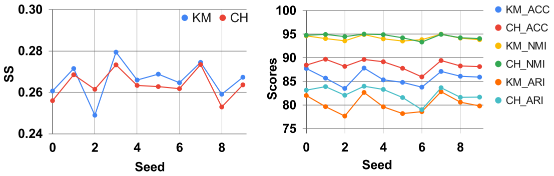

Figure 5: CLINC150 (KIR=75%) *DSSCC-CH* vs *DSSCC-KM* where we use *SBERT* as PLM. The left subfigure shows silhouette scores over different seeds and the right subfigure shows ACC, NMI, and ARI with DSSCC-KM and DSSCC-CH over these seeds.

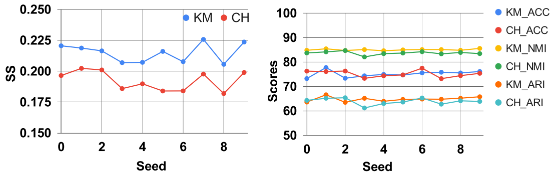

Figure 6: BANKING77 (KIR=75%) *DSSCC-CH* vs *DSSCC-KM* where we use *SBERT* as PLM. The left subfigure shows silhouette scores over different seeds and the right subfigure shows ACC, NMI, and ARI with DSSCC-KM and DSSCC-CH over these seeds.

A.7 Representations from *SBERT* vs *DSSCC*$_{SBERT}$

To showcase the effectiveness of representations learnt by $DSSCC_{SBERT}$, we plot the utterance embeddings ($\boldsymbol{h_t}$) with ground truth labels for all five datasets as shown in Fig. 7 and Fig. 8. Initial and final representations correspond to utterance embeddings obtained from *SBERT* and $DSSCC_{SBERT}$ respectively. It can be observed that for all five datasets, intents are clearly separable with final representations as compared to initial representations.

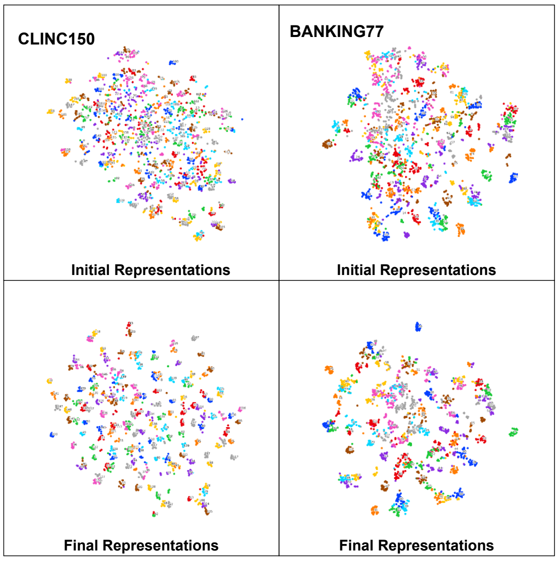

Figure 7: TSNE (van der Maaten and Hinton, 2008) plot for CLINC150 and Banking77 (75% KIR) before and after DSSCC Training.

Dataset	$\mathcal{D}_{train}$	$\mathcal{D}_{val}$	$\mathcal{D}_{test}$	$len(max/mean)$	$\mathcal{T}(n+m)$
CLINC150	18,000	2,250	2,250	25/8.31	150(112+38)

Abstract

NLP models that process multiple texts often struggle in recognizing corresponding and salient information that is often differently phrased, and consolidating the redundancies across texts. To facilitate research of such challenges, the *sentence fusion* task was proposed, yet previous datasets for this task were very limited in their size and scope. In this paper, we revisit and substantially extend previous dataset creation efforts. With careful modifications, relabeling and employing complementing data sources, we were able to more than triple the size of a notable earlier dataset. Moreover, we show that our extended version uses more representative texts for multi-document tasks and provides a more diverse training-set, which substantially improves model performance.

1 Introduction

Despite recent advances reported in NLU benchmarks for single document tasks, cross-document tasks, such as multi-document summarization (MDS) have not progressed with the same pace. The handling of information across documents requires effective measures for identifying overlapping content. Moreover, generative tasks require consolidating the relevant and redundant content into a coherent utterance. In light of this, several works proposed a focused sentence-level task, called *sentence fusion*, which focuses on summarizing multiple sentences with overlapping content into a non-redundant one. This allows a fine-grained analysis of which information units are shared among the input sentences, as well as control over different degrees of information inclusion and exclusion.

However, the available datasets for fusing sentences which exhibit significant content overlap are still lacking, with the most recent containing only several hundreds of examples (McKeown et al., 2010; Thadani and McKeown, 2013), impeding further research. In this work, we follow Thadani and McKeown (2013) and extend their described sentence fusion dataset, which is derived from expertly written and annotated summaries based on the Pyramid MDS evaluation method by Nenkova and Passonneau (2004). Table 1 illustrates an example where the gold label is a summary of the content intersection in the input sentences.

a.	**Fisheries in parts of the Philippines have been decimated by the use of cyanide** in fishing.
b.	Philippine fishermen use **cyanide in fishing**, needlessly **destroying immature fish**.
c.	Sodium **cyanide use by fisherman decimates fish**.
d.	In the Philippines some fishermen use homemade explosives and **cyanide for driving fish away from reefs and into nets**.
Label	Sodium cyanide use by fisherman decimates fish

Table 1: Sentence fusion example from Thadani and McKeown (2013). (a-d) are the input sentences, originating from different documents. Text spans (in bold) that are considered as contributing to the same unit of content (SCU) are annotated with the same concise label. The sentences where the spans appear in are grouped to be input for sentence fusion, while the SCU label becomes the fusion target.

We find that the heuristics and filters applied by Thadani and McKeown (2013) result in short and highly related sentences, which may not reflect more complex and long sentences that are often found in multi-text consolidation tasks. Moreover, their dataset uses exclusively sentences from expert summaries and exclude the actual source documents that are used in practice for summarization. The resulting high similarity within input sentences makes them amenable to extractive methods, where a representative sentence can be selected as the summary, curbing the efforts to develop an abstractive fusion of sentences.

In this work, we modify Thadani and McKeown (2013)'s pre-processing pipeline after careful anal-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1854 - 1860
July 10-15, 2022

ysis, re-label a portion of the instances, and supplement the data with source document sentences (§3). Our contribution therefore is an extended sentence-fusion dataset[1], more than 4x times larger than its original, with 18% manually relabeled instances. We show that our final extended dataset better reflects challenges in multi-source summarization tasks (§4), with highly redundant salient content, originating in more representative sentences from the wild. In addition, we show (§5) that a contemporary generative model produces more abstractive output after training on our extended training set than on the original one. Similarly, it also outperforms the latter on the original test set. Given that sentence fusion was originally motivated as a step in modular multi-document summarization pipelines (Barzilay and McKeown, 2005; Marsi and Krahmer, 2005), we hope that progress on sentence fusion may contribute to broader contexts of multi-document consolidation and fusion tasks.

2 Background

The sentence fusion task deals with combining multiple sentences with overlapping content into a single summary sentence that represents the shared information across the inputs (Barzilay and McKeown, 2005; Filippova and Strube, 2008; Marsi and Krahmer, 2005; McKeown et al., 2010; Thadani and McKeown, 2013). Several other variants of sentence fusion have also been explored, such as sentence union – fusing the union of information in the input (Marsi and Krahmer, 2005). In another variant, "disparate" sentence fusion (Elsner and Santhanam, 2011; Geva et al., 2019; Lebanoff et al., 2019, 2020), the input sentences do not exhibit considerable content overlap but are rather related in discourse. Such sentences often originate in a single document and pose a different kind of challenge to generate the right discourse structure that will fluently connect the inputs.

For pragmatic purposes, a "loose" variant of sentence intersection is desired, since redundant content is most likely salient, yet additional important but non-overlapping information may be relevant for a final summarized sentence. For this reason, our extended dataset follows the fusion as "loose" intersection approach applied by Barzilay and McKeown (2005), McKeown et al. (2010) and Thadani and McKeown (2013). The latter compiled a dataset for sentence fusion by leveraging annotations made during post-hoc evaluation of multi-document summarization systems.

A	Statoil's internal investigation acknowledged inadequate planning and a lack of risk appreciation led to the leak.
B	Statoil admitted the leak resulted from inadequate planning and appreciation of risk, and failure to observe governing documentation.
Label	Statoil admitted responsibility for the leak

Table 2: Originally filtered SCU instance in PyrFus. This example was excluded due to the SCU contributing spans in A and B being much longer than the label itself.

2.1 From MDS Evaluation to Fusion

The Pyramid method (Nenkova and Passonneau, 2004), is a well-known evaluation method for content selection in summarization, which was used in the DUC[2] and TAC[3] benchmarks for MDS.

Applying this method, a set of reference summaries per topic are written by expert annotators and divided into informational units. Each unit, named Summary Content Unit (*SCU*), denotes a short statement. For example, the SCU labeled: *cyanide use by fisherman decimates fish* may be expressed in multiple summaries and source documents under different manifestations. To compile a list of content units for MDS evaluation, the annotator marks text spans (see bold spans in Table 1) across reference summaries with equivalent content that directly expresses or contributes to the summary unit (*SCU contributors*). Next, she labels the content unit by writing a concise statement in natural language, named *SCU Label*. The source sentences of each contributing span may then be grouped into a cluster bearing the same SCU label. Table 1 presents an example of such a cluster, containing four source sentences with contributing spans (in bold), along with their associated SCU label that concisely summarizes them. Thadani and McKeown (2013) creates a fusion instance by using each cluster's sentences as input, and the SCU label as the target for fusion output.

[3] https://tac.nist.gov/, years used 2009-2011

3 Data Collection

After carefully analyzing Thadani and McKeown (2013)'s pre-processing pipeline described in subsection 3.1, we decided to substantially modify it (subsection 3.2), recovering significantly more data. We proceed with relabeling some of the targets, and adding samples from source documents (i.e. not just from expertly written summaries) that were mapped to SCUs but overlooked in the past.

3.1 Previous Pre-processing pipeline

Thadani and McKeown (2013) applied several filtering steps to generate a fusion dataset (termed here PYRFUS) from SCUs. Specific details regarding these filters as well as examples are in Appendix A. While the original intention was to reduce noisy samples, these steps removed a significant portion of challenging fusion instances. Potential clusters were removed for having differences in length either between the source sentences to the marked span contributions, or between the target SCU label and the marked span contributions, denoting possibly non-shared information that appeared in the input, but not in the output. Another filtering criterion had been to discard all clusters whose target label contains content words unused by any input sentence, discouraging paraphrasing between input and output. Such filtering has left the dataset, whose inputs and outputs are quite similar in both length and content (see §4), missing realistic challenges in a multi-document setup, where lexically differing and non-overlapping content may appear. Moreover, such setup inadvertently biases generative models to be more extractive (see §5) than abstractive, relying on a single input sentence to convey all shared information in a cluster.

This dataset was the largest available source to date for supervised sentence fusion focused on multi-text, with a total of 1705 fusion instances.[4]

3.2 Extending Fusion Dataset

We discovered that most of the above filtering criteria were safe to forgo save a few sanity checks. This has recovered new fusion instances by either adding back removed SCU labels or input sentences. Following, we noticed that 18% of the input clusters share more than one SCU label, mostly due to the original Pyramid annotators splitting conjunctions along different SCUs. For correctness, we manually re-labeled such clusters using all shared labels into a single sentence (see Appendix C).

Fusion Data	**Total**	**Avg Clus.**	**R_1 L-to-S**	**R_1 S-to-S**
DISPARATE	**1599**	2	32.7	15.0
PYRFUS	**1705**	2.8	46.5	35.0
Δ-PYRFUS	**5842**	3.3	34.6	31.6
PYRFUS++	**7505**	3.3	37.8	32.2

Table 3: Comparisons of fusion datasets and variations. DISPARATE (Lebanoff et al., 2020) introduced a disparate-fusion dataset, containing exactly 2 input sentences. L-to-S and S-to-S refer to label-to-sentence and sentence-to-sentence ROUGE scores, respectively.

Additionally, DUC also made available the SCU Marked Corpus (Copeck and Szpakowicz, 2005), which automatically maps *source* document sentences to SCU labels using lexical matching. We use this resource to extend our dataset with document sentences, which were overlooked in PYRFUS. Document sentences tend to be longer and more varying than summary sentences, with 30 tokens vs. 20 on average. Clusters containing document sentences also tend to have more inputs, since reference summaries were limited to four, while the number of source documents per summarized topic is much higher. In total, we have extended the fusion dataset from its original 1705 instances to 7505, with 37% containing at least one document source sentence, creating a much more varied dataset, as analyzed next.

4 Data Analysis

We suggest that the additional instances previously skipped would more closely resemble challenges in a multi-document setting. To show that, we compare our extended dataset PYRFUS++ to its predecessor PYRFUS, that uses closely knit sentence clusters, and to DISPARATE (Lebanoff et al., 2020), that contains mostly non-overlapping within *document* sentences. The latter allows to estimate a lower bound for overlap for document sentences with little shared content that still relate to each other, making the bound tighter than for randomly picked sentences (some examples are shown in Appendix D). We denote by Δ-PYRFUS the instances that we added exclusively as part of our extension.[5] To assess content overlap empirically, we calculate the micro-average of ROUGE (Lin, 2004) word-

---

[4] This count was reproduced using the author's published code, the originally reported count is slightly higher.

[5] The original clusters may have grown as well due to the added input sentences, but we exclude those clusters from Δ-PYRFUS for ease of analysis

Train Data	**Dev**	**Test**	**Test++**
PYRFUS	36.4	40.9	28.5
PYRFUS++	**42**	**45.4**	**32.5**

Table 4: Rouge-2 F1 results for the baseline model (BART). Test++ refers to the test set of the extended PYRFUS++ dataset. The other evaluation splits refer to the original PYRFUS data.

SCU Label	Sodium cyanide use by fisherman **decimates** fish
PYRFUS	In the Philippines some fishermen use cyanide in fishing
PYRFUS++	In the Philippines cyanide use by fisherman **decimates** fish

Table 5: The gold SCU label vs the predictions made by the baseline model trained on PYRFUS and PYRFUS++

overlap between every sentence in the cluster to its target label ($R_1^{L \to S}$) and between every pair of input sentences in the same cluster ($R_1^{S \to S}$).

The results in Table 3 show that the content overlap among input sentences ($R_1^{S \to S}$) of our added instances in Δ-PYRFUS is much closer to PYRFUS than to disparate sentences, indicating they are viable and highly-related input examples. This reinforces our claim that in a true multi-document setting a system will be challenged with dealing with significantly more redundant information then exhibited within a single document (as in DISPARATE), and this has to be specifically addressed by a multi-document fusion dataset.

As expected, PYRFUS contains a much higher label to sentence content overlap ($R_1^{L \to S}$), given that the original pre-processing explicitly removed instances with less overlap between the SCU output and the source sentences. In fact, our analysis revealed that in PyrFus, extractive target labels, where the target sentence is an approximate copy of one of the input sentences (up to two words), account for 29% of the clusters, while in our extended dataset they account only for 11%. Overall our new fusion clusters express high relatedness between the source sentences and their label, while exhibiting higher diversity.

5 Baselines and Data Effectiveness

We implement a modern baseline (see Appendix E for details) for PYRFUS (Thadani and McKeown, 2013), which outperforms their pre-neural one.[6] To that end, we employ the pre-trained auto-encoder BART (Lewis et al., 2020) as our end-to-end generation model due to its demonstrated performance on summarization tasks.

Results, as shown in Table 4, were measured with the Rouge-2 F1 metric on the original PYRFUS evaluation splits. These results show that a fusion model trained on our extended data (PYRFUS++) significantly outperforms the same model trained on the original training data, by roughly 5 R_2 points. Notably, the model trained on PYRFUS++ scored 13 points lower on its own test set, indicating that the new dataset is much more challenging, and yet enables the model to reach better generalizations.

Examining the outputs of both models, we find that many are similar and are often extracted from source sentences[7]. To study the differences between model outputs, we first sample 50 instances where the PYRFUS++ model performed worse. We notice that in most (78%) of these cases the PYRFUS++ model output is acceptable, while the lower score stems from ROUGE artifacts due to sentence rephrasing. Only 22% do suffer from lack of salient content. On the contrary, inspecting 50 instances where the PYRFUS model performed worse, we find that only 54% of these are acceptable, while the rest suffer from lack of salient content. This sample analysis suggests that the advantage of the PYRFUS++ model is even greater than reflected by the ROUGE scores. Finally, an example for missing information in the PYRFUS model output appears in Table 5, not including a critical detail that all input sentences (in Table 1) discuss – fish decimation, while the PYRFUS++-trained model correctly includes it. Such instances show the necessity of a large and realistic fusion dataset for model training.

6 Conclusion

In this work we extended a sentence fusion dataset by almost four times its original size, while relabeling some of the data. The new dataset includes more complex and relevant training instances, better reflecting those that could be found in "the wild", and thus facilitates further research on data consolidation in multi-text tasks. In addition, we

---

[6] PyrFus evaluation used bigram-F1 (Unno et al., 2006) that is similar to Rouge-2 F1, reporting 24.92 points for their best model. We use the widely accepted Rouge metric to be inline with contemporary works.

[7] A fairly large proportion of targets are inevitably extractive, since the original (manual) Pyramid data contains many extractive SCU labels (Thadani and McKeown, 2013)

train baseline fusion models and show that when trained on our extended data we achieve notably better performance on the original available fusion test set, while also generating qualitatively better ("loose") sentence intersections.

A Modifications to the preprocessing pipeline

Thadani and McKeown (2013) applied several preprocessing steps to generate a fusion dataset from

	Filter	Filtered SCU Labels
1	SL	Saudi Arabia urged withdrawal
2	NV	Resignation of Prime Minister Karami and his government
3	NV | SL	Murder in Boulder, Colorado
4	NV	Confirmed bird flu cases in Hong Kong
5	SL	FARC commits slaughters
6	SL	Water being diverted

Table 6: Originally filtered SCU instances in PyrFus. NV – No Verb, SL – Short Label. Ex. 1-4 are clusters that were excluded based on the label alone in the original dataset, but kept in our extension. Ex. 5-6 were discarded in both datasets.

SCUs. These include *discarding* all clusters that: [1] have more than 4 contributing sentences; [2] have SCU labels that don't contain a verb after the first token; [3] have SCU labels and source sentences with less than 5 words or more than 100; [4] have contributing spans that are shorter than half of their source sentence; [5] have SCU labels that are shorter than half of the shortest contributing span in the input; and [6] have SCU labels with any tokens not appearing in any of the source sentences.

Table 6 represents examples of fusion instances that were filtered out in PyrFus due to various filters. First four examples were recovered in our dataset, but the last two were deemed too short and not specific enough, and were left out due to lack of informativeness.

We found that certain filters were safe to remove. We discard filter [2] since the majority of SCU labels without a verb use a nominalization (affecting 601 instances). Similarly, we ease the length requirement of SCUs to be between 4-100, as they were found to be coherent and descriptive, affecting 497 instances. Additionally, we allow SCU clusters that have low overlap between their label and their marked contributing spans, discarding filters [4] and [5], affecting 2410 instances (see Table 2). And finally, we keep fusion instances whose SCU label tokens are not fully covered by their input sentences to allow paraphrases (affecting 2410 instances). [8]

B Pyramid-based Fusion Data

For the fusion instances containing summary source sentences as inputs, we used the same years reported in Thadani and McKeown (2013) (years 2005-2007 for DUC and 2008-2011 for TAC). The source document sentences found in Copeck and Szpakowicz (2005) were made available from 2005-2008. We made use of all the years except 2005, since we found this year to be containing more varied documents within a topic, which yielded noisier automatic alignments between SCU labels and source document sentences.

C Manual Target Re-annotation

Once we removed most of the filtering pipeline of PyrFus, we noticed that almost 20% of the fusion input clusters share more than one SCU label. To accommodate, we manually re-label such clusters using all shared SCU labels into a single sentence. For example, for the following two SCU labels: *Clinical trials typically involve three phases* and *Clinical trials involve an average of 200 patients per trial*, a new merged fusion label would be: *Clinical trials typically involve three phases and an average of 200 patients per trial.*

D Examples of Fusion Instances

Table 7 presents 3 examples of fusion instances originating from different datasets. As previously mentioned, DISPARATE fusion involves the fusion of input sentences that often originate from a single document, containing little content overlap but related in discourse. The data used was taken from Lebanoff et al. (2020) and included 1599 samples. PyrFus and PyrFus++ contain examples originating from multi-text settings, while PyrFus contains only inputs from reference summaries, and PyrFus++ is enhanced with document source sentences, along with more complex examples.

E Training a Fusion Baseline

As described in section 5, we train two sentence fusion baselines using a pre-trained auto-encoder BART base model (Lewis et al., 2020), on PyrFus and PyrFus++ respectively. We used the training script [9] made available by the transformers library (Wolf et al., 2020) with the following parameters: 4 training epochs and a learning rate of 3e-5. A "steps" evaluation parameter was used with 5000 evaluation steps and an evaluation beam of 6. Max source input was limited to 265 while max target length was set to 30. Minimum target length were

---

[8] Filters are not mutually exclusive, therefore there can be an instance that is affected by multiple filters.

Source	**Fusion Inputs**	**Fused Output**
DISPARATE	(A) **The bodies** showed signs of torture. (B) **They** were left on the side of a highway in Chilpancingo, about an hour north of the tourist resort of Acapulco in the state of Guerrero.	The bodies of the men, which showed signs of torture, were left on the side of a highway in Chilpancingo.
PyrFus++	(A) Secret zombie networks, called botnets, infect up to millions of personal computers and **countries such as China restrict internet usage.** (B) **China and Iran censor the Internet against subversion or immorality.**	China uses censorship to fight internet crimes.
PyrFus	(A) Overseas **hackers accessed confidential information from South Korea.** (B) **South Korea's presidential mansion came under attack during 2008 from overseas hackers**.	Hackers accessed information from South Korea.

Table 7: Examples of different fusion instances from separate sources. PyrFus and PyrFus++ contain sentences originating from a multi-text setting, with related events expressed redundantly and differently, motivating information consolidation. The DISPARATE fusion dataset (Lebanoff et al., 2020) uses related sentences originating in the same document, but do not necessarily carry redundancies. Instead, it tries to model the correct discourse structure that can fuse the inputs into one sentence.

set to 4, given our minimum requirements for fusion labels. The final evaluated score reported was an average score over 20 different trained models. This is due to BART being highly sensitive to the ordering of the input sentences. Both baseline models were trained using the train/test splits that were reported in Thadani and McKeown (2013), using DUC years 2005-2007 for test, TAC 2011 for dev, and TAC 2008-2010 for train.

The Devil is in the Details:
On the Pitfalls of Vocabulary Selection in Neural Machine Translation

Abstract

Vocabulary selection, or lexical shortlisting, is a well-known technique to improve latency of Neural Machine Translation models by constraining the set of allowed output words during inference. The chosen set is typically determined by separately trained alignment model parameters, independent of the source-sentence context at inference time. While vocabulary selection appears competitive with respect to automatic quality metrics in prior work, we show that it can fail to select the right set of output words, particularly for semantically non-compositional linguistic phenomena such as idiomatic expressions, leading to reduced translation quality as perceived by humans. Trading off latency for quality by increasing the size of the allowed set is often not an option in real-world scenarios. We propose a model of vocabulary selection, integrated into the neural translation model, that predicts the set of allowed output words from contextualized encoder representations. This restores translation quality of an unconstrained system, as measured by human evaluations on WMT newstest2020 and idiomatic expressions, at an inference latency competitive with alignment-based selection using aggressive thresholds, thereby removing the dependency on separately trained alignment models.

1 Introduction

Neural Machine Translation (NMT) has achieved great improvements in translation quality, largely thanks to the introduction of Transformer models (Vaswani et al., 2017). However, increasingly larger models (Aharoni et al., 2019; Arivazhagan et al., 2019) lead to prohibitively slow inference when deployed in industrial settings. Especially for real-time applications, low latency is key. A number of inference optimization speedups have been proposed and are used in practice: reduced precision (Aji and Heafield, 2020), replacing self-attention with Average Attention Networks (AANs) (Zhang et al., 2018), Simpler Simple Recurrent Units (SSRUs) (Kim et al., 2019), or model pruning (Behnke and Heafield, 2020; Behnke et al., 2021).

Figure 1: Examples of subword-segmented idiomatic expressions (EN) and their German correspondences (DE) as well as an English gloss (GL) of the German expression. Alignment-based vocabulary selection: output tokens missing from the allowed set of top-k output tokens are marked in orange/bold (red/italic) for k=200 (k=1000).

Another technique that is very common in practice is vocabulary selection (Jean et al., 2015) which usually provides a good tradeoff between latency and automatic metric scores (BLEU) and reduced inference cost is often preferred over the loss of ∼0.1 BLEU. Vocabulary selection is effective because latency is dominated by expensive, repeated decoder steps, where the final projection to the output vocabulary size contributes to a large portion of time spent (Bérard et al., 2021). Despite

July 10-15, 2022 ©2022 Association for Computational Linguistics

high parallelization in GPUs, vocabulary selection is still relevant for GPU inference for state-of-the-art models.

However, we show that standard methods of vocabulary selection based on alignment model dictionaries lead to quality degradations not sufficiently captured by automatic metrics such as BLEU. We demonstrate that this is particularly true for semantically non-compositional linguistic phenomena such as idiomatic expressions, and aggressive thresholds for vocabulary selection. For example, see Figure 1 for alignment-model based vocabulary selection failing to include tokens crucial for translating idiomatic expressions in the set of allowed output words. While less aggressive thresholds can reduce the observed quality issues, it also reduces the desired latency benefit. In this paper we propose a neural vocabulary selection model that is jointly trained with the translation model and achieves translation quality at the level of an unconstrained baseline with latency at the level of an aggressively thresholded alignment-based vocabulary selection model.

Our contributions are as follows:

- We demonstrate that alignment-based vocabulary selection is not limited by alignment model quality, but rather inherently by making target word predictions out of context (§2).
- We propose a Neural Vocabulary Selection (NVS) model based on the contextualized deep encoder representation (§3).
- We show that alignment-based vocabulary selection leads to human-perceived translation quality drops not sufficiently captured by automatic metrics and that our proposed model can match an unconstrained model's quality while keeping the latency benefits of vocabulary selection (§4).

2 Pitfalls of vocabulary selection

We first describe vocabulary selection and then analyze its shortcomings. Throughout the paper, we use the recall of unique target sentence tokens as a proxy for measuring vocabulary selection quality, i.e. the reachability of the optimal translation. We use the average vocabulary size in inference decoder steps across sentences as a proxy for translation latency since it directly impacts decoding speed (Kasai et al., 2020).

2.1 Vocabulary selection

Vocabulary selection (Jean et al., 2015), also known as lexical shortlisting or candidate selection, is a common technique for speeding up inference in sequence-to-sequence models, where the repeated computation of the softmax over the output vocabulary $\mathcal{V}$ of size V incurs high computational cost in the next word prediction at inference time:

$$p(y_t|y_{1:t-1}, x; \theta) = \text{softmax}(\boldsymbol{W}\boldsymbol{h} + \boldsymbol{b}), \quad (1)$$

where $\boldsymbol{W} \in \mathbb{R}^{V \times d}$, $\boldsymbol{b} \in \mathbb{R}^{V}$ and $\boldsymbol{h} \in \mathbb{R}^{d}$, d being the hidden size of the network. Vocabulary selection chooses a subset $\bar{\mathcal{V}} \subset \mathcal{V}$, with $\bar{V} \ll V$, to reduce the size of matrix multiplication in Equation (1) such that

$$\bar{p}(y_t|y_{1:t-1}, x; \theta) = \text{softmax}(\bar{\boldsymbol{W}}\boldsymbol{h} + \bar{\boldsymbol{b}}), \quad (2)$$

where $\bar{\boldsymbol{W}} \in \mathbb{R}^{\bar{V} \times d}$ and $\bar{b} \in \mathbb{R}^{\bar{V}}$. The subset $\bar{\mathcal{V}}$ is typically chosen to be the union of the top-k target word translations for each source token, according to the word translation probabilities of a separately trained word alignment model (Jean et al., 2015; Shi and Knight, 2017). Decoding with vocabulary selection usually yields similar scores according to automatic metrics, such as BLEU (Papineni et al., 2002), compared to unrestricted decoding but at reduced latency (L'Hostis et al., 2016; Mi et al., 2016; Sankaran et al., 2017; Junczys-Dowmunt et al., 2018). In the following, we show that despite its generally solid performance, vocabulary selection based on word alignment models negatively affects translation quality, not captured by standard automatic metrics. We use models trained on WMT20 (Barrault et al., 2020a) data for all evaluations in this section, see Section 4.1 for details.

2.2 Alignment model quality

In practice, the chosen subset of allowed output words is often determined by an alignment model, such as `fast_align` (Dyer et al., 2013), which provides a trade-off between the speed of alignment model training and the quality of alignments (Jean et al., 2015; Junczys-Dowmunt et al., 2018). `fast_align`'s reparametrization of IBM model 2 (Brown et al., 1993) places a strong prior for alignments along the diagonal. We investigate whether more sophisticated alignment models can lead to better vocabulary selection, especially for language pairs with high amount of reordering. To evaluate this we compute the recall of translation model and reference tokens using GIZA++ (Och and Ney, 2003) and MaskAlign[1] (Chen et al., 2021) as seen in Table 1. We extract top-k word translation tables (from `fast_align`, GIZA++, and MaskAlign) by force-aligning the training data. Overall, GIZA++ achieves the best recall, and it is just slightly better than `fast_align`. MaskAlign, a state-of-the-art neural alignment model, underperforms `fast_align` with respect to recall. While performance of MaskAlign may be improved with careful tuning of its hyperparameters via gold alignments (Chen et al., 2021), we choose `fast_align` as a strong, simple baseline for vocabulary selection in the following.

2.3 Out-of-context word selection

Alignment-based vocabulary selection does not take source sentence context into account. A top-k list of translation candidates for a source word will likely cover multiple senses for common words, but may be too limited when a translation is highly dependent on the source context. Here we consider *idiomatic expressions* as a linguistic phenomenon that is highly context-dependent due to its semantically non-compositional nature.

EN-RU	literal	91.2	99.2
	idiomatic	67.6	88.9

Table 3: Recall on English proverbs and their literal and idiomatic translations sourced from Wikiquote.

Table 2 compares the recall of tokens in the reference translation when querying the translation lexicon of the alignment model for two different top-k settings. Recall is computed as the percentage of unique tokens in the reference translation that appear in the top-k lexicon, or more generally, in the set of predicted tokens according to a vocabulary selection model. We evaluate two scopes for test sets of idiomatic expressions: the full source and target sentence vs. the source and target idiomatic multi-word expressions according to metadata. The Idioms test set is an internal set of 100 English idioms in context and their human translations. ITDS is the IdiomTranslationDS[2] data released by Fadaee et al. (2018) with 1500 test sentences containing English and German idiomatic expressions for evaluation into and out of German, respectively. The results show that recall increases when increasing k but is consistently lower for the idiomatic expressions than for full sentences. Clearly, the idiom translations contain tokens that are on average less common than the translations of "regular" inputs. As a consequence, increasing the output vocabulary is less effective for idiom translations, with recall lagging behind by up to 9.3%. This can directly affect translation quality because the NMT model will not be able to produce idiomatic translations given an overly restrictive output vocabulary.

Table 3 shows a similar comparison but here we evaluate full literal translations vs. full idiomatic translations on a data set of English proverbs from Wikiquote[3]. For EN-DE, we extracted 94 triples of English sentence and two references, for EN-RU we extracted 262 triples. Although in both cases recall can be improved by increasing k, it helps considerably less for idiomatic than for literal translations.

Figure 1 shows examples of idiomatic expressions from the ITDS set and the output tokens belonging to an idiomatic translation that are missing from the respective lexicon used for vocabulary

selection. While for some of the examples, increasing the lexicon size solves the problem, for others the idiomatic translation can still not be generated because of missing output tokens.

These results demonstrate that there is room for improvement in vocabulary selection approaches when it comes to non-literal translations.

2.4 Domain mismatch in adaptation settings

Using a word alignment model to constrain the NMT output vocabulary means that this model should ideally also be adapted when adapting the NMT model to a new domain. Table 4 shows that adapting the word alignment model with relevant in-domain data (in this case, idiomatic expressions in context) yields strong recall improvements for vocabulary selection. Compared to increasing the per-source-word vocabulary as shown in Table 2, the improvement in recall for idiom tokens is larger which highlights the importance of having a vocabulary selection model which matches the domain of the NMT model. This also corroborates the finding of Bogoychev and Chen (2021) that vocabulary selection can be harmful in domain-mismatched scenarios.

We argue that integrating vocabulary prediction into the NMT model avoids the need for mitigating domain mismatch because domain adaptation will update both parts of the model. This simplifies domain adaptation since it only needs to be done once for a single model and does not require adaptation or re-training of a separate alignment model.

2.5 Summary

We use target recall as a measure for selection model quality. We see that alignment model quality only has a limited impact on target token recall with more recent models actually having lower recall overall. In domain adaptation scenarios vocabulary selection limits translation quality if the selection model is not adapted. The main challenge for alignment-based vocabulary selection comes from its out-of-context selection of target tokens on a token-by-token basis, shown to reduce recall for translation of idiomatic, non-literal expressions. Increasing the size of the allowed set can compensate for this shortcoming at the cost of latency. However, this begs the question of whether context-sensitive selection of target tokens can achieve higher recall without increasing vocabulary size.

3 Neural Vocabulary Selection (NVS)

We incorporate vocabulary selection directly into the neural translation model, instead of relying on a separate statistical model based on token translation probabilities. This enables predictions based on contextualized representations of the full source sentence. It further simplifies the training procedure and domain adaptation, as we do not require a separate training procedure for an alignment model.

The goal of our approach is three-fold. We aim to (1) keep the general Transformer (Vaswani et al., 2017) translation model architecture, (2) incur only a minimal latency overhead that amortizes by cheaper decoder steps due to smaller output vocabularies, and (3) scale well to sentences of different lengths.

Figure 2 shows the Neural Vocabulary Selection (NVS) model. We base the prediction of output tokens on the contextualized hidden representation produced by the Transformer encoder $\boldsymbol{H} \in \mathbb{R}^{d \times t}$ for t source tokens and a hidden size of d. The t source tokens are comprised of $t-1$ input tokens and a special `<EOS>` token. To obtain the set of target tokens, we first project each source position to the target vocabulary size V, apply max-pooling across tokens (Shen et al., 2018), and finally use the sigmoid function, $\sigma(\cdot)$, to obtain

$$\boldsymbol{z} = \sigma(\text{maxpool}(\boldsymbol{W}\boldsymbol{H} + \boldsymbol{b})), \qquad (3)$$

where $\boldsymbol{W} \in \mathbb{R}^{V \times d}$, $\boldsymbol{b} \in \mathbb{R}^{V}$ and $\boldsymbol{z} \in \mathbb{R}^{V}$. The max-pooling operation takes the per-dimension maximum across the source tokens, going from $\mathbb{R}^{V \times t}$ to $\mathbb{R}^{V}$. Each dimension of $\boldsymbol{z}$ indicates the probability of a given target token being present in the output given the source. To obtain the target Bag-of-words (BOW), we select all tokens where $\boldsymbol{z}_i > \lambda$ as indicated in the right-hand side of Figure 2, where λ is a free parameter that controls the size $\bar{V}$ of the reduced vocabulary $\bar{\mathcal{V}}$. At inference time, the output projection and softmax at every

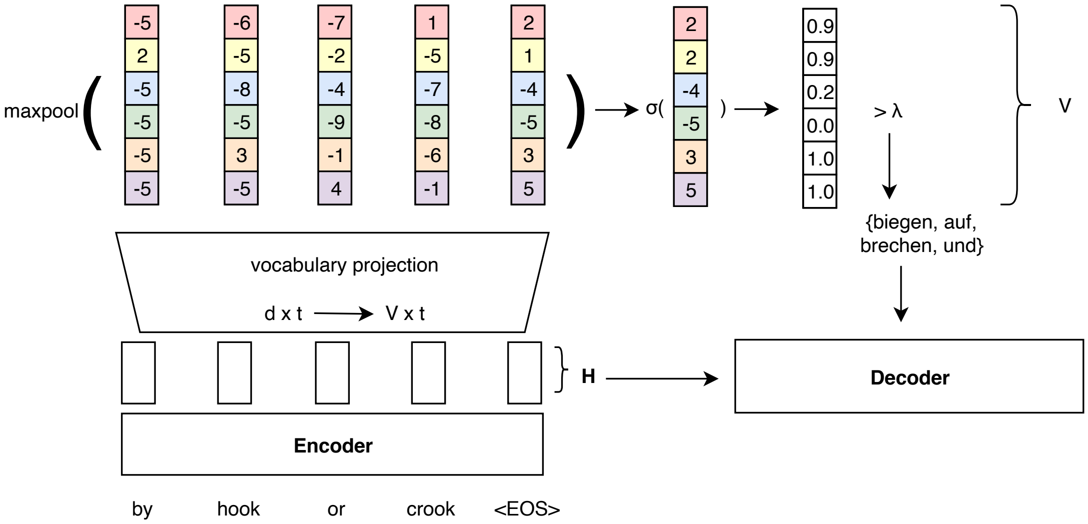

Figure 2: The proposed Neural Vocabulary Selection (NVS) model. A subset of the full vocabulary is selected based on encoder representation H and passed to the decoder for a reduced output projection at every decoder step.

decoder step are computed over the predicted BOW of size $\bar{V}$ only.

We achieve goal (1) by basing predictions on the encoder representation already used by the decoder. Goal (2) is accomplished by restricting NVS to a single layer and basing the prediction on the encoder output, where we can parallelize computation across source tokens. Inference latency is dominated by non-parallelizable decoder steps (Kasai et al., 2020). By projecting to the target vocabulary per source token, each source token can "vote" on a set of target tokens. The model automatically scales to longer sentences via the max-pooling operation, acting as a union of per-token choices, fulfilling goal (3). Max-pooling does not tie the predictions across timesteps as they would be with mean-pooling which would also depend on sentence length. Additionally, we factor in a sentence-level target token prediction based on the `<EOS>` token. The probability of a target word being present is represented by the source position with the highest evidence, backing off to a base probability of a given word via the bias vector $\boldsymbol{b}$.

To learn the $V \times d + V$ parameters for NVS, we use a binary cross-entropy loss with the binary ground truth vector $\boldsymbol{y} \in \mathbb{R}^V$, where each entry indicates the presence or absence of target token $\boldsymbol{y}_i$. We define the loss as

$$L_{\text{NVS}} = \frac{1}{Z} \sum_{i=0}^{V} \boldsymbol{y}_i \log(\boldsymbol{z}_i) \lambda_p + (1-\boldsymbol{y}_i) \log(1-\boldsymbol{z}_i),$$

where λ_p is a weight for the positive class and $Z = V + (\lambda_p - 1) * n_p$ is the normalizing factor, with $n_p = \sum_i \boldsymbol{y}_i$ being the number of unique target words. Most dimensions of the V-dimensional vector $\boldsymbol{y}$ will be zero as only a small number of target words are present for a given sentence. To counter the class imbalance of the negative class over the positive class the λ_p weight allows overweighting the positive class. This has the same effect as if each target word had occurred λ_p times. The NVS objective (L_{NVS}) is optimized jointly with the standard negative log-likelihood translation model loss (L_{MT}): $L = L_{\text{NVS}} + L_{\text{MT}}$.

4 Experiments

4.1 Setup

Our training setup is guided by best practices for efficient NMT to provide a strong low latency baseline: deep Transformer as encoder with a lightweight recurrent unit in the shallow decoder (Bérard et al., 2021; Kim et al., 2019), int8 quantization for CPU and half-precision GPU inference. We use the constrained data setting from WMT20 (Barrault et al., 2020b) with four language pairs English-German, German-English, English-Russian, Russian-English and apply corpus cleaning heuristics based on sentence length and language identification. We tokenize with *sacremoses*[4] and byte-pair encode (Sennrich et al., 2016) the data with 32k merge operations.

Table 5: Experimental results for unconstrained decoding (baseline), alignment-based VS with different k, and Neural Vocabulary Selection with varying λ. BLEU and COMET: mean and std of three runs with different random seeds. Human evaluation: source-based direct assessment renormalized so that the unconstrained baseline is at 100%, with 95% CI of a paired t-test. We ran two sets of human evaluations comparing 4 systems each. CPU/GPU: p90 latency in ms with 95% CI based on 30 runs with batch size 1, shown as a percentage of the baseline.

All models are Transformers (Vaswani et al., 2017) trained with the Sockeye 2 toolkit (Domhan et al., 2020). We release the NVS code as part of the Sockeye toolkit[5]. We use a 20-layer encoder and a 2-layer decoder with self-attention replaced by SSRUs (Kim et al., 2019).

NVS and NMT objectives are optimized jointly, but gradients of the NVS objective are blocked before the encoder. This allows us to compare the different vocabulary selection techniques on the same translation model that is unaffected by the choice of vocabulary selection. All vocabulary selection methods operate at the BPE level. We use the translation dictionaries from `fast_align` for alignment-based vocabulary selection. We use a minimum of $k = 200$ for alignment-based vocabulary selection which is at the upper end of what is found in previous work. Junczys-Dowmunt et al. (2018) set $k = 100$, Kim et al. (2019) set $k = 75$, and Shi and Knight (2017) set $k = 50$. Smaller k would lead to stronger quality degradations at lower latency. GPU and CPU latency is evaluated at single-sentence translation level to match real-time translation use cases where latency is critical. We evaluate translation quality using SacreBLEU (Post, 2018)[6] and COMET (Rei et al., 2020)[7]. Furthermore, we conduct human evaluations with two annotators on the subsets of newstest2020 and IDTS test sentences where outputs differ between NVS $\lambda = 0.9$ (0.99) and align $k = 200$. Professional bilingual annotators rate outputs of four systems concurrently in absolute numbers with increments of 0.2 from 1 (worst) to 6 (best). Ratings are normalized so that the (unconstrained) baseline is at 100%. Complementary details on the training setup, vocabulary selection model size, human and latency evaluation setup can be found in Appendix A.

4.2 Results

Table 5 shows results of different vocabulary selection models on newstest2020 and the ITDS idiom set, compared to an unconstrained baseline without vocabulary selection. Automatic evaluation metrics show only very small differences between models. For three out of four language pairs, the alignment model with $k = 200$ performs slightly worse than the unconstrained baseline (0.2-0.3 BLEU). This corroborates existing work that quality measured by automatic metrics is not significantly affected by alignment-based vocabulary selection (Jean et al., 2015; Shi and Knight, 2017; Kim et al., 2019).

However, human-perceived quality of alignment-based vocabulary selection with $k = 200$ is consistently lower than the baseline. COMET, found to correlate better with human judgements than BLEU (Kocmi et al., 2021), only reflects this drop in two out of the four language pairs, considering confidence intervals across random seeds. Increasing k to 1000 closes the quality gap with respect to human ratings taking the confidence intervals into account. The same is true for vocabulary selection using NVS at both $\lambda = 0.9$ and $\lambda = 0.99$, where quality is also within the confidence intervals of the unconstrained baseline. However, NVS is consistently faster than the alignment-based model. For $\lambda = 0.9$ we see CPU latency improvements of 95 ms on average across language arcs. Increasing the threshold to $\lambda = 0.99$ latency compared to $k = 1000$ is reduced by 157 ms on average. The same trend holds for GPU latency but with smaller differences. Figure 3 compares the NVS model against the alignment model according to the speed/quality tradeoff reflected by average vocabulary size vs. reference token recall on newstest2020. NVS consistently outperforms the alignment model, especially for small average vocabulary sizes where NVS achieves substantially higher recall. This demonstrates that the reduced vocabulary size and therefore faster decoder steps can amortize the cost of running the lightweight NVS model, which is fully parallelized across source tokens as part of the encoder.

To evaluate a domain adaptation setting, we fine-tune the NVS models on a set of 300 held-out sentences of idioms in sentence context for 10 epochs. For a fair comparison, we also include the same data for the alignment-based vocabulary selection. Figure 4 shows that NVS yields pareto optimality over the alignment model with and without domain adaptation to a small internal training set of idiomatic expressions in context. This highlights the advantage of NVS which is automatically updated during domain fine-tuning as it is part of a single model. See Appendix C for additional figures on the proverbs and ITDS test sets, where the same trend holds.

4.3 Analysis

Our proposed neural vocabulary selection model benefits from contextual target word prediction. We demonstrate this by comparing the predicted BOW when using the source sentence context versus predicting BOWs individually for each input word (which may consist of multiple subwords) and taking the union of individual bags. We use the NVS models that are adapted to a set of idiomatic expressions for this analysis to ensure that the unconstrained baseline models produce reasonable translations for the Idiom test set.

	Ref tokens	λ	Context	No Context
EN-DE	All	0.9	0.93	0.62
		0.99	0.73	0.31
	All excl	0.9	0.32	0.01
		0.99	0.43	0.01
EN-RU	All	0.9	0.75	0.43
		0.99	0.57	0.25
	All excl	0.9	0.37	0.05
		0.99	0.38	0.06

Table 6: Percentage of segments with all idiomatic reference tokens included in the BOW (All), or exclusively included in the contextual or non-contextual BOW (All excl) for NVS threshold λ.

Table 6 shows the percentage of segments for which all reference tokens are included in the contextual vs. the non-contextual BOW for an acceptance threshold of 0.9 and 0.99. Independent of the threshold, predicting the BOW using source context yields significantly larger overlap with idiomatic reference tokens. We also measure the extent to which idiomatic reference tokens are included exclusively in the contextual or non-contextual BOW. For 32% of EN-DE segments, only the contextual BOW contains all idiomatic reference tokens. For non-contextual BOWs, this happens in only 1% of the segments (with λ=0.9). For EN-RU, the values are 38% versus 6%, respectively. This shows that the model makes extensive use of contextualized source representations in predicting the relevant output tokens for idiomatic expressions.

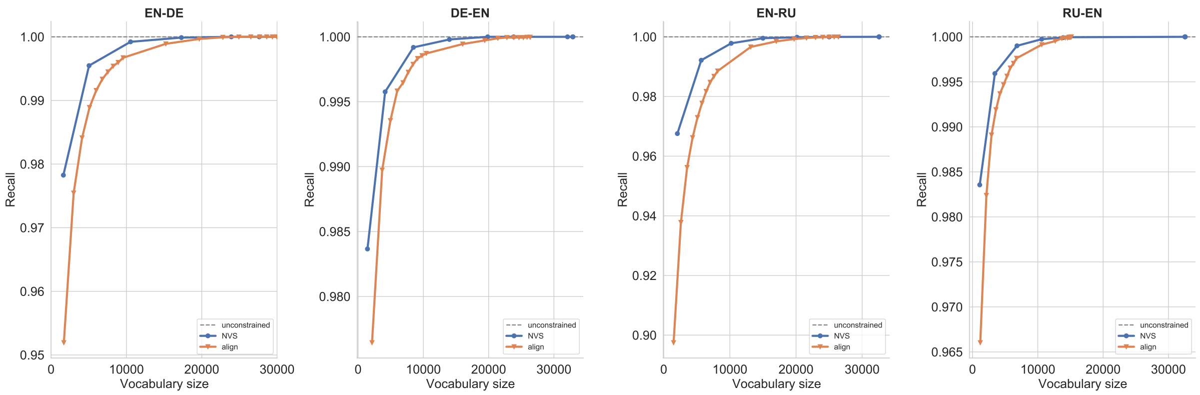

Figure 3: Vocabulary size (speed) vs. recall of reference tokens (quality) for newstest2020. For NVS, values correspond to $\lambda \in [0.99, 0.9, 0.5, 0.1, 0.01, .., 0.000001]$. For align, values correspond to $k \in [100, 200, .., 1000, 2000, .., 10000]$.

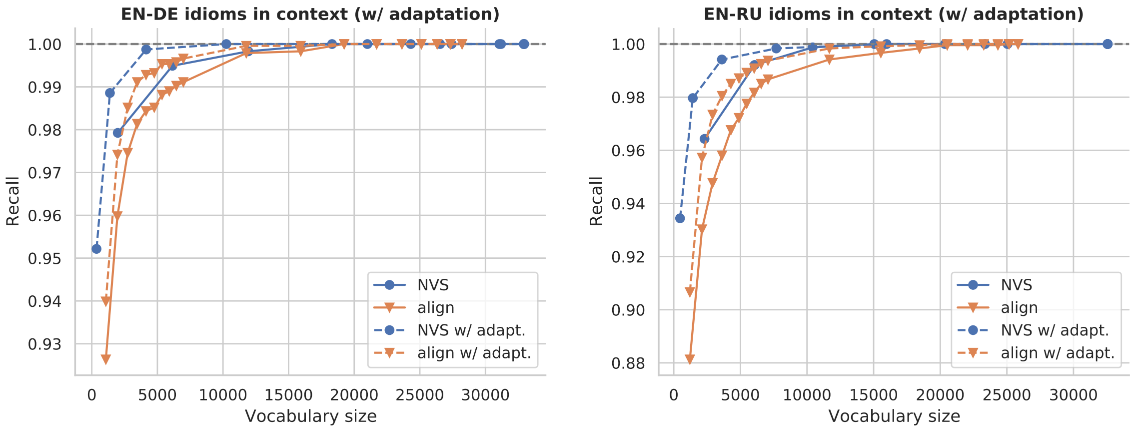

Figure 4: Vocabulary size (speed) vs recall of reference tokens (quality) for the internal Idioms test set *with* and *without* adapting on idioms for NVS and align models. For NVS, the values correspond to setting $\lambda \in [0.99, 0.9, 0.5, 0.1, 0.01, .., 0.000001]$. For align, the values correspond to setting $k \in [100, 200, .., 1000, 2000, .., 10000]$.

Figure 5 shows a few illustrative examples where the idiomatic reference is only reachable with the contextual BOW prediction. Consider the last example containing the English idiom "to wrap one's head around it". Even though the phrase is rather common in English, the German translation "verstehen" (*to understand*) would not be expected to rank high for any of the idiom source tokens. Evaluating the tokens in context however yields the correct prediction.

5 Related work

There are two dominant approaches to generate a restricted set of target word candidates (i) using an external model and (ii) using the NMT system itself.

In the first approach, a short-list of translation candidates is generated from word-alignments (Jean et al., 2015; Kim et al., 2019), phrase table, and the most common target words (Mi et al., 2016). L'Hostis et al. (2016) propose an additional method using support vector machines to predict target candidates from a sparse representation of the source sentence.

In the second approach, Sankaran et al. (2017) build alignment probability table from the soft-attention layer from decoder to encoder. However, applying their method to multi-head attention in Transformer is non-trivial as attention may not capture word-alignments in multiple attention layers (Li et al., 2019). Shi and Knight (2017) use local sensitive hashing to shrink the target vocabu-

lary during decoding, though their approach only reduces latency on CPUs instead of GPUs.

Chen et al. (2019) reduce the softmax computation by first predicting a cluster of target words and then perform exact search (i.e., softmax) on that cluster. The clustering process is trained jointly with the translation process in their approach.

Closely related to our work is Weng et al. (2017), who predict all words in a target sentence from the initial hidden state of the decoder. Our NVS model differs from theirs in that we make a prediction for each source token and aggregate the results via max-pooling to scale with sentence length. Recent work of Bogoychev and Chen (2021) illustrates the risk associated with reducing latency via vocabulary selection in domain-mismatched settings. Our work takes this a step further by providing a detailed analysis on the shortcomings of vocabulary selection and proposing a model to mitigate them.

Related to our findings on non-compositional expressions, Renduchintala et al. (2021) evaluate the effect of methods used to speed up decoding in Transformer models on gender bias and find minimal BLEU degradations but reduced gendered noun translation performance on a targeted test set.

6 Conclusions

Alignment-based vocabulary selection is a common method to heavily constrain the set of allowed output words in decoding for reduced latency with only minor BLEU degradations. We showed with human evaluations and a targeted qualitative analysis that such translations are perceivably worse. Even recent automatic metrics based on pre-trained neural networks, such as COMET, are only able to capture the observed quality degradations in two out of four language pairs. Human-perceived quality is negatively affected both for generic translations, represented by newstest2020, as well as for idiomatic translations. Increasing the vocabulary selection threshold can alleviate the quality issues at an increased single sentence translation latency. To preserve both translation latency and quality we proposed a neural vocabulary selection model that is directly integrated into the translation model. Such a joint model further simplifies the training pipeline, removing the dependency on a separate alignment model. Our model has higher reference token recall at similar vocabulary sizes, translating into higher quality at similar latency.

A Reproducibility Details

Data We use the constrained data setting from WMT20 (Barrault et al., 2020b) with four language pairs English-German, German-English, English-Russian, Russian-English. Noisy sentence pairs are removed based on heuristics, namely sentences with a length ratio > 1.5, $> 70\%$ token overlap, > 100 BPE tokens and those where source or target language does not match according to LangID (Lui and Baldwin, 2012) are filtered.

Model We train pre-norm Transformer (Vaswani et al., 2017) models with an embedding dimension of 1024 and a hidden dimension of 4096.

Model	Size
align k=200	6,590,600
align k=1000	32,953,000
NVS	33,776,825

Table 7: Model size in terms of in-memory float numbers for EN-DE model with a target vocabulary size of 32953. This does not reflect actual memory consumption, as the computation of the NVS layer may require more intermediate memory.

Table 7 compares the memory consumption of the different vocabulary selection models in terms of float numbers. We see that the NVS model requires a similar number of floating point numbers as the alignment-based model at $k = 1000$. Note, that this only represent the disk space requirements as other intermediate outputs would be required at runtime for either vocabulary selection model.

Training The NMT objective uses label smoothing with constant 0.1, the NVS objective sets the positive class weight λ_p to 100,000. Models train on 8 Nvidia Tesla V100 GPUs on AWS p3.16xlarge instances with an effective batch size of 50,000 target tokens accumulated over 40 batches. We train for 70k updates with the Adam (Kingma and Ba, 2015) optimizer, using an initial learning rate of 0.06325 and linear warmup over 4000 steps. Checkpoints are saved every 500 updates and we average the weights of the 8 best checkpoints according to validation perplexity.

Inference For GPU latency, we run in half-precision mode (FP16) on AWS g4dn.xlarge instances. CPU benchmarks are run with INT8 quantized models run on AWS c5.2xlarge instances. We decode using beam search with a beam of size 5. Each test set is decoded 30 times on different hosts, and we report the mean p90 latency with its 95% confidence interval. Alignment-based vocabulary selection includes the top k most frequently aligned BPE tokens for each source token based on a `fast_align` model trained on the same data as the translation model. NVS includes all tokens that are scored above the threshold λ. All vocabulary selection methods operate at the BPE level.

Evaluation Human Evaluations and COMET / BLEU use full precision (FP32) inference outputs. We decided to use FP32 for human evaluation as we wanted to evaluate the quality of the underlying model independent of whether it gets used on CPU or GPU and the output differences between FP16/FP32/INT8 being small. We report mean and standard deviation of SacreBLEU (Post, 2018)[8] and COMET (Rei et al., 2020) scores on detokenized outputs for three runs with different random seeds. For human evaluations, bilingual annotators see a source segment and the output of a set of 4 systems at once when assigning an absolute score to each output. The size of the evaluation set was 350 for EN-DE and EN-RU and 200 for DE-EN and RU-EN for newstest2020. We used the full sets of sentences differing between NVS $\lambda = 0.9$, align $k = 200$ for the ITDS test set (309 for EN-DE and 273 for DE-EN).

Adaptation For domain adaptation, we fine-tune the NVS model for 10 epochs using a learning rate of 0.0001 and a batch size of 2048 target tokens. To adapt the alignment-based vocabulary selection model, we include the adaptation data as part of the training data for the alignment model. We upsample the adaptation data by a factor of 10 for a comparable setting with NVS fine-tuning.

B Positive class weight ablation

Based on preliminary experiments we had used a weight for the positive class (λ_p) of 100k in the experiments in §4. Here the positive class refers to tokens being present on the target side and the negative class to tokens being absent from the target side. For a Machine Translation setting there are many more words that are not present than are present on the target side. The negative class therefore dominates the positive class. This can be

Table 8: Translation quality in terms of BLEU and COMET on newstest2020 with different weights for the positive class. *auto* x refers to setting the weight according to the ratio of the negative class to the positive class with a factor x.

counteracted by using a large value for the positive weight λ_p.

Instead of setting λ_p to a fixed weight one can also define it as

$$\lambda_p = x\frac{n_n}{n_p}$$

with n_p as the number of unique target words, $n_n = V - n_p$ as the number of remaining words and x being a factor to increase the bias towards recall. This way the positive class and negative class are weighted equally. Table 8 shows the result of different positive weights, including the automatic setting according to the ratio (*auto*). We see that not increasing the weight of the positive class results in large quality drops. For positive weights > 1000 the quality differences are small. The *auto* setting provides an alternative that is easier to set than finding a fixed positive weight.

C Additional vocabulary size vs. recall plots

Figures 6 and 7 provide results for the proverbs and ITDS test sets, respectively. We see the same trend across all test sets of NVS offering higher recall at the same vocabulary size compared to alignment-based vocabulary selection. For the proverbs test set this is true both for the literal and the idiomatic translations.

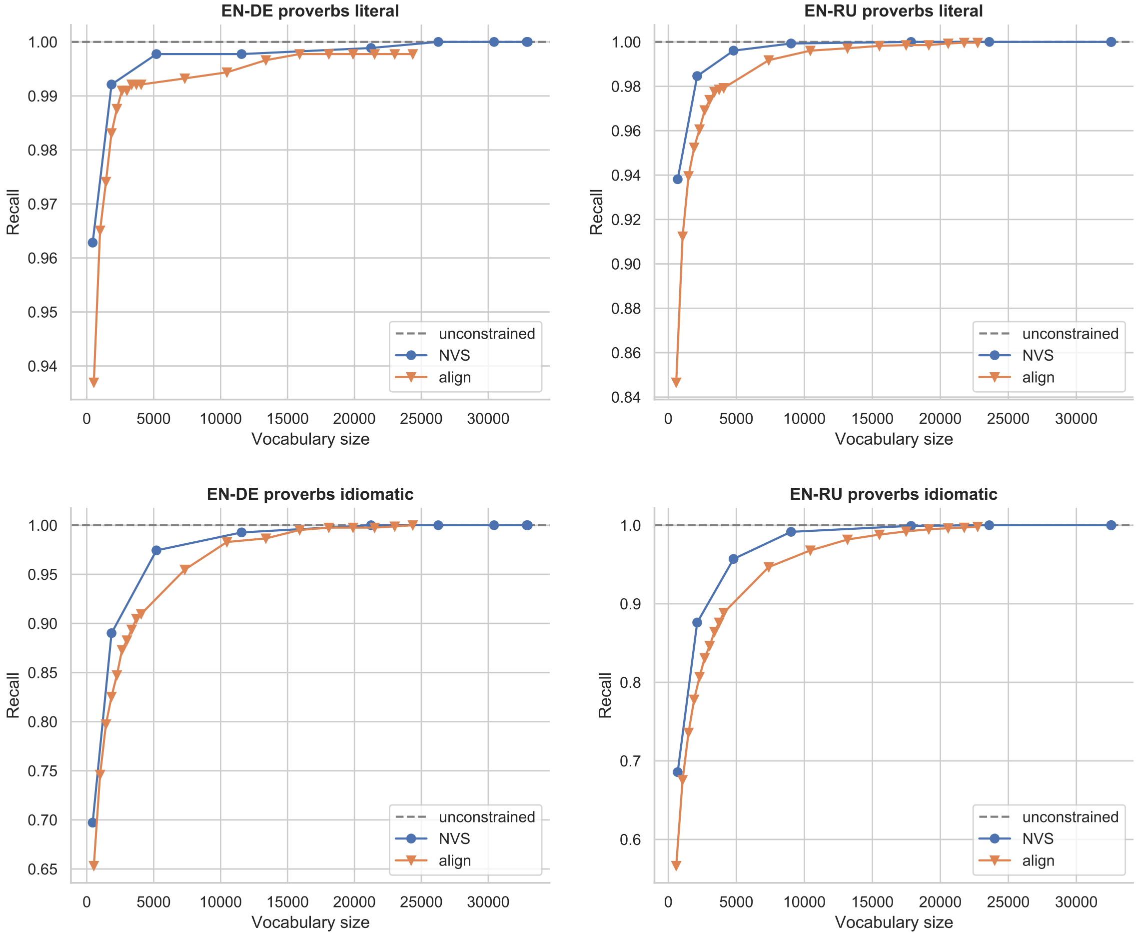

Figure 6: Vocabulary size (speed) vs. recall of reference tokens (quality) for proverbs test set. For NVS, the values correspond to setting $\lambda \in [0.99, 0.9, 0.5, 0.1, 0.01, .., 0.000001]$. For align, the values correspond to setting $k \in [100, 200, .., 1000, 2000, .., 10000]$.

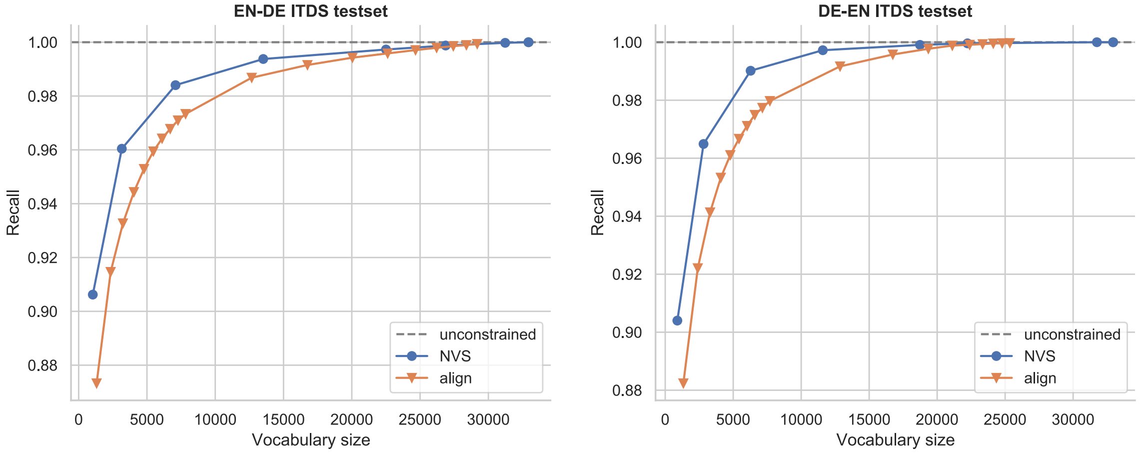

Figure 7: Vocabulary size (speed) vs. recall of reference tokens (quality) for ITDS test set. For NVS, the values correspond to setting $\lambda \in [0.99, 0.9, 0.5, 0.1, 0.01, .., 0.000001]$. For align, the values correspond to setting $k \in [100, 200, .., 1000, 2000, .., 10000]$.

MULTICITE: Modeling realistic citations requires moving beyond the single-sentence single-label setting

Abstract

Citation context analysis (CCA) is an important task in natural language processing that studies *how* and *why* scholars discuss each others' work. Despite decades of study, computational methods for CCA have largely relied on overly-simplistic assumptions of how authors cite, which ignore several important phenomena. For instance, scholarly papers often contain rich discussions of cited work that span multiple sentences and express multiple intents concurrently. Yet, recent work in CCA is often approached as a single-sentence, single-label classification task, and thus many datasets used to develop modern computational approaches fail to capture this interesting discourse. To address this research gap, we highlight three understudied phenomena for CCA and release MULTICITE, a new dataset of 12.6K citation contexts from 1.2K computational linguistics papers that fully models these phenomena. Not only is it the largest collection of expert-annotated citation contexts to-date, MULTICITE contains multi-sentence, multi-label citation contexts annotated throughout entire full paper texts. We demonstrate how MULTICITE can enable the development of new computational methods on three important CCA tasks. We release our code and dataset at https://github.com/allenai/multicite.

1 Introduction

Citations connect the current paper to the broader discourse of science (e.g., Garfield, 1955; Siddharthan and Teufel, 2007), help signal future impact and uses (e.g., McKeown et al., 2016), and, in downstream applications, can aid in summarizing a work's contributions (e.g., Qazvinian and Radev, 2008; Cohan and Goharian, 2015; Lauscher et al., 2017a). The study of the role and purpose of citations, known as **citation context analysis** (CCA Swales, 1986), has uncovered traces of how ideas have influenced a field, collaboration and competition among peers, and trends in scientific fields.

Computational approaches to CCA have largely focused on classifying the intent or purpose of a particular citation. With the advent of deep neural models, recent CCA research efforts have focused on increasing the size of the published resources (Cohan et al., 2019; Tuarob et al., 2019; Pride and Knoth, 2020). However, larger data sets have come at the expense of oversimplifying the rich discourse patterns surrounding citations, especially as complexity of annotation is often traded for large-scale data collection. The aforementioned recent large-scale resources, for instance, have approached CCA as a single-sentence, single-label classification task, overlooking the richness and nuance with which citations are used in discourse.

Contributions. In this work, we aim to fuel and inspire research into new or understudied tasks in CCA and their respective computational methods motivated by complex phenomena in scholarly citations. Our contributions are three-fold.

1) First, we identify three phenomena of citation behavior in scholarly literature that remain understudied by prior work in CCA (§2). We then propose future CCA research also consider efforts into three tasks well-motivated by these phenomena: (§5) multi-label classification given a variable-length citation context, (§6) context identification given a citation, and the novel (§7) evidence-based assessment of citing-cited paper relationships.

2) Second, to support these tasks and other new forms of CCA research, we introduce a novel resource (§4), the **Multi**-Sentence **Multi**-Label **Multi**-Mention **Cit**ation (MULTICITE) corpus, an expert-annotated collection of 1.2K full-text English-language publications from computational linguistics with 12.6K labeled citation contexts. MULTICITE substantially opens up new op-

portunities in CCA by being the only dataset which captures all three understudied phenomena *and* is large enough to support development of modern computational methods, i.e., deep neural models.

3) Finally, we lay the groundwork for future CCA research by demonstrating how one can use our new resource to develop modern computational methods to tackle each of the proposed analysis tasks. Our experiments establish strong baselines against which future work can compare.

2 Understudied Phenomena in CCA

Using examples, we highlight and motivate three understudied phenomena in CCA, showing that each reflects natural ways in which authors cite.

Multi-sentence contexts. While a citation appears in a particular sentence, its discussion may span that sentence and beyond. For example, consider the sentence:

> *"Gliozzo et al., (2005) succeeded eliminating this requirement by using the category name alone as the initial keyword, yet obtaining superior performance within the keyword-based approach."*

This sentence alone provides background information about a previous approach and consequently, one could describe its function as *Background* from that text. However, the subsequent sentence continues the discussion of the citation:

> *"The goal of our research is to further improve the scheme of text categorization from category name, which was hardly explored in prior work."*

Only by including this sentence can we identify the underlying intent of the authors: the cited publication is used as *Motivation* for the presented research. Through our annotation process (§4) we find that 17.1% of citation contexts involve multiple sentences. Thus, we argue that correctly modeling the precise scope of a citation – that is, its associated *context* – is necessary for understanding the discourse role it plays in the citing paper.

Multiple interpretations of function. A single citation may have multiple concurrent interpretations for its function. Not to be dismissed as simply being ambiguous, these multiple interpretations can stem from extended discussion of how the citing paper relates to the cited paper. Consider the sentence:

> *"In our experiments we use the same definition of structural locality as was proposed for the ISBN dependency parser in (Titov and Henderson, 2007b)."*

This sentence can be labeled as *Similarities*. However, another possibility is to label this sentence as *Uses*, as the authors are adopting a definition of the cited work. Further, a citation can exhibit multiple interpretations through partially overlapping or entirely different contexts:

> *"Results Table 1 compares the published BERT BASE results from Devlin et al. (2019) to our reimplementation with either static or dynamic masking. We find that our reimplementation with static masking performs similar to the original BERT model, and dynamic masking is comparable or slightly better than static masking."*

Here, the published results from the well-known BERT paper are a research artefact that is *Used* as a baseline (sentence 1). Then, the authors compare their reimplementation as well as their extension to these results (sentence 2), resulting in expressed *Similarities* as well as *Differences*. Through our annotation process (§4) we find that 19.3% of citations have multiple interpretations. These multiple concurrent interpretations partially explain the existence of citation contexts that extend beyond the sentence boundary, and consequently are necessary to fully model how a particular citation contributes to the scientific discourse within a paper.

Multiple mentions densely throughout paper. A single reference may be cited (or *mentioned*) multiple times throughout a paper, potentially with each citation's occurrence serving a different function(s) depending on what the citing author is trying to communicate. Modeling these different citation mentions is critical to understanding all the ways a single reference paper may influence another. For instance, in §4, our paper *Extends* the citation labeling scheme of Jurgens et al. (2018) and then reports *Similarities* in dataset patterns in a separate mention. Through our annotation process in §4, we find referenced papers can be mentioned throughout a citing paper on average 9.1 times, yielding an average of 3.8 distinct interpretations over the course of a citing paper. Recognizing all the myriad functions a single reference can play throughout a citing paper is key to fully understanding the complex relationship between papers.

Motivated by these phenomena, we curate a novel resource (§4) from which we derive and formalize three CCA tasks that account for these phenomena. Systems developed to tackle these tasks can be viewed as answering the following CCA questions: (1) Given a citation context, what are all the different possible interpretations of its function or role within the citing paper (§5)? (2) Given a citation mention, what constitutes the relevant, surrounding passage that comprises its "context" (§6)? (3) Given a pair of citing-cited works, what function(s) does the cited work serve within the citing work and what are the evidential passages supporting this assessment (§7)?

3 Related Work

The importance and role of citations in understanding scholarly work has been recognized across multiple disciplines, from sociology (e.g., Garfield et al., 1964, 1970) to computer science (e.g., McKeown et al., 2016; Yasunaga et al., 2019; Lauscher et al., 2019; Daquino et al., 2020). Prior work in CCA has largely focused on classifying interpretations of a citation along varying dimensions, such as function (e.g., Teufel et al., 2006; Lauscher et al., 2017b), sentiment (e.g., Athar, 2011; Jha et al., 2016), or relative importance to a paper (Valenzuela et al., 2015). However, these works have frequently simplified their analyses, overlooking the important phenomena in §2.

We describe prior computational work on CCA with respect to the three phenomena pursued here. Table 1 overviews their corresponding published resources[1] and shows the variation in which datasets support different lines of citation inquiry.

Mostly single-sentence or fixed-width contexts. While social scientists studying citations have acknowledged the broader context needed to understand citations (Swales, 1986), computational work has largely treated the citing sentence as the only context needed for CCA methods (e.g., Athar, 2011; Dong and Schäfer, 2011). In particular, while annotators in many works had access to larger context, the resulting resources still labeled only a single sentence. A handful of works have acknowledged the importance of multi-sentence, precise, and flexible or *variable-length* context windows (e.g., Elkiss et al., 2008; Kaplan et al., 2009; Athar and Teufel, 2012; Abu-Jbara et al., 2013; Kaplan et al., 2016, *inter alia*); yet, the resources associated with these works have either primarily focused on sentiment, rather than the more complex notion of citation function, or have opted for an arbitrary *fixed-sized* window as the correct context. In contrast, our work provides precisely-defined contexts for each citation function present. The exception is Abu-Jbara et al. (2013), who also annotate variable-length contexts, but unlike us, first extract a fixed window of 4 sentences and do not consider how citations with multiple functions can each have their respective (different) contexts.

Few capture multiple interpretations. Prior computational work has largely assumed a citation has only a single rhetorical function, or when multiple intents are present, that there is only one *primary* function that warrants annotation. Indeed, in some of the preceding works, ambiguous citations were reportedly removed (e.g., Cohan et al., 2019), leading to an artificial simplification of the task. Of computational work, only Athar and Teufel (2012) has attempted to model multiple interpretations. In their work, up to four sentences surrounding a citation are each assigned one sentiment-related label. In contrast, our new resource recognizes the existence of citations with multiple concurrent labels (possibly with varying contexts for a single citation) and each label is annotated with the specific context associated with that interpretation.

Lack intentional sampling for dense citations. Prior works have employed different strategies for selecting which citations they annotate. Works focused on citation sentiment have tended to label all citations within a paper or all mentions of a particular paper. However, works focusing on more complex interpretations like rhetorical function have included more selective sampling, e.g., targeting or up-sampling certain sections. For instance, while Abu-Jbara et al. (2013) model more complex citation contexts, they focus only on citations to a small specific set of highly-cited references found within a much larger set of papers. This sampling strategy can result in many references occurring only once within the citing paper, which yields datasets not much different from ones from works that do not consider multiple mentions at all (Cohan et al., 2019). Such datasets would not support CCA methods that attempt to learn holistic interpretations of how papers relate via access to many within-paper mentions. Our work is the first to consider a dedicated sampling strategy that identifies papers likely to be densely populated with myriad mentions of a particular reference (§4).

4 MULTICITE: A New Resource for CCA

We describe the curation process and present dataset statistics for MULTICITE, the first resource

---

Figure 1: Results of corpus-level analysis in §4 revealing interactions between phenomena present in MULTICITE. We use the following abbreviations for the functions: *Background* (bg), *Motivation* (mot), *Uses* (use), *Similarities* (sim), *Extends* (ext), *Differences* (diff), *Future Work* (fw).

for CCA that captures all three phenomena of interest *and* is large enough to support development of modern neural approaches—It is the largest collection of expert-annotated citation contexts to-date.

4.1 Curation process

Sampling. We procure an initial corpus of 50K full-text papers from the ACL Anthology and arXiv (with `cs.CL` category) using S2ORC (Lo et al., 2020), a large collection of papers released to support computing research.[2] To find papers that likely exhibit our phenomena of interest, we employ the following strategy: For each paper's references, we compute the number of distinct paragraphs in which the reference's citation marker(s) appear, normalized by the total number of paragraphs. Retrieving the top k paper-reference pairs yields papers in which the target reference is cited many times (hopefully in many different ways).

Labeling scheme. We extend the labeling scheme of Jurgens et al. (2018) for classified citations by their rhetorical function, mirroring the approach of Teufel (2014) to differentiate between citations that identify *Similarities* versus those identifying *Differences*. The full scheme with examples is shown in Supplemental Table 5.

Annotation protocol. Annotators were given a citing paper's full text and a target reference whose citations to consider. They were instructed to (1) read the text surrounding each mention of the target reference (highlighted automatically), (2) consider all rhetorical function labels associated with the

---

[2] Like S2ORC, our data is licensed as CC-BY-NC 2.0.

mention, (3) and for each candidate label, to indicate every sentence[3] belonging to the context for that label. To reduce ambiguity around what does (or doesn't) belong in a citation context, we trained annotators to resolve non-citation coreferences to the cited paper as the dominant (but not only) way to observe a multi-sentence context and to continue reading until they felt confident about the labels assigned. Furthermore, for difficult cases, we instructed them to temporarily remove context sentences to see whether the label could still be inferred. Furthermore, annotators were encouraged to skip and leave comments for difficult cases which were routed to two experienced annotators for adjudication.

Recruiting and training. We hired nine NLP graduate students via Upwork. Each student went through an hour of one-on-one training and another hour of independent annotations, which were manually reviewed and used for another hour of one-on-one training focused on feedback and correcting common mistakes. Annotators were then allowed to work independently on batches of 20 papers at a time with manual annotation review after each batch for quality control. Annotators were paid between \$25-35 USD per hour[4] and understood that their annotations would be publicly-released as a resource for research.

Inter-annotator agreement (IAA). Producing a single measure of IAA is difficult for data collected in this manner: annotators might agree on labels but disagree on the choice of context, vice versa, or disagree on both fronts. While some prior work has developed IAA measures that capture both context selection and labeling, e.g., γ by Mathet et al. (2015), such methods aren't widely-adopted in NLP and thus resulting IAA values can be difficult to interpret. We opted instead to recruit two *new* annotators to perform two tasks: (a) identify all function labels when shown a gold context, and (b) identify context sentences when shown a citation mention and gold label pair. For (a), the two achieved an average accuracy of 0.76 when counting *any* gold label match as correct, and 0.70 when only counting cases when *all* predicted labels match the gold annotations as correct ($n = 54$). For (b), the two achieved an average sentence-level F1 score of 0.64, 0.63 and 0.65, respectively for gold contexts of length 1, 2 or 3+ sentences, and an overall Cohen's Kappa of 0.65 ($n = 120$).

4.2 Corpus statistics

MULTICITE consists of 1,193 papers from CL and NLP (with an average of 139.7 sentences per paper) with 12,653 annotated citation contexts. We highlight three key aspects. **(1)** We find that over one in six contexts (17.1%) extends beyond a single sentence. MULTICITE provides 2,167 multi-sentence contexts, with 161 reaching 5+ sentences. See Supplemental Figure 5a for further breakdown. **(2)** Nearly one in five citations (19.3%) also have multiple interpretations. Of the 2,084 multi-labeled citations, most have two labels but a handful have up to four. Our label distribution is skewed with the *Background* and *Uses* appearing most frequently and *Future Work* the least; this is in-line with prior work (e.g., Pride and Knoth, 2020). See Supplemental Figure 5b for a full label distribution. **(3)** Regarding mention occurrence, we find that our sampling strategy successfully finds interesting paper-reference pairs as the average of citation occurrences in a paper is 9.1. In addition, our intuition about mentions exhibiting different interpretations is supported by an average of 3.8 unique functions across all mentions of a given reference.

Looking at interactions between phenomena, we observe two interesting findings. First, we observe in Figure 1a that while every label is capable of being expressed with only a few sentences, there are surprisingly few single-sentence *Motivation* contexts. Second, pointwise mutual information (PMI) between the labels (Figure 1b) shows high co-occurrence in *Extends* and *Differences*.

4.3 Limitations

While our new resource is the largest citation dataset, our design choices introduce some limitations. Due to task complexity, annotators labeled only direct citations but not indirect mentions (e.g. entity names used without citation). Our choice in open data, including the full texts, potentially allows future work to add these to our corpus. Further, our citation annotation scheme features seven classes, which itself is a simplification of the complex ways in which citations are used. While others have proposed 12-class (Teufel, 2014) or even 35-class (Garzone and Mercer, 2000) annotation schemes to capture long-tail citation uses, we ultimately opted for a simpler scheme that facilitates scalable annotation and easier model development.

---

[3] Identified using ScispaCy (Neumann et al., 2019).

[4] Median wage for similar work on the platform, and well above minimum wage in ANONYMIZED.

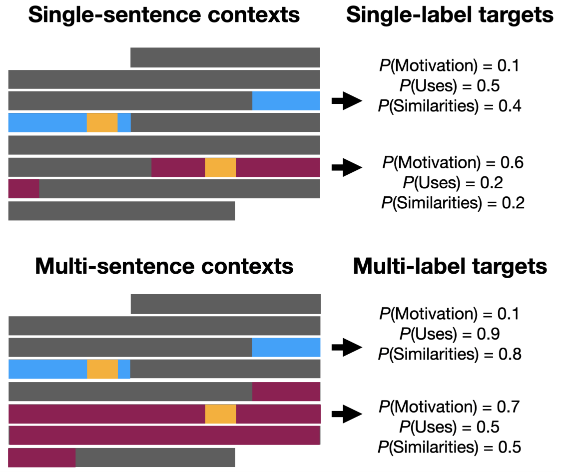

Figure 2: Shift in task form for citation context classification. Within a document (grey), each citation mention (orange) is associated with a surrounding context. Multi-sentence setting can contain both single-sentence (blue) and multi-sentence (purple) contexts. Multi-label scores need not sum to one as in the single-label setting.

5 Citation Context Classification

The first task we consider makes use of both the multi-sentence and multi-label phenomena described in §2: **multi-label classification**. One can view this as the multi-label extension to the traditional multi-class classification task common in prior work (see Figure 2), but we show experimentally that models using *variable-length* gold contexts yield superior results. This motivates (1) a shift in computational research away from assuming fixed-window (often 1-sentence) inputs, and (2) additional investment in understudied tasks like citation context identification (§6).

5.1 Modeling approach

Using Transformer (Vaswani et al., 2017) models, which have demonstrated success on many text classification tasks and datasets, we train both multi-class and multi-label predictors. For multi-class predictors (which output a single label), we follow common practices in adding a linear classification layer over the `[CLS]` token at the beginning of each input context and applying a softmax for prediction. For multi-label classification, we deviate by replacing the softmax with a sigmoid operation per label to produce multi-label outputs; we set our sigmoid prediction threshold to 0.5.

5.2 Experimental Setup

We conduct a series of experiments aligned with previous works (e.g., Jha et al., 2016), in which we feed varying amounts of context sentences to a text classification model. These experiments aim to *understand the importance of variable-length inputs* and to *establish computational baselines* to support future research on MULTICITE.

Data processing. We perform a train-validation-test split of MULTICITE at a paper-level; to avoid leakage, all examples from the same paper are assigned to the same split resulting in 5,491 training, 2,447 validation, and 3,313 test instances. Because citation contexts can contain mentions of multiple papers, we remove task ambiguity by tagging the target paper's mention with `[CITE]` tokens.

Training and optimization. We use pretrained SciBERT-base and RoBERTa-large weights from Huggingface Transformers (Wolf et al., 2020). We optimize the models using the average over binary cross-entropy losses for each label using Adam (Kingma and Ba, 2015) with a batch size of 32. We use grid search based on validation set performance to set the learning rate (1e-5 or 2e-5) and number of epochs (between 1 and 9).

Evaluation. We compute two types of accuracies: a *strict* version, in which a prediction is correct iff all predicted labels match exactly the gold annotation; and a *weak* version, in which a prediction is correct if at least one of the predicted labels matches the gold classes. The weak measure reflects an upper bound on performance (i.e., whether the model can detect *any* of the correct intents) and allows us to compare our multi-label models with models that only return single-labels. We perform this evaluation both across all MULTICITE test examples as well as broken down by specific gold context sizes (up to 4 sentences).

5.3 Results

We present single run results on the test set in Table 2,[5] and observe two important findings:

Variable-length contexts improve performance. Despite high occurrence of 1-sentence contexts in our corpus, a model trained on variable-length gold contexts still outperforms that trained only on single-sentence inputs (see rows "1" versus "gold"). Surprisingly, the variable-length model even outperforms the single-sentence model even on single-sentence test examples (see column "size = 1").

---

[5] For brevity, we leave RoBERTa-large scores in the supplemental Table 7 as we observe the same patterns as SciBERT and arrive at the same conclusions.

	size = 1		size = 2		size = 3		size = 4		all	
train on:	weak	strict	weak	strict	weak	strict	weak	strict	weak	strict
1	0.78	0.69	0.45	0.28	0.47	0.24	0.51	0.18	0.74	0.62
3	0.74	0.64	0.59	0.39	0.54	0.29	0.62	0.23	0.72	0.60
5	0.71	0.61	0.50	0.33	0.46	0.27	0.54	0.18	0.68	0.57
7	0.62	0.54	0.43	0.28	0.48	0.27	0.51	0.15	0.60	0.50
9	0.56	0.50	0.37	0.25	0.37	0.21	0.56	0.18	0.53	0.46
gold	**0.80**	**0.70**	**0.68**	**0.46**	**0.66**	**0.39**	**0.64**	**0.26**	**0.78**	**0.66**

Table 2: Weak and strict accuracy scores of multi-label classifiers on MULTICITE. Column "train on:" reflects the size of contexts seen at training time; rows "1", "3", "5", "7" and "9" are fixed-width window sizes that contain gold citation context, while row "gold" means training with variable-length gold contexts. Columns "size = ?" correspond to the size of gold contexts supplied at test time. Best performances per column are **bolded**.

We hypothesize that due to the training on variable length gold contexts, the model is able to better capture the fine-grained differences between the many intent classes, and thus, performs better than a model that has seen restricted contexts only. For instance, as the label distribution varies across the different context lengths (cf. Figure 1), the input context length might serve as an additional signal to the variable-length classification model, while a model trained on a fixed window can not make any use of such length-dependent signals.

Fixed-width windows don't cut it. One cannot simply train on fixed-width windows and hope to achieve the same performance boost as we see with variable-length contexts. In fact, the variable-length model outperforms fixed-width models even on test examples where the gold context and fixed-width window exactly match (see rows "3" versus "gold", column "size = 3").

6 Identifying Citation Contexts

Motivated by the need for variable-length gold contexts, the second task we consider is **citation context identification** (Abu-Jbara et al., 2013), which has seen little research since the advent of neural models. We demonstrate experimentally how MULTICITE can be used to train modern neural models for this understudied task, thereby setting *first Transformer baselines* to support future study.

6.1 Experimental setup

Task formulation. We adopt the task formulation from Abu-Jbara et al. (2013): given a *window* of sentences around a target paper citation mention, predict the sentences belonging to that citation's context—a set of sentences that are sufficient for identifying that citation's label(s), e.g., intent.

Modeling approach. We consider models for sentence-level sequence tagging (Dernoncourt and Lee, 2017; Cohan et al., 2018), which have been used successfully to group sentences in scholarly abstracts by their discourse roles. We establish a first computational baseline on this task by adapting the approach from Cohan et al. (2018)—a SciBERT (Beltagy et al., 2019) model trained to receive as input a window of sentences separated by separator tokens `[SEP]`, and apply a linear classification to these tokens to output sentence-level predictions.

Data processing. To study how model performance may depend on window sizes, we generate examples from every gold citation context in MULTICITE with windows of 2, 4, 6, 8 and 10 sentences.[6] For each window size, we follow four desiderata: (1) As in §5, we reduce task ambiguity by tagging the target paper's citation mention with `[CITE]` tokens. (2) Windows must contain non-zero context and non-context sentences. (3) Windows must contain gold contexts entirely without truncation. This results in fewer total examples for small window sizes. For instance, for windows of 2 and 6 sentences, we create 10,453 and 12,506 examples, respectively, a 20% increase in data from multi-sentence contexts. (4) To prevent exploiting positional information, gold contexts cannot always be centered in the window. We construct windows by, randomly appending non-context sentences around golds until the desired window size.

We perform 5-fold cross validation with a 70-10-20 train-validation-test data split. To avoid leakage, all examples from the same paper are assigned to the same split in a given fold.

---

[6] Due to the 512 SciBERT token limit, some examples may have fewer than the stated number of sentences. We ensure examples contain whole sentence inputs without truncation.

Window	Micro-F1	Macro-F1
2	75.17	80.17
4	**81.16**	**85.61**
6	79.91	84.35
8	76.64	81.56
10	72.14	77.42

Table 3: Test results for citation context identification across models trained with various input window size configurations. Best performing model row is **bolded**.

Training and optimization. We use pretrained weights for SciBERT-base available on Huggingface Transformers (Wolf et al., 2020), which we fine-tune with a binary (context or not) cross-entropy loss over the sentence-level predictions. We use the Adam (Kingma and Ba, 2015) optimizer with a linear learning rate scheduler (with max learning rate of 3e-5 after 100 warmup steps, batch size of 36, and up to a maximum of 5 epochs). We manually chose these hyperparameters using validation performance across all folds.

Evaluation. We evaluate these models using two sentence-level F1 metrics. The *micro-averaged* F1 evaluates the performance across all sentences across the entire corpus as to whether they were correctly (or incorrectly) classified as belonging to the context of the target citation mention. The *macro-averaged* F1 averages F1-scores across sentences first computed within each paper.

We take special care to ensure fair comparison across models trained on different window sizes. For instance, the Window=2 processing only contains single-sentence contexts and model performance on *only considering these examples* reaches high 90 F1 scores. Instead, our evaluation is processing-agnostic—small window models are penalized for defaulting to "not context" predictions for sentences beyond their window.

6.2 Results

As we increase window size, performance on both metrics increases as shown in Table 3, but only to a point. Large context windows create difficulty in the model's training due to the increased number of non-context sentences. While the performance is high enough that our model can likely serve as an effective preprocessing step for other CCA models needing variable-sized windows, our results point to the challenge and potential for new models to improve upon in identifying contextual boundaries of citation discourse.

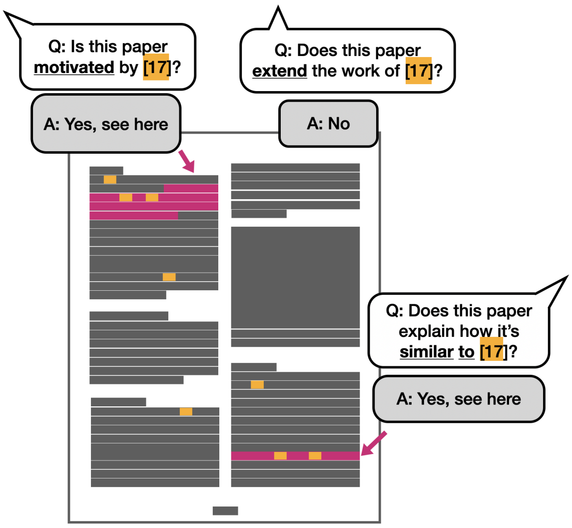

Figure 3: Evidence-based assessment of citing-cited paper relationships. Given a document with all citation mentions (orange) of a target paper identified, we aim to answer questions about the function of the cited paper (`[17]`) within the citing work, and provide snippets as supporting evidence (pink).

7 Evidence-based Assessment of Citing-Cited Paper Relationships

Dense citations to a single reference reveal a multifaceted relationship between the citing and cited papers. The dense annotations in MULTICITE allow development of CCA methods that model these document-level relationships, e.g., assessing holistically how the cited work has influenced the design or outcome of the citing work. Consider an application scenario where a user wants to know why a given paper cites another. A hypothetical system might provide a *paper-level assessment* of their relationship and citation contexts as supporting *evidence* from the citing paper's full text.

Motivated by this aspirational application, we *propose a CCA task* requiring document-level understanding of dense citations: **Answering questions about citing-cited paper relationships** by operating across multiple mentions within paper full-text. Figure 3 provides a schematic of this task, which demonstrates the novel research potential of MULTICITE at supporting higher-level CCA, and by casting CCA as a form of question answering (QA), highlights compatibility with modern attempts on scientific QA (Dasigi et al., 2021).

7.1 Experimental Setup

While building such a system is beyond the scope of our work, we demonstrate through experiments how MULTICITE can support development of QA models behind such applications.

Task formulation. We adapt the scientific QA task form in Dasigi et al. (2021) to our CCA setting by mapping each citation function to a question-answer template. For instance, *Background* becomes a question *"Does the paper cite `[TARGET]` for background information?"* and answer *"Yes"*, and the *Background* citation context then becomes evidence for that answer.

Modeling approach. We consider the Qasper (Dasigi et al., 2021) document-grounded QA model pretrained to answer questions about NLP papers with supporting evidence. Qasper is based on the Longformer-Encoder-Decoder (LED) (Beltagy et al., 2020) architecture, which enables it to encode an entire paper's full text as a single input string. Like the model in §6, input sentences are separated by tokens `</s>`, which are used to predict binary labels of *Evidence* (or not) via a linear classification layer. Unlike the model in §6, LED also generates strings, which we train to produce answer strings *"Yes"* or *"No"*.

Data processing. We use the same train-validation-test split from §5. For each citing-cited paper pair, we create seven questions (one for each of our seven rhetorical functions). To create positive examples, for all functions with at least one gold citation context, we create a *"Yes"*-answer and provide the first[7] gold context as evidence. To create negative examples, we create a *"No"*-answer without evidence. This results in 4,074 training, 1,764 validation, and 2,499 test question-answer pairs.

Training and optimization. We use code and pretrained weights from Dasigi et al. (2021), which we finetune on our derived QA pairs using a joint answer-evidence loss (and within-batch loss scaling for class imbalance) from the original work. We train using Adam (Kingma and Ba, 2015) for up to 5 epochs. We use the validation set for early stopping and grid search over batch sizes 2, 4, 8 or 16 and max learning rate of 3e-5 or 5e-5.

Evaluation. Following Dasigi et al. (2021), we evaluate the model using the Answer-F1 and Evidence-F1 metrics defined in that work, where Answer-F1 captures correctness of the generated answer span and Evidence-F1 captures performance in extracting gold citation context sentences.

	Answer F1	**Evidence F1**
Majority SL	0.61	0.48
Majority ML	0.72	0.48
Qasper	**0.75**	**0.48**

Table 4: Test results of the Qasper model finetuned on document-level QA examples from MULTICITE.

Baselines. We compare our model to two heuristic baselines. In MAJORITY SINGLE LABEL (SL), we always predict *"Yes"* for the majority class—*Background*. In MAJORITY MULTIPLE LABELS (ML), we predict for each of the seven question templates the majority answer (*"Yes"* or *"No"*).

7.2 Results

We present single run results on the test set in Table 4. While the Qasper model outperforms the heuristics at assessing citing-cited paper relationships (Answer F1), the gains from supervision are minor, and citation contexts retrieval (Evidence F1) does not outperform simple heuristics. This highlights the difficulty in this document-level understanding task and the potential for future research into powerful models capable of higher-level CCA.

8 Conclusion

Aiming to inspire novel research in CCA, we have acknowledged the existence of three understudied phenomena, and present MULTICITE, a novel resource that is both the largest corpus of citation contexts to-date *and* captures all three phenomena. We employ MULTICITE in three experiments demonstrating the importance of these phenomena, establishing strong baselines, and showcasing ways of conducting novel CCA. In the future, we intend to increase diversity of the dataset by extending it to cover more disciplines of science. We make all code and data publicly available at https://github.com/allenai/multicite.

Acknowledgements

This work was supported in part by NSF Convergence Accelerator Award #2132318. We thank Sam Skjonsberg and Mark Neumann for their help on the annotation interface. We would also like to thank Noah Smith for helping us connect with collaborators on this project and the anonymous reviewers for their insightful feedback.

A Reliability of the Mention Annotation

To compute the reliability of the automatic mention annotation, we let annotators manually identify all references to the cited work including citation markers, scientific entity names, and other co-references, e.g., *"The authors ..."*, in a small sample of 262 publication pairs. We then compute the agreement with the gamma tool (Mathet et al., 2015) and obtain a mean score of 0.60 gamma macro averaged over the publications. We therefore explicitly instruct our annotators to use the highlighting as a rough guidance but to manually check for other mentions and co-references.

B Intent Labeling Scheme

We describe each intent of our labeling scheme in Table 5.

C Annotation Interface

A screenshot of the annotation interface is shown in Figure 4.

D Detailed Data Analysis

We show the detailed context length distribution and intent distribution in Figures 5. While most citations contexts are only a single sentence, our analysis shows a substantial long tail of context lengths. The distribution of citation functions mirrors results seen in similar annotation schemes such as Jurgens et al. (2018) and Pride and Knoth (2020). However, note that the *Differences* and *Similarities* classes occur with different frequencies, with authors more likely to highlight distinguishing features of their own work. This finding helps support our choice in explicitly splitting the *CompareOrContrast* category of Jurgens et al. (2018) in the labeling scheme we use for MULTICITE.

E Detailed Model Descriptions

SciBERT is only available in base configuration (12 layers, 12 attention heads, 768 as hidden size, cased vocabulary with size $31,116$). For RoBERTa, we employ the large version (24 layers, 16 attention heads, hidden size 1024, cased vocabulary with size $50,265$). Links to code base and pretrained models are given in Table 6.

F Full table for §5

Intent	Description
Background	The target paper provides relevant information for this domain.
Motivation	The target paper provides motivation for the source paper. For instance, it illustrates the need for data, goals, methods etc.
Uses	The source paper uses an idea, method, tool, etc. of the target paper.
Extends	The source paper extends an idea, method, tool, etc. of the target paper.
Similarities	The source paper expresses similarities towards the target paper. Either similarities between the source and the target paper or similarities between another publication and the target paper.
Differences	The source paper expresses differences towards the target paper. Either differences between the source and the target paper or differences between another publication and the target paper.
Future Work	The target paper is a potential avenue for future research. Often corresponds to hedging or speculative language about work not yet performed.

Table 5: Our citation intent labeling scheme based on Jurgens et al. (2018). We differ from their scheme by splitting their *ComparisonOrContrast* into separate categories—*Similarities* or *Differences*—which are represented in other annotation schemes

DEGREE: A Data-Efficient Generation-Based Event Extraction Model

Abstract

Event extraction requires high-quality expert human annotations, which are usually expensive. Therefore, learning a *data-efficient* event extraction model that can be trained with *only a few* labeled examples has become a crucial challenge. In this paper, we focus on *low-resource end-to-end* event extraction and propose DEGREE, a data-efficient model that formulates event extraction as a conditional generation problem. Given a passage and a manually designed prompt, DEGREE learns to summarize the events mentioned in the passage into a natural sentence that follows a predefined pattern. The final event predictions are then extracted from the generated sentence with a deterministic algorithm. DEGREE has three advantages to learn well with less training data. First, our designed prompts provide semantic guidance for DEGREE to leverage *label semantics* and thus better capture the event arguments. Moreover, DEGREE is capable of using additional *weakly-supervised* information, such as the description of events encoded in the prompts. Finally, DEGREE learns triggers and arguments jointly in an *end-to-end manner*, which encourages the model to better utilize the shared knowledge and dependencies among them. Our experimental results demonstrate the strong performance of DEGREE for low-resource event extraction.

1 Introduction

Event extraction (EE) aims to extract events, each of which consists of a trigger and several participants (arguments) with their specific roles, from a given passage. For example, in Figure 1, a *Justice:Execute* event is triggered by the word *"execution"* and this event contains three argument roles, including an *Agent* (*Indonesia*) who carries out the execution, a *Person* who is executed (*convicts*), and a *Place* where the event occurs (not mentioned in the passage). Previous work (Yang et al., 2019a; Fincke et al., 2021) usually divides EE into two subtasks: (1) **event detection**, which identifies event triggers and their types, and (2) **event argument extraction**, which extracts the arguments and their roles for given event triggers. EE has been shown to benefit a wide range of applications, e.g., building knowledge graphs (Zhang et al., 2020), question answering (Berant et al., 2014; Han et al., 2021), and other downstream studies (Han et al., 2019a; Hogenboom et al., 2016; Sun and Peng, 2021).

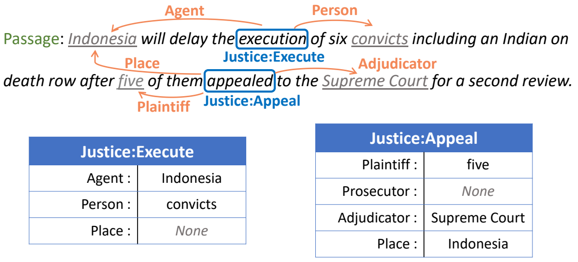

Figure 1: Two examples of events (*Justice:Execute* and *Justice:Appeal*) extracted from the given passage.

Most prior works on EE rely on a large amount of annotated data for training (Nguyen and Grishman, 2015; Nguyen et al., 2016; Han et al., 2019b; Du and Cardie, 2020; Huang et al., 2020; Huang and Peng, 2021; Paolini et al., 2021). However, high-quality event annotations are expensive to obtain. For example, the ACE 2005 corpus (Doddington et al., 2004), one of the most widely used EE datasets, requires two rounds of annotations by linguistics experts. The high annotation costs make these models hard to be extended to new domains and new event types. Therefore, how to learn a *data-efficient* EE model trained with *only a few* annotated examples is a crucial challenge.

In this paper, we focus on *low-resource* event extraction, where only a small amount of training examples are available for training. We propose DEGREE (**D**ata-**E**fficient **G**ene**R**ation-Based **E**vent **E**xtraction), a generation-based model that takes a passage and a manually designed prompt as the input, and learns to summarize the passage into a

Event Trigger	detonated
Attacker	Palestinian
Target	jeep, soldiers
Instrument	bomb
Place	Gaza Strip

Passage: *Earlier Monday , a 19-year-old Palestinian riding a bicycle detonated a 30-kilo (66-pound) bomb near a military jeep in the Gaza Strip , injuring three soldiers.*

Prompt	
Event Type Description	*The event is related to conflict and some violent physical act.*
Event Keywords	*Similar triggers such as war, attack, terrorism.*
E2E Template	*Event trigger is <Trigger>. \n* *some attacker attacked some facility, someone, or some organization by some way in somewhere.*

Output Text

Event trigger is detonated. \n Palestinian attacked jeep and soldiers by bomb in Gaza Strip.

Figure 2: An illustration of DEGREE for predicting a *Contact:Attack* event. The input of DEGREE consists of the given passage and our design prompt that contains an event type description, event keywords, and a E2E template. DEGREE is trained to generate an output to fill in the placeholders (underlined words) in the E2E template with triggers and arguments. The final event prediction is then decoded from the generated output.

natural sentence following a predefined template, as illustrated in Figure 2. The event triggers and arguments can then be extracted from the generated sentence by using a deterministic algorithm.

DEGREE enjoys the following advantages to learn well with less training data. First, the framework provides *label semantics* via the designed template in the prompts. As the example in Figure 2 shows, the word *"somewhere"* in the prompt guides the model to predict words being similar to *location* for the role *Place*. In addition, the sentence structure of the template and the word *"attacked"* depict the semantic relation between the role *Attacker* and the role *Target*. With these kinds of guidance, DEGREE can make more accurate predictions with less training examples. Second, the prompts can incorporate additional weak-supervision signal about the task, such as the description of the event and similar keywords. These resources are usually readily available. For example, in our experiments, we take the information from the annotation guideline, which is provided along with the dataset. This information facilitates DEGREE to learn under a low-resource situation. Finally, DEGREE is designed for end-to-end event extraction and can solve event detection and event argument extraction at the same time. Leveraging the shared knowledge and dependencies between the two tasks makes our model more data-efficient.

Existing works on EE usually have only one or two of above-mentioned advantages. For example, previous classification-based models (Nguyen et al., 2016; Wang et al., 2019; Yang et al., 2019b; Wadden et al., 2019; Lin et al., 2020) can hardly encode label semantics and other weak supervision signals. Recently proposed generation-based models for event extraction solved the problem in a pipeline fashion; therefore, they cannot leverage shared knowledge between subtasks (Paolini et al., 2021; Li et al., 2021). Furthermore, their generated outputs are not natural sentences, which hinders the utilization of label semantics (Paolini et al., 2021; Lu et al., 2021). As a result, our model DEGREE can achieve significantly better performance than prior approaches on low-resource event extraction, as we will demonstrate in Section 3.

Our contributions can be summarized as follows:

- We propose DEGREE, a generation-based event extraction model that learns well with less data by better incorporating label semantics and shared knowledge between subtasks (Section 2).
- Experiments on ACE 2005 (Doddington et al., 2004) and ERE-EN (Song et al., 2015) demonstrate the strong performance of DEGREE in the low-resource setting (Section 3).
- We present comprehensive ablation studies in both the low-resource and the high-resource setting to better understand the strengths and weaknesses of our model (Section 4).

Our code and models can be found at `https://github.com/PlusLabNLP/DEGREE`.

2 Data-Efficient Event Extraction

We introduce DEGREE, a generation-based model for low-resource event extraction. Unlike previous works (Yang et al., 2019a; Li et al., 2021), which separate event extraction into two pipelined tasks (event detection and event argument extraction), DEGREE is designed for the end-to-end event extraction and predict event triggers and arguments at the same time.

2.1 The DEGREE Model

We formulate event extraction as a conditional generation problem. As illustrated in Figure 2, given a passage and our designed prompt, DEGREE generates an output following a particular format. The final predictions of event triggers and argument roles can be then parsed from the generated output with a deterministic algorithm. Compared to previous classification-based models (Wang et al., 2019; Yang et al., 2019b; Wadden et al., 2019; Lin et al., 2020), the generation framework provides a flexible way to include additional information and guidance. By designing appropriate prompts, we encourage DEGREE to better capture the dependencies between entities and, therefore, to reduce the number of training examples needed.

The desired prompt not only provides information but also defines the output format. As shown in Figure 2, it contains the following components:

- **Event type definition** describes the definition for the given event type.[1] For example, *"The event is related to conflict and some violent physical act."* describes a *Conflict:Attack* event.
- **Event keywords** presents some words that are semantically related to the given event type. For example, *war*, *attack*, and *terrorism* are three event keywords for the *Conflict:Attack* event. In practice, we collect three words that appear as the triggers in the example sentences from the annotation guidelines.
- **E2E template** defines the expected output format and can be separated into two parts. The first part is called ED template, which is designed as *"Event trigger is <Trigger>"*, where *"<Trigger>"* is a special token serving as a placeholder. The second part is the EAE template, which differs based on the given event type. For example, in Figure 2, the EAE template for a *Conflict:Attack* event is *"some attacker attacked some facility, someone, or some organization by some way in somewhere"*. Each underlined string starting with *"some-"* serves as a placeholder corresponding to an argument role for a *Conflict:Attack* event. For instance, *"some way"* corresponds to the role *Instrument* and *"somewhere"* corresponds to the role *Place*. Notice that every event type has its own EAE template. We list three EAE templates in Table 1. The full list of EAE templates and the construction details can be found in Appendix A.

2.2 Training

The training objective of DEGREE is to generate an output that replaces the placeholders in E2E template with the gold labels. Take Figure 2 as an example, DEGREE is expected to replace *"<Trigger>"* with the gold trigger (*detonated*), replace *"some attacker"* with the gold argument for role *Attacker* (*Palestinian*), and replace *"some way"* with the gold argument for role *Instrument* (*bomb*). If there are multiple arguments for the same role, they are concatenated with *"and"*; if there is no predicted argument for one role, the model should keep the corresponding placeholder (i.e, *"some-"* in the E2E template). For the case that there are multiple triggers for the given event type in the input passage, DEGREE is trained to generate the output text that contains multiple E2E template such that each E2E template corresponds to one trigger and its argument roles. The hyperparameter settings are detailed in Appendix B.

2.3 Inference

We enumerate all event types and generate an output for each event type. After we obtain the generated sentences, we compare the outputs with E2E template to determine the predicted triggers and arguments in string format. Finally, we apply string matching to convert the predicted string to span offsets in the passage. If the predicted string appears in the passage multiple times, we choose all span offsets that match for trigger predictions and choose the one closest to the given trigger span for argument predictions.

2.4 Discussion

Notice that the E2E template plays an important role for DEGREE. First, it serves as the control signal and defines the expected output format. Second,

---

[1] The definition can be derived from the annotation guidelines, which are provided along with the datasets.

Event Type	**EAE Template**
Life:Divorce	somebody divorced in somewhere.
Transaction:Transfer-Ownership	someone got something from some seller in somewhere.
Justice:Sue	somebody was sued by some other in somewhere. The adjudication was judged by some adjudicator.

Table 1: Three examples of EAE templates for the ACE 2005 corpus.

it provides label semantics to help DEGREE make accurate predictions. Those placeholders (words starting with *"some-"*) in the E2E template give DEGREE some hints about the entity types of arguments. For instance, when seeing *"somewhere"*, DEGREE tends to generate a location rather than a person. In addition, the words other than *"some-"* describe the relationships between roles. For example, DEGREE knows the relationship between the role *Attacker* and the role *Target* (who is attacking and who is attacked) due to E2E template. This guidance helps DEGREE learn the dependencies between entities.

Unlike previous generation-based approaches (Paolini et al., 2021; Li et al., 2020; Huang et al., 2021), we intentionally write E2E templates in natural sentences. This not only uses label semantics better but also makes the model easier to leverage the knowledge from the pre-trained decoder. In Section 4, we will provide experiments to demonstrate the advantage of using natural sentences.

Cost of template constructing. DEGREE does require human effort to design the templates; however, writing those templates is much easier and more effortless than collecting complicated event annotations. As shown in Table 1, we keep the EAE templates as simple and short as possible. Therefore, it takes only about one minute for people who are not linguistic experts to compose a template. In fact, several prior works (Liu et al., 2020; Du and Cardie, 2020; Li et al., 2020) also use constructed templates as weakly-supervised signals to improve models. In Section 4, we will study how different templates affect the performance.

Efficiency Considerations. DEGREE requires to enumerate all event types during inference, which could cause efficiency considerations when extending to applications that contain many event types. This issue is minor for our experiments on the two datasets (ACE 2005 and ERE-EN), which are relatively small scales in terms of the number of event types. Due to the high cost of annotations, there is hardly any public datasets for end-to-end event extraction on a large scale,[2] and we cannot provide a more thorough studies when the experiments scale up. We leave the work on benchmarking and improving the efficiency of DEGREE in the scenario considering more diverse and comprehensive types of events as future work.

2.5 DEGREE in Pipeline Framework

DEGREE is flexible and can be easily modified to DEGREE(PIPE), which first focuses event detection (ED) and then solves event argument extraction (EAE). DEGREE(PIPE) consists of two models: (1) DEGREE(ED), which aims to exact event triggers for the given event type, and (2) DEGREE(EAE), which identifies argument roles for the given event type and the corresponding trigger. DEGREE(ED) and DEGREE(EAE) are similar to DEGREE but with different prompts and output formats. We describe the difference as follows.

DEGREE(ED). The prompt of DEGREE(ED) contains the following components:

- **Event type definition** is the same as the ones for DEGREE.
- **Event keywords** is the same as the one for DEGREE.
- **ED template** is designed as *"Event trigger is <Trigger>"*, which is actually the first part of the E2E template.

Similar to DEGREE, the objective of DEGREE(ED) is to generate an output that replaces *"<Trigger>"* in the ED template with event triggers.

DEGREE(EAE). The prompt of DEGREE(EAE) contains the following components:

- **Event type definition** is the same as the one for DEGREE.
- **Query trigger** is a string that indicates the trigger word for the given event type. For example, *"The event trigger word is detonated"* points out that *"detonated"* is the given trigger.

---

[2] To the best of our knowledge, MAVEN (Wang et al., 2020) is the only publicly available large-scale event dataset. However, the dataset only focuses on event detection without considering event arguments.

- **EAE template** is an event-type-specific template mentioned previously. It is actually the second part of E2E template.

Similar to DEGREE, the goal for DEGREE(EAE) is to generate an outputs that replace the placeholders in EAE template with event arguments.

In Section 3, we will compare DEGREE with DEGREE(PIPE) to study the benefit of dealing with event extraction in an end-to-end manner under the low-resource setting.

3 Experiments

We conduct experiments for *low-resource* event extraction to study how DEGREE performs.

3.1 Experimental Settings

Datasets. We consider ACE 2005 (Doddington et al., 2004) and follow the pre-processing in Wadden et al. (2019) and Lin et al. (2020), resulting in two variants: **ACE05-E** and **ACE05-E$^+$**. Both contain 33 event types and 22 argument roles. In addition, we consider **ERE-EN** (Song et al., 2015) and adopt the pre-processing in Lin et al. (2020), which keeps 38 event types and 21 argument roles.

Data split for low-resource setting. We generate different proportions (1%, 2%, 3%, 5%, 10%, 20%, 30%, and 50%) of training data to study the influence of the size of the training set and use the original development set and test set for evaluation. Appendix C lists more details about the split generation process and the data statistics.

Evaluation metrics. We consider the same criteria in prior works (Wadden et al., 2019; Lin et al., 2020). (1) **Trigger F1-score**: an trigger is correctly identified (Tri-I) if its offset matches the gold one; it is correctly classified (Tri-C) if its event type also matches the gold one. (2) **Argument F1-score**: an argument is correctly identified (Arg-I) if its offset and event type match the gold ones; it is correctly classified (Arg-C) if its role matches as well.

Compared baselines. We consider the following classification-based models: (1) **OneIE** (Lin et al., 2020), the current state-of-the-art (SOTA) EE model trained with designed global features. (2) **BERT_QA** (Du and Cardie, 2020), which views EE tasks as a sequence of extractive question answering problems. Since it learns a classifier to indicate the position of the predicted span, we view it as a classification model. We also consider the following generation-based models: (3) **TANL** (Paolini et al., 2021), which treats EE tasks as translation tasks between augmented natural languages. (4) **Text2Event** (Lu et al., 2021), a sequence-to-structure model that converts the input passage to a tree-like event structure. Note that the outputs of both generation-based baselines are not natural sentences. Therefore, it is more difficult for them to utilize the label semantics. All the implementation details can be found in Appendix D. It is worth noting that we train OneIE with named entity annotations, as the original papers suggest, while the other models are trained without entity annotations.

3.2 Main Results

Table 2 shows the trigger classification F1-scores and the argument classification F1-scores in three data sets with different proportions of training data. The results are visualized in Figure 3. Since our task is *end-to-end* event extraction, the argument classification F1-score is the more important metric that we considered when comparing models.

From the figure and the table, we can observe that both DEGREE and DEGREE(PIPE) outperform all other baselines when using less than 10% of the training data. The performance gap becomes much more significant under the extremely low data situation. For example, when only 1% of the training data is available, DEGREE and DEGREE(PIPE) achieve more than 15 points of improvement in trigger classification F1 scores and more than 5 points in argument classification F1 scores. This demonstrates the effectiveness of our design. The generation-based model with carefully designed prompts is able to utilize the label semantics and the additional weakly supervised signals, thus helping learning under the low-resource regime.

Another interesting finding is that DEGREE and DEGREE(PIPE) seem to be more beneficial for predicting arguments than for predicting triggers. For example, OneIE, the strongest baseline, requires 20% of training data to achieve competitive performance on trigger prediction to DEGREE and DEGREE(PIPE); however, it requires about 50% of training data to achieve competitive performance in predicting arguments. The reason is that the ability to capture dependencies becomes more important for argument prediction than trigger prediction since arguments are usually strongly dependent on each other compared to triggers. Therefore, the improvements of our models for argument prediction

Table 2: Trigger classification F1-scores and argument classification F1-scores for low-resource event extraction. Highest scores are in bold and the second best scores are underlined. "Cls" and "Gen" represent classification-based models and generation-based models, respectively. If the model is a pipelined model, then its argument predictions are based on its predicted triggers. DEGREE achieves a much better performance than other baselines. The performance gap becomes more significant for the extremely low-resource situation.

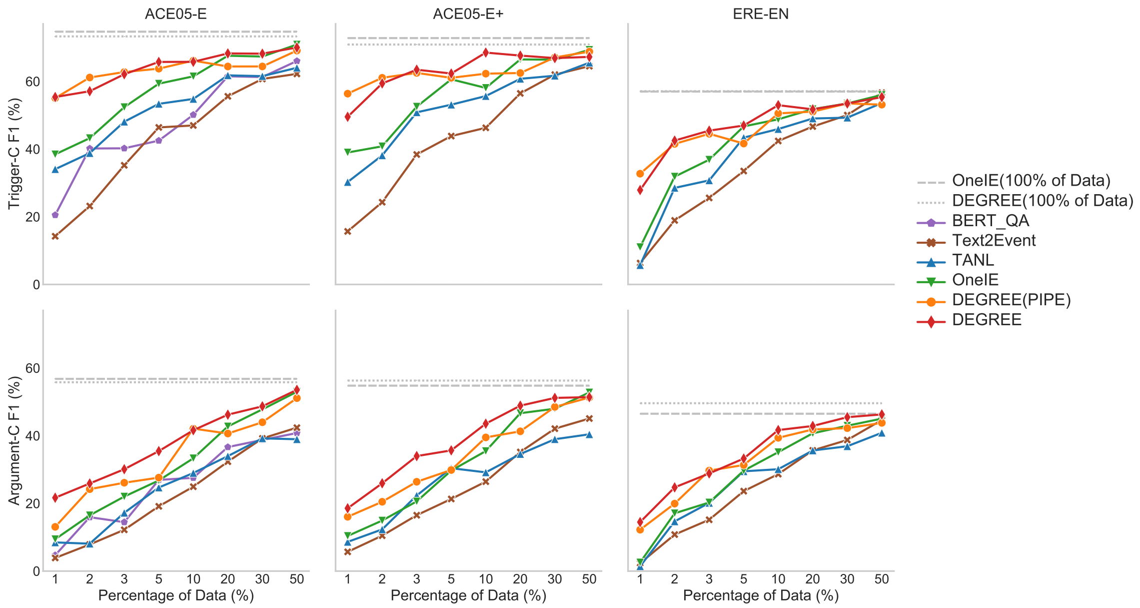

Figure 3: Trigger classification F1-scores and argument classification F1-scores for low-resource event extraction. DEGREE achieves a much better performance than other baselines. The performance gap becomes more significant for the extremely low-resource situation.

are more significant.

Furthermore, we observe that DEGREE is slightly better than DEGREE(PIPE) under the low-resource setting. This provides empirical evidence on the benefit of jointly predicting triggers and arguments in a low-resource setting.

Finally, we perform additional experiments on few-shot and zero-shot experiments. The results can be found in Appendix E.

3.3 High-Resource Event Extraction

Although we focus on data-efficient learning for low-resource event extraction, to better understand the advantages and disadvantages of our model, we additionally study DEGREE in the high-resource setting for controlled comparisons.

Compared baselines. In addition to the EE models mentioned above: **OneIE** (Lin et al., 2020), **BERT_QA** (Du and Cardie, 2020), **TANL** (Paolini et al., 2021), and **Text2Event** (Lu et al., 2021), we

also consider the following baselines focusing on the high-resource setting. **dbRNN** (Sha et al., 2018) is classification-based model that adds dependency bridges for event extraction. **DyGIE++** (Wadden et al., 2019) is a classification-based model with span graph propagation technique. **Joint3EE** (Nguyen and Nguyen, 2019) is a classification-based model jointly trained with annotations of entity, trigger, and argument. **MQAEE** (Li et al., 2020) converts EE to a series of question answering problems for argument extraction . **BART-Gen** (Li et al., 2021) is a generation-based model focusing on *only* event argument extraction.[3] Appendix D shows the implementation details for the baselines.

Results for event extraction. Table 3 shows the results of high-resource event extraction. In terms of trigger predictions (Tri-C), DEGREE and DEGREE(PIPE) outperforms all the baselines except for OneIE, the current state-of-the-art model. For argument predictions (Arg-C), our models have slightly better performance than OneIE in two out of the three datasets. When enough training examples are available, models can learn more sophisticated features from data, which do not necessarily follow the learned dependencies. Therefore, the advantage of DEGREE over DEGREE(PIPE) becomes less obvious. This result justifies our hypothesis that DEGREE has better performance for the *low-resource setting* because of its ability to better capture dependencies.

Model	10% Data		100% Data	
	Tri-I	Tri-C	Tri-I	Tri-C
Full DEGREE(ED)	**69.3**	**66.1**	**75.4**	**72.2**

- only Event type definition	66.3	63.5	72.6	68.9
- only Event keywords	69.2	63.8	70.8	66.2

Table 5: Ablation study for the components in the prompt on event detection with ACE05-E.

Results for event argument extraction. In Table 4, we additionally study the performance for event argument extraction task, where the model makes argument predictions *with the gold trigger provided*. Interestingly, DEGREE(EAE) achieves pretty strong performance and outperforms other baselines with a large margin. Combining the results in Table 3, we hypothesize that event argument extraction is a more challenging task than event trigger detection and it requires more training examples to learn well. Hence, our proposed model, which takes the advantage of using label semantics to better capture dependencies, achieves a new state-of-the-art for event argument extraction.

4 Ablation Studies

In this section, we present comprehensive ablation studies to justify our design. To better understand the contribution of each component in the designed prompt and their effects on the different tasks, we ablate DEGREE(EAE) and DEGREE(ED) for both low-resource and high-resource situations.

Impacts of components in prompts. Table 5 lists the performance changes when removing the components in the prompts for event detection on ACE05-E. The performance decreases whenever removing any one of event type definition, event keywords, and ED template. The results suggest that three components are all necessary.

Table 6 demonstrates how different components in prompts affect the performance of event argument extraction on ACE05-E. Removing

---

[3] We follow the original paper and use TAPKEY as their event detection model.

Model	10% Data		100% Data	
	Arg-I	Arg-C	Arg-I	Arg-C
Full DEGREE(EAE)	**63.3**	**57.3**	**76.0**	**73.5**

Table 6: Ablation study for the components in the prompt on event argument extraction with ACE05-E.

any one of event type definition, query trigger, and EAE template leads to performance drops, which validates their necessity. We observe that query trigger plays the most important role among the three and when less training data is given, the superiority of leveraging any of these weakly-supervised signal becomes more obvious.

Effects of different template designs. To verify the importance of using natural sentences as outputs, we study three variants of EAE templates:

- **Natural sentence.** Our proposed templates described in Section 2, e.g., "*somebody was born in somewhere.*", where *"somebody"* and *"somewhere"* are placeholders that can be replaced by the corresponding arguments.
- **Natural sentence with special tokens.** It is similar to the natural sentence one except for using role-specific special tokens instead of "some-" words. For example, "*<Person> was born in <Place>*." We consider this to study the *label semantics* of roles.
- **HTML-like sentence with special tokens.** To study the importance of using natural sentence, we also consider HTML-like sentence, e.g., "*<Person> </Person> <Place> </Place>*". The model aims to put argument predictions between the corresponding HTML tags.

The results of all variants of EAE templates on ACE05-E are shown in Table 7. We notice that writing templates in a natural language style get better performance, especially when only a few data is available (10% of data). This shows our design's capability to leverage pre-trained knowledge in the generation process. Additionally, there are over 1 F1 score performance drops when replacing natural language placeholders with special tokens. This confirms that leveraging label semantics for different roles is beneficial.

Model	10% Data		100% Data

DEGREE(EAE) + variant template 2	**63.9**	56.9	75.5	72.5

Table 8: Study on the effect of different template constructing rules. Experiments is conducted on ACE05-E.

Sensitivity to template design. Finally, we study how sensitive our model is to the template. In addition to the original design of templates for event argument extraction, we compose other two sets of templates with different constructing rules (e.g., different word choices and different orders of roles). Table 8 shows the results of using different sets of templates. We observe a performance fluctuation when using different templates, which indicates that the quality of templates does affect the performance to a certain degree. Therefore, we need to be cautious when designing templates. However, even though our model could be sensitive to the template design, it still outperforms OneIE and BART-Gen, which are the best classification-based model and the best generation-based baseline, respectively.

5 Related Work

Fully supervised event extraction. Event extraction has been studied for over a decade (Ahn, 2006; Ji and Grishman, 2008) and most traditional event extraction works follow the fully supervised setting (Nguyen et al., 2016; Sha et al., 2018; Nguyen and Nguyen, 2019; Yang et al., 2019b; Lin et al., 2020; Liu et al., 2020; Li et al., 2020). Many of them use classification-based models and use pipeline-style frameworks to extract events (Nguyen et al., 2016; Yang et al., 2019b; Wadden et al., 2019). To better leverage shared knowledge in event triggers and arguments, some works propose incorporating global features to jointly decide triggers and arguments (Lin et al., 2020; Li et al., 2013; Yang and Mitchell, 2016).

Recently, few generation-based event extraction models have been proposed (Paolini et al., 2021;

Huang et al., 2021, 2022; Li et al., 2021). TANL (Paolini et al., 2021) treats event extraction as translation tasks between augmented natural languages. Their predicted target—augmented language embed labels into the input passage via using brackets and vertical bar symbols. TempGen (Huang et al., 2021) is a template-based role-filler entity extraction model, which generate outputs that fill role entities into non-natural templated sequences. The output sequence designs of TANL and TempGen hinder the models from fully leveraging label semantics, unlike DEGREE that generates natural sentences. BART-Gen (Li et al., 2021) is also a generation-based model focusing on document-level event argument extraction. They solve event extraction with a pipeline, which prevents knowledge sharing across subtasks. All these fully supervised methods can achieve substantial performance with a large amount of annotated data. However, their designs are not specific for low-resource scenarios, hence, these models can not enjoy all the benefits that DEGREE obtains for low-resource event extraction at the same time, as we mentioned in Section 1.

Low-resource event extraction. It has been a growing interest in event extraction in a scenario with less data. Liu et al. (2020) uses a machine reading comprehension formulation to conduct event extraction in a low-resource regime. Text2Event (Lu et al., 2021), a sequence-to-structure generation paradigm, first presents events in a linearized format, and then trains a generative model to generate the linearized event sequence. Text2Event's unnatural output format hinders the model from fully leveraging pre-trained knowledge. Hence, their model falls short on the cases with only extremely low data being available (as shown in Section 3).

Another thread of works are using meta-learning to deal with the less label challenge (Deng et al., 2020; Shen et al., 2021; Cong et al., 2021). However, their methods can only be applied to event detection, which differs from our main focus on studying end-to-end event extraction.

6 Conclusion & Future Work

In this paper, we present DEGREE, a data-efficient generation-based event extraction model. DEGREE requires less training data because it better utilizes label semantics as well as weakly-supervised information, and captures better dependencies by jointly predicting triggers and arguments. Our experimental results and ablation studies show the superiority of DEGREE for low-resource event extraction.

DEGREE assumes that some weakly-supervised information (the description of events, similar keywords, and human-written templates) is accessible or not expensive for the users to craft. This assumption may holds for most situations. We leave the automation of template construction for future work, which can further ease the needed efforts when deploying DEGREE in a large-scale corpus.

Acknowledgments

We thank anonymous reviewers for their helpful feedback. We thank the UCLA PLUSLab and UCLA-NLP group members for their initial review and feedback for an earlier version of the paper. This work is supported in part by the Intelligence Advanced Research Projects Activity (IARPA), via Contract No. 2019-19051600007, and research awards sponsored by CISCO and Google.

Ethics Considerations

DEGREE fine-tunes the pre-trained generative language model (Lewis et al., 2020). Therefore, the generated output is potentially affected by the corpus for pre-training. Although with a low possibility, it is possible for our model to accidentally generate some malicious, counterfactual, and biased sentences, which may cause ethics concerns. We suggest carefully examining those potential issues before deploying the model in any real-world applications.

A EAE Template Constructing

Our strategy to create an EAE template is first identifying all valid argument roles for the event type,[4] such as *Attacker*, *Target*, *Instrument*, and *Place* roles. Then, for each argument role, according to the semantics of the role type, we select natural and fluent words to form its placeholder (e.g., some way for *Instrument*). This design aims to provide a simple way to help the model learn both the roles' label semantics and the *event structure*. Finally, we create a natural language sentence that connects all these placeholders. Notice that we try to keep the template as simple and short as possible. Table 9 lists all designed EAE templates for ACE05-E and ACE05-E$^+$. The EAE templates of ERE-EN can be found in Table 10.

B Training Details of Proposed Model

Given a passage, its annotated event types are consider as positive event types. During training, we additionally sample m event types that are not related to the passage as the negative examples, where m is a hyper-parameter. In our experiments, m is usually set to 13 or 15.

For all of DEGREE, DEGREE(ED), and DEGREE(EAE), we fine-tune the pre-trained BART-large (Lewis et al., 2020) with Huggingface package (Wolf et al., 2020). The number of parameters is around 406 millions. We train DEGREE with our machine that equips 128 AMD EPYC 7452 32-Core Processor, 4 NVIDIA A100 GPUs, and 792G RAM. We consider AdamW optimizer (Loshchilov and Hutter, 2019) with learning rate set to 10^{-5} and the weight decay set to 10^{-5}. We set the batch size to 6 for DEGREE(EAE) and 32 for DEGREE(ED) and DEGREE. The number of training epochs is 45. It takes around 2 hours, 18 hours, 22 hours to train DEGREE(EAE), DEGREE(ED), and DEGREE, respectively.

We do hyper-parameter search on m, the number of negative examples, from $\{3, 5, 7, 10, 13, 15, 18, 21\}$, and our preliminary trials shows that m less than 10 are usually less useful. For the learning rate and the weight decay, we tune it based on our preliminary experiment for event argument extraction from $\{10^{-5}, 10^{-4}\}$, while they are both fixed to 10^{-5} for all the experiments.

C Datasets

We consider ACE 2005[5] (Doddington et al., 2004) and ERE[6] (Song et al., 2015). Both consider *LDC User Agreement for Non-Members*[7] as the licenses. Both datasets are created for entity, relation, and event extraction while our focus is only event extraction in this paper. In the original ACE 2005 dataset, it contains data for English, Chinese, and Arabic and we only take the English data for our experiment. In the original ERE dataset, it contains data for English, and Chinese and we only take the English data for our experiment as well.

Because both datasets contain event like *Justice:Execute* and *Life:Die*, it is possible that some offensive words (e.g., killed) would appear in the passage. Also, some real names may appear in the passage as well (e.g., Palestinian president, Mahmoud Abbas). How to accurately identify these kinds of information is part of the goal of the task. Therefore, we do not take any changes on the datasets for protecting or anonymizing.

We split the training data based on documents, which is a more realistic setup compared to splitting data by instance. Table 11 lists the statistics of ACE05-E, ACE05-E$^+$, and ERE-EN. Specifically, we try to make each proportion of data contain as many event types as possible.

D Implementation Details

This section describes the implementation details for all baselines we use. We run the experiments with three different random seeds and report the best value.

- **DyGIE++**: we use their released pre-trained model[8] for evaluation.
- **OneIE**: we use their provided code[9] to train the model with default parameters.
- **BERT_QA**: we use their provided code[10] to train the model with default parameters.
- **TANL**: we use their provided code[11] to train the

---

[4] The valid roles for each event type are predefined in the event ontology for each dataset, or can be decided by the user of interest.

Table 11: Dataset statistics. Our experiments are conducted in sentences, which were split from documents. In the table, "#Docs" means the number of documents; "#Sents" means the number of sentences, "#Events" means the number of events; "#Event Types" means the number of event types in total; "#Args" means the number of argument in total; "#Arg Types" means the number of argument role types in total.

E Few-Shot and Zero-Shot Event Extraction

In order to further test our models' generaliability, we additionally conduct zero-shot and few-shot experiments on the ACE05-E dataset with DEGREE(ED) and DEGREE(EAE).

Settings. We first select the top n common event types as "seen" types and use the rest as "unseen/rare" types, where the top common types are listed in Table 12. To simulate a zero-shot scenario, we remove all events with "unseen/rare" types from the training data. To simulate a few-shot scenario, we keep only k event examples for each "unseen/rare" type (denoted as k-shot). During the evaluation, we calculate micro F1-scores only for these "unseen/rare" types.

n	Seen Event Types for Training/Development
5	Conflict:Attack, Movement:Transport, Life:Die, Contact:Meet, Personnel:Elect
10	Conflict:Attack, Movement:Transport, Life:Die, Contact:Meet, Personnel:Elect, Life:Injure, Personnel:End-Position, Justice:Trial-Hearing, Contact:Phone-Write, Transaction:Transfer-Money

Table 12: Common event types in ACE05-E.

Compared baselines. We consider the following baselines: (1) **BERT_QA** (Du and Cardie, 2020) (2) **OneIE** (Lin et al., 2020) (3) **Matching baseline**, a proposed baseline that makes trigger predictions by performing string matching between the input passage and the event keywords. (4) **Lemmatization baseline**, another proposed baseline that performs string matching on lemmatized input passage and the event keywords. (Note: (3) and (4) are baselines only for event detection tasks.)

Experimental results. Figure 4, Table 13, and Table 14 show the results of $n = 5$ and $n = 10$. From the two subfigures in the left column, we see that DEGREE(ED) achieves promising results in the zero-shot setting. In fact, it performs better than BERT_QA trained in the 10-shot setting and OneIE trained in the 5-shot setting. This demonstrates the great potential of DEGREE(ED) to discover new event types. Interestingly, we observe that our two proposed baselines perform surprisingly well, suggesting that the trigger annotations in ACE05-E are actually not diverse. Despite their impressive performance, DEGREE(ED) still outperforms the matching baseline by over 4.7% absolute trigger classification F1 in both $n = 5$ and $n = 10$ cases in zero-shot scenario. Additionally, with only one training instance for each unseen type, DEGREE(ED) can outperform both proposed baselines.

Next, we compare the results for the event argument extraction task. From the two middle subfigures, we observe that when given gold triggers, our model performs much better than all baselines with a large margin. Lastly, we train models for both trigger and argument extraction and report the final argument classification scores in the two right subfigures. We justify that our model has strong generalizability to unseen event types and it can outperform BERT_QA and OneIE even when they are both trained in 5-shot settings.

Abstract

Large-scale cross-lingual pre-trained language models (xPLMs) have shown effectiveness in cross-lingual sequence labeling tasks (xSL), such as cross-lingual machine reading comprehension (xMRC) by transferring knowledge from a high-resource language to low-resource languages. Despite the great success, we draw an empirical observation that there is a training objective gap between pre-training and fine-tuning stages: e.g., mask language modeling objective requires *local* understanding of the masked token and the span-extraction objective requires *global* understanding and reasoning of the input passage/paragraph and question, leading to the discrepancy between pre-training and xMRC. In this paper, we first design a pre-training task tailored for xSL named Cross-lingual Language Informative Span Masking (CLISM) to eliminate the objective gap in a self-supervised manner. Second, we present ContrAstive-Consistency Regularization (CACR), which utilizes contrastive learning to encourage the consistency between representations of input parallel sequences via unsupervised cross-lingual instance-wise training signals during pre-training. By these means, our methods not only bridge the gap between pretrain-finetune, but also enhance PLMs to better capture the alignment between different languages. Extensive experiments prove that our method achieves clearly superior results on multiple xSL benchmarks with limited pre-training data. Our methods also surpass the previous state-of-the-art methods by a large margin in few-shot data settings, where only a few hundred training examples are available.

1 Introduction

Sequence labeling (SL) tasks are common conditions and have considerable impact in natural language processing communities, such as named entity recognition (NER) (Lample et al., 2016), and machine reading comprehension (MRC) (Hermann et al., 2015; He et al., 2018; Asai et al., 2018; Yuan et al., 2020; You et al., 2020b; You et al.), to name a few. For instance, MRC models are required to predict whether each token in the input passage is the start or end position of the ground-truth answer span given a pre-defined question. Many promising results have been achieved using deep-learning based methods (Seo et al., 2017; Liang et al., 2021b) on popular benchmarks (Rajpurkar et al., 2016, 2018; Reddy et al., 2019; You et al., 2020a). Recently, there is a growing body of literature that recognizes the importance of cross-lingual sequence labeling tasks (xSL for short) (Huang et al., 2019; Lewis et al., 2020; Artetxe et al., 2019a), where translation systems are utilized to translate high-resource languages into low-resource languages so as to enrich the training data. However, the performance of xSL models is severely affected by translation quality (Yuan et al., 2020; Liang et al., 2021a).

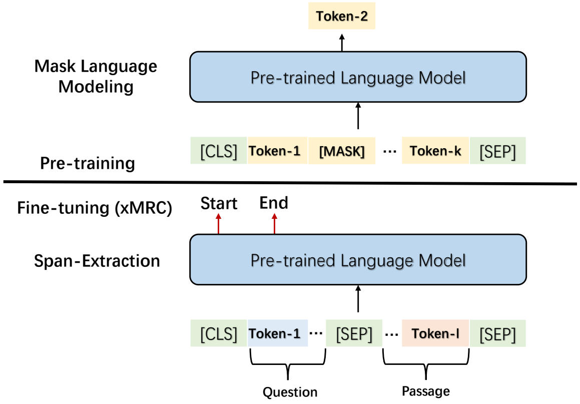

Figure 1: Mask language modeling objective in the pre-training stage and span-extraction objective of xMRC in the fine-tuning stage.

Recently, thanks to multilingual pre-trained language models (xPLMs) (Huang et al., 2019; Liang et al., 2020; Conneau et al., 2019; Chi et al., 2021a) pre-trained on large multilingual corpus (billion-level), the pre-training + fine-tuning paradigm

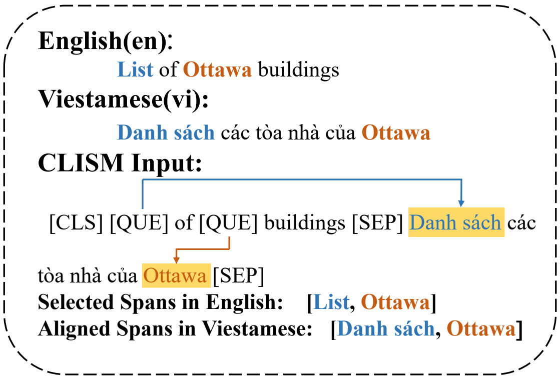

Figure 2: The example of our proposed CLISM. Here we present the input sequence in English and Vietnamese. Selected spans in English are from off-the-shelf NER tools like Spacy and the corresponding aligned spans in Vietnamese obtained by GIZA++ toolkit (Pei et al., 2020).

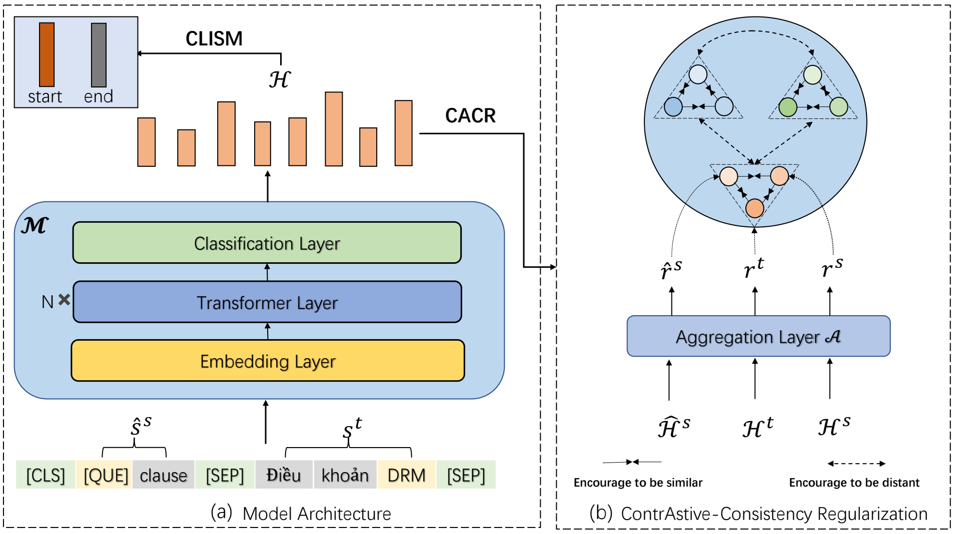
starts dominating various cross-lingual understanding tasks including entity recognition (Liang et al., 2021a,b) and question answering (Asai et al., 2018; Chen et al., 2021b). Even if in zero-shot or few-shot settings, these effective xPLMs still achieve remarkable improvements during fine-tuning via transfer learning. Despite the promising results in such settings, there is an objective gap between pre-training and fine-tuning for xSL tasks. Take the xMRC task as an example. During pre-training, PLMs are always trained with mask language modeling (MLM) (Devlin et al., 2018; Lan et al., 2020), Next Sentence Prediction (NSP) (Pires et al., 2019; Conneau et al., 2019) or translation replaced token detection (TRTD) (Chi et al., 2021c) tasks. Subsequently, these state-of-the-art models are typically trained for span extraction using distantly supervised multilingual task-related examples during fine-tuning. This is somewhat expected, since *local* context understanding around the mask token is mainly needed to perform pre-training tasks like MLM or TRTD, while span-extraction MRC requires the model to understand the interaction between question and *global* context of passage, as shown in Figure 1. Suffering from different objectives, the performance of the model inevitably deteriorates (Jiao et al., 2021; Ram et al., 2021).

Motivated by these factors, we first design a cross-lingual language-informative span masking (CLISM) task for bridging the gap between pre-training and fine-tuning in the context of xSL, which can be seen as a question answering task. A primary concern of such a self-supervised task is how to create corresponding multilingual <question, answer> training pairs. Concretely, we group the parallel corpus into several sub-groups. Each sub-group is called a language-informative group and contains the same sentence in two different languages, a source language and a target language. Considering aligned spans in the cross-lingual parallel sentences can be seen as a signal for coreference and lead to information short-cut (Jiao et al., 2021). Subsequently, we mask n-grams (e.g., named entities) spans which occur in a given source language sentence, and then we take the *masked* sentence and the unmasked counterpart in target language as input. Thus, we form question answering by masking all selected spans with a special token `[QUE]`, and requiring the model to find the correct start and end positions for each of such tokens based on understanding global context of the sentence in source and target languages, as shown in Figure 2. Correspondingly, each `[QUE]` is regarded as a *question*, and its corresponding span in the target language sentence that is unmasked acts as the *answer*. With this strategy, the model needs to predict whether each token is the answer start or end index, which is essentially consistent with xSL tasks (Ram et al., 2021). Hence the training objectives are connected, and thus, cross-lingual PLMs can be more adequate for xSL.

Considering to better capture the alignment between the same content in different languages and avoid learning representations that are covariant with the noisy parallel input (e.g., `[QUE]` and `[MASK]`), we also design a strategy called ContrAstive-Consistency Regularization (CACR) during pre-training. Our core idea behind CACR is to push representations of the same sequence in various languages to be similar, while pushing it away from other examples via contrastive learning (You et al., 2022, 2021c). The overview of our architecture is presented in Figure 3.

The resulting language model exhibits surprising performances in multiple xSL benchmarks, such as xMRC and xNER. Of note, compared with other new state-of-the-art xPLMs such as Info-XLM and XLM-Align which utilize billion-level pre-training data, our model pre-trained with limited data e.g., 1 million achieve better performances across various datasets. As an additional benefit of our methods, our model also achieves superior performances given a few training instances. For example, ours achieve 35.9%/50.8% EM/F1 score



(a) Model Architecture

(b) ContrAstive-Consistency Regularization

Figure 3: Model Architecture: In this example, we choose English (en) as our source language and Vietnamese (vi) as our target language, separately. In the input sequence, the original sentence in English is "DRM clause", "DRM" is the selected span. We mask "DRM" with the special token `[QUE]`. Then the designed CLISM is required the model to predict the start and end positions of the correct answer for `[QUE]` ("DRM" in target language).

with only 512 examples on MLQA dataset, outperforming all baselines by a very wide margin (vs. 15.5%/26.8%).

In general, we make the following technical contributions in this paper:

- We present a new cross-lingual pre-training paradigm named CLISM to bridge the training objective gap between language models and cross-lingual sequence labeling tasks.
- We design a novel pre-training strategy termed CACR, which encourages xPLMs to better capture alignment between cross-lingual representations.
- The resulting models achieve state-of-the-art performances with limited parallel pre-training data on multiple xSL benchmarks. Moreover, we demonstrate that our method also shows significant improvements in few shot data settings during fine-tuning.

2 Related Work

Pre-trained Language Models During the past few years, PLMs (Devlin et al., 2018; Liu et al., 2019; Lan et al., 2020; Sun et al., 2020) dominate natural language understanding and generating areas due to their promising results in various downstream tasks. Taking a step forward a more real world, there is a growing body of communities extent PLMs to multi-lingual language (xPLMs), and some representative works have been done such as XLM-R (Conneau et al., 2019) (short for XLM-Roberta), info-XLM (Chi et al., 2021a) and XLM-Align (Chi et al., 2021b). Almost these efforts trained with *token-level* pre-training tasks on large multi-lingual corpus. Directly utilizing xPLMs lead high performances in the fine-tuning stage, but when transferred to downstream tasks can result the objective gap between pretrain-finetune, making xPLMs sub-optimized in downstream tasks especially for xSL (Jiao et al., 2021; Ram et al., 2021). Our proposed CLISM and CACR not only alleviate the pretrain-finetune discrepancy, but also strong the ability of xPLMs to capture alignment between cross-lingual representations in sentence-level.

Sequence Labeling Sequence Labeling tasks are of great significance in web mining, such as named entity recognition (Shen et al., 2021; Cui et al., 2021), relation identification (Akhmouch et al., 2021), event extraction (Lu et al., 2021; Lyu et al., 2021), and even machine reading comprehension (Wu et al., 2021; Chen et al., 2021a; You et al., 2021a,b; Chen et al., 2021c). However, when pushing the boundary of SL to low-resource languages, xSL can be very challenging, due to limited training data. To tackle this challenge, various efforts have been proposed (Huang et al., 2019; Liang et al., 2020; Conneau et al., 2019; Liang et al., 2021a). Cui et al. (2019) and Singh et al. (2019) utilized machine translation to get parallel data as the data argumentation method. But the performance of these methods are restricted to the quality of translation. Hence, Yuan et al. (2020) proposed to generate low-resource language weakly labeled data from Wikipedia articles. Similarly, we also collect pre-training parallel data for CLISM from web sources. We tackle the objective gap between language models and xSL tasks, an challenge overlooked by the previous methods.

Recent Works Currently, several studies have explored to bridge the gap between pre-training and fine-tuning, including two main categories: (1) *knowledge-driven*, which introduces external commonsense knowledge into the pre-training for improving model performance in down-stream tasks (Varkel and Globerson, 2020; Sun et al., 2020), (2) The latter is *task-oriented*, which includes several well designed pre-training or fine-tuning tasks (Jiao et al., 2021; Deng et al., 2021). However, none of these works target cross-lingual areas, especially for xSL tasks. Recently, concurrent with our research, Ram et al. (2021) studied aligning the pre-training and fine-tuning stages in the context of question answering via introducing a novel pre-training task. Nevertheless, Ram et al. (2021) focused on few-shot question answering, and didn't explore the relation between different languages.

3 Methodology

In this section, we first illustrate our two pre-training strategies: CLISM and CACR in detail. Then we introduce how to apply our methods in down-stream tasks to obtain high performances. Due to the excellent versatility of our proposed methods, which can build on top of any xPLMs. Hence, we leverage $\mathcal{M}$ to represent a series of pre-trained language models. Our goal aims at aiding $\mathcal{M}$ to eliminate the influence of objective gap between pretrain-finetune, and enhancing the consistency between parallel data representations.

3.1 Cross-lingual Language Informative Span Masking

Definition Heading for bridging the objective gap between pre-training and fine-tuning in xSL, we formulate a new pre-training task named Cross-lingual Language Informative Span Masking (CLISM) from the unlabeled data. Given an input sentence $\mathbf{s}^s$ in source language and its counterpart in the target language $\mathbf{s}^t$. We first utilize name entity recognition tools like Spacy to select entities[1] in source language. Considering the translation of the same phrase may be different when pushing it into translation systems separately or concat it with a whole sentence. Therefore, we leverage the off-the-shelf alignment tool like GIZA++ (Pei et al., 2020) to align the corresponding words of the selected entity in the target language. After extracting entity spans and alignment[2], we replace these selected spans with a special token `[QUE]` in source language sentence $\mathbf{s}^s$, and the corresponding alignment spans in $\mathbf{s}^t$ act as the“ground-truth answer" span for each masked "question" (`[QUE]`). For instance, as the example presented in the Figure 3 (a), the span “DRM" is the selected span, we replace it in source language with `[QUE]` and utilize the aligned span “DRM" in target language as the correct answer.

Pre-training After getting identical language-informative spans $\mathcal{S}$ in $\mathbf{s}^s$, where each of $\mathcal{S}$ is replaced with a single `[QUE]` token `Q`. Hence, we can get the final input sequence $\mathbf{X}$ via concatenating the masked source language sentence $\hat{\mathbf{s}}^s$ and unmasked target language sentence $\mathbf{s}^t$ with two special tokens `[SEP]` and `[CLS]`, as shown in Figure 3 (a). Concretely, the goal of CLISM can be seen as to predict the correct answer (corresponding aligned span in $\mathbf{s}^t$) for a given $\mathtt{Q} \in \mathcal{S}$ based on understanding the meaning of input $\mathbf{X}$. Subsequently, our method converts unlabeled text into a set of specific questions that need to be answered simultaneously. Thus, in order to find the correct answer span of each `Q`, we pass $\mathbf{X}$ through $\mathcal{M}$, producing contextualized representations for each token, and then use the representation of `Q` to compute dynamic start and end vectors $\mathbf{s}_q$, $\mathbf{e}_q$:

$$\mathbf{s}_q = \mathbf{W}_s \mathbf{x}_q \qquad \mathbf{e}_q = \mathbf{W}_e \mathbf{x}_q \tag{1}$$

where $\mathbf{W}_s$ and $\mathbf{W}_e$ are learnable parameters and $\mathbf{x}_q$ denotes the representation of `Q`. Subsequently. we follow the standard span-extraction setting (Huang et al., 2019) to obtain the start and end position probability distributions via computing the inner product of learned vectors $\mathbf{s}_q$, $\mathbf{e}_q$ with each token representation in $\mathbf{X}$:

---

[1] If the extracted entities of one sentence is none, we will remove it.

[2] We further conduct informative span selection strategy, reducing the bias of the extracted entities. Details can be seen in the Appendix B.

$$\mathcal{P}(s=k|\mathbf{X},\texttt{Q}) = \frac{\texttt{exp}(\mathbf{x}_k^T\mathbf{s}_q)}{\sum_j \texttt{exp}(\mathbf{x}_j^T\mathbf{s}_q)} \tag{2}$$

$$\mathcal{P}(e=k|\mathbf{X},\texttt{Q}) = \frac{\texttt{exp}(\mathbf{x}_k^T\mathbf{e}_q)}{\sum_j \texttt{exp}(\mathbf{x}_j^T\mathbf{e}_q)} \tag{3}$$

Finally, we optimize the model via standard cross-entropy loss:

$$\mathcal{L}_{clism} = -\texttt{log}\mathcal{P}(s=a_i^s|\mathbf{X}) - \texttt{log}\mathcal{P}(e=a_i^e|\mathbf{X}) \tag{4}$$

where a_i denotes the aligned span of i-th $\texttt{Q}$ in $\mathcal{S}$. Thus, the capability of evidence extraction across different languages is enhanced during pre-training, and will be smoothly transferred to xSL during fine-tuning.

3.2 ContrAstive-Consistency Regularization

We design CACR from two points of view: (1) Misalignment between parallel sequences representations still hinders xPLMs advancing in downstream tasks, (2) prior works tend to learn corrupted representations (e.g., `[MASK]` token) which are covariant with the noise during pre-training (Luo et al., 2021). In contrast, our CACR aims at not only aiding $\mathcal{M}$ in learning noise invariant representations during pre-training, but also promoting $\mathcal{M}$ to better capture alignment between representations of parallel input sequences. Therefore, the proposed CACR could support CLISM to better optimize $\mathcal{M}$ during pre-training.

Definition Aforementioned, the input sequence $\mathbf{X} = \{\texttt{[CLS]}\hat{\mathbf{s}}^s\texttt{[SEP]}\mathbf{s}^t\texttt{[SEP]}\}$. We then take $\mathbf{X}$ as input to get the contextual representations of sentences:

$$\mathcal{H} = [\mathcal{H}_{cls}, \hat{\mathcal{H}}^s, \mathcal{H}^t, \mathcal{H}_{sep}] = \mathcal{M}(\mathbf{X}) \tag{5}$$

where $\mathcal{H} \in \mathbf{R}^{l\times d}$, l and d are the max input sequence length and hidden size, separately. $\hat{\mathcal{H}}^s \in \mathbf{R}^{n\times d}, \mathcal{H}^t \in \mathbf{R}^{m\times d}$ denote the representations of $\hat{\mathbf{s}}^s$ and $\mathbf{s}^t$. Also m and n represent the sequence length of $\hat{\mathbf{s}}^s$ and $\mathbf{s}^t$. Note that we can not directly utilize $\hat{\mathcal{H}}^s$ and $\mathcal{H}^t$ as the input of our CACR because of the mismatch between m and n. Thereafter, we apply an extra aggregation layer (e.g., mean-pooling) $\mathcal{A}$ to obtain final global semantics of $\hat{\mathbf{s}}^s$ and $\mathbf{s}^t$:

$$\hat{\mathbf{r}^s} = \mathcal{A}(\hat{\mathcal{H}}^s) \qquad \mathbf{r}^t = \mathcal{A}(\mathcal{H}^t) \tag{6}$$

where $\hat{\mathbf{r}^s}$ and $\mathbf{r}^t$ belong to $\mathbf{R}^d$. Intuitively, the most simple implement of our CACR is to regard $\hat{\mathbf{r}^s}$ and $\mathbf{r}^t$ as positives and others in mini-batch are negatives to optimize the $\mathcal{M}$ via a standard contrastive objective (Hjelm et al., 2019):

$$\mathcal{L}(\mathbf{r}^t,\hat{\mathbf{r}^s}) = -\texttt{log}\frac{\texttt{exp}(\Psi(\mathbf{r}^t,\hat{\mathbf{r}^s})/\tau)}{\sum_{j=1}^{B}\texttt{exp}(\Psi(\mathbf{r}^t,\mathbf{r}_j)/\tau)} \tag{7}$$

where B and τ are mini-batch and temperature, $\Psi(,)$ denotes the cosine similarity function. Nevertheless, considering $\hat{\mathbf{s}}^s$ is the corrupted input, which contains the `[QUE]` token. Inspired by (Luo et al., 2021), optimizing our $\mathcal{M}$ only with Eq.7 may lead the model to learn representations that are covariant with the noise text, causing incorrectly represented alignment between source language and target language. Therefore, we further introduce the original unmasked sentence in source language $\mathbf{s}^s$ as input. Similarly, the pre-trained model $\mathcal{M}$ encodes $\mathbf{s}^s$ to obtain the hidden representation $\mathcal{H}^s$. Also the designed aggregation layer $\mathcal{A}$ is responsible for getting the final semantic representation $\mathbf{r}^s$. Thereafter, the positive threefold is collected: $\{\mathbf{r}^s, \mathbf{r}^t, \hat{\mathbf{r}^s}\}$. Each representation in this set is regarded as positive, that is, we expect each two of them should be similar as possible in the latent space. By these means, $\mathcal{M}$ is encouraged to learn noise-invariant representations and better capture cross-lingual representations alignment, alleviating pretrain-finetune discrepancy to some extent, as shown in Figure 3 (b). The final loss of our CACR can be formulated as:

$$\mathcal{L}_{cacr} = \mathcal{L}(\mathbf{r}^t,\hat{\mathbf{r}^s}) + \mathcal{L}(\mathbf{r}^s,\hat{\mathbf{r}^s}) + \mathcal{L}(\mathbf{r}^t,\mathbf{r}^s) \tag{8}$$

3.3 Pre-training Strategy

To be consistent with previous methods (Liu et al., 2019; Chi et al., 2021a), we also pre-train $\mathcal{M}$ with the mask language modeling (MLM) training objective. In detail, we train the model in multi-task setting during pre-training. The total objective of our model can be defined as:

$$\mathcal{L} = \mathcal{L}_{clism} + \mathcal{L}_{cacr} + \mathcal{L}_{mlm} \tag{9}$$

3.4 Fine-tuning

Inspired by (Ram et al., 2021), to be consistent with our proposed pre-training strategies, we also leverage the special token used in pre-training stage for downstream tasks. In other words, we append the `[QUE]` token to the input sequence during fine-tuning. Extensive results show this strategy achieve

Data	<en,ar>	<en,hi>	<en,vi>	Total
	0.4M	0.3M	0.3M	1M

Table 1: Sentence number we used in pre-training.

better performances in xSL tasks, especially in few-shot data setting. For example, we can get the following input sequence in xMRC task with adding `[QUE]` after the input question. :

$$\bar{\mathbf{X}} = \{\texttt{[CLS]}\,\mathbf{Q}\,\texttt{[QUE]}\,\texttt{[SEP]}\,\mathbf{P}\,\texttt{[SEP]}\} \quad (10)$$

where $\mathbf{Q}$ and $\mathbf{P}$ denote the input question and passage. Due to `[QUE]` token acts as a question during our pre-training. Hence after pre-training, we expect it captures enough information about the question, and thus, we utilize the representation of `[QUE]` to select the ground-truth answer span in xMRC task. The following process is the same as Section 3.1.

4 Experiments

In this section, we first present the pre-training data collection. Then we illustrate experiments on xSL tasks, including specific implementation and detailed results.

4.1 Pre-training Data

Aforementioned, our proposed CLISM and CACR require parallel data. Therefore we utilize MT dataset (Conneau and Lample, 2019) to construct our input sequences. In detail, we only utilize four languages including English(en), Arabic(ar), Vietamese(vi) and Hindi(hi) from MT dataset to train our model, proving our method also achieves great improvements in other languages which we don't obtain any data. Concretely, the inputs of our model consist of two languages: source language and target language. Considering the promising performance of off-the-shelf NER tools (e.g., Spacy) in English, thus we choose English as our source language and another three languages are regarded as the target language in turn. Thereafter, the number of our pre-training data is reported at Table 1, the total amount data is 1 million.

4.2 Training Details

Model Structure We initialize the parameters of our model from XLM-R and Info-XLM base version published in Hugging Face Transformers[3], showing the generalization of our methods. Hence, the resulting model $\mathcal{M}$ contains 12 transformer layers and hidden state is set to 768.

Pre-training Details In our implementation of MLM, we follow the setting in (Devlin et al., 2018), which randomly mask 15% tokens of the input sequence[4]. We optimize our model with the Adam optimizer, using batch size of 64 for a total of 15K steps in pre-training. And learning rate is set to 1e-5 with 1.5K warmup steps. The total max input sequence length is set to 256, that is, the max length of each sentence is set to 128. Notice that τ in Eq.7 is set to 20. We pre-train our model using 8×V100-32G GPUs for 4-5 hours. Fine-tuning details can be seen in the Appendix C.

4.3 Evaluation

We conduct experiments over two xSL tasks: xMRC and xNER including four datasets: MLQA (Lewis et al., 2020), XQUAD (Artetxe et al., 2019b), CoNLL (Sang, 2002) and WikiAnn (Pan et al., 2017). Detailed introduction about these datasets presented in the Appendix D.

For all datasets, we fine-tune our model in *zero-shot* setting, which denotes we only utilize the English training set to optimize the model, and test the resulting model on other target languages.

For xMRC task, we use two evaluation metrics, Exact Match (EM) and span-level F1 score , which are popularly used for accuracy evaluation of MRC models. Span-level F1 measures the span overlap between ground-truth answer and model predictions. Exact match (EM) score is 1 if the prediction is exactly the same as the ground truth, otherwise 0. As for xNER task, we use entity-level F1 score to evaluate our model, which requires the boundary and type between the prediction and the ground-truth entity should be matched precisely.

4.4 Experiment Results

Baselines We compare our model with the following pre-trained baselines: (1) M-BERT (Devlin et al., 2018) pre-trained with MLM task on Wikipedia data in 102 languages; (2) XLM (Conneau and Lample, 2019), another multilingual PLM pre-trained with MLM and TLM tasks in 100 languages; (3) XLM-R (Conneau et al., 2019), a strong effective xPLM pre-trained with MLM in more large corpus; (4) Info-XLM (Chi et al., 2021a),

---

[4] The pre-defined answers in CLISM will not be masked to avoid missing labels.

Models	#data	#languages	MLQA	XQUAD	CoNLL	WikiAnn
M-BERT	-	102	57.80/42.40	69.63/53.72	78.2	69.1
XLM	-	100	61.70/44.20	70.93/53.18	79	69.5
CalibreNet	-	-	65.40/48.84	-	80.92	-
Chen et al. (2021b)	-	-	66.00/48.88	75.06/59.87	-	-
XLM-R	-	-	64.14/46.00	73.54/57.55	78.48	70.28
Info-XLM*	130M	94	65.85/48.23	75.79/59.50	79.52	72.23
XLM-Align*	130M	94	65.66/48.47	75.35/59.10	78.87	72.66
Ours (XLM-R)*	1M	4	67.34/49.11	76.73/60.87	80.63	73.31
Ours (Info-XLM)	1M	4	**69.07/50.81**	**78.22/61.99**	**81.13**	**73.87**

Table 2: Average evaluation results on four datasets. #data denotes the amount of pre-training data. #languages represents the language diversities in pre-training data. The results of our model are averaged over 5 runs. * denotes the model build upon of XLM-R. The results of each language are represented in the Appendix E.

a recent xPLM which continues training XLM-R with MLM, TLM and XLCO in 94 languages; (5) XLM-Align (Chi et al., 2021b), a more recent but effective xPLM, also built on top of XLM-R with MLM and DWA in 94 languages. Besides, we also utilize strong baselines which are specifically designed for xSL tasks: (1) CalibreNet (Liang et al., 2021b) designed for enhancing the boundary detection of xPLMs in xSL tasks; (2) AA-CL (Chen et al., 2021b), a more recent approach to construct hard-negatives via contrastive learning for xMRC. Note that, we reimplement the base version of these baselines in our local environment with 3 times and report the average results of baselines.

We represent two main results in *full-data* setting and *few-shot data* setting. That is, our model utilizes all data in training set to train the model in *full-data* setting. In contrast, the model is fine-tuned with smaller training sets in *few-shot data* setting.

xMRC Results Table 2 shows the comparison between our approach and representative systems on four datasets. Specifically, our models surpass these baselines by a large margin on two xMRC datasets. For examples, our model initialized from Info-XLM achieve 69.07%/50.81% (vs. 65.85%/48.23%) in terms of F1/EM score. Compared with Info-XLM or XLM-Align, which both build on top of XLM-R with 130 million data across 94 languages, our model initialized from XLM-R obtains better performances like 67.34%/48.91% (vs. 65.85%/48.23%) on MLQA dataset. It is worthwhile to indicate that our model only pre-tained with 1 million parallel data across 4 languages. The results bear out the effectiveness of our proposed methods even if with limited pre-training data across several languages (1M≪130M).

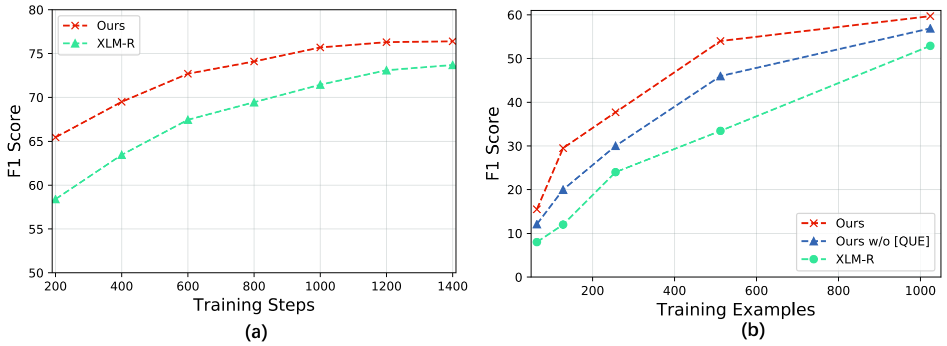
Also when looked into the Table 3, our models dramatically improve performances in the more challenging *few-shot data* setting. Given a small training set with only 512 examples, our model built on top of XLM-R improve the baseline by 24%/20.4% and 20.59%/18% in terms of F1/EM score on both two datasets. The results show that our method presents a new paradigm for xSL tasks in *few-shot data* setting.

xNER Results As presented in Table 2, first compared with baseline XLM-R, our resulting model on top of XLM-R achieves an average F1 score gain of 1.15% and 3.03%. Then compared with Info-XLM and XLM-Align on top of XLM-R which pre-trained on 130 million large corpus across 94 languages, ours still show superior performances. That is, with less than one percent of the corpus they used, our approach has shown its full potential.

5 Ablation Study and Analysis

In this section, we first discuss the importance of each key component in our model. Then we conduct an analysis of alleviating pretrain-finetune discrepancy by ours and independent contribution of the proposed CLISM at *few-shot data* seting. We further analyse the relation between pre-trainig data and our methods in the Appendix G.

Key components We perform an ablation study to better understand the independent contributions



(a) (b)

Figure 4: (a): Average F1 score of both Ours and base architecture XLM-R on the XQUAD test set at different training steps. (b): Average F1 score of all methods with giving different few-shot training examples on the XQUAD test set. It is worthwhile to notice that ours denotes the resulting model build on top of XLM-R in these experiments.

Models	MLQA	XQUAD
64 examples		
XLM-R	6/1.5	8/2
Info-XLM	7/3.2	8.7/5.1
Ours (XLM-R)	**14/7.2**	**15.5/8.2**
128 examples		
XLM-R	10/3.5	12/4
Info-XLM	11.4/4.5	15.7/7
Ours (XLM-R)	**26.4/15.9**	**29.5/19.7**
512 examples		
XLM-R	26.8/15.5	33.35/19.1
Info-XLM	29.7/18.9	36.0/21.0
Ours (XLM-R)	**50.8/35.9**	**53.94/37.1**

Table 3: Model performances across xMRC datasets when the number of training examples is 64, 128 and 512. The more comprehensive results in few-shot data setting are described in Appendix F.

Algorithms	MLQA	XQUAD
Ours (XLM-R)	**67.34/49.11**	**76.73/60.87**
w/o CLISM	64.56/46.80	74.34/58.43
w/o CACR	66.40/48.01	75.87/59.95
w/o MLM	66.18/47.89	75.34/59.61

Table 4: Ablation study of pre-training schemes.

of the proposed pre-training schemes. Table 4 shows the performances when removing each key component of our model on MLQA and XQUAD datasets. Obviously, when removing CLISM, the model performances drop dramatically in both two datasets, showing the effectiveness of the proposed pre-training task. Meanwhile, we observe that with CACR or MLM also giving performance improvement, proving each of them plays an important role in our pre-training scheme.

Analysis of alleviating pretrain-finetune discrepancy We conduct extra experiments to verify the proposed methods whether alleviate the pretrain-finetune discrepancy in cross-lingual sequence labeling tasks. As shown in the Figure 4 (a), in the early stage of training, ours manages to maintain an absolute lead of 5%-15% on F1 score over XLM-R consistently, showing the resulting model not only speed the fine-tuning time but also achieve superior performances. This demonstrates representations learned by ours are more suitable for data distribution in xSL tasks, leading to better performance.

Independent Contribution of CLISM Moreover, in order to understand the independent contribution of the proposed CLISM at few-shot data setting. Figure 4 (b) gives the performance of individual models when giving $\{64, 128, 256, 512, 1024\}$ examples. It is evident that our model outperforms baseline by large margins. Interestingly, we conduct the following experiments to verify effectiveness of using the `[QUE]` token during fine-tuning: We don't append `[QUE]` in the input sequence when fine-tuning our model in down-stream tasks, and thus, we can not utilize its representation as *question*. Thereafter, we follow the standard setting (Liang et al., 2021a; Chen et al., 2021b) to fine-tune ours in xSL tasks. Nevertheless, as shown in the 4 (b), the model performance drops heavily especially at smaller training data setting, such as 64, 128 examples. We interpret this phenomenon as follows: After pre-training, the `[QUE]` token captures much information about question that can be used to select the span from context in xSL tasks.

6 Conclusion

In this paper, heading for bridging the discrepancy including the objective and representation gap between pre-training and fine-tuning stages in cross-lingual sequence labeling tasks. We propose two pre-training strategies: cross-lingual language informative span masking (CLISM) and ContrAstive-Consistency Regularization (CACR), reaching surprisingly superior results on various benchmarks even when only a hundred examples available. We further prove that even with less than a hundredth of the data needed to train other xPLMs, our model still achieves better performances. As an extension of our future work, we will explore how to apply our methods to other nlp tasks.

Appendix

A Broader Impacts

The main contributions of this paper are towards tackling fundamental issue during pre-training and fine-tuning in xSL tasks when leveraging pre-trained language models. The proposed method alleviates the discrepancy between pretrain-finetune paradigm, and thus improving the results of xPLMs in these tasks. Therefore, ideas of this paper can be applied in xPLM-based application systems such as cross-lingual question answering systems or robots. More generally, we expect the core idea of this paper can give insights of other research communities who want to build a more robust and effective xPLM-based model in their down-stream tasks. Admittedly, the proposed strategies are restricted with cross-lingual sequence labeling tasks, and biases in training dataset also influence the performance of the resulting model. These concerns warrant further research and consideration when utilizing this work to build cross-lingual application systems.

B Informative Span Selection

As illustrated in the paper Section 3.1, it is essential to select semantically meaningful spans before pre-training. And some extracted entities could be unreasonable due to the performance limit of off-the-shelf NER tools. Hence, we make several rules to filer out some recurring spans which tend to be uninformative:

- Spans which only consist of stop words will be filtered out.
- The boundary of spans must be the words.
- The max sequence length of each span is limited to 10.

.

C Fine-tuning Settings

Fine-tuning Details We train our model on two xSL tasks: xMRC and xNER. For both two tasks, we utilize Adam optimizer to train the model and batch size is set to 32. For xMRC, the learning rate is 3e-5, the maximum sequence length is set to 384. We train our model using 8×V100-32G GPUs with 5 epochs for fine-tuning. For xNER, the learning rate is set to 5e-5, the max length is 128. It takes 5 epochs with using 8×V100-32G GPUs to get the best checkpoint of our model.

Few-shot Data Details We also conduct few-shot data experiments on downstream datasets in xMRC. For each, dataset, we random sample few-shot training datasets from the original full-data sets, with the sampling size $\{64, 128, 256, 512, 1024\}$. To reduce variance, for each few-shot training dataset size, we random sample 5 times with different seeds, and report average results. When training our model on few-shot datasets, we choose 200 steps for optimizing the resulting model.

D xSL datasets

Cross-Lingual Machine Reading Comprehension MLQA and XQUAD are two popular xMRC benchmarks, which provide train dataset in English and test datasets in multiple low-resouce language. In this work, we evaluate our methods on six languages: including *English, Arabic, German, Spanish, Hindi, Vietnamese*.

Cross-lingual Name Entity Recognition CoNLL and WikiAnn are common xNER benchmarks. All of those datasets are annotated with 4 types of entities, namely PER, LOC, ORG and MISC in BIO tagging schema following (Pan et al., 2017). Of note, CoNLL and WikiAnn both contain four language test sets: *Spanish, Dutch, English, German*. Besides, WikiAnn additional consists of another two language test sets: *Hindi, Arabic*

E Detailed Results on cross-lingual sequence labeling tasks

G Pre-training data for CLISM

In this component, we further conduct extensive experiments to explore the relation between pre-training data and model performances. As shown in Figure 5, we present the resulting model performances on xMRC datasets with different number of pre-training data: $\{1M, 2M, 4M, 8M, 12M\}$. Obviously, ours achieve best results given 1 million pre-training data. With the amount of pre-training data increased, the performances drop gradually due to overfitting. The results prove the effectiveness of our proposed pre-training paradigm, that is, our methods could optimize the xPLMs sufficiently even if with limited pre-training data.

Abstract

Named entity recognition (NER) is a fundamental and important task in NLP, aiming at identifying named entities (NEs) from free text. Recently, since the multi-head attention mechanism applied in the Transformer model can effectively capture longer contextual information, Transformer-based models have become the mainstream methods and have achieved significant performance in this task. Unfortunately, although these models can capture effective global context information, they are still limited in the local feature and position information extraction, which is critical in NER. In this paper, to address this limitation, we propose a novel Hero-Gang Neural structure (HGN), including the Hero and Gang module, to leverage both global and local information to promote NER. Specifically, the Hero module is composed of a Transformer-based encoder to maintain the advantage of the self-attention mechanism, and the Gang module utilizes a multi-window recurrent module to extract local features and position information under the guidance of the Hero module. Afterward, the proposed multi-window attention effectively combines global information and multiple local features for predicting entity labels. Experimental results on several benchmark datasets demonstrate the effectiveness of our proposed model.[1]

1 Introduction

Named entity recognition (NER) is one of the most important and fundamental research topics in natural language processing (NLP), which recognizes named entities (NEs), such as person, location, disease from raw text. NER has attracted substantial attention in the past decades owing to its importance in downstream tasks, e.g., knowledge graph construction (Bosselut et al., 2019), question-answering (Pergola et al., 2021), and relation extraction (He et al., 2019).

In the early stage, the popular methods for solving NER are some traditional machine learning methods, e.g., Hidden Markov Model (HMM) (Morwal et al., 2012) and conditional random field (CRF) (Mozharova and Loukachevitch, 2016), which require extracting features manually, making the process inefficient and time-consuming. With the breakthrough of recurrent neural networks (RNN) in NLP, Long short-term memory (LSTM) (Hochreiter et al., 1997) and Gated Recurrent Unit (GRU) (Cho et al., 2014) have become mainstream methods for this task and have achieved promising results since neural networks can automatically extract features from the sequence and also take each token's position information into consideration (Lample et al., 2016; Chiu and Nichols, 2016; Huang et al., 2015). Nevertheless, RNN fails to perform well with long sequences due to the gradients exploding and vanishing. In recent years, Transformer-based models (Vaswani et al., 2017) have become mainstream methods because these models are able to capture long-term dependencies with the help of multi-head attention and thus provide better global context information, especially for long sequences (Lee et al., 2020; Yang et al., 2019b). However, these Transformer-based models usually are insensitive to the local context since the representation of each token is computed by the canonical point-wise dot-product self-attention (Li et al., 2019; Huang et al., 2021). Besides, although some studies (Shaw et al., 2018; Devlin et al., 2018; Liu et al., 2019) have been proposed to inject position information into Transformer, they are still inadequate to help Transformer obtain appropriate position information (Huang et al., 2020; Qu et al., 2021). In other words, the self-attention mechanism is effective in overcoming the constraints of RNN from the perspective of long-sequence con-

July 10-15, 2022

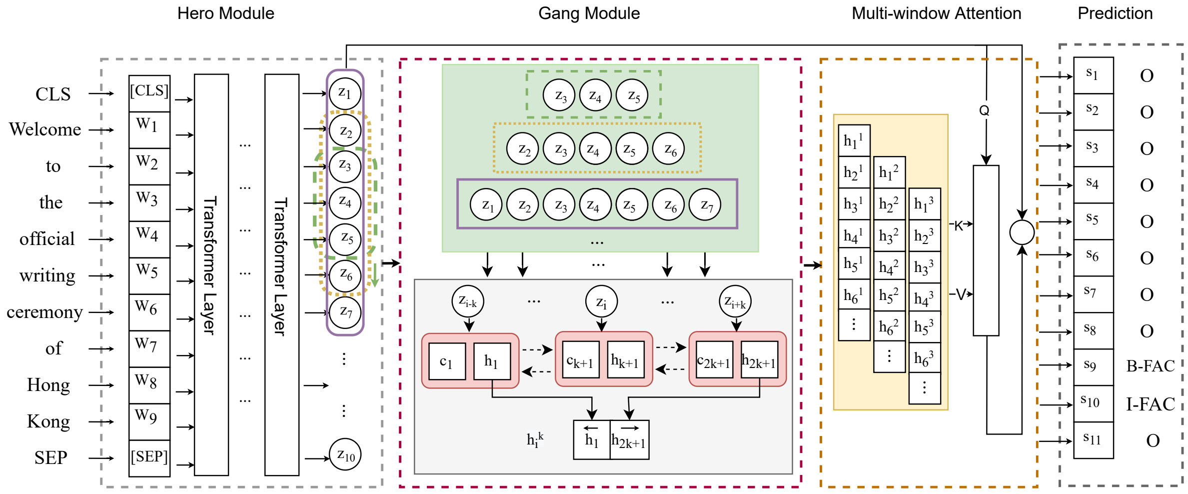

Figure 1: The overall architecture of our proposed model. From left to right are the Hero module, Gang module, and multi-window attention, respectively, shown in different dashed boxes. The purple solid frame, green, and yellow dashed frames in the Hero module are sliding windows with different window sizes. The green box in the Gang module shows the multiple sub-sequences generated by the sliding windows for $\mathbf{z}_4$, and the grey box represents the bidirectional recurrent mechanism that is used to capture local features from these sub-sequences. Note that $\overleftarrow{\mathbf{h}_1}$ and $\overrightarrow{\mathbf{h}_{2k+1}}$ are the last hidden states of backward and forward recurrent structures. The extracted local information is shown in the yellow box with its corresponding sub-sequences in the green box.

text information extraction, but is inferior to RNN in terms of local contextual and position information extraction. Yet, both long-term dependencies and local context information are essential for the NER model to correctly identify entities.

Thus, to alleviate the shortcomings in RNN and Transformers while maintaining their respective strengths, in this paper, we propose a novel Hero-Gang Neural model to leverage both global and local contextual information to improve NER. In doing so, on the one hand, we utilize a Transformer-based sequence encoder (i.e., Hero module) to extract effective global contextual information with the help of the self-attention mechanism. On the other hand, a multi-window recurrent unit (i.e., Gang module) is applied to extract local features from multiple sub-sequences under the guidance of the extracted global information. Afterward, we propose to use multi-window attention to elaborately combine global and local contextual features. The performance of our proposed model significantly outperforms the strong baseline models on several NER benchmark datasets (including both general and biomedical domains) and achieves new state-of-the-art results on some datasets.

2 Method

NER is usually performed as a sequence labeling problem. In detail, given a sequence of $X = x_1, x_2, ..., x_N$ with N tokens, we aim to learn a function that maps the input sequence into another one with the corresponding label $\hat{Y} = \hat{y_1}, \hat{y_2}, \hat{y_3}, ..., \hat{y_n}$ in the same length. As summarized in Figure 1, the Transformer-based models (e.g., BERT (Devlin et al., 2018), XLNET (Yang et al., 2019b)) are regarded as the Hero module to model the entire sentence for global sequence information extraction and the Gang module is responsible for local and relative position information extraction. Afterward, we employ the multi-window attention to elaborately combine these different features (i.e., features extracted from the Hero and Gang modules), which is then used to predict labels for each token. Therefore, the aforementioned process can be formulated as:

$$\hat{Y} = f(X, \mathrm{H}(X), \mathrm{G}(X)), \tag{1}$$

where $\mathrm{H}(\cdot)$ and $\mathrm{G}(\cdot)$ refer to the Hero and Gang modules, respectively, and the details of them are presented in the following subsections.

2.1 Hero Module

The role of the Hero module in our proposed model is similar to that of the leader in a team, who is responsible for providing guidance, offering instructions, giving directions, and assigning sub-tasks to fellow memberships. Therefore, the Hero module is required to have a comprehensive understanding of the task, including overall and local progress. Thanks to the characteristics of the multi-head self-attention mechanism, Transformer is powerful in modeling long sequences and can provide more effective global information than other counterpart models, and it has already achieved promising results in the NER task (Luo et al., 2020; Beltagy et al., 2019). Thus, we employ a Transformer-based encoder as our Hero module to obtain the global context information $\mathbf{z}_i$ for each token x_i by

$$[\mathbf{z}_1, \mathbf{z}_2, \cdots, \mathbf{z}_N] = f_{\mathrm{H}}(x_1, x_2, ..., x_N). \qquad (2)$$

Herein, $f_{\mathrm{H}}(\cdot)$ refers to a pre-trained Transformer-based sequence encoder (e.g., BERT (Devlin et al., 2018) and BioBERT (Lee et al., 2020)). The features $\mathbf{z}$ are then input to the Gang module for extracting local contextual features and their corresponding relative position information.

2.2 Gang Module

As introduced in the previous section, although pre-trained models are able to provide effective global contextual representation, it lacks the ability to extract local features and relative position information. Thus, we propose a multi-window recurrent module, named Gang, to enhance local information extraction. Recurrent structures (RS), such as LSTM, GRU, and tradition RNN are effective in extracting both local and relative position information from the sequence, owing to characteristics of the recurrent mechanism. To better emphasize the local features of each word without being disturbed by long-distance information, we construct a sliding window with a fixed length to generate shorter sub-sequences, where each sub-sequence includes several consecutive elements in $\mathbf{z}$. An additional advantage of this operation is that, in comparison with the whole sequence, the sub-sequence is much shorter so that it is easier to be modeled by the RS.

In detail, for a single sliding window with length k, each hidden state z_i from the Hero module, the corresponding sub-sequence is $\mathbf{z}_{i-k}, \mathbf{z}_{i-k+1}, ..., \mathbf{z}_i, ..., \mathbf{z}_{i+k-1}, \mathbf{z}_{i+k}$ that includes $2k+1$ consecutive tokens. This sub-sequence of length $2k+1$ contains rich local contextual information of x_i, and thus we utilize an RS to encode it for obtaining local semantic and relative position information. To extract the local information of two directions, we utilize a bidirectional structure to encode this sequence span, where the forward RS computes a representation $\overrightarrow{\mathbf{h}_{2k+1}}$ from left to right, and the other backward RS computes a vector $\overleftarrow{\mathbf{h}_1}$ for the same sub-sequence in reverse. We concatenate the $\overleftarrow{\mathbf{h}_1}$ and $\overrightarrow{\mathbf{h}_{2k+1}}$ as the local feature $\mathbf{h}_i = [\overleftarrow{\mathbf{h}_1}, \overrightarrow{\mathbf{h}_{2k+1}}]$ for token x_i, and then we can obtain local features for each token in sequence X via the similar way, denoted as $\mathbf{h} = \mathbf{h}_1, \mathbf{h}_2, \cdots, \mathbf{h}_N$.

In practice, we need to consider two situations. First, each token might have multiple levels of local information, such as phrase-level and clause-level, which may affect the understanding of the current token. Second, since different tokens or the same token in various contexts might have different relationships with their surrounding words, we need to consider more sub-sequences with varying lengths for obtaining more comprehensive local contextual information. Therefore, we propose to utilize multiple sliding windows with different window sizes to extract richer local features to alleviate the above issues. We assume that local features $\mathbf{h}^1, \mathbf{h}^2, \cdots, \mathbf{h}^M$ are extracted from different groups of sub-sequences, whose corresponding window lengths are $k^1, k^2, \cdots, k^M$. This process can be formulated as:

$$\mathbf{h}^1, \mathbf{h}^2, \cdots, \mathbf{h}^M = \mathrm{Gang}(k^1, k^2, \cdots, k^M, \mathbf{z}), \qquad (3)$$

where M is the number of sliding windows and $\mathbf{h}^j$ is a group of local features extracted from the corresponding sliding window with length k^j. The process is similar to the task assignment in the team, where different members are responsible for their own sub-tasks.

2.3 Multi-window Attention

We obtain global representation $\mathbf{z}$ from the Hero module and multiple local features $\mathbf{h}^1, \mathbf{h}^2, \cdots, \mathbf{h}^M$ from the Gang module. Next, we apply the multi-window attention to effectively combine global contextual information and local features. In doing so, two types of attention methods are proposed in our model: MLP-Attention and DOT-Attention, respectively.

MLP-Attention We first concatenate these local features with global information and obtain the intermediate state $\mathbf{m}$ by a fully connected layer.

$$\mathbf{m} = \mathrm{MLP}([\mathbf{z}, \mathbf{H}]), \qquad (4)$$

where $\mathbf{H} = [\mathbf{h}^1, \mathbf{h}^2, \cdots, \mathbf{h}^M]$ and $\mathbf{m}$ have the same dimension as $\mathbf{z}$. MLP represents a fully connected layer. Then $\mathbf{m}$ is used as a query vector and $[\mathbf{z}, \mathbf{H}]$ serves as the key and value matrix. The final token representation can be computed by

$$\mathbf{s} = \mathrm{softmax}(\mathbf{m}([\mathbf{z}, \mathbf{H}])^\top)[\mathbf{z}, \mathbf{H}]. \qquad (5)$$

DOT-Attention Instead of using a fully connected

Type	Dataset	Train			Val			Test

Table 1: The statistics of the six benchmark datasets w.r.t. their training, validation and test sets, including the number of sentences (#Sent.), the number of entities (#Ent.), and the averaged word-based length (#AS.).

layer to generate a query vector, in this approach, we directly regard $\mathbf{z}$ as the query vector and $\mathbf{H}$ as the key and value matrix. We can obtain the final local feature by

$$\mathbf{u} = \text{softmax}(\mathbf{z}(\mathbf{H})^\top)\mathbf{H}. \tag{6}$$

Since $\mathbf{u}$ is a weighted sum of different local features without considering global information, we use the sum of $\mathbf{u}_i$ and $\mathbf{z}_i$ as the final representation for each token x_i. Thus, the final representation can be obtained by

$$\mathbf{s} = \{\mathbf{z}_1 + \mathbf{u}_1, \mathbf{z}_2 + \mathbf{u}_2, \cdots, \mathbf{z}_N + \mathbf{u}_N\}. \tag{7}$$

After obtaining the final representation from MLP-Attention or DOT-Attention, $\mathbf{s}$ is sent to the corresponding classifier implemented by the softmax function to predict the distribution of labels for each token in X.

3 Experiments Settings

3.1 Dataset and Metrics

In our experiments, six datasets are used in our experiments, WNUT17 (W17) (Strauss et al., 2016), WNUT16 (W16) (Derczynski et al., 2017), OntoNotes 5.0 (ON5e) (Pradhan et al., 2013), BC5CDR-disease (BC5-D), BC2GM, and BC5CDR-chem (BC5-C). The W17 and W16 are social media benchmark datasets constructed from Twitter, and ON5e is a general domain dataset consisting of diverse sources like telephone conversations, newswire, etc. BC5CDR, including both BC5-D and BC5-C, is a dataset used for the BioCreative V Chemical Disease Relation Task and contains chemical and disease mentions, where humans manually annotate the annotations. BC2GM is the dataset that is usually utilized for the BioCreative II gene mention tagging task and contains 20000 sentences from the abstracts of biomedical publications. For all datasets, we utilize the official splits for a fair evaluation and the statistics of the datasets are shown in Table 1. Besides, we follow previous studies that the final models are trained on training and validation sets on each dataset except the ON5e dataset.

For metrics, we exploit the same evaluation metrics used by previous works where precision (P), recall (R), and F-1 score are reported to evaluate the performance of our model.

3.2 Implementation Details

We implement our model based on transformers (Wolf et al., 2020)[2] and employ pre-trained models to obtain global contextualized representation. Specifically, for general domain datasets (i.e., W16, W17 and ON5e), we use BERT-cased-large (Devlin et al., 2018)[3] and XLNET-large-cased (Yang et al., 2019b)[4] as our Hero module. For biomedical datasets, BioBERT (Lee et al., 2020)[5] is utilized to obtain global information. We follow their default settings for all BERT, XLNET, and BioBERT: 24 layers of self-attention with 1024 dimensional embeddings. For hyperparameters of the Gang module, the hidden sizes of bidirectional recurrent structures for each window size are half of the embedding dimension from the output of the Hero module (i.e., 512). During the training process, we use Adam (Kingma and Ba, 2014) to optimize the negative log-likelihood loss function. More training details are shown in the Appendix A.1. Besides, we also compare four operations to combine different level features from the Hero and Gang module: MLP-Attention, DOT-Attention, concatenation, and summation, respectively, where concatenation is to connect all features directly through

Table 2: Comparisons of our proposed models with previous studies on the W16, W17, and ON5e, respectively, with respect to precision, recall, and F-1 score for NER. Previous studies are divided into two parts from top to bottom, representing methods requiring extra resources and without such requirements, respectively.

$\mathbf{s} = [\mathbf{h}^1, \mathbf{h}^2, \cdots, \mathbf{h}^M, \mathbf{z}]$, and summation is to add up these features by $\mathbf{s} = \mathbf{h}^1 + \mathbf{h}^2 + \cdots + \mathbf{h}^M + \mathbf{z}$.

3.3 Baselines

To explore the impact of our proposed model, we compare our model to the previous studies. For general domain, following baselines are compared in our experiment on W16, W17 and ON5e.

- **CNN-BILSTM-CRF** (Chiu and Nichols, 2016) utilizes a hybrid bidirectional and CNN architecture to detect word-and character-level features.
- **BERT** (Devlin et al., 2018) is a pre-trained language model and we apply it to the NER task by direct fine-tuning.
- **SANER** (Nie et al., 2020b), **CL-KL** (Wang et al., 2021) and **AESUBER** (Nie et al., 2020a) improve entity recognition by leveraging syntactic information or semantically relevant texts.
- **HIRE-NER** (Luo et al., 2020) utilizes both sentence-level and document-level representations to improve sequence labeling.
- **SYN-LSTM-CRF** (Xu et al., 2021) integrates the structured information by graph-encoded representations obtained from GNNs.
- **BARTNER** (Yan et al., 2021) formulates NER tasks as a span sequence generation problem.

In addition, we also compare our proposed model with the following baselines on the aforementioned biomedical datasets:

- **MTM-CW** (Wang et al., 2019a), **BILM** (Sachan et al., 2018), **NCBI_BERT** (Peng et al., 2019), **MT-BIONER** (Tong et al., 2021) utilize multi-task learning or transfer learning to enhance biomedical NER.
- **BIOBERT** (Lee et al., 2020) is a pre-trained model trained with a large amount of biomedical corpus and then applied by directly fine-tuning.
- **KEBIO-LM** (Yuan et al., 2021) proposes a biomedical pre-trained language model that incorporates knowledge from the Unified Medical Language System (UMLS).

Note that in both general and biomedical domains, our model **does not require external resources.**

4 Results and Analyses

4.1 General Domain NER

In this subsection, to explore the effectiveness of our proposed model, we conduct experiments to compare our model with existing studies, and the results are reported in Table 2. There are several observations drawn from different aspects. First, when we make a fair comparison without extra resources (e.g., BERT, XLNET, and ASTRA), our model obtains significant improvements on all datasets in terms of Precision, Recall, and F-1, which confirms the effectiveness of our proposed Hero-Gang neural structure. This is because multiple-level features can be reasonably encoded into the model and thus alleviate the limitations of

Table 3: Comparisons of our proposed models with previous studies on the BC5-D, BC2GM, and BC5-C, respectively, for biomedical NER in terms of precision, recall, and F-1 score. Previous works are divided into two sections, indicating methods requiring extra resources and without such requirements.

Transformer in local feature extraction. Second, although some complicated models enhance NER by incorporating extra knowledge, e.g., SANER uses augmented semantic information, Hire-NER utilizes two-level hierarchical contextualized representations, and CL-KL selects a set of semantically relevant texts to improve NER, our model achieves competitive results without such requirements. This is because each word in the natural text usually has a closer relationship with its surrounding words, especially the adjacent words, such that features extracted by the Gang module can provide more valuable information for NER, and thus our model achieves promising performance. Third, the XLNET-based model obtains better results than the BERT-based model, which indicates that XLNET can generate more effective representations on the NER task. The reason behind this might be that XLNET combines the permutation operation with the autoregressive technology to further improve representation learning, so that XLNET can provide a better text understanding than BERT.

4.2 Biomedical NER

We also compare our model with state-of-the-art models in the biomedical NER on the aforementioned datasets with all results reported in Table 3. There are several observations. First, we can see that our model outperforms existing methods, regardless of whether they introduce external knowledge, which further confirms the validity of our innovation in combining local and global features to enhance feature extraction. Second, although some models utilize higher-level features, e.g., BIOKM-NER leverages POS labels, syntactic constituents, dependency relations, and MTM-CW employs multi-task learning to train the model, our model can achieve better results through a simple Hero-Gang structure. This means that local features extracted from the Gang module under the guidance of global information are also effective in assisting biomedical text representations and even show more significant potential than those special designs for the medical domain (i.e., domain-related multi-task learning). Third, the models using the multi-window attention (i.e., DOT-Attention and MLP-Attention) outperform those using concatenation or summation. This observation suggests that multi-window attention can elaborately weigh local features from different sliding windows to enhance feature combinations.

4.3 Analyses

Effect of position information Recurrent structures are able to extract both context and position information by its token-by-token manner while other network structures, including CNN and MLP, fail to encode the relative position information. Thus, to explore the effect of position information, we compare models with different structures to construct the Gang module and report the improvements of F-1 score based on different Gang modules in Figure 2. First, we can observe that models with Gang module are better than Base (i.e., BERT), where all the values in Figure 2 are positive, further illustrating the effectiveness of our innovation in combining both global and local features, no matter what type of structure is used to construct the Gang module. Second, models with LSTM and GRU outperform those with CNN and MLP, indi-

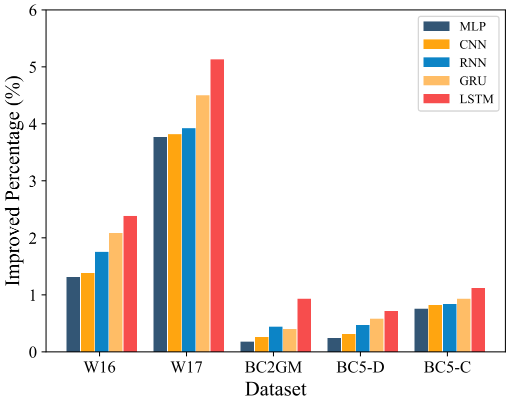

Figure 2: The improvement values (%) compared to Base models (i.e., BERT for general domain datasets and BioBERT for biomedical datasets) in terms of F-1 score from different Gang modules, MLP, CNN, RNN, GRU, and LSTM, respectively.

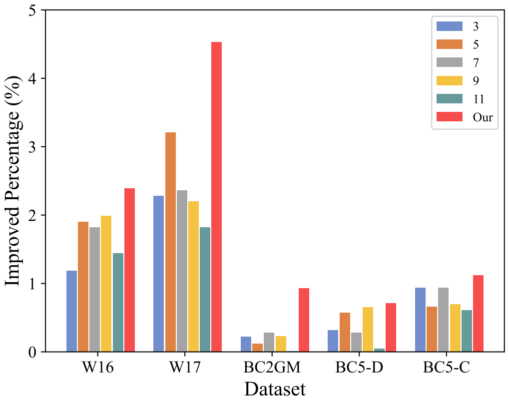

Figure 3: The improvement values (%) of models with single windows or multi-window compared to Base models (BERT or BioBERT w.r.t. datasets), where 3, 5, 7, 9, 11 represents the single window size when models only use a single window to construct the Gang module.

cating that recurrent structures are more promising in short sequence feature extraction. Since the recurrent structures can effectively capture position information by its token-by-token manner and help the model understand word-word relations based on their relative positions, we may conclude that position information is vital for improving performance. Third, the comparison between CNN and MLP shows the power of CNN in extracting features from sub-sequences since CNN can leverage more fine-grained features, such as n-gram.

Ablation studies In this subsection, we compare our multi-window model with single-window models, and the improvements compared with Base model are shown in Figure 3. We have following observations. First of all, illustrated by the comparisons among Base (i.e., BERT) and others, models with sliding windows achieve better performance, where all the improvement values in Figure 3 are positive. This illustrates that both single window and multi-window recurrent structures can help to enhance token representation and bring different degrees of improvement, which further shows the importance of local features in this task. Second, we can observe that the optimal single window sizes for different datasets are also different. For example, the optimal single window size of W17 is 5, while that for BC2GM is 7, which indicates that the best length of the local sequence depends on the characteristics of datasets to some extent. Third, compared with those models using a single window, the multi-window recurrent module obtains better performance, illustrating that features extracted from multiple sub-sequences are more effective than those captured from a single one. The reason could be that multi-window can help the model pay attention to different local context sub-sequences and give them appropriate weights through the multi-window attention mechanism, such that it can provide more reasonable local information and alleviate the impact of the characteristics of the datasets themselves.

Case Study To further show the validity of our model, we perform qualitative analysis on some cases with their real labels and predicted labels from different models. Figure 4 shows two cases from ON5e and BC5-C, respectively. We can observe that our model can predict more complete entities than Base. Specifically, in the first case, our model can recognize all the words in the entity *"a period of years"* while Base model only recognizes the word *"years"*. In the second case, our model is able to identify *"Monosodium glutamate"*, but Base model regards these words as two different entities. In addition, in the first example, compared with real labels, our model can label two *"of"* correctly with the help of local features, which are O and I-date, respectively, while Base classifies both *"of"* as O. The sub-sequence (i.e.,*"a period of years,"*) from the second *"of"* is usually used to describe time such that this information is able to assist the model in marking the *"of"* as I-date. However, for the first *"of"*, its sub-sequence *"divest themselves of such speculative"* does not contain any meaning related to the entity themes, and thus the model marks the corresponding *"of"* as O.

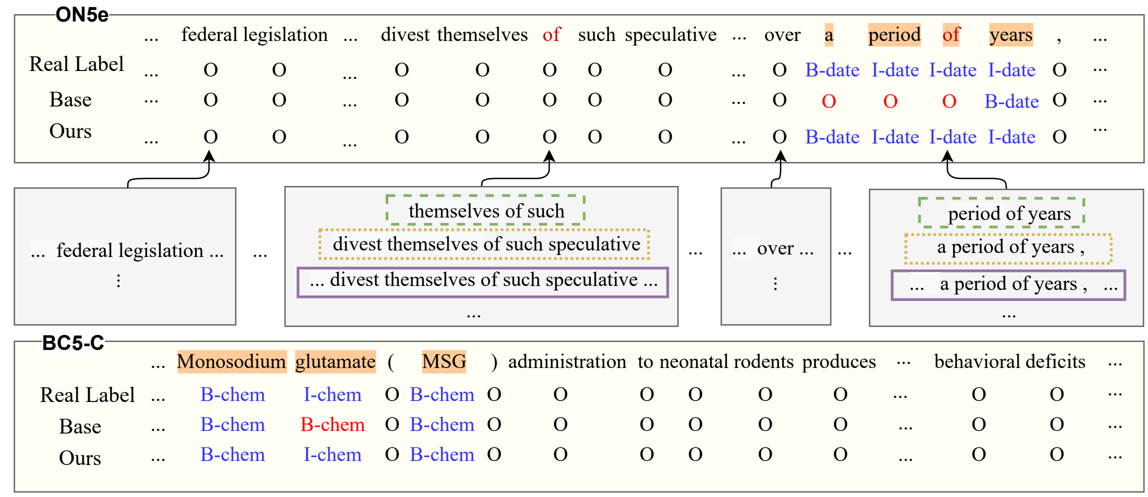

Figure 4: Examples of two predicted labels from BASE and OURS as well as their corresponding source sentence and real label. Note that the BASE for these two cases are BERT and BIOBERT, respectively.

5 Related Work

NER is a fundamental task in NLP (Huang et al., 2015), which has drawn substantial attention over the past years and there have been many studies to address this task. Recently, deep learning has played a dominant role in NER due to its effectiveness in capturing contextual information from sequences. The recurrent neural networks (RNN), including its variants such as LSTM (Hochreiter et al., 1997), and GRU (Cho et al., 2014), is a promising structure for solving this task since it can effectively learn sequence information with its recurrent mechanism (Ma and Hovy, 2016; Huang et al., 2015; Chiu and Nichols, 2016; Zhu and Wang, 2019). However, it is ineffective for RNN to learn long sequences due to the gradients exploding and vanishing. Thus, Transformer-based models, such as BERT (Devlin et al., 2018), BioBERT (Lee et al., 2020), and XLNET (Yang et al., 2019b), are proposed to alleviate these problems with the help of the self-attention mechanism. Compared to RNN, Transformer is able to capture long-distance information through multiple multi-head attention layers and has achieved impressive performance in this task (Nie et al., 2020b; Luo et al., 2020; Yamada et al., 2020; Gui et al., 2019).

However, multi-head attention usually treats every position identically, which lead to the loss of position information. To mitigate this problem, several approaches have been proposed to advance the Transformer (Dai et al., 2019; Shaw et al., 2018; Yan et al., 2019). Shaw et al. (2018) proposed cross-lingual position representation to help self-attention alleviate word order divergences in different languages and learn position information. Yan et al. (2019) introduced the directional relative positional encoding and an adapted Transformer Encoder to model the character-level and word-level features. Although these position embeddings are able to help the model learn position information, they are still not enough to solve the issue appropriately (Wang et al., 2019b; Huang et al., 2020; Qu et al., 2021). Besides, Transformer-based approaches cannot effectively extract local features that are also important for sequence learning tasks, and some studies have been proposed to alleviate this problem (Xu et al., 2017; Li et al., 2019; Yang et al., 2019a). Xu et al. (2017) proposed to use the fixed-size ordinally forgetting encoding to model sentence fragments, which is then used to predict the label for each text fragment. Li et al. (2019) utilized convolutional self-attention by producing queries and keys with causal convolution to incorporate local contextual information into the attention mechanism. To address these issues, we offer an alternative solution, namely Hero-Gang Neural model, to enhance local and position information extraction via multiple recurrent structures under the guidance of global information.

6 Conclusion

In this paper, we propose a novel Hero-Gang Neural (HGN) structure to effectively combine global and local features for enhancing NER. In detail, the Hero module aims to capture global understanding by a Transformer-based encoder, which is then used to guide the Gang to extract local features and relative position information through a multi-window recurrent module. Afterward, we utilize the multi-window attention to elaborately combine the global information and local features for enhancing representations that are then used to predict the entity label for each token. Empirically, our proposed model achieves new state-of-the-art results on several NER benchmark datasets, including both general and biomedical domains. Besides, we compare different structures to construct the Gang model and investigate the effect of the number of sliding windows, which further illustrates the effectiveness of our proposed model.

Abstract

Text classification struggles to generalize to unseen classes with very few labeled text instances per class. In such a few-shot learning (FSL) setting, metric-based meta-learning approaches have shown promising results. Previous studies mainly aim to derive a prototype representation for each class. However, they neglect that it is challenging-yet-unnecessary to construct a compact representation which expresses the entire meaning for each class. They also ignore the importance to capture the inter-dependency between query and the support set for few-shot text classification. To deal with these issues, we propose a meta-learning based method **MGIMN** which performs instance-wise comparison followed by aggregation to generate class-wise matching vectors instead of prototype learning. The key of instance-wise comparison is the interactive matching within the class-specific context and episode-specific context. Extensive experiments demonstrate that the proposed method significantly outperforms the existing SOTA approaches, under both the standard FSL and generalized FSL settings.

1 Introduction

Few-shot text classification has attracted considerable attention because of significant academic research value and practical application value (Gao et al., 2019; Yin, 2020; Brown et al., 2020; Bragg et al., 2021; Liu et al., 2021). Many efforts are devoted towards different goals like generalization to new classes (Gao et al., 2019; Ye and Ling, 2019; Nguyen et al., 2020; Bragg et al., 2021), adaptation to new domains and tasks (Bansal et al., 2020; Brown et al., 2020; Schick and Schütze, 2020; Gao et al., 2020; Bragg et al., 2021). Low-cost generalization to new classes is critical to deal with the growing long-tailed categories, which is common for intention classification (Geng et al., 2019; Krone et al., 2020) and relation classification (Han et al., 2018; Gao et al., 2019).

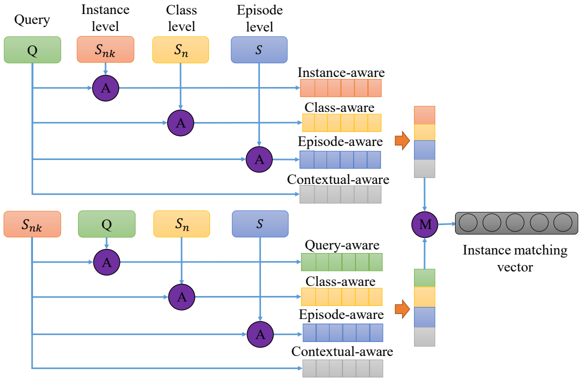

Figure 1: The example of multi-grained few-shot text classification. The "S_{nk}, S_n" and "S" represent the instance level, class level and episode level interaction respectively. While "A" in the purple circle denotes alignment between query and instances. The "'M" stands for matching operation.

To prevent over-fitting to few-shot new classes and avoid retraining the model when the class space changes, metric-based meta learning has become the major framework with significant results (Yin, 2020; Bansal et al., 2020). The core idea is that episode sampling is employed in meta-training phase to learn the relationship between query and candidate classes (Bragg et al., 2021). A key challenge is inducing class-wise representations from support sets because nature language expressions are diverse (Gao et al., 2019) and highly informative lexical features are unshared across episodes (Bao et al., 2019).

Under metric-based meta learning framework, many valuable backbone networks have emerged. Snell et al. (2017) presented prototypical network that computes prototype of each class using a simple mean pooling method. Gao et al. (2019) proposed hybrid attention mechanism to ease the negative effects of noisy support examples. Geng et al. (2019) proposed an induction network to

July 10-15, 2022

induce better prototype representations. Ye and Ling (2019) obtained each prototype vector by aggregating local matching and instance matching information. Bao et al. (2019) proposed a novel method to compute prototypes based on both lexical features and word occurrence patterns. All these previous works first obtain class-wise representations and then perform class-wise comparisons. However, it is challenging-yet-unnecessary to construct a compact representation which expresses the entire meaning for each class (Parikh et al., 2016). In text matching research, compare-aggregate methods which perform token-level comparisons followed by sentence-level aggregation has already been successful (Parikh et al., 2016; Tay et al., 2017; Yang et al., 2019). Besides backbone networks,there are still some work that can be further combined. Luo et al. (2021) utilized class-label information for extracting more discriminative prototype representation. Bansal et al. (2020) generated a large-scale meta tasks from unlabeled text in a self-supervised manner.

In this paper we propose **M**ulti-**g**rained **I**nteractive **M**atching **N**etwork, a backbone network for few-shot text classification. The core difference between us with previous efforts is that our work performs instance-level comparisons followed by class-wise aggregation. Specifically, first, all text sequences including query and all support instances are encoded to contextual representations. Second, as depicted in Figure 1, we design a novel multi-grained interactive matching mechanism to perform instance-wise comparisons which capture the inter-dependency between query and all support instances. Third, class-wise aggregate layer obtains class-wise matching vector between query and each class. Finally, a prediction layer predicts final results. In contrast to standard FSL setting, generalized FSL setting is a more challenging-yet-realistic setting where seen classes and new classes are co-existent (Nguyen et al., 2020; Li et al., 2020a). In such a setting, we analyze the relationship between inference speed and the number of classes, and verify the necessity of retrieval, which is ignored by previous studies.

Our contributions are listed as follows:

- We propose **MGIMN** which is more concerned with matching features than semantic features through multi-grained interactive matching.
- We verify the necessity of retrieval for realistic applications of few-shot text classification when the number of classes grows.
- We conduct extensive experiments and achieve SOTA results under both the standard FSL and generalized FSL settings.

2 Background

2.1 Few-Shot Learning

Few-shot learning focuses on construct a classifier $G(S, q) \to y$ which maps the query q to the label y given the support set S. Few-shot learning is significantly different from traditional machine learning. In traditional machine learning tasks, we directly sample batches of training data during training. Unlike traditional machine learning models, few-shot learning models usually adopt episode training strategy which means we build meta tasks using sampled training data in each training step.

Specifically, during each training step, N different classes are randomly chosen. After the classes are chosen, we sample R samples as query set Q and K samples for each class as support set S where $Q \bigcap S \in \emptyset$. For training, given the support set $S = \{S_n^k; i = 1, .., N, j = 1, .., K\}$, and query set $Q = \{(q_i, y_i); i = 1, 2, .., R, y_i \in 1, .., N\}$ which has R samples in each training step, the training objective is to minimize:

$$J = -\frac{1}{R} \sum_{(q,y) \in Q} log(P(y|(S, q))). \qquad (1)$$

For evaluation, as we described in introduction section, there are two settings. In standard FSL setting, we do N-way K-shot sampling on the classes for validation and test (which are unseen during training) to construct episodes for validation and test. In generalized FSL setting, we reformulate the FSL task as C-way K-shot classification where C is the count of all classes for training, validation and test, and usually is far greater than N. In this setting, we construct episodes by sampling on all classes for test.

2.2 Matching Network

Matching Network (Vinyals et al., 2016) is a typical few-shot learning approach, which leverages the cosine similarity to perform few-shot classification. Specifically, for the query instance q and each support instance $S_n^k \in S$, the cosine similarity

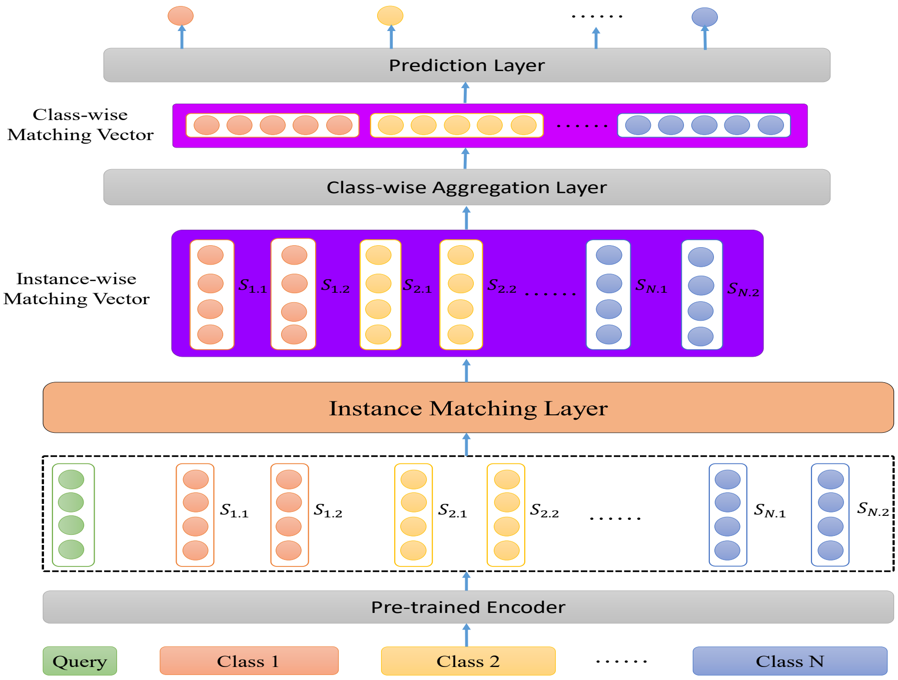

Figure 2: The main architecture of multi-grained few-shot text classification model. The details of "Instance Matching Layer" totally same as depicted as Figure 1.

between q and S_n^k is computed as follow:

$$sim(q, S_n^k) = \frac{q \cdot S_n^k}{||q||\ ||S_n^k||}. \tag{2}$$

Then, we compute the probability distribution of the label y of the query q using attention:

$$P(y|S,q) = \frac{\sum_{k=1}^{K} \exp(sim(q, S_y^k))}{\sum_{n=1}^{N}\sum_{k=1}^{K} \exp(sim(q, S_n^k))}. \tag{3}$$

Finally, for any query instance q, we regard the class with the maximum probability as its label y:

$$y = \arg\max_n P(y = n|S,q). \tag{4}$$

2.3 Text Classification

As a basic task in NLP, text classification has attracted much attention. In previous works, different model architectures, including RNN (Zhou et al., 2016) and CNN (Kim, 2014) are used for text classification. After the appearance of pre-trained language models like BERT (Devlin et al., 2019), they have become the mainstream method for text classification. In such methods, the input sentence is encoded into its representation using the Transformer (Vaswani et al., 2017) architecture through adding $[CLS]$ token before the original input sentence $\mathbf{x}$ and then computing the output representation of $[CLS]$ using the model.

$$\mathbf{h}_{\text{CLS}} = Transformer([\text{CLS}], \mathbf{x}; \theta), \tag{5}$$

where θ represents the model's parameters.

Then, according to the representation, the probability distribution of y can be computed as follow:

$$P(y|\mathbf{x};\theta) = softmax(\mathbf{W}_{\text{softmax}}\mathbf{h}_{\text{CLS}}), \tag{6}$$

where $\mathbf{W}_{\text{softmax}}$ is the parameters of the softmax layer.

3 Method

As illustrated in the Figure 2, MGIMN consists of four modules: Encoder Layer, Instance Matching Layer, Class-wise Aggregation Layer and Prediction Layer.

3.1 Encoder Layer

We employ transformer encoder from pre-trained BERT as encoder layer. Similar to the original work, we add a special token [CLS] before original text. Then the encoder layer takes a token sequence as input and outputs token-wise sequence representation. Instead of using the vector of [CLS] token as sentence-wise representation, we adopt final hidden states of the rest tokens for further fine-grained instance-wise matching.

We denote $x = \{w_1, w_2, ..., w_l\}$ as a token sequence. Encoder Layer outputs the token-wise representation $h = \{h_1, h_2, ..., h_l\}$, where l denotes length of the token sequence. Query and each support instance are encoded individually. We denote q as encoded result of query and s_{nk} as encoded result of the k_{th} support instance of n_{th} class.

3.2 Instance Matching Layer

This is the core of our model. Instance-wise matching vectors are obtained by comparing query with each support instance.

3.2.1 Bidirectional Alignment

Following previous works(Parikh et al., 2016; Yang et al., 2019) in text matching , we use bidirectional alignment to capture inter-dependency between two text sequences.

$$\widehat{a}, \widehat{b} = BiAlign(a, b) \tag{7}$$

where a and b denote the token-wise sequence representations and $BiAlign$ denotes the bidirectional alignment function defined as follows:

$$e_{ij} = \mathbf{F}(a_i)^{\mathrm{T}}\mathbf{F}(b_j) \tag{8}$$

$$\widehat{a_i} = \sum_{j=1}^{l_b} \frac{exp(e_{ij})}{\sum_{k=1}^{l_b} exp(e_{ik})} b_j \tag{9}$$

$$\widehat{b_j} = \sum_{i=1}^{l_a} \frac{exp(e_{ij})}{\sum_{k=1}^{l_a} exp(e_{kj})} a_i \tag{10}$$

where a_i and b_j denotes representation of i_{th} and j_{th} token of a and b, respectively, $\widehat{a_i}$ and $\widehat{b_j}$ denote the aligned representations, and F is a single-layer feed forward network.

3.2.2 Multi-grained Interactive Matching

In few-shot text classification, judging whether query and each support instance belong to the same category cannot be separated from class-specific context and episode-specific context. There are three components including alignment, fusion and comparison.

For alignment, besides local alignment between query and each support instance, we also consider their alignments with global context information. We denote $S_n = concat(\{s_{nj}\}_{j=1}^{K})$ as class-specific context and $S = concat(\{S_i\}_{i=1}^{N})$ as episode-specific context. The multi-grained alignments for query and each support instance are performed as follows:

$$\begin{aligned} q_{nk}^{'}, s_{nk}^{'} &= BiAlign(q, s_{nk}) \\ q_{n}^{''}, \_ &= BiAlign(q, S_n) \\ s_{nk}^{''}, \_ &= BiAlign(s_{nk}, S_n) \\ q^{'''}, \_ &= BiAlign(q, S) \\ s_{nk}^{'''}, \_ &= BiAlign(s_{nk}, S) \end{aligned} \tag{11}$$

where $q_{nk}^{'}$, $q_{n}^{''}$ and $q^{'''}$ denote instance-aware, class-aware and episode-aware query representations respectively, $s_{nk}^{'}$, $s_{nk}^{''}$ and $s_{nk}^{'''}$ denote query-aware, class-aware and episode-aware support instance representations respectively.

For fusion, we fuse original representation and three kinds of aligned representations together as follows:

$$\begin{aligned} \boldsymbol{q_{nk}^{'}} &= H_1(q; q_{nk}^{'}; \left|q - q_{nk}^{'}\right|; q \odot q_{nk}^{'}) \\ \boldsymbol{q_{nk}^{''}} &= H_2(q; q_{n}^{''}; \left|q - q_{n}^{''}\right|; q \odot q_{n}^{''}) \\ \boldsymbol{q_{nk}^{'''}} &= H_3(q; q^{'''}; \left|q - q^{'''}\right|; q \odot q^{'''}) \\ \boldsymbol{s_{nk}^{'}} &= H_1(s_{nk}; s_{nk}^{'}; \left|s_{nk} - s_{nk}^{'}\right|; s_{nk} \odot s_{nk}^{'}) \\ \boldsymbol{s_{nk}^{''}} &= H_2(s_{nk}; s_{nk}^{''}; \left|s_{nk} - s_{nk}^{''}\right|; s_{nk} \odot s_{nk}^{''}) \\ \boldsymbol{s_{nk}^{'''}} &= H_3(s_{nk}; s_{nk}^{'''}; \left|s_{nk} - s_{nk}^{'''}\right|; s_{nk} \odot s_{nk}^{'''}) \end{aligned} \tag{12}$$

$$\begin{aligned} \boldsymbol{q_{nk}} &= H(\boldsymbol{q_{nk}^{'}}; \boldsymbol{q_{nk}^{''}}; \boldsymbol{q_{nk}^{'''}}) \\ \boldsymbol{s_{nk}} &= H(\boldsymbol{s_{nk}^{'}}; \boldsymbol{s_{nk}^{''}}; \boldsymbol{s_{nk}^{'''}}) \end{aligned} \tag{13}$$

where H_1, H_2, H_3, H are feed forward networks with single-layer and initialize with independent parameters, $\odot$ denotes the element-wise multiplication operation, and ; denotes concatenation operation.

For comparison, the instance-wise matching vector is computed as follows:

$$\begin{aligned} \vec{q_{nk}} &= [max(\{\boldsymbol{q_{nk}}\}); avg(\{\boldsymbol{q_{nk}}\})] \\ \vec{s_{nk}} &= [max(\{\boldsymbol{s_{nk}}\}); avg(\{\boldsymbol{s_{nk}}\})] \\ \vec{m_{nk}} &= G(\vec{q_{nk}}; \vec{s_{nk}}; |\vec{q_{nk}} - \vec{s_{nk}}|; \vec{q_{nk}} \odot \vec{s_{nk}}) \end{aligned} \tag{14}$$

where $\boldsymbol{q_{nk}}$ is a $l_q \times D$ matrix, $\boldsymbol{s_{nk}}$ is a $l_s \times D$ matrix, $\vec{q_{nk}}$ and $\vec{s_{nk}}$ are vectors with shape $(1 \times 2D)$, G is single-layer feed forward networks, l_q and l_s are sequence length of query and support instance respectively, and D is hidden size.

3.3 Class Aggregation Layer

This layer aggregate instance-wise matching vectors into class-wise matching vectors for final prediction.

$$\vec{c_n} = [max(\{\vec{m_{nk}}\}_{k=1}^{K}); avg(\{\vec{m_{nk}}\}_{k=1}^{K})] \quad (15)$$

where $\vec{c_n}$ denotes the final matching vector of n_{th} class, ";" denotes the concatenation of two vectors and $\vec{m_{nk}}$ denotes instance-wise matching vector produced by instance matching layer.

3.4 Prediction Layer

Finally, prediction layer, which is a two-layer fully connected network with the output size is 1, is applied to the matching vector $\vec{c_n}$ and outputs final predicted result.

$$logit_n = MLP(\vec{c_n}), n = 1, .., N \quad (16)$$

4 Experiments

4.1 Setup

4.1.1 The preparation of dataset

The proposed method has been evaluated on five diverse corpora: OOS (Larson et al., 2019), Liu (Liu et al., 2019), FaqIr (Karan and Šnajder, 2016), Amzn (Yury., 2020) and Huffpost (Misra., 2018). Among them, OOS, Liu and FaqIr datasets are all intent classification datasets. Amzn dataset is designed for fine-grained classification of product reviews. Huffpost dataset is constructed to identify the types of news based on headlines and short descriptions. The dataset characteristics is listed in Table 1. For the standard FSL setting, we construct the "support & query" set by sampling the unique N classes and K samples each class, and R samples for each of classes, respectively. We conduct two groups of experiments using $N = [5, 10], K = 5$ and $R = 5$. In the evaluation phase, we sample 500 episodes and report the average accuracy. In generalized FSL setting(GFSL for short), we train the model with episode sampling of 5-way 5-shot. And then we evaluate the model performance with C-way K-shot.

For all experiments, we divide all datasets for 5 times using different random seeds, just like the way of cross validation, to remove the impact of dataset division. And we conduct 3 experiments for each model by using different random seeds for model initialization. The final results are reported by averaging $5 \times 3 = 15$ runs.

For fair comparison, all models implemented in this paper adopt BERT-Tiny[1] as encoder layer which is a 2-layer 128-hidden 2-heads version of BERT. Meanwhile, these models initialized their paramaeters using the PTM published by Google and fine-tuned during training procedure. Besides, the encoder layer and all parameters of other layers are randomly initialized. We fix some hyper-parameters with default values such as the hidden size 128, we also exploit Adam optimizer in all experiment settings. The learning rate is tuned from $1e^{-5}$ to $1e^{-4}$ on validation dataset. Dropout with a rate of 0.1 is applied before each fully-connected layer. The feed-forward networks described in section 3 (e.g. F, H_1, H_2, H_3, H and G) are all single fully-connected layers. The prediction layer is a two-layer fully-connected layer.

4.1.2 Baselines

It is vital to compare the introduced method with some strong baselines with two evaluation metrics mentioned above. Note that we re-implement all methods with the same pre-trained encoder for fairly comparison.

- **Prototypical Network (Proto)**(Snell et al., 2017) is the first designed and applied to image classification and has also been used to deal with the text classification issue in recent studies.
- **Matching Network (Matching)**(Vinyals et al., 2016) computes the similarity both on each query and per support samples, and then averages them as final prediction score.
- **Induction network (Induction)**(Geng et al., 2019) proposes an induction module to induce the prototype by using dynamic routing.
- **Proto-HATT**(Gao et al., 2019) is introduced to deal with the issue of noisy and diverse by leveraging instance-level attention and feature-level attention.
- **MLMAN**(Ye and Ling, 2019), can be regarded as one of the variants of Proto, encodes query and support in an interactive way.

4.2 Main results

Overall Performance Our key experiment results are given in Table 2, 3 and 4. We report

the averaged scores over 15 runs (different seen-unseen class splits and random seeds as introduced in section 4.1.1) for each dataset and model. Our method remarkably better than all baselines on the five diverse corpora, especially in more challenging generalized FSL setting: the improvements on Huffpost and Amzn datasets are 2.83% and 2.75% respectively.

Generalized FSL In most studies of text classification (Bao et al., 2019; Gao et al., 2019) with few-shot manner, N-way K-shot accuracy is the standard evaluation metric. There are two problems: (1) The metric is not challenging, usually $N = 5$ or $N = 10$, much smaller than C. We also can see that high scores are often reported in some work(Bao et al., 2019; Gao et al., 2019). (2) It is unable to reflect the real application scenarios where we usually face the entire class space (both seen classes and unseen classes). Consequently, the more challenging generalized FSL evaluation metric is employed to focus on the problems. As shown in Table 2, 3 and 4, the performance of generalized FSL evaluation is worse and more challenging than standard FSL. It is very meaningful in realistic scenario and can contribute to the further research. It is noteworthy that, comparing with Proto, our proposed approach makes bigger improvement in the challenging generalized FSL metric (GFSL) than the improvements in standard FSL metric(FSL), e.g. OOS dataset: 14.29% of GFSL vs 6.09% of FSL and FaqIr dataset: 15.03% of GFSL vs 9.13% of FSL. Obviously, it can be implied from the experiment results that, the presented approach has higher effectiveness among such challenging scenarios.

Huffpost Dataset Samples of the same class are more diverse and scattered on Huffpost. For instance, "green streets are healthy streets", "the real heroes of Pakistan" and "what next for Kurdistan ?" are from the same class:"WORLD NEWS". In this scenario, a single class-wise prototype is difficult

Methods	Huffpost		
	5-way	10-way	GFSL
Proto	51.57	36.74	16.47
Matching	49.77	34.28	14.18
Induction	44.69	29.35	10.40
Proto-HATT	51.23	36.65	16.06
MLMAN	52.76	38.22	16.78
MGIMN(ours)	**54.98**	**40.12**	**19.61**

Table 4: Experiment results of standard FSL and generalized FSL settings on Huffpost datasets, while the FSL setting is same with Table 2.

to represent the entire class semantic. Interestingly, our approach improves more significantly than other datasets, 2.22% of 5-way 5-shot standard FSL metric,1.9% of 10-way 5-shot standard FSL metric and 2.83% of generalized FSL metric. In our approach, richer matching features gained through interacting from low level with multi-grained interaction, are effective on the dataset with diverse expressed samples.

4.3 Ablation Study

To further validate the effect of different interaction levels and instance matching vector, we make some ablation studies on both the datasets Liu and Huffpost. The settings are totally same with the main experiments.

4.3.1 Different Interaction Levels

We respectively take out the single-level interaction layer and see how the specific alignment feature affects the performance. As shown in the Table 5, when taking out the specific interaction layer, the performance decreases in varying degrees, which explains that each alignment layer has positive effect on the performance and can complement each other. It is noted that class-level interaction layer has the greatest impact. The model can pay attention to the whole class context through class-level interaction, which makes the model encode more precise class semantic information. It is the key to judge the relationship between query and class.

4.3.2 Instance-wise Matching Vector

We remove all interaction layers in our model, named 'w/o instance & class & episode' in Table 5. Then it is the same as matching network except that the scalar matching score is replaced by instance-wise matching. We make comparison with matching network. As given in the Table 5, 2 and 4, it performs better than matching network, e.g. Liu dataset improves 3.49% of 10-way 5-shot FSL score and Huffpost dataset improves 2.30% of GFSL score. Unlike scalar comparison in matching network, our approach can make fine-grained instance vector comparisons in fine-grained feature dimensional level.

4.4 Number of Classes and Inference Speed

As shown in Table 6, the inference speed increases linearly with the increase of the number of classes, from $315ms/query$ to $1630ms/query$ when c increases from 50 to 318. It is challenging for deploying the model to the online application. To address the problem of inference speed, motivated by the idea of retrieval in traditional search system, we propose the retrieval-then-classify method(RTC for short). (1)Stage1-retrieval: We construct the class-wise representation by averaging the vector of each support instance, produced by MGIMN encoder and then calculate the similarity between query and class-wise representation. In our experiments, we retrieve top $N = 10$ classes with $K = 5$ instances per class. (2)Stage2-classify: Retrieved support instances by stage1 are classified by MGIMN proposed in this paper. The C-way 5-shot task is reduced to a 10-way 5-shot which can greatly save the inference time and computation cost.

In addition to the generalized FSL metric score, we also report the inference speed (processing time per query) to show the effectiveness of retrieval-then-classify. We can see that the inference speed of retrieval-then-classify is greatly increased by 5 × to 23 × , with a small amount of performance loss. At the same time, comparing with other retrieval methods (e.g. BM25 and original bert), our approach can further improve the performance

5 Related Work

5.1 Few-shot Learning

Intuitively, the few-shot learning focus on learn a classifier only using a few labeled training examples, which is similar to human intelligence. Since the aim of few-shot learning is highly attractive, researchers have proposed various few-shot learning approaches.

Generally, the matching network encodes query text and all support instances independently (Vinyals et al., 2016), then computes the cosine similarity between query vector and each support

sample vector, and finally computes average of all scores for per class. The prototypical network basically encodes query text and support instances independently (Snell et al., 2017), then computes class-wise vector by averaging vectors of all support instances in each class, and finally computes euclidean distances as final scores. Sung et al. (2018) introduced relation network (Sung et al., 2018) that exploits a relation module to model relationship between query vector and class-wise vectors rather than leveraging the distance metric (e.g., euclidean and cosine). Geng et al. (2019) introduced the induction network and leverage the induction module that take the dynamic routing as a vital algorithm to induce and generalize class-wise representations. In the few-shot scenario, the model-agnostic manner usually viewed as the improved version of few-shot, and defined as MAML (Finn et al., 2017), which can be exploited in different fields MT (Gu et al., 2018; Li et al., 2020b), dialog generation (Qian and Yu, 2019; Huang et al., 2020).

For few-shot text classification, researchers have also proposed various techniques to improve the existing approaches for few-shot learning. Basically, the one of our strong baselines **Proto-HATT** is introduced by Gao et al. (2019), that leverages the attention with instance-level and feature-level then highlight both the vital features and support point. Ye and Ling (2019) also tries to encode both query and per support set by leveraging the interactive way at word level with taking the matching information into account.

5.2 Text Matching

Text matching model aims to predict the score of text pair dependent on massive labeled data. Before BERT, related work focuses on deriving the matching information between two text sequences based on the matching aggregation framework. It performs matching in low-level and aggregates matching results based on attention mechanism. Many studies are proposed to improve performance. The attend-compare-aggregate method (Parikh et al., 2016) which has an effectiveness on alignment, meanwhile aggregates the aligned feature by using feed-forward architecture. The previous work extracts fine-grained matching feature with bilateral matching operation by considering the multi-perspective case(Wang et al., 2017). Tay et al. (2017) exploit the factorization layers to enhance the word representation via scalar features with an effective and strong compressed vectors for alignment. Yang et al. (2019) present a straightforward but efficient text matching model using strong alignment features. After the PTM (e.g., BERT) is presented (Devlin et al., 2019), it has became commonly used approach on the various fields of NLP. Thus, many text matching methods are also leveraging the PTM. For example, Reimers and Gurevych (2019) use the sentence embeddings of BERT to conduct text matching, and Gao et al. (2021) use contrastive learning to train text matching models. Additionally, to handle the issue of few-shot learning architecture, we employ the similar idea of comparison, aggregation and introduce new architecture multi-grained interactive matching network.

6 Conclusion

In this research investigation, we introduce the **M**ulti-**g**rained **I**nteractive **M**atching **N**etwork(**MGIMN**) for the text classification task with few-shot manner. Meanwhile, we introduce a two-stage method retrieval-then-classify (RTC) to solve the inference performance in realistic scenery. Experiment results illustrate that the presented method obtains the best result in all five different kinds of datasets with two evaluation metrics. Moreover, RTC method obviously make the inference speed getting faster. We will make further investigations on the the task of domain adaptation problem by extending our proposed method.

Abstract

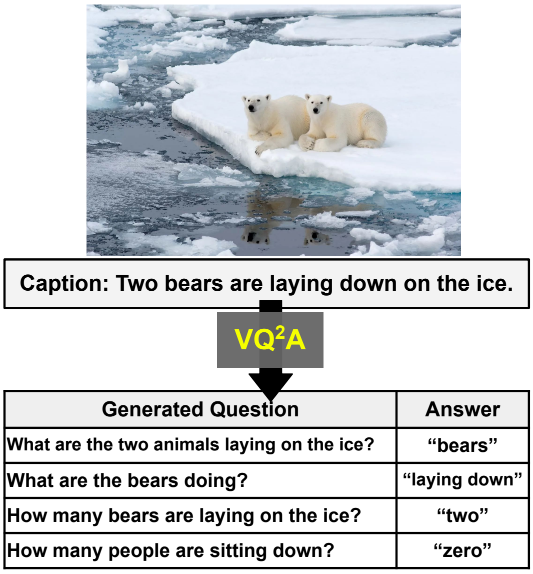
Visual Question Answering (VQA) has benefited from increasingly sophisticated models, but has not enjoyed the same level of engagement in terms of data creation. In this paper, we propose a method that automatically derives VQA examples at volume, by leveraging the abundance of existing image-caption annotations combined with neural models for textual question generation. We show that the resulting data is of high-quality. VQA models trained on our data improve state-of-the-art zero-shot accuracy by double digits and achieve a level of robustness that lacks in the same model trained on human-annotated VQA data.

1 Introduction

Visual Question Answering (VQA) is a complex multimodal task that, to be successfully modeled and evaluated, requires large amounts of annotations that are not naturally produced by existing business processes, the way translation-pair annotations (Guo et al., 2018) or image alt-text annotations (Sharma et al., 2018) are produced.

At present, a main bottleneck for developing robust VQA systems that are useful for downstream applications, such as for visually-impaired people and in the medical and education domains, appears to be a lack of large image-question-answer training triplets (on the order of millions). Manual annotation of such triplets is costly, time-consuming, and prone to a variety of human biases that are difficult to account for (Yuan, 2021). In addition, the brittleness of VQA systems trained on such manual annotations is well-understood and documented (Agrawal et al., 2018; Kafle and Kanan, 2017).

To address the data limitation, we turn to a potential source for creating VQA examples: image-English caption pairs (Chen et al., 2015; Sharma et al., 2018). Large-scale image caption datasets exist with millions (Changpinyo et al., 2021), several hundreds millions (Radford et al., 2021), or even billions (Jia et al., 2021) of examples. Captions come mostly in the form of declarative sentences, e.g., "*two bears are laying down on the ice*". Yet, the task of converting declarative captions into VQA question/answer pairs is still largely unexplored. It requires automatically inducing candidate answers fitting the VQA task, along with their respective questions based on the caption text (Fig. 1). We note that transforming declarative form to interrogative form plus answer(s) seems crucial, as there exists evidence that a vision-and-language model trained on declarative-language data cannot be successfully adapted or transferred "out-of-the-box" for VQA (Wang et al., 2021).



Caption: Two bears are laying down on the ice.

Generated Question	Answer
What are the two animals laying on the ice?	"bears"
What are the bears doing?	"laying down"
How many bears are laying on the ice?	"two"
How many people are sitting down?	"zero"

Figure 1: Given an English caption (along with its corresponding image), our VQ^{2}A method generates high-quality question-answer pairs. These image-question-answer triplet data can be automatically produced at volume (millions of examples) and used to effectively train VQA systems.

In this paper, we explore the automatic creation of millions of VQA training data using neural models for textual question generation and question answering. We refer to this method as VQ^{2}A,

for **V**isual **Q**uestion Generation with **Q**uestion **A**nswering validation. We demonstrate that VQA models trained on such data, with no exposure to human-annotated VQA data at all, exhibit high zero-shot performance. Our best models obtain 61.1% accuracy on VQA2.0, 52.1% on GQA, around 15-17 points higher than previous zero-shot state-of-the-art results, and getting close to fully-supervised performance. In addition, taking our generated examples as a test set, we provide further evidence for the brittleness of VQA systems built with human-annotated examples, as well as evidence for the robustness of VQA systems built with the automatically-induced VQ^{2}A data.

2 Related Work

2.1 Question generation in NLP

Question Generation (QG) is an active research topic in NLP. It is explored as a standalone task (Heilman and Smith, 2009; Nema et al., 2019), as a pre-training task for language models (Narayan et al., 2020) and as a component in solutions for other textual tasks, such as question answering (Alberti et al., 2019; Puri et al., 2020), information retrieval (Mass et al., 2020; Gaur et al., 2021) and generation evaluation (Durmus et al., 2020; Wang et al., 2020; Honovich et al., 2021). There are two main directions to QG: template-based (Heilman and Smith, 2009; Lyu et al., 2021; Dhole and Manning, 2020) and neural-based, with the latter achieving state-of-the-art results (Alberti et al., 2019; Narayan et al., 2020).

2.2 Question generation in computer vision

Question generation in computer vision aims at generating *visual* questions about a given image (or video), either for generating questions without knowing the answer (Mostafazadeh et al., 2016; Zhang et al., 2017; Yang et al., 2018; Uehara et al., 2018; Krishna et al., 2019), e.g., for them to to be answered by humans, or to help improving the VQA task (Kafle et al., 2017; Li et al., 2018; Shah et al., 2019; Xu et al., 2021; Kil et al., 2021; Akula et al., 2021), e.g., for additional evaluation and as means of data augmentation. Such QG models are typically based on VQA triplets as training data, whose language complexity is often limited, or require the collection of visual QG data (Mostafazadeh et al., 2016). We take a different approach by leveraging models trained on *textual* QA datasets instead.

Multiple works leverage image captions or video transcripts as training sources (Ren et al., 2015a; Banerjee et al., 2021; Yang et al., 2021a; Lee et al., 2021). In this approach, question-answer pairs are automatically generated from the text, ignoring the visual source, and are then combined with the related image/video to produce image-question-answer triplets. Banerjee et al. (2021) propose WeaQA, in which they generate questions from MSCOCO image captions (Chen et al., 2015) using an improved template-based approach in COCOQA (Ren et al., 2015a) as well as QA-SRL methods, enhanced by paraphrasing and backtranslation for linguistic variations. Lee et al. (2021) similarly train a VQA model from question-answer pairs derived from MSCOCO Captions but only use noun phrases as candidate answers, focusing on using it to verify generated captions but not on the VQA task itself. Yang et al. (2021a) generate question-answer pairs from instructional video ASR transcripts, which are then coupled with the related video.

In this work, we follow this direction, investigating what requires to generate data with good coverage for the VQA task in the image domain. We show that our neural-based textual question generation approach with captions is much more effective than previous approaches. Further, unlike previous work, we also explore automatically-curated out-of-domain image-text data sources.

2.3 Transfer learning for and in VQA

Existing work also explores the relationship between the image captioning task and the VQA task without question generation (Section 2.2). Fisch et al. (2020) perform image captioning by anticipating visual questions (i.e., using VQA data as additional supervision and post-inference evaluation). Wu et al. (2019) generate question-relevant image captions to aid VQA. Yang et al. (2021b) prompt the GPT-3 (Brown et al., 2020) to answer knowledge-based visual questions based on generated captions and tags and a few VQA examples.

Evidence suggests that image-text pre-training, especially when performed at scale, benefits vision-and-language tasks, including VQA (Lu et al., 2019; Li et al., 2019; Chen et al., 2020; Tan and Bansal, 2019; Su et al., 2020; Lu et al., 2020; Zhou et al., 2020; Li et al., 2020; Zhang et al., 2021; Cho et al., 2021; Wang et al., 2021; Yuan et al., 2021). However, these approaches do not work well without fine-tuning on the downstream VQA data (Wang et al., 2021). Further, prompt-based learning and inference (Liu et al., 2021) from a pre-trained image-text model that works for VQA is still an open research problem. In contrast, our approach directly works with the training data, explicitly transforms them into the interrogative form of question-answer pairs.

Our focus is the *zero-shot* transfer setting in WeaQA (Banerjee et al., 2021) in which no manually-created VQA triplets are available during training. Note that the term zero-shot here is different from the one used in (Teney and Hengel, 2016), in which the model still has access to manually-created VQA triplets but is evaluated with unseen questions at test time. Similar to this, Chao et al. (2018b) explore cross-dataset VQA but they solely focus on human-annotated data along with approaches to transfer.

3 Textual Question Generation for VQA

We study whether automatically producing VQA annotations from existing image-text resources can alleviate or completely replace the need for manual data annotation. We only focus on English in this paper. To this end, we follow and improve upon some of the recent directions in Section 2.2 on automatic question-answer generation from text.

We start with a given dataset of image-caption pairs D=$\{\mathrm{img}_i, \mathrm{cap}_i\}_{i=1}^{N}$. An important assumption we take is that the information conveyed by the caption is, in the vast majority of cases, present in the image, i.e., captions do not contain an excessive amount of external-world or personal knowledge (e.g., "*my friend at my birthday party*").

For each pair $\{\mathrm{img}_i, \mathrm{cap}_i\}$, an initial set of candidate answers $\{\mathrm{a}_{i,j}\}_{j=1}^{M_i}$ is first automatically derived from cap_i. For each such candidate answer, a question is generated by a neural model $\mathrm{q}_{i,j} = QG(\mathrm{a}_{i,j}, \mathrm{cap}_i)$. Each generated question-answer pair undergoes a validation step, and, if validated, is coupled with the corresponding image img_i to induce a VQA example triplet $\{\mathrm{img}_i, \mathrm{q}_{i,j}, \mathrm{a}_{i,j}\}$.

We refer to this method as VQ^{2}A (**V**isual **Q**uestion Generation with **Q**uestion **A**nswering validation). Figure 2 provides an overview of our approach. We next detail the steps in VQ^{2}A.

3.1 Candidate Answer Extraction

The only prior work on neural question generation from captions we are aware of, Lee et al. (2021), focuses on noun phrases as candidate answers. Yet, these are not enough to cover the answer types included in typical VQA benchmarks such as VQA2.0 (as we will show in Section 5.1), such as boolean, attribute, and verb answers, to name a few, which are required for questions like as "*Is there...*", "*What color...*", "*What is the dog doing*". We present a method that covers all of these answer types.

To extract candidate answers from a given caption, we parse it using spaCy[1] and then extract candidates based on the Part-of-Speech (POS) and dependency parse tree annotations, as follows:

Noun Phrases. We extract all noun phrases annotated by spaCy, including named entities.

POS Spans. We extract sequences that begin with an open-class POS (nouns, verbs, adjectives and adverbs), that end with an open-class POS or an adverbial particle, and that do not contain any other POS in between except closed-class POS for determiners, adpositions and conjunctions.

Parse Tree Spans. We consider all sub-trees that include at least one open-class POS and no more than 3 words altogether. We only extract maximal spans, i.e., not extracting sub-trees that are fully included in other extracted sub-trees.

Boolean. Boolean questions are frequent in VQA benchmarks (Goyal et al., 2017). Yet, '*yes*' and '*no*' are not found in captions, and so cannot be extracted as candidates by extracting text spans from captions. To this end, we also add '*yes*' and '*no*' as candidate answers and generate one question per candidate (see Section 3.2).
